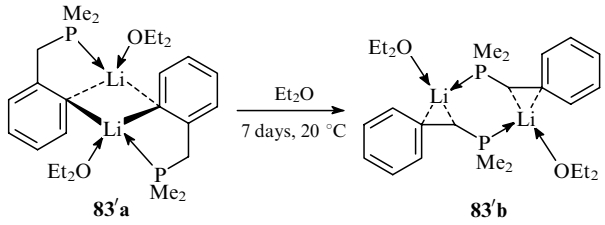
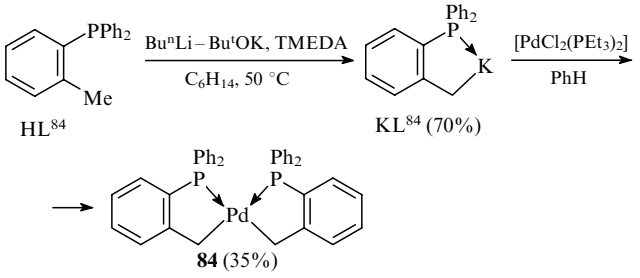
Detailed investigation of the behaviour of two *ortho*-lithiated benzylphosphines, $R_2PCH_2C_6H_4Li$-2 (R = Me, Ph), has shown that in donor-type solvents and in the presence of *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine (TMEDA), they are easily isomerised into the corresponding thermodynamically more stable α-lithiated derivatives *via* 1,3 proton migration. The structures of two isomeric products of lithiation of dimethylbenzylphosphine, **83′a** and **83′b**, were confirmed by X-ray diffraction.[299]



83′a **83′b**

For the synthesis of spiro complexes with the $C(sp^3)-Pd$ bond from *o*-tolylphosphines, an alternative approach involving the potassium salt of the ligand (for example, HL[84]) has been proposed.[304, 305] Among obvious advantages of this method, one should mention the possibility of direct metallation of the *o*-methyl group of the tolyl substituent. Butyllithium in the presence of TMEDA and an approximately equimolar amount of potassium *tert*-butoxide was used as the reagent.

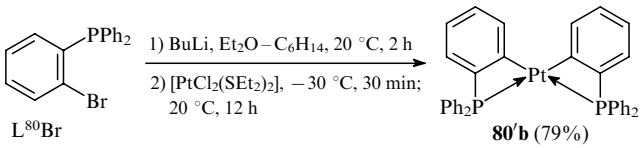


HL[84] KL[84] (70%)

84 (35%)

Presumably,[305] the success of metallation is determined by the exchange between two reagents, Bu^tOK and Bu^nLi, resulting in the formation of butylpotassium species. When Bu^tONa is used, the yields decrease to 40%, and in the presence of Bu^tOLi, metallation does not proceed at all.[305] For the synthesis of PC-palladacycles, the coordination complexes *trans*-$[PdQ_2Cl_2]$ are used (Q = PEt_3, SEt_2). This choice is determined by good solubility of these reagents, the volatility of the auxiliary ligands Q, and their indifference with respect to metallated KL ligands. Unfortunately, the yield of complex **84** obtained in this way did not exceed 35%.

All the above examples refer to the preparation of five-membered PC-palladacycles. In a recent study,[306] this method was used to prepare platinum(II) *cis*-spiro-complex **80′b** with two four-membered PC-metallacycles on the basis of the *ortho*-brominated triphenylphosphine $L^{80}Br$.

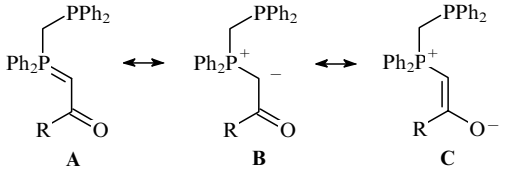


$L^{80}Br$ **80′b** (79%)

It is noteworthy that most of bis(chelate) spiro complexes of both PC- and NC-type[307] are formed as *cis*-isomers, which is explained by the 'antisymbiosis' effect,[308] namely, in transition metal complexes, the *trans*-arrangement of two 'soft' donor atoms markedly destabilises the system. However, in the case of mixed-ligand complexes with different donor atoms in two metallacycles (for example, of the PC and NC types), the formation of the *trans*-isomer is also possible, the isomer ratio being dependent on the order in which the metallacycles are closed.[284]

V. P,C-Chelation of phosphine-substituted phosphorus ylides

In the coordination chemistry of α-stabilised P-ylides, C-binding to soft metals, in particular, palladium and platinum, is usually preferred.[309] The functionalisation of these P-ylides by an additional phosphine fragment opens up the new route to the closure of phosphapalladacycles by simple chelation. A fundamental feature that distinguishes phosphino-P-ylides from other classes of ligands considered in this review is their zwitter-ionic structure, which imparts quasi-carbanionic properties to the ylide carbon atom (structure **B**) even before the reaction with the metal.[309, 310]

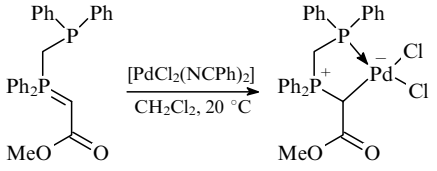


A **B** **C**

The presence of electron-withdrawing substituents (in particular, the carbonyl group) in the P-ylide molecule provides partial delocalisation of the negative charge of the ylide carbon with participation of the carbonyl oxygen (structure **C**), which makes ligands of this class rather stable in the free state and convenient to work with. An adverse consequence of this α-stabilisation is the somewhat reduced nucleophilicity of the ylide carbon; however, it remains sufficiently quasi-anionic to enable direct efficient binding to soft transition metals. Due to the presence of an additional phosphine group, the process of formation of PC-palladacycles is reduced to mere chelation of the zwitter-ionic ligand with Pd(II) compounds involving no activation of the C–H bond or deprotonation. The X-ray diffraction data available for complexes of this class[282, 311–314] clearly demonstrate that the greatest contribution to the electronic structure of the PC-bound phosphino-P-ylides is made by the bipolar canonical form **B**, whereas for free ligands, form **C** prevails.

Phosphino-P-ylide ligands are readily available; they are prepared by condensation of a diphosphine, namely, 1,1-bis(diphenylphosphino)methane (dppm) or dppe, with the corresponding α-halogen-substituted carbonyl compound of the $HalCH_2C(O)R$ type and subsequent deprotonation of the intermediate phosphino-phosphonium salt.[310, 315]

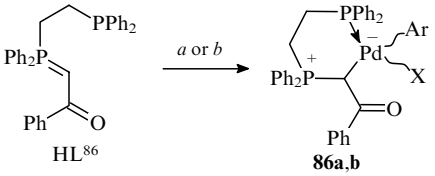
Cyclopalladated derivatives of phosphino-P-ylides are prepared using both preliminarily isolated ylide ligands and their precursors, phosphonium salts (see Table 3). The former version can be illustrated by the synthesis of the simplest monochelate dichloride complex **85a** by the reaction of phosphino-P-ylide L[85] with the benzonitrile reagent.



L[85] **85a** (80%)

The reaction is carried out under mild conditions and with high yields[315–317] almost irrespective of the size of the metallacycle to be formed (five- or six-membered) or the nature of the substituent R in the carbonyl fragment (R = Ph, Me, MeO, EtO). The monochelate P-ylide complexes of this type are thermally and oxidatively stable; compounds with five-membered PC-rings are more stable than those with six-membered rings; and the stability depends on the nature of the substituent R in the carbonyl fragment (Ph > Me > MeO).[317]

The same principle of simple chelation of phosphino-P-ylides is applicable to the synthesis of mono- and diaryl complexes **86a** and **86b**.[318] The corresponding binuclear complexes, [{ArPd.(μ-Hal)(THT)}$_2$] (THT is tetrahydrothiophene) or [Bu_4N]$_2$.[{Ar_2Pd(μ-Hal)}$_2$], are used as the reagents. In this case, too, reactions proceed under mild conditions and give products in satisfactory yields (60% – 80%).



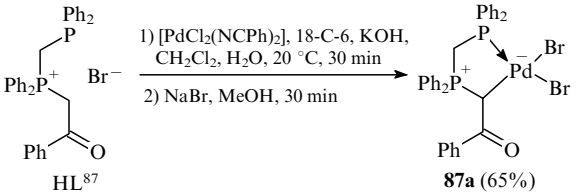
X = Cl, Ar = C_6Cl_5 (**86a**); X = Ar = C_6F_5 (**86b**);

(*a*) [{Pd(μ-Cl)(C_6Cl_5)(THT)}$_2$], PhH, 20 °C, 20 min, 69%;

(*b*) (Bu_4N)$_2$[{Pd(μ-Cl)(C_6F_5)$_2$}$_2$], Me_2CO, 20 °C, 30 min, 57%.

Asymmetrical monoarylated compounds such as **86a** are formed as mixtures of *trans*-C,C-/*cis*-C,C-isomers in 10 : 1 to 2 : 1 ratios.[318]

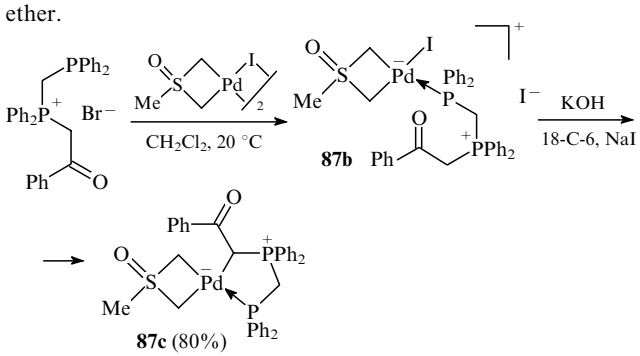
The synthesis of cyclopalladated derivatives of phosphino-P-ylides from the corresponding phosphonium salts [HL]$^+$X$^-$ is also reduced to direct chelation, as it implies generation of the P-ylide ligand *in situ* by deprotonation of the phosphonium precursor by a base. Since phosphonium bromides are normally used and an additional amount of bromide ions is introduced, phosphapalladacycles are formed as dibromide complexes (for example, **87a**).[313]



18-C-6 is 18-crown-6 ether.

The problem of solubility is solved by conducting the reaction in a two-phase system with the addition of 18-crown-6 ether (0.2 equiv.) as a phase transfer catalyst. The possibility of using less expensive reagents, for example, Na_2PdCl_4 can also be considered as an advantage. However, under any conditions (including experiments with a crown ether), the yields of the dibromide complex **87a** remained moderate (60% – 65%).

The phase transfer strategy has also been applied to prepare peculiar spiro complexes in which the metal is incorporated simultaneously into a five- or six-membered P-ylide phosphapalladacycle and a four-membered C,C-metallacycle formed by dianionic bis-S-ylides.[313] In this case, the PC-palladacycle (for example, that in the complex **87c**) is formed in a two-stage process through the intermediate monodentate P-coordination of the cationic [HL^{87}]$^+$ ligand to the S-ylide reagent and subsequent deprotonation under the action of a base in the presence of crown ether.

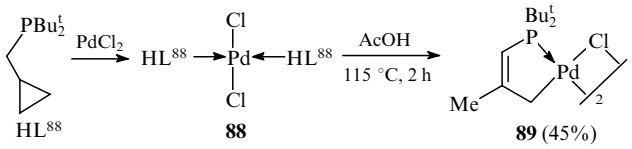


Although the yields of spiro complexes such as **87c** are, most often, relatively high (60% – 80%), the effect of the crown ether is still insignificant. Indeed, five-membered PC-palladacycles can be closed not only in the absence of a phase transfer catalyst but even without a base — due to the activation of the C – H bond with palladium. The structure of the complex **87c** was confirmed by X-ray diffraction data.[313]

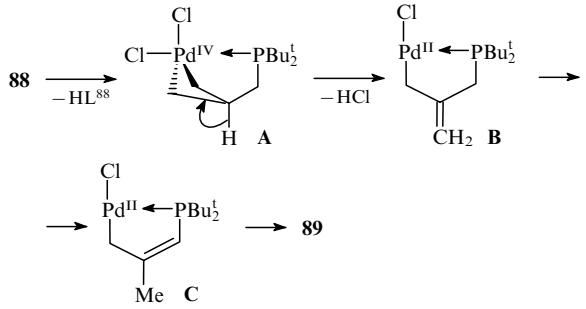
VI. Other routes to phosphapalladacycles

This Section describes a number of unusual transformations, giving rise to PC- or PCP-palladacycles due to activation of the C – C, C = P, C – F or C – O bonds; in these processes, the new ligand is formed on a metallic template.

The key step in the transformation of the cyclopropylmethylphosphine HL^{88} into the dimer **89** is the activation of the C – C bond in the strained cyclopropane ring in the coordination complex *trans*-[$PdCl_2(HL^{88})_2$] (**88**) during its thermolysis in glacial acetic acid.[319]



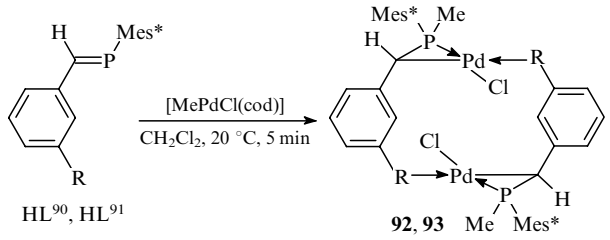
It is assumed [319] that the HL^{88} ligand is converted into dimer **89** by a route usual for the chemistry of cyclopropane.



The elimination of one of the phosphine ligands from precursor **88** is followed by activation of the C – C bond in the three-membered ring in the coordinatively unsaturated [$PdCl_2(HL^{88})$] species. The β-elimination of the proton from intermediate **A** yields phosphapalladacycle **B** with an *exo*-double bond; this product is then isomerised through a 1,3-hydride shift to form the PC-palladacycle **C** with an *endo*-double bond. The last-mentioned species further dimerises to give complex **89**.[319]

A similar process takes place at a platinum(II) centre;[320] meanwhile, in the reactions of the phosphine HL^{88} with iridium(I) [321] and di-*tert*-butyl(cyclobutylmethyl)phosphine with platinum(II),[321] the C – H bond of the small ring (retained in the final product) is subjected to activation.

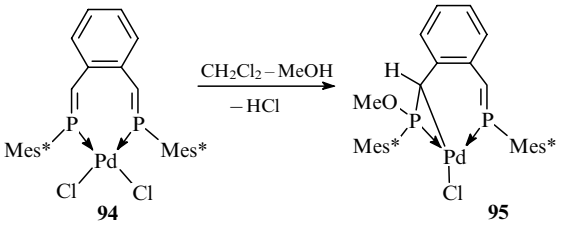
Unusual results have been obtained in a study of the reactions between the HL^{90} and HL^{91} phosphaalkene ligands and the organometallic reagent, [MePd(cod)Cl].[322] Although cyclometallated derivatives of phosphaalkenes of both PC- [117, 323] and PCP-types [117, 125, 127] are known (see Tables 1 and 4), these reactions were found to give three-membered PC-palladacycles under very mild conditions, instead of the expected cyclopalladated products of PC- or PCN-type with the optimal five-membered metallacycles or coordination complexes with P-mono- or P,N-bidentate ligands. One can see that the phosphaalkenes HL^{90} and HL^{91} with N-donor substituents R are converted into macrocyclic binuclear complexes **92** and **93** in high yields.



R = 2-Py (HL^{90}, **92**, 90%); R = CH=NPh (HL^{91}, **93**, 71%).

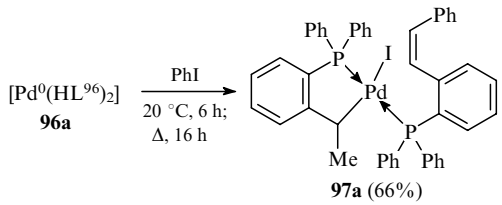
It has been suggested [322] that this process includes carbopalladation of the C=P bond in the starting ligand, *i.e.*, the formal addition of the Pd–Me fragment to the C=P double bond. The regiochemistry of the reaction complies with the polarisation of this bond ($C^{\delta-}=P^{\delta+}$) caused by the higher electronegativity of the carbon atom (2.5) compared to phosphorus (2.1):[324] the quasi-carbanionic methyl group attacks the phosphorus atom, while the metal goes to the carbon atom. Although the researchers do not discuss the stereochemistry of this process in which two stereocentres arise (C* and P*), the presence of only one signal in the ^{31}P NMR spectrum and only one set of ^{1}H NMR signals suggest that the reaction is highly diastereoselective. In the case of dimer **92**, this was confirmed by X-ray diffraction data: the crystal contains only enantiomeric three-membered PC-palladacycles of the (S_CR_P)- and (R_CS_P)-configurations.[322] It should be noted that despite the strained character of such structures, three-membered palladacycles with other heteroatoms, for example, CS- [325, 326] and CO-types are also known.[327]

Non-symmetrical bicyclic PCP-structures (for example, **95**) with annelated three- and six-membered PC-palladacycles and two chemically different P-donor centres (phosphaalkene and phosphinite ones) are formed in the reaction of the coordination complex **94** with alcohols. The regiochemistry of this process is also dictated by the inverted polarity of the $C^{\delta-}=P^{\delta+}$ bond (with respect to the polarity of the C=N bond): the nucleophilic attack by ROH occurs regioselectively involving only the $P^{\delta+}$ atom. This reaction is also diastereoselective; the formal *syn*-addition of the alcohol gives rise to two stereocentres with the same configuration, either (S_CS_P) or (R_CR_P).[328]

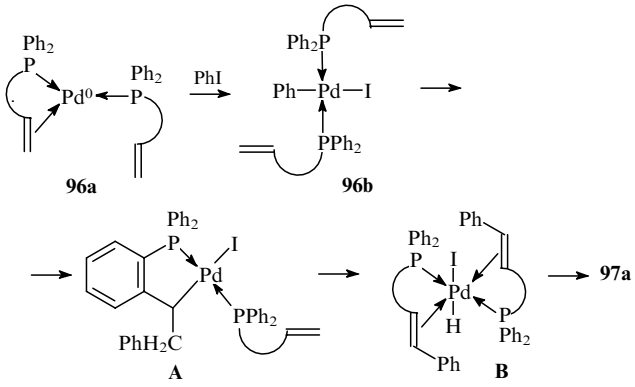


It should be noted that strained three-membered PC-metallacycles are also found in structures with other metals: Ru,[329, 330] Os,[331, 332] W,[333] and Ta [334] and so on.

The formation of a PC-palladacycle upon the reaction of iodobenzene and the Pd(0) complex with the (2-vinylphenyl)diphenylphosphine ligand HL^{96} is based on a complex sequence of transformations, resulting finally in the modification of the starting ligand (the structure of adduct **97a** was confirmed by X-ray diffraction [335]).



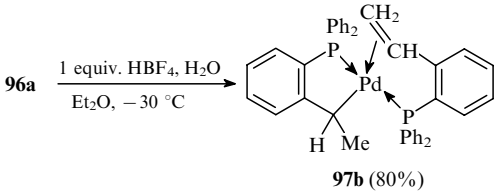
The process is assumed to start with the oxidative addition of PhI to the initial complex **96a** to give adduct **96b**, which appears quite reasonable in view of the coordinative unsaturation of the 16-electron particles. The migration of the metal-bound Ph group to the vinyl fragment of the monodentate P-coordinated HL^{96} ligand in intermediate **96b** gives rise to a new phenylated phosphine HL^{97} (*via* a transformation similar to the Heck reaction). Further, the HL^{97} ligand is closed to give a five-membered PC-palladacycle as adduct **A** with the starting phosphine HL^{96}.



The subsequent steps include β-elimination of hydrogen from the σ-bound alkyl group in the intermediate **A** to afford Pd(IV) hydride derivative **B** and, as the final step, the addition of the hydride to the olefinic fragment, which is either linked to the metal (or merely located close to the metal in space).[335]

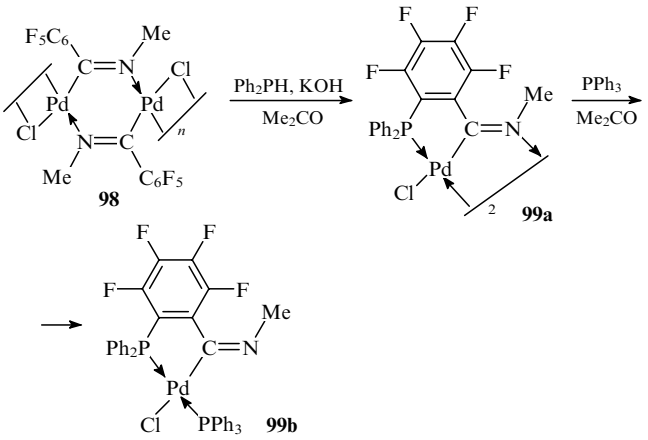
A similar cyclopalladated compound is also formed in the reaction of the complex **96a** with bromobenzene, whereas chlorobenzene is inactive in this process. The decrease in the reactivity of aryl halides in the sequence PhI ⩾ PhBr ≫ PhCl is typical of palladium-catalysed cross-coupling [336] and implies the crucial role of the oxidative addition of aryl halide.

An X-ray diffraction study of the starting complex **96a** has shown a shortened contact between Pd(0) and the α-hydrogen of the non-coordinated vinyl group of the phosphine HL^{96} (the Pd···H distance is 2.46 Å,[34] which is much shorter than the sum of the van der Waals radii of these atoms, equal to 3.1 Å, see Ref. 220). The attractive nature of this interaction seems obvious in view of both the displacement of the palladium atom toward the α-vinyl hydrogen by 0.22 Å and the existing way for a monodentately linked phosphine to avoid these contacts through rotation about the P–C bonds. Interactions of this type are usually considered as an intermediate step in the activation of the C–H bonds.[261, 262] Moreover, study of the temperature dependence of the ^{31}P NMR spectra of complex **96a** has shown that this complex exists in solutions in equilibrium with two-coordinate [Pd(κ^1-HL^{96})$_2$] species, the latter being the predominant form. Hence, the real state of the complex **96a** is nearly 14-electron, and this coordinative unsaturation should stimulate efficiently the oxidative addition. Indeed, treatment of the complex **96a** with an equimolar amount of aqueous HBF_4 under low-temperature conditions gives cationic cyclopalladated compound **97b** stabilised by η^2:κ^1-coordination of the non-metallated HL^{96} ligand.[34]

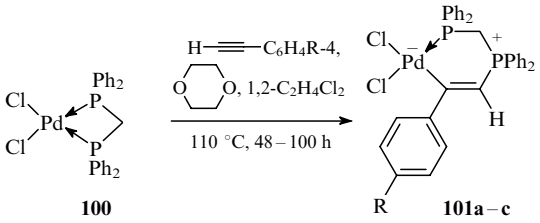


Yet another unusual route to the PC-palladacycle has been discovered in a study of reactions of polynuclear μ-imidoyl complex **98** with phosphides.[337] In this case, a new phosphine ligand is formed due to activation of the C–F bond in the C_6F_5 aryl group. The *ortho*-direction of the attack by the nucleophile (Ph_2P^-) is presumably caused by assistance by the metallic centre.

The product of this reaction, dimeric complex **99a**, differs from the analogues considered previously in that the bridging function is performed by the N-donor atoms of the C-metallated aldimine $(L^{99})^-$ rather than by the halide anions. The dimer **99a** is easily converted into mononuclear adducts (for example, complex **99b**) upon the reaction with auxiliary ligands. The initial compound **98** results from insertion of MeNC into the Pd–Ar bond of the organometallic reagent $[Pd(C_6F_5)_2(CNMe)_2]$ upon its interaction with $[PdCl_2(NCPh)_2]$.[338]

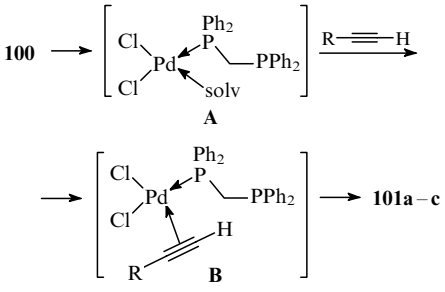


The formation of the P–C bond underlies an unusual pathway of the transformation of methylenediphosphine (dppm) into alkenyl phosphorus ylide ligands on a palladium(II) template.[339] The coordination complex **100**[340] with P,P-chelated diphosphine serves as the starting substrate. Long-term thermolysis of this compound in the presence of excess terminal alkyne yields complexes **101a–c** with zwitter-ionic phosphonium-alkenyl-P-ylide ligands, which possess high stability (thermal, oxidative and hydrolytic).



R = NMe_2 (**101a**, 31%), Ph (**101b**, 49%), NO_2 (**101c**, 73%).

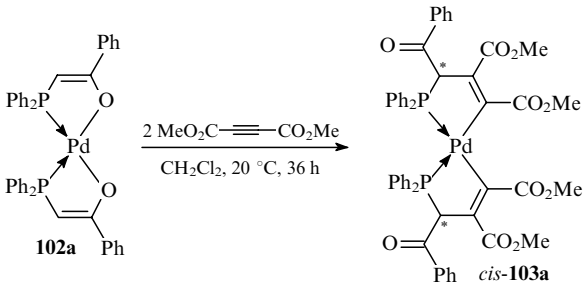
Reactions of this type are regiospecific: the Pd–C bond is formed only with the terminal carbon atom of the monosubstituted alkyne. This regiochemistry may be due to the substantial steric crowding of the reacting P-donor atom of the diphosphine and relatively slight shielding of the metallic centre (disubstituted alkynes cannot be introduced in this process). Although this reaction looks formally to be the insertion of the alkyne into the Pd←P bond, the researchers proposed a more realistic mechanism including (i) solvolytic dechelation of diphosphine in complex **100** to give coordinatively unsaturated species **A**; (ii) η^2-binding of alkyne to the metal at the newly formed coordination vacancy;



(iii) nucleophilic attack of the free PPh_2 group of the monodentate phosphine in intermediate **B** on the π-coordinated alkyne.

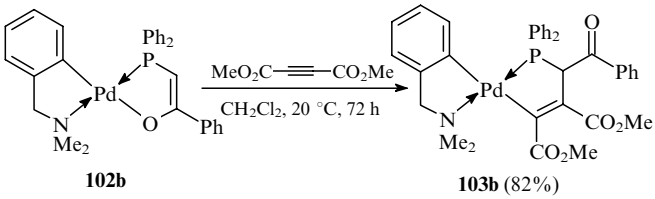
A number of experimental observations are consistent with this scheme. First, the reaction occurs only in the complex with dppm, which forms a strained (and, hence, unstable) four-membered chelate ring.[341] Transformation of this type proved impossible for the similar $[PdCl_2(dppe)]$ complex with diphosphine which forms a stable five-membered chelate ring. Second, the success of this transformation depends appreciably on the coordination capacity of the solvents used, which is important for dechelation of diphosphine: the reaction proceeds only in the presence of dioxane. Third, the coordination of alkynes to the metal should make them more susceptible to the nucleophilic attack. This is consistent with the regular increase in the reactivity of alkynes of the $4\text{-}RC_6H_4C{\equiv}CH$ type following the introduction of electron-withdrawing substituents R (Me_2N < H < NO_2) in the aromatic ring (the yields of complexes **101a–c** increase in this series).[339] A similar process proved possible for platinum(II) complexes with dppm.[342]

Alkenyl phosphametallacycles can be constructed from anionic β-phosphino enolates P,O-chelated to palladium through the formation of a new C–C bond.[343–345] The specific reactivity of ligands of the $R^1_2PCH{=}C(R^2)O^-$ type is due to high nucleophilicity of the carbon atom adjacent to phosphorus. Experiments were carried out with two spiro complexes of phosphino enolates, namely, the symmetrical bis(chelate) coordination compound **102a** and mixed-ligand analogue **102b** containing a CN-metallacycle.[346] Bis(chelate) **102a** reacts with dimethyl acetylenedicarboxylate to give spiro complex *cis*-**103a** of the alkenyl type containing a $C(sp^2)$–Pd bond.[343, 344]

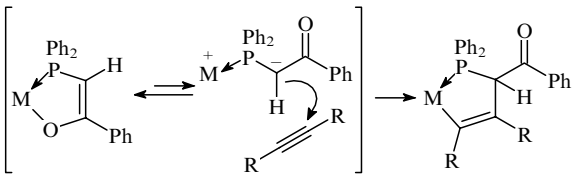


The stereoselectivity of this process, which gives rise to a C*-stereocentre in each of the metallacycles, is relatively low: complex **103a** is formed as a mixture of two diastereomers (3 : 1) with the same geometric *cis*-P,P-configuration. The predominant *meso*-form was isolated from the mixture by fractional crystallisation and characterised by X-ray diffraction.[343]

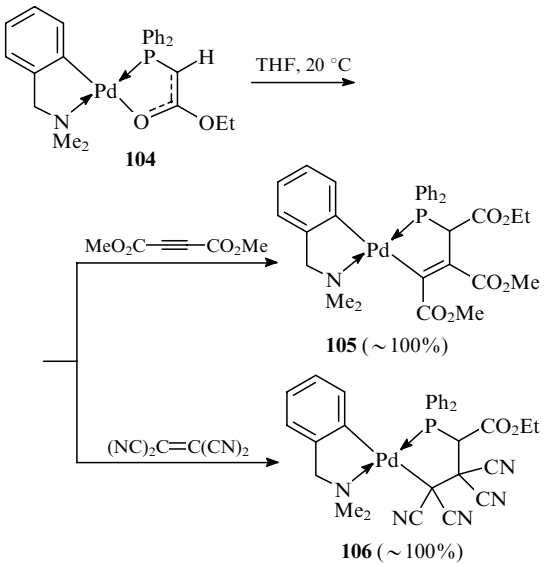
The same phosphapalladacycle as a part of a mixed-ligand spiro complex **103b** is formed in the reaction of alkyne with a phosphino enolate P,O-chelated to the benzylaminate CN-palladacycle (**102b**).[344, 345]



The mechanism of C–C-coupling of the enolate fragment of the P,O-bound ligand with the alkyne triple bond has not been studied. The activating role of the metallic centre is evident from the dependence of the reactivity of complexes on the nature of the metal (Ni > Pd > Pt). β-Phosphino enolates may be activated towards nucleophilic attack upon dechelation and tautomerisation to the keto form $M^+ \leftarrow PPh_2CH^-C(=O)Ph$, in which the α-carbon atom at phosphorus has a more pronounced carbanionic nature.[343–345]



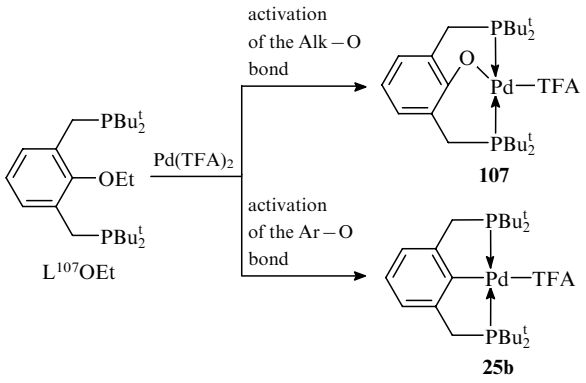
This suggestion seems quite reasonable from general considerations: the Pd—O bond between the 'soft' metal and the 'hard' oxygen donor atom cannot be strong. The dissociative mechanism is supported indirectly by a sharp acceleration of the process when carried out in an efficiently coordinating solvent. Thus complex **104** with a modified P,O-ligand reacts instantaneously with dimethyl acetylenedicarboxylate in THF to give spiro complex **105**,[345] whereas a similar reaction involving complex **102b** in dichloromethane proceeds to completion in 72 h.[344]



The reaction of complex **104** with an electron-deficient alkene (tetracyanoethylene) gives a phosphapalladacycle **106** of the alkyl type with the C(sp^3)—Pd bond whose structure was confirmed by X-ray diffraction.[345]

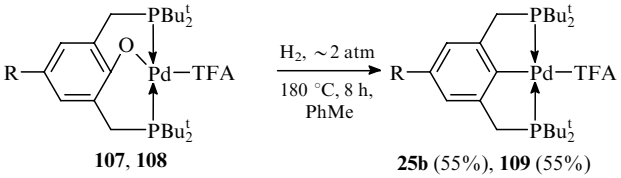
By contrast with homoleptic spiro complexes of type **103a**, which are formed as *cis*-C,C-isomers (but are completely isomerised into thermodynamically more stable *trans*-isomers on long-term heating),[344] their mixed-ligand analogues **103b**, **105** and **106** have initially the *trans*-C,C-geometry, which is at variance with the 'antisymbiosis' concept,[308] according to which the *trans*-arrangement of two soft donor atoms at a soft metallic centre destabilises the system.

The method for the synthesis of PCP-structures from derivatives of 2,6-bis(phosphinomethyl)phenols developed by Milstein [151, 347] seems fairly unusual, if one takes into account the high strength of the Ar—O bonds. Although this transformation can be easily performed on rhodium(I) centres, in the case of Pd(II), an attack on the weaker ArO—Alk bond to give phenoxy complexes is preferred under similar conditions (the structure of one of such complex has been confirmed by X-ray diffraction).[151] Also surprising is the effect of the minor modification of the alkyl group in the phenol ether on the direction of reaction with palladium(II) trifluoroacetate. Whereas in the case of the methyl ether L^{107}OMe, no cyclopalladation signs were found, in the case of ethyl-substituted analogue L^{107}OEt, $Pd(TFA)_2$ reacts along two competing pathways to give products of the formal insertion of the metal into the ArO—Alk (**107**) and Ar—OAlk (**25b**) bonds in the kinetically controlled 9 : 1 ratio, *i.e.*, the former pathway remains preferred.[151]



The differences in the behaviour of analogous substrates, L^{107}OMe and L^{107}OEt, have been attributed [151] to steric effects. Since the mechanism of the formation of phenoxy complex **107** postulated by these researchers includes an S_N2 attack by the anion (here, the $CF_3CO_2^-$ group) on the alkyl group of the ether, the replacement of the MeO group by the EtO group makes the nucleophilic attack on the α-carbon atom sterically more hindered, which opens up the way for competing cyclopalladation.

The POP-phenolate complexes **107** and **108** predominating in these processes can be converted into cyclometallated PCP-structures **25b** and **109** by long-term thermolysis in a hydrogen atmosphere, resulting in activation of the Ar—O bond.[151]



R = H (**107**, **25b**), Me (**108**, **109**).

Presumably, the mechanism of this process includes opening of the ArO—Pd σ-bond under the action of excess hydrogen, and the phenol ArOH thus formed participates further in two competing reactions, namely, reversible activation of the O—H bond and irreversible activation of the Ar—O bond, the latter being responsible for the closure of the phosphapalladacycles. Unusual as it may seem, this hydrodeoxygenation process is of no preparative value, because these products are available *via* direct activation of C—H bonds under mild conditions (see Table 4).

VII. Supplement

Table 1. Phosphapalladacycles of the PC-type.

[a] The structure of the primary cyclopalladation product is shown. [b] In the case of two- and three-stage syntheses, the overall yield is given, and the value in parentheses is the yield in the stage of closure of the PC-palladacycle. [c] The structure of the complex was confirmed by X-ray diffraction analysis. [d] Prepared by a two-stage route *via* a coordination intermediate of the *trans*-$[PdCl_2(HL^n)_2]$ type. [e] Prepared by a two-stage route *via* coordination intermediates of the *trans*-$[PdCl_2(HL^n)_2]$ and $[\{Pd(HL)Cl(\mu\text{-}Cl)\}_2]$ types without isolation of the latter. [f] Obtained by a two-stage route *via* binuclear coordination complex of the $[\{Pd(HL)Cl(\mu\text{-}Cl)\}_2]$ type. [g] Prepared *via* the intermediate complex $[Pd(hfac)_2(P(o\text{-}Tol)_3)]$ characterised by X-ray diffraction analysis.[196] [h] Two-stage synthesis through the intermediate [Pd(P⁀P)(Me)(H_2L^{71})]OTf complex, where P⁀P is ditertiary diphosphine. [i] Obtained by a two-stage route *via* the $[Pd^0(HL')_2]$ complex (HL′ = 2-$Ph_2PC_6H_4CH=CH_2$), whose structure was confirmed by X-ray diffraction.[34] [j] Binuclear complex **81b** is formed as a mixture with the mononuclear derivative of the same palladacycle with κ^1-bound diphosphine dippp. [k] Obtained by a three-stage route *via* two coordination intermediates, *trans*-$[PdCl_2(HL^n)_2]$ and $[\{Pd(HL)Cl(\mu\text{-}Cl)\}_2]$. [l] The reaction proceeds through a hydride intermediate, $[Pd(H)(X)(HL^{20})_2]$. [m] The starting complex was prepared by a known method.[357] [n] Isolated from a mixture with *trans*-$[PdCl_2(HL^{67})_2]$ by manual separation of the crystals. [o] The complex was characterised by X-ray diffraction analysis.[359] [p] Prepared by a two-stage route *via* the coordination intermediate *cis*-$[PdCl_2(HL^n)_2]$. [q] The synthesis of the intermediate coordination complex has been reported.[360] [r] Prepared by four-stage route *via* intermediate complexes, [η^5-CpPd(HL^2)(η^1-All′)], where All′ is $CH_2C(Cl)=CH_2$, [η^5-CpPdCl(HL^2)] and [η^5-CpPd(η^2-L^2)]. [s] A mixture of diastereomers. [t] A mixture of *cis* – *trans* isomers. [u] Prepared *via* the intermediate $[\{Pd(\mu\text{-}L^{80})_2Pd(\mu\text{-}Br)_2\}_2]$ complex whose synthesis has been reported.[277]

	**106b**		$[\{Pd(\eta^2\text{-}2\text{-}Me_2NCH_2C_6H_4)(\kappa^2\text{-}L')\}]$ [c] – $(NC)_2C{=}C(CN)_2$, THF, 20 °C; $(L')^-$ = $Ph_2PCH{=}C(OEt)O^-$	~100	345
	**103b**	Ph	$[Pd\{\eta^2\text{-}2\text{-}Me_2NCH_2C_6H_4)(\kappa^2\text{-}L')\}]$ [c] – $MeO_2CC{\equiv}CCO_2Me$ (1 : 1), CH_2Cl_2, 20 °C, 72 h; $(L')^-$ = $Ph_2PCH{=}C(Ph)O^-$	82	344
	105	OEt	$[Pd\{\eta^2\text{-}2\text{-}Me_2NCH_2C_6H_4)(\kappa^2\text{-}L')\}]$ [c] – $MeO_2CC{\equiv}CCO_2Me$ (1 : 1), THF, 20 °C; $(L')^-$ = $Ph_2PCH{=}C(OEt)O^-$	~100	345
	**103a** [b, d]		(*a*) *cis*-$[Pd(\kappa^2\text{-}L')_2]$ [c] – $MeO_2CC{\equiv}CCO_2Me$ (1 : 2), CH_2Cl_2, 20 °C, 36 h; (*b*) fractional crystallisation of a 3 : 1 mixture of diastereomers; $(L')^-$ = $Ph_2PCH{=}C(Ph)O^-$	66	343 [b], 344
	**36d** [e]	Ph	1) *trans*-$[PdCl_2(SEt_2)_2]$ – LiL^{36} (1 : 2), Et_2O, −20 to 20 °C, 2 h 2) *trans*-$[PdCl_2(SEt_2)_2]$ – LiL^{36} (1 : 2), PhH, 20 °C, 2 h	90 76	283 285
	83	Me	*trans*-$[PdCl_2(SEt_2)_2]$ – LiL^{83} (1 : 2), Et_2O, −20 to 20 °C, 2 h	70	283
	22c	Bu^t	*trans*-$[PdCl_2(SEt_2)_2]$ – LiL^{22} (1 : 2), Et_2O, −20 to 20 °C, 2 h	86	283
	**36e**	Ph	1) $[\{Pd(\eta^2\text{-}C_6H_4CH_2PBu^t_2\text{-}2)(\mu\text{-}Cl)\}_2]$ [f] – LiL^{36} [g] (1 : 2), PhH, 20 °C, 2 h 2) $[\{Pd(\eta^2\text{-}C_6H_4CH_2PBu^t_2\text{-}2)(\mu\text{-}Cl)\}_2]$ [f] – LiL^{36} [g] (1 : 2), Et_2O, −20 to 20 °C, 2 h	87 –	285, 301 283, 298
	83b	Me	$[\{Pd(\eta^2\text{-}C_6H_4CH_2PBu^t_2\text{-}2)(\mu\text{-}Cl)\}_2]$ [f] – LiL^{83} (1 : 2), Et_2O, −20 to 20 °C, 2 h	61	283, 298
	**36f** [b, e]		$[\{Pd(\eta^2\text{-}2\text{-}Me_2NCH_2C_6H_4)(\mu\text{-}Cl)\}_2]$ [h] – LiL^{36} (1 : 2), Et_2O, −20 to 20 °C, 2–3 h	89	284, 287, 361 [b]

[a] The structure of the primary cyclopalladation product is shown. [b] The complex was characterised by X-ray diffraction. [c] The synthesis of the starting complex has been reported.[346] [d] Complex *cis*-**103a** quantitatively isomerises into the *trans*-form upon thermolysis (THF, Δ, 12 h).[344] [e] A *cis*–*trans*-isomer mixture. [f] The starting complex was prepared by a known method.[82] [g] The synthesis of the LiL ligand has been reported.[301] [h] The synthesis of the starting complex has been reported.[357]

[a] The structure of the primary cyclopalladation product is shown. [b] In the case of two- and three-step syntheses, the total yield is given, while the yield in the stage of phosphapalladacycle closure is given in parentheses. [c] The structure of the complex was confirmed by X-ray diffraction analysis. [d] The major reaction product (62%) is the macrocyclic coordination complex, $[Cl_2Pd(\mu{:}\kappa^2\text{-}HL^{24})_2PdCl_2]$. [e] Prepared *via* the $[Cl_2Pd(\mu\text{-}HL^{24})_2PdCl_2]$ coordination complex whose synthesis has been reported.[128] [f] Prepared *via* the intermediate $[Pd(\kappa^2\text{-}L^{94})Cl_2]$ complex, where $L^{94} = C_6H_4(CH{=}PMes^*)_2$-1,2, whose structure has been confirmed by X-ray diffraction analysis.[328] [g] The product is formed as a mixture with $[(\kappa^3\text{-}L^{25}O)Pd(TFA)]$ (1 : 9 ratio), which was characterised by X-ray diffraction.[151] [h] Prepared through the intermediate $[(\kappa^3\text{-}L^{25}O)Pd(TFA)]$ complex, whose synthesis has been reported.[347] [i] The major reaction product (71%) is the dimeric $[Cl_2Pd(\mu{:}\kappa^2\text{-}HL^{62})_2PdCl_2]$ complex. [j] Prepared in two stages *via* the intermediate $[\{Cl_2Pd(\mu\text{-}HL)\}_2]$ coordination complex. [k] The yield is given over two stages including the removal of ligand protection. [l] Prepared in two stages *via* the intermediate $[(\kappa^3\text{-}L^{109}O)Pd(TFA)]$ complex. [m] The complex was obtained *via* the PCP-intermediate $[(\eta^3\text{-}L^{68}H)PdCl]^+Cl^-$. [n] The ligand structure was confirmed by X-ray diffraction analysis. [o] The complex was obtained through the $[(PdCl_2)_2(\mu{:}\ \kappa^2,\kappa^2\text{-}H_2L^{49})]$ intermediate.

VIII. Conclusion

Despite the diversity of the known structural types of phosphapalladacycles and routes for their synthesis, the topicality of further development of the chemistry of this highly interesting and practically valuable class of organometallic compounds is beyond doubt.

Among the preparative aspects of this field of chemistry, development of the processes based on the use of highly reactive organometallic reagents for direct intramolecular activation of the C – H bonds of P-donor ligands seems to be most fruitful. For

example, η^3-allylic palladium complexes have been barely used for this purpose as yet, and examples of using other metallating agents with the Pd—C bond are sparse. From the structural standpoint, of interest are the synthesis and evaluation of properties and reactivity of CPC-, CPP- and CPN-type bicyclic complexes and diverse tricyclic compounds with phosphapalladacyclic fragments.

Apparently, further development of the chemistry of phosphapalladacycles would not be limited to the extention of the collection of mono- and bicyclic complexes of this class. Highly topical is detailed investigation into the mechanisms of direct intramolecular activation of the C—H-bonds in P-donor ligands, which would enable more purposeful construction of new structures of this class.

* * *

As the manuscript was being prepared for publication, a number of studies appeared that cover to some extent the 'blank spots' mentioned above. A significant contribution to the development of this domain of chemistry has been made by the synthesis of a number of cyclopalladated derivatives of P-donor ligands of new structural types. The first PCP-complex with two fused six-membered metallacycles with a palladated sp^2-hybridised carbon atom has been prepared by oxidative addition of the bromo-substituted diphosphine 2,6-$(Ph_2PCH_2CH_2)_2C_6H_3Br$ to $Pd(dba)_2$.[365] The earlier attempts to produce such a structure by direct activation of the C—H bond failed.[67] Methods of synthesis of new non-symmetrical tricyclic PCP-[366,367] and PCN-type structures,[368,369] differing in the sizes of two metallacycles (five- and six-membered [366–369]) and/or the nature of two heterodonor centres (with a phosphino [367] or amino group [368,369] in combination with a phosphinite branch) from mono- and bis(phosphinites) have been developed. Previously, only three asymmetrical PCP-complexes with phosphine donor groups were known.[60,61,68]

In addition to the known PC-complexes with a six-membered metallacycle (based on the exotic sydnonylphosphine ligand [63]), two other representatives of this class have been synthesised from (2-diphenylphosphinophenyl)ferrocene [370] and 2-(dicyclohexylphosphino)biphenyl.[371] Double cyclopalladation of the same aromatic ring of 2-methylresorcinolbis(phosphinite) was implemented for the first time.[372] The collection of monocyclic cyclopalladated phosphite [373–375] and phosphinite [376] derivatives with five-membered PC-palladacycles has been substantially extended. Most of the new PC- and PCP-complexes have been obtained by direct activation of the C—H bonds in the corresponding ligands on treatment with $PdCl_2$,[374–376] $[PdCl_2(cod)]$,[366,367] $[PdCl_2(NCR)_2]$,[373,376] $Pd(OAc)_2$ [370,371] or $Pd(TFA)_2$,[372] the product yields ranging from moderate (43%–48% [367,375]) to nearly quantitative (92%–94% [370,371]). A new approach based on chloropalladation of alkynes bearing heterodonor substituents has been developed for the preparation of asymmetrical pincer PCN-structures.[368,369] An interesting way of generating PCC-complexes from bis(phosphonium) salts (precursors of P-ylides) has been developed only for platinum(II): the process formally includes the activation of three C—H and one C—P bond.[377]

The vast majority of new complexes have been synthesised with the aim of being tested as (pre)catalysts. The presence of persisting interest in this line of practical use of phosphapalladacycles is indicated by the multitude of new reviews [378–383] devoted to this topic. For solving the problem of regeneration of cyclopalladated catalysts, methods of fixing of one of the PCP-complexes on silica gel have been developed, in particular, by direct activation of the C—H bond of the pre-immobilised diphosphine ligand under the action of $Pd(TFA)_2$.[384]

The authors are sincerely grateful to Prof. I P Smolyakova (USA, The University of North Dakota) and to Dr. M Yu Rubina (USA, The University of Illinois at Chicago) for valuable aid in the work on the manuscript. The work was done with partial financial support of the NATO (Grant PST.CLG.979757), the Russian Foundation for Basic Research (Project No. 04-03-3298a), and the Foundation for the Support of Russian Science.

Abstract. The fundamentals of the theory of formation of surface complexes (or the surface complexation theory, SCT), which is used in processing the results of studies on the equilibria in multicomponent ion exchange sorption systems, are outlined. The advantage of the theory is the use of the sorption characteristics of binary ion exchange systems for the description and calculation of multicomponent equilibria with allowance for the medium pH value. The solutions to some problems of nonlinear sorption dynamics theory obtained using the description of multicomponent equilibria in the framework of the SCT model are considered. Experimental data on the concentration distributions of components in frontal and displacement chromatograms are compared with the results of corresponding numerical calculations using various sets of parameters of the SCT model (including versions with allowance for the effect of complexation reactions in the mobile phase). The bibliography includes 88 references.

I. Introduction

The aim of this review is to highlight a recently developed model for the description of multicomponent ion exchange equilibria and its applications to nonlinear sorption dynamics theory. The model is called the theory of formation of surface complexes (or the surface complexation theory, SCT), because it assumes that near the surface of a sorbent (ion exchanger) each kind of counterion is located in the form of a surface complex within an individual Stern layer. Application of the SCT approach to nonlinear theory of multicomponent sorption dynamics and chromatography is a specific, complicated theoretical problem, which is solved by the authors of this review.

In the text below we will briefly outline a number of earlier models for the description of sorption phenomena (in some cases, with consideration of surface ion complexation).

Inorganic and organic ion exchange sorbents consist of either a crystalline or a polymeric matrix and various functional groups. Depending on the pH value of the solution contacting the ion exchanger, functional groups can be protonated or dissociated. Therefore, such sorbents can interact with ions in the liquid phase. As a result, sorption of ions at the surface of the ion exchanger becomes possible.[1] The surface charges produce an electric field directed normal to the surface. Consideration of the resulting electrostatic interactions led to development of various models for the description of sorption equilibria.[2–5]

Helmholtz postulated [1] that the surface charges are compensated by counterions which are located within an ordered (outer Helmholtz) layer some distance from the sorbent surface. The distribution of counterions is governed by the degree of hydration of the solute molecules. Gouy and Chapman [3,4] treated counterions as mass points randomly distributed over a diffusion layer. In this model, the corresponding electrostatic potential and charge density are described by the Poisson equation.

Later, Stern [5] used a combination of the two approaches mentioned above. He assumed that a fraction of counterions is located within an ordered layer near the sorbent surface, while the rest of the counterions are distributed over the neighbouring diffusion layer. The Stern model included finite sizes and thermal motion of hydrated ions.

Modern models consider not only electrostatic interactions but also chemical interactions (solvation of metal ions,[6–8] protonation of ligands,[9] adsorption) and a specific interaction between protons and hydroxyl ions.[10]

Yet another theoretical approach treats the adsorption of counterions as a result of (mainly) chemical interactions between functional groups located on the sorbent surface and dissolved species. Sorption of protons (or other ions) is considered as a local equilibrium established as a result of corresponding reactions. Specific (in the case of protons and hydroxyl ions) and nonspecific (for other ions) interactions cause the formation of ion

pairs at the sorbent surface, which can be treated as various types [1,2] of surface complexes.[11]

In this case, to include the additional contribution of electrostatic interactions to the adsorption,[7,8,12–16] one should know the electric capacitance of the sorbent. This parameter is usually unknown; therefore, a constant ion exchanger capacity model [15,17,18] is employed. Detailed consideration of this model can be found in the literature.[12,19,20]

Spectroscopic studies of the surfaces of ion exchangers revealed [21] that correct description of the adsorption of counterions requires a sorption model with more than one near-surface ion layer to be used. This led to the development [12,22,23] of a triple-layer model with the sorbent surface, β-plane and the diffusion layer as the first, second and third layers, respectively. In the framework of this model counterions can be adsorbed on both the outer layer (β-plane) and the inner layer (sorbent surface).

The surface adsorption of counterions on ion exchange resins was studied [24] using the Gouy–Chapman model [3,4] taking a weakly functionalised Amberlite XAD-2 resin as an example. Applicability of the SCT approach to the description of individual properties of different types of sorption sites was first appreciated by Horst [25] who used the triple-layer model to describe the ion exchange equilibrium on commercially available weakly acid resins.

Initially, the SCT model was developed only for weakly acid polymeric ion exchangers.[25] Further stages of its development and application to the quantitative description of ion equilibria in various organic ion exchange materials have been well documented.[26–36] In this model individual sorption layers are credited to each kind of counterion. Then, the model was extended to other ion exchange systems and currently it permits the description of pure cation or anion exchange equilibria [26,29,36] on various resins [27,28,35] and activated alumina and carbons,[30–32,36] as well as of the adsorption of heavy metal salts.[33,34]

The basic SCT model assumptions and the results obtained by applying the model to the description of equilibria in various multicomponent ion exchange systems including different types of ion exchangers [25–36] are presented in Sections II–V.

The use of the SCT approach appeared to be rather fruitful for solving a number of problems of nonlinear dynamics of multicomponent ion exchange sorption.[37–53] Methods for solution of these theoretical problems with consideration of equilibria using the SCT model as well as the results obtained are described in Sections VI–X.

II. Uptake of ions due to protonation/dissociation reactions of surface groups

1. Simplified description of reactions on charged surfaces of amphoteric ion exchange resins

In deriving mathematical relationships of the surface complexation theory we will consider an idealised planar sorbent surface containing OH groups as sorption sites. We also assume that the sorption sites are uniformly distributed over the sorbent surface.[26,27] In liquid-phase systems the surface OH groups can be protonated in two ways.

In acid media the sorbent surface (S) containing the OH functional groups can be protonated following the reaction

$$S-OH + H^+ \rightleftharpoons S-OH_2^+. \quad (1)$$

To meet the condition for electroneutrality, the positive charge of the surface must be balanced by the negative charge of an anion (*e.g.*, Cl^- ion)

$$S-OH_2^+ + Cl^- \rightleftharpoons S-OH_2Cl. \quad (2)$$

From Eqns (1) and (2) it follows that sorption of acids can occur in sufficiently acid media similarly to the uptake of acids with weakly basic ion exchangers.

In alkaline solutions the surface hydroxy groups can dissociate and release protons to the liquid phase

$$S-OH \rightleftharpoons S-O^- + H^+. \quad (3)$$

The negative surface charges must be compensated by the positive charges of, *e.g.*, Na^+ cations

$$S-O^- + Na^+ \rightleftharpoons S-ONa. \quad (4)$$

Taken together, Eqns (3) and (4) describe a cation exchange on an arbitrary cation exchanger.[30,31,36]

Each protolysis model mentioned above holds for the description of the uptake of acids or the exchange of protons for other monovalent cations in arbitrary pure anion or cation exchange processes. If the equilibrium state is considered for amphoteric ion exchangers and a liquid phase containing various cations and anions, the uptake of anions will decrease with an increase in the pH value until sorption is completely suppressed. The exchange of protons for cations increases in the same way. The pH regions of almost exclusive sorption of cations (or anions) are separated by the region corresponding to the maximum possible concentration of neutral surface groups. In this transient region, sorption of both cations and anions occurs, resulting in coverage of the surface with equal amounts of chemical equivalents of positively and negatively charged counterions.[30,31,36]

2. Basic SCT model assumptions

During the protonation or dissociation of the surface OH groups either a positive or negative electrostatic potential is generated, which depends on the pH value and on the ionic strength of the liquid phase. Due to the sorption of counterions at functional groups this potential is decreased. The SCT model assumes that each kind of counterion (i) is located at a characteristic distance from the surface. Therefore, ordered electrical double layers of Stern layers (1, ..., i, ... , N) are formed near the surface. The layer sequence begins at the sorbent surface: $S|1|...|i|...|j|...|N|D$, where D is the most distant diffusion layer. The excess surface charge is balanced by the charges of counterions in the diffusion layer, which also contains co-ions (Fig. 1 *a*).[26–36]

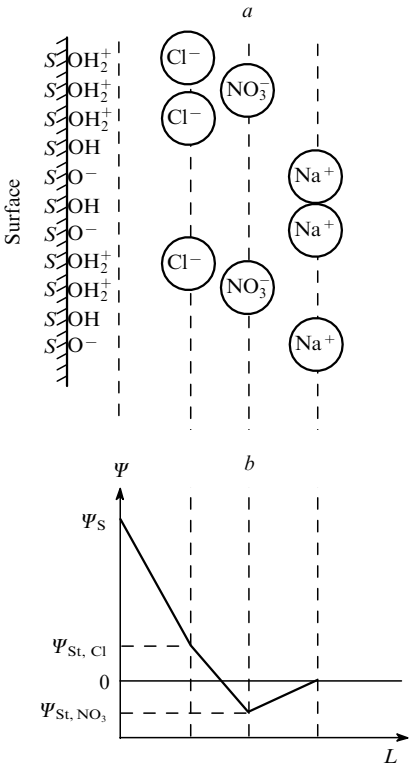

Figure 1. Stern layers (St) near an amphoteric surface (*a*) and the plot of electrostatic potential Ψ *vs.* distance, L, from the surface of sorbent (*b*).[30]

As a consequence, the electrostatic potential Ψ continuously decreases along the normal to the surface. The arrangement of counterions and the potential distribution within the Stern layers and within the diffusion layer for different types of ion exchangers have been well documented (see, *e.g.*, Refs 26–28, 30, 31, 34, 36). The arrangement of counterions and co-ions within the Stern layers is schematically depicted in Fig. 1 *a* and the corresponding electrostatic potential distribution for a solution containing Cl^-, NO_3^- and Na^+ ions is shown in Fig. 1 *b*. The $\Psi(L)$ dependence between the layers $i|(i+1)$ is linear, because each electrical double layer is an electric capacitor of capacitance $C(i, i+1)$. The ions sorbed within the layers $1|...|j|...|N$ form a system of capacitors connected in series. The potential distribution in the diffusion layer D (this layer is not shown in Fig. 1) is described by the Poisson – Boltzmann equation [26–31, 36] and the potential reaches a zero value in the liquid phase (see Fig. 1 *b*).

The equilibrium between the solid and liquid phases is mainly governed by protolytic reactions (1)–(4). Therefore, it is protons (H^+) sorbed at the surface that are responsible for the electrostatic potential. It is assumed that the anion rather than the cation layers are located closer to the surface (see Fig. 1 *a*).

3. Sorption equilibrium relationships in the SCT model

a. General assumptions

The equilibrium relationships in the SCT model were derived assuming that

— functional groups are uniformly distributed across a planar surface;

— activity coefficients in the ion exchanger phase equal unity;

— any ion exchange is treated as replacement of a surface complex by a new one [as a consequence, the charge of the surface sorption sites (z_R) is defined as the least common multiple of the charges of the counterions involved in the exchange process].

b. Surface reactions

Let us consider the derivation of the equilibrium relationships taking a simple system containing Cl^- and Na^+ ions as an example (for the arrangement of the Stern sorption layers, see Fig. 1 *a* except for the NO_3^- ions). The protolytic reactions (1) and (3) at the surface can be described using the mass action law (the corresponding expressions contain the local equilibrium constants). For instance, the protonation and dissociation/neutralisation reactions are characterised by the following constants:[30, 31, 36]

protonation [reaction (1)]

$$K_H^+ = \frac{c(S{-}OH_2^+)}{c(H^+)_{St}\, c(S{-}OH)}, \tag{5}$$

dissociation/neutralisation [reaction (3)]

$$K_H^- = \frac{c(S{-}OH)}{c(S{-}O^-)\, c(H^+)_{St}}. \tag{6}$$

The sorption of counterions (Cl^- and Na^+) is considered in a similar way:[30, 31, 36]

sorption of anions [reaction (2)]

$$K_{Cl}^- = \frac{c(S{-}OH_2Cl)}{c(S{-}OH_2^+)\, c(Cl^-)_{St}}, \tag{7}$$

sorption of cations [reaction (4)]

$$K_{Na}^+ = \frac{c(S{-}ONa)}{c(S{-}O^-)\, c(Na^+)_{St}}. \tag{8}$$

The subscript St denotes the corresponding Stern sorption layer. The unknown concentrations, $c(i)_x$, of the component i at a point x of the electric field within the sorption layers are excluded from consideration. They are expressed *via* the experimentally determined liquid-phase concentrations [$c(i)$, mol litre^{-1}] using the Poisson – Boltzmann relationship [26–28, 30, 31, 36]

$$c(i)_x = c(i)\exp\left[-\frac{z(i)F}{RT}\Psi_x\right], \tag{9}$$

where F is the Faraday constant (in C kmol^{-1}) and Ψ_x is the electrostatic potential at the distance x from the sorbent surface (in volts).

The sorption of anions (in this case, chloride ions) includes the sorption of protons [see Eqn (1)] followed by the sorption of chloride ions [see Eqn (2)]. Since we have a sequence of reactions (1) and (2), the equilibrium constant for this process in the $S{-}OH_2^+$ portions (see Fig. 1 *a*) is given by [30, 31, 36]

$$K_{Cl}^H = K_H^+ K_{Cl}^-. \tag{10}$$

The uptake of cations (in this case, Na^+) develops as the competitive sorption of protons and sodium ions. As a consequence, the equilibrium constant for cation exchange equals the ratio of the corresponding individual equilibrium constants given by expressions (6) and (8) (see Refs 30, 31, 36)

$$K_{Na}^H = \frac{K_H^-}{K_{Na}^+}. \tag{11}$$

Using Eqns (5)–(11), we get [30, 31]

$$K_{Cl}^H = \frac{c(S{-}OH_2Cl)}{c(S{-}OH)c(Cl^-)c(H^+)}\exp\left[\frac{F}{RT}(\Psi_S - \Psi_{Cl})\right], \tag{12}$$

$$K_{Na}^H = \frac{c(S{-}OH)c(Na^+)}{c(S{-}ONa)c(H^+)}\exp\left[\frac{F}{RT}(\Psi_S - \Psi_{Na})\right], \tag{13}$$

where Ψ_S is the electrostatic potential of the sorbent surface (in Volts).

It was shown [30, 31, 36] that the concentrations of the surface complexes, $c(S{-}Oi)$, are converted into solid-phase loadings $q(i)$ (in mg-equiv g^{-1}) of the sorbent, namely, q(OH), $q(Cl^-)$ and $q(Na^+)$ [q(OH) denotes the surface groups which remain undissociated and unprotonated].

Therefore, the pre-exponents in relationships (12) and (13) contain exclusively those quantities which can be determined experimentally. In the SCT model both expressions are called the generalised separation factors (Q_j^i) (see Refs 26–36). After introducing dimensionless sorbent loadings

$$y(i) = \frac{q(i)}{q_{max}}, \tag{14}$$

where q_{max} is the maximum loading, the coefficients Q_j^i are given by:[30, 31, 36]

$$Q_{Cl}^H = \frac{q(Cl^-)}{q(HO^-)c(H^+)c(Cl^-)} = \frac{y(Cl)}{y(HO^-)c(H^+)c(Cl^-)},$$
$$Q_{Na}^H = \frac{q(HO^-)c(Na^+)}{q(Na^+)c(H^+)} = \frac{y(HO^-)c(Na^+)}{y(Na^+)c(H^+)}. \tag{15}$$

Similar relationships can be derived for any monovalent counterions.

c. Binary parameters

The electrostatic potential differences in Eqns (12) and (13) can be expressed *via* the surface charge densities in the series of electric capacitors formed by the Stern layers, *via* the charge densities in the diffusion layer [26–28] and *via* the loadings, $y(i)$, of the amphoteric sorbent surface with Cl^- and Na^+ ions.[30, 31, 36] Mathematical treatment of the corresponding equations in the framework of

the SCT approach gives the following expressions for the generalised separation factors:[30,31,36]

$$\log Q^{H}_{Cl} = \log K^{H}_{Cl} + m(H,Cl)[-y(Cl) + y(Na)], \quad (16)$$

$$\log Q^{H}_{Na} = \log K^{H}_{Na} + m(H,Cl)y(Cl) + m(H,Na)y(Na). \quad (17)$$

The parameters $m(H,i)$ in Eqns (16) and (17) depend on the electric capacitance [$C(S,i)$, in F m^{-2}] of the capacitor formed by the sorbent surface and the corresponding Stern layer (i). They are defined as follows[26–31,36]

$$m(H,i) = \frac{1}{\ln 10}\frac{z_R q_{max} F^2}{A_0 C(S,i) RT}, \quad (18)$$

where A_0 (in m^2 g^{-1}) is the specific surface area of the sorbent, $z_R < 0$ for cation exchangers and $z_R > 0$ for anion exchangers. For binary exchange the numerical value of the parameter z_R equals the least common multiple of the charges of two counterions.[30,31,36]

The general relationship of the SCT model for a system containing an arbitrary number of monovalent counterions can be deduced from similar considerations. For the component i it has the form[30,31,36]

$$\log Q^{H}_{i} = \log K^{H}_{i} + \sum_{j=2}^{i-1}[m(H,j)V(j)y(j)] + m(H,i)\sum_{i}^{n} V(i)y(i). \quad (19)$$

Here i and j are the indices of counterions ($i = 2, 3, ..., n$; $j = 2, 3, ..., i-1$); $i = 1$ corresponds to hydrogen ions; and $V(j)$ and $V(i)$ are the signs of the charges of the counterions, namely, $V(i) = -1$ for anions and $V(j) = +1$ for cations.

For a given component i the second term in expression (19) describes summation of the parameters for those counterions j, which in these Stern layers are located closer to the surface than the species i. The third term comprises the parameters for the counterions located at longer distances from the surface than the ions i. For an ion exchange system containing n counterions there are $n-1$ equations of the type (19).

It is of great importance that all binary parameters of the SCT model $\{\log K^{H}_{i}; m(H,i)\}$ from $i = 2$ on can be successively evaluated from the experimental data for binary exchanges. Since in the framework of the SCT approach all equilibria are calculated using these pairs of binary parameters, the equilibrium constants for multicomponent ion exchange systems can be determined in a similar way. Some examples of calculations of multicomponent equilibria using the SCT model are given below.

d. Extension to systems containing mixtures of monovalent and multivalent counterions

During the exchange of a divalent counterion for two monovalent counterions the divalent species replaces two adjacent ions at the surface. If the liquid phase contains one kind of divalent ions to be exchanged for the monovalent ions initially present in the sorbent, it is necessary that the sorbent have divalent sorption sites. They can be formed by two monovalent sites. As a consequence, two types of surface complexes, namely, two monovalent counterions (*e.g.*, Cl^-) — two monovalent sites (type a) and divalent counterion (*e.g.*, SO_4^{2-}) — two monovalent sites (type b) exist and exchange near the surface.

For a system containing H^+, Na^+, Cl^- and SO_4^{2-} counterions the generalised separation factors are given by the following expressions:[30,31,36]

for exchange of SO_4^{2-} anions involving protonation [see Eqns (1) and (2)] and the formation of a complex of the type b

$$Q^{H}_{II\,SO_4} = \frac{c[(S{-}OH_2^+)_2{=}SO_4^{2-}]}{c(S{-}OH, S{-}OH)[c(H^+)]^2 c(SO_4^{2-})}; \quad (20)$$

for exchange of Cl^- anions involving protonation [see Eqns (1) and (2)] and the formation of a complex of the type a

$$Q^{H}_{II\,Cl} = \frac{c(S{-}OH_2Cl, S{-}OH_2Cl)}{c(S{-}OH, S{-}OH)[c(H^+)]^2[c(Cl^-)]^2}; \quad (21)$$

for Na^+/H^+ exchange and the formation of a complex of the type a

$$Q^{H}_{II\,Na} = \frac{c(S{-}OH, S{-}OH)}{c(S{-}ONa, S{-}ONa)[c(H^+)]^2}. \quad (22)$$

The subscript 'II' means that expressions (20)–(22) were derived assuming the presence of divalent sorption sites.

The probability, $p(i,i)$, for two adjacent monovalent counterions i,i to be found on the surface is given by[31,32]

$$p(i,i) = \left[\frac{y(j)}{\sum y(j)}\right]^2 \sum y(j), \quad (23)$$

where $\sum y(j)$ is the sum of the dimensionless loadings of the sorbent with all monovalent counterions. Using the dimensionless loadings $y(i)$, the separation factors (20)–(22) can be expressed as follows:[30,31,36]

$$Q^{H}_{II\,SO_4} = \frac{y(SO_4)[y(H) + y(Cl) + y(Na)]}{[y(HO)]^2[c(H^+)]^2 c(SO_4^{2-})}, \quad (24)$$

$$Q^{H}_{II\,Cl} = \frac{[y(Cl)]^2}{[y(HO)]^2[c(H^+)]^2[c(Cl^-)]^2} \equiv (Q^{H}_{I\,Cl})^2, \quad (25)$$

$$Q^{H}_{II\,Na} = \frac{[y(HO)]^2[c(Na^+)]^2}{[y(Na)]^2[c(H^+)]^2} \equiv (Q^{H}_{I\,Na})^2. \quad (26)$$

Analogous relationships can be derived for those relatively rare cases where trivalent cations (*e.g.*, Al^{3+}) are involved in ion exchange processes.

e. Equilibrium parameters for differently charged counterions

If an ion exchange system contains exclusively monovalent counterions and a sorbent contains divalent sorption sites, the equilibrium parameters $\log K^{H}_{II\,i}$ and $m_{II}(H,i)$ should be transformed to the parameters for monovalent sorption sites $\log K^{H}_{I\,i}$ and $m_I(H,i)$ using the following relationships[30,31,36]

$$\log K^{H}_{I\,i} = \frac{\log K^{H}_{II\,i}}{2}, \quad (27)$$

$$m_I(H,i) = \frac{m_{II}(H,i)}{2}. \quad (28)$$

If an ion exchange system contains a mixture of monovalent and divalent counterions, calculations should be carried out assuming divalent sorption sites. The equilibrium parameters $\log K^{H}_{I\,i}$ and $m_I(H,i)$ derived for systems with monovalent counterions should be replaced by the parameters $\log K^{H}_{II\,i}$ and $m_{II}(H,i)$ converted using relationships (27) and (28).

4. Pure cation (anion) exchange on weak electrolyte resins

a. Weakly acid ion exchangers

The equilibrium of the uptake of, *e.g.*, Na^+ cations on weakly acid ion exchangers can be schematically described as follows:

$$\overline{R-COOH} + Na^+ \rightleftharpoons \overline{R-COO^- - Na^+} + H^+, \quad (29)$$

where $\overline{R}$ is the polymeric matrix of the ion exchanger (according to commonly accepted designations, the species under the horizontal line refer to the ion exchanger phase). Normally, weakly

acid ion exchangers cannot adsorb anions. Hence, the terms for anions in the general Eqn (19) of the SCT model vanish. Correspondingly, the equation of the SCT model is simplified [30, 31, 36]

$$\log Q^{H}_{Na} = \log K^{H}_{Na} + m(H, Na)y(Na). \quad (30)$$

b. Weakly basic ion exchangers

The uptake of a mixture of cations and anions (*e.g.*, H^+ and Cl^-) by weakly basic polymeric ion exchangers can be written as

$$\overline{R-NH_2} + H^+ + Cl^- \rightleftharpoons \overline{R-NH_3^+-Cl^-}. \quad (31)$$

Because weakly basic ion exchangers do not sorb alkali metal and alkaline-earth metal cations, Eqn (16) is simplified [30, 31, 36]

$$\log Q^{H}_{Cl} = \log K^{H}_{Cl} - m(H, Cl)y(Cl). \quad (32)$$

The uptake of chloride ions by the protonated functional groups of the ion exchanger is also described as the exchange of Cl^- ions for hydroxy groups [34]

$$\overline{(R-NH_2)\cdot H_2O} + Cl^- \rightleftharpoons \overline{R-NH_3^+-Cl^-} + OH^-. \quad (33)$$

In this case consideration of the ion equilibrium in the framework of the SCT model is performed analogously to that given in Section II.3 and leads to the following relationship

$$\log Q^{OH}_{Cl} = \log K^{OH}_{Cl} + m(OH, Cl)y(Cl). \quad (34)$$

5. Strongly acid and strongly basic ion exchangers

The SCT model also allows the relationships for the description of equilibria for sorption of ions by strongly acid and strongly basic resins to be derived from Eqn (19). However, one should keep in mind that in the case of cation exchangers the hydrogen ions cannot be assumed to be adsorbed on the surface, because of complete dissociation of the ion exchanger. Besides, protons are surrounded by the hydration shell and therefore cannot closely approach the surface. Similar considerations also hold for another sorbent–sorbate pair, namely, a strongly basic anion exchanger and OH^- ions. For both strongly acid and strongly basic ion exchangers the sequence of the Stern layers begins with the layer corresponding to that kind of counterions which is located in the closest proximity to the surface.[30, 31, 36]

6. Liquid-phase equilibrium relationships

The liquid-phase ion equilibria are calculated using the following equations: relationships for the dissociation of water, mass balances for each component and the condition for electroneutrality. The activity coefficients in the liquid phase can be calculated from the ionic strength of the solution using the Debye–Hückel relationship.[54]

Note that in systems containing water, hydrolysis of trivalent (*e.g.*, Al^{3+}) cations should be taken into account. The formation constants of the charged and neutral molecules can be found in the literature (see, *e.g.*, Refs 54–57).

III. Uptake of ions due to Lewis acid/Lewis base interactions

1. Reactions on the sorbent surface

The sorption of chloride ions by weakly basic anion exchangers can be treated as adsorption of the acid by free amino groups [see Eqn (31)]. A similar character of the uptake of cations and an equivalent amount of anions is due to the Lewis-base properties of amino groups, which can be coordinatively bound to Lewis acids (metals, M). Taking chloride and copper ions as examples, the equation for this kind of sorption can be written as follows:[33, 34, 38, 55]

$$\overline{R-NH_2} + Cu^{2+} + 2Cl^- \rightleftharpoons \overline{R-NH_2[Cu^{2+}(Cl^-)_2]}. \quad (35)$$

Metal coordination can occur in a variety of fashions. Figure 2 shows a schematic (in the framework of the SCT model) diagram of the Stern layers for an ion exchange system containing protons, two kinds of divalent metal cation M_A^{2+} and M_B^{2+} and monovalent and divalent anions X_A^- and X_B^{2-}.

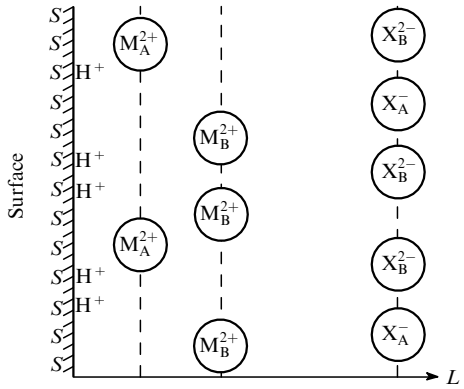

Figure 2. Ion layers near the surface of a weakly basic ion exchanger during the uptake of metal salts (L is the distance from the surface).[34]

We will assume that metals are present in the liquid phase exclusively as divalent cations. To derive the equilibrium relationships, let us consider the competitive uptake of metal salts and the corresponding strong acids.[33, 34] First, we will analyse a simple ion exchange system containing one kind of metal and one kind of anion species, namely, protons (H^+), metal cations (M^{2+}) and monovalent anions (X^-). As mentioned above, the surface charge of the ion exchanger equals the least common multiple of the charges of the ions sorbed. In the case under study (divalent metals M^{2+}), for the parameter z_R we have $z_R = 2$ (see Ref. 34). The surface reactions can be written as follows:[33, 34]

sorption of strong acids $(HX)_2$ or H_2X_2

$$\overline{R-(NH_2)_2} + 2H^+ \rightleftharpoons \overline{R-(NH_3^+)_2}, \quad (36)$$

$$\overline{R-(NH_3^+)_2} + 2X^- \rightleftharpoons \overline{R-(NH_3^+-X^-)_2}, \quad (37)$$

overall

$$\overline{R-(NH_2)_2} + 2H^+ + 2X^- \rightleftharpoons \overline{R-(NH_3^+-X^-)_2}; \quad (38)$$

sorption of metal salts

$$\overline{R-(NH_2)_2} + M^{2+} \rightleftharpoons \overline{R-(NH_2)_2-M^{2+}}, \quad (39)$$

$$\overline{R-(NH_2)_2-M^{2+}} + 2X^- \rightleftharpoons \overline{R-(NH_2)_2-[M^{2+}, (X^-)_2]}, \quad (40)$$

overall

$$\overline{R-(NH_2)_2} + M^{2+} + 2X^- \rightleftharpoons \overline{R-(NH_2)_2-[M^{2+}, (X^-)_2]}. \quad (41)$$

The concentrations of surface complexes $\overline{R-(NH_3^+-X^-)_2}$ and $\overline{R-(NH_2)_2-[M^{2+}, (X^-)_2]}$ (in mg-equiv g^{-1}) in the reactions (38) and (41) characterise the loadings of the resin with the acid and metal salt, respectively. Applying the mass action law to processes (38) and (41) and taking into account relationship (14), we get the following relationships for calculations of the formation constants of the complexes

$$K_{H_2X_2} = \frac{y(H)}{y(\overline{R-NH_2})c_{St}(M^{2+})[c_{St}(X^-)]^2}, \quad (42)$$

$$K_{MX_2} = \frac{y(M)}{y(\overline{R-NH_2})c_{St}(M^{2+})[c_{St}(X^-)]^2}, \quad (43)$$

where $y(H)$, $y(M)$ and $y(\overline{R-NH_2})$ are the loadings of the resin with the acid and metal salt and the concentration of neutral functional groups, respectively.

By applying the Boltzmann relationship and using the description of the sequence of electrical double layers as electric capacitors connected in series near the surface in the framework of the SCT model it is possible to derive the expressions relating the generalised separation factors to the loadings of the resin with the metal salt and acid [33, 34]

$$\log Q_{MX_2} = \log K_{MX_2} - \frac{2}{\ln 10}\frac{F^2 q_{max}}{RTA_0C_2}y(X), \quad (44)$$

$$\log Q_{H_2X_2} = \log K_{H_2X_2} - \frac{2}{\ln 10}\frac{F^2 q_{max}}{RTA_0C_1}y(H) - \frac{2}{\ln 10}\frac{F^2 q_{max}}{RTA_0C_2}y(X). \quad (45)$$

Using designation

$$B = \frac{2}{\ln 10}\frac{F^2 q_{max}}{RTA_0},$$

Eqns (44) and (45) can be written in a more compact form

$$\log Q_{MX_2} = \log K_{MX_2} + m_2 y(X), \quad (46)$$

$$\log Q_{H_2X_2} = \log K_{H_2X_2} + m_1 y(H) + m_2 y(X), \quad (47)$$

where

$$m_1 = -\frac{B}{C_1(H,M)}, m_2 = -\frac{B}{C_2(H,M)}. \quad (48)$$

From Eqns (46) and (47) it follows that four parameters (m_1, m_2 and the formation constants of the complexes K_{MX_2}, $K_{H_2X_2}$) are required for the description of equilibria in the system under study.

2. Ion exchange systems containing two different metals

Competitive sorption in a system with higher dimension compared to that of the system considered above can be treated in a similar way. For instance, for a ternary system containing two different metal cations, M_A and M_B, and one kind of anion, $X^{z(X)}$, we get the system of three equilibrium relationships [33, 34]

$$\log Q_{M_BX_n} = \log K_{M_BX_n} - \frac{B}{C_3}y(X), \quad (49)$$

$$\log Q_{M_AX_n} = \log K_{M_AX_n} + \frac{B}{C_2}\left[y(M_B) - y(X)\right] - \frac{B}{C_3}y(X), \quad (50)$$

$$\log Q_{H_2X_n} = \log K_{H_2X_n} - \frac{B}{C_1}y(H) + \frac{B}{C_2}\left[y(M_B) - y(X)\right] - \frac{B}{C_3}y(X), \quad (51)$$

where

$$m_1 = -\frac{B}{C_1(H,M_A)}, \quad (52a)$$

$$m_2 = \frac{B}{C_2(M_A,M_B)}, \quad (52b)$$

$$m_3 = -\frac{B}{C_3(M_B,X)}. \quad (52c)$$

As a consequence, six equilibrium parameters of the SCT model are needed for the ternary ion exchange system containing two kinds of metal ion, M_A^{2+} and M_B^{2+}, and the acid H^+X^-. The geometric interpretation of Eqns (44)–(47) is straightforward and evaluation of the binary parameters $\{\log K, m\}$ of the SCT model is simple.[26–31, 33–36] In the text below we will give some illustrative examples.

Note that numerical values of the parameters $\{\log K, m\}$ of the SCT model for the binary (bin) systems remain unchanged for ternary (tern) systems, namely [33, 34]

$$\log K_{tern} = \log K_{bin}, \quad (53)$$

$$m_{1,tern} = m_{1,bin}. \quad (54)$$

The quantity m_3 of the ternary system corresponds to m_2 in the binary case [33, 34]

$$m_{3,tern} = m_{2,bin}; \quad (55)$$

the parameter m_2 of the ternary system $H/M_A/M_B$ is calculated as the difference between the respective m_1 values of the binary subsystems H/M_A and H/M_B

$$m_{2,tern} = m_{1,bin}(M_A) - m_{1,bin}(M_B). \quad (56)$$

This treatment of the ternary ion exchange system can be extended to multicomponent systems containing N different metal cations (M_i, $i = A, \ldots i, \ldots, N$) and one type of anion, $X^{z(X)}$.

IV. Evaluation of the SCT model parameters from experimental data

Experimental studies of ion exchange equilibria were carried out taking systems containing either cation or anion exchangers [26, 29, 36] as well as systems containing amphoteric ion exchangers (in particular, activated alumina and activated carbon) [30–32, 36] as examples. Adsorption equilibria were studied for the sorption of heavy metal salts by commercially available ion exchangers and by weakly basic anion exchangers.[33, 34] Methods of pre-treatment of these materials and the experimental conditions necessary for obtaining the corresponding equilibrium data have been well documented.[26–36] In particular, experimental studies of equilibria in amphoteric systems were carried out at constant concentrations of counterions in the liquid phase and at constant amounts of alumina or activated carbon in each sample. The sample volume-to-mass ratios were adjusted in such a way that the degree of sorption and the equilibrium concentration were sufficiently high to be measured reliably. The equilibrium state is mainly governed by the pH value of the liquid phase; therefore, this parameter was varied in each series of samples. The experimental conditions have been reported in detail.[29–31]

To investigate the adsorption of heavy metal salts, the ion exchange resin samples were equilibrated with acid–metal salt mixtures of different composition. Systems containing hydrochloric and sulfuric acids were studied.[33, 34] Numerous experimental data for ion exchange systems were processed using the SCT model in order to evaluate the binary parameters $\{\log K_j^i; m(i,j)\}$ (see Refs 26–32, 34–36).

1. Calculations of the SCT model parameters using experimental data

a. Pure cation or anion exchange

In evaluating the equilibrium parameters of the SCT model the generalised separation factors Q_i^j can be determined using the experimental data (the equilibrium concentrations of counterions and resin loadings). Then, a linear dependence of $\log Q_i^j$ on y_i must be plotted. For binary cation or anion exchange systems the corresponding plots allow sets of binary equilibrium parameters $\{\log K_j^i, m(i,j)\}$ of the SCT model to be determined from the Y-intercept and the slope of the straight line, respectively.

Figures 3–8 show a number of examples for different types of polymeric ion exchangers.[26–31, 33–36] In Fig. 3 we present linear dependences for two weakly acid resins. Systematic deviations from linearity were found only at small loadings. This is due to the

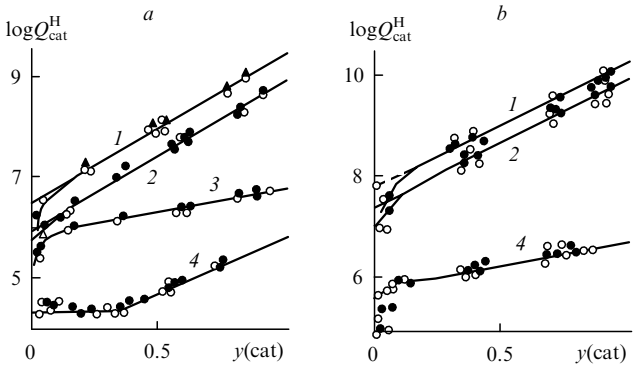

Figure 3. Generalised separation factors Q_{cat}^{H} plotted *vs.* loading of sorbent with cations (cat) for the exchange of various divalent cations for protons with two weakly acid ion exchange resins, Lewatit CNP 80 (*a*) and Amberlite IRC 50 (*b*).[31]
Cation: Mg^{2+} (*1*), Ca^{2+} (*2*), Zn^{2+} (*3*) and Cu^{2+} (*4*). Experimental data (full and open circles and full and open triangles) were obtained at different metal salt concentrations in the liquid phase.

fact that basic relationships (19) of the SCT model were derived neglecting low concentrations of counterions in the diffusion layer *D*. They can be included for simple systems (see above), which leads to good agreement between the results of calculations and experimental data for the dependence of $\log Q_i^j$ on y_i.[27] Two kinds of sorption sites were discriminated for the sorption of Cu^{2+} counterions by acrylic resin Lewatit CNP 80 (see Fig. 3 *a*): the amount of copper ions adsorbed directly on the surface reaches up to one third of the maximum resin loading, while other Cu^{2+} ions are located far from the resin surface. This is in agreement with the published data on the character of the bonding of Cu^{2+} ions to an acrylic matrix.[57]

Experimental data and the results of SCT calculations of exchange of several anions on a weakly basic ion exchanger are shown in Fig. 4. The visual appearance of the straight lines in the plots indicates that sulfate ions are sorbed at a longer distance from the sorbent surface (larger slope of the corresponding line) compared to chloride and nitrate ions in spite of preferred uptake of the SO_4^{2-} ions by the ion exchanger.

Figure 5 presents the results obtained in evaluating the equilibria with two strongly acid ion exchangers. Exchange of magnesium and sodium counterions and protons for the same

Plots of generalised separation factors for $H^+ - Mg^{2+}$ (*1*), $H^+ - Ca^{2+}$ (*2*), $H^+ - Ni^{2+}$ (*3*), $H^+ - Cu^{2+}$ (*4*) and $H^+ - Zn^{2+}$ (*5*) cation exchange with the Lewatit TP 207 (*a*) and Amberlite IRC 718 (*b*) ion exchangers.[26] Experimental data (full and open circles and full and open triangles) were obtained at different metal salt concentrations in the liquid phase.

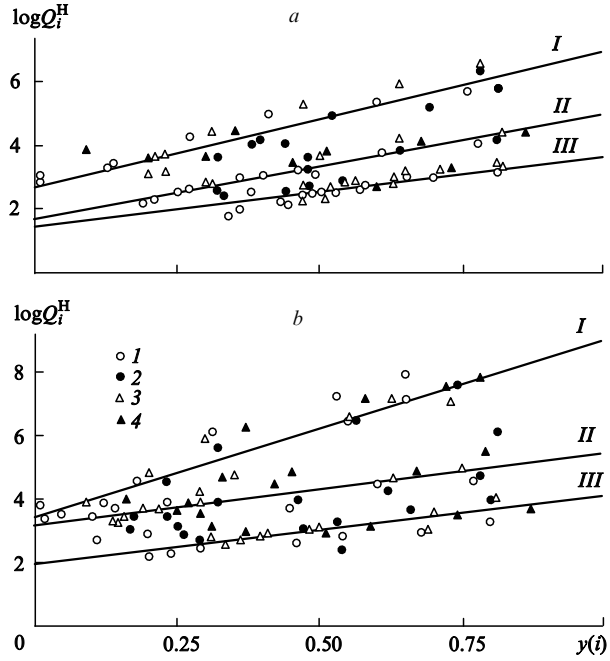

Figure 8. Development of generalised separation factors for the exchange of Ni^{2+} (*I*), Cd^{2+} (*II*) and Cu^{2+} (*III*) (*a*) and Ca^{2+} (*I*), Co^{2+} (*II*) and Zn^{2+} (*III*) (*b*) for protons with the Purolite S 940 ion exchanger containing aminophosphonate functional groups (Purolite S 940).[35] $c_0(HCl) = 10$ mmol litre^{-1}; $c(MCl_2)$ /mmol litre^{-1}: 0 (*1*), 5 (*2*), 10 (*3*) and 25 (*4*); the straight lines were plotted using the linear regression technique.

and 4, the dependences of $\log Q^j_i$ on y_i are approximated by straight lines. However, the regions of deviations from linearity are somewhat larger, which can be due to higher mobility of the counterions in such resins.

Data for anion exchange equilibria on a strongly basic ion exchanger are shown in Fig. 6. As can be seen, the exchange of monovalent anions (Cl^-/NO_3^-, Cl^-/HCO_3^-) is described by horizontal straight lines. A slightly negative slope was found for the Cl^-/HCO_3^- exchange (see Fig. 6 *b*). The SCT approach treats this as an artifact, which is due to the fact that the ternary ion exchange system contains not only HCO_3^- ions but also CO_3^{2-} species ignored in the binary calculations. The exchange of sulfate ions is characterised by an increase in the slopes of the $\log Q^j_i - y_i$ dependences with an increase in $y(SO_4)$ (kink of the lines in Figs 6 *c*, *d*). Obviously, in this case different near-surface Stern layers are formed, which are successively filled with sulfate ions. This is consistent with the fact that strongly basic anion exchangers contain a variety of functional groups. Again, we can state that divalent sulfate ions are sorbed at longer distances from the surface compared to monovalent counterions (see Figs 6 *c*, *d*).

Evaluation of ion exchange equilibria using the SCT model were successfully extended to the systems containing organic counterions, *e.g.*, oxalate, malate and EDTA species. It was found that the corresponding separation factors $\log Q^j_i$ are linear functions of y_i and the binary parameters $\{\log K^i_j; m(i,j)\}$ of the SCT model were determined (Table 1).

Figure 7 presents the results of calculations of equilibria on two chelating selective resins Lewatit TP 207 and Amberlite IRC 718 containing iminodiacetate groups for the exchange of protons for divalent (calcium, magnesium, copper, zinc and nickel) cations. Analogous dependences obtained in calculations of equilibria on resins containing aminophosphonate functional groups are shown in Fig. 8. In both cases linear dependences of $\log Q^j_i$ on y_i can be deduced. The equilibrium constants $\{\log K^A_B; m(A,B)\}$ calculated using the experimental data for equilibria on different resins are listed in Table 1.

b. Amphoteric surfaces

In the framework of the SCT model evaluation of equilibria on amphoteric surfaces requires a more sophisticated procedure compared to those considered above. The first step (prior to calculations) is the assumption of a certain sequence of the Stern layers. Calculations begin with the evaluation of the equilibrium for the exchange of protons at the surface and counterions in the adjacent (first) layer. Calculations of the sorption of ions in the next Stern layer require the corresponding parameters for the first layer. Determination of the SCT model parameters for the third Stern layer requires both sets of binary parameters $\{\log K^A_B; m(A,B)\}$ of the two inner (first and second) layers. The procedure should be continued until all sets of binary parameters for all the Stern layers are calculated. The sequence of the Stern layers is treated as determined correctly if both calculated sets of binary parameters $\{\log K^A_B; m(H,i)\}$ of the SCT model show a monotonic increase in the parameter values with the distance from the surface. If this condition is not met, the computational procedure must be repeated using a modified sequence of Stern layers.

Let us consider a system of Stern layers for H^+, Cl^-, NO_3^- and Na^+ on activated alumina (see Fig. 1) as a simple example. The equilibrium parameters are calculated using the following relationships of the SCT model:[30, 31, 36]

$$\log Q^H_{Cl} = \log K^H_{Cl} + m(H,Cl)[y(Na) - y(Cl) - y(NO_3)], \quad (57)$$

Table 1. Parameters of the surface complexation theory for strongly basic resins.[26, 32, 33–35]

[a] $y(SO_4) > 0.6$. [b] X = EDTA. [c] Y is oxalate ion. [d] Z is malate ion. [e] $y(Cu) > 0.33$.

$$\log Q^H_{NO_3} - m(H, Cl)[-y(Cl)] = \log K^H_{NO_3} + \\ + m(H, NO_3)[y(Na) - y(NO_3)], \quad (58)$$

$$\log Q^H_{Na} - m(H, Cl)[-y(Cl)] - m(H, NO_3)[-y(NO_3)] = \\ = \log K^H_K + m(H, K)y(Na). \quad (59)$$

Evaluation of the equilibrium data on the sorption of Cl^-, NO_3^- and SO_4^{2-} ions on the Compalox AN7V 800 alumina and on the uptake of carbonate and sulfate ions and Na^+ cations by activated carbon using relationships (57)–(59) has been reported.[26, 30, 31, 36] Although the experimental data obtained for the sorption of sodium ions were not satisfactory, calculations led to linear dependences of $\log Q_i^j$ on y_i.

2. Sorption of metal salts

The binary SCT parameters $\{\log K_B^A; m(A,B)\}$ characterising the sorption equilibria for metals (M) are calculated using Eqns (46) and (47). The SCT parameters for the sorption of metal salts (m_1, m_2 and the formation constants of complexes, K_{MX_2} and $K_{H_2X_2}$) can be evaluated from experimental data as follows. The first step involves plotting $\log Q_{MX_2}$ *vs.* the dimensionless loading of the resin with the anions X^-, y_X. Linear regression (lines in Fig. 9 *a*) gives the parameters $\log K_{MX_2}$ as the *Y*-intercept and m_2 as the slope of the regression line. Then, the quantity $(\log Q_{MX_2} - m_2 y_X)$ is plotted *vs.* $y(H^+)$ using the experimental data and the m_2 value obtained (full and open circles and full and open triangles in Fig. 9 *b*). Linear regression using Eqn (47) again gives the parameters $K_{H_2X_2}$ and m_1 (see the corresponding line in Fig. 9 *b*).[34] The results of calculations for a number of systems for exchange of various metal cations and Cl^- anions with a weakly basic ion exchanger are illustrated in Fig. 9. The binary SCT parameters $\{\log K_B^A; m(A, B)\}$ for the $H^+/M^{2+}/Cl^-$ systems on the Purolite A 109 anion exchanger were calculated [34] using relationships (46) and (47) with consideration of the sorption (see Fig. 2) of two kinds of anions (Cl^- or SO_4^{2-}).

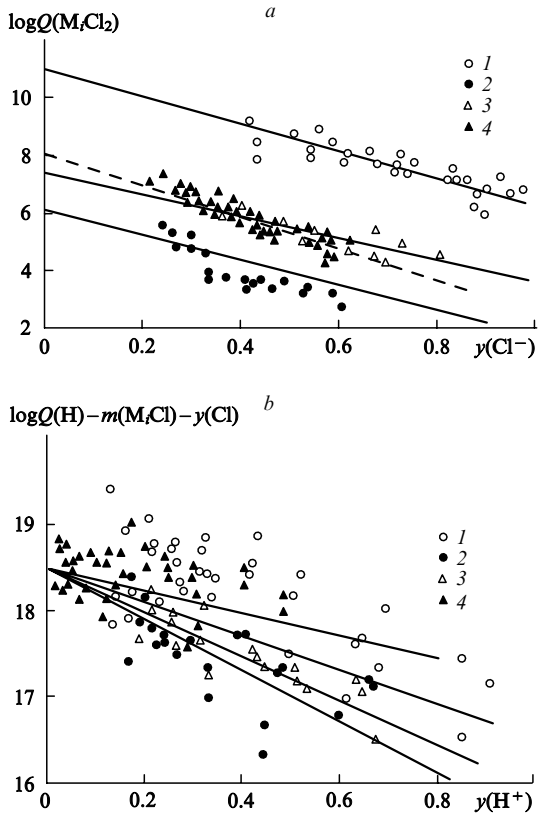

Figure 9. Plots of generalised separation factors for the sorption of hydrochloric acid and different metal chlorides (M_i) onto the weakly basic ion exchanger Purolite A 109.[34]
The parameter m_2 was calculated using Eqn (46) (*a*); the parameter m_1 was calculated using Eqn (47). M_i: Cu (*1*), Ni (*2*), Cd (*3*) and Zn (*4*).

V. Calculations of multicomponent equilibria using the SCT model

Calculations of multicomponent ion exchange equilibria in an arbitrary system require a system of conditions to be fulfilled. These are conservation of masses of the components, electroneutrality in the liquid phase and in the ion exchanger phase and chemical equilibria (for, *e.g.*, dissociation or complexation) in the liquid phase.[26–36]

The conditions for electroneutrality (stoichiometry) of exchange describe the constancy of chemical equivalents of components in the liquid phase (X_s) and in the resin phase (y_s), respectively

$$\sum_{s=\mathrm{A}} X_s = 1, \sum_{s=A} y_s = 1, s = \mathrm{A, B, C, E...}, \tag{60}$$

$$X_s = \frac{z_s c_s}{c_0}, y_s = \frac{a_s}{a_0},$$

where c_0 and a_0 are the coefficients for conversion of the corresponding concentrations c_s and a_s into dimensionless form.

The major advantage of the SCT approach is that the equilibria in multicomponent ion exchange systems {1, ..., *i*, ..., *j*, ...} can be predicted with ease provided that the binary parameters $\{\log K_j^i;\ m(i,j)\}$ for a number of binary exchanges, *i*/*j*, of the components of the system under study are known. It is particularly convenient if the binary parameters for the exchange of different counterions for the same (reference) counterion are obtained. Consideration of equilibria in a ternary system containing three ions, namely, A (reference), B and C leads to the following relationships:[26]

$$\log Q_{\mathrm{B}}^{\mathrm{A}} = \log K_{\mathrm{B}}^{\mathrm{A}} + m(\mathrm{A,B})[y(\mathrm{B}) + y(\mathrm{C})], \tag{61}$$

$$\log Q_{\mathrm{C}}^{\mathrm{B}} = \log K_{\mathrm{C}}^{\mathrm{B}} + m(\mathrm{B,C})y(\mathrm{C}). \tag{62}$$

As shown above, the equilibrium parameters of the SCT model for the binary exchange A/B in the ternary system A/B/C are the same as in the pure binary case. This also holds for the binary parameters of the A/C exchange. Therefore, only the B/C exchange parameters should be determined, which can be done with ease. The $\log K_{\mathrm{C}}^{\mathrm{B}}$ values are calculated using the relationship[26]

$$\log K_{\mathrm{C}}^{\mathrm{B}} = \log K_{\mathrm{C}}^{\mathrm{A}} - \log K_{\mathrm{B}}^{\mathrm{A}}, \tag{63}$$

while the unknown slope m(B,C) in Eqn (62) can be determined using representation of the sequence of Stern layers by electric capacitors connected in series (for substantiation, see above).[26–31] Since the parameter $m(i,j)$ is defined in relationships (18) or (48) *via* the electric capacitance, $C(i,j)$, of the capacitor formed by two Stern layers (i,j), one can make use of the well-known expression for the capacitance (C) of two capacitors connected in series (AB and BC)

$$\frac{1}{C(\mathrm{A,C})} = \frac{1}{C(\mathrm{A,B})} + \frac{1}{C(\mathrm{B,C})}. \tag{64}$$

Thus, we get[26, 31, 32, 36]

$$m(\mathrm{B,C}) = m(\mathrm{A,C}) - m(\mathrm{A,B}). \tag{65}$$

Similar relationships were also derived for multicomponent ion exchange systems containing more than three types of counterions.

In Figs 10–12 we present a number of examples of the experimental data and the results of calculations of multicomponent equilibria using the SCT model and corresponding data on binary ion exchange.

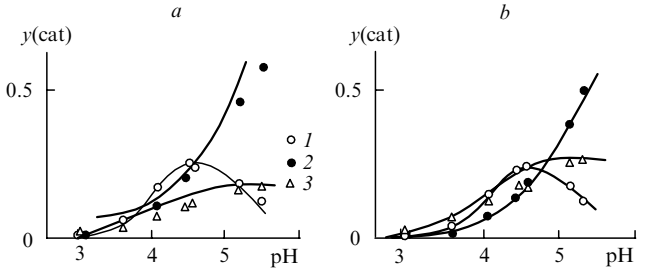

Figure 10. Experimental data (full and open circles and open triangles) and the calculated curves of ion exchange equilibria in the quaternary system $Mg^{2+}/Ca^{2+}/Zn^{2+}/H^+$ on the Lewatit CNP 80 weakly acid ion exchanger (originally in the Ca^{2+} form) obtained using the SCT model at $MgCl_2$ concentrations of 25 (*a*) and 50 mol litre^{-1} (*b*), $ZnCl_2$ concentration of 5 mol litre^{-1} and HCl concentration of 10 mol litre^{-1} (see Ref. 26)
Zn^{2+} (*1*), Ca^{2+} (*2*) and Mg^{2+} (*3*).

Figure 10 shows the results obtained for the sorption of different counterions by a weakly acid resin, which originally was in the Ca^{2+} form, in a quaternary ion exchange system. The equilibria are represented as the dimensionless loadings of different cations plotted *vs.* the pH value. As can be seen, the experimental data and the SCT predictions are in good agreement. Similar results were also obtained for strongly acid and strongly basic ion exchangers.[26, 31, 32, 36] In both cases the results of calculations exhibit reasonable agreement with the experimental data.

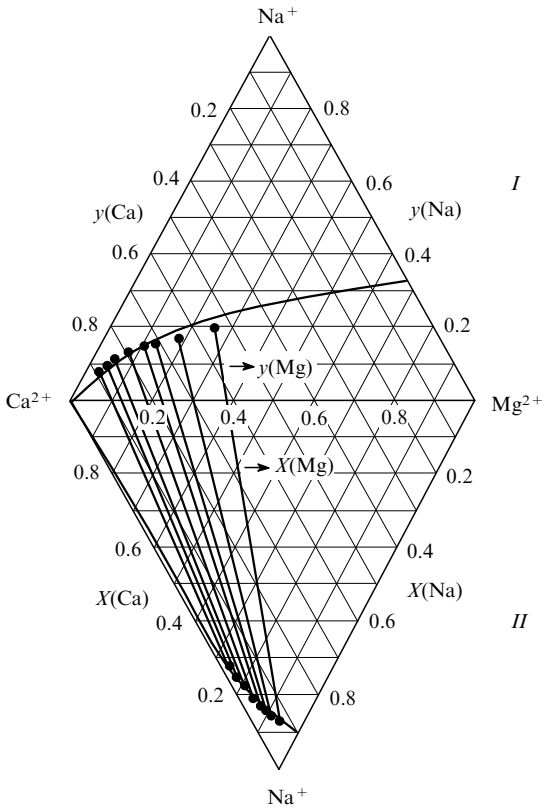

Figure 11. Experimental data (full circles) and the calculated curves of ion exchange equilibria in the ternary system $Na^+/Mg^{2+}/Ca^{2+}$ on the Lewatit S 100 strongly acid ion exchanger for the resin phase (*I*) and liquid phase (*II*) obtained using the SCT model.[26]
$y(Na) + y(Ca) + y(Mg) = 1$; $X(Na) + X(Ca) + X(Mg) = 1$; $c_0(Mg) = 2.5$, $c_0(Na) = 50$ mmol litre^{-1}.

The exchange of three ions with a strongly acid ion exchanger (Lewatit S 100), which exhibits no preferred affinity towards a particular ion, is illustrated by Fig. 11. Here, we deal with similar concentrations of all components; therefore, the ternary equilibrium can be represented using the triangular diagram. Some differences between the experimental and calculated values for the resin phase can be explained by neglect of the concentration of the counterions in the diffusion layer *D* adjacent to the most distant Stern layer: *N*|*D* (see above).

Figure 12 presents a comparison of the experimental data (full and open circles) with the loadings $y(i)$ calculated using the SCT model for the $NiCl_2/NiSO_4/HCl/H_3BO_3$ and $Ni(SO_3NH_2)_2/HCl/H_3BO_3$ systems on the Purolite S 950 resin containing aminophosphonate functional groups.

The individual equilibrium parameters of amphoteric sorbents were determined above. In Fig. 13 we compare the experimental data on the adsorption equilibria for various counterions (protons, carbonate and chloride ions and calcium cations) on activated carbon. As can be seen, an increase in the pH value of the solution causes the relative loading with chloride ions to decrease and the loadings with calcium, hydrogen and carbonate ions to increase. Nevertheless, the uptake of calcium is small (*i.e.*, the sorbent capacity towards the sorption of these cations is low). Comparison of the results of calculations and experimental data also demonstrates a high predictive power of the SCT model.

The results of an experimental study on the adsorption of $CuCl_2$ and $NiCl_2$ on the Purolite A 109 weakly basic anion exchanger are presented in Fig. 14 as functions of the pH value. These data are in reasonable agreement with the results of calculations using the sets of binary parameters $\{\log K_B^A; m(A,B)\}$ of the SCT model.[26–36]

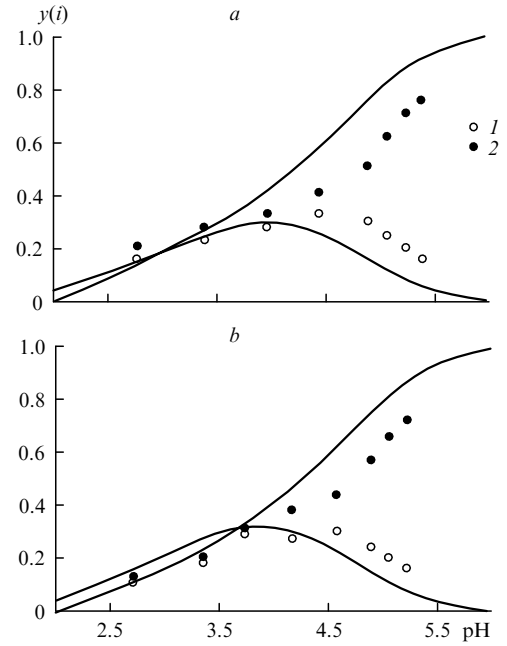

Figure 12. Experimental data (full and open circles) and the calculated curves of ion exchange equilibria in the systems $NiCl_2/NiSO_4/HCl/H_3BO_3$ (*a*) and $Ni(SO_3NH_2)_2/HCl/H_3BO_3$ (*b*) on the Purolite S 950 aminophosphonate resin (originally in the Ca^{2+} form) obtained using the SCT model.[35]
(*a*): $c_0(NiCl_2) = 4$, $c_0(NiSO_4) = 6$, $c_0(HCl) = 10$, $c_0(H_3BO_3) = 5$ mmol litre;
(*b*): $c_0(Ni(SO_3NH_2)_2) = 10$, $c_0(HCl) = 10$, $c_0(H_3BO_3) = 5$ mmol litre^{-1}; Ni (*1*) and Ca (*2*).

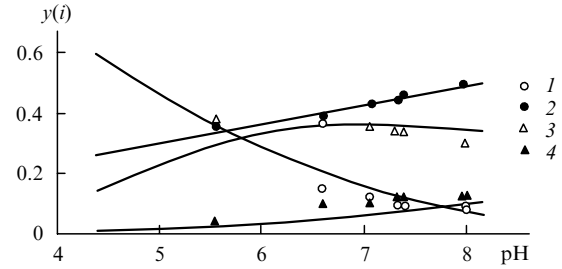

Figure 13. Experimental data (full and open circles and full and open triangles) and the predicted loadings of activated carbon (Chemivron F 100) with various species calculated using the SCT model (curves) .[32]
Species: SOH_2Cl (*1*), SOH (*2*), $(SOH_2) = CO_3$ (*3*) and $(SO_2) = Ca$ (*4*).

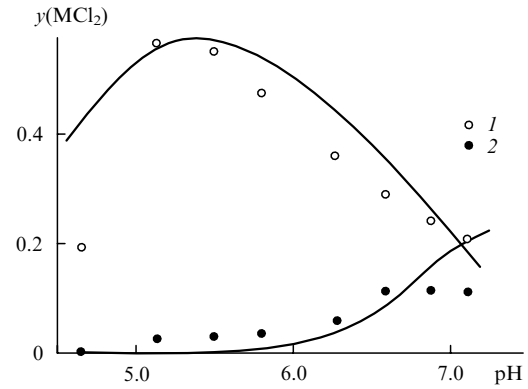

Figure 14. Experimental data (full and open circles) and the predicted loadings of the Purolite A 109 anion exchanger with copper chloride (*1*) and nickel chloride (*2*) calculated using the SCT model (curves).[34]
$c_0(CuCl_2) = c_0(HCl) = 5$, $c_0(NiCl_2) = 25$ mmol litre^{-1}.

VI. Application of the SCT model to nonlinear theory of multicomponent sorption dynamics and chromatography

The sorption equilibria characterise the fundamental thermodynamic properties of an ion exchange system.[58–68] The first step in solving problems of multicomponent sorption dynamics is to choose a model for multicomponent equilibria. Until recently the main difficulty consisted in the lack of models suitable for correct description of multicomponent equilibria in real sorption systems. However, in spite of the development of such models, the model of competitive multicomponent sorption proposed by Langmuir remains the most popular as yet. It should be considered as an idealised model, because the separation coefficients, α_{ij}, of components in such a nonlinear system of multicomponent equilibria are assumed to be constant and independent of the concentrations $\{X_1,..., X_n\}$ in the mixture of n ions (components).[58–66] In this case the exchange of equally charged ions is described by the following analytical relationships:[58–66]

$$X_i^{eq} = \frac{\alpha_{1i} y_i}{U} = y_i / \sum_{s=1}^{n} \alpha_{is} y_s \,,$$

$$U = \sum_{s=1}^{n} \alpha_{1s} y_s = \alpha_{1n} + \sum_{s=1}^{n-1} (\alpha_{1s} - \alpha_{1n}) y_s,$$

or

$$y_i^{eq} = \frac{\alpha_{i1} X_i}{V} = X_i / \sum_{s=1}^{n} \alpha_{si} X_s \,,$$

$$V = \sum_{s=1}^{n} \alpha_{s1} X_s = \alpha_{n1} + \sum_{s=1}^{n-1} (\alpha_{s1} - \alpha_{n1}) X_s, \qquad (66)$$

$$V = \frac{1}{U}.$$

Here α are the binary separation coefficients, (s,i) or (i,s), of the components in the n-component mixture

$$\alpha_{is} = \frac{y_i / X_i}{y_s / X_s},$$

$$\alpha_{is} = \frac{1}{\alpha_{si}}, \; i,s = 1, 2, ..., n, \qquad (67)$$

and y and X are the dimensionless concentrations of ions (i or s) in the sorbent phase and in solution, respectively.

The Langmuir model[67] of an idealised localised monolayer was proposed for a one-component system. This simple model is inapplicable to multicomponent mixtures; however, it was formally extended to multicomponent systems.[58–66, 68] Studies on the multicomponent Langmuir model and a number of related phenomenological models were thoroughly reviewed.[58–62, 65, 66] In particular, it was shown[58] that application of the mass action law relationships to the exchange of equally charged ions in a mixture [with consideration of the condition for electroneutrality (60)] allows the sorption equilibria to be formally described by Eqns (66). Analytical relationships (66) and (67) for the description of competitive multicomponent sorption equilibria have long been known.[58–66, 68] The symmetric and simple form of these relationships permits their use in not only numerical solution to problems of the sorption and ion exchange dynamics (for analysis, see Refs 58–66, 69–71) but also electrophoresis theory.[72]

In his review[64] Tondeur analysed theoretical concepts and problems of multicomponent sorption dynamics and chromatography. He pointed out three properties of the Langmuir model which have a significant impact on the modern view of competitive multicomponent sorption dynamics. These are the kinetic approach to the description of equilibria, the symmetric form of relationships (66) and (67) for the Langmuir isotherms and the implications beyond the scope of adsorption theory (see, *e.g.*, Ref. 72).

The basics of the kinetic approach leading to relationships (66) are as follows:[64] (1) an adsorption equilibrium is treated as equality of the sorption–desorption rates simultaneously for all components; (2) the desorption rate of each component is proportional to the relative coverage of the sorbent surface with the corresponding component; and (3) the adsorption rate is proportional to the product of two factors, *viz*., the concentration of a given component in the liquid phase and the fraction of uncovered sorbent surface.

Using relationships (19) and (60), it was shown[26] that the Langmuir competitive model (66) and (67) is naturally described as a particular case for the SCT model provided that two conditions are simultaneously met, namely, all exchanging counterions have equal charges and all SCT parameters $m(i,j)$ are equal to zero. The latter condition means that all the electrical double layers $|i\,j|$ have infinitely large electric capacities [see Eqn (18)]. Therefore, in the framework of the SCT model the Langmuir multicomponent sorption corresponds to the formation of surface complexes of various ions on the same Stern layer (at the surface near the reactive sites).[26] In this case, the generalised separation factors Q_j^i of the SCT model [see Eqn (19)] are transformed into the constants α_{is} [see Eqn (67)] of multicomponent Langmuir isotherms [see Eqn (66)].

The separation factors α_{ij} characterise the relative selectivity of the sorbent in binary exchange i/j. Namely, if $\alpha_{ij} > 1$, the component i has a higher affinity than the component j. The ith concentration distribution ratio

$$\gamma_i = \frac{y_i}{X_i}$$

characterises the affinity towards sorbent of each ith component of an n-component mixture. Using the concentration distribution ratios, an 'affinity sequence' of the species $(1 > 2 > ... > i > ... > j > ... > n)$ is determined, which is widely used in studies of the dynamics of multicomponent sorption systems. In the 'affinity sequence' the species are arranged in order of decreasing γ ($\gamma_i > \gamma_j$). Therefore, the species i (with smaller number in the affinity sequence) possesses a higher affinity towards the sorbent compared to the species j, because $\gamma_i > \gamma_j$ (or $\gamma_i/\gamma_j > 1$).

When the mixture composition $\{X_1, ..., X_n\}$ is varied, the position of the components in the 'affinity sequence' may remain unchanged (the so-called 'invariant affinity sequence') or it may vary (this is called 'inversion' or 'selectivity reversal').[51–53, 58, 60, 65] For the Langmuir isotherms (66) inversion is impossible because the separation factors are constants and the affinities of the mixture components remain unchanged. Using Eqns (49)–(51) of the SCT model, the effect of affinity inversion on the shape of multicomponent frontal and displacement chromatograms in the case of ion exchange in the $H^+/M_A^{2+}/M_B^{2+}/An^-$ (An^- is an anion) systems was studied.[51–53]

From the general theory of chromatography it follows that the behaviour of multicomponent concentration waves propagating in a sorption column is mainly governed by the set of adsorption properties of the mixture components which form the corresponding 'affinity sequence'.[51–53, 58–66] Multicomponent sorption equilibria are mainly responsible for the order, shape and velocities of propagation of such waves (examples can be found in the literature[46, 47, 51–53, 58–66]).

The sorption dynamics is described using, *e.g.*, the term 'effect of interference of mixture components' (see a monograph[58] and reviews[63–65]). Generally, the interference of species can arise as a consequence of various forms of their interaction. There are the equilibrium interference effects (mutual influence of species on the equilibrium interphase distributions) and the kinetic interference effects (mutual influence of species on the time taken to establish the equilibrium between the concentrations of a given component in the disperse and continuous phases in the presence of other components). The equilibrium and kinetic interference effects can arise simultaneously upon changes in the state of components

(molecules or ions) due to chemical reactions (*e.g.*, complexation).[58]

Successful solution to a number of problems of sorption dynamics and chromatography related to interference of species and propagation of multicomponent concentration waves became possible after introducing the fundamental coherence concept.[58, 73–76]

The multicomponent model of liquid chromatography is described by a system of nonlinear mass balance equations for each *i*th component of a mixture containing *n* components [58–66, 77]

$$\delta\frac{\alpha_0}{c_0}\frac{\partial y_i}{\partial t}+\frac{\partial X_i}{\partial t}+u\frac{\partial X_i}{\partial Z}=0, \tag{68}$$

$$\frac{\alpha_0}{c_0}\frac{\partial y_i}{\partial t}=\zeta_i[X_i-X_i^{eq}(y_i)], \tag{69a}$$

or

$$\frac{\partial y_i}{\partial t}=\beta_i[y_i^{eq}(X_i)-y_i]. \tag{69b}$$

Here $\delta\equiv(1-\varepsilon)/\varepsilon$ (ε is the layer porosity); t is time (in s); u is the flow rate of the mobile phase (in m s^{-1}); Z is the distance along the sorption layer (in m); and ζ_i and β_i are the kinetic coefficients (in s^{-1}) for the film diffusion kinetics and intraparticle diffusion kinetics of limiting stages, respectively.

The mass balance equations (68) and (69) make use of the dimensionless concentrations of the components in the liquid phase (X_i) and in the sorbent phase (y_i). The equations (69a) or (69b) represent phenomenological model equations of sorption kinetics for mixtures. They are based on the concept of linear driving forces,[78–82] according to which the rate of a kinetic process in the sorbent phase for a given component i is proportional to the corresponding kinetic coefficient ζ_i or β_i. In the case under study the effects of longitudinal dispersion are considered insignificant; therefore, the mass balance equation (68) ignores the longitudinal dispersion in the sorption layer of the column.

The system of equations (68) and (69a) [or (69b)] should be augmented with the system of equations for multicomponent sorption isotherms $y_i^{eq}(X)$ [or the system of reverse relationships $X_i^{eq}(y)$], which determines the equilibria between the concentrations of the mixture components in the mobile liquid phase (X_i) and in the sorbent phase (y_i^{eq}):

$$\begin{aligned} &y_i^{eq}(X)=[X_i^{eq}(y)]^{-1},\\ &y_i^{eq}(X)=y_i^{eq}(X_1, X_2, ..., X_n),\\ &X_i^{eq}(y)=X_i^{eq}(y, y_2, ..., y_n). \end{aligned} \tag{70}$$

To include the relationships of the SCT model of the type (19) for multicomponent ion exchange equilibria in these considerations, one should elaborate relevant computational methods, as well as procedures for solving the dynamic equations (68) and (69). Here, the condition for stoichiometry (equivalence of exchange) [see Eqns (60)] should be taken into account.

The SCT model was employed to describe the dynamics of simple (A/B) binary ion exchange systems in which the concentration fronts of the A/B exchange in the column are considered.[37–39, 43] The shape of the concentration profile, $X_A(Z,t)$, is governed by the shape of the binary isotherm $y^{eq}(X_A)$, which depends on the binary parameters $\{K_B^A; m(A,B)\}$ of the SCT model and on the counterion charge ratio, z_A/z_B (see Refs 26, 36–39, 50). The corresponding relationships of the SCT model for the (A/B) binary ion exchange systems have the form

$$\frac{y_A^{eq}(X_B^{eq}/z_B)^{2/z_B}}{y_B^{eq}(X_A^{eq}/z_A)^{2/z_A}}=K_B^A\exp[\ln 10(m_{AB}y_B^{eq})], \tag{71}$$

where $y_B^{eq}=1-y_A^{eq}$; $X_B^{eq}=1-X_A^{eq}$.

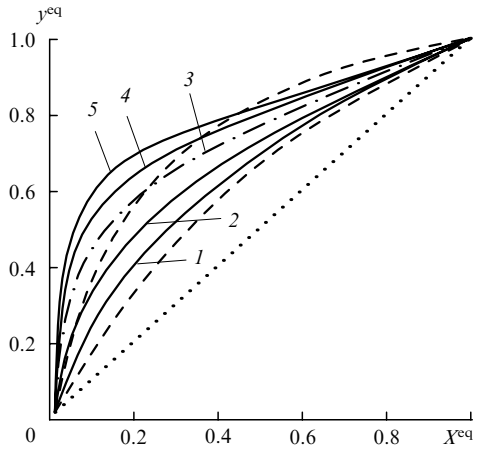

Figure 15. Binary A/B ion exchange isotherms at $z_A/z_B = 1$ and $K_B^A = 2$; $m(A,B) = 0.2$ (*1*), 0.5 (*2*), 1.0 (*3*), 1.5 (*4*) and 2 (*5*).[50]
Two Langmuir isotherms [$m(A,B) = 0$; $K_B^A = 2$ and 5] are shown by the dashed lines and the diagonal of the 'concentrational rectangle' is shown by the dotted line.

The binary exchange isotherms calculated at different values of the parameters $\{K_B^A; m(A,B)\}$ and different z_A/z_B ratios are shown in Figs 15 and 16 (see also Ref. 26). As can be seen, their curvatures and asymmetries depend on the joint effects of the two SCT parameters. The curvatures of the isotherms monotonically increase with an increase in the parameters $m(A,B)$ (see Fig. 15) and K_B^A (see Fig. 16). A comparison of the plots for the same values of the SCT parameters at different z_A/z_B ratios (dash-and-dotted curves in Figs 15 and 16) shows that the larger the z_A/z_B ratio, the higher the curvature of the isotherm.

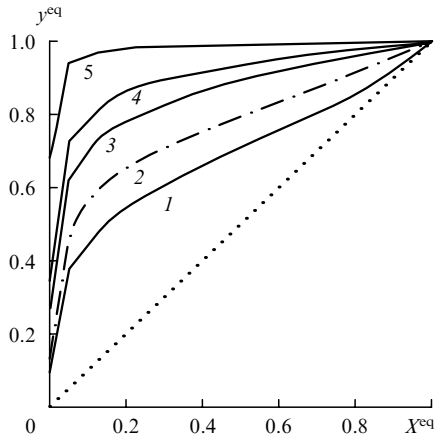

Figure 16. Binary A/B ion exchange isotherms at $z_A/z_B = 3/2$ and $m(A,B) = 1$; $K_B^A = 1$ (*1*), 2 (*2*), 5 (*3*), 10 (*4*) and 100 (*5*).[50]
The diagonal of the 'concentrational rectangle' is shown by the dotted line.

The SCT isotherms for equally charged counterions at $m = 0$ (dashed lines in Fig. 15) are reduced to the Langmuir isotherms. In the region of normalised concentrations ($0 < y^{eq}, X^{eq} < 1$), the binary Langmuir isotherms are symmetrical with respect to the back diagonal.[26] At the same time, the binary SCT isotherms for exchange of differently charged counterions ($z_A \neq z_B$) are essentially asymmetric (see, *e.g.*, inflection points in the plots in Fig. 16).

VII. Steady-state binary concentration distributions

The results of computer simulation were compared with the theoretical results obtained using analytical solutions of the mass balance equations (68) and (69) for binary (A/B) ion exchange and a steady-state concentration front X_A using relationship (71) at different values of the binary parameters $\{K_B^A; m(A,B)\}$.[37–39, 42, 43] This was done (for analytical solutions, including differently charged ions z_A, z_B and the case $m = 0$, see Refs 37 and 38) using an original code written for calculations of the dynamics of ion exchange in multicomponent systems. To test the code and evaluate the accuracy of the results obtained, the breakthrough binary output curves were calculated for both intraparticle (see Ref. 38) and film diffusion kinetics [37, 43] in various nonlinear ion exchange systems.

The mass balance equation (69a) for binary exchange of equally charged ions ($z_A = z_B$) was found to be integrable at $0 < m(A,B) < 1$ assuming film diffusion kinetics. The corresponding analytical solutions which describe steady-state concentration waves for A/B binary exchange were first reported recently.[42] In Fig. 17 we compare the results of numerical simulation and the theoretical results obtained using analytical solutions.[42,50] Shown are the output concentration distribution curves for a binary ion exchange system at different HETP values. The parameter HETP characterises the efficiency of the sorption layer in the column. It is related to the kinetic coefficient ζ (or β) by a simple algebraic relationship,[82] which in the case of film diffusion kinetics has the form

$$\mathrm{HETP} = \frac{2u(a_0/c_0)^2}{\zeta(1 + \delta a_0/c_0)^2}.$$

From the general theory of chromatography it follows that the higher the curvature of the SCT isotherms the greater the slope of the calculated profiles of the corresponding concentration fronts.[39, 42, 50] Clearly, the smaller the HETP value for the same isotherm the narrower the concentration front (*cf.* curves *1–3* in Fig. 17).

Agreement between the results obtained using analytical solutions and numerical calculations for steady-state concentration fronts in A/B binary exchange systems points, first, to high accuracy of the iterative numerical procedure employed for both ion exchange equilibria and component concentrations in a dynamic sorption process and, second, to successful implementation of the SCT model in computer simulation of the ion exchange dynamics in nonlinear multicomponent systems.

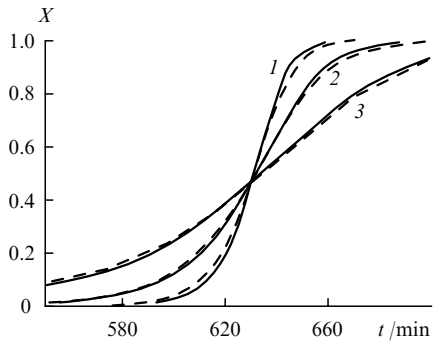

Figure 17. Steady-state breakthrough concentration distributions for binary exchange at the SCT model parameters $K_B^A = 2$, $m = 0.12$ and different heights of equivalent theoretical plate (HETP). HETP = 0.5 (*1*), 1 (*2*) and 2 cm (*3*).[42] Solid lines correspond to analytical solutions and dashed lines correspond to the results of numerical calculations; column length is $L = 30$ cm; film diffusion kinetics.

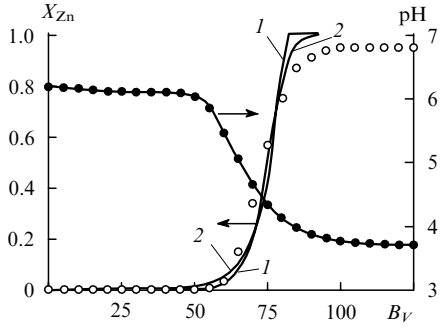

Figure 18. Breakthrough concentration dependences for the Zn^{2+}/Ca^{2+} exchange on the Purolite S 940 ion exchanger.[83]
Film diffusion kinetics (*1*) and intraparticle diffusion kinetics (*2*). Full and open circles stand for experimental data while the results of calculations are shown as solid curves; B_V is the number of column volumes.

Summing up, note that Kiefer [83] studied a number of binary systems containing metal ions (Cu^{2+}/Ca^{2+}, Ni^{2+}/Ca^{2+}, Zn^{2+}/Ca^{2+}, Cd^{2+}/Ca^{2+}) and compared the calculated and experimental output concentration curves obtained with columns filled with various Purolite resins (S 950, S 940, D 3342, D 3343). As an example in Fig. 18 we present the curves for the Zn^{2+}/Ca^{2+} ion exchange system on the Purolite S 940 resin. As can be seen, the results of numerical calculations are in agreement with experimental data.

VIII. Computerised description of ion exchange dynamics in multicomponent systems using the SCT model

Nonlinear mass balance equations for multicomponent systems are solved using the method of finite differences and an appropriate explicit numerical computational scheme (predictor–corrector).[84] To calculate various types of multicomponent equilibria based on the SCT model, iterative procedures have been developed.[37–40, 43, 44, 46–53]

Test calculations of multicomponent frontal and displacement chromatograms using an original code have been reported.[37–39, 50] As an example, in Figs 19 and 20 we present such chromatograms for Langmuir-type ion exchange systems [see Eqns (66)] containing equally charged ions (A, B, C, E) that form the 'affinity sequence' A > B > C > E in order of decreasing affinity towards sorbent. The chromatograms in Figs 19 and 20 were obtained for the ternary (A/B/C) and quaternary (A/B/C/E) exchange systems, respectively.

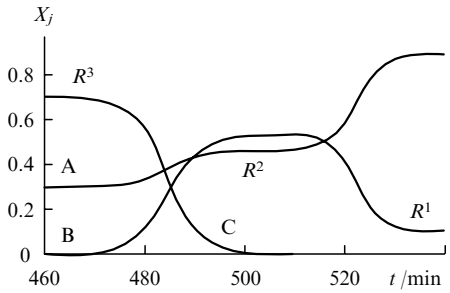

Figure 19. Steady-state concentration profiles in the output chromatogram for a ternary exchange system of equally charged ions A/B/C; column length $L = 100$ cm.[38, 39]
Concentration plateau: R^1 {0.9; 0.1; 0}, R^2 {0.466; 0.533; 0}, R^3 {0.3; 0.7; 0}.

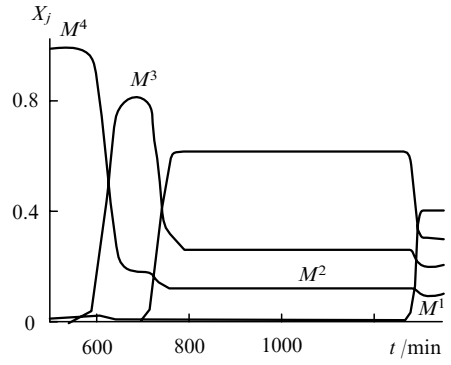

Figure 20. Steady-state concentration profiles in the output chromatogram for a quaternary exchange system of equally charged ions A/B/C/E; column length $L = 30$ cm.[38,39]
Concentration plateau: M^1 {0.4; 0.3; 0.2; 0.1}, M^2 {0; 0.616; 0.264; 0.118}, M^3 {0; 0; 0.885; 0.115}, M^4 {0; 0; 0; 1}.

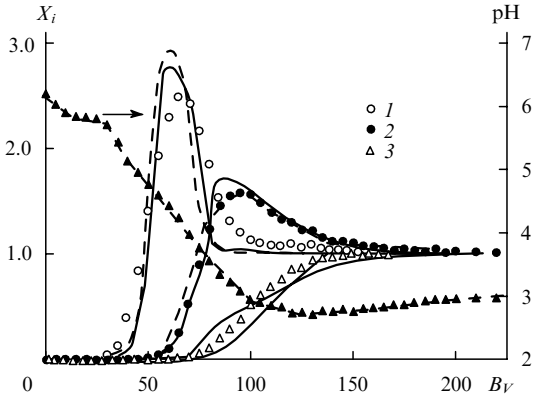

Figure 21. Experimental (full and open circles and open triangles) and calculated (curves) chromatograms for the $Cu^{2+}/Ni^{2+}/Zn^{2+}$ exchange on a column with the Purolite S 940 ion exchanger (originally in the Ca^{2+} form).[50,83]
The dashed lines correspond to film diffusion kinetics and the solid lines correspond to intraparticle diffusion kinetics; Ni (*1*), Zn (*2*) and Cu (*3*).

For multicomponent Langmuir systems the concentrations at the plateau R^s (see Fig. 19) or M^s (see Fig. 20) separating the concentration s-waves (s is the wave number; $s = 1, 2,...$) were calculated[37–41] analytically using the relations derived for the idealised equilibrium dynamic model (see Refs 58 and 74). In the steady-state regime the concentrations at the plateau on the left (R^s or M^s) and on the right (R^{s+1} or M^{s+1}) of a concentration s-wave depend exclusively on the equilibrium properties of the ion exchange systems and are determined by the parameters of multicomponent Langmuir isotherms [separation factors α_{ij}, see Eqn (67)].[58] Both analytical solutions and computer simulation of the dynamic process gave the same values of the concentrations $X_i^{(s)}$ at the multicomponent concentration plateau.

The results of numerical calculations of the concentration profiles shown in Figs 19 and 20 were compared with the results obtained using a number of analytical solutions[63,69–71] for multicomponent Langmuir systems assuming that all components of the mixture are characterised by the same dispersion parameters ($\beta_1 = \beta_2 = ... = \beta_m$ or $\zeta_1 = \zeta_2 = ... = \zeta_m$). Here, it is convenient to use a simple criterion derived from analytical solutions for the Langmuir isotherms.[63,69–71] At equal kinetic dispersion factors of the steady-state waves of the mixture components, relationships between the dimensionless and normalised concentration distributions (N_i^s) for each ith component of the multicomponent mixture are linear

$$N^s = N_i^s = \frac{X_i - X_i^s}{X_i^{s+1} - X_i^s} = N_j^s = \frac{X_j - X_j^s}{X_j^{s+1} - X_j^s}, \qquad (72)$$

$1 < i, ..., j < m$.

From this it follows that the variable concentration N^s in the multicomponent concentration s-wave is the same for all components. Similar linear relationships were obtained[37–39] in computer simulation of the R^sR^{s+1} and M^sM^{s+1} concentration waves (see Figs 19 and 20) in the Langmuir systems, which indicates a high accuracy of numerical calculations.

Column experiments[83] with a number of ternary and quaternary ion exchange systems showed that the corresponding equilibria are well described by the SCT model.[25–36] Multicomponent frontal and displacement chromatograms for the exchange of various metal ions (Cu^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Ca^{2+}) were obtained. Experimental studies[83] and numerical calculations[37–39] were carried out for both film diffusion and intraparticle diffusion kinetics. As an example, Fig. 21 shows the experimental chromatographic data obtained for a quaternary exchange system and the corresponding results of numerical calculations. A comparison revealed reasonable agreement between the theory and experiment, especially taking into account the difficulties in obtaining such multicomponent chromatograms and their relative accuracy.

Thus, the above-mentioned method of numerical calculations of the ion exchange dynamics in multicomponent systems and the iterative procedure for calculations of multicomponent equilibria allows the SCT model to be successfully employed in studies of the dynamic behaviour of nonlinear multicomponent ion exchange systems.

IX. Modelling of the dynamics of ion exchange due to Lewis acid/Lewis base interactions, as applied to multicomponent systems

The approach to modelling of multicomponent ion exchange systems based on the SCT model (see Section VIII) was extended[49,51–53] to calculations of the dynamics of the sorption of metal salts involving coordination bonding due to the Lewis-base properties of amino groups of weak-electrolyte ion exchangers (see Section III). In this case, anions of these metal salts are also sorbed in solution near the surface of the weak-electrolyte ion exchanger. According to the SCT model, the distribution of counterions (M^{2+}) and co-ions (X^-) near the resin surface is shown in Fig. 2.[33,34]

To model this mechanism of sorption, the system of dynamic equations (68) and (69) must be augmented with the SCT equilibria (49)–(52). The corresponding SCT equilibria are calculated iteratively and the equilibrium ion concentrations (y_i^{eq}; X_i^{eq}) thus obtained are included in the computational scheme for the concentration distributions in the concentration wave moving through the column.[49,51–53]

Two examples illustrating the results of computer simulation of frontal and displacement chromatograms for the $H^+/M_A^{2+}/M_B^{2+}/An^-$ ($An^- = Cl^-$, SO_4^{2-}) ion exchange systems[43,49,51–53] are shown in Fig. 22. Since in this system the $H^+/M_A^{2+}/M_B^{2+}/An^-$ ion exchange due to the Lewis acid/Lewis base interaction is accompanied by sorption of metal salt anions, the conditions for electroneutrality in solution and in the sorbent phase have the form:[49,51–53]

$$X_{An^-} = X_A + X_B + X_H, \qquad (73a)$$

$$y_{An^-} = y_A + y_B + y_H. \qquad (73b)$$

Ion exchange systems for exchange of various metals (Cu^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}) accompanied by sorption of various anions,

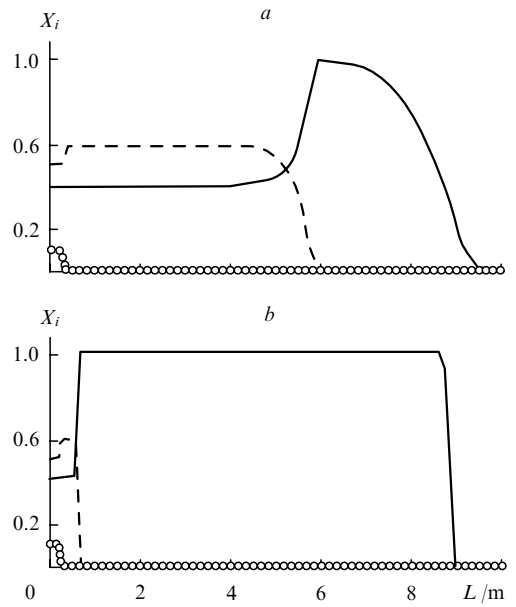

Figure 22. Calculated concentration (X_i) distributions along a chromatographic column filled with the Purolite A 109 weakly basic anion exchanger for the $H^+/Cu^{2+}/Ni^{2+}/An^{-1}$ exchange accompanied by sorption of Cl^- (*a*) and SO_4^{2-} anions (*b*).[51]
H^+ (open circles), Cu^{2+} (dashed lines) and Ni^{2+} (solid lines);
$c_0 = 0.3$ mol litre^{-1}, $X^0_H = 0.1$, $X^0_{Cu} = 0.5$, $X^0_{Ni} = 0.4$; $B_V = 7.4\,(a), 2\,(b)$.

namely, chloride ions (Cl^-, see Fig. 22 *a*) or sulfate ions (SO_4^{2-}, see Fig. 22 *b*) were studied.[49, 51–53] The anion distribution was calculated using Eqn (73a). Dynamic calculations were carried out using the experimental[33, 34] values of the binary SCT parameters $\{K^A_B; m(A,B)\}$.

The total concentration c_0 (in mol litre^{-1}) of the components, metal salt ions and protons at the column input was kept constant

$$z_A c^0_A + z_B c^0_B + z_H c^0_H = c_0$$

or in the dimensionless form

$$X^0_A + X^0_B + X^0_H = 1.$$

A dimensionless parameter commonly accepted in chromatography (see Fig. 22)

$$B_V = \frac{V_t}{V_0} = \frac{ut}{L}$$

denotes the number of the column volumes, V_0, which passed through the cross section of the column of length L, and characterises the elapsed time t from the start of the process. The B_V values (see Fig. 22) indicate that the dynamic displacement of metal ions accompanied by the sorption of Cl^- anion is more than three times slower than an analogous process accompanied by the sorption of SO_4^{2-} anions. Indeed, Figs 22 *a* and 22 *b* show that displacement of metal ions (both Ni^{2+} and Cu^{2+}) is much more efficient in the presence of divalent SO_4^{2-} anions compared to monovalent Cl^- anions. The influence of the inversion effects on the dynamic behaviour of various related systems for two types of weakly basic anion exchangers has been considered.[51–53]

X. Dynamics of ion exchange in multicomponent systems with allowance for ion complexation in the mobile liquid phase

Using the SCT model, relationships describing chemical reactions in the liquid phase can be included in calculations of multicomponent equilibria in a relatively simple way.[26, 32] However, in this case the theory of chromatography requires that the nonlinear multicomponent system of dynamic mass balance equations be transformed and represented in the form:[44, 46, 47, 50]

$$\delta \frac{\alpha_0}{c_0} \frac{\partial y_i}{\partial t} + \frac{\partial X_{\text{sum}\,i}}{\partial t} + u \frac{\partial X_{\text{sum}\,i}}{\partial Z} = 0,\ i = 1, 2, \ldots . \tag{74}$$

Now the total concentration of each component, $X_{\text{sum}\,i}$, includes not only the concentration of the ion i in the liquid phase but also the corresponding fractions of this component in various compounds formed as a result of chemical reactions. This approach to simulation of the dynamics of various ion exchange systems with allowance for chemical reactions was employed[44–50] in calculations of the dynamics of the $H^+/M^{2+}_A/M^{2+}_B$ ion exchange with inclusion of complexation reactions.

Let us calculate various ion concentrations taking the $H^+/M^{2+}_A/M^{2+}_B$ exchange with inclusion of complexation reactions in the mobile (liquid) phase of a chromatographic column as an example. Multicomponent equilibria in these systems are described by the SCT model (see Section II) while the accompanying complexation reactions in the mobile (liquid) phase of the column are described by relationships related to the mass action law.

For instance, the ion exchange $H^+/Ni^{2+}/Co^{2+}$ ('affinity sequence' H > Ni > Co) in the presence of citrate ion (Cit^{3-}) as a complex-forming agent can be calculated using the following system of relationships:[44, 46, 47, 50]

$$\begin{aligned}
&K_1 = X_1X_4, && K_2 = X_1X_7/X_6,\\
&K_3 = X_1X_8/X_7, && K_4 = X_1X_5/X_8,\\
&K_5 = X_3X_5/X_{14}, && K_6 = X_2X_5/X_9,\\
&K_7 = X_2X_5^2/X_{10}, && K_8 = X_2X_8/X_{11},\\
&K_9 = X_2X_7/X_{12}, && K_{10} = X_5X_{11}/X_{13},\\
&K_{11} = X_3X_8/X_{15}, && K_{12} = X_3X_7/X_{16}.
\end{aligned} \tag{75}$$

Here the constant parameters are $K_1 = 10^{-14}$ [the dissociation constant of water, in (mol litre^{-1})^2] and the reaction constants $K_2 - K_{12}$ listed in Table 2; X_i are the dimensionless concentrations of the ions ($i = 1-3$) and the components formed as a result of chemical reactions ($i = 6-16$):

i	Species	i	Species
1	H^+	9	$NiCit^-$
2	Ni^{2+}	10	$NiCit_2^{4-}$
3	Co^{2+}	11	$NiHCit$
4	OH^-	12	NiH_2Cit^+
5	Cit^{3-}	13	$NiHCit_2^{3-}$
6	H_3Cit	14	$CoCit^-$
7	H_2Cit^-	15	$CoHCit$
8	$HCit^{2-}$	16	CoH_2Cit^+

In accordance with the mass conservation law we have

$$X_0(\text{Cit}) = X_5 + X_6 + X_7 + X_8 + X_9 + 2X_{10} + X_{11} + X_{12} + 2X_{13} + X_{14} + X_{15} + X_{16}. \tag{76}$$

This equality describes the constancy of the total amount of the complex-forming agent (Cit^{3-}) in solution.

As usual, in describing the ion exchange we have to take into account the relations of equivalence for the concentrations of free ions ($H^+/Ni^{2+}/Co^{2+}$) in the ion exchanger and in solution:

$$y_1 + y_2 + y_3 = 1, \tag{77a}$$

$$X_1 + X_2 + X_3 = 1. \tag{77b}$$

Table 2. Parameters for calculations of ion exchange dynamics in multicomponent systems with inclusion of exchange equilibria described in the framework of the SCT model and complexation reactions.[46, 47, 50]

System No.	Purolite resin	Ion exchange	Complex-forming agents	Reaction constants [a]	Binary SCT parameters	
					$\log K_j^H$	$m(H,j)$
1	S 950	$H^+/Ni^{2+}/Ca^{2+}$	$H_2BO_3^-$, $SO_3NH_2^-$, Cl^-	K_1-K_{12}	3.03	3.31
					2.81	4.81
2	S 950	$H^+/Ni^{2+}/Ca^{2+}$	$H_2BO_3^-$, SO_4^{2-}, Cl^-	K_1-K_{12}	3.03	3.31
					2.81	4.81
3	S 940	$H^+/Cu^{2+}/Ca^{2+}$	SO_4^{2-}	K_1-K_4	1.44	2.15
					3.37	5.62
4	S 940	$H^+/Cd^{2+}/Ca^{2+}$	NH_3, NO_3^-	K_1-K_{12}	1.65	3.28
					3.37	5.62
5	S 940	$H^+/Zn^{2+}/Ca^{2+}$	NH_3, Cl^-	K_1-K_{12}	1.96	2.02
					3.37	5.62
6	S 950	$H^+/Ni^{2+}/Zn^{2+}$	Cit^{3-}	K_1-K_{12}	3.03	3.31
					2.3	1.18
7	S 950	$H^+/Ni^{2+}/Na^+$	Cit^{3-}	K_1-K_{10}	3.03	3.31
					1.95	1.82
8	S 940	$H^+/Co^{2+}/Na^+$	Cit^{3-}	K_1-K_8	3.11	2.22
					1.34	3.71
9	S 940	$H^+/Zn^{2+}/Co^{2+}$	Cit^{3-}	K_1-K_{11}	1.96	2.02
					3.11	2.22
10	S 950	$H^+/Ni^{2+}/Co^{2+}$	Cit^{3-}	K_1-K_{12}	3.03	3.31
					2.96	2.11

[a] $K_2 = 102$, $K_3 = 4.4$, $K_4 = 6.3 \times 10^6$, $K_5 = 6.2$, $K_6 = 1.26$, $K_7 = 1.66$, $K_8 = 50.1$, $K_9 = 4 \times 10^{-3}$, $K_{10} = 0.008$, $K_{11} = 831$.

In this case the number of the differential mass balance equations (74) for the concentrations $X_{sum\,1}(H^+)$, $X_{sum\,2}(Ni^{2+})$ and $X_{sum\,3}(Co^{2+})$ equals three ($n = 3$):

$$X_{sum\,1}(H^+) = X_1 - X_4 + 3X_6 + 2X_7 + X_8 + X_{11} + 2X_{12} + X_{13} + X_{15} + 2X_{16}, \quad (78a)$$

$$X_{sum\,2}(Ni^{2+}) = X_2 + X_9 + X_{10} + X_{11} + X_{12} + X_{13}, \quad (78b)$$

$$X_{sum\,3}(Co^{2+}) = X_3 + X_{14} + X_{15} + X_{16}. \quad (78c)$$

Numerical simulation of the dynamics of such ion exchange systems was carried out using the experimental[83] values of the binary SCT parameters $\{K_B^A; m(A,B)\}$ obtained for various Purolite resins. The corresponding parameters of the Purolite S 940 and S 950 resins are listed in Table 2. The complexation constants K_i included in relationships (75) can be found in the literature (see, *e.g.*, Ref. 54). To illustrate the large differences between the values of these constants (orders of magnitude), the corresponding data are listed in Table 2.

The nonlinear multicomponent system of dynamic mass balance equations (74)–(78) was numerically solved by the method of finite differences. In this case, in addition to the numerical schemes based on the SCT equilibria (19), iterative procedures for solving the Eqns (75) and (76) describing the complexation reactions with allowance for the relations of equivalence (77) must be included. A software package for calculations of the dynamics of various multicomponent ion exchange systems including quinary systems has been created.[44–48, 50] Some examples are given in Table 2.

Based on the models elaborated, the propagation of n-component concentration waves formed in the sorption field of the column was calculated. A number of calculated output frontal-displacement curves for the ion exchange sorption and regeneration in two ion exchange systems are presented in Figs 23 and 24 as examples. Here, shown are the distributions for the exchange of metal ions (A^{2+}/B^{2+}); the concentration of the third exchanging ion (H^+) is low and the corresponding curves are therefore omitted.

The multicomponent output frontal and displacement chromatograms presented in Fig. 23 in the pseudo-3D space $\{X_i, t, s\}$ are the same as those given in two dimensions in Fig. 24 *c*. The distributions in Fig. 23 clearly illustrate the relative positions of the output concentration curves during the sorption and regeneration processes, obtained for columns of different length L_s. The s values ($s = 1, 2, 3, 4$) for columns of different length $L_{1,2,3,4}$ (L_s/HETP = 30 or 60) are plotted on the y axis directed 'perpendicular' to the plane of Fig. 23.

In Fig. 24 *a*, *b* we present the calculated output concentration curves obtained for the ion exchange systems Nos 1 and 8 (see Table 2) with allowance for the effect of chemical reactions.[44–48, 50] To compare the dynamic behaviour of different

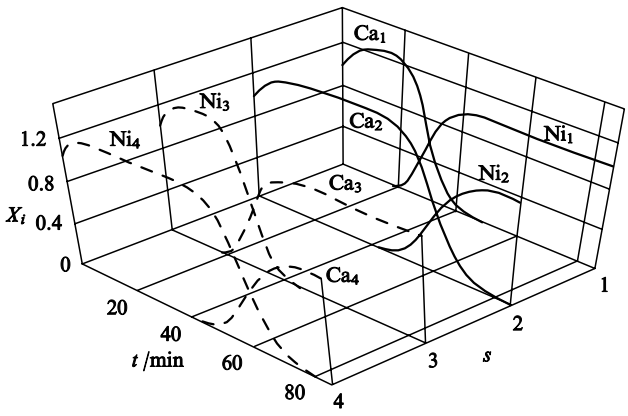

Figure 23. Output concentration distributions $X_i(t)$ shown in the $\{X_i, t, s\}$ space for $H^+/Ni^{2+}/Ca^{2+}$ exchange; column lengths are $L_{1,3} = 30$ HETP and $L_{2,4} = 60$ HETP.[46, 50]
$Ni_{1,2}/Ca_{1,2}$ sorption (solid lines), $L_{1,2}$; $Ca_{3,4}/Ni_{3,4}$ regeneration (dashed lines), $L_{3,4}$.

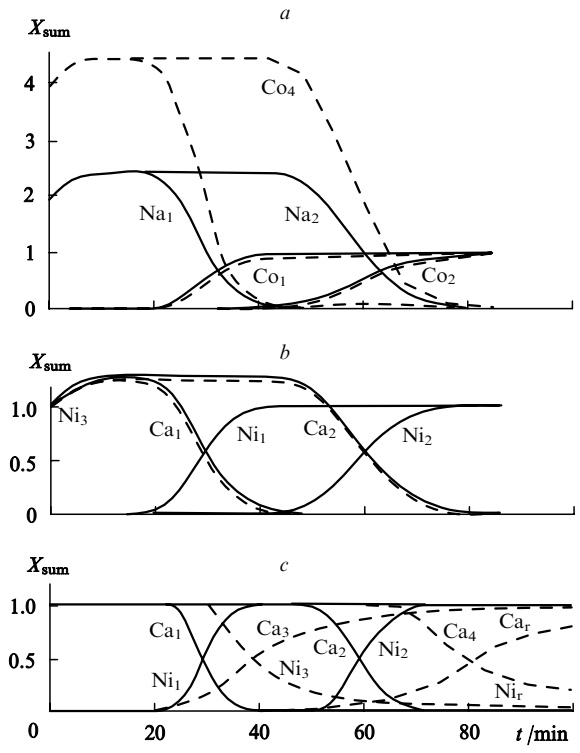

Figure 24. Calculated concentration distributions for $H^+/A^{2+}/B^{2+}$ ion exchange on columns of different length L_s.[46,47]
$H^+/Co^{2+}/Na^+$ exchange with inclusion of chemical reactions (*a*); $H^+/Ni^{2+}/Ca^{2+}$ exchange with inclusion of chemical reactions (*b*); and $H^+/Ni^{2+}/Ca^{2+}$ exchange ignoring chemical reactions (*c*); solid lines describe the ion exchange (B/A) sorption of the mixture, $X_i(t)$; dashed lines describe the ion exchange regeneration (A/B) of the column, $X_{ir}(t)$ (Ca_r, Ni_r).

ion exchange systems, Fig. 24 *c* also shows the calculated output curves obtained for the former system in the absence of complexation reactions.

A comparison reveals essential changes in the character of the output concentration curves for the same system caused by the effect of complexation reaction. The output curves of both sorption and regeneration processes obtained with inclusion of complexation exhibit no long 'tails' (see Fig. 24 *a*, *b*); the shapes of the output curves in Fig. 24 *b* obey an identical pattern and the corresponding solid and dashed lines nearly match one another.

In the case of conventional ion exchange the regeneration processes are characterised by the output concentration curves with very long 'tails' (see Fig. 24 *c*), which significantly slow down the regeneration. Besides, both sorption and regeneration accompanied by complexation proceed at higher rates and the output concentrations of the displaced ions are much higher. Therefore, the allowance for chemical reactions permits a more efficient regeneration of ion exchange columns.

XI. Conclusion

The surface complexation theory used for calculations of multicomponent equilibria has been developed during the last decade.[25–36] It is based on a relatively simple model for the arrangement of ions, which are assumed to be located in ordered Stern layers extended parallel to the planar sorbent surface.

The description of arbitrary equilibria in the framework of the SCT model is based on the concept of generalised separation factors, which can be determined using experimental data on binary exchange. The dependence of these coefficients on the sorbent composition provides valuable information on the binary equilibria. An individual sorption equilibrium can be characterised by two constant parameters of the SCT model, $\{K_{i+1}, m(i,i+1)\}$, which are independent of the pH value or the ionic strength of the solution (liquid phase).[26,30,31,36] These parameters also remain constant in arbitrary multicomponent systems for which simple (binary) equilibria can be calculated for a wide range of experimental conditions.[26–36] The SCT model treats multicomponent equilibria as a kind of superposition of several simple equilibria and allows them to be calculated using the parameters of binary subsystems.[26–36] Arbitrary chemical equilibria in the liquid phase with inclusion of dissociation, association or complexation phenomena can be taken into account in a relatively simple manner for both multicomponent equilibria [30,31,36] and dynamic systems.[44–48,50]

One field of application of the SCT model is the prediction of multicomponent ion exchange kinetics. The potentialities of the approach were demonstrated in calculations of the film diffusion kinetics where this method for the description of equilibria was implemented in solving the Nernst–Planck equations.[85,86]

Sorption equilibria in ternary and quaternary systems with strong- and weak-electrolyte ion exchangers can be predicted very accurately even with inclusion of chemical reactions. The method was incorporated into commercially available software for the design of demineralisers in ultrapure water production.[87]

The theory of formation of surface complexes (or the surface complexation theory, SCT model) can be applied with ease to calculations of the performance of sorption filters. It has been implemented in simple approximate equilibrium calculations using an idealised model in which the filter is represented by a series of stirred tanks (layer-by-layer calculation technique). This approach was shown [88] to be suitable for quite correct prediction of, *e.g.*, combined softening and dealkalisation of water with weakly acid ion exchangers.

The SCT model has also been incorporated into more sophisticated procedures for calculations of dynamic systems based on the theory of multicomponent sorption dynamics and chromatography. This field of application of the SCT approach seems to be quite promising because no appropriate models for multicomponent equilibria suitable for the description of the properties of real sorbents (ion exchangers) were proposed until recently.[37–53]

In a particular case where the SCT parameters $m(i,i+1)$ of all binary exchanges equal zero, the SCT equilibrium relationships are reduced to the well-known multicomponent Langmuir isotherms. This allows the accuracy and correctness of the methods elaborated for solving problems of multicomponent sorption dynamics to be evaluated.[37–42]

Currently, evaluation of the dynamic behaviour of nonlinear multicomponent ion exchange systems is based on the results of calculations of the output column concentration distributions for various ion exchangers.[37–53] Newly developed iterative procedures for calculations of multicomponent equilibria and new software permit successful implementation of the SCT model in the computational schemes for calculations of the dynamic behaviour of nonlinear multicomponent ion exchange systems.

In spite of obvious simplifications of the SCT model, the results obtained demonstrate the efficiency of this method in the calculations of multispecies equilibria and the kinetics and dynamics of sorption in multicomponent systems. The SCT approach can be used in both basic research and applied (in particular, engineering) studies.

Calculations of the propagation of multicomponent concentration waves in the sorption fields of ion exchange columns involve computer simulation. To facilitate perception of the complex dynamics of ion exchange, a kind of computer visualisation is used, namely, animation of the dynamic processes occurring in the chromatographic column.[48–53]

The results presented in this review have been obtained with financial support from the Deutsche Forschungsgemeinschaft (DFG, joint German–Russian Project Nos 463 RUS 113/596/0-1 (R) and 436 RUS 113/83), Deutsche Akademische Aus-

TauschDienst (DAAD, Project No. 325 sm) and the NATO Foundation (Project No. SA 12-2-02, CRG.971709).

Abstract. Properties of lead difluoride are considered. Phase equilibria in $PbF_2 - MF_n$ systems ($n = 1 - 5$) and data on compounds and solid solutions formed in these systems are analysed. The characteristic features of phase diagrams of systems involving lead difluoride are discussed. Composites of PbF_2 with other inorganic compounds hold promise as a basis for the design of new functional materials. The bibliography includes 331 references.

I. Introduction

In 1834, M Faraday discovered [1] that PbF_2 has high electrical conductivity when heated. This was the second (after silver sulfide) example of a solid electrolyte and the first example of anion (fluoride ion) conductors. Later on, both lead difluoride and fluoride ion conductors, *viz*., solid solutions, composite materials and glasses based on lead difluoride, were the subjects of extensive studies (see, for example, Refs 2 – 12). Of known chemical compounds, $PbSnF_4$ (see Refs 10 and 12) and non-stoichiometric phases in the $PbF_2 - KF$ system have the highest fluoride ion conductivity.

The high-temperature cubic modification of lead difluoride crystallises in one of the simplest structure types, the so-called fluorite structure type.[2] The phase transition discovered by Faraday appeared to be an inherent characteristic of all compounds with the fluorite structure (this transition is also known as the Faraday transition). This transition involves mass displacements of anions from their crystallographic positions, *viz*., disordering of the anion sublattice, without a change in symmetry (sometimes, this phenomenon is referred to as sublattice melting) resulting in the appearance of high ionic conductivity. This phenomenon attracts considerable attention and is studied both experimentally and theoretically.[13 – 32] Apparently, this disorder is responsible for the formation of wide regions of heterovalent solid solutions based on the fluorite modification of lead fluoride.

Lead difluoride has a relatively low melting point, due to which it is used as a component of fluxes for growing single crystals using the flux technique.[33 – 36] Examples are $PbF_2 - PbO$, $PbF_2 - V_2O_5$, $PbF_2 - Bi_2O_3$, $PbF_2 - B_2O_3$ and more complex systems.

Certain eutectic composites involving lead difluoride hold promise as operating materials for nuclear reactors (breeders), because they are characterised by good fusibility and high density.[37] Due to low affinity for fluorine, lead difluoride can be used as a fluorinating agent. Single crystals of refractory fluorides (CaF_2, LaF_3, *etc*.) are grown in the presence of small additives (2 mass % – 5 mass %) of PbF_2 as scavengers to purify melts from oxygen contamination.[38, 39] In this case, the following reactions proceed

$$CaO + PbF_2 \longrightarrow CaF_2 + PbO.$$

Melts are purified from PbF_2 and PbO due to high volatility of these components. Lead difluoride is used in fluorination of organic compounds.[40, 41]

Single-crystalline lead difluoride, PbF_2, is known as an optical functional material, which has transparency in a wide region from UV to mid-IR.[42, 43] Lead difluoride can form films with a high index of refraction and is involved in the composition of various optical antireflection coatings.[44 – 48]

A new generation of elementary particle accelerators (AAC in Protvino, Moscow region; LEP and LHC at the CERN Accelerator Complex, Switzerland) † imposes more stringent requirements on materials for high-energy particle detectors, which gave impetus to a search for new materials.[39, 49] High-speed combined systems of detectors involving scintillation and Cherenkov color-

† AAC is the Accelerator Accumulator Complex; LEP is the Large Electron Positron Collider (electron-positron ring); LHC is the Large Hadron Collider.

imeters (total absorption spectrometers) are used in experiments performed on accelerators. Requirements on working substances of such colorimeters are as follows: a radiation resistance of no lower than 10^7 rads per year; a high density ($> 5.5-6.5$ g cm^{-3}); a luminescence decay time, which determines the detector time resolution, shorter than 3–30 ns and at least a moderate specific light yield ($\sim 1\%$ of the specific light yield of NaI : Tl) for scintillators; good mechanical characteristics and the absence of hygroscopicity; low price of raw materials and high manufacturability of optical elements several tens of centimetres in length. The cubic modification of PbF_2, which meets most of these requirements, can be considered as a promising material for electromagnetic colorimetry.[39,49–54] The study [55] was devoted to a search for improved PbF_2-based materials, which could be prepared as homogeneous bulk single crystals.

Scintillation efficiency of dopant ions is enhanced as the matrix density increases. Hence, lead difluoride as well as PbF_2-based crystals and glasses are investigated taking into account this dependence. However, it appeared that divalent lead ions very efficiently quench luminescence, in particular, from trivalent cerium, in fluorides.[56–59]

Lead difluoride forms numerous compounds, in which it generally acts as a Lewis base. This compound is a constituent of many fluoride and oxofluoride glasses serving as one of the most important modifying agents.[60,61] The introduction of PbF_2 into a glass causes network depolymerisation, thus stabilising the glass. Binary composites of lead fluoride with all main glass-forming materials, such as fluorides of aluminium, indium, gallium, zinc, zirconium, *etc*., are parent compounds of families (parent compositions) of fluoride glasses containing large amounts (tens of percent) of PbF_2.[59–67] Examples are provided by the so-called 'transition metal fluoride glasses' in $PbF_2-M'F_2-M''F_3$ systems (M' and M'' are transition metals)[66] and CLAP glasses ($CdF_2-LiF-AlF_3-PbF_2$).[68,69] In the pure form, a lead difluoride melt does not undergo a glass transition even at very high cooling rates (10^6 K s^{-1}). However, glasses can be prepared in the presence of oxygen-containing dopants.[63,70–72] Stable lead fluoride oxide glasses are formed in the PbF_2-GeO_2, $PbF_2-PbO-SiO_2$, and $PbF_2-AlF_3-PbO-B_2O_3$ [71,72] systems. Additives of PbF_2 make it possible to vary the physical properties of fluoride glasses, for example, to increase the density[60] and the index of refraction.[61,73,74] This fact is used in the design of optical fibres, whose cladding should possess a higher index of refraction than their core, all other properties being similar. In particular, the ZBLAN ($ZrF_4-BaF_2-LaF_3-AlF_3-NaF$) glasses with various PbF_2 contents were studied for this purpose.[75–77]

The foregoing demonstrates that lead difluoride and PbF_2-based materials are of practical importance. Data on the properties of PbF_2 are often contradictory and disembodied. In the present review, data on the phase diagrams of PbF_2-based systems with inorganic fluorides are analysed and chemical compounds involving PbF_2 are briefly characterised. Taking into account that, according to N S Kurnakov,[78] phase diagrams provide a special language for the description of chemical properties, data on phase diagrams of systems including PbF_2 form the basis of our review.

II. Properties of lead difluoride

Lead difluoride can easily be prepared by the reaction of hydrofluoric acid with lead hydroxide (or carbonate) or by precipitation of lead salts from aqueous solutions with ammonium fluoride.[79,80] At 25 °C, the solubility of PbF_2 in water is 0.66 g litre^{-1}.

Crystals of lead difluoride are colourless. They are stable in dry air at ambient temperature. At high temperature, PbF_2 is subject to pyrohydrolysis in a wet atmosphere. This process occurs at a noticeable rate starting at 400 °C. The reaction affords oxyfluoride Pb_2OF_2 as an intermediate. Lead difluoride is hydrolysed more readily than alkaline-earth (Mg–Ba) fluorides, is more resistant to water vapour than Cd, Zn, Co, Ni, Fe, Cr and Ag fluorides and is comparable in stability to MnF_2.[81]

Unlike other metal difluorides with the fluorite structure, lead fluoride has two structural modifications under normal pressure. The Pb^{2+} ion has a lone electron pair,[31] which is responsible for such properties of lead difluoride as high deformability of the electron shell of the cation, high polarisability, high refraction and index of refraction as well as high dielectric permeability [2,32] and a low melting point.

There are two structural modifications of PbF_2, *viz*., orthorhombic (low-temperature) and cubic (high-temperature).‡ The melting point of the latter modification is 822 ± 3 °C.

The low-temperature modification of PbF_2 crystallises in the structure type of the mineral cotunnite $PbCl_2$, space group *Pnma*, $Z = 4$. The structure consists of lead nine-vertex polyhedra, which can be described as trigonal prisms with additional anions (caps) in the vicinity of each lateral face.[82] It should be noted that other (non-standard) settings of the orthorhombic unit cell (having the interchanged *a*, *b*, *c* axes and described by different symbols of the space group) are also possible. This problem was exemplified by isostructural $PbCl_2$.[83]

The high-temperature modification of PbF_2 crystallises in the fluorite (CaF_2) structure type [space group $Fm\bar{3}m$ (O_h^5), $Z(F) = 4$, the coordination polyhedron is a tetrahedron, $Z(Pb) = 8$, the coordination polyhedron is a cube].

In the cubic modification, the anion sublattice is disordered on heating (the Faraday transition), which was assumed to be a second-order phase transition. However, detailed experimental and theoretical investigations revealed only a strong symmetric anomaly of heat capacity with a maximum at 710 ± 10 K and a half-width of ~ 70 K. Therefore, sublattice disordering occurs gradually and, strictly speaking, this process does not belong to phase transitions. According to the nomenclature used in the study,[84] such a disordering process can be assigned to 'supercritical' phase transitions. In terms of the catastrophe theory,[85] this is a catastrophe flag. The term 'diffuse phase transition' is also used.[13] Its physical meaning is that cooperative interactions between anti-Frenkel anion point defects appear as their concentration increases with increasing temperature resulting in strong anharmonism of anion vibrations, mass displacements of anions from their crystallographic positions and the possible formation of cluster defects. The heat and entropy of melting of the fluorite modification of lead difluoride are abnormally small.[86]

Under standard conditions, both modifications have similar thermodynamic characteristics.[86,87] There is a strongly hindered first-order transition from the low-temperature modification to the high-temperature one, the transition being irreversible at normal pressure. The transition temperature determined in different studies [17,80,88–91] varies from 280 to 460 °C. The transition temperature of 447 °C was reported in the handbook.[86] Such a large difference is, apparently, associated with non-stoichiometry as well as with the fact that the reaction rate depends substantially on the particle size and the presence of stable-phase nuclei and impurities. The transition temperature and enthalpy are 330 ± 5 °C and 1.51 ± 0.13 kJ mol^{-1}, respectively.[92,93] After cooling to room temperature, the cubic modification remains in a metastable state for an indefinitely long time.§

Both modifications can be prepared from aqueous solutions. Single crystals of the orthorhombic modification are prepared by precipitation using cross diffusion of solutions,[88] crystallisation from perchlorate solutions [57] and the hydrothermal synthesis

‡ In the literature, there is a confusion about the notations of the modifications of PbF_2 by the Greek letters α and β; hence, we tried not to use these notations; where these notations are, however, used, α and β denote the high- and low-temperature modifications, respectively.

§ According to the results of the study by G Ren, D Qun, Z Li, D Shen *J. Crystal Growth* **247** 141 (2003), an oxygen impurity promotes the phase transition.

from KF solutions.[90] Single crystals of the cubic modification can be prepared by directed crystallisation using the flux techniques.[43, 50–55]

The orthorhombic modification is stabilised with increasing pressure. The density of the orthorhombic modification (8.47 g cm^{-3}) is higher than that of the cubic modification. The cubic → orthorhombic transition occurs at room temperature under a pressure of ~ 4 kbar (0.4 GPa). Even grinding of a sample in a mortar or mechanical treatment of single crystals can lead to a partial transformation.

The temperature of the orthorhombic → cubic transition increases with increasing pressure. At ~4 kbar, the transformation becomes reversible.[94, 95] Yet another first-order phase transition was observed at ~11 GPa (a Co_2Si-type phase, the orthorhombic system, the space group *Pnma*).[95, 96] The high-pressure phase retains the space group and the main structural motif of orthorhombic PbF_2 based on trigonal prisms with caps above the lateral faces.

The unit cell parameters of orthorhombic PbF_2 determined in the different studies are in good agreement with each other.[79, 80, 97] Typical values are as follows: $a = 3.89098 \pm 0.00003$, $b = 6.42689 \pm 0.00002$, $c = 7.63574 \pm 0.00018$ Å (see Ref. 88) and $a = 3.8999(7)$, $b = 7.6479(9)$, $c = 6.4436(9)$ Å.[96] A different situation is observed for the cubic modification. Abundant published data [79, 80, 97] give the following two groups of values: 5.940 ± 0.003 and 5.927 ± 0.003 Å. Generally, the smaller value corresponds to samples prepared from aqueous solutions (see, for example, Ref. 88), whereas the larger value corresponds to samples prepared by melting or high-temperature annealing. Intermediate values of the lattice parameter for PbF_2 were observed [98, 99] depending on the thermal prehistory of samples. It is highly probable that the larger lattice parameter is attributable to a frozen configuration of defects corresponding to a high-temperature disordered form of cubic PbF_2.

There are experimental data (A I Boltalin and N S Tkachenko, Moscow State University, 1990) providing evidence that the transformation of orthorhombic PbF_2 into the cubic modification is a complex process, which involves the formation of a liquid phase co-existing with the solid one on heating of the orthorhombic modification from 510 to 550 °C.

Polish researchers [100–102] revealed complex polymorphism of PbF_2 (five polymorphs) by differential thermal analysis (DTA). In the range of existence of the cubic phase, phase transitions at 560 and 720 °C were additionally observed. However, to our knowledge, these facts were not confirmed by other researchers and with the use of other methods.

The temperature dependences of the vapour pressure of PbF_2 and some other fluorides are shown in Fig. 1. The thermal expansion coefficients were documented.[88, 106] The results of NMR studies were published.[107] The electronic structure and selected properties were calculated.[108]

Phase equilibria involving PbF_2 are studied primarily by DTA and using the solid-phase synthesis followed by powder X-ray diffraction analysis of samples. Operations with PbF_2 and PbF_2-containing samples have a number of characteristic features, which can influence the validity of construction of phase diagrams. Because of a high vapour pressure of PbF_2, it is desirable to perform studies in closed systems under an inert atmosphere (N_2, Ar or He). Since lead difluoride is prone to hydrolysis (in particular, due to the presence of water adsorbed on the powder particle surface), it is essential that the starting compounds should be fluorinated. Due to high reactivity of PbF_2 and the ease of reduction of Pb^{2+}, one must use hermetically sealed gold or platinum crucibles (tubes); in some cases, copper or open graphite crucibles can be used.[55, 105] Open platinum crucibles are unusable, because partial reduction of lead fluoride gives rise to a low-melting Pb–Pt alloy and leads to destruction of crucibles. Crystallisation of the cubic modification of PbF_2 and solid solutions based on this modification occurs virtually without supercooling of the melt.

III. Systems PbF_2 – MF

PbF_2 – LiF. The phase diagram of this system (Fig. 2 *a*) was described in two studies [109, 110] (points *1* and *2*, respectively). The results of these studies are in good agreement with each other. The thermal effects in the solid state at 430 °C were assigned to the polymorphic transformation of PbF_2.[109] A narrow region of a LiF-based solid solution with the maximum PbF_2 content (3 ± 1 mol.%) was found to exist at the eutectic temperature.[110] The PbF_2-based solid solution region is very narrow. These data are in contradiction with the results of the study,[111] where single crystals of PbF_2 containing 6% of LiF (the percentage type was not reported) were prepared by melt crystallisation. The formation of a solid solution is evidenced by a substantial decrease in the lattice parameter from 5.94 to 5.83 Å. Apparently, this system has a retrograde solubility. The possibility of the existence of the $LiPbF_3$ compound with the inverse perovskite structure containing octahedrally coordinated Li^+ ions (analogous to the structure of the known $LiBaF_3$ compound) in the PbF_2–LiF system was examined.[112] However, attempts to synthesise this compound failed. Nevertheless, the existence of this compound was mentioned in the studies [113, 114] with a reference to the investigation.[112] The ionic conductivity of a eutectic composite was studied.[115]

PbF_2 – NaF. The system was examined in two studies [110, 116] (Fig. 2 *b*; points *1* and *2*, respectively). The results of these studies are in good agreement with each other. This system is of the eutectic type without the formation of compounds. Solid solution regions based on the components are very small.[110] However, high ionic conductivity of a eutectic composite in this system is indicative of the existence of the $Pb_{1-x}Na_xF_{2-x}$ solid solution.[117] The mechanism of the formation of the solid solution was confirmed by NMR spectroscopy.[118]

It should be noted that compounds are not formed in the condensed state. However, the $LiPbF_3$ and $NaPbF_3$ molecules were found in the vapour phases of the above-mentioned systems.[119]

Phase diagrams of systems involving potassium and rubidium fluorides are substantially more complicated and the results of different studies are in poorer agreement. These systems (and the PbF_2–CsF system to an even greater extent) are difficult to study due to high hygroscopicity of alkali metal fluorides.

PbF_2 – KF. Phase equilibria in this system (Fig. 2 *c*) were studied in detail.[116, 120–124] There is a consensus about the existence of the fluorite solid solution $Pb_{1-x}K_xF_{2-x}$, the limiting concentration being attained at $x = 0.10–0.12$. This solid solution is one of the best fluoride ion conductors.[118, 121, 123, 125–127]

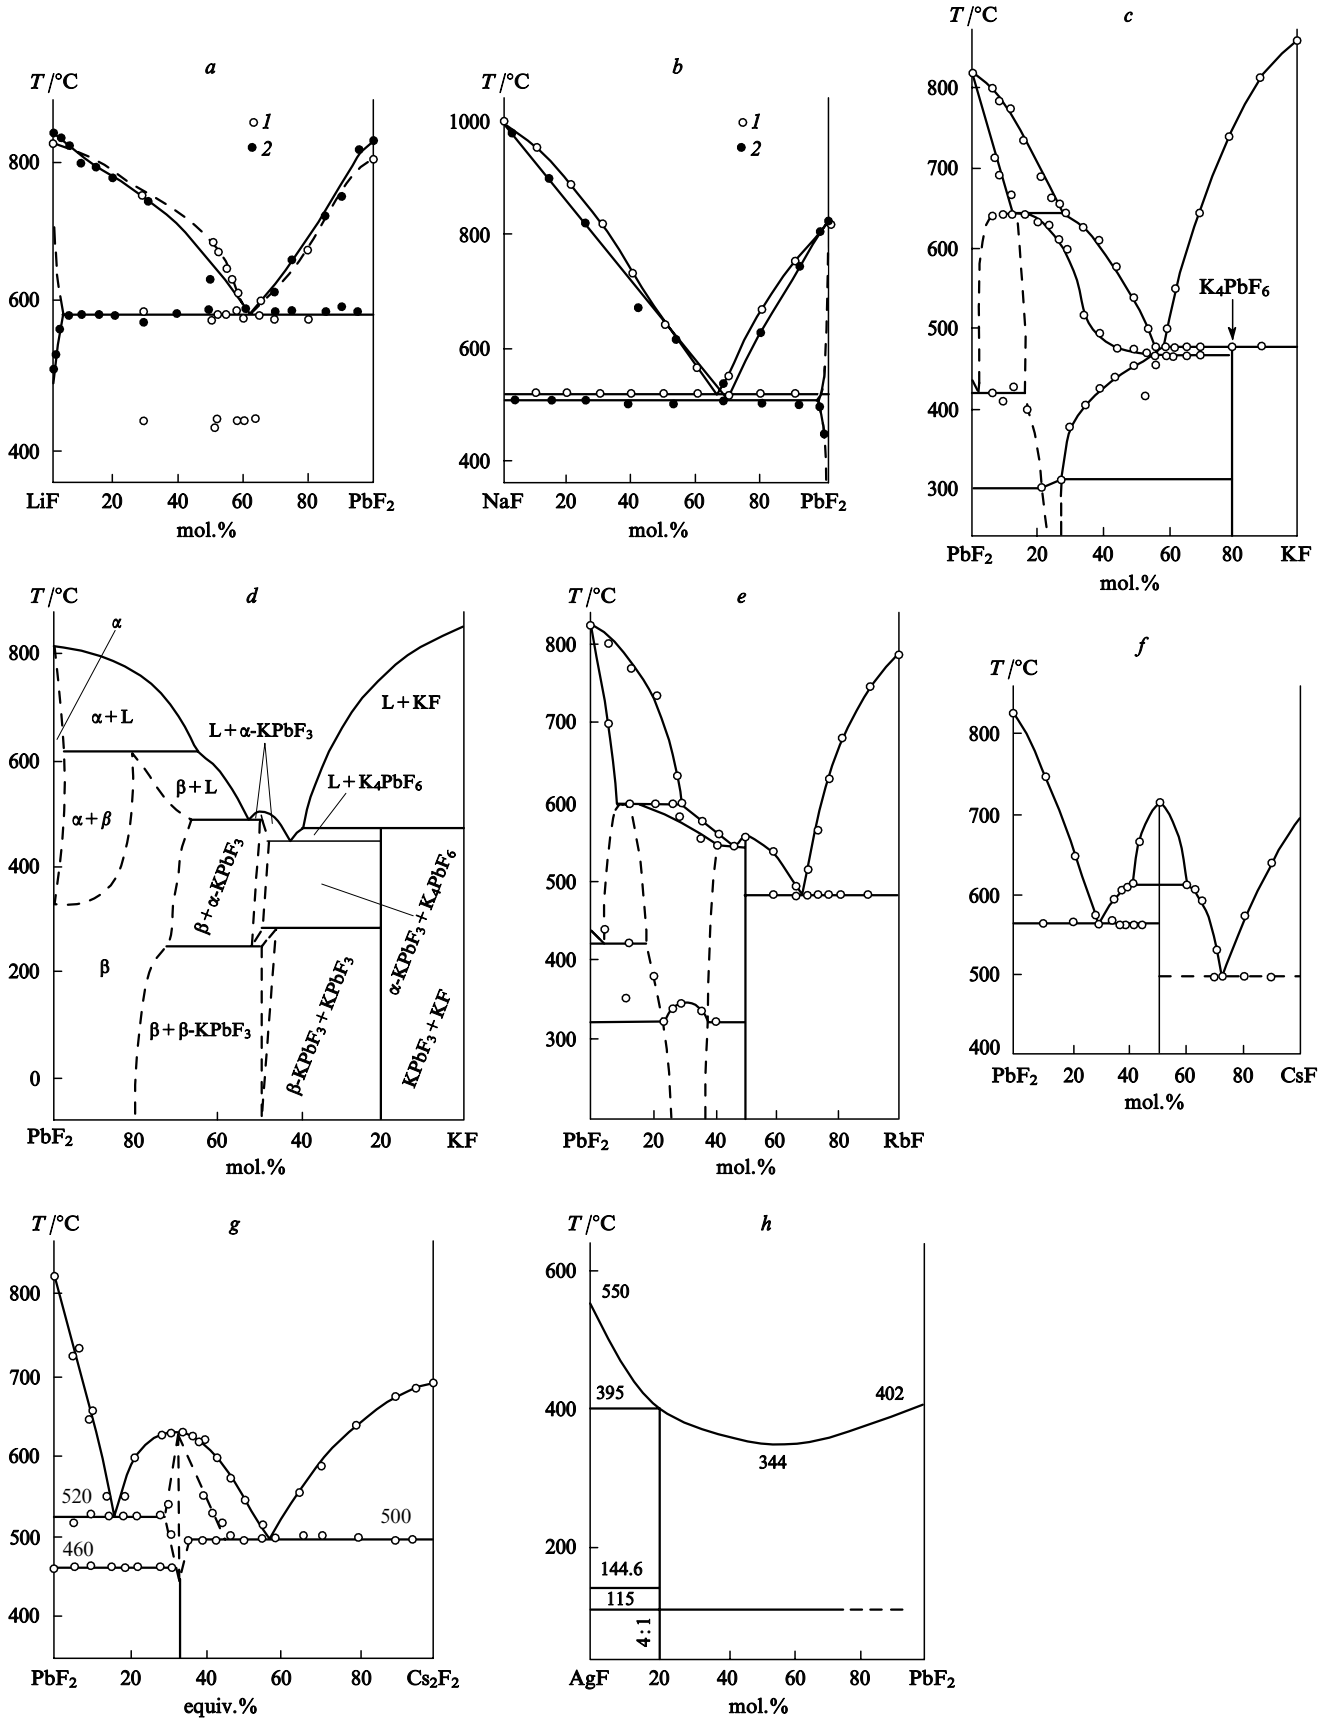

Figure 2. Phase diagrams of the PbF_2–LiF (*a*),[109,110] PbF_2–NaF (*b*),[110,116] PbF_2–KF (*c*),[116] PbF_2–KF (*d*),[122] PbF_2–RbF (*e*),[116] PbF_2–CsF (*f*),[116] PbF_2–CsF (*g*)[91] and PbF_2–AgF (*h*)[134] systems.
The numbers at the curves indicate the temperature in °C, (*1*) DTA data, (*2*) powder X-ray diffraction data.

According to the results of the study,[116] this system has an incongruently melting phase of the variable composition $K_nPb_{1-n}F_{2-n}$ ($\sim$15%–55% of KF), which undergoes a reversible polymorphic transition in the range of 300–315 °C, and the K_4PbF_6 compound, which melts according to a peritectic reaction. The high-temperature modification of the $K_nPb_{1-n}F_{2-n}$ phase has a body-centred cubic (BCC) structure of the defect anti-α-AgI type. Under a pressure of up to 40 kbar, the $KPbF_3$ compound, which undergoes a polymorphic transformation at 300 °C (the low-temperature low-symmetry modification of $KPbF_3$ II), was synthesised.[120] Attempts to synthesise $K_nPb_{1-n}F_{2-n}$ or K_4PbF_6 failed.[120] The $K_nPb_{1-n}F_{2-n}$ phase and a phase which is X-ray identical to $KPbF_3$ II (this metastable phase was observed on cooling of melts containing 25 mol.% of KF), were revealed in the investigation.[121]

A radically different interpretation of phase equilibria was proposed in the publication.[122] A solid solution based on the low-temperature orthorhombic modification of PbF_2, which is stabilised by the addition of potassium fluoride, was hypothesised to exist instead of an individual phase of variable composition (Fig. 2*d*). This solid solution melts according to a peritectic reaction. The $KPbF_3$ compound melts congruently at 500 °C, has a homogeneity region and undergoes a polymorphic transition. According to the results of high-temperature neutron diffraction measurements,[123, 124] the $2\,PbF_2 \cdot KF$ composite adopts a BCC structure of the defect anti-α-AgI type upon heating above 250 °C, which was confirmed by the results of the investigation.[116] This process is accompanied by a step increase in the ionic conductivity to $\sim 1\ \Omega^{-1}\ cm^{-1}$ (this value is higher than the conductivity of the fluorite phase), which corresponds to the superionic state. The X-ray diffraction pattern of this composite at room temperature is similar to that of orthorhombic PbF_2, but it was non interpreted. The homogeneity region of the BCC phase extends from 33 mol.% to 68 mol.% of KF.[124] It should be noted that the procedure for the preparation of samples used in the studies [123, 124] did not involve fluorination and, consequently, oxygen contamination of these samples cannot be ruled out. The $KPbF_3$ molecules were found in the vapour phase of the system.¶

PbF_2–RbF. A cubic non-stoichiometric phase of the anti-α-AgI type, which is analogous to that present in the potassium system, was found to exist in this system (Fig. 2*e*).[116, 124] The homogeneity region of the BCC phase extends from 33 mol.% to 50 mol.% of RbF, *i.e.*, includes the $RbPbF_3$ composite.[124] The authors of the study [116] believed that the $RbPbF_3$ compound exists in the individual state, melts congruently and is characterised by a complicated X-ray diffraction pattern. In the investigation,[128] this compound was mentioned as a cubic phase with the perovskite structure (a = 4.790 Å). According to the results of investigations,[129, 130] the transformation into the high-temperature cubic perovskite-type modification takes place at 206 °C. Data on the melting points of eutectics and $RbPbF_3$ obtained in the study [37] differ substantially from those published in the investigation.[116] It was noted [131] that non-stoichiometric phases in this system have high ionic conductivity. The $RbPbF_3$ molecules were found in the vapour phase of the system.¶

PbF_2–CsF. In this system, only the $CsPbF_3$ compound was revealed.[91, 116, 124, 129, 130, 132] According to the results of the study,[116] this compound melts congruently and undergoes the first-order polymorphic transition (Fig. 2*f*). At 145 K, this compound undergoes the second-order phase transition from the tetragonal modification to the perovskite cubic modification.[130, 132] In the study,[91] $CsPbF_3$-based solid solutions (up to 4 mol.% of PbF_2 at 520 °C and 10 mol.% of CsF at 495 °C) were found to exist, the polymorphism of $CsPbF_3$ being unobservable (Fig. 2*g*). The melting point (630 °C) is substantially lower than that reported in the study [116] and could correspond to metastable melting of the low-temperature modification of $CsPbF_3$.[116] An ordered perovskite structure was established for $CsPbF_3$ in the investigation.[124] The $CsPbF_3$ molecules were also found in the vapour phase (see¶ and Ref. 133).

PbF_2–AgF. The phase diagram of this system constructed in the study [134] (Fig. 2*h*) does not satisfy the phase rule. The $Pb_{1-x}Ag_xF_{2-x}$ solid solution is characterised by high ionic conductivity.[3]

PbF_2–TlF. The system was not studied, but the $TlPbF_3$ compound with the cubic perovskite structure was described (a = 4.62 Å).[129]

IV. Systems PbF_2–MF_2

PbF_2–BeF_2. This system (Fig. 3*a*) was examined in the study.[135] Two compounds with compositions Pb_3BeF_6 and $PbBeF_4$ and a wide region of a $PbBeF_4$-based solid solution were revealed. X-ray diffraction data for this system were not interpreted. According to the results of the study,[136] $PbBeF_4$ crystallises in the orthorhombic system. The $Pb_3Be_2F_{14}$ compound available in the JCPDS (Joint Committee on Powder Diffraction Standards) database under the entry number 37-1055 is erroneous, because the $Pb_3Ge_2F_{14}$ compound was described in the original publication.[137]

PbF_2–MgF_2. The system is characterised by the phase diagram (Fig. 3*b*) of the eutectic type.[55, 138] The Pb_2MgF_6 compound was found to exist in the solid state in this system. The exact temperature of its decomposition into components was not determined, but it was determined that it is in the range from 510 to 670 °C.

PbF_2–CaF_2. An outline of the phase diagram of the system is shown in Fig. 3*c*.[101, 139] This diagram was analysed in more detail in the investigations [55, 140, 141] (Fig. 3*d*). The phase diagram of the peritectic type containing solid solutions based on both components is presented in Fig. 3*c*. The peritectic temperature is 860 ± 5 °C. The limiting solubility of CaF_2 in PbF_2 increases from 6 mol.% to 15 mol.% as the temperature increases from 510 to 750 °C. According to the results of the studies,[101, 139] the solid solution regions based on both components cover ranges of approximately 18 mol.%–20 mol.%. The interpretation of numerous phase transitions presented in Fig. 3*c* is still an open question.

PbF_2–SrF_2 and PbF_2–BaF_2. Continuous fluorite solid solutions are formed in these systems (Fig. 3*e*, *f*).[55, 140–144]

Continuous solid solutions were prepared by co-precipitation from Pb and Sr nitrate solutions with HF followed by calcination of the precipitate at 500 °C.[143] By the third law of thermodynamics, continuous solid solutions should either decompose or undergo ordering with decreasing temperature. According to the results of two studies,[55, 144] the critical solid solution temperatures in the PbF_2–SrF_2 and PbF_2–BaF_2 systems are below 500 °C and at about 450 °C, respectively.

PbF_2–CdF_2. A continuous solid solution formed in this system has a minimum in the liquidus curve (Fig. 3*g*, *h*).[5, 55, 100, 141, 145–159] The coordinates of the minimum were evaluated at 60 mol.% of PbF_2 and 720 °C,[149] 60 mol.% of PbF_2 and 745 °C [150] and 67 ± 2 mol.% of PbF_2 and 745 ± 5 °C,[55, 141] *i.e.*, the composition corresponds to the stoichiometry Pb_2CdF_6. The addition of CdF_2 to lead difluoride stabilises the high-temperature cubic phase. The solid solution (particularly, in the vicinity of the minimum) is characterised by high fluoride ion conductivity.[5, 55, 151–157] The solid solution can undergo ordering at low temperature.[157, 158]

Systems of PbF_2 with Mn, Fe, Co, Ni, Cu and Zn difluorides were studied [145, 146] by DTA and powder X-ray diffraction analysis of samples synthesised in platinum tubes (Fig. 4). In all systems, the Pb_2MF_6 compounds were revealed. In the case of M = Mn, Fe, Co, Ni and Zn, these compounds have a tetragonal fluorite-like structure similar to the Ba_2MF_6 structure but with the doubled a parameter of the tetragonal unit cell. The Pb_2MnF_6 compound exhibits antiferromagnetic ($T_N = 30 \pm 1$ K) and

¶ See A I Boltalin, A N Rykov, Yu M Korenev *Zh. Neorg. Khim.* **34** 2617 (1989); **34** 2908 (1990) [*Russ. J. Inorg. Chem. (Engl. Transl.)*]

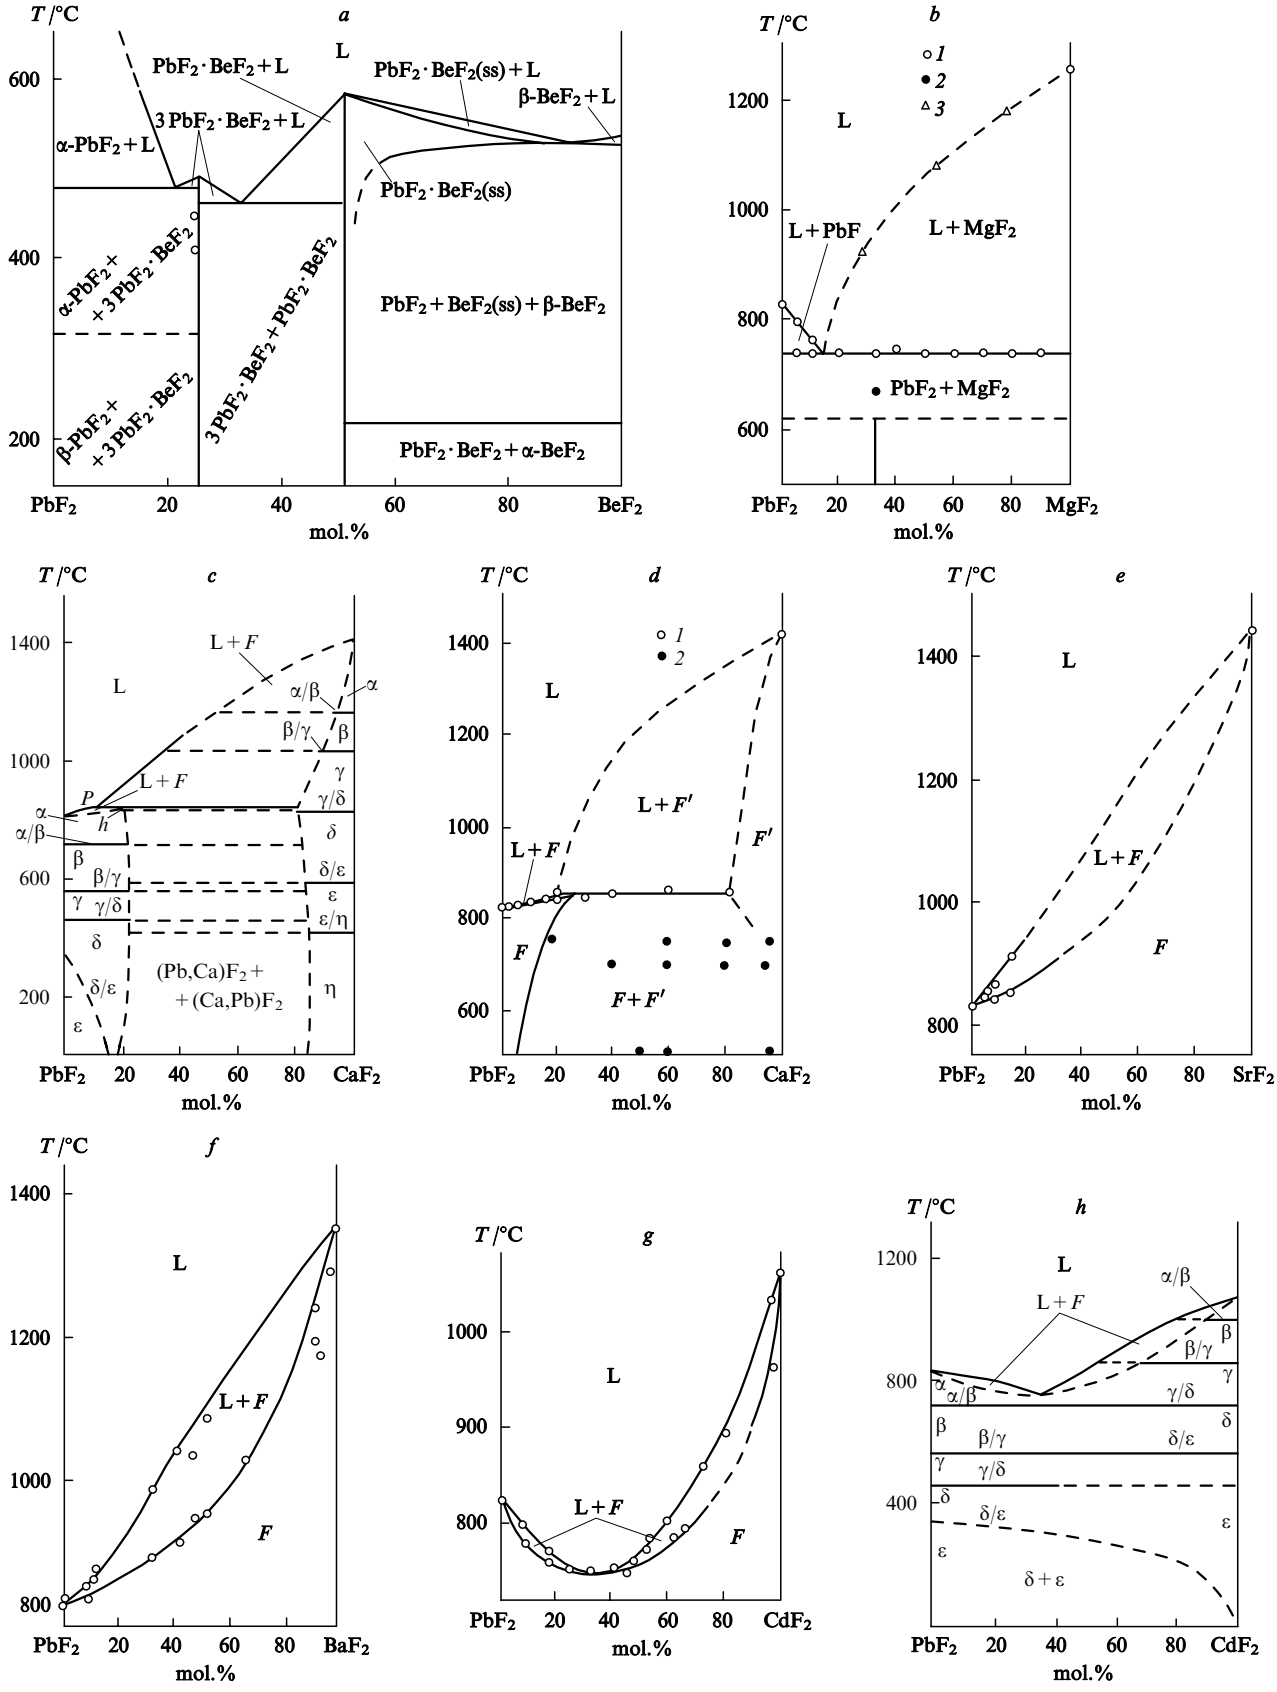

Figure 3. Phase diagrams of the PbF_2-BeF_2 (*a*),[135] PbF_2-MgF_2 (*b*),[55,138] PbF_2-CaF_2 (*c*),[101,139] PbF_2-CaF_2 (*d*),[55,140] PbF_2-SrF_2 (*e*),[55,140] PbF_2-BaF_2 (*f*),[55,144] PbF_2-CdF_2 (*g*)[55,141] and PbF_2-CdF_2 (*h*)[100] systems.
(*1*) DTA data, (*2*) powder X-ray diffraction data, (*3*) calculations using a model of an ideal liquid solution.

superionic (~500 K) properties.[147] Not only Pb_2MnF_6 but also $PbMnF_4$ was found in products of crystallisation of an amorphous phase prepared by rapid (10^6 K s^{-1}) quenching of a melt in the PbF_2-MnF_2 system.[63]

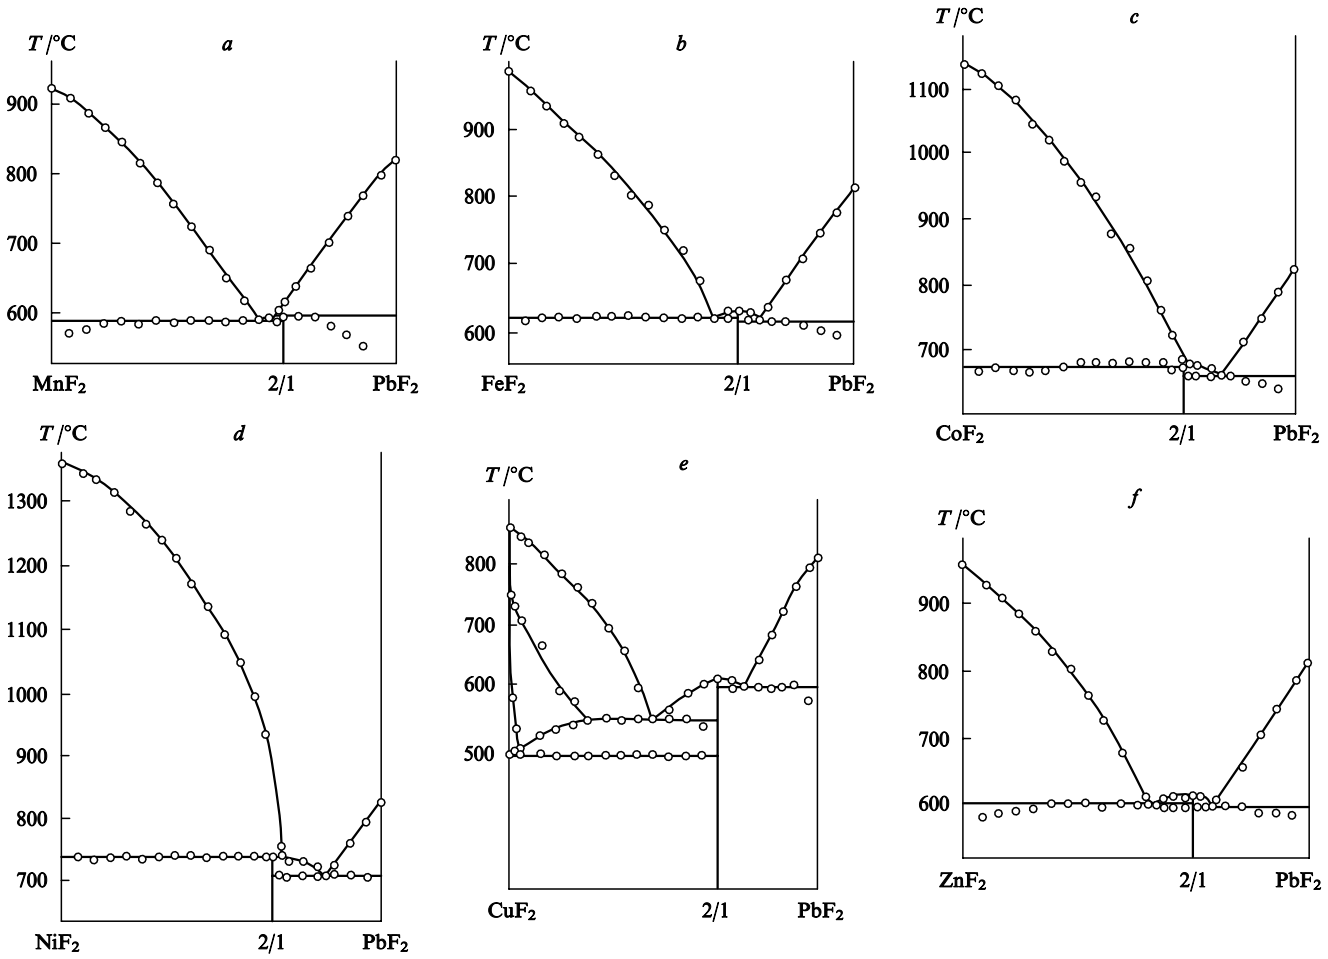

Figure 4. Phase diagrams of the PbF_2-MnF_2 (*a*), PbF_2-FeF_2 (*b*), PbF_2-CoF_2 (*c*), PbF_2-NiF_2 (*d*), PbF_2-CuF_2 (*e*) and PbF_2-ZnF_2 (*f*) [146] systems.

The Pb_2CuF_6 compound crystallises in the monoclinic system.[146, 148] Judging from the phase diagram reported in the study,[146] the starting CuF_2 compound presumably undergoes partial pyrohydrolysis (Fig. 4 *e*).

PbF_2-SnF_2. The $PbSnF_4$ compound is formed in this system (Fig. 5).[10, 12, 160–176] The superionic conductivity revealed in this compound [10] gave impetus to extensive experimental studies. The $PbSnF_4$ compound is characterised by complex polymorphism. The following scheme of polymorphism was proposed:[165, 166]

$$\left.\begin{matrix}\alpha\text{-}PbSnF_4\\ \alpha'\text{-}PbSnF_4\end{matrix}\right\} \xrightarrow{80\ ^\circ C} \beta\text{-}PbSnF_4 \xrightarrow{350\ ^\circ C} \beta'\text{-}PbSnF_4 \xrightarrow{380\ ^\circ C}$$

$$\longrightarrow \gamma\text{-}PbSnF_4 \xrightarrow{390\ ^\circ C} \text{melt.}$$

The high-temperature γ modification has a cubic fluorite structure; the β and β′ modifications have tetragonal structures, the α and α′ modifications belong to the monoclinic system. A somewhat different scheme was published in the study [163] (without monoclinic phases). A monoclinic distortion of the tetragonal lattice was observed below room temperature.[173] The crystal structure of $PbSnF_4$ was solved in several studies.[170, 171, 173, 174] The investigation [169] provided evidence for the existence of a $PbSnF_4$-based homogeneity region.[169] The influence of the synthesis condition on the character of distortions of the fluorite lattice in samples of $PbSnF_4$ was examined.[175]

A PbF_2-based cubic solid solution containing ~20 mol.% of SnF_2 exists in the PbF_2-SnF_2 system. In addition, a series of fluorite-like phases were revealed in the solid state in the region of 30 mol.% – 50 mol.% of SnF_2.[169]

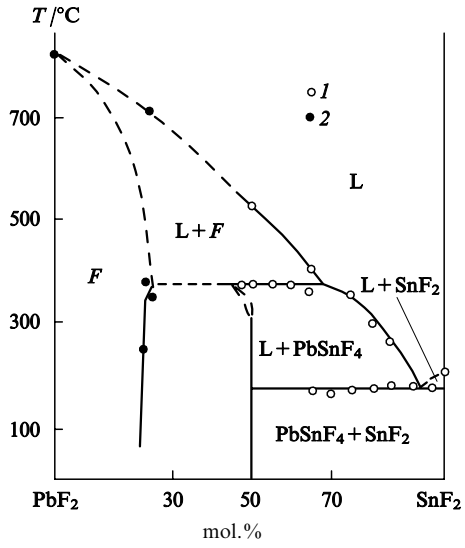

Figure 5. Phase diagram of the PbF_2-SnF_2 system.
(*1*) unpublished data of T Yu Glazunova, A I Boltalin (Moscow State University) and P P Fedorov, (*2*) according to the results of the studies.[10, 164, 169, 174]

The $PbSnF_4$ compound melts incongruently at 370 °C. The liquidus temperature for this composition is 520 °C. The compounds which were reported in the study [160] based on the DTA data, are apparently artefacts. A phase with the fluorite structure was prepared [175] by quenching a melt with composition $PbSn_4F_{10}$. This phase rapidly decomposes at room temperature. The thermogram of this sample shows reversible effects at 190 (non-variant) and 280 °C (monovariant), which agrees well with the phase diagram shown in Fig. 5.

$PbF_2 - PdF_2$. The $PbPdF_4$ compound (the tetragonal system, the $K[BrF_4]$ structure type) was synthesised at 820 °C by the reaction of PbF_2 with PdF_2 in a gold bomb.[177]

V. Systems $PbF_2 - MF_3$

The common characteristic feature of the $PbF_2 - MF_3$ systems is the formation of the heterovalent solid solutions $Pb_{1-x}M_xF_{2+x}$ and ordered fluorite-like compounds.

$PbF_2 - BF_3$. Two compounds, *viz*., $Pb_2(BF_4)F_3$ and $Pb_4(BF_4)F_7$, exist in this system. These compounds were prepared by the reaction of BF_3 with PbF_2.[178, 179] Two allotropic modifications of $Pb_4(BF_4)F_3$ are formed by the reaction of BF_3 with orthorhombic and cubic PbF_2.

$PbF_2 - AlF_3$. The system was studied in detail.[62, 180–197] The cubic solid solution $Pb_{1-x}Al_xF_{2+x}$ with a limiting concentration of ~10 mol.% – 12 mol.% of AlF_3 was revealed in this system by several research groups.[180, 181, 183, 184, 191] This solid solution is characterised by high fluoride ion conductivity. In addition to the solid solution, the $PbAlF_5$ (the tetragonal system, the $SrAlF_5$/$BaFeF_5$ structure type), $PbAl_2F_8$ and $Pb_9Al_2F_{24}$ compounds were found to exist in the solid state at 550 °C.[181, 182] However, examination of the phase diagram (Fig. 6 *a*) revealed only one incongruently melting intermediate compound with composition $Pb_3Al_2F_{12}$,[180] whose powder X-ray diffraction pattern is similar to that of $PbAlF_5$.[181] A careful reinvestigation of the phase diagram [184] (Fig. 6 *b*) confirmed the $Pb_3Al_2F_{12}$ composition of this compound. In addition, the $Pb_9Al_2F_{24}$ compound, which was described in earlier publications,[181, 182] was revealed. In the solid state, the latter compound decomposes according to a peritectoid reaction, whose temperature is close to the eutectic temperature. The $PbAl_2F_8$ compound was not observed.

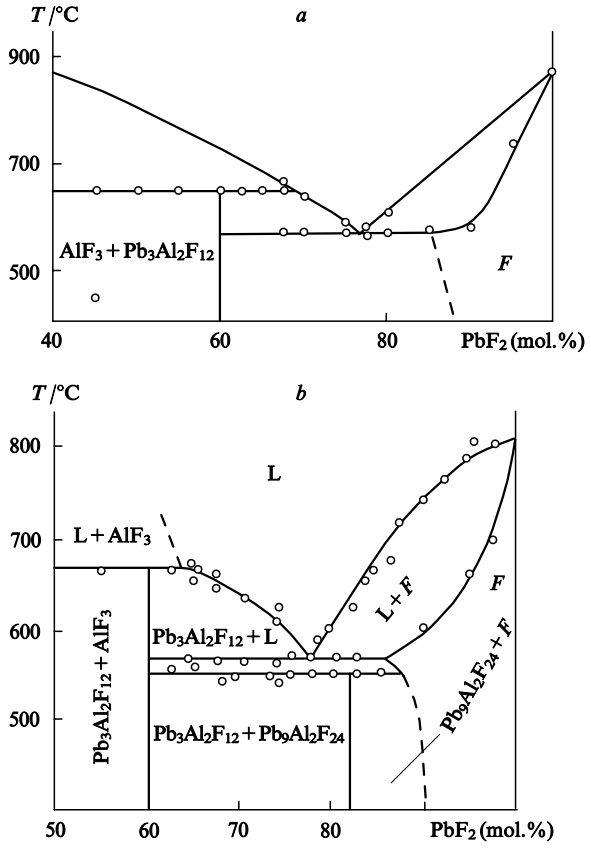

Figure 6. Fragments of the phase diagram of the $PbF_2 - AlF_3$ system. (*a*) according to the results of the study,[180] (*b*) according to the results of the study.[184]

The tetragonal phase in the $PbF_2 - AlF_3$ system and its analogues in the $M'F_2 - MF_3$ systems (M′ = Pb, Sr, Ba; M = Ti, V, Cr, Fe, Ga) attract interest because of detection of ferroelectric phase transitions.[185, 192] This transition was observed in $PbAlF_5$ at 312 °C.[192] The composition of the tetragonal phase was refined in the study.[185] The existence of the $Pb_5Al_3F_{19}$ compound was postulated by analogy with the chromium analogue, whose crystal structure was established. The $Pb_5Al_3F_{19}$ compound was prepared (along with analogues for Ti, V, Cr, Fe and Ga) by solid-phase synthesis. The parameters of the tetragonal unit cell of $Pb_5Al_3F_{19}$ determined in the study [185] are similar to those reported for $PbAlF_5$.[181] For this compound, a ferroelectric phase transition was revealed at close to room temperature. It should be noted that the phase transition temperature determined for $Pb_5Al_3F_{19}$ differs substantially (by 300 °C) from that of $PbAlF_5$.[185, 192] This indicates that either different compounds were studied or the researchers dealt with non-stoichiometry of the same phase.

Later on, the coordinates of the peritectic and eutectic equilibria in this system were reproduced with a good accuracy (±3 mol.%, ±10 °C).[186] Single crystals of an incongruently melting compound were grown from a flux containing an excess of PbF_2. It was determined that this compound has the composition $Pb_5Al_3F_{19}$. An investigation of these single crystals revealed a monoclinic distortion of the tetragonal unit cell. Further studies of the crystal structure of $Pb_5Al_3F_{19}$ did not clarify this problem. For example, different space groups were reported for these crystals.[188–190] Investigations of other compounds of the ferroelectric family $Pb_5M_3F_{19}$ showed that doubling of the *a* parameter is typical of high-temperature paraelectric phases.[185]

The compound with composition $Pb_3Al_2F_{12}$ was prepared by hydrothermal synthesis. However, this phase differs in the packing of octahedra.[186]

$PbF_2 - GaF_3$. The system (Fig. 7) has the fluorite-type solid solution $Pb_{1-x}Ga_xF_{2+x}$ ($0 < x \leqslant 0.11$) and three intermediate phases,[182, 198] *viz*., the congruently melting $Pb_3(GaF_6)_2$ phase and the incongruently melting $PbGaF_5$ and $Pb_9Ga_2F_{24}$ phases (in the study,[182] the latter phase was denoted as the β phase with the

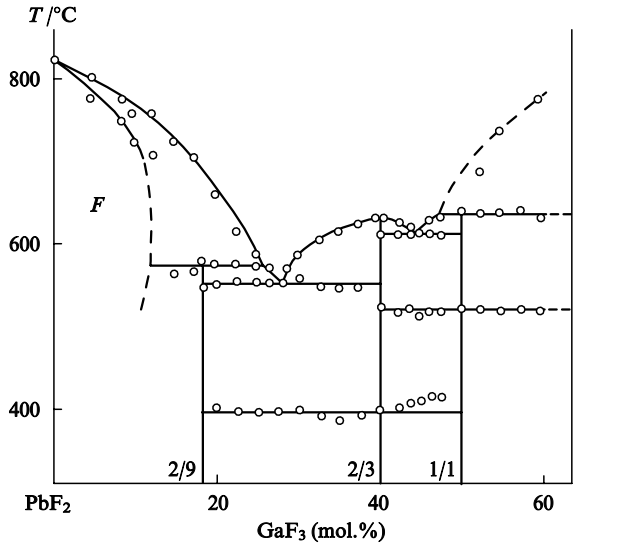

Figure 7. Fragment of the phase diagram of the $PbF_2 - GaF_3$ system.[198]

range of existence of ~20 mol.% of GaF_3). The $Pb_9Ga_2F_{24}$ phase has a distorted fluorite-like lattice. The structural model for this phase was proposed in the study.[199] The $Pb_3(GaF_6)_2$ compound is transformed into the ferroelectric state at 347 °C.[200]

The $PbGaF_5$ compound was found[192] to undergo a ferroelectric phase transition at 312 °C. The formula $Pb_5Ga_3F_{19}$ was proposed[185] for the tetragonal phase by analogy with other ferroelectric compounds. This composition is intermediate between $Pb_3(GaF_6)_2$ and $PbGaF_5$.[182] According to the results of two studies,[185,200] $Pb_5Ga_3F_{19}$ and $Pb_3(GaF_6)_2$ have the same phase transition temperature. Apparently, the authors studied the same sample, to which different compositions were assigned. The same statement is true for other $Pb_3(MF_6)_2$ compounds, where M = Ti, Fe, V or Cr (for M = V, the difference in the temperature is 4 K; for M = Cr, the difference is 5 K). This problem requires additional investigation. The position of the maximum in the liquidus curve for $Pb_3(GaF_6)_2$ (see Ref. 198) corresponds to the composition containing 40 mol.% of PbF_2. The phase equilibria in the PbF_2-GaF_3 system unambiguously indicate that there are at least two compounds. The difference in the phase transition temperature determined for $Pb_3(GaF_6)_2$ in two studies[198,200] is substantially larger than the experimental error.

PbF_2-InF_3. The system was studied by several research groups.[182,201–203] A fragment of the phase diagram of this system is shown in Fig. 8 *a*. The fluorite-type $Pb_{1-x}In_xF_{2+x}$ solid solution and the Pb_2InF_7 and $Pb_7In_5F_{29}$ compounds were observed in this system. In the study,[201] the composition $Pb_5In_4F_{22}$ was reported instead of $Pb_7In_5F_{29}$.[182] The limiting concentration of the solid solution is $x = 0.25$; $a = 5.82$ Å.[201] After quenching, a tetragonal distortion with metastable ordering was observed at $x = 0.25$. The $Pb_7In_5F_{29}$ compound melts according to a peritectic reaction at 525 °C. The phase diagram shown in Fig. 8 *b* agrees satisfactorily with the results of the study.[201] The difference is that a small homogeneity region was revealed for the $Pb_7In_5F_{29}$ compound in the study[201] and thermal effects were interpreted differently: the temperature of 525 °C corresponds to a eutectic rather than to decomposition of the $Pb_7In_5F_{29}$ compound, which melts according to a peritectic reaction at 535 ± 5 °C. The ionic conductivity of phases in this system was studied.[202] The structure of the solid solution was investigated by NMR spectroscopy.[204,205]

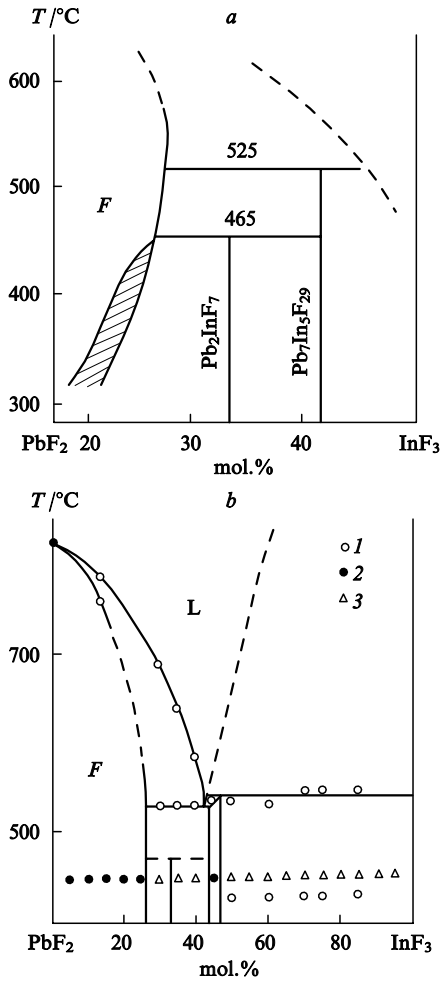

Figure 8. Phase diagram of the PbF_2-InF_3 system;
(*a*) according to the results of the study,[201] (*b*) according to the results of the study;[203] (*1*) DTA data, (*2*) single-phase samples, (*3*) two-phase samples (according to the results of the solid-phase synthesis and powder X-ray diffraction analysis); the numbers at the curves indicate the temperature in °C.

PbF_2-ScF_3. The system is of the eutectic type (Fig. 9) without the formation of compounds.[9] The $Pb_{1-x}Sc_xF_{2+x}$ solid solution ($0 < x \leqslant 0.16$), which exhibits high fluoride ion conductivity, was described.[6,7,9,12]

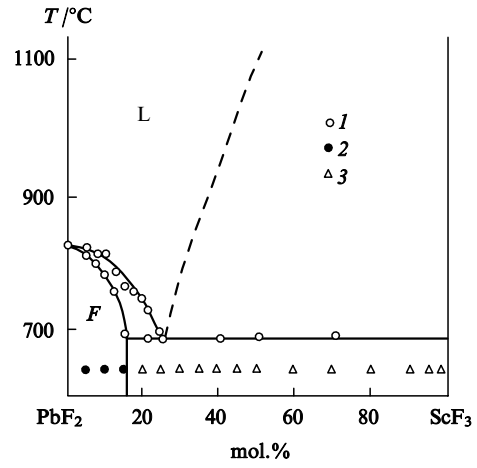

Figure 9. Phase diagram of the PbF_2-ScF_3 system.[9]
(*1*) DTA data, (*2*) single-phase samples, (*3*) two-phase samples (according to the results of the solid-phase synthesis and powder X-ray diffraction analysis).

PbF_2-RF_3 (R = Y, La–Lu). A series of PbF_2-containing systems with rare-earth fluorides were investigated[9,28,105,206–208] by DTA and powder X-ray diffraction analysis of annealed and quenched samples (Fig. 10). Similar results were obtained in studies of phase equilibria in the solid state.[209,210] The $Pb_{1-x}R_xF_{2+x}$ solid solutions with the fluorite structure exist in these systems. The character of melting of these solid solutions changes from peritectic (LaF_3-EuF_3) to eutectic with a maximum in the melting curve. The phase diagram of the PbF_2-GdF_3 system is very similar to that of the transition type. A change in the coordinates of non-variant transformations in the PbF_2-LnF_3 systems in a series of rare-earth elements is shown in Fig. 11. Trigonal fluorite-like $Pb_4R_3F_{17}$-based phases are formed in systems involving RF_3 (R = Sm–Lu, Y) (Fig. 12). Their stability increases with decreasing ionic radius of R^{3+}.[28,206,210,211] The regions of existence of the cubic solid solutions $Pb_{1-x}R_xF_{2+x}$ are limited by the $Pb_4R_3F_{17}$ compounds. The precision lattice parameters of $Pb_4R_3F_{17}$ were determined.[212] An investigation of the crystal structure of $Pb_4Y_3F_{17}$ revealed oxygen contamination of the samples corresponding to the formula $Pb_8Y_6F_{32}O$.[210] In addition, phases with a tetragonally distorted fluorite lattice were observed. A tetragonal distortion for the phase containing ~48 mol.% of YF_3 was observed.[207] A similar phase was demonstrated[209] to have the composition Pb_2YF_7. Dissolution

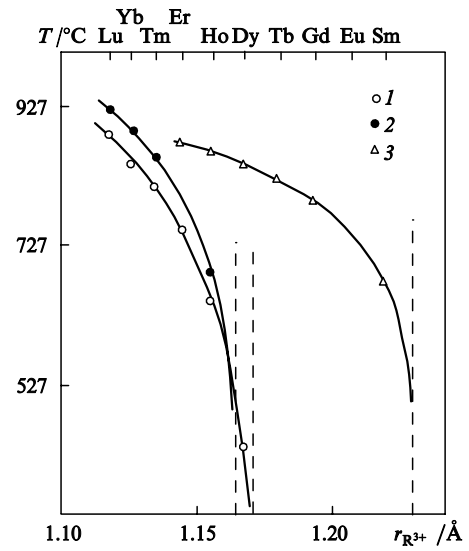

Figure 12. Decomposition temperature of the Ca_2RF_7 (*1*), $Ca_8R_5F_{31}$ (*2*) and $Pb_4R_3F_{17}$ (*3*) compounds *vs.* the ionic radius of R^{3+} (equation $T = 1430|r-1.23|^{[0.091]}$).[105, 211]

of PbF_2 in RF_3 (R = La–Gd) afforded trigonal solid solutions with the LaF_3-type (tysonite-type) structure. For R = Tb–Ho and Y, berthollide phases of variable composition with the tysonite structure occur. The regions of existence of these phases decrease with decreasing ionic radius of R^{3+}. The electrical conductivity and defect structures of the $Pb_{1-x}R_xF_{2+x}$ solid solutions were investigated in detail.[4, 6–9, 205, 213–216]

PbF_2-MF_3 (M = Ti, V, Cr, Fe). These systems are similar to the PbF_2-MF_3 systems with M = Al or Ga .[182, 185] In addition to the fluorite solid solutions, fluorite-like phases with an orthorhombically distorted structure derived from the fluorite structure were revealed for systems with M = Ga, Ti, V, Cr and Fe. For M = Ga and Cr, $x = 0.20$, the doubled unit cell of fluorite undergoes an orthorhombic distortion.[182] In the study,[199] it was hypothesised that excess anions in ordered anion-excess fluorite-like phases are located in the seven-vertex polyhedra $[MF_7]$, which form various parallel structures of zigzag chains incorporated into the fluorite lattice. One-dimensional clusters formed by chains of the $[MF_7]$ polyhedra can be considered as basic structural units for the homologous series $Pb_nM_2F_{2n+6}$ ($n \geqslant 2$). For titanium, $n = 3$; for vanadium, $n = 4$; and for gallium, $n = 5$. An analogous situation was observed also for ordered fluorite-like phases in the PbF_2-MF_4 system (see the next section).

PbF_2-TiF_3. Solid-phase equilibria were partially studied at 500 °C.[182, 217] The $Pb_{1-x}Ti_xF_{2+x}$ solid solution with the fluorite structure at $0 < x \leqslant 0.15$, an ordered β phase with an orthorhombically distorted fluorite structure at $0.25 \leqslant x \leqslant 0.26$ [199] and the $Pb_3(TiF_6)_2$ compound belonging to the tetragonal system were found to exist in this system. In the publication,[185] the composition $Pb_5Ti_3F_{19}$ rather than $Pb_3(TiF_6)_2$ was assigned to the ferroelectric phase.

PbF_2-VF_3. Phase equilibria in this system were investigated.[182, 218, 219] The phase diagram is shown in Fig. 13 *a*. The $Pb_{1-x}V_xF_{2+x}$ solid solution with the fluorite structure exists at $0 < x \leqslant 0.15$ (see Refs 182 and 218) or $0 < x \leqslant 0.22$ (see Ref. 219). An ordered fluorite-like phase characterised by an orthorhombic distortion of the cubic lattice exists in this system in the range of 27 mol.% – 28.5 mol.% of VF_3.[182, 218] In the study,[219] the composition Pb_4VF_{11} was assigned to this phase, the phase undergoing a polymorphic transformation. The high-temperature modification has a homogeneity region. The structural model for this phase was described in the study.[199] In addition, the system contains a tetragonal phase. The data on the composition of this phase (in spite of similar unit cell parameters) are contradictory (analogously to the system with aluminium trifluoride). For example, the composition $PbVF_5$ was assigned to this phase in the study, [218] where it was mentioned that this phase melts congruently at 566 ± 7 °C. By contrast, the composition $Pb_3(VF_6)_2$ was proposed for this phase in the

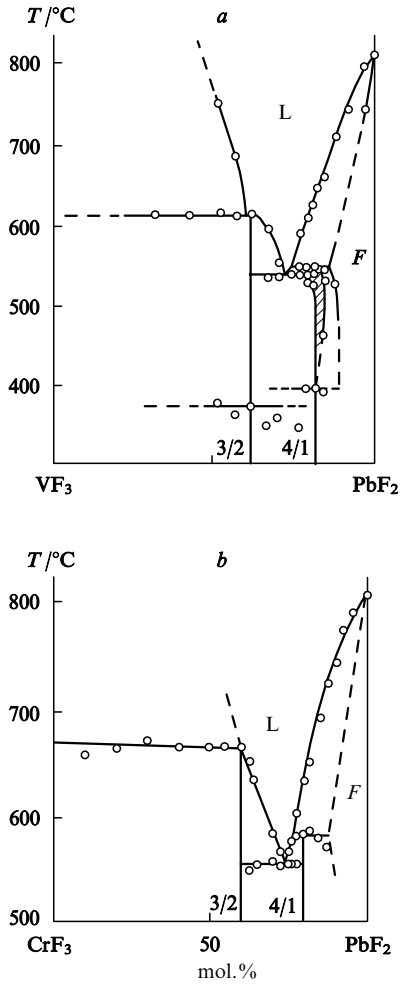

Figure 13. Phase diagrams of the PbF_2-VF_3 (*a*)[219] and PbF_2-CrF_3 (*b*) systems.[220]

studies,[182,219] the compound undergoing a polymorphic transformation and the character of melting being intermediate between congruent and incongruent (see Fig. 13 *a*). The same composition was reported in the investigation.[200] However, this composition was corrected to $Pb_5V_3F_{19}$ in the more recent study.[185]

PbF_2-CrF_3. The system was studied in-depth (Fig. 13 *b*).[182,185,193,220–222] The $Pb_{1-x}Cr_xF_{2+x}$ solid solution with the fluorite structure at $0 < x \leqslant 0.12$ and two compounds, Pb_4CrF_{11} and $Pb_3(CrF_6)_2$, were revealed in this system. The character of melting of $Pb_3(CrF_6)_2$ is intermediate between congruent and incongruent. The composition of the $Pb_3(CrF_6)_2$ compound was refined[185,193,222] based on results of X-ray diffraction analysis, and the compound was found to have the composition $Pb_5Cr_3F_{19}$ rather than $Pb_3(CrF_6)_2$.

PbF_2-FeF_3. The solid-phase equilibrium in the system was studied at 500 °C.[182,223] The $Pb_{1-x}Fe_xF_{2+x}$ solid solution with the fluorite structure at $0 < x \leqslant 0.17$, the new $Pb_{1-x}Fe_xF_{2+x}$ phase with an orthorhombically distorted fluorite structure at $0.26 \leqslant x \leqslant 0.27$ and the $Pb_3(FeF_6)_2$ compound belonging to the tetragonal system were found to exist in this system. In the study,[185] the composition $Pb_5Fe_3F_{19}$ instead of $Pb_3(FeF_6)_2$ was assigned to the ferroelectric phase. The $Pb_3(FeF_6)_2$ compound was prepared by hydrothermal synthesis,[224] but this was another phase, which belongs to the triclinic system and contains the ring-like $[Fe_4F_{20}]^{8-}$ tetramers consisting of the $(FeF_6)^{3-}$ octahedra.

PbF_2-SbF_3. Solid-phase equilibria in this system were studied at 250 °C.[225] The $Pb_{1-x}Sb_xF_{2+x}$ solid solution with the fluorite structure at $0 < x \leqslant 0.40$ and the $Pb_2Sb_3F_{13}$ compound were revealed. The structure of the latter compound was not established.

PbF_2-BiF_3. The system was studied by several research groups.[226–230] The phase diagram of the system is shown in Fig. 14. The following two phases of variable composition exist in this system: the fluorite solid solution $Pb_{1-x}Bi_xF_{2+x}$ based on high-temperature PbF_2 with a maximum in the melting curve at ~25 mol.% of BiF_3 and 890 °C and the berthollide phase $Bi_{1-y}Pb_yF_{3-y}$ with the tysonite structure. The homogeneity region of $Pb_{1-x}Bi_xF_{2+x}$ extends up to 50 mol.% of BiF_3.[226] However, the dependence of the lattice parameter on the composition (a linear decrease up to $x = 0.3$ followed by concentration independence) is abnormal. A careful X-ray diffraction study[227,228] showed ordering and the formation of the $PbBiF_5$ compound with a tetragonally distorted structure. The homogeneity region of the tysonite phase is $0.05 \leqslant y \leqslant 0.25$ (see Ref. 230) or $0.075 \leqslant y \leqslant 0.175$ (see Ref. 228). The polymorphic transition for BiF_3 described in the study[230] is indicative of possible oxygen contamination because no polymorphic transformations are observed in pure BiF_3.[231,232]

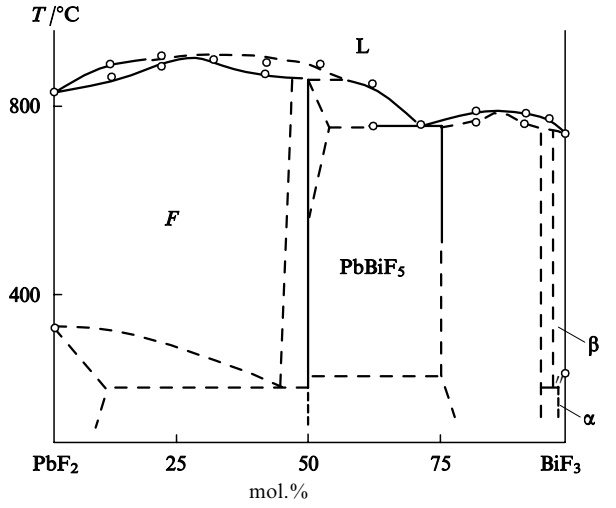

Figure 14. Phase diagram of the PbF_2-BiF_3 system.[230]

PbF_2-RhF_3. The system was not studied, but the Pb_2RhF_7 compound was synthesised.[233,234]

VI. Systems PbF_2-MF_4

PbF_2-UF_4. The phase diagram of the system (Fig. 15 *a*) has two maxima in the liquidus curve, which were assigned to the formation of compounds. The homogeneity regions are absent. The interpretation of compositions in the region of high PbF_2 concentrations was found to be erroneous.[236,237] The reinvestigation (Fig. 15 *b*) revealed the $Pb_{1-x}U_xF_{2+2x}$ solid solution (0 mol.% – 25 mol.% of UF_4), which has a maximum in the liquidus curve at 923 °C corresponding to the composition $Pb_{0.85}U_{0.15}F_{2.3}$.[238,239] In addition, a phase of variable composition with the tysonite structure (45 mol.% – 50 mol.% of UF_4) was observed. The maximum in the liquidus curve of the solid solution at 836 °C corresponds to the composition $Pb_{0.55}U_{0.45}F_{2.9}$. The phases formed in the system under consideration are characterised by high fluoride ion conductivity.[239,240] In the $Pb_{1-x}U_xF_{2+2x}$ solid solution, a decrease in the temperature and diffusion of the Faraday phase transition are observed with increasing concentration of uranium fluoride.

PbF_2-ThF_4. The system was studied with the aim of revealing ion transport. There is evidence for the existence of the $Pb_{1-x}Th_xF_{2+2x}$ solid solution ($0 < x \leqslant 0.2$) with the fluorite

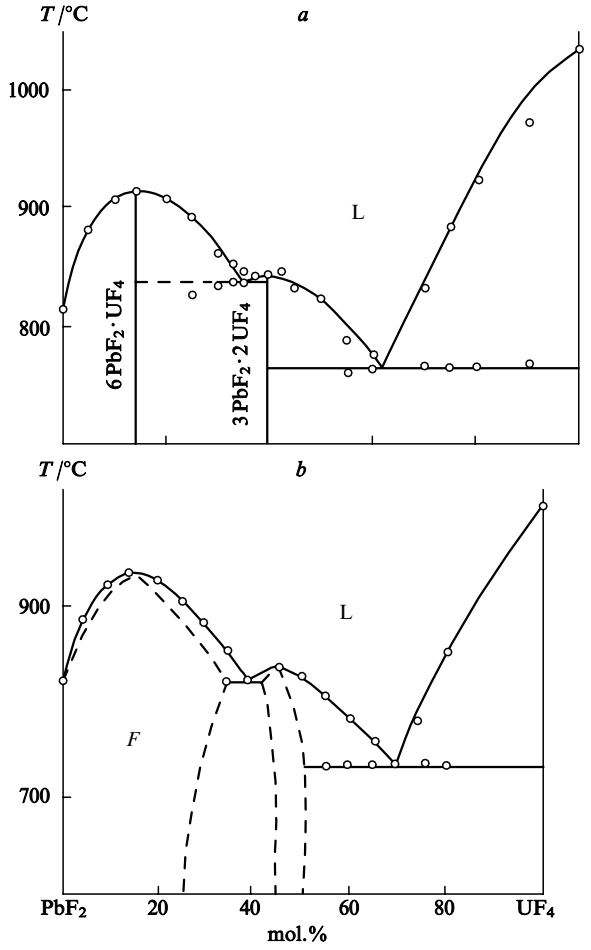

Figure 15. Phase diagram of the PbF_2-UF_4 system.
(*a*) according to the results of the study;[235] (*b*) according to the results of the study.[238]

structure.[241,242] The $PbThF_6$ compound with the tysonite structure was synthesised.[56,243] In this compound, a substantial amount of PbF_2 can be dissolved.[241] The mobility of fluoride ions in $PbThF_6$ was investigated.[244]

PbF_2-ZrF_4. The system was examined by several research teams.[199,245–251] The phase diagram of the system is shown in Fig. 16. The system contains the congruently melting $PbZrF_6$ compound, the incongruently melting Pb_3ZrF_{10} compound and the cubic solid solution $Pb_{1-x}Zr_xF_{2+2x}$ ($0 < x \leqslant 0.18$), whose structure undergoes ordering with decreasing temperature.[248] Like Pb_3ZrF_{10} ($n = 6$),[199] the monoclinic pseudotetragonal fluorite-like phase ($a \simeq a_F$, $b \simeq c \simeq 3a_F$) with approximate composition Pb_5ZrF_{14} is apparently a member of the homologous series $Pb_nR_2F_{2n+8}$ ($n = 10$). Ordering is based on formation of one-dimensional infinite clusters consisting of the ZrF_8 antiprisms.

A phase formed in the temperature range of $510 \leqslant T \leqslant 560$ °C at $0.34 \leqslant x \leqslant 0.35$ was interpreted[248] as a series of microphases, which can be described as orthorhombic superstructures with the unit cell parameters $a \simeq n \cdot 10$, $b \simeq 11.6$, $c \simeq 5.4$ Å. The case $n = 3$ corresponds to the Pb_2ZrF_8 compound.

According to the results of the study,[251] ZrF_4 is characterised by polymorphic transformations, which is apparently indicative of oxygen contamination.[252]

The $PbZrF_6$, Pb_5ZrF_{14} and Pb_2ZrF_8 compounds were synthesised by the reactions of solutions of ammonium fluorozirconates with lead nitrate.[253,254]

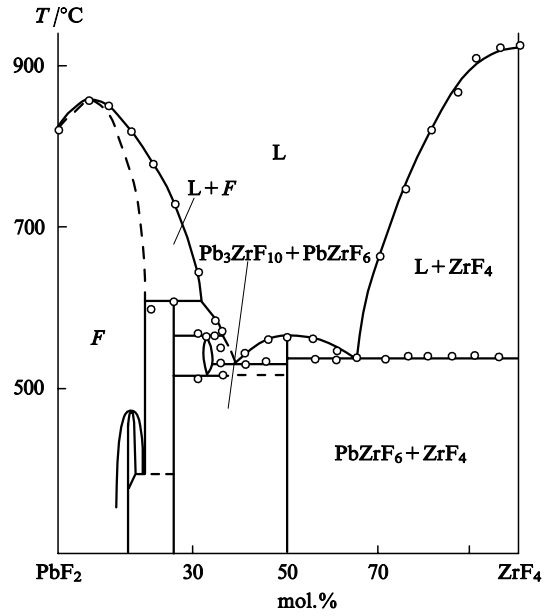

Figure 16. Phase diagram of the PbF_2-ZrF_4 system constructed based on the unpublished data of V K Goncharuk, G D Lukiyanchuk (Institute of Chemistry, Far-East Branch of the Russian Academy of Sciences) and P P Fedorov taking into account low-temperature equilibria published in the study.[248]

PbF_2-GeF_4. The system has[137] the $Pb_{1-x}Ge_xF_{2+2x}$ solid solution with the fluorite structure in the concentration range $0 < x \leqslant 0.08$ and the Pb_3GeF_{10}, $Pb_3Ge_2F_{14}$ and $PbGeF_6$ compounds. The liquidus of the system was not studied.

PbF_2-SnF_4. An analogous solid solution at $0 < x \leqslant 0.10$ and one $PbSnF_6$ compound exist in the system.[137] The liquidus of the system was not examined. The ionic conductivity of $Pb_{1-x}Sn_xF_{2+2x}$ was examined.[255]

PbF_2-TeF_4. The system was investigated[256] with the aim of revealing ionic conductivity in the solid state at 200 °C (TeF_4 decomposes above 193 °C). The PbF_2-based solid solution $Pb_{1-x}Te_xF_{2+2x}$ was found to exist at $0 \leqslant x \leqslant 0.2$. The lattice parameter sharply non-linearly increases as x increases to ~6.05 Å. The $Pb_7Te_4F_{30}$, $PbTeF_6$ and $PbTe_2F_{10}$ compounds were also mentioned, but their characteristics were not reported.

A series of compounds of lead difluoride with tetravalent metal fluorides were synthesised: $PbCeF_6$, $PbNpF_6$,[243] $PbPbF_6$ (PbF_3)[257] and $PbPtF_6$.[258]

VII. Systems PbF_2-MF_5

PbF_2-NbF_5. Interactions in this system were examined in detail[259,260] (Fig. 17). Five compounds formed at the NbF_5/PbF_2 ratios of 4/1, 5/2, 2/1, 1/1 and 1/3 were revealed.

PbF_2-TaF_5. The system was partially studied by DTA and X-ray diffraction analysis of annealed samples.[261] In the range $0 < x \leqslant 0.14$, the $Pb_{1-x}Ta_xF_{2+3x}$ solid solution with the fluorite structure exists. The lattice parameter of this solid solution changes from 5.940 ± 0.005 for $x = 0$ to 5.946 ± 0.005 Å for $x = 0.14$. Annealing of samples from $0.14 \leqslant x \leqslant 0.15$ at 400 °C demonstrated the presence of a low-temperature phase with the idealised composition Pb_6TaF_{17} ($x = 0.143$), which is transformed into the high-temperature modification at 460 °C. The ordered fluorite-like Pb_3TaF_{11} phase exists at $x = 0.25$.

The $PbAs_2F_{12}$ and $PbSb_2F_{12}$ compounds were synthesised.[262,263] The coordinates of eutectics in the PbF_2-MF_n binary systems and characteristics of the compounds formed in these systems are given in Tables 1 and 2, respectively.

Table 1. Coordinates of eutectics in PbF_2-MF_n systems.

(*1*) DTA data, (*2*) single-phase samples (powder X-ray diffraction data).

VIII. Ternary systems involving PbF_2

Numerous compounds involving PbF_2 were synthesised [264–271] (see Table 2). Data on phase equilibria in the corresponding systems are scarce.

$NaF-PbF_2-CdF_2$. The system was examined [55,272] using the $NaF-Pb_{0.67}Cd_{0.33}F_2$ section passing through a minimum in the melting curves of the phase diagram of the PbF_2-CdF_2 system (Fig. 18). Sodium fluoride was found to be readily dissolved in a fluorite matrix, the solubility being as much as 16 mol.%.

$NaF-PbF_2-BiF_3$. Phase equilibria in the system were studied at 400 °C (Fig. 19). The system has a band of a continuous solid solution F between a non-stoichiometric fluorite phase in the $NaF-BiF_3$ system and the $Pb_{1-x}Bi_xF_{2+x}$ solid solution based on cubic PbF_2 as well as the $NaBiF_4$ phase with the gagarinite structure ($NaNdF_4$) characterised by a narrow homogeneity region. A change in the lattice parameter of the ternary solid solution does not follow Vegard's law. Apparently, a melt was present in the concentration triangle formed by the $NaF-F-NaBiF_4$ phases at the experimental temperature (400 °C). Non-stoichiometry is typical of compounds with the gagarinite-type structure. Phases with the idealised composition $KPbRF_6$ (R = REM) belong to this family (see Table 2).

$RbF-PbF_2-BiF_3$. The melting points of a number of composites in the system were determined [37] (Fig. 20). These results provided evidence for the existence of the congruently melting $RbPbBiF_6$ compound.

Note. The following notations are used: c is congruent melting, i is incongruent melting, p is a phase transition, d is decomposition in the solid state.

$NaF-PbF_2-UF_4$ and $KF-PbF_2-UF_4$. The liquidus surfaces for these systems are shown in Figs 21 and 22, respectively. In both cases, solid-phase equilibria were not reported.

$PbF_2-CdF_2-RF_3$. The systems were partially examined in the studies.[55,274,275] The PbF_2-CdF_2-based $(Pb_{1-y}Cd_y)_{1-x}Ce_xF_{2+x}$ solid solution with the fluorite structure and the CeF_3-based $(Pb_{1-y}Cd_y)_{1-x}Ce_xF_{3-x}$ solid solution with the tysonite structure were found to exist in the $PbF_2-CdF_2-CeF_3$ system in the temperature range of 600–760 °C (Fig. 23).

Regions of the $Pb_{0.67}Cd_{0.33}F_2-RF_3$ polythermal sections of the $PbF_2-CdF_2-RF_3$ ternary systems (R = Ce, Gd, Er, Lu, Sc, Y) were investigated.[55,275] These sections are similar to quasibinary sections (Fig. 24). The $(Pb_{0.67}Cd_{0.33})_{1-x}R_xF_{2+x}$ solid solutions (phases F) are observed in these sections. In the sections with R = Ce and Gd, the phases F melt according to peritectic reactions. In the section with Er, the phases F melt according to a eutectic reaction, the melting curves of the solid solution in this section having a maximum. This maximum is also observed in the section with Lu, where the fluorite-like phase R containing 40 mol.% of LuF_3 is involved in phase equilibria with the melt. This character of the sections is indicative of the existence of saddle points on liquidus surfaces of solid solutions in systems with rare-earth elements of the yttrium group.

The $PbF_2-Sn_2F_6$ section belonging to the $PbF_2-SnF_2-SnF_4$ ternary system was partially studied[255] and the boundary of the $Pb_{1-x}(Sn^{II}_{0.5}Sn^{IV}_{0.5})_xF_{2+x}$ solid solution ($x \leqslant 0.15$) with the fluorite structure was determined.

IX. Other compounds involving fluorine and divalent lead

Lead compounds with mixed anions, including $Pb_2SO_4F_2$, $Pb_6SO_4F_{10}$, $Pb_2CO_3F_2$ and $Pb_5(PO_4)_3F$, were studied.[102] Lead fluoride halides PbXF (X = Cl, Br, I; the rare mineral matlockite PbClF occurs in nature) and other compounds with a more complex stoichiometry were synthesised.[276–283]

Lead oxofluoride Pb_2OF_2 is known.[79, 284] Oxofluoride phases involving lead fluoride hold promise as solid electrolytes and fluxes. Numerous compounds occur in the PbF_2-MO_x systems [for example, with M = V (see Ref. 36) or Te (see Ref. 285)]. Many studies were devoted to phases formed in the Pb,Bi//O,F system (see Refs 286–291) and in more complex systems.[292]

X. Characteristic features of phase diagrams involving PbF_2

1. Formation of compounds

As a rule, both solid solutions based on the cubic modification of PbF_2 and numerous compounds are formed in systems involving lead difluoride. Generally, the formation of chemical compounds (phases characterised by narrow homogeneity regions) leads to limitation of homogeneity regions of solid solutions according to the Hume-Rothery rule.[293]

To gain insight into the nature of compounds formed, let us consider the diagram presented in Fig. 25, where the representative points of cations are shown in the generalised

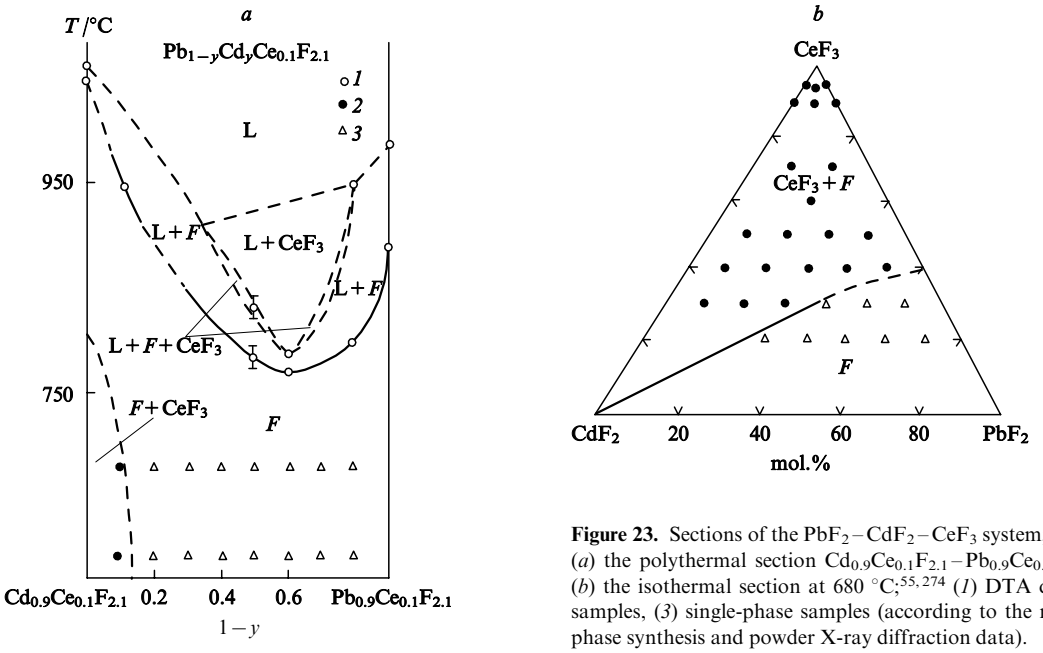

Figure 23. Sections of the $PbF_2-CdF_2-CeF_3$ system; (*a*) the polythermal section $Cd_{0.9}Ce_{0.1}F_{2.1}-Pb_{0.9}Ce_{0.1}F_{2.1}$ (see Ref. 55), (*b*) the isothermal section at 680 °C;[55,274] (*1*) DTA data, (*2*) two-phase samples, (*3*) single-phase samples (according to the results of the solid-phase synthesis and powder X-ray diffraction data).

moment† – electronegativity coordinates. This combination of variables, which was first proposed in the study,[294] is convenient for classification of binary salt systems according to the formation of compounds in systems containing one constant component.[295,296] Figure 25 was constructed with the use of the ionic radii of fluorine according to Schannon (the coordination number is 6)[297] and the electronegativities according to Batsanov.[298] Some required parameters (for example, characteristics of divalent tin) were estimated by us.

Two regions of existence of compounds are observed in the $M-x$ diagram (in Fig. 25, these regions are separated by a dark field), which is indicative of the amphoteric character of the basic compound PbF_2. Lead difluoride serves as Lewis acid and Lewis base in the lower left and upper right regions, respectively. Lead difluoride exhibits very weak acidic properties. This compound can be considered as a complex-forming agent only in combination with fluorides MF, where M is heavy alkali metal (K, Rb or Cs) or monovalent thallium. Compounds with francium and monovalent gold are predicted to exist. In the $MPbF_3$ compounds with the perovskite structure belonging to this group, lead has an octahedral coordination. Since the phase diagram of the PbF_2-AgF system[134] is incorrect, it is necessary to study this system in more detail.

In addition, PbF_2 acts as a base in numerous compounds. The structures of this type of compounds are determined by the structure of a complex-forming agent. Lead plays a passive role. The structures contain constructions of tetrahedra (compounds involving BeF_2), octahedra (compounds involving aluminium, iron, chromium, *etc.* trifluorides), eight- and nine-vertex polyhedra (compounds involving rare-earth or zirconium fluorides).

† The ratio of the oxidation state to the ionic radius.

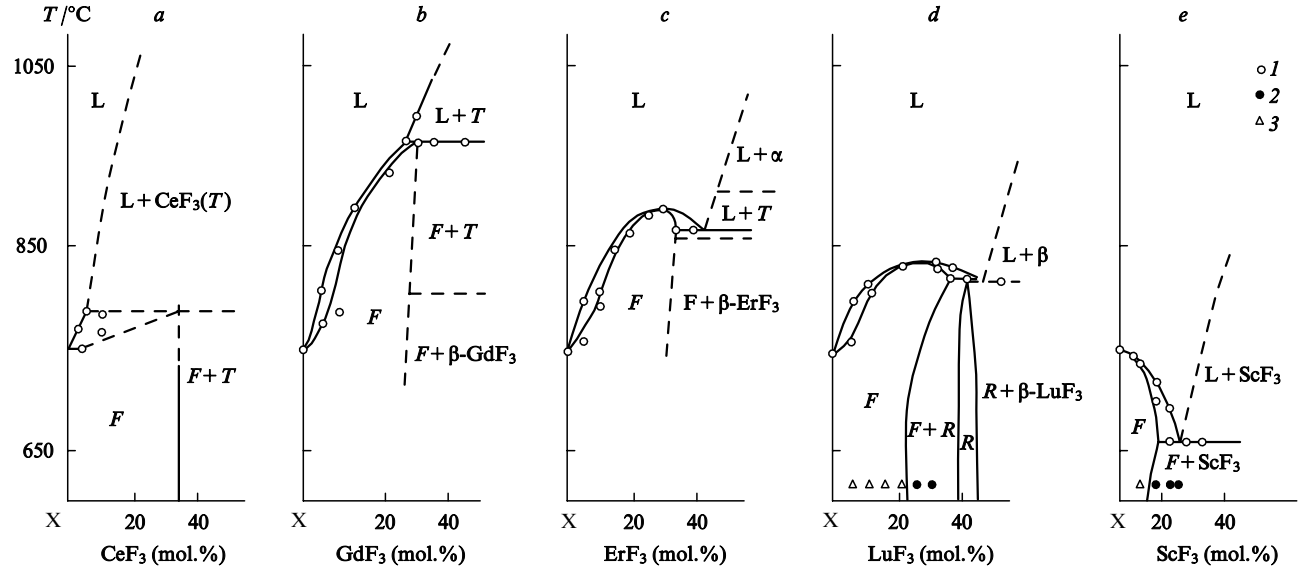

Figure 24. Polythermal sections $X-RF_3$ ($X = Pb_{0.67}Cd_{0.33}F_2$) of the $PbF_2-CdF_2-RF_3$ systems, where R = Ce (*a*), Gd (*b*), Er (*c*), Lu (*d*) and Sc (*e*). (*1*) DTA data, (*2*) two-phase samples, (*3*) single-phase samples (according to the results of the solid-phase synthesis and powder X-ray diffraction data).[55,275]

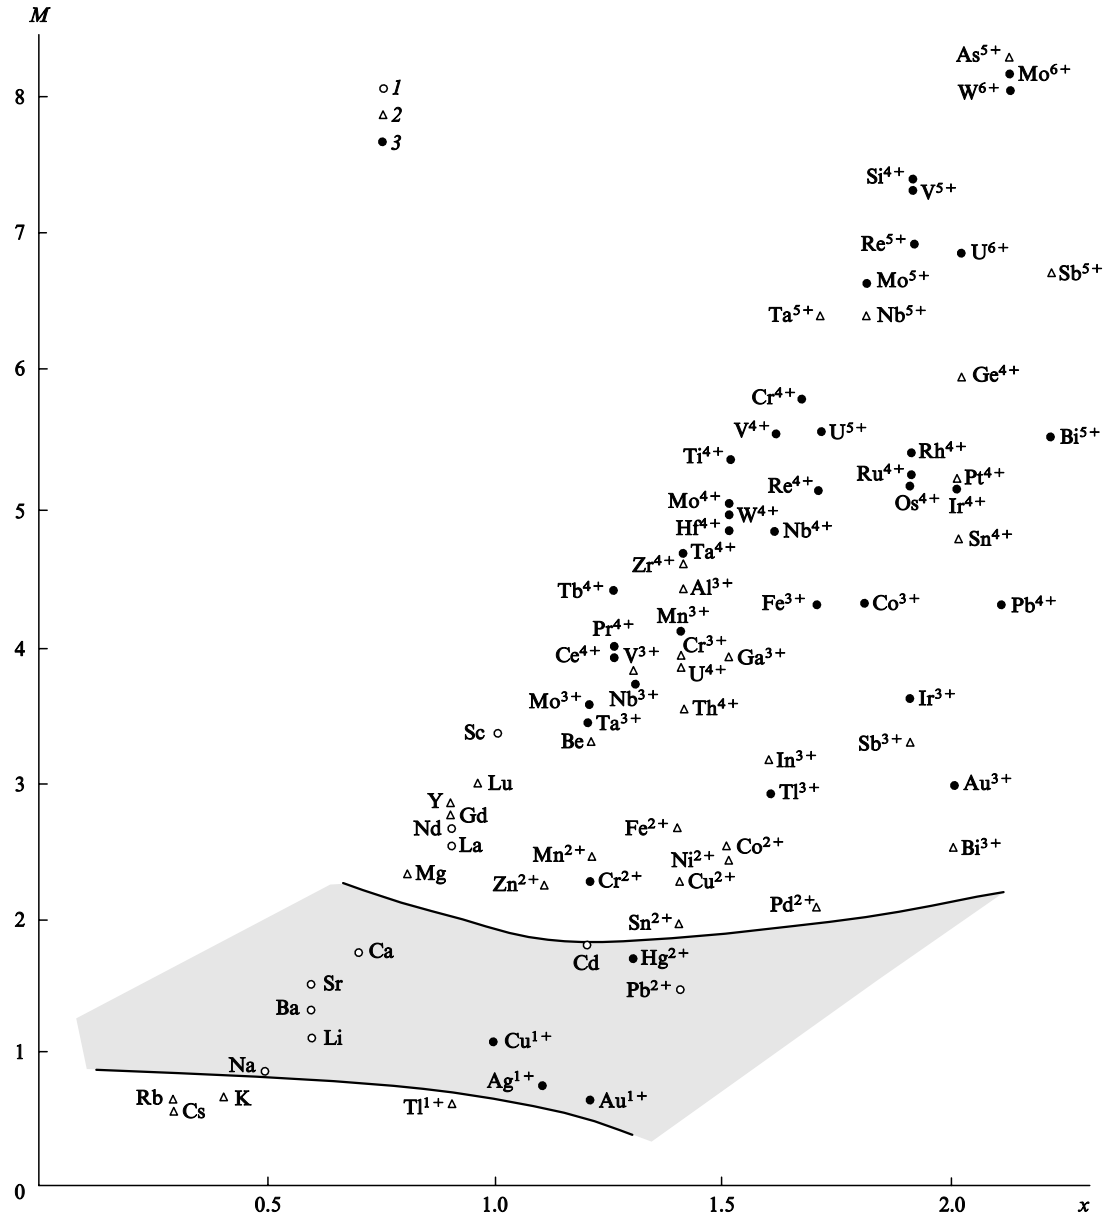

Figure 25. Generalised moment of a cation (M) – electronegativity (x) diagram for the $PbF_2 - MF_n$ systems.
(*1*) The corresponding fluoride does not form compounds with PbF_2, (*2*) the corresponding fluoride forms compounds with PbF_2, (*3*) the system was not studied.

An analysis of the diagram presented in Fig. 25 provides evidence for the existence of compounds which are as yet unknown. These are primarily compounds in systems with TiF_4, SiF_4 and molybdenum fluorides, $PbHfF_6$, Pb_3HfF_{10} and other phases analogous to lead fluorozirconates.[248] By analogy with the known $PbF_2 - NbF_5$ system,[259,260] a series of compounds are predicted to exist in a system with tantalum pentafluoride in addition to those isolated in the study.[261] It is worthwhile searching for compounds in the $PbF_2 - ScF_3$ system. Such compounds can be formed in the solid state at low temperatures. It should be taken into account that there are restrictions on the formation of compounds with fluorides of metals in high oxidation states due to the possibility of redox reactions (accompanied by transformations of lead into higher oxidation states), but there are no such restrictions on the formation of compounds containing metals in low oxidation states, even exotic (for example, divalent chromium and vanadium).

2. Phases of variable composition

According to the third law of thermodynamics, both iso- and heterovalent solid solutions undergo ordering and/or decomposition with decreasing temperature.

The $PbSnF_4$ and Pb_2MF_6 compounds (M = Mg, Mn, Fe, Co, Ni, Zn, Cu) can (should) be considered as ordered fluorite-like phases formed in the $PbF_2 - MF_2$ systems. The distribution of cations in their structures leads to lowering of the symmetry, the fluorite motif being retained.

Figures 26 and 27 present possible phase diagrams of the $PbF_2 - MF_2$ systems taking into account decomposition and ordering of solid solutions according to the mechanism of first-order phase transitions as well as possible transformations of phase diagrams caused by an increase in the temperature of the upper critical points. The critical temperatures of the domes of decomposition of continuous high-temperature solid solutions in the $PbF_2 - MF_2$ systems (M = Ba, Sr) are higher than the temperature of the polymorphic transformation between the orthorhombic and cubic modifications of PbF_2.[140,144] Hence, Fig. 26 *c*

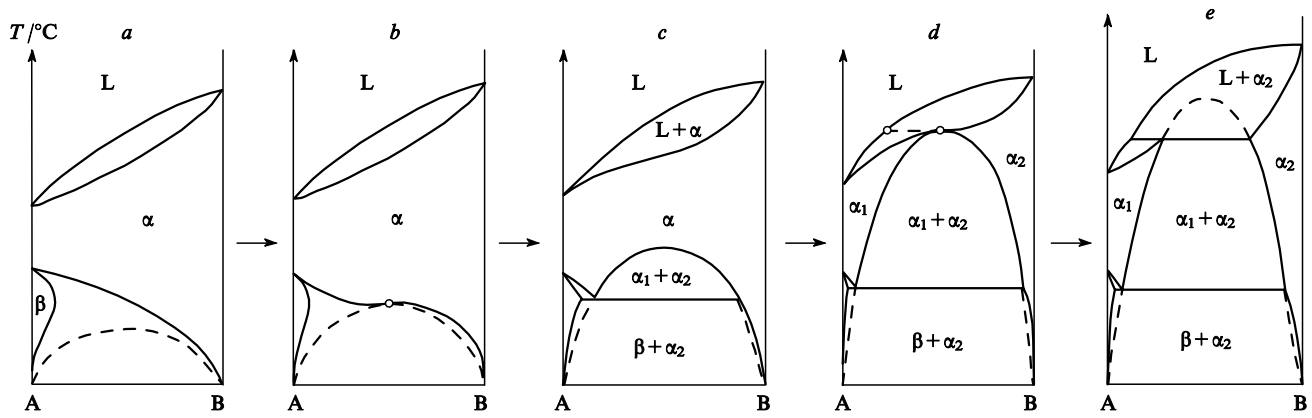

Figure 26. Transformation of the phase diagram of the binary system (A – B) with a high-temperature continuous solid solution α and polymorphism (α ⇌ β) of one of the components (*a*) with increasing temperature of the upper critical point of the dome of decomposition.
Metastable equilibria are indicated by dashed lines, bifurcations are shown by circles; (*b* – *e*) see comments in the text.

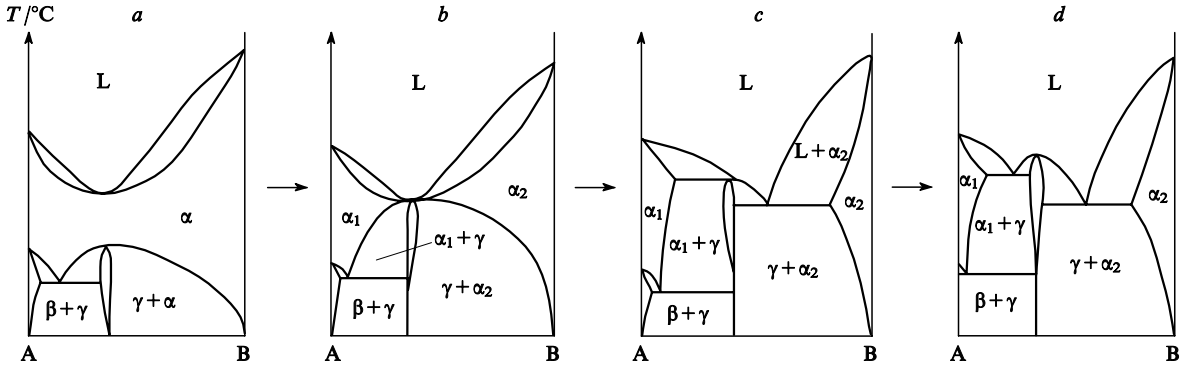

Figure 27. Transformation of the phase diagram of the binary A – B system with a high-temperature continuous solid solution, a minimum in the melting curve, polymorphism (α ⇌ β) of one of the components and the formation of a low-temperature compound γ with increasing temperature stability of the latter; (*a* – *d*) see comments in the text.

corresponds apparently to phase diagrams of these systems. The phase diagram with a discontinuity of miscibility shown in Fig. 26 *e* corresponds to the $PbF_2 - CaF_2$ system. Phase diagrams with transition points (Fig. 26 *b*, *d*) correspond to a change in the topology (bifurcations). According to the classification proposed in the studies,[105, 299, 300] these bifurcations belong to types B_1III and B_1VI, respectively.

The diagram presented in Fig. 27 *a* corresponds apparently to the $PbF_2 - CdF_2$ system. In this system, the composition corresponding to a minimum in the melting curves is characterised (within the experimental error) by the ratio $PbF_2 : CdF_2 = 1 : 2$ analogously to the Pb_2MF_6 compounds revealed in systems with difluorides of other metals with smaller ionic radii. The structure of single crystals of $Pb_{0.67}Cd_{0.33}F_2$ was studied by different methods.[157, 158] Analysis of these results suggests that single crystals contain domains with the corresponding structure.

Phase diagrams shown in Fig. 27 *b* – *d* correspond to a bifurcation point and incongruent and congruent melting of the γ phase, respectively. Figure 27 *c*, where incongruent melting of a compound is observed, corresponds to the $PbF_2 - MnF_2$ system taking into account a change in the crystal structure of MnF_2 as a result of a morphotropic transformation in the MF_2 series. Correspondingly, a noticeable region of a cubic PbF_2-based solid solution would be expected to exist in this system. Actually, the experimental data [145] provided evidence for the existence of this solid solution. However, these data were ignored in the construction of the phase diagram.

Experimental studies of compounds in low-temperature regions of phase diagrams present methodological difficulties. The time of solid-phase annealing required for the establishment of equilibrium increases exponentially with decreasing temperature. The dependence of the time required for sintering of samples in the $PbF_2 - RF_3$ systems on the annealing temperature was experimentally determined [105, 301] (Fig. 28). According to these results, ~100 and ~1000 h are required for the establishment of the equilibrium at 600 and 500 °C, respectively. At lower temperatures, the equilibrium cannot be attained with the use of this procedure. Data on solid-phase equilibria in the $PbF_2 - ZrF_4$ system in the range of 600 – 300 °C were reported.[248] According to these results, a sample of the Pb_5ZrF_{14} compound was synthesised at 450 °C over 8 days. The above difference is attributable to the lower melting point of ZrF_4 compared to those of rare-earth fluorides.

To accelerate chemical reactions and gain information on low-temperature states, it is worthwhile performing the synthesis with the use of a solvent [although this procedure can give rise to non-equilibrium compounds (modifications) as well]. One can perform precipitation from nitrate solutions, hydrothermal synthesis and synthesis by the flux techniques. It should be noted that water and nitrates can serve as a source of oxygen contamination. Hence, a search for appropriate low-temperature solvents is an important problem. For example, the former method was used for the preparation of compounds in the $PbF_2 - SrF_2$ (see Ref. 143) and $PbF_2 - ZrF_4$ systems (see Refs 253 and 254). The second method was used for the synthesis of $PbSnF_4$.[12, 170]

(*1*) Results of the studies,[105, 180, 184, 198, 201, 203, 208, 219, 221] (*2*) data obtained in the study[225] for 250 °C, (*3*) data obtained in the study[182] for 500–550 °C; the solid line corresponds to the equation $x = 44\exp[-36(r-1.22)^2]$; the dashed line corresponds to the equation $x = 42\exp[-90(r-0.9)^2]$.

3. Heterovalent solid solutions

The above-considered systems are characterised by the formation of heterovalent solid solutions based on the cubic modification of PbF_2. Anion-deficient (PbF_2-MF systems) and anion-excess (PbF_2-MF_n systems, $n = 3$, 4, 5) solid solutions are distinguished.

The characteristic features of heterovalent isomorphism with a variable number of ions in the unit cell were analysed.[206, 302] In the simplest case, the dependence of the limiting concentration of heterovalent solid solutions on the ionic radius of the replacing component can be described by the Gaussian. The maximum solubility corresponds to neither the equality of the ionic radii of isomorphous cations nor the constancy of the lattice parameter upon the formation of a solid solution. The dependence of this type satisfactorily describes the data on the PbF_2-MF systems (Fig. 29). In the case of the $Pb_{1-x}R_xF_{2+x}$ solid solutions in the PbF_2-RF_3 system, the situation is much more complicated (Figs 30 and 31).

In the first approximation, the mechanism of formation of solid solutions involves the replacement of lead ions with cations of different valence. The electrostatic compensation occurs through the formation of an equivalent number of anion vacancies (in the case of anion deficient solid solutions) according to the equation

$$Pb^{2+} + F^- \rightleftharpoons M^+ + V_F$$

or through the introduction of additional (interstitial) fluoride ions (in the case of anion excess solid solutions, $n > 2$) according to the equation

$$Pb^{2+} \rightleftharpoons M^{n+} + (n-2)F^-_{int}.$$

Association of point defects and cluster formation are natural processes at high concentrations of a solid solution. The cluster formation in heterovalent fluorite solid solutions is studied by different methods. The data on the fluorite solid solutions $M_{1-x}R_xF_{2+x}$ (M are alkaline-earth metals, cadmium or lead) were surveyed in publications.[2, 25, 304–310]

The first step of association involves the formation of dipoles, *viz.*, associates of oppositely charged defects of the $R^{3+}-F^-_{int}$ type. In the fluorite structure (Fig. 32 *a*), two types of dipoles can exist, the so-called *nn* (nearest neighbour) dipoles with tetragonal (C_{4v}) symmetry and *nnn* (next nearest neighbour) dipoles with trigonal (C_{3v}) symmetry. As the concentration of solid solutions increases,

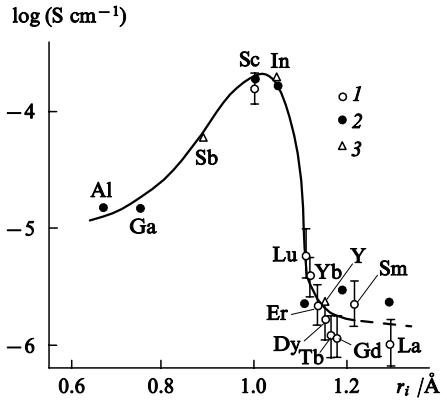

Figure 31. Dependence of the ionic conductivity of $Pb_{0.9}R_{0.1}F_{2.1}$ on the ionic radius.
(*1*) Results of the study,[8] (*2*) results of the study,[303] (*3*) results of the study.[207]

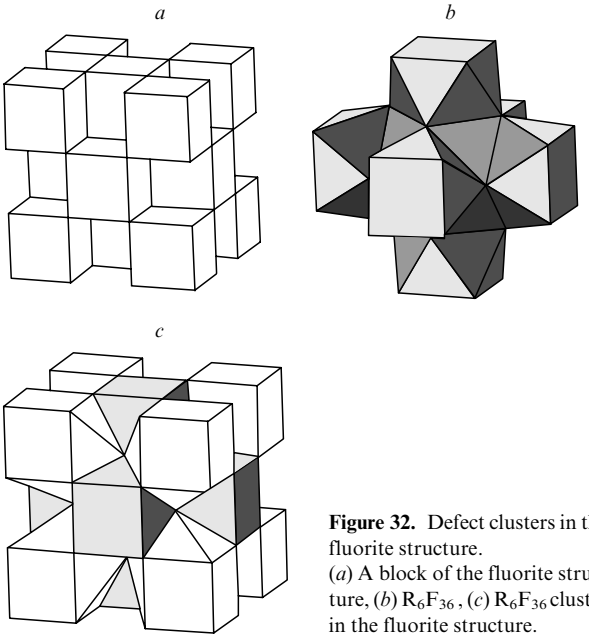

Figure 32. Defect clusters in the fluorite structure.
(*a*) A block of the fluorite structure, (*b*) R_6F_{36}, (*c*) R_6F_{36} cluster in the fluorite structure.

dipoles are transformed into more complex clusters, which coalesce into superclusters due to percolation. These processes are accompanied by the development of short-range order in the cation sublattice and substantial rearrangement of the anion sublattice of the solid solution. Hence, the corresponding solid solutions are nanocrystalline composites.[206, 306, 311] The formation of ordered phases proceeds as ordering of the cluster arrangement. The structure of ordered phases determines the structure of solid solutions (*i.e.*, the type of clusters present in these solutions).

In dilute solid solutions of rare-earth fluorides based on the fluorite modification of lead fluoride containing ~0.1 mol.% of RF_3, the type of major dipoles changes from *nn* to *nnn* on going from metals of the cerium group to metals of the yttrium group. This change is typical also of SrF_2-based and, in part, of BaF_2-based solid solutions, but is untypical of CaF_2-based solid solutions.[307] However, a very complicated pattern of defect association was revealed[213, 214] for dilute solid solutions (even at 0.1 mol.% – 0.01 mol.% of RF_3 in PbF_2) by laser spectroscopy and dielectric relaxation spectroscopy.

In concentrated solid solutions ($x > 0.05$) with rare-earth fluorides of the yttrium subgroup (R = Sm – Lu, Y), the presence of clusters of the R_6F_{36}/R_6F_{37} type is highly probable (Fig. 32 *b*). These clusters contain six trivalent cations. The coordination polyhedron about each cation is a Thompson cube (antiprism) formed by 8 fluoride ions. The cluster has a cuboctahedral cavity, which can be occupied by fluoride ions (or oxygen ions in the case of partial pyrohydrolysis). These clusters were observed in many ordered fluorite-like structures, including $Ba_4R_3F_{17}$, isostructural with lead compounds.[306, 312] Clusters containing oxygen ions in the cuboctahedral cavity were observed in single crystals of $Pb_4Y_3F_{18}O$.[210] Clusters of this type are readily incorporated into the fluorite structure.[313] The results of X-ray diffraction study of $Pb_{1-x}Y_xF_{2+x}$ (see Ref. 219) are consistent with the presence of Y_6Y_{37} in the solid solution, although the authors proposed another cluster model.

It should be noted that thermal stability of the $Pb_4R_3F_{17}$ compounds in the REM series passes through a maximum in a series R = Y – Er. This indicates that the cluster structure of solid solutions varies with the ionic radius of the cations. Since the coordination number of 8 is untypical of R = La – Nd, the $Pb_4R_3F_{17}$ phases with these rare-earth elements lose stability. In such solid solutions, the R_4F_{26}-type clusters, in which the cations have a coordination number of 10, can exist.[314] A decrease in the ionic radius of the rare-earth metal leads to a decrease in the coordination number. Seven-vertex polyhedra observed in the ordered fluorite-like phase Pb_2InF_7 (see Refs 201, 205, 234) should prevail for indium. It was hypothesised[199] that in ordered fluorite-like compounds observed in the $PbF_2 – MF_3$ systems (M = Ga, Ti, V), the seven-vertex polyhedra are linked to form infinite linear clusters. In fluorides (including the $Pb_3Al_2F_{12}$ compound[315]), the coordination number of 6 is typical of Al^{3+}, which has an even smaller radius. Hence, octahedral clusters would be expected to occur in the solid solution.[191]

The structure solution of the ordered fluorite-like Pb_3ZrF_{10} phase revealed yet another type of clusters, whose existence in heterovalent solid solutions is highly probable.[199] These clusters, like the R_6F_{36} clusters, contain also eight-vertex polyhedra, *viz.*, the ZrF_8 antiprisms. The antiprisms are linked to form infinite zigzag chains giving rise to a family of one-dimensional clusters. The existence of clusters of this type is assumed in solid solutions of lead fluoride with fluorides of both tetravalent and trivalent elements.

A comparison of the data on the defect structures of the $Pb_{1-x}R_xF_{2+x}$ solid solutions depending on their limiting solubility (Fig. 33) provides evidence that there are three dependences corresponding to different types of rearrangement of the anion sublattice upon the replacement of cations in their crystallo-

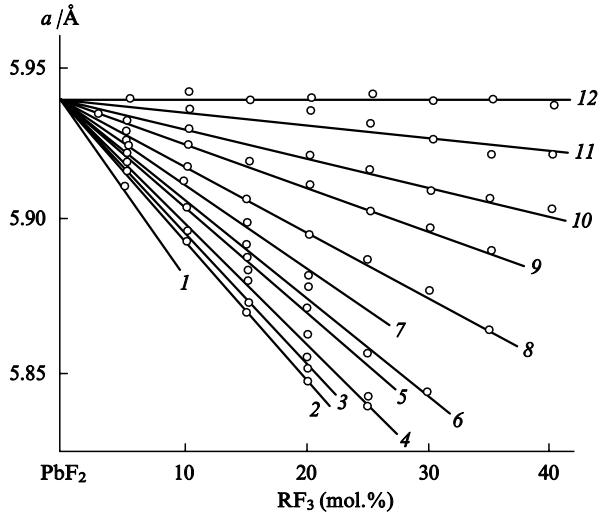

Figure 33. Dependence of the lattice parameters of the $Pb_{1-x}R_xF_{2+x}$ solid solutions on their composition.[105, 316]

graphic positions giving rise to eight- or ten-vertex, seven-vertex and six-vertex polyhedra RF_n linked in clusters. The ionic conductivity changes with a change in the defect structure (see Fig. 32).

The formation of heterovalent solid solutions is accompanied by a change in the lattice parameter depending on the concentration of RF_3.[105,316] In the first approximation, this change is linear, *i.e.*, Vegard's law is fulfilled (see Fig. 33). The results of accurate measurements (see, for example, Refs 201 and 248) and the data on the high-pressure synthesis of solid solutions, which extends the concentration range of their existence,[215,317] are indicative of deviations from linear dependences. We ignore these deviations in subsequent analysis.

The slopes α depend linearly on the ionic radius of rare-earth metals (Fig. 34). Hence, in the general form, the data on the PbF_2-RF_3 systems can be described [105,316] by the expression

$$\alpha = 5.490 + [2.48(r-r_0) + \varepsilon_1]x,$$

where r_0 is the ionic radius of Pb^{2+}, $\varepsilon_1 = 0.3694$ Å mol^{-1} is the contribution of excess fluoride ions with respect to the stoichiometry PbF_2 upon the formation of the $Pb_{1-x}R_xF_{2+x}$ solid solutions, x is the mole fraction of RF_3. In the studies, [105,316] r_0 was corrected compared to its value in the Schannon table [297] (for the coordination number of 8, $r_0 = 1.456$ instead of 1.43 Å).

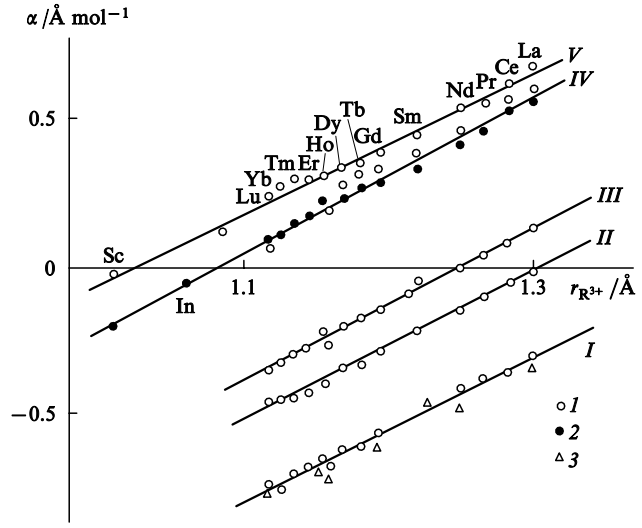

Figure 34. Slopes of the concentration dependences of the lattice parameters of the heterovalent solid solutions $M^{II}_{1-x}R_xF_{2+x}$ *vs.* the ionic radii of trivalent cations.[105,316]
(*1*) Samples quenched after solid-phase annealing, (*2*) slowly cooled samples, (*3*) sintered samples; M = Ba (*I*), Pb (*II*), Sr (*III*), Ca (*IV*), Cd (*V*).

Based on the published data,[238,242,248] we derived the following equation for solid solutions of tetravalent metal fluorides in lead fluoride:

$$\alpha_{cal} = 2.48(r-1.456) + 0.804. \quad (1)$$

Analogous dependences are observed for solid solutions of tetravalent metal fluorides in other fluorite matrices (Fig. 35). Taking into account that $\varepsilon_2 \simeq 2\varepsilon_1$ (this corresponds to insertion of two additional fluoride ions into the lattice in the case of heterovalent isomorphism), an approximate expression can be obtained for solid solutions of pentavalent element fluorides ($\varepsilon_3 \simeq 1.5\varepsilon_2 \simeq 3\varepsilon_1$).

The experimental and calculated slopes are given in Table 3. Discrepancies observed in some cases require a careful experimental verification.

4. Non-stoichiometry of lead difluoride

Taking into account a possible change in the valence state of lead in fluorides (from two to four) and the ease of formation of heterovalent solid solutions of the cubic modification of PbF_2 with tetravalent metal fluorides, a region of the $Pb^{II}_{1-x}Pb^{IV}_{x}F_{2+2x}$ ($PbF_{2+\delta}$) solid solutions would be expected to occur. In the region of existence of lead difluoride, the PbF_2-PbF_4 system (Pb–F) (Fig. 36) should have features in common with the $EuCl_2-EuCl_3$ system (Eu–Cl). Europium dichloride $EuCl_2$ undergoes a polymorphic transformation, both modifications being isostructural with lead difluoride (the low-temperature orthorhombic cotunnite-type phase and the high-temperature cubic fluorite-type phase). A close examination of the experimental data [321] revealed the region of the $EuCl_{2+x}$ solid solution, which decomposes according to a eutectoid scheme.[322]

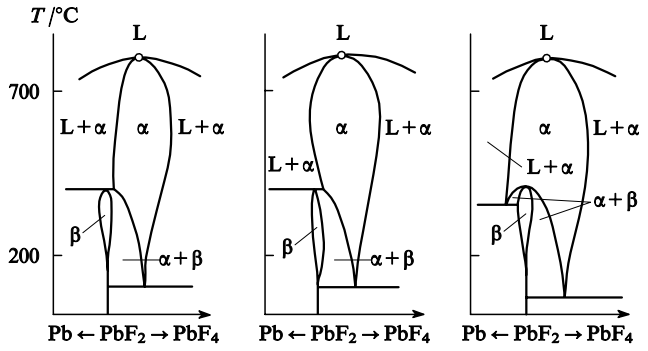

Figure 36. Schemes of possible phase equilibria in the Pb–F system.

The assumed non-stoichiometry is one of the possible reasons for the observed difference in the lattice parameter of cubic PbF_2 determined in different studies. The substitution of the ionic radius of Pb^{4+} [r = 1.08 Å (see Ref. 297)] into Eqn (1) gives $\alpha_{cal} = -0.14$ Å mol^{-1}. Therefore, if these estimates (including those for the ionic radius of Pb^{4+}) are correct, an additive of tetravalent lead should cause an insignificant decrease in the lattice parameter of PbF_2.

In addition, a consideration of the fluorite phase $PbF_{2\pm\delta}$ as non-stoichiometric provides an explanation for the data obtained by A I Boltalin (Moscow State University) on the polymorphism of PbF_2: a liquid phase, which appears upon heating of the low-temperature orthorhombic modification, is apparently a melt enriched in metallic lead (according to the medium phase diagram shown in Fig. 36). In the general case, the maximum in the melting curve for a non-stoichiometric phase does not correspond to stoichiometry (PbF_2). This phenomenon was observed for the fluorite solid solution EuF_{2+x}.[316] It is also worthwhile searching for low-temperature ordered intermediate phases of lead fluoride, for example, $Pb^{II}_3Pb^{IV}F_{10}$ (Pb_2F_5).

5. Partition coefficients of additives

For crystallisation of a PbF_2 melt, the partition coefficients of additives k can be estimated using phase diagrams of binary systems. For infinitely diluted solutions, the coefficients can be estimated using the modified cryoscopy method [323, 324] based on the Van't Hoff equation

$$\lim\left(\frac{dT_L}{dx}\right) = \frac{RT^2}{\Delta H}(k-1),$$

where T is the temperature, ΔH is the enthalpy of melting of the matrix. This method differs from conventional cryoscopy in that the limiting slope of the liquidus line dT_L/dx with $x \to 0$ is determined by differentiation of a polynomial approximating the experimental curve in a wide concentration range. The error of the calculation of k is, on average, 10%–15%.

Calculations were carried out using ΔH = 3000 cal mol^{-1}.[325] The results of calculations are presented in Table 4. The dependences of the partition coefficients on the ionic radius of the replacing cation are described by Gaussian-type distribution functions (Fig. 37).

Table 4. Partition coefficients k of additives for crystallisation of PbF_2.

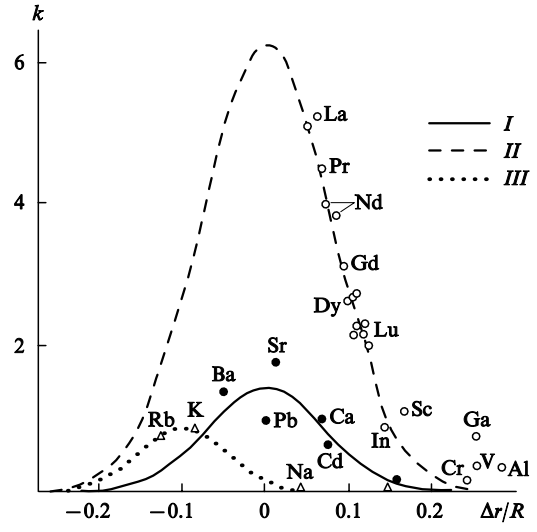

Figure 37. Partition coefficients of MF_n (k) for crystallisation of a PbF_2 melt as a function of the normalised difference in the ionic radii $\Delta r/R$.[206] $\Delta r = r_{Pb} - r_M$, $R = a\sqrt{3}/4$ is the cation–anion distance in the lattice of PbF_2, a is the lattice parameter, n = 2 (*1*), 3 (*2*), 1 (*3*); curves *I*–*III* were constructed according to the equations $k = 1.44\exp[-102(\Delta r/R)^2]$, $k = 6.25\exp[-82.2(\Delta r/R)^2]$ and $k = 0.89\exp[-174(\Delta r/R + 0.09)^2]$, respectively.

6. Saddle points

The $PbF_2-CdF_2-RF_3$ systems (R = Er, Lu, Y) are characterised [275] by the presence of specific stationary (corresponding to congruent melting) points, the so-called saddle points, on the liquidus surface (Fig. 38). The compositions of congruently melting solid solutions are favourable for growing homogeneous crystals. Hence, a search for such solutions is of importance.

Saddle points on equilibrium surfaces of two-phase multicomponent systems were theoretically predicted by Gibbs.[326] The corresponding phase diagrams were constructed,[327] but they were

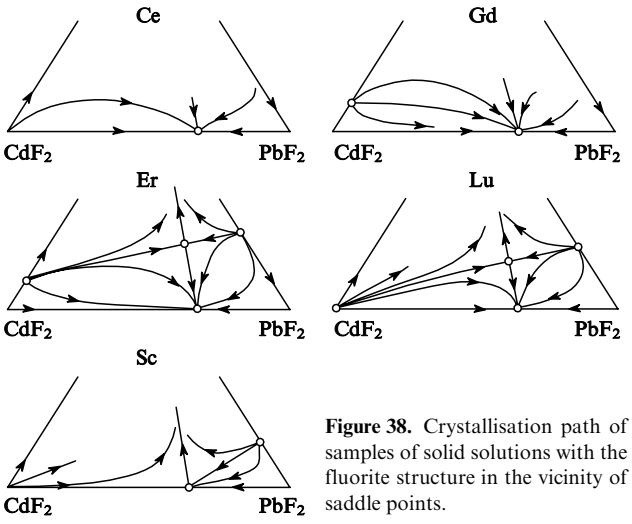

Figure 38. Crystallisation path of samples of solid solutions with the fluorite structure in the vicinity of saddle points.

not studied experimentally until 1996, when the first publication on this problem appeared.[275] According to the thermodynamic topological analysis,[328] saddle points can appear in ternary systems that have two maxima (minima) and one minimum (maximum) in the melting curves of binary systems, which form the ternary system. Therefore, about 40 congruently melting composites would be expected to occur in the $MF_2-M'F_2-RF_3$ systems. This prediction [329] was confirmed when we performed an experimental study of the $PbF_2-CdF_2-RF_3$ systems (R = Tb–Lu). Analysis of the polythermal sections revealed the positions of compositions corresponding to saddle points. For example, the coordinates of the saddle points in such systems with Er, Lu and Y are as follows:

Er: 30 ± 2 mol.% of ErF_3, 23 ± 2 mol.% of CdF_2, 890 ± 5 °C;

Lu: 25 ± 2 mol.% of LuF_3, 25 ± 2 mol.% of CdF_2, 835 ± 5 °C;

Y: 17.5 ± 2 mol.% of YF_3, 27 ± 2 mol.% of CdF_2, 885 ± 5 °C;

It appeared that these points lie virtually exactly in the section which links the minimum in the CdF_2-PbF_2 system to the point corresponding to RF_3.

7. Tetragonal phases in the PbF_2-MF_3 systems (M = Al, Ti, V, Cr, Fe, Ga)

As mentioned above, there is no consensus among experts as to stoichiometry and regions of stability for phases with a tetragonal structure formed in the PbF_2-MF_3 systems (M = Al, Ti, V, Cr, Fe, Ga) in the region of 50 mol.% – 62.5 mol.% of PbF_2. It was hypothesised that the $PbMF_5$, $Pb_3M_2F_{12}$ and $Pb_5M_3F_{19}$ compounds exist in these systems. In some cases, different compositions were assigned to the same samples. According to the results of different studies,[188–190, 192–196] $Pb_5M_3F_{19}$ (M = Al, Cr), $SrAlF_5/BaFeF_5$ and $Sr_3Fe_2F_{12}$ are characterised by rather similar structural motifs, which can be described as infinite chains of vertex-sharing octahedra oriented along the *c* axis of the tetragonal unit cell. A change in the composition from 1:1 to 2:3 is attained due to the presence of additional fluoride ions. In the PbF_2-AlF_3 system, like in other analogous systems consisting of di- and trivalent metal fluorides, several phases of similar composition and structure can exist in the region between 40 mol.% and 50 mol.% of AlF_3. Ravez *et al.*[185] believed that a solid solution exists in this region.

Apparently, this structural motif serves as a structural basis of fluoride aluminate glasses.[62, 64] A tetragonal phase systematically appears upon crystallisation of glasses of the Ba,In,Pb,Al//F system.[64, 197] In the study,[197] the composition $Pb_3Al_2F_{12}$ was assigned to the tetragonal phase in the PbF_2-AlF_3 system.

An analogous situation is observed in systems with $M'F_2-MF_3$ (M′ = Sr, Ba); Sc and In can be involved along with trivalent ions (see, for example, Refs 330 and 331).

Presumably, the compositions of compounds and the types of phase equilibria in the systems under consideration can be correctly determined on the assumption that these phases are characterised by high-temperature non-stoichiometry accompanied by the formation of ordered compounds with particular stoichiometry on cooling. Real samples prepared by high-temperature syntheses and cooled to room temperature could contain domains corresponding to various low-temperature compounds. Studies of samples by high-resolution electron microscopy and electron microdiffraction are desirable.

XI. Conclusion

The present review demonstrates that lead difluoride and its composites with other inorganic compounds hold promise as a basis for the construction of new functional materials, which will find use in such fields as photonics and solid-state ionics.

Analysis of the data on phase equilibria in PbF_2-containing systems revealed a number of problems, which call for further experimental studies. To solve these problems, it is necessary to:

— study a lead–fluorine system and construct the corresponding phase diagram; carry out experimental studies and determine the width of the homogeneity region of the $PbF_{2+\delta}$ phase, the concentration dependence of the lattice parameter, the position of the maximum in the melting curve and the presence of low-temperature ordered fluorite-like intermediate phases, *viz*., lead fluorides;

— elucidate the reasons for doubling of the lattice parameter for the cubic modification of PbF_2, find the relationship between this phenomenon and ordering of the anion sublattice, reveal the influence of the lattice parameter on the properties of PbF_2;

— synthesise a series of lead fluorides ($PbHfF_6$, Pb_3HfF_{10}, *etc*.), whose existence was predicted based on analysis of phase diagrams for systems involving PbF_2;

— reveal the effect of the lone electron pair of the Pb^{2+} ion on the properties of lead compounds;

— investigate polymorphism and non-stoichiometry in tetragonal phases of the $PbMF_5$, $Pb_5M_3F_{19}$ and $Pb_3M_2F_{12}$ types;

— reveal factors responsible for high fluoride ion mobility in materials based on lead difluoride and the relationship between the mobility and the characteristic features of the cluster structure of solid solutions with the fluorite structure.

Disaccharide nucleosides

E V Efimtseva, S N Mikhailov

Contents

I. Introduction 401
II. Structures and properties of natural disaccharide nucleosides 401
III. General methods for the synthesis of disaccharide nucleosides 406

Abstract. Structural features and biological properties of natural disaccharide nucleosides and related compounds are considered. The main methods for the synthesis of these compounds are described and their advantages and disadvantages are discussed. These methods include condensations of a protected disaccharide with a heterocyclic base or of a protected nucleoside with an activated monosaccharide. The bibliography includes 172 references.

I. Introduction

Disaccharide nucleosides constitute an important group of natural compounds, but in contrast to ordinary nucleosides, it is their disaccharide rather than monosaccharide moiety that is linked to a heterocyclic base. Over one hundred such compounds and their derivatives have been isolated from various sources.[1] These compounds manifest a broad spectrum of biological (including antibacterial, fungicidal, herbicidal, antitumour and antiviral) activities. The review by Lerner[2] published in 1991 provides a detailed description of the structures of disaccharide nucleoside antibiotics and the approaches to the synthesis of some of them (the works cited therein were published up to 1988). Since that time, many new publications devoted to this problem have appeared in the current literature. Disaccharide nucleosides occur in nature not only in the free state, but also as components of biopolymers, such as poly(ADP-ribose) and tRNA which play an important role in the vital activities of living organisms. The first part of the present review is devoted to analysis of structural peculiarities and biological activities of natural disaccharide nucleosides and their analogues. The second part deals with the description of general methods for the synthesis of disaccharide nucleosides, *i.e.*, the formation of O- and N-glycosidic bonds.

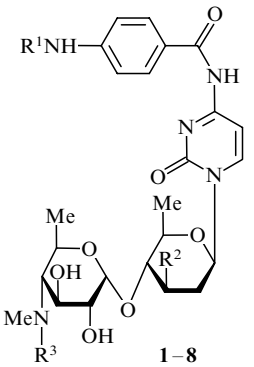
II. Structures and properties of natural disaccharide nucleosides

1. Low-molecular-mass disaccharide nucleosides

A sufficiently large number of disaccharide nucleosides and related compounds are found among antibiotics, which has significantly stimulated the interest in their investigation. The structures and biological activities of nucleoside antibiotics were reviewed by Isono[3,4] in 1988 and 1991. The methods for their isolation and structural elucidation and some approaches to their synthesis are surveyed by Buchanan and Wightman.[5] Some of the published data on the synthesis of complex nucleoside antibiotics are summarised in the reviews by Garner[6] and Knapp.[7]

The structures of nucleoside antibiotics are extremely diverse[2–5] and their elucidation is rather a complicated task. In addition to a heterocyclic base and two monosaccharide residues, these compounds contain various functional substituents, such as acyl and alkyl groups as well as phosphate and sulfate residues, fatty acids, amino acids and peptides. Their degradation by acid and alkaline hydrolysis or methanolysis, periodate oxidation and subsequent reduction yields fragments the structures of which can be established by physicochemical methods. At present, the structures of many complex antibiotics are determined mainly by NMR spectroscopy and mass spectrometry supplemented by hydrolysis and oxidative degradation.

The first disaccharide nucleoside antibiotic amicetin (**1**) was isolated from *Streptomyces sp.* in the early 1950's; [8] however, its structure was established only in the 1960's.[9,10] Its structural analogues, *viz.*, the antibiotics bamicetin (**2**), plicacetin (**3**),[11]



1–8

Compound	R^1	R^2	R^3
Amicetin (**1**)	$COCMe(NH_2)CH_2OH$	H	Me
Bamicetin (**2**)	$COCMe(NH_2)CH_2OH$	H	H
Plicacetin (**3**)	H	H	Me
Norplicacetin (**4**)	H	H	H
Oxamicetin (**5**)	$COCMe(NH_2)CH_2OH$	OH	Me
Oxyplicacetin (**6**)	H	OH	Me
SF2457 (**7**)	$COCHMeNH_2$	OH	H
Cytosaminomycin B (**8**)	Me	OH	Me

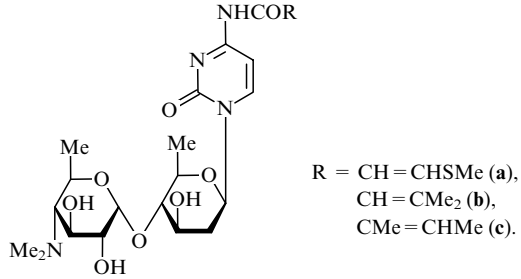
Received 18 April 2003
Uspekhi Khimii **73** (4) 435 – 448 (2004); translated by R L Birnova

norplicacetin (**4**),[12] oxamicetin (**5**),[13] oxyplicacetin (**6**),[14] SF2457 (**7**)[15] and cytosaminomycin (**8**)[16] were isolated and characterised starting from 1958. The presence of an α-(1→4)-glycoside bond between 4-methylamino- or 4-dimethylamino-4,6-dideoxy-D-glucose and 2,6-dideoxy- or 2,3,6-trideoxyhexose is the most characteristic feature of this group of antibiotics. The amino group of cytosine is acylated by *p*-aminobenzoic acid to which an (+)-α-methylserine or D-alanine residue is attached. The amicetin group antibiotics inhibit bacterial peptidyl transferase[17,18] and are active against gram-negative and gram-positive bacteria.

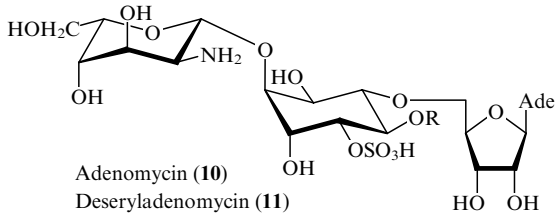
Oxyplicacetin **6** analogues, *viz*., cytosaminomycins A, C and D (**9a–c,** respectively) have been isolated recently.[16,19] In contrast to the antibiotics **1–8**, the amino group of cytosine in cytosaminomycins **9** is acylated by unsaturated acids.



R = CH=CHSMe (**a**),
CH=CMe$_2$ (**b**),
CMe=CHMe (**c**).

Cytosaminomycins (**9a–c**)

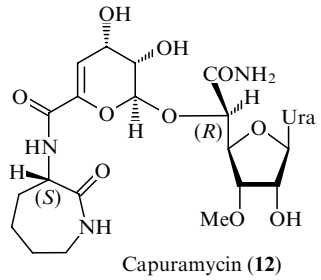
Adenomycin (**10**)[20] produced by *Streptomyces griseoflavus* is not formally related to disaccharide nucleosides, since it is devoid of the disaccharide fragment. It contains adenosine, (−)-*chiro*-inositol and L-gulosamine as well as L-serine.[20] This antibiotic inhibits growth of gram-positive and gram-negative bacteria and is endowed with antitumour activities. Yet another structurally similar compound, *viz*., deseryladenomycin (**11**)[21] isolated from *Str*. *pseudogriseolus,* possesses insecticidal properties.



Adenomycin (**10**)
Deseryladenomycin (**11**)

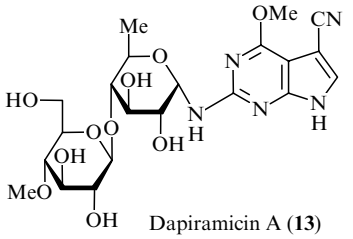
R = COCH(NH$_2$)CH$_2$OH (**10**), H (**11**).

The antibiotic capuramycin (**12**)[22] isolated from *Str*. *griseus* contains uracil and a derivative of L-talofuranuronamide glycosylated by 4-deoxy-D-*erythro*-hex-4-enuronic acid; its carboxylic group is linked to 2(*S*)-aminocaprolactam through an amide bond. The antibiotic **12** is active against certain streptococci and mycobacteria. Capuramycin was the first natural product which was found to contain caprolactam as a substituent.

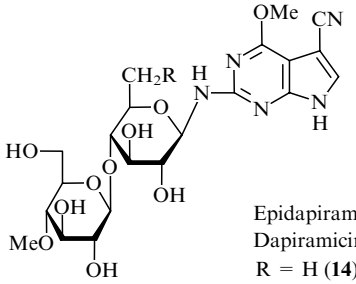


Capuramycin (**12**)

Dapiramicins (**13–15**) isolated from *Micromonospora sp*. contain 7-deazaguanine.[23,24] Its exocyclic amino group is involved in the formation of the N-glycosidic bond between the heterocyclic base and the disaccharide fragment (4′-*O*-methylcellobiose or 4′-*O*-methyl-6-deoxycellobiose). This bond is α in dapiramicin A (**13**) and β in the antibiotics **14** and **15**. It is believed that the configuration of the N-glycosidic bond determines the biological activities of dapiramicins. Dapiramicin A (**13**) exhibits strong fungicidal properties, while epidapiramicin A (**14**) and dapyramicin B (**15**) are less active.[24]



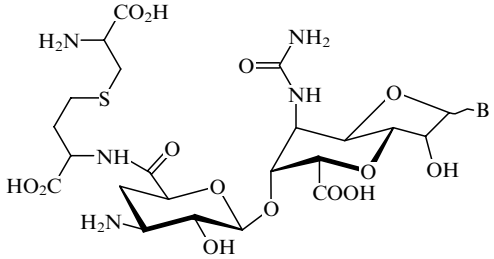
Dapiramicin A (**13**)



Epidapiramicin A (**14**)
Dapiramicin B (**15**)
R = H (**14**), OH (**15**).

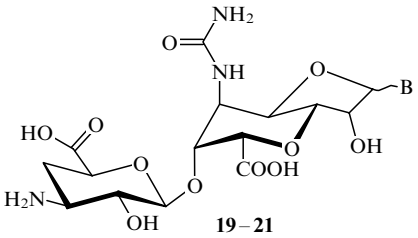
Ezomycins (**16–21**) isolated from the cultural medium of *Streptomyces sp*. and possessing fungicidal activities[25] belong to the group of nucleoside antibiotics which includes higher monosaccharides; the β-anomers **16** and **17** are more active.

A characteristic structural feature of ezomycins **16–21** is the presence of N- or C-glycosides of 3,7-anhydrooctofuranuronic acid glycosylated by ezoaminuronic acid which is linked with L-cystathionine in the case of compounds **16–18**.[25–27] Ezomycins A$_2$, B$_2$ and C$_2$ (**19–21**) do not contain this amino acid.[26] Compounds **17**, **18** and **20**, **21** contain 5-substituted uracil and can therefore be regarded as pseudouridine derivatives. Under mild conditions, ezomycins B$_1$ and B$_2$ (**17**, **20**) are easily anomerised into thermodynamically more stable ezomycins C$_1$ and C$_2$ (**18**, **21**).[27] Similar interconversions in acidic media are typical of pseudouridine. The α-configuration of compounds **18** and **21** was established based on circular dichroism (CD) and NMR spectroscopic studies. The ease of anomerisation of pseudouridine derivatives accounts for the formation of ezomycins C$_1$ and C$_2$ (**18**, **21**) during the isolation of compounds B$_1$ and B$_2$ (**17**, **20**) from biological objects.



16–18

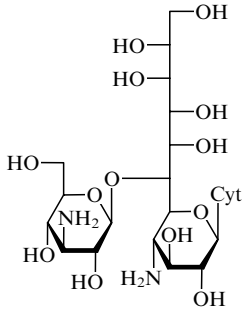
Compound	B
Ezomycin A$_1$ (**16**)	β-Cytosin-1-yl
Ezomycin B$_1$ (**17**)	β-Uracil-5-yl
Ezomycin C$_1$ (**18**)	α-Uracil-5-yl



19–21

Compound	B
Ezomycin A_2 (**19**)	β-Cytosin-1-yl
Ezomycin B_2 (**20**)	β-Uracil -5-yl
Ezomycin C_2 (**21**)	α-Uracil -5-yl

Anthelmycin (or hikizimycin, **22**) was isolated from *Str. longissimus* and *Str. hikiziensis*.[28,29] Analysis of the degradation products of compound **22** revealed that the latter contains cytosine, 3-amino-3-deoxy-D-glucopyranose (canosamine) and 4-aminoundecose (hikosamine).[29,30] The β-configurations of O- and N-glycosidic bonds of both amino sugars were established by NMR spectroscopy. The antibiotic **22** manifests antiparasitic and fungicidal properties and inhibits prokaryotic and eukaryotic peptidyl transferase.[31]



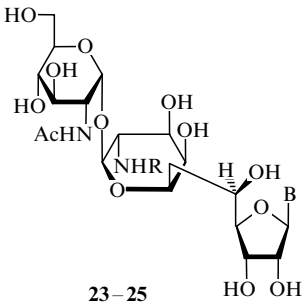
Anthelmycin or hikizimycin (**22**)

Many disaccharide nucleoside antibiotics contain fatty acid residues.

The microorganism *Str. lysosuperificus* is a producer of tunicamycins (**23**).[32] This group of antibiotics contains uracil, an undecose derivative (tunicamine) glycosylated by *N*-acetyl-D-glucosamine and a higher fatty acid residue.[33] At least ten tunicamycin derivatives **23** differing in acyl residues have been described.[33] α,β-Unsaturated acids are usually present as *trans*-isomers. Tunicamycins possess antibacterial and antiviral activities and effectively inhibit the biosynthesis of glycoproteins and peptidoglycans.[34,35]

The antibiotics streptovirudins (**24**) isolated from *Str. griseoflavus* are structurally similar to tunicamycins, they contain dihydrouracil along with uracil.[36]

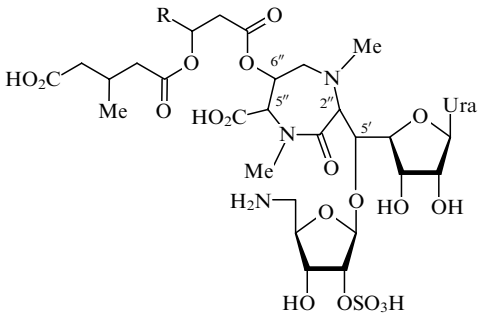
Corynetoxins (**25**), which are structurally similar to tunicamycins, were isolated from the pasture crops-damaging bacterium *Corynebacterium rathay* by Australian scientists.[37,38]



23–25

Compound	B	R
Tunicamycins I–X (**23**)	uracil-1-yl	$COCH=CH(CH_2)_nPr^i$, $n = 7–11$; $COCH=CH(CH_2)_nMe$, $n = 10–13$; $CO(CH_2)_{11}Pr^i$
Streptovirudins A_1, B_1, B_{1a}, C_1, D_1 (**24**)	uracil-1-yl	$COCH=CH(CH_2)_nPr^i$, $n = 6–8$; $COCH=CH(CH_2)_nBu^s$, $n = 6, 8$
Streptovirudins A_2, B_2, B_{2a}, C_2, D_2 (**24**)	dihydro-uracil-1-yl	$COCH=CH(CH_2)_nPr^i$, $n = 6–8$; $COCH=CH(CH_2)_nBu^s$, $n = 6, 8$
Corynetoxins (**25**)	uracil-1-yl	$COCH=CH(CH_2)_nBu^s$, $n = 10, 12$; $COCH_2CH(OH)(CH_2)_nBu^s$, $n = 10, 12$

The lipid-containing nucleoside antibiotics liposidomycins A I, B and C (**26a–c,** respectively) were isolated from *Str. griseosporeus*.[39,40] Liposidomycins **26** contain uridine glycosylated by 5-amino-5-deoxy-D-ribofuranose, 1,4-diazepane and β-hydroxy fatty acids acylated by 3-methylglutaric acid. The configuration of the double bonds of the lipid moiety of liposidomycin A I is *cis*.[40] It is of note that the absolute configuration of the chiral centres 5″ and 6″ has not been finally established yet. A series of papers devoted to the stereoselective synthesis of the disaccharide[41] and 1,4-diazepan-3-one[42–46] fragments and their comparison with the degradation products of liposidomycin have been published recently.[45,46] This enabled the determination of configurations of the other two chiral centres, *viz*., 5′(*S*) and 2″(*S*).[41,46]



Liposidomycins (**26a–c**)

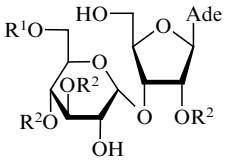
R = $(CH_2)_3CH=CHCH_2CH=CHC_5H_{11}$ (**a**), $(CH_2)_8Pr^i$ (**b**), $(CH_2)_{10}Me$ (**c**).

A series of liposidomycins produced by *Streptomyces sp*. SN-1061M have recently been discovered.[47] In contrast to liposidomycin A I, liposidomycin A II does not contain a sulfate group, while liposidomycin A III lacks the 3-methylglutaric acid residue and liposidomycin A IV is devoid of both substituents. Like tunicamycins, liposidomycins control the synthesis of glycoproteins and peptidoglycans[35,48] and inhibit bacterial translocase;[41,48] their cytotoxicities are significantly lower than those of tunicamycins.[48] Liposidomycins A II and A IV contain no sulfate groups and manifest high antimicrobial activities.[47]

A series of biologically active *O*-hexopyranosyl ribonucleosides (**27–29**), which are not related to antibiotics, have been isolated from various natural sources.

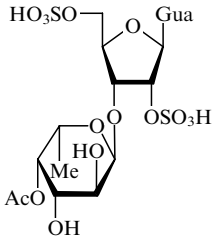
The adenosine derivatives adenophostins A and B (**27a**,**b**) are produced by the microorganism *Penicillum brevicompactum*.[49,50] Compounds **27** are the strongest agonists of receptors of inositol triphosphate which plays a crucial role in the release of Ca^{2+} ions (see Refs 51 and 52). The presence of an α-glycosidic bond between the glucopyranose and ribofuranose residues is a characteristic structural feature of adenophostins (**27**). A vast variety of analogues of compounds **27** have been synthesised and their structure–activity relationships have been studied.[53–55] The presence, in adenophostins (**27**), of an adenine residue is essential

for the manifestation of their biological activity. Adenophostin A derivatives where adenine is lacking or replaced by other heterocyclic bases are less active.[55]



Adenophostins (**27a**,**b**)

R^1 = H (**a**), Ac (**b**);
R^2 = PO_3H_2.

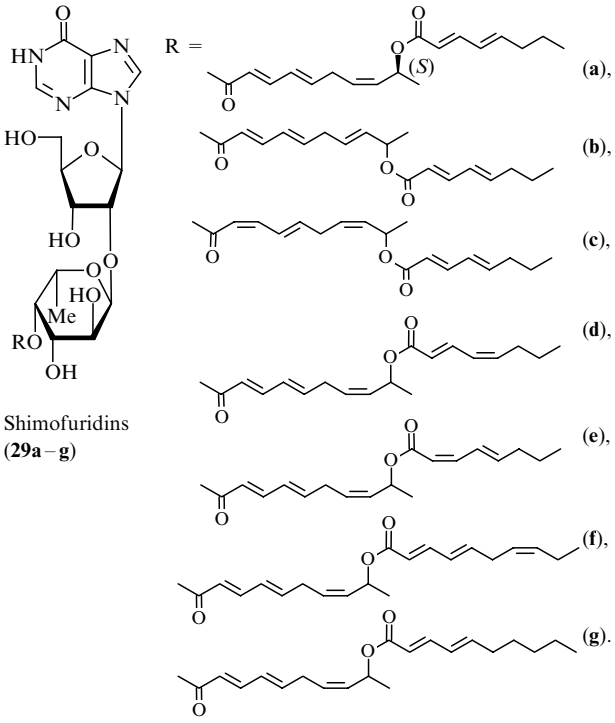


HF-7 (**28**)

A neuroactive compound HF-7 (**28**) was isolated from the venom of the spider *Hololena curta* and its chemical synthesis was carried out.[56] Compound **28** is an anionic nucleoside and, similar to adenophostins **27**, affects intracellular concentrations of Ca^{2+} ions in nervous tissues.

Sea algae, invertebrates (sponges, tunicata, molluscs) and symbiotic microorganisms (bacteria, fungi, microalgae, *etc*.) represent an abundant source of biologically active compounds as potential medicinal drugs.[57] Thus 9-(β-D-arabinofuranosyl)adenine, which possesses antiviral activity, was isolated from sea sponges as early as the 1950's. Several examples of disaccharide nucleosides from different marine organisms can be given.

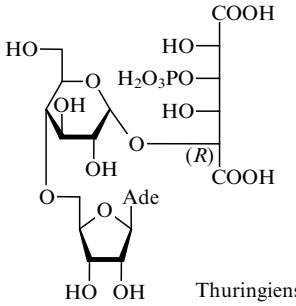
Thus a group of Japanese investigators have isolated a series of disaccharide nucleosides, *viz*., shimofuridins A–G (**29a**–**g**, respectively), which differ in the geometries of the double bonds and the lengths of the hydrocarbon chains of the acyl residues.[58,59] The configuration of the chiral centre (*S*) was established only for shimofuridin A.[58] 2′-*O*-α-L-Fucopyranosylinosine is the main structural element of shimofuridins. Shimofuridin A is active against gram-positive bacteria and manifests antifungal activity.



Shimofuridins (**29a**–**g**)

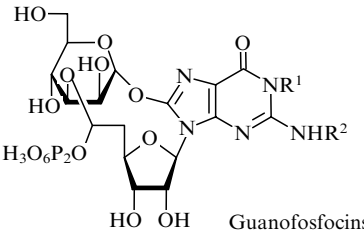
5′-*O*-α-D-Glucopyranosyl derivatives of tubercidin and toyocamycin, which contain 7-deazaadenosine and 7-cyano-7-deazaadenosine, respectively, were isolated from blue-green algae.[60] These compounds possess fungicidal properties and manifest cytotoxic activities. The crustacean *Ligia exotica* serve as a source of 3′-*O*-α-D-glucopyranosylinosine.[61] Disaccharide nucleosides were also isolated from plants. Thus an N^6-benzyl adenosine derivative glucosylated in the 3′-*O*-position is formed in petunia seedlings grown on an artifical medium in the presence of N^6-benzyladenine.[62]

Let us consider some structurally similar analogues of disaccharide nucleosides where the nucleoside fragment and the monosaccharide residue are linked through a non-O-glycosidic bond in more detail. Thuringiensin (or β-exotoxin, **30**) isolated from *Bacillus thuringiensis* simultaneously by two independent groups of investigators is an example.[63,64] This is built of adenosine linked to α-D-glucopyranose through an ether bond and a phosphorylated allaric acid.[65] The α-configuration of the O-glycosidic bond and the (*R*)-configuration of the C(2) atom of allaric acid have been established. Thuringiensin (**30**) possesses insecticidal properties and manifests pronounced cytotoxic activity. Compound **30** inhibits DNA-dependent RNA polymerase in prokaryotes and eukaryotes.[66]



Thuringiensin (**30**)

The recently discovered antibiotics guanofosfocins (**31a**–**c**) have unusual structures.[67,68] Guanofosfocin A (**31a**) was isolated from *Streptomyces sp*. and guanofosfocins B (**31b**) and C (**31c**), from *Trichoderma sp*. They contain a hemiacetal bond between the monosaccharide residues. Guanofosfocins (**31**) inhibit chitin synthetase and are effective antifungal agents. However, these compounds are highly labile, which significantly complicates their synthesis and further studies.[68,69]

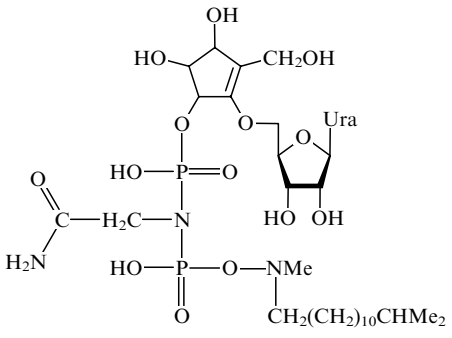


Guanofosfocins (**31a**–**c**)

R^1 = Me (**a**), H (**b**); R^2 = H;

R^1 = H, R^2 =  (**c**).

By way of illustration, the antibiotic EM 2487 (**32**) isolated from *Streptomyces sp*. represents a carbocyclic analogue of a disaccharide nucleoside.[70] Its cyclopentene fragment is linked to



EM 2487 (**32**)

uridine through an ether bond. The antibiotic **32** manifests pronounced anti-HIV activity.[71]

Even a brief survey demonstrates the diversity of structural peculiarities and biological activities of disaccharide nucleosides. In conclusion, special mention should be made of the studies devoted to the chemical synthesis of some of the compounds mentioned above. Complete syntheses of plicacethin (**3**),[72] capuramycin (**12**),[73] hikizimycin (**22**),[74] tunicamycin V (**23**) [75–77] and thuringiensin (**30**) [78] have been performed and approaches to the synthesis of fragments of the most complex antibiotics ezomycin A_1 (**16**) [79,80] and liposidomycin C (**26**) have been developed.[41–46,81,82] The syntheses of adenophostin (**27**), HF-7 (**28**) and shimofuridin A (**29**) will be considered in detail in the second part of the review. The development of methods for the synthesis of guanofosfocins (**31**) and EM 2487 (**32**) still presents a problem for modern bioorganic chemistry.

2. Disaccharide nucleosides as structural elements of biopolymers

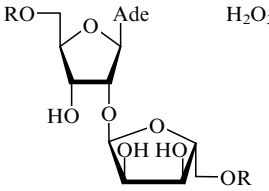
Purine disaccharide nucleosides with two O-glycosidically linked ribofuranose residues were identified as components of poly(ADP-ribose) and transfer RNA.

An enzyme responsible for the conversion of nicotinamide adenine dinucleotide (NAD^+) into a homopolymer, poly(ADP-ribose), with simultaneous release of nicotinamide was discovered in eukaryotic cell nuclei in the 1960's.[83–85] The polymer is covalently linked to histones and other nuclear proteins, as a rule, through glutamic acid and, less frequently, through aspartic acid.[84,85] Its multifaceted biological role is highlighted in a review.[84] Thus it is known that poly(ADP-ribose) is involved in structural modulation of chromatin, in replication, transcription and repair of DNA and in cell differentiation. In-depth studies on intracellular functions of poly(ADP-ribose) are currently underway.

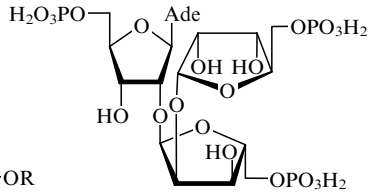
Molecules of poly(ADP-ribose) both isolated from natural sources and synthesised *in vitro* using the corresponding poly(ADP-ribose) polymerase have a branched structure and contain over 200 monomeric units.[86,87] Their linear fragments contain 20–50 units and alternate with branched fragments, which probably confer stability on the conformation of the biopolymer.

The degradation of poly(ADP-ribose) is mediated by two enzymes, *viz*., ADP-ribosyl protein lyase and poly(ADP-ribose) glycohydrolase.[83,84] The former is involved in the hydrolysis of the bond between the protein and the ADP ribose fragment. Glycohydrolase, which is endowed with both exo- and endoglycosidase activities, cleaves the bonds between ribofuranose and adenosine resulting in ADP ribose.[84,88]

Accessibility of polymerase enables an easy synthesis of poly(ADP-ribose) *in vitro*. Enzymatic hydrolysis of poly(ADP-ribose) synthesised *in vitro* by snake venom phosphodiesterase yields compound **33**; its structure was established by NMR spectroscopy.[89–91] Treatment of compound **33** with alkaline phosphatase results in 2′-*O*-α-D-ribofuranosyl adenosine (**34**). The absence of a signal for the 2′-hydroxy group of the adenosine residue in the ^1H NMR spectrum of the latter in DMSO-d_6 suggests the presence of a 1″→2′-glycosidic bond between the ribofuranose and adenosine residues.[91] The configurations of the O-glycosidic bond were established by ^{13}C NMR spectroscopy of compound **33** and anomeric methyl D-ribofuranosides.[89] A comparison of the spin–spin coupling constants $J_{1',2'}$ in the diphosphate **33**, methyl-β- and -α-D-ribofuranosides ($J_{1',2'}$ = 4.2, 1.2 and 4.5 Hz, respectively) confirmed the α-configuration of the O-glycosidic bond.[91] The structure of the nucleoside **35** localised in the branching point was also established using physicochemical methods.[92]

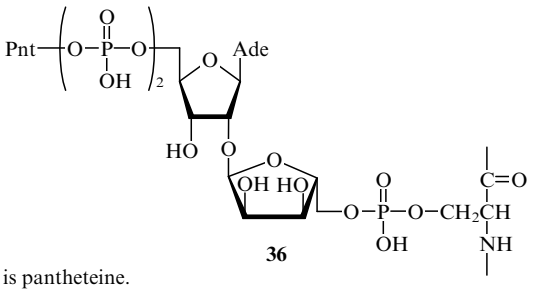


33: R = PO_3H_2;
34: R = H.



35

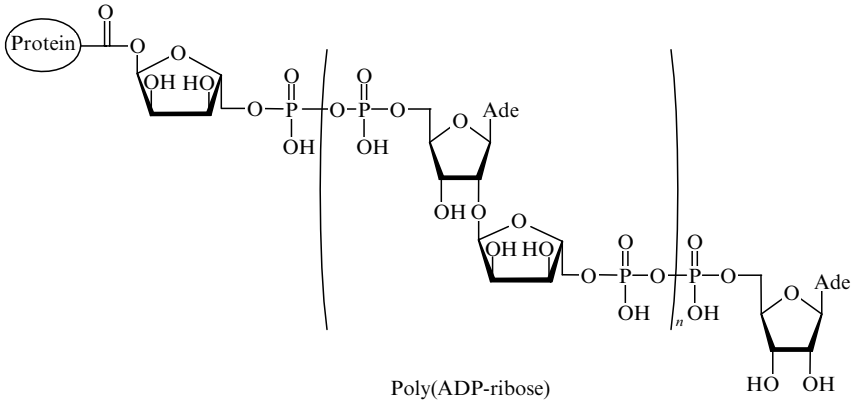
It is of note that compound **33** represents a fragment of the prosthetic group of compound **36** which is linked to the serine residue of bacterial citrate lyase [93,94] and malonate decarboxylase.[95] In contrast to poly(ADP-ribose), dephosphorylated coenzyme A is a precursor of compound **36**, while ATP is a contributor of an additional 5-phosphoribofuranose residue.[94,95]



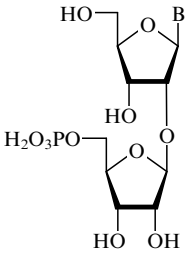
36

Pnt is pantheteine.

The purine disaccharide nucleosides **37** and **38** were isolated from lower eukaryotic initiator tRNAs ($tRNA_i^{Met}$) and several plant sources.[96,97] These minor nucleosides located in the steam of the T-loop of $tRNA_i^{Met}$ and occupy the 64th position in the primary structure of the molecule.[98–101] The 3′- and 5′-hydroxy groups of the nucleoside residue take part in the formation of internucleotide bonds. The site of the attachment of the ribofuranose residue to the nucleoside and the position of an additional phosphate group were established using periodate oxidation of mono- and dinucleotides containing fragments **37** and **38** with subsequent β-elimination under the action of cyclohexylamine.[99,100] In contrast to the monomeric unit of poly(ADP-ribose) (compound **33**), the additional ribofuranose residues in the disaccharide nucleosides **37** and **38** are linked to the nucleoside by a β-glycosidic bond.



Poly(ADP-ribose)



37: B = Ade;
38: B = Gua.

Total chemical synthesis of these minor nucleosides, *O*-β-D-ribofuranosyl-(1″→2′)-adenosine 5″-phosphate (**37**)[102] and *O*-β-D-ribofuranosyl-(1″→2′)-guanosine 5″-phosphate (**38**), has been carried out recently;[103] the synthesis of the α-anomer **33** has not been described so far.

The values of the spin–spin coupling constants of the natural disaccharide nucleoside **33** (see Ref. 91) and its synthetic isomer **37** as revealed by ^{1}H NMR spectroscopy are listed in Table 1.[102] These compounds possess similar coupling constants with the exception of $J_{1',2'}$ and $J_{3',4'}$ of the ribofuranose fragment.

Table 1. Experimental values of spin–spin coupling constants determined from the ^{1}H NMR spectra of compounds **33**[91] and **37**[102] (in D_2O).

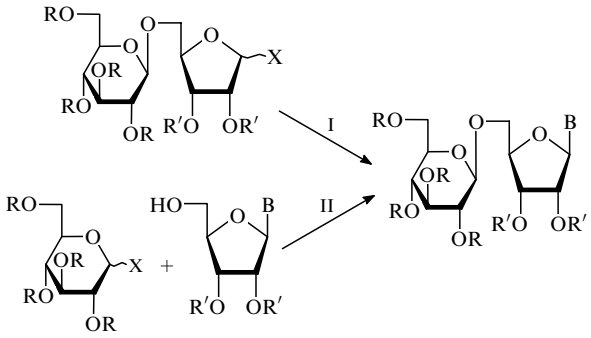
Coupling protons	*J* /Hz			
	fragment **33**		fragment **37**	
	Ado	α-ribosyl	Ado	β-ribosyl
1′–2′	5.5	4.6	6.4	1.2
2′–3′	5.1	6.4	5.5	4.6
3′–4′	3.7	0.7	3.1	6.4
4′–5′a	2.8	4.4	2.7	4.3
4′–5′b	3.8	4.1	3.7	5.7
5′a–5′b	−11.6	−11.3	−12.8	−11.6
5′a–P	4.3	5.8		6.4
5′b–P	4.8	4.4		7.0

It is believed that the presence of the disaccharide nucleosides **37** and **38** in position 64 is the most characteristic feature of lower eukaryotic $tRNA_i^{Met}$. According to data from X-ray diffraction analysis, the bulky 5″-phosphoribofuranosyl residue of the nucleoside **37** occupies a strictly definite position in the minor groove in the tertiary structure of yeast $tRNA_i^{Met}$ (see Ref. 104). The additional phosphate group forms a hydrogen bond with the 2-amino group of the vicinal guanosine residue G_{63}. After selective removal of the 5″-phosphoribofuranose residue (oxidation, β-elimination), tRNA begins to act as an elongator one, however, with a lower efficiency in comparison with native $tRNA_i^{Met}$ (see Refs 105 and 106). This suggests that the modification of the purine nucleoside **64** in $tRNA_i^{Met}$ plays a role in the discrimination of the initiation–elongation process of protein synthesis and thus prevents the formation of a tRNA complex with the elongation factor EF-1α and guanosine triphosphate characteristic of the elongation reaction.

The mechanisms of biosynthesis of modified nucleosides **37** and **38** have not been finally elucidated yet. It is hypothesised that adenosine and guanosine undergo post-transcriptional ribosylation in the precursor $tRNA_i^{Met}$ with involvement of 5-phosphoribosyl-1-pyrophosphate.[99]

III. General methods for the synthesis of disaccharide nucleosides

Disaccharide nucleosides can be synthesised by one of two routes. These consist of coupling of a protected disaccharide with a heterocyclic base derivative or the formation of an O-glycosidic bond between a nucleoside carrying one free hydroxy group and an activated monosaccharide.



X = Hal, OAcyl, SAlk, SPh *etc.*; B is heterocyclic base.

The choice of the order of formation of O- and N-glycosidic bonds is essential in the design of methods for the synthesis of disaccharide nucleosides. In each concrete case, the reaction sequence is determined by the structure and stability of final and intermediate products as well as by availability of starting compounds. Obviously, the use of readily available natural carbohydrates and nucleosides can significantly shorten the synthetic procedure. Special attention should be given to the choice of protective groups, estimation of their stability under various coupling conditions and stereoselectivity of formation of glycosidic bonds. The strategy and tactics of the syntheses of capuramycin (**13**), ezomycin A_1 (**16**), hikizimycin (**22**), tunicamycin (**23**), liposidomycin C (**26**) and thuringiensin (**30**) are reviewed by Knapp.[7]

1. Coupling of disaccharides with nucleic bases (N-glycosylation)

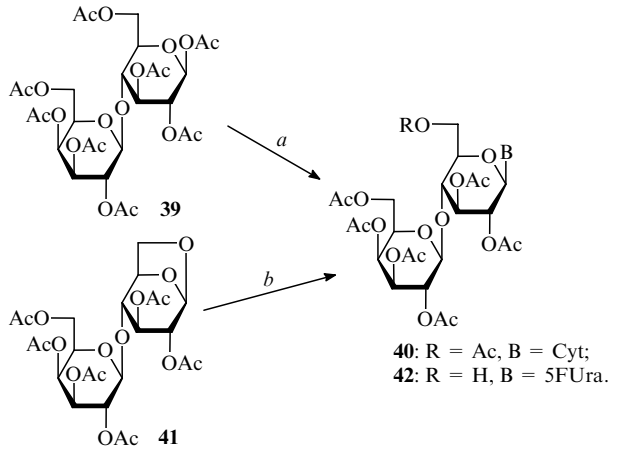
The classical methods for the synthesis of nucleosides[107] include coupling of acylglycosyl halides with silver or mercury salts of purine bases or with 2,4-dialkoxypyrimidines. A detailed account of the use of these methods in the first syntheses of disaccharide nucleosides starting from heterocyclic bases and derivatives of accessible natural disaccharides (lactose, maltose, cellobiose, melibiose, *etc.*) is given in a review by Lerner.[2] The yields in the coupling step did not usually exceed 50%. The main drawback of these methods is the necessity to prepare rather unstable glycosyl halides. Besides, the synthesis of purine derivatives demands the use of toxic mercury salts.

Stereoselective formation of the N-glycosidic bond is the key step in the synthesis of nucleosides. This problem is considered in detail in several reviews.[107–111] The presence of a participating 2-*O*-acyl group in the monosaccharide ensures stereoselective formation of 1,2-*trans*-products; in other cases, mixtures of α- and β-anomers are formed. These regularities hold also for the reactions involving disaccharides.

A procedure proposed by Vorbruggen[108,110,111] has replaced virtually completely the previously employed methods for the synthesis of nucleosides and their analogues. This consists of the interactions of silyl derivatives of heterocyclic bases with peracylated sugars in aprotic solvents in the presence of Lewis acids ($SnCl_4$ or trimethylsilyl trifluoromethanesulfonate, TMSOTf). The use of this approach has significantly simplified the reaction procedure and increased the yields of the target products.

Thus the glycosylation of bis(trimethylsilyl)cytosine [$(TMS)_2$-Cyt] by octaacetyllactose (**39**), octaacetylcellobiose and octaacetylmaltose in the presence of $SnCl_4$ in boiling dichloroethane occurred at a sufficiently high rate (2 h) and afforded disaccharide nucleosides (*e.g.*, lactosylcytosine **40**) in high yields (60%–90%).[112] The use of acylglycosyl chlorides resulted in the formation of regioisomers.[112] The glycosylation of the silyl derivative of 5-fluorouracil $(TMS)_2$-5FUra by 1,6-anhydrolactose hexaacetate (**41**) required more drastic conditions (boiling in

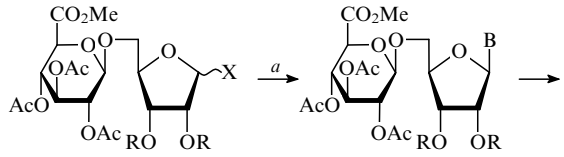
acetonitrile, 10 h); the yield of the β-anomer **42** was 35%.[113] Peracylated tri- and tetrasaccharides can also be involved in the coupling.[112]



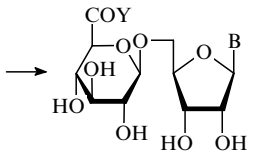
(*a*) $(TMS)_2$ – Cyt, $SnCl_4$, DCE (1,2-dichloroethane), Δ, 2 h;
(*b*) $(TMS)_2$ – 5FUra, $SnCl_4$, MeCN, Δ, 10 h.

The reaction of octaacetylcellobiose with a silyl derivative of theophylline was carried out under similar conditions ($SnCl_4$, acetonitrile, 75 °C, 16 h) and gave 7-(hepta-*O*-acetyl-β-cellobiosyl)theophylline in 90% yield.[114]

Preparation of 5′-*O*-glucuronides of the known antitumour nucleosides, 5-fluorouridine and 5-fluorocytidine, has been described.[115] The coupling of the glycosyl chloride **43** with a trimethylsilyl derivative of 5-fluorocytosine (boiling in acetonitrile, 24 h) resulted in the disaccharide nucleoside **44** in 49% yield. Under similar conditions (boiling in 1,2-dichloroethane, 35 min), the peracetylated disaccharide **45** reacted much faster; the products **46** were obtained in 90% yield. Removal of protective groups gave the free acid **47** or the amide **48**.



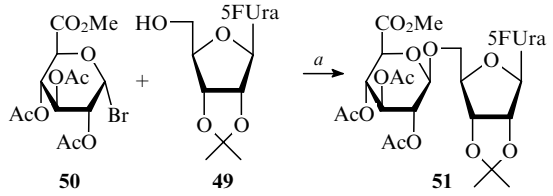
43: X = α- or β-Cl, R = Bz;
45: X = β-OAc, R = Ac.
44: R = Bz, B = 5FCyt;
46: R = Ac, B = 5FCyt, 5FUra.



47: Y = OH; **48**: Y = NH_2;
B = 5FCyt, 5FUra.

(*a*) $(TMS)_2$ – 5FCyt or $(TMS)_2$ – 5FUra, $SnCl_4$, MeCN or DCE.

An alternative route to the synthesis of 5′-*O*-glycosylribonucleosides entailed the Koenigs – Knorr *O*-glycosylation of 2′,3′-*O*-isopropylidene-5-fluorouridine (**49**) by glucuronosyl bromide **50**; the yield of the disaccharide nucleoside **51** was 65%. However,



50 **49** **51**

(*a*) Ag_2O, C_6H_6 – MeCN, Δ, 16 h.

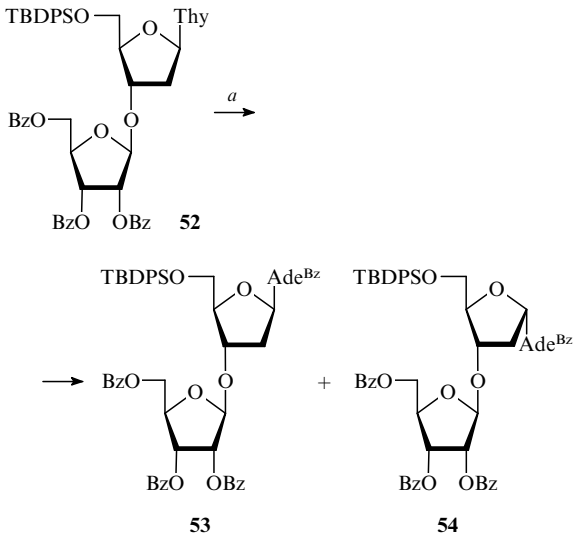
subsequent removal of the 2′,3′-*O*-isopropylidene group in an acidic medium (boiling in 80% AcOH, 30 min) was accompanied by a significant cleavage of the O-glycosidic bonds and the formation of the target product in a low yield.

A comparison of these approaches to the synthesis of 5′-*O*-glycosylribonucleosides has demonstrated a salient advantage of the Vorbruggen *N*-glycosylation by acetate **45** which is also employed in the synthesis of purine disaccharides. Thus the coupling of bis(trimethylsilyl)hypoxanthine with peracetylated 5-*O*-(β-D-glucopyranosyl)-β-D-ribofuranose and subsequent deacetylation gave 5′-*O*-(β-D-glucopyranosyl)inosine.[116]

At present, the synthesis of disaccharide nucleosides is usually performed by the Vorbruggen procedure. Thus the disaccharide fragment of the antibiotic liposidomycin (**26**)[41] and some of its derivatives have recently been synthesised using this method.[117] The reaction of fully protected 1-*O*-acetyl-5-*O*-(5-azido-5-deoxy-β-D-ribofuranosyl)-D-allofuranose or -L-talofuranose derivatives with bis(trimethylsilyl)uracil in the presence of TMSOTf in acetonitrile was carried out under mild conditions (room temperature, 3 h); the yields were up to 70%. Similar glycosylation was used[53,54,118] in the synthesis of numerous analogues of adenophostin (**27**).

In all cases studied, *N*-glycosylation by furanose derivatives occurs under milder conditions and at much faster rates than by pyranoses. The best results were obtained when 1-*O*-acetyl sugars were used.

Substitution of heterocyclic bases is an alternative route to the synthesis of disaccharide nucleosides.[111] A mixture of compounds **53** and **54** was prepared starting from a thymine disaccharide (compound **52**[119]) and a 1.5-fold excess of bis(trimethylsilyl)-N^6-benzoyladenine, the overall yield of the reaction products being 68%.[120] As expected, the β- and α-anomers **53** and **54** are formed in a 1 : 2 ratio in the absence of a participating group at the C(2′) atom.



TBDPS is *tert*-butyldiphenylsilyl;
(*a*) $(TMS)_2$ – Ade^{Bz}, TMSOTf, MeCN, Δ, 2.5 h.

2. Coupling of monosaccharides with nucleosides (O-glycosylation)

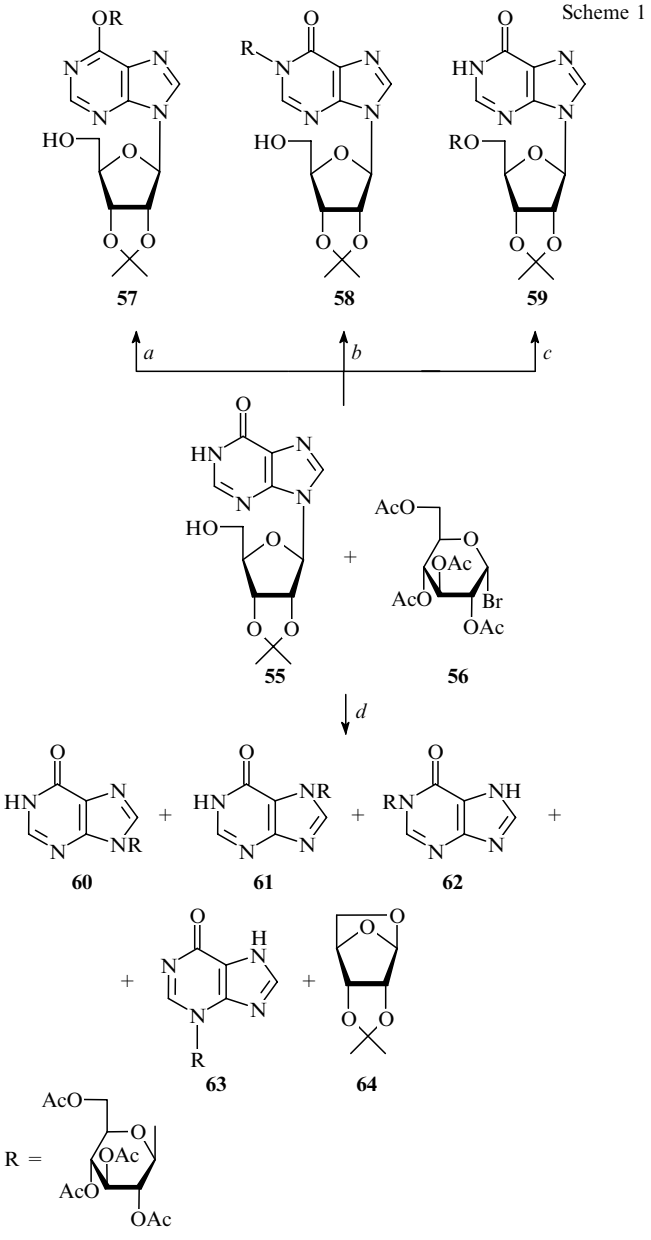
The formation of the O-glycosidic bond is considered in detail in the reviews devoted to carbohydrate chemistry.[121–123] Early syntheses of disaccharide nucleosides were carried out using the Koenigs – Knorr method or its modifications, *i.e.*, coupling of glycosyl halides with alcohols in the presence of mercuric or silver salts. As in the case of N-glycoside synthesis, the presence of a participating acyl group at the O(2) atom of a monosaccharide favours stereoselective formation of 1,2-*trans*-substituted products, while in its absence a mixture of α- and β-anomers is usually

formed. Directed synthesis of 1,2-*cis*-substituted products is a more complicated process.

Studies by Lichtenthaler *et al.*[124–126] have shown that the yields in the Koenigs–Knorr glycosylation of 2′,3′-*O*-isopropylidene nucleosides by per-*O*-acetylglycopyranosyl bromides strongly depend on the nature of the solvent and the promoter. The reaction of 2′,3′-*O*-isopropylideneinosine (**55**) with tetra-*O*-acetyl-α-D-glucopyranosyl bromide (**56**) (Scheme 1) in the presence of silver carbonate in chloroform (24 h, 60 °C) gave predominantly the O^6-glycoside **57** (yield 66%); prolonged heating (3–4 days) gave the second product, *viz.*, N^9-glycoside **58**. The disaccharide nucleoside **59** was obtained in 41% yield when the reaction was carried out in the presence of a silver carbonate–silver perchlorate mixture in chloroform (24 h, 0 °C).[125]

Similar reactions of 2′,3′-*O*-isopropylideneadenosine and -guanosine afforded complex mixtures of products.[125] Thus the glycosylation of compound **55** in nitromethane in the presence of mercuric cyanide (2 days, 40 °C) yielded a mixture of all possible

Scheme 1

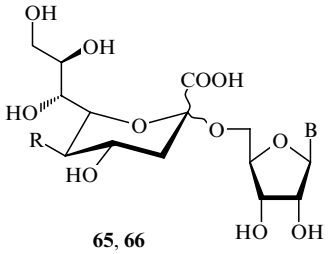


(*a*) Ag_2CO_3, $CHCl_3$, 60 °C, 24 h; (*b*) Ag_2CO_3, $CHCl_3$, 60 °C, 3–4 days; (*c*) Ag_2CO_3–$AgClO_4$, $CHCl_3$, 0 °C, 24 h; (*d*) $Hg(CN)_2$, $MeNO_2$.

N-glycopyranosylhypoxanthines **60**–**63** and 2,3-*O*-isopropylidene-1,5-anhydro-D-ribofuranose (**64**).[124]

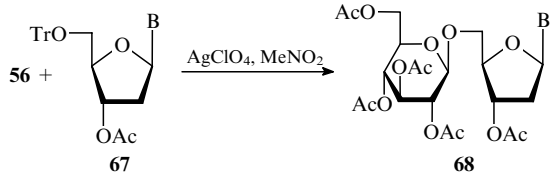
More encouraging results were obtained when this method was used in the synthesis of pyrimidine nucleosides. Thus the reaction of 2′,3′-*O*-isopropylideneuridine with glycosyl bromide **56** under identical conditions occurred at much faster rates (3 h, 55 °C) and gave a protected 5′-*O*-glucopyranosyluridine derivative in 73% yield.[126] Good yields of disaccharide derivatives were achieved upon glycosylation of 2′,3′-*O*-isopropylideneuridine with tetra-*O*-acetyl-α-D-galactopyranosyl bromide in the presence of mercuric cyanide.[126, 127] A similar reaction of 2′,3′-*O*-isopropylideneuridine with 3,4,6-tri-*O*-acetyl-2-*O*-benzyl-α-D-glucopyranosyl bromide yielded a mixture of α- and β-anomers (2 : 1).[126]

As expected, the Koenigs–Knorr glycosylation of nucleosides by 3-deoxynon-2-ulosonic acid derivatives gave a mixture of α- and β-anomers; the overall yields of the derivatives **65** and **66** after deprotection were rather small.[128, 129]

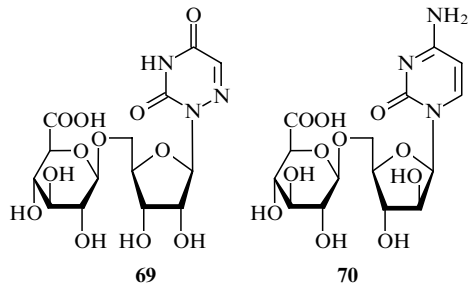


65: R = NHAc, B = Cyt, Hyp; **66**: R = OH, B = Ura, Cyt, 5FUra.

In some studies,[130–132] 5′-*O*-glucopyranosylnucleoside derivatives were synthesised using the Bredereck modification. The reactions of 5′-*O*-trityl-2′-deoxynucleosides (**67**) with glucosyl bromide **56** in nitromethane in the presence of silver perchlorate gave compounds **68** in 22% and 41% yields.[130] 5′-*O*-Glucuronides of 6-azauridine **69**[131] and 1-(β-D-arabinofuranosyl)cytosine **70**[132] were synthesised in a similar way; the yields in the coupling step were 38% and 20%, respectively.

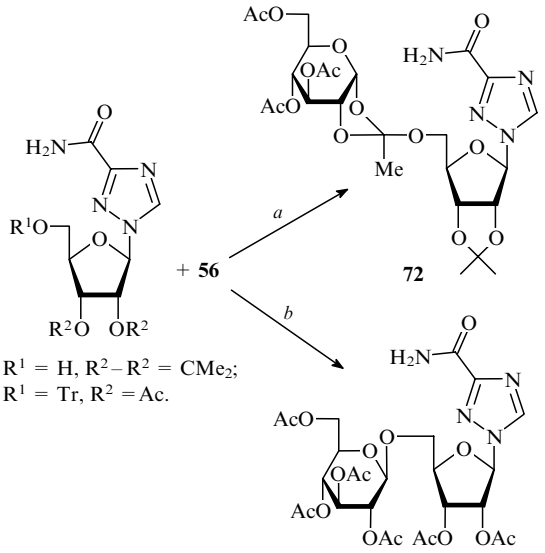


B = Cyt^{Ac}, Thy.



The glycosylation of ribavirin derivatives has been described.[133] The Koenigs–Knorr coupling of glucosyl bromide **56** with 2′,3′-*O*-isopropylideneribavirin (**71**) in the presence of silver carbonate and silver perchlorate gave a complex mixture; the orthoester **72** was isolated in 30% yield. At the same time, the Bredereck glycosylation of the trityl ether **73** afforded the disaccharide nucleoside **74** in 15% yield. Similar results were obtained in the glycosylation of compounds **71** and **73** by galactosyl bromide.[133] It is noteworthy that the formation of an orthoester derivative (27%) also took place upon Koenigs–Knorr coupling of tetra-*O*-acetyl-α-D-glucopyranosyl bromide

56 with 2′-deoxy-N^4-acetylcytidine in nitromethane in the presence of silver carbonate.[130]



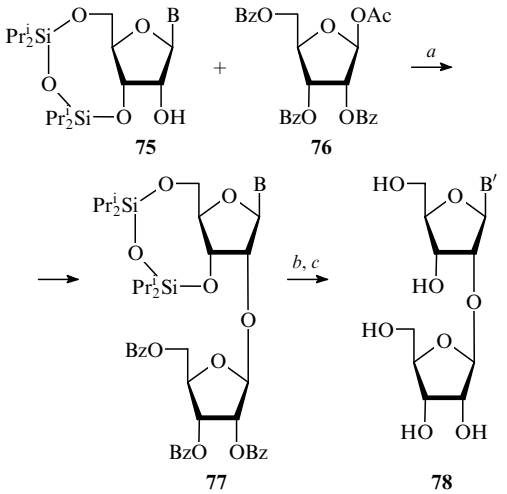
71: R^1 = H, R^2–R^2 = CMe_2;
73: R^1 = Tr, R^2 = Ac.

Tr is triphenylmethyl (trityl);
(*a*) Ag_2CO_3–$AgClO_4$, CH_2Cl_2; (*b*) $AgClO_4$, $MeNO_2$.

The aforementioned data clearly demonstrate that the Koenigs–Knorr method and its modifications have been often employed for the glycosylation of 5′-hydroxy groups of nucleosides by glycopyranosyl bromide derivatives. These reactions are usually accompanied by the formation of side products; the yields of target disaccharide nucleosides (with rare exceptions) are rather low. The glycosylation of the 5′-hydroxy group of uridine derivatives by acylglycofuranosyl halides was used in the synthesis of analogues of the disaccharide fragment of liposidomycin.[41, 134]

Later, alternative methods of *O*-glycosylation of nucleosides were developed. A simple and efficient synthesis of disaccharide nucleosides has been performed which includes coupling of a peracylated monosaccharide with a partly protected nucleoside in the presence of Lewis acids under conditions similar to those used in the synthesis of alkyl β-D-ribofuranosides.[135]

Coupling of *N*-protected 3′,5′-*O*-tetraisopropyldisiloxane-1,3-diyl ribonucleosides (**75**)[136] with a small excess of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose (**76**) in the presence of $SnCl_4$ was stereospecific and afforded protected 2′-*O*-β-D-ribofuranosyl nucleosides (**77**).[137–140] This reaction was carried out



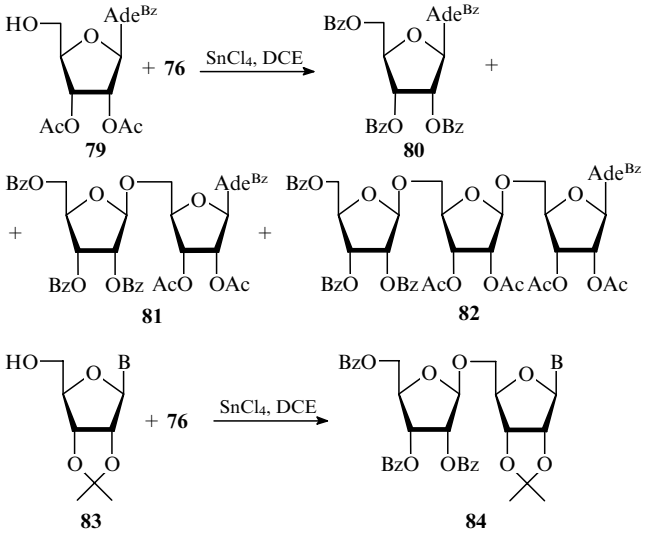
B = Ura, Thy, Cyt^{Bz}, Ade^{Bz}, Gua^{Bu^i}; B′ = Ura, Thy, Cyt, Ade, Gua;
(*a*) $SnCl_4$, DCE; (*b*) Bu_4NF, THF; (*c*) NH_3, MeOH.

under mild conditions (0 °C, 1,2-dichloroethane, 2 h for pyrimidine nucleosides, 7–16 h for purine derivatives); the yields of the target compounds **77** were 74%–82%.[138, 139] At room temperature, this reaction occurred faster (30 min), but the yields in the coupling steps were lower (40%–77%).[137, 140] After deprotection, the disaccharide nucleosides **78** were obtained in good overall yields.[137–140] The synthesis of the minor nucleosides **37** and **38** could be performed using this method.[102, 103]

The use of the above-described procedure ensures an easy and efficient synthesis of pyrimidine 3′-*O*-β-D-ribofuranosyl- [119] and 5′-*O*-β-D-ribofuranosyl-2′-deoxynucleosides [141, 142] as well as 5′-*O*-β-D-ribofuranosyl nucleosides.[143, 144] Other peracylated furanoses and pyranoses [145] (D- and L-arabinofuranose, D-erythrofuranose, 5-azido-5-deoxyribofuranose, D-ribopyranose) were successfully employed in the glycosylation of the nucleoside **75**.[145] The synthesis of numerous 2′-*O*-β-D-ribofuranosylnucleoside derivatives (**77**) containing various monosaccharide residues at O(2′) shows explicitly the versatility of the coupling based on the use of peracylated sugars as glycosyl donors in the presence of $SnCl_4$.

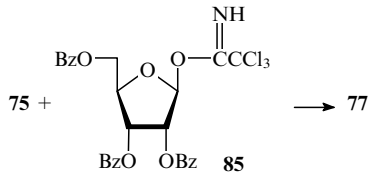
The stabilities of various protective groups in O-glycosylation have been studied.[141, 142] It was found that TMSOTf can be used as a Lewis acid. This glycosylation procedure was used in the synthesis of disaccharide fragments of liposidomycin (**26**).[134] It is of note that incorporation of 2′-*O*-β-D-ribofuranosylnucleosides and their analogues into synthetic oligonucleotides has found application in the studies of enzymes of nucleic acid metabolism.[146–150]

Despite good reproducibility of *O*-glycosylation in the presence of peracylated sugars, side reactions occur sometimes. For example, the synthesis of purine 5′-*O*-β-D-ribofuranosylnucleosides was sometimes accompanied by the formation of trisaccharide nucleosides.[144] Coupling of the nucleoside **79** with fully protected ribofuranose **76** in the presence of $SnCl_4$ yielded a mixture of mono-, di- and trisaccharide nucleosides (**80**–**82**) in 18%, 29% and 17% yields, respectively. The formation of compounds **80** and **82** is attributed to the instability of the N-glycosidic bond in the starting purine ribonucleoside **79** and/or in the disaccharide nucleoside **81** in the presence of $SnCl_4$.[144] The use of 2′,3′-*O*-isopropylidene derivatives **83** containing a more stable N-glycosidic bond has made it possible to avoid the formation of trisaccharide nucleosides and to obtain target purine 5′-*O*-ribofuranosylnucleosides (**84**) in 60%–65% yields.[144]



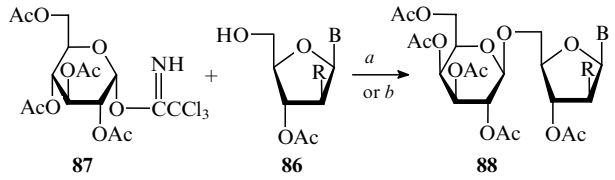
B = Ade^{Bz}, Gua^{Bu^i}.

Recently, sugar trichloroacetimidates have found application as glycosyl donors.[151] The coupling of nucleoside **75** (B = Ade^{Bz}) with trichloroacetimidate **85** in tetrahydrofuran was carried out under different conditions.[152]



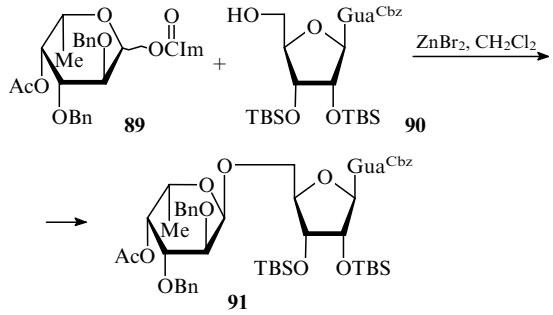
Conditions	TMSOTf, 0 °C	$BF_3 \cdot Et_2O$, 20 °C	TfOH, 0 °C
Yield (%)	64	57	93

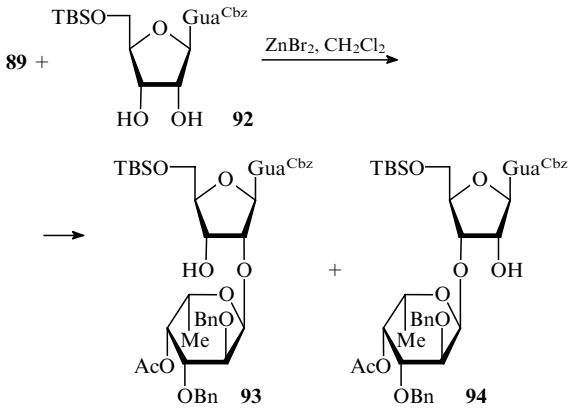
It was found[153, 154] that the glycosylation of the primary hydroxy group of the pyrimidine nucleosides **86** by trichloroacetimidate **87** is far less efficient. After activation with $BF_3 \cdot Et_2O$ (conditions *a*), the yields of the products **88** did not exceed 24%, whereas the use of TfOAg in $CHCl_3$ (*b*) made it possible to increase the yields up to 35%–41%.[153, 154] The acetylation of the free 5′-hydroxy group in nucleosides **86** is the main side reaction. Low reactivity of the primary 5′-hydroxy group with respect to *O*-glycosylation was attributed to the presence of a hydrogen bond with a 2-carbonyl group of the pyrimidine heterocycle observable in the ^1H NMR spectra in aprotic solvents.[153]



R = H: B = Cyt^{Ac}, Thy, 5FUra; R = OAc, B = Cyt^{Ac};
(*a*) $BF_3 \cdot Et_2O$, CH_2Cl_2; (*b*) TfOAg, $CHCl_3$.

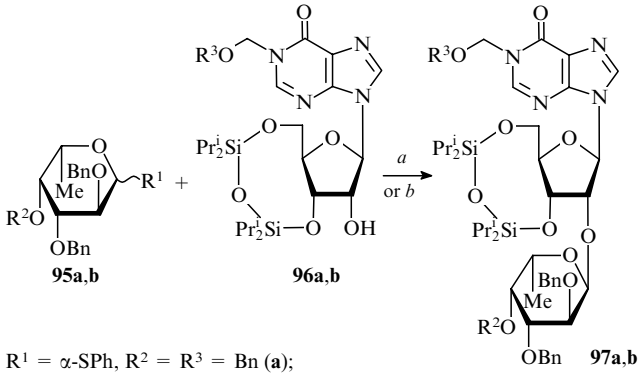
A series of isomeric α-L-fucopyranosylguanosines have been synthesised in order to establish the structure of the disaccharide nucleoside HF-7 (**28**).[56] L-Fucopyranosyl 1-*O*-imidazolecarboxylate **89** containing a benzyloxy group at the C(2) atom, which ensures good stereoselectivity in the formation of the α-glycosidic bond, was used as a glycosyl donor. The coupling of the nucleoside **90** with the glycosyl donor **89** in the presence of $ZnBr_2$ in CH_2Cl_2 gave the disaccharide nucleoside **91** in 80% yield. A mixture of 2′- and 3′-isomers **93** and **94** was prepared starting from nucleoside **92** under identical conditions (yields 38% and 40%, respectively). Compound **28** identical to the natural product was obtained upon removal of the silyl protective group in compound **94** with subsequent sulfation and hydrogenolysis. Attempts to use the glycosyl donor **89** for the glycosylation of the guanosine derivative **92** containing an additional 2′-*O*-*tert*-butyldimethylsilyl group failed, apparently due to the steric hindrance of the 3′-hydroxy group.[56]





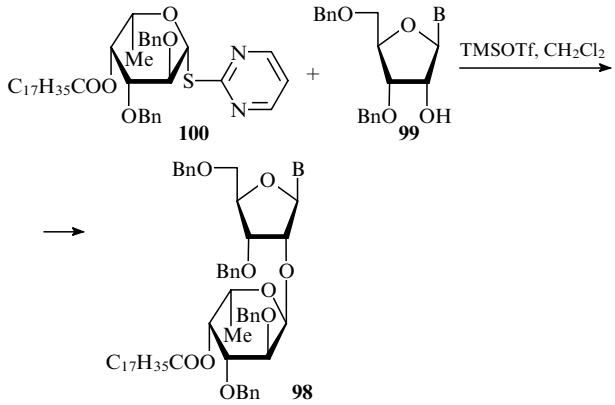
Im is imidazolyl; TBS is *tert*-butyldimethylsilyl.

The synthesis of the shimofuridin analogues **29** also included the formation of the O-glycosidic bond. The coupling of the phenyl 1-thioglycoside **95a** with a selectively protected inosine derivative **96a** in the presence of *N*-iodosuccinimide (NIS) and TfOH gave the product **97a** in a moderate yield of 37%.[155] If the heterocyclic base did not contain a protective group, no desired disaccharide nucleoside was formed. This can be attributed to the glycosylation at the O(6) of hypoxanthine, which was earlier observed by Lichtenthaler *et al.*[124, 126] The use of L-fucopyranose dibutyl phosphate **95b** as a glycosyl donor has been described; its reaction with the pivaloyl derivative **96b** in the presence of TMSOTf made it possible to increase the yield of the disaccharide **97b** to 53%.[156]



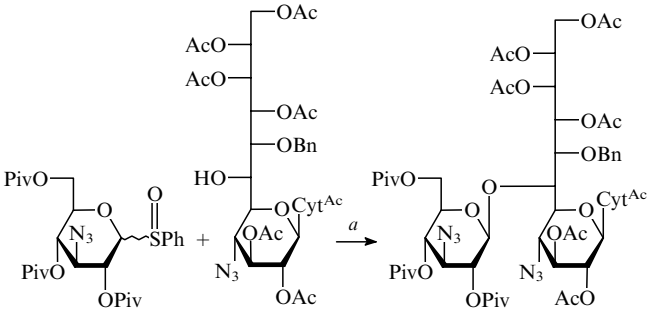
R^1 = α-SPh, R^2 = R^3 = Bn (**a**);
R^1 = α- or β-OP(O)$(OBu)_2$, R^2 = Ac, R^3 = Piv (**b**);
(*a*) NIS, TfOH, CH_2Cl_2; (*b*) TMSOTf, Et_2O, DCE.

The highest (90%) yields of α-L-fucopyranosylthymidine and -uridine **98** were achieved in the glycosylation of the pyrimidine nucleosides **99** by pyrimidin-2-yl 1-thiofucopyranoside **100** in the presence of trimethylsilyl triflate.[157, 158]



B = Thy, Ura.

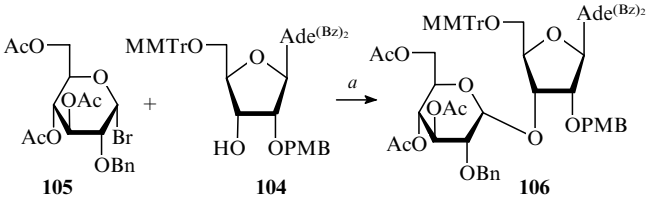
O-Glycosylation of the sterically hindered secondary hydroxy group in the nucleoside **101** was a problem in the synthesis of the antibiotic hikizimycin (**22**).[74] It was suggested to use glycosyl sulfoxides as glycosyl donors in the glycosylation of non-reactive alcohols.[121, 159] Compound **103** was prepared from glycosyl sulfoxide **102** and the nucleoside **101** in a satisfactory yield (38%).[74] Deprotection and reduction of the azido groups afforded the target hikizimycin (**22**).



102 **101** **103**

(*a*) Tf_2O, PhMe.

Two different routes of the formation of disaccharide nucleosides were explored in the synthesis of the adenophostin derivatives (**27**).[160–163] The coupling of the selectively protected nucleoside **104** with the glycosyl bromide **105** in the presence of $AgClO_4$ and γ-collidine afforded the product **106** (yield 48%).[160] The use of Ag_2CO_3 as an *O*-glycosylation promoter as described earlier was ineffective.[126]

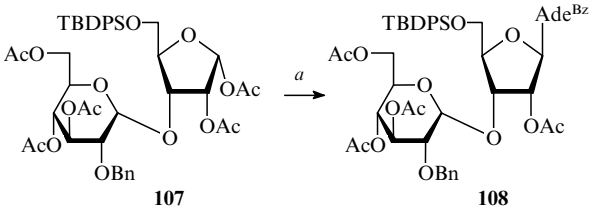


105 **104** **106**

MMTr is mono-*p*-methoxytrityl, PMB is *p*-methoxybenzyl;
(*a*) $AgClO_4$, γ-collidine, $CHCl_3$.

The synthesis of adenophostin A (**27**) starting from the disaccharide nucleoside **106** included the following steps: removal of the methoxybenzyl (oxidation by dichlorodicyanoquinone, DDQ), acid-labile monomethoxytrityl and acyl groups; *N*,*O*-monomethoxytritylation of the exocyclic amino group of adenine and primary hydroxy groups; phosphorylation, detritylation and hydrogenolysis in the presence of palladium black. The overall yield of adenophostin A was 22%.[160]

The Vorbruggen *N*-glycosylation of the bis(trimethylsilyl) derivative of N^6-benzoyladenine by the disaccharide glycosyl donor **107** (see Refs 161–163) is an alternative route to the synthesis of adenophostin **27**.[108–111] The yield of the disaccharide nucleoside **108** in the coupling step was significantly higher (71%) than in the former case; the overall yield of the product **27** was 28%.



107 **108**

(*a*) $(TMS)_2$–Ade^{Bz}, TMSOTf, DCE.

* * *

While considering the methods for the synthesis of disaccharide nucleosides, special mention should be made of the possibility of microbiological and enzymatic *O*-glycosylation. Some papers are devoted to the synthesis of *O*-hexopyranosyl derivatives of purine nucleosides [164, 165] and 1-(β-D-arabinofuranosyl)cytosine [166] using various glycosidases. Thus the use of β-galactosidase and 4-nitrophenyl β-D-galactopyranoside as glycosyl donors has made it possible to synthesise *O*-galactosides of adenosine, guanosine, inosine, uridine, 2′-deoxyuridine and thymidine.[167–170] In these syntheses, the formation of 5′-O- and 3′-O-derivatives of galactopyranosyl nucleosides usually occurred. The glycosylation of thymidine and 1-(β-D-arabinofuranosyl)cytosine in the presence of glycosidases isolated from various sources using di- and polysaccharide donor substrates was studied.[171, 172] The yields of disaccharide nucleosides in enzymatic glycosylation rarely exceeded 10%.

An analysis of the published data prompts a conclusion that the majority of natural disaccharide nucleosides[2] were synthesised by coupling of a protected disaccharide with a heterocyclic base. This synthetic route is more common, since *O*-glycosylation of nucleosides is sometimes concomitant with *N*-glycosylation of the heterocyclic base and hydrolysis of the N-glycosidic bond of purine nucleosides. In some cases, protective groups cause a further decrease in the stability of the N-glycosidic bond under reaction conditions. It is noteworthy that acid hydrolysis of the O-glycosidic bond in purine disaccharide nucleosides occurs simultaneously with apurinisation, whereas the fragmentation of pyrimidine disaccharides occurs exclusively at the O-glycosidic bond and yields a nucleoside and a monosaccharide.[141] Despite the aforementioned difficulties, efficient procedures for *O*-glycosylation of nucleosides that have been developed significantly simplify and supplement the first approach to the synthesis of disaccharide nucleosides.

In conclusion, it may be noted that several reliable and reproducible *N*- and *O*-glycosylation procedures are known, which enable successful synthesis of natural disaccharide nucleosides and their analogues.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 02-04-49125 and 02-04-48570) and the Programme 'Research and Development of Priority Trends in Science and Technology'.

A N Nesmeyanov Institute of Organoelement Compounds of the Russian Academy of Sciences

This issue of the Journal comprises reviews written by researchers of the A N Nesmeyanov Institute of Organoelement Compounds of the Russian Academy of Sciences (INEOS), one of the leading chemical research institutes of the Russian Academy of Sciences. This year INEOS is celebrating its 50th anniversary.

The Institute was founded in 1954 on the initiative of Academician A N Nesmeyanov on the basis of several laboratories of the N D Zelinsky Institute of Organic Chemistry concerned with organoelement (organometallic) and polymer chemistry.

Academician A N Nesmeyanov, who was President of the USSR Academy of Sciences in that period (1951 – 1961), became the first director of INEOS and remained in this post until 1980. In later periods, the Institute was directed by Academicians A V Fokin (1980 – 1988) and M E Vol'pin (1989 – 1996). Since 1996, INEOS has been headed by Academician Yu N Bubnov.

From the very beginning, research activities at INEOS were envisaged as a harmonious combination of synthetic and theoretical studies; therefore, investigations in many laboratories of the Institute were carried out at the junction of different branches of chemistry and physics. According to the figurative expression of Academician A N Nesmeyanov, this trend has charted the 'points of growth' in the development of modern science and technology. Following this principle, the chemistry of organic compounds of transition metals, π-complexes of metals and clusters has emerged at the interface between organic, organometallic and coordination chemistry. The unique properties of these compounds have enabled the preparation of novel organometallic catalysts and the development of processes for activating small molecules, such as nitrogen, carbon oxides, hydrocarbons, *etc*. A combination of organic and organoelement chemistry with modern experimental and theoretical methods in physical chemistry has fostered investigations into reactivities of organic and organoelement compounds which in turn has made it possible to obtain new in principle data on their structures and molecular dynamics.

At present, INEOS is one of the leading research centres in the area of organoelement and polymer chemistry. The main investigations carried out by the Institute are developing successfully along the following lines:

— development of novel methods for the synthesis of organoelement compounds and their application in organic synthesis and catalysis;

— fundamental studies in the field of organoelement and organic chemistry including investigations of novel structures, chemical activities and kinetics;

— development of novel methods of catalytic asymmetric synthesis;

— synthesis of biologically active compounds possessing a broad range of action for their possible use in medicine and agriculture;

— fundamental studies of the synthesis, structure and properties of polymers and composites, organoelement and organometallic polymers; development of methods for introducing organometallic and metallic fragments into polymeric matrices;

— development of novel experimental approaches to the analysis of organic and organoelement compounds.

Other remarkable achievements of the Institute researchers in the field of development of novel methods for the synthesis of organoelement compounds and their application in organic synthesis and catalysis over the past decade include synthesis of

multidecker sandwich-type metallocenes, of novel classes of σ-, π- and mixed metal complexes with alkene, acetylene and vinylidene ligands, of organoelement compounds with polyhedral substituents (carboranes and fullerenes) and of novel Hg-containing anticrowns binding complex anions, which significantly expands the range of practical applications of these unusual compounds. A new generation of rhodium, iridium and platinum chelate complexes based on metallocenes conjugated to tridentate P,C,P ligands synthesised in INEOS can find use in hydrogen production. Methods have been developed for the synthesis of methylcarbamoylmethylphosphinic acids and their derivatives as inexpensive and efficient bidentate extractants and sorbents of transuranium elements, from raw materials in the framework of a conversion programme. Flame suppressants based on phosphites, phosphates and phosphonates of lower primary alkanols and polyfluoroalkanols, which surpass currently used trifluorobromomethane banned by the Montreal Protocol in efficiency, have also been prepared.

The most impressive results in the field of chemistry of polymers and composites include synthesis of a novel class of polymers consisting of organoelement and inorganic chains, of polymers with remarkable thermal, catalytic, sorption and electrophysical properties; preparation of engineering plastics, thermostable composite materials and adhesives, membranes and polymers for electronic engineering and medicine; synthesis of novel aromatic and heterocyclic polymers including polyconjugated, super-rigid and network polymers. Special attention is given to the development of procedures for introducing organometallic and metallic fragments into a polymeric matrix; the use of polymeric systems for the synthesis of nanoparticles; preparation of liquid-crystalline polymers. Polymeric semiconductors possessing novel in principle structural properties and high electroconducting characteristics have been prepared by radiation-induced template gas-phase copolymerisation on extended polyamide films. Compounds that both manifest catalytic activity in polycyclotrimerisation of diisocyanates and behave as dyes have also been obtained. Other achievements include the development of an environmentally safe method for the synthesis and modification of polymers in supercritical media and synthesis of self-assembling hydrophobised ternary copolymers (terpolymers) by micellar polymerisation in aqueous solutions.

Many important discoveries made by researchers of INEOS have won international recognition. These include the first synthesis of carboranes and their numerous analogues, which represent a novel class of cage boron derivatives (L I Zakharkin, 1963); synthesis and analysis of carbyne, the third form of carbon (V V Korshak and A M Sladkov, 1971); theoretical prediction of fullerene C_{60}, the fourth form of carbon (D A Bochvar and E G Gal'pern, 1973) and discovery of a 1,2-rearrangement of polyhaloaliphatic radicals in the liquid phase (A N Nesmeyanov and R Kh Freidlina, 1973). Such important achievements as chemical fixation of molecular nitrogen and other small molecules under mild conditions (M E Vol'pin and V B Shur, 1967) and ionic hydrogenation (D N Kursanov, 1979) have acquired worldwide recognition. The discovery of an ability of achiral molecular structures to recognise enantiomers (V A Davankov and S V Rogozhin, 1992) has stimulated the development of ligand-exchange chromatography. And, last but not least, cyclic migration of unpaired electrons through polyvalent atoms of non-transition elements is yet another important discovery made in the mid-1990's (M I Kabachnik).

The priority in the development of 'synthetic food', of 'synthetic caviar' in particular also goes to INEOS. The idea of A N Nesmeyanov to introduce advanced chemical technology for the conversion of irrationally utilised natural proteins into a foodstuff has been realised in the production of synthetic caviar. Implementation of this process has been carried out by researchers of INEOS headed by S V Rogozhin and G L Slonimsky.

The staff of INEOS exceeds 550 researchers including 5 Full Members and Corresponding Members of the RAS, 78 Doctors of Science and 262 Ph.Ds. The Institute has in its structure 58 laboratories and research teams. About 2000 publications and 13 monographs summarise the achievements of INEOS over the past 5 years. The Institute collaborates with more than 150 universities, institutes and industrial centres both in Russia and abroad. It takes an active part in organization of diverse conferences, symposia and seminars, primarily those in the field of organometallic and organoelement chemistry. Among them are 'Chemistry of Organophosphorus Compounds' (1998), 'Horizons of Organic and Organometallic Chemistry' (1999), 'IMEBORON-XI' (2002), 'New Trends in Organometallic Chemistry and Catalysis' (to mark the 80th birthday of M E Vol'pin, 2003).

Some of the papers published in this issue reflect the main trends of research carried out at the Institute.

The review by A Z Kreindlin and M A Rybinskaya 'Cationic and neutral transition metal complexes with a tetramethylfulvene or trimethylallyldiene ligand' is devoted to systematisation of the published data on the synthesis, chemical properties and structures of transition metal complexes with tetramethylfulvene and trimethylallyldiene ligands formed from the respective precursor compounds (cyclopentadienyl complexes of these metals) upon thermolysis, photolysis, redox conversions and reactions with strong bases. A quantum-chemical description of the structures of these complexes has been given.

The review by V I Bregadze, S V Timofeev, I B Sivaev, I A Lobanova 'Substitution reactions at boron atoms in metallacarboranes' is a survey of the published data on substitution reactions in 10–12-apical metallacarboranes, which are being studied especially intensively. Special emphasis is laid on putative reaction mechanisms and effects of the metal fragment on the substitution site in the polyhedron.

The results of structural investigations of fullerene derivatives using diffraction methods are considered in the review by I S Neretin and Yu L Slovokhotov 'Crystal chemistry of fullerenes' which deals with an analysis of peculiarities of crystal structures of this type of compounds. This review presents the first generalisation of molecular and crystal structures of this group of compounds, which is one of the most difficult objects for investigation by diffraction methods.

The review by S V Vinogradova and V A Vasnev 'Trends in the development of polycondensation and condensation polymers' is an overview of progress in the polycondensation procedures. It provides a detailed description of the main principles of macromolecular design of condensation polymers and of some novel types of condensation polymers.

The review by L M Bronstein, S N Sidorov, P M Valetsky 'Nanostructured polymeric systems as nanoreactors for nanoparticle formation' gives a detailed description of the methods for the preparation of polymeric nanocomposites containing nanoparticles (block copolymers, dendrimers, nanoporous polymers, polyelectrolyte gel-surfactant complexes, multilayer films prepared by application of oppositely charged polyelectrolytes, *etc*.). Properties of nanostructurised polymeric nanocomposite materials are described.

The limited size of the issue prevents comprehensive presentation of the main research lines of the Institute.

All those who are interested in more detailed information about the Institute are invited to visit our web-site: http://www.ineos.ac.ru

Abstract. Published data on the synthesis and chemical properties of complexes of Group 4 – 10 transition metals (d elements) with η^6-tetramethylfulvene and η^7-trimethylallyldiene ligands, formed from the pentamethylcyclopentadienyl complexes of these metals, are described systematically. A description of the structures of these complexes in terms of a 'specific' resonance hybrid of fulvene and methylenecyclopentadienyl (or allyldiene and dimethylenecyclopentadienyl) structures is proposed. It is noted that similar properties or behaviours of the fulvene and allyldiene complexes can be followed both for compounds formed by metals of the same Group and for compounds of elements of the same transition row with identical electron configurations. The bibliography includes 102 references.

I. Introduction

The discovery of ferrocene in 1951 [1,2] and elucidation of its structure [3,4] and properties [5–7] triggered vigorous development of the chemistry of cyclopentadienyl organometallic complexes. Cyclopentadienyl derivatives have now been synthesised for the vast majority of chemical elements. More than 80% of known organometallic complexes contain either unsubstituted cyclopentadienyl ligand (Cp) or its derivatives (Cp′).[8] In the latter group, a special place is occupied by transition metal complexes with the pentamethylcyclopentadienyl ligand (Cp^*). The chemistry of these complexes started to develop intensively only in recent years, after facile methods for the synthesis of pentamethylcyclopentadiene and some of its derivatives had been proposed.[9] The key feature of metal complexes with pentamethylcyclopentadienyl ligands is the ability to split off one or two hydrogen atoms of methyl groups to be converted into cationic or neutral complexes with the $C_5Me_4CH_2$ or $C_5Me_3(CH_2)_2$ ligands, which are often referred to as tetramethylfulvene and trimethylallyldiene complexes, respectively. The chemistry of these complexes is of substantial interest not only because they have been prepared for many Group 4 – 10 transition metals but also due to the fact that the mode of metal coordination to these ligands depends essentially on the nature of the metal.

Vast experimental information concerning the chemistry of this class of compound has now been accumulated; however, to the best of our knowledge, the data have not been generalised. This stimulated us to compose this review, which covers the synthesis, the reactivity, and the structures of pentamethylcyclopentadienyl complexes of transition metals and quantum chemical calculations of their structures. As follows from the literature, the way of describing the structures of these complexes is debatable; this also calls for systematic consideration of the results of theoretical studies.

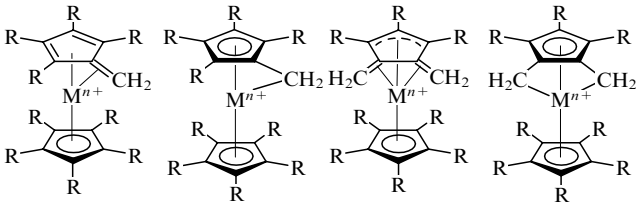
II. Metal complexes with tetramethylfulvene and trimethylallyldiene ligands

Metal complexes with the $C_5Me_4CH_2$ and $C_5Me_3(CH_2)_2$ ligands are formed in various transformations of compounds with the pentamethylcyclopentadienyl ligand. However, before we discuss properties of the coordinated η^5-Cp^* ligand, it is expedient to characterise briefly non-coordinated pentamethylcyclopentadiene. The properties of pentamethylcyclopentadiene (Cp^*H) differ from those of unsubstituted cyclopentadiene (CpH). It is a weaker acid ($pK_a = 26.1$) than CpH ($pK_a = 18.0$);[10] the non-aromatic 5π and 4π species, $C_5Me_5^{\bullet}$ ($Cp^{*\bullet}$) and $C_5Me_5^+$ (Cp^{*+}), it forms are more stable than their non-methylated analogues. The permethylated $Cp^{*\bullet}$ radical has been detected by EPR,[11] and the Cp^{*+} cation has been found as an intermediate [12] in the reactions of the metal Cp^* complexes with nucleophiles (alcohols, alkoxides, amines, organolithium compounds). The transformations of the η^5-Cp^* ligand in the coordination sphere of the metal atom proceed rather easily during a variety of processes.

Theoretically, the fulvene ligand $C_5H_4CH_2$ can be coordinated to a metal according to the η^2-, η^4-, and η^6 -modes. The same mode of coordination is typical of the tetramethylfulvene ligand. η^2-Coordination is encountered very rarely. Complexes with η^4-coordination of the $C_5Me_4CH_2$ and $C_5Me_3(CH_2)_2$ ligands are typical only of Groups 9 and 10 metals. Most abundant are neutral and cationic η^6-complexes formed by Group 4 – 8 metals.

When describing the structure of complexes with the $C_5Me_4CH_2$ ligand, researchers use either fulvene (**A**) or methylenecyclopentadienyl (**B**) structures; in some cases, they give preference to structure **A** without good reason. Complexes with the $C_5Me_3(CH_2)_2$ ligand are described by either an allyldiene (**C**) or dimethylenecyclopentadienyl (**D**) structure.



A (η^2,η^4) **B** (σ,η^5) **C** (η^4,η^3) **D** (σ,σ,η^5)

However, it is impossible to give preference to a particular structure without deciding beforehand which parameters characterise each of the structures. Apparently, it should be postulated that complexes with the fulvene structure contain a planar or nearly planar fulvene ligand, while complexes in which the tilt angle of the $C_{Cp}-C_{(\alpha)}H_2$ bond to the metal atom (α) equals 40° should be classified as methylenecyclopentadienyl complexes. It is evident that the deviation of the CH_2 group from the cyclopentadienyl plane by 40° virtually removes this group from conjugation with the ring; therefore, this ligand should not be termed as a fulvene ligand. A similar type of description should be applied to complexes with the $C_5Me_3(CH_2)_2$ ligand. Note that complexes with this extreme type of geometry are seldom encountered; those with an intermediate geometry are more common. The structure of complexes with the $C_5Me_4CH_2$ and $C_5Me_3(CH_2)_2$ ligands can be described using a 'specific' resonance hybrid, which takes into account the presence of both forms, $\mathbf{A} \leftrightarrow \mathbf{B}$ and $\mathbf{C} \leftrightarrow \mathbf{D}$, respectively. It should be taken into account that, unlike classical resonance, in this case, not only electrons are displaced but also the geometry changes. Note that in most of original publications, no clear or unambiguous assignment of the structures of transition metal complexes with the $C_5Me_4CH_2$ and $C_5Me_3(CH_2)_2$ ligands to forms **A** and **B** ($\eta^2,\eta^4 \leftrightarrow \sigma,\eta^5$) or **C** and **D** ($\eta^4,\eta^3 \leftrightarrow \sigma,\sigma,\eta^5$) has been carried out; therefore, in this review, we describe them as complexes with η^6- and η^7-modes of coordination, respectively.

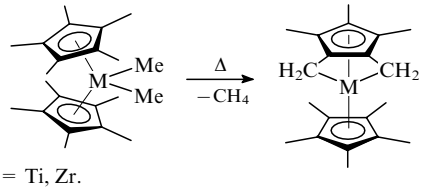
In all studies considered below, the researchers discuss rather comprehensively the structure of each complex they prepare and give numerous facts obtained by chemical, structural, spectral, and quantum-chemical methods supporting one or another structure.

The description of the structures of these compounds in terms of a 'specific' resonance hybrid proposed in this review is underlain by earlier views. As will be shown below, these views were formulated on the basis of systematic research of cationic complexes, but they can also be applied to neutral analogues.

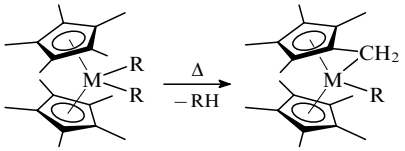
It is worth noting that similar properties or behaviours of complexes can be followed, first of all, for compounds of metals of the same Group. However, in some cases, analogies can also be traced for 16- and/or 18-electron compounds of elements of the same transition row. Therefore, when describing the chemical and spectroscopic properties of complexes, we will emphasise, as far as possible, the analogies found within the Groups or transition rows of elements.

III. The synthesis of complexes with tetramethylfulvene and trimethylallyldiene ligands

Metal complexes with the $C_5Me_4CH_2$ and $C_5Me_3(CH_2)_2$ ligands are often prepared by thermolysis of pentamethylcyclopentadienyl complexes Cp^*ML_n (L_n = Cp, Cp^*) of transition metals. Apparently, the reaction proceeds *via* radical intermediates. For example, heating of 16-electron $(\eta^5\text{-}Cp^*)_2MMe_2$ complexes (M = Ti, Zr) affords η^7-complexes, while the compounds $(\eta^5\text{-}Cp^*)_2MR_2$ (M = Zr, R = Ph; M = Hf, R = Bn) are converted into η^6-complexes.[13–15]

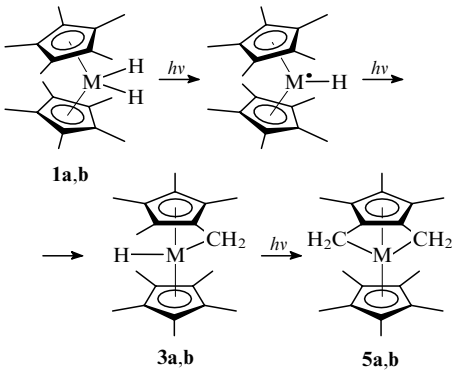


M = Ti, Zr.



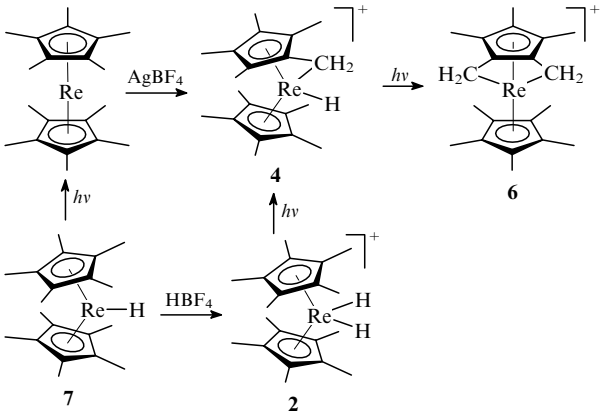
M = Zr, R = Ph; M = Hf, R = Bn.

Usually, $\eta^6\text{-}C_5Me_4CH_2$ complexes are synthesised starting from neutral and positively charged hydride complexes, $[(\eta^5\text{-}Cp^*)_2MH]^+An^-$, which are formed upon protonation of bis(pentamethylcyclopentadienyl) complexes of Group 8 metals or upon the reaction of Cp^*H with vapours of Group 6 and 7 transition metals. Ultraviolet photolysis of solutions of 18-electron metallocenes in acids (*in situ*) or the hydrides $[(\eta^5\text{-}Cp^*)_2MH_m]^{n+}An_n^-$ (M = Mo, W, Re,[16] Ru,[17] Os;[18] n = 0, 1; m = 0, 1, 2), isolated in a pure state, results in the complexes $[(\eta^5\text{-}Cp^*)MH_{m-1}(\eta^6\text{-}C_5Me_4CH_2)]^{n+}$. Thus UV irradiation of 18-electron neutral (**1a**,**b**) and cationic (**2**) η^5-complexes of Group 6 (Mo, W) and 7 (Re) metal hydrides yields successively η^6- (**3a**,**b**, **4**) and η^7-complexes (**5a**,**b**, **6**).[16] Apparently, in the case of Mo, W and Re, the final products are formed *via* 17-electron intermediates, $[\eta^5\text{-}Cp_2^*M^{\bullet}H]^{n+}$ (n = 0, 1), similar to complexes **3a**,**b**.



1a,**b** **3a**,**b** **5a**,**b**

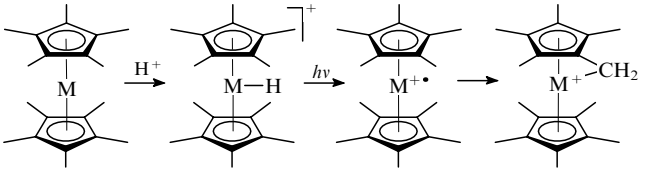
M = Mo (**a**), W (**b**).



7 **4** **2** **6**

The 17-electron complex Cp_2^*Re (unlike the Mo and W analogues) is quite stable and has been isolated. Photolysis of Cp_2^*Re furnishes initially complex **4**, which is then transformed

into complex **6**.[16] The same products are formed from the cationic rhenium dihydrate **2**, resulting from protonation of $(\eta^5\text{-Cp}^*)_2\text{ReH}$ (**7**) (synthesised by co-condensation of Re vapour with Cp^*H)[16] on treatment with HBF_4 . Photolysis of cationic complexes of Group 8 metal hydrides, $[(\eta^5\text{-Cp}^*)_2\text{MH}]^+$ (**9a**,**b**) (M = Ru, Os), prepared from complexes $(\eta^5\text{-Cp}^*)_2\text{M}$ (**10a**,**b**) and a number of acids (CF_3CO_2H, HBF_4, HPF_6 and CF_3SO_3H), proceeds in a similar way (giving rise to η^5-complexes **8a**,**b**).[17,18] A ^{1}H NMR study showed the intermediate formation of the $[(\eta^5\text{-Cp}^*)_2\text{M}]^{+\bullet}$ radical cations (**11a**,**b**), which confirms the radical mechanism of the reaction.



10a,**b** **9a**,**b** **11a**,**b** **8a**,**b**

M = Ru (**a**), Os (**b**).

The difference in the behaviours of neutral and cationic hydrides of Group 6–8 transition metals in the photolysis is manifested in the rate of formation of neutral and cationic products.

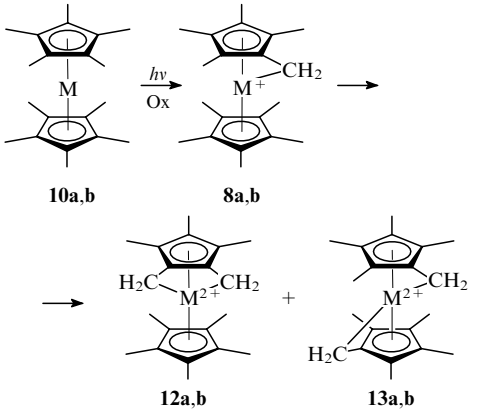
The 4d-metal $[(\eta^5\text{-Cp}^*)\text{MH}_x(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^{y+}$ complexes are formed faster than similar 5d-metal derivatives (Table 1).[16–18] However, for complexes formed by 3d metals, Cr, Mn and Fe, such transformations are unknown.

Table 1. Time (τ) of formation of $[(\eta^5\text{-Cp}^*)\text{MH}_x(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^{y+}$ from $[\text{Cp}_2^*\text{MH}_n]^{m+}$.

M	*n*	*m*	*x*	*y*	τ /h
Mo	2	0	1	0	3
W	2	0	1	0	24
Re	2	1	1	1	1
Ru	1	1	0	1	3
Os	1	1	0	1	15

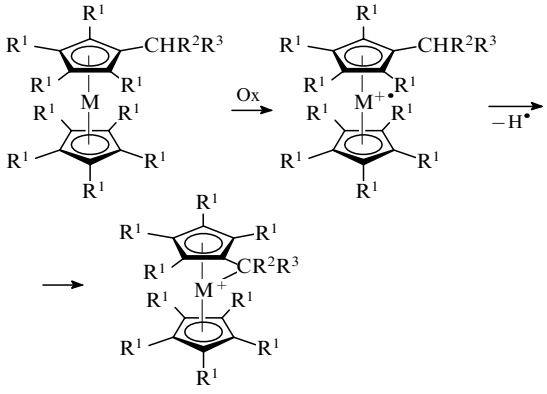
These results are consistent with the data of theoretical calculations of diatomic cations $(\text{MH})^+$; the strength of the M—H bond for elements of the 4d row (Mo and Ru) is lower than that for 5d-row elements (W and Os).[19] Indeed, the $\text{Cp}'_n\text{ML}_m$ compounds (Cp′ = Cp, Cp*) formed by 5d elements tend to have higher basicities than their analogues formed by 4d elements; as a consequence, the dihydride $[(\eta^5\text{-Cp}^*)_2\text{MH}_2]^{n+}$ (M = Re, *n* = 1; M = Os, *n* = 2) or monohydride $[(\eta^5\text{-Cp}^*)\text{MH}.(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^{n+}$ (M = Re, *n* = 1; M = Os, *n* = 2) complexes with the η^6-fulvene ligand are formed in the first stage.[16,20] Note that doubly charged ruthenium complexes, $[(\eta^5\text{-Cp}^*)_2\text{RuH}_2]^{2+}$ and $[(\eta^5\text{-Cp}^*)\text{RuH}(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^{2+}$, are not formed under these conditions. (In original publications, doubly and triply charged cations are sometimes referred to as di- and trications, respectively.)

The formation of dimethylene neutral complexes **5a**,**b** and cationic complex **6** upon UV irradiation requires 48, 96 and 20 h, respectively, whereas monomethylene complexes are formed within 3, 24 and 1 h, respectively (see Table 1).[16] For preparing doubly charged Ru- and Os-containing complexes $[(\eta^5\text{-Cp}^*)\text{M}(\eta^7\text{-C}_5\text{Me}_3(\text{CH}_2)_2\text{-1,2})]^{2+}$ (**12a**,**b**) and $[\text{M}(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)_2]^{2+}$ (**13a**,**b**), a mere increase in the time of $[\text{Cp}_2^*\text{MH}]^+$ irradiation is insufficient (more than 3 and 15 h, respectively, see Table 1). The reaction medium must also contain an oxidant (Ox) or a substance that promotes oxidation. Indeed, mixtures of complexes **12a**, **13a** and **12b**, **13b** are formed in a high yield only upon UV photolysis in the presence of 20%–25% of oleum in the reaction mixture.[17,18,20–23]



10a,**b** **8a**,**b** **12a**,**b** **13a**,**b**

The key stages in this process include (i) the formation of 16- and 17-electron intermediates of the $[\text{Cp}_2^*\text{Re}]^+$ or $[\text{Cp}_2^*\text{M}]^{+\bullet}$ type (M = Ru, Os) as a result of homolytic cleavage of the M—H bond followed by activation of the C—H bonds and (ii) the transformation of these intermediates into the $[(\eta^5\text{-Cp}^*)\text{ReH}(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^+$ and $[(\eta^5\text{-Cp}^*)\text{M}(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^+$ complexes (M = Ru, Os), respectively. These intermediates can also be prepared by oxidation of $(\eta^5\text{-Cp}^*)_2\text{M}$ (M = Re, Ru, Os) with one-electron oxidants, AgX (X = CO_2CF_3, BF_4). One-electron oxidation proved to be a versatile approach to the synthesis of a number of complexes of the $\text{LMC}_5\text{R}^1_4\text{CR}^2\text{R}^3$ type [M = Ru, Os; L = Cp, Cp*, η^5-C_9H_7 (indenyl); R^1, R^2, R^3 = H, Me]. Thus it was shown[21] that oxidation of LRuCp^* with $AgBF_4$ yields the complexes $[\text{LRu}(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)]^+\text{BF}_4^-$ (L = η^5-Cp, η^5-C_9H_7). A number of publications describe one-electron oxidation of methylated derivatives of ferrocene,[24] ruthenocene[25–27] and osmocene[28] and non-methylated ruthenocene[29,30] to give $[(\eta^5\text{-C}_5\text{R}^1_5)\text{M}(\eta^6\text{-C}_5\text{R}^1_4\text{CR}^2\text{R}^3)]^+\text{An}^-$ (M = Ru, Os; R^1 = H, Me; R^2, R^3 = Alk, Ar; An = BF_4, PF_6) from 17-electron metallocenium derivatives $[(\eta^5\text{-C}_5\text{R}^1_5)\text{M}(\eta^5\text{-C}_5\text{R}^1_4\text{CHR}^2\text{R}^3)]^{+\bullet}$



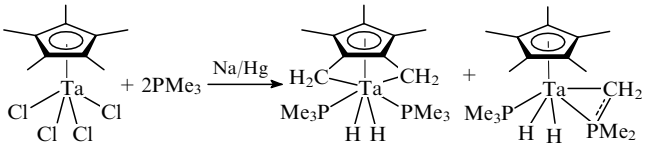
M = Ru, Os; R^1 = H, Me; R^2, R^3 = Alk, Ar.

For iron derivatives, this reaction does not occur and η^6-$C_5Me_4CH_2$ complexes are not formed.

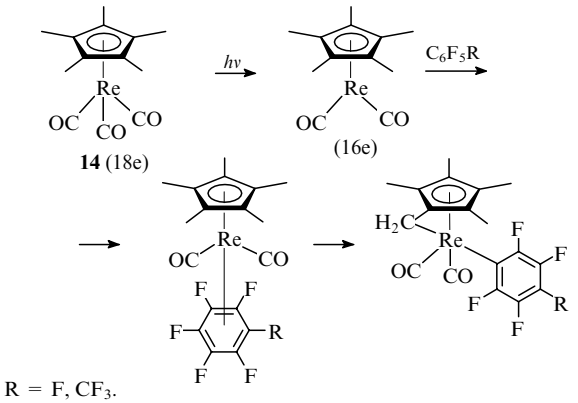
Thus, any 17-electron radical cation, $[\text{LM}(\eta^5\text{-C}_5\text{R}^1_4.\text{CHR}^2\text{R}^3)]^{+\bullet}$ (M = Ru, Os; L = Cp, Cp*, η^5-C_9H_7; R^1 = H, Me; R^2, R^3 = Alk, Ar), having at least one α-C—H bond is capable of being converted into an 18-electron cationic complex,[21] $[\text{LM}(\eta^6\text{-C}_5\text{R}^1_4\text{CR}^2\text{R}^3)]^+$. It was shown that the radical cations add the nucleophile Nu^{n-} (n = 0, 1) giving rise to 19-electron radical cations (n = 0) or radicals (n = 1). The subsequent transformations of these 19-electron species furnish the reaction products. Detailed putative schemes of these reactions are documented.[31,32] It is noteworthy that 19-electron intermediates play a

fairly important role in the transformations of compounds of late transition metals (Groups 9 and 10, see below).

The photolysis, reduction and oxidation of half-sandwich complexes of Group 5–8 metals also occur *via* the formation of 16- and 17-electron intermediates. Thus the reduction of Cp^*TaCl_4 with trimethylphosphine yields two complexes,[33] one containing the η^7-$C_5Me_3(CH_2)_2$ ligand.

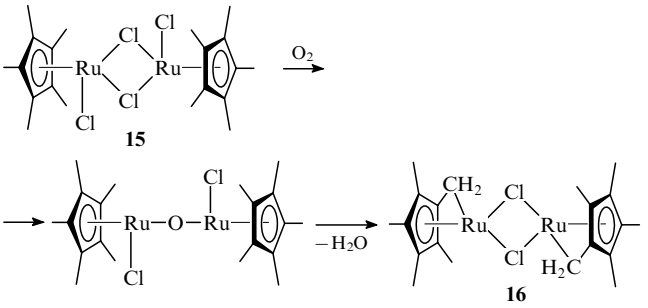


Rhenium complex **14** tends to undergo the following transformations:[34]

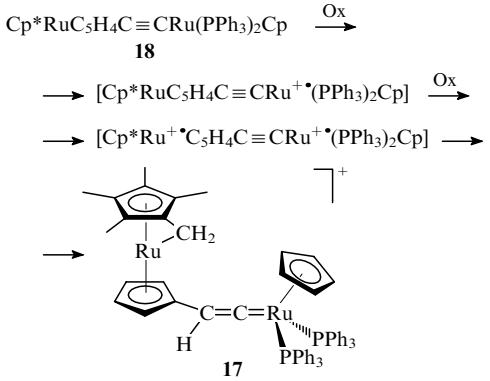


R = F, CF_3.

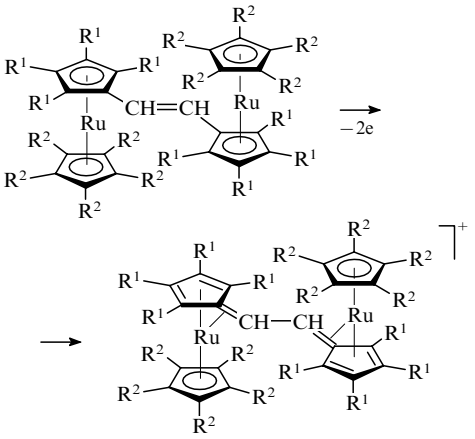
The formation of ruthenium complexes with the η^6-$C_5Me_4CH_2$ ligand is observed in various oxidation processes. For example, oxidation of binuclear halide complex **15** with oxygen involves the intermediate formation of oxide and affords dimeric complex **16**.[35]



The cationic complex **17** is formed upon the oxidation of the binuclear ruthenium complex **18**.[36] In this case, intramolecular interligand transfer of a hydrogen atom takes place in the intermediate 17-electron radical cation.

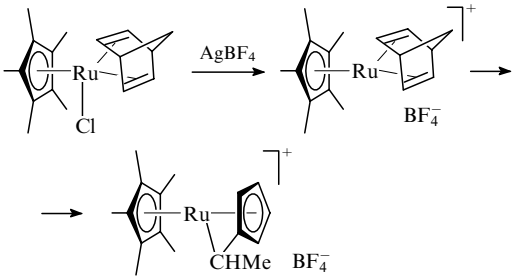


The oxidation of ruthenocene derivatives containing no Me or CHR^1R^2 substituents but having a multiple bond (C=C or C≡C) in the α-position affords compounds with the μ-η^6:η^6-ligand, which is an extensive polyconjugated system.[37]



R^1, R^2 = H, Me.

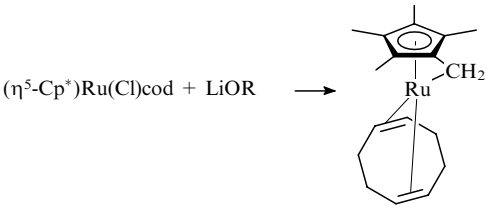
The transformation of a ruthenium complex with the η^4-norbornadiene ligand into a complex with the η^6-$MeCHC_5H_4$ ligand (rather than η^6-$C_5Me_4CH_2$) *via* a 16-electron η^4-complex (activation or cleavage of the C–C bonds) has been reported.[38]

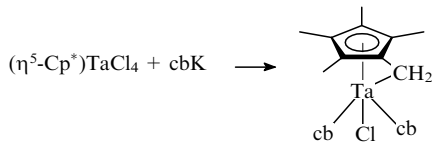


The oxidation of metallocenes Cp^*_2M (**10a**,**b**) in oleum or in the CF_3SO_3H – O_2 system, like photolysis, affords a mixture of η^5:η^7-(**12a**,**b**) and bis-η^6-complexes (**13a**,**b**). Note that the salts $[(\eta^5\text{-}Cp^*)M(\eta^6\text{-}C_5Me_4CH_2)]^+An^-$ (**8a**,**b**, An = BF_4 , PF_6) are preferred over metallocenes as the starting compounds for the preparation of the mixture of doubly charged cations; in this case, the product yield is higher and the reaction proceeds under milder conditions.[18,23]

The most interesting feature of the oxidation of metallocenes **10a**,**b** and cations **8a**,**b** on treatment with molecular oxygen in CF_3SO_3H is the fact that the reaction can proceed further and end in the formation of complexes containing three CH_2 groups, $[(\eta^6\text{-}C_5Me_4CH_2)M\{\eta^7\text{-}C_5Me_3(CH_2)_2\text{-}1,2\}]^{3+}$, which have no analogues among organometallic compounds. The properties and the possible structure of these compounds[20,39] are discussed below.

η^6-Fulvene complexes are also formed on treatment of the corresponding precursors with strong bases (for example, lithium alkoxides Pr^iOLi, Bu^tOLi or carbazolyl potassium).[40,41]



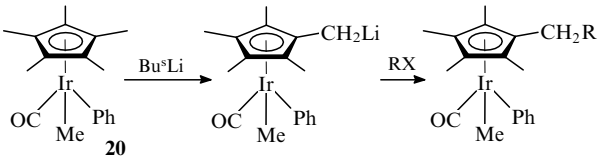


19

cod is 1,5-cyclooctadiene, cb is carbazolyl.

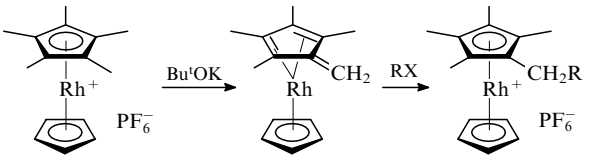
The reaction of chloride **19** with $LiCH_2SiMe_3$ or BnMgCl involves replacement of Cl by CH_2SiMe_3 or Bn without cleavage of the $Ta-CH_2$ bond.[41]

Deprotonation of cationic complexes under the action of strong bases is fairly typical of Group 9 metal derivatives. Generally, this gives rather labile complexes with the η^4-fulvene ligand with a non-coordinated exocyclic double bond. These complexes cannot be isolated due to high reactivity; their formation is indicated by the products of their reactions with various electrophiles. Thus deprotonation of iridium complex **20** followed by the reaction with electrophiles RX gives complexes with the ligands $C_5Me_4CH_2R$ (R = $SiMe_3$, All, Bn, CPh_2OH, CPh(Me)OH, CO_2Li).[42]



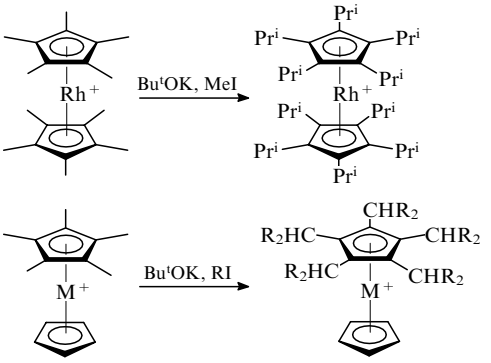
20

For penta- and decamethylrhodocenium and pentamethylcobaltocenium, deprotonation and the reaction with RX (X = Cl: R = Me_3Si, Bn; X = I: R = Me, Et) proceed by an elimination–addition mechanism *via* hypothetical intermediate η^4-fulvene complex **21**, the reaction involving all five (or ten) methyl groups. Treatment with alkyl iodides results in replacement of two hydrogen atoms at each Me group.[43, 44]



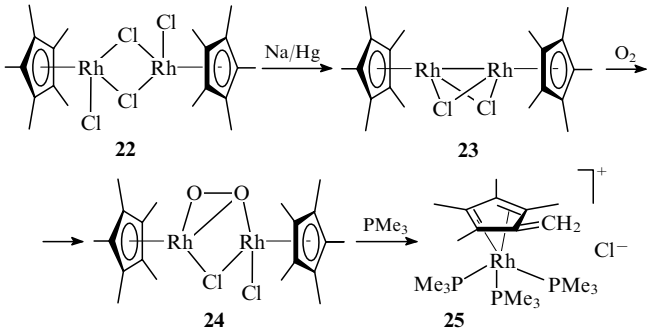
21

R = $SiMe_3$, Bn.



M = Rh, Co; R = Me, Et.

For compounds of Group 9 metals, η^4-fulvene complexes may also arise in oxidation and reduction processes. The reduction of the dimeric rhodium complex **22** and subsequent oxidation of the resulting compound **23** through intermediate complex **24** afford cationic η^4-complex **25**[45] rather than η^6-complexes, as in the case of Group 4–8 metals.

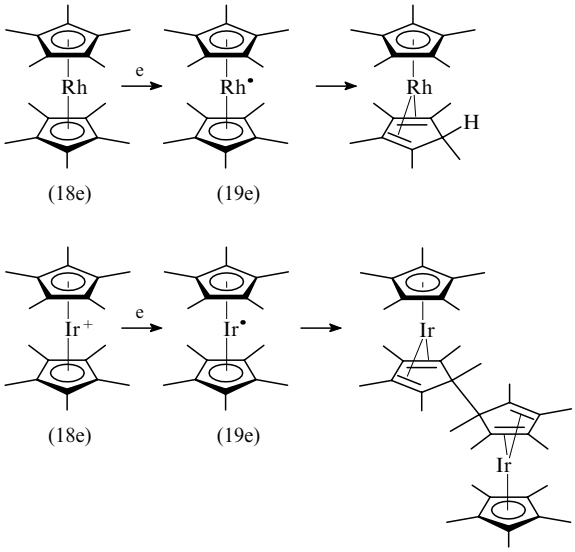


22 **23** **24** **25**

X-Ray diffraction analysis of complex **25** has shown that the CH_2 group and the carbon atom of the cyclopentadienyl ring attached to it are not involved in coordination with the Rh atom and that the methylene group is deflected from the metal atom by 23°.[45]

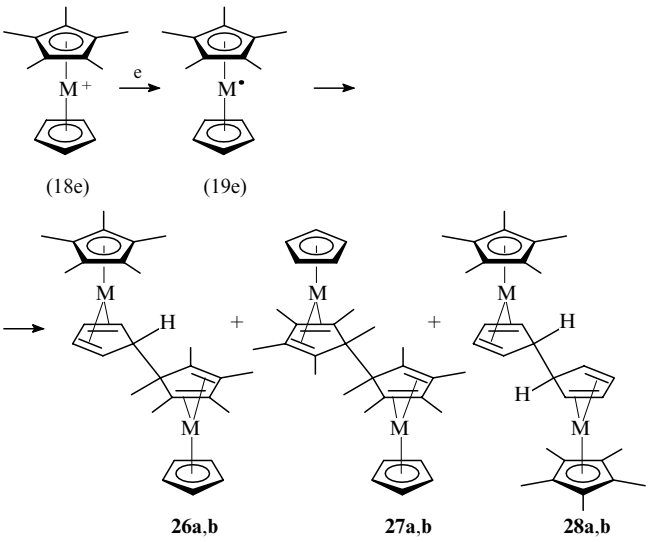
It is noteworthy that transformations of the η^5-cyclopentadienyl complexes of Group 9 metals (Co, Rh, Ir) do not often give mononuclear η^4-coordinated fulvene or cyclopentadiene complexes. For example, the reduction of 18-electron cationic complexes $[Cp^*_2M]^+X^-$ and $[Cp^*MCp]^+X^-$ (M = Rh, Ir, X is an anion) gives, in the first stage, extremely reactive 19-electron radicals, which either trap a hydrogen atom or react with the initial 18-electron cations to give bi- or polynuclear complexes with μ-η^4:η^4-ligands. Nevertheless, it is expedient to consider these transformations for obtaining the general picture of the reactivity of Cp^* compounds of Group 4–10 d-elements.

It is worth noting that the 19-electron intermediates resulting from reduction of complexes formed by Group 9 and 10 metals show more substantial differences between the behaviours of the derivatives of the second (4d) and third (5d) transition row metals than the 17-electron intermediates. Thus the reduction of $[Cp^*_2Rh]^+X^-$ gives rise to mononuclear η^5:η^4-complex, while that of its Ir analogue affords η^5 :η^4-dimer.[46, 47]



(18e) (19e)

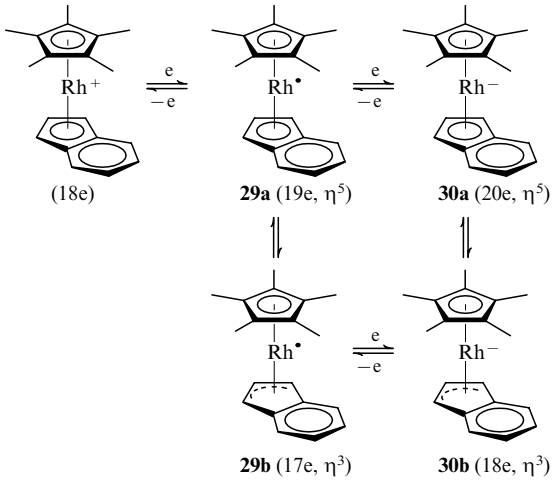
The rhodium and iridium complexes having one pentamethyl-substituted and one unsubstituted Cp ligand are converted into dimers with different contents of spatial isomers. The formation of only one Rh-containing complex (**26a**) and predominance of one isomer for the Ir analogue (**26b**) (isomer ratio **26b** : **27b** = 2 : 1) with total absence of the third isomer **28b** (which is spatially the less hindered isomer with the μ-η^4:η^4-$C_5H_5C_5H_5$ ligand) attests to a reaction of the 19-electron radical with the initial 18-electron cation, because dimerisation of radicals would have yielded a random mixture (1 : 1 : 1) of all three spatial isomers.[47]



M = Rh (**a**), Ir (**b**).

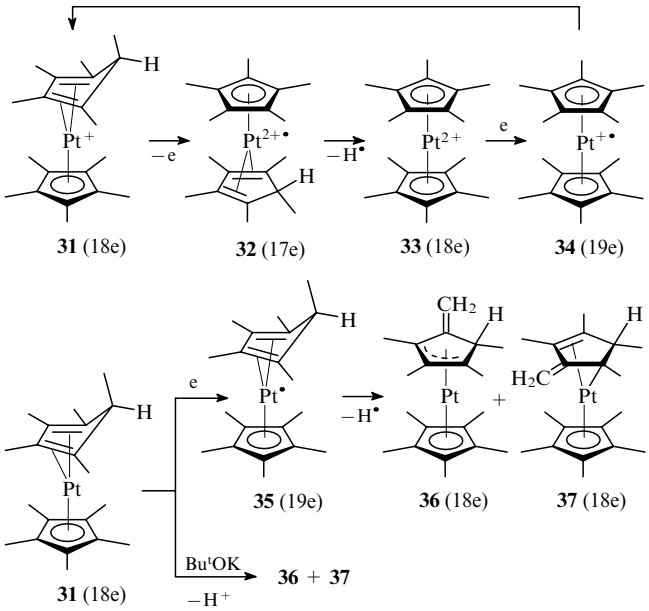
Metal	Compound	Isomer content (%)
Rh	**26a**	100
	27a	0
	28a	0
Ir	**26b**	66
	27b	33
	28b	0

The reduction of Rh and Ir complexes containing η^5-Cp* and η^5-C_9H_7 ligands proceeds in a different way. For instance, electrochemical reduction of the 18-electron rhodium complex is a two-step process, each step being reversible.[46] The reaction gives mononuclear 19-electron radical **29a** and 20-electron anion (**30a**), respectively (or their 17- and 18-electron η^3-isomers **29b** and **30b**, respectively) (*i.e.*, a decrease in the hapticity of the indenyl ligand is involved).

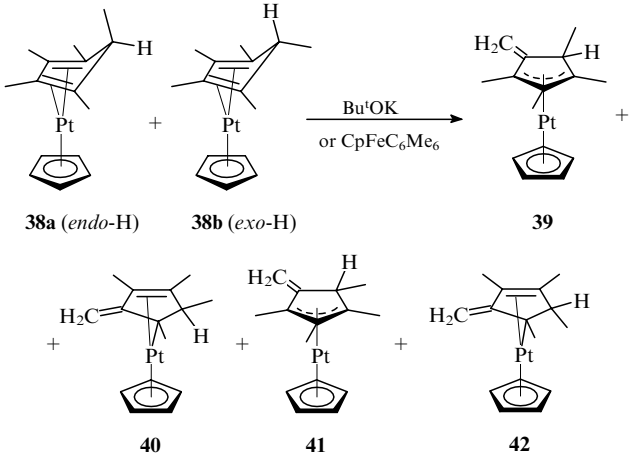


Chemical (1% Na amalgam in THF) or electrochemical reduction of $[(\eta^5\text{-Cp}^*)\text{Ir}(\eta^5\text{-C}_9\text{H}_7)]^+$ proceeds irreversibly, giving rise to a large tetranuclear splayed six-decked complex $[(\eta^5\text{-Cp}^*)\text{Ir}(\mu\text{-}\eta^5\text{-C}_9\text{H}_7)\text{Ir}(\mu\text{-}\eta^4\text{:}\eta^4\text{-C}_5\text{Me}_5\text{C}_5\text{Me}_5)\text{Ir}(\mu\text{-}\eta^5\text{-C}_9\text{H}_7)\text{Ir}.(\eta^5\text{-Cp}^*)]$.[47] Presumably, the reduction of the initial cation results in a 19-electron radical (analogous to the Rh-containing radical **29**), which splits off an indenyl ligand to give the solvate $[(\eta^5\text{-Cp*})\text{Ir}(\text{THF})_x]$. This complex then reacts with the initial cation yielding the cationic dimer $[(\eta^5\text{-Cp}^*)\text{Ir}(\mu\text{-}\eta^5\text{-C}_9\text{H}_7)\text{Ir}(\eta^5\text{-Cp}^*)]^+$. The reduction of this cation results in the final tetranuclear reaction product.

The electrochemical properties of some Cp* complexes of Group 10 metals (M = Pd, Pt) have been studied in detail.[48–51] For example, it was shown that oxidation of cationic 18-electron complexes $[(\eta^5\text{-Cp}^*)\text{M}(\eta^4\text{-Cp}^*\text{H})]^+$ (**31**) through 17-electron doubly charged radical cations (**32**) furnishes previously unknown 18-electron doubly charged pallado- and platinocenes **33**.[48,51] The electrochemically reversible reduction of platinocene *via* 19-electron radical cation **34** gives the initial complex **31**. Meanwhile, the successive reduction of the Pd analogue reversible in each one-electron stage gives no identifiable products. Further reduction of Pt complex **31** *via* 19-electron radical **35** or its reaction with a strong base (Bu^{t}OK) yields a mixture of η^3- (**36**) and σ:η^2-complexes (**37**).[51] It should be noted that in the intermediate 19-electron complex $(\eta^5\text{-Cp}^*)\text{Pt}(\eta^4\text{-Cp}^*\text{H})$, it is the C—H bond in the methyl group of the η^4-C_5Me_5H ligand that is cleaved rather than the C—H bond in the C(Me)H fragment of this ligand. No transformations of this type are known for Pd complexes.[48]

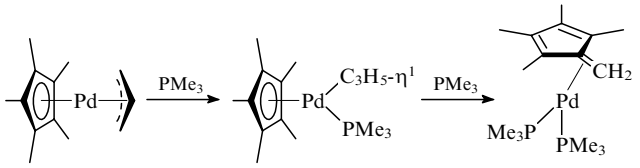


Deprotonation with potassium *tert*-butoxide or reduction with 19-electron $CpFeC_6Me_6$ of dienic Pt complexes containing simultaneously the C_5Me_5H and Cp ligands (**38a**,**b**) yields a mixture of compounds **39**, **40** and **41**, **42**, respectively.[48]



It should be noted that in the reactions listed above, the ligand hapticity decreases as follows: $\eta^5 \rightarrow \eta^4$ and $\eta^4 \rightarrow \eta^3$. Cases of $\eta^5 \rightarrow \eta^2$ transition are also known. For example, the reaction of $(\eta^3\text{-}C_3H_5)\text{Pd}(\eta^5\text{-Cp}^*)$ with PMe_3 affords $(Me_3P)_2\text{Pd}(\eta^2\text{-}$

$CH_2C_5Me_4$), in which the Pd atom is coordinated at the exocyclic double bond of the fulvene ligand.[52]



Apparently, the reaction of the Rh complex with isonitriles under UV radiation follows the same pattern to give 1,2,3,4-tetramethylfulvene *via* intermediate η^5-Cp*, η^3-Cp* and η^1-Cp* complexes.[53]

$$(\eta^5\text{-Cp}^*)\text{Rh(CNR)}_2 \xrightarrow{\text{RNC, } h\nu} (\eta^3\text{-Cp}^*)\text{Rh(CNR)}_3 \xrightarrow{\text{RNC, } h\nu}$$

$$\longrightarrow (\eta^1\text{-Cp}^*)\text{Rh(CNR)}_4 \longrightarrow C_5Me_4CH_2$$

R = CH_2Bu^t.

IV. The reactivity of neutral and cationic complexes

The reactivities of neutral and cationic fulvene complexes towards nucleophiles are fairly similar. Neutral complexes of Group 4–8 metals can also react with electrophilic reagents.[34] In some cases, the reactions of η^6-fulvene complexes with electrophiles (strong acids) proceed without rupture of the M–C_α bond to yield a singly or doubly charged cationic complex. For example, the neutral Re complex [16] and the cationic Os complex [23] react in this way.

$$\text{Cp*Re}(\eta^6\text{-}C_5Me_4CH_2) + HBF_4 \longrightarrow$$

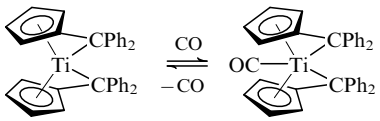
$$\longrightarrow [\text{Cp*ReH}(\eta^6\text{-}C_5Me_4CH_2)]^+BF_4^-,$$

$$[\text{Cp*Os}(\eta^6\text{-}C_5Me_4CH_2)]^+BF_4^- + CF_3SO_3H \longrightarrow$$

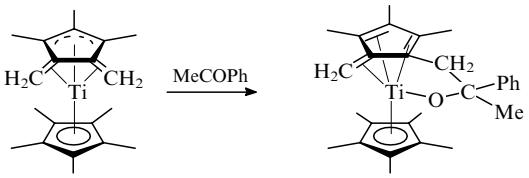
$$\longrightarrow [\text{Cp*OsH}(\eta^6\text{-}C_5Me_4CH_2)]^{2+}An_2^-.$$

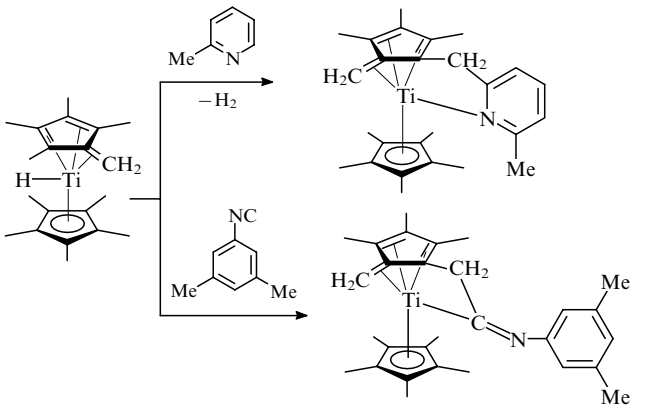
An = BF_4, CF_3SO_3.

For a 16-electron titanium complex containing two fulvene ligands,[54] reversible CO addition without rupture of the Ti– C_α bonds is also possible.



In addition, the 16-electron complexes of Group 4 metals (Ti, Zr, Hf) tend to undergo insertion into the M–CH_2 bonds with extension of the chelate ring and formation of a metal–hetero-atom bond.[55–57]





However, more often, reactions of cationic and neutral η^6-fulvene complexes with electrophiles are accompanied by rupture of the M–CH_2 bond, as for example, in the case of Re complexes.[34]

$$[(C_6F_5)(CO)_2\text{Re}(\eta^6\text{-}C_5Me_4CH_2)] + HHal \longrightarrow$$

$$\longrightarrow \textit{cis}\text{-}[(C_6F_5)(CO)_2\text{Re(Hal)}(\eta^5\text{-Cp}^*)] \longrightarrow$$

$$\longrightarrow \textit{trans}\text{-}[(C_6F_5)(CO)_2\text{Re(Hal)}(\eta^5\text{-Cp}^*)],$$

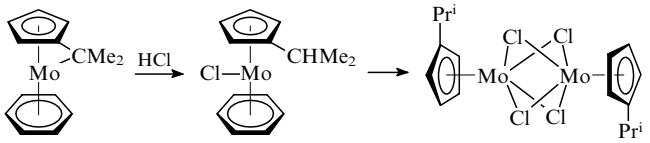
$$[(C_6F_5)(CO)_2\text{Re}(\eta^6\text{-}C_5Me_4CH_2)] + Hal_2 \longrightarrow$$

$$\longrightarrow \textit{cis}\text{-}[(C_6F_5)(CO)_2\text{Re(Hal)}(\eta^5\text{-}C_5Me_4CH_2Hal)] \longrightarrow$$

$$\longrightarrow \textit{trans}\text{-}[(C_6F_5)(CO)_2\text{Re(Hal)}(\eta^5\text{-}C_5Me_4CH_2Hal)].$$

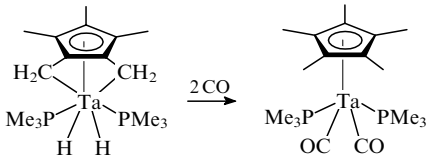
Hal = Cl, Br, I.

In the reaction of neutral molybdenum complex **43** with HCl, the M–C_α bond is also cleaved to give binuclear complex **44** with halide bridges.[58]

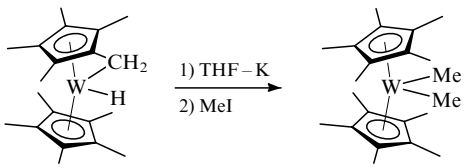


43 **44**

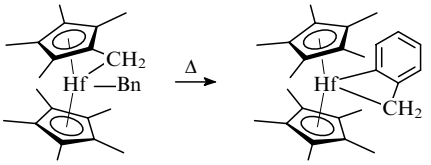
The rupture of two M–C_α bonds also takes place in the reaction of Ta complex with CO.[33]



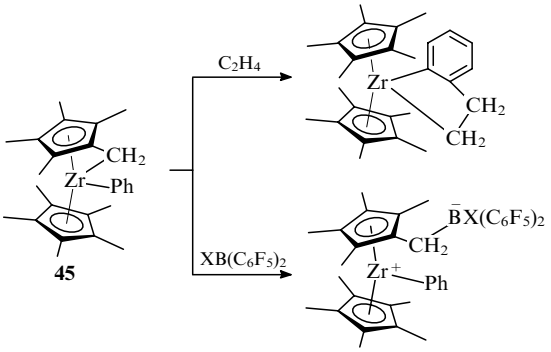
Rupture of the M–C_α bonds can also occur during the reduction of complexes.



In some cases, the reactions of fulvene complexes involve not only the M–C_α bonds but also the bonds of the metal atom with other ligands;[15, 16, 59] in this case, rather unusual transformations, for example *ortho*-metallation, can occur in the metal coordination sphere.

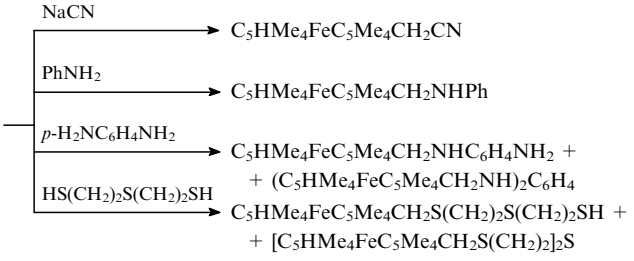


The neutral zirconium fulvene complex **45** reacts with ethylene and electrophilic boranes $XB(C_6F_5)_2$ (X = H, C_6F_5) with cleavage of the $M-C_\alpha$ bond. In the latter case, the reaction gives a zwitterionic complex, which has found use in homogeneous catalysis.[60, 61]



The reactivity of the non-methylated cationic fulvene complexes $[CpMC_5H_4CR^1R^2]^+X^-$ (M = Fe, Ru, Os) has been studied in detail (mainly in relation to ferrocene derivatives) in numerous studies by Russian and foreign researchers (see the reviews [62, 63] and references cited therein). Methylated derivatives are much less studied. Only a few papers dealing with the properties of cationic metal complexes containing the η^6-$C_5Me_4CH_2$ ligand have been published. The reactions of $[C_5HMe_4FeC_5Me_4CH_2]^+BF_4^-$ with a number of nucleophiles accompanied by rupture of the $Fe-CH_2$ bond have been studied.[64]

$[(\eta^5\text{-}C_5HMe_4)Fe(\eta^6\text{-}C_5Me_4CH_2)]^+BF_4^- \longrightarrow$

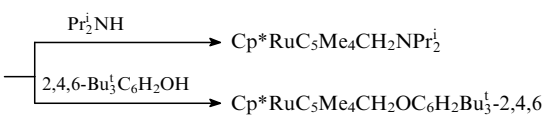


The reactions of salts of nonamethylruthenocenylmethyl cations with nucleophiles have been studied by Kölle *et al.*[25, 65] and Rybinskaya *et al.*[17]

$[Cp^*M(\eta^6\text{-}C_5Me_4CH_2)]^+An^- + KOH \longrightarrow Cp^*MC_5Me_4CH_2OH$

M = Fe, Ru; An = PF_6, CF_3SO_3.

$[Cp^*Ru(\eta^6\text{-}C_5Me_4CH_2)]^+PF_6^- \longrightarrow$



In cationic complexes, the M–CHR bond is easily cleaved under the action of $NaBH_4$, the complexes being reduced to metallocenes.

$[Cp^*M(\eta^6\text{-}C_5Me_4CHR)]^+An^- \xrightarrow{NaBH_4} Cp^*M(\eta^5\text{-}C_5Me_4CH_2R)$

M = Fe: R = H, Ph, Mes; M = Ru, Os: R = H; An = BH_4, PF_6.

The reactions of cationic complexes with the most typical nucleophiles have been studied.[27, 66]

$[Cp^*M(\eta^6\text{-}C_5Me_4CH_2)]^+An^- + MeONa \longrightarrow Cp^*MC_5Me_4CH_2OMe,$

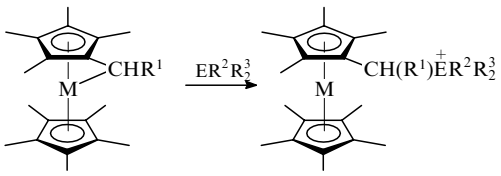
M = Fe, Ru; An = BF_4, PF_6.

$[Cp^*Fe(\eta^6\text{-}C_5Me_4CH_2)]^+An^- + PhSH \longrightarrow Cp^*FeC_5Me_4CH_2SPh,$

An = BF_4, PF_6.

The C–O and C–S bonds in the resulting neutral ethers and thioethers are easily cleaved on treatment with acids yielding the initial cationic compounds.

The salts containing metallocenylmethyl (metallonium) cations readily react with amines and phosphines to give ammonium and phosphonium salts (onium exchange reactions).[67, 68]



M = Os: R^1 = H, $ER^2R^3_2$ = $PPhMe_2$, PPh_3, NMe_3;
M = Ru: R^1 = H, $ER^2R^3_2$ = $PPhMe_2$; R^1 = Ph, $ER^2R^3_2$ = PPh_3.

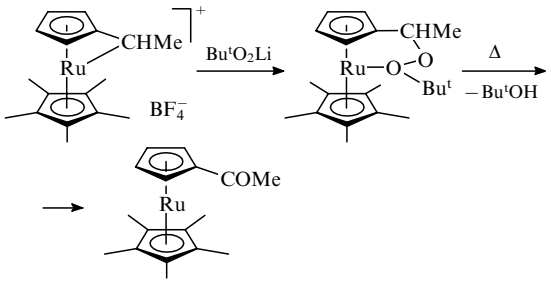
Unlike neutral ethers and thioethers, in cationic metallocenylmethylammonium and -phosphonium cations, the C–N or C–P bonds are not cleaved in the reaction with CF_3SO_3H; instead, protonation at the metal atom to give dications takes place.[67]

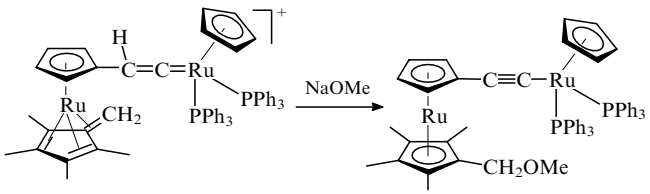
$Cp^*MC_5Me_4CH_2P^+PhMe_2 \xrightarrow{CF_3SO_3H}$

$\longrightarrow Cp^*M^+H(C_5Me_4CH_2P^+PhMe_2)$

M = Ru, Os.

The reaction of $[Cp^*RuC_5H_4CHMe]^+$ with Bu^tOOLi [38] and the reaction of the cationic binuclear Ru complex with MeONa [36] have been studied.





These reactions can be used to prepare functional derivatives of methylated metallocenes and their analogues.

V. Structural characteristics of metal complexes with a fulvene or allyldiene ligand

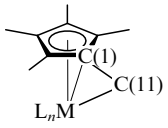
When discussing the structural characteristics of the complexes considered in this review, one should follow first of all the effect of the covalent radii of Group 4–10 transition metal atoms on the structure of compounds and, in particular, on the interatomic distances and bond angles. The covalent radii of Group 4–10 metals have been derived [69] from plenty of experimental data (Table 2). It can be seen from Table 2 that the radii of metal atoms of the 4th Period (3d metals) are much smaller, irrespective of the Group, than the radii of metal atoms of the 5th and 6th Periods (4d and 5d metals †). By following the variation of the radii over the Periods, one can see that the greatest values are found for Group 4 elements, then they smoothly decrease to reach the smallest values for Group 9 elements, and for Group 10 elements, they again somewhat increase.

Table 2. Covalent radii of transition metals (Å).[69]

Period	Group						
	4	5	6	7	8	9	10
4	Ti	V	Cr	Mn	Fe	Co	Ni
	1.56	1.49	1.46	1.38	1.34	1.29	1.35
5	Zr	Nb	Mo	Tc	Ru	Rh	Pd
	1.76	1.66	1.58	1.53	1.49	1.46	1.49
6	Hf	Ta	W	Re	Os	Ir	Pt
	1.77	1.66	1.59	1.51	1.50	1.47	1.43

When considering the structural characteristics of the neutral $L_nM(\eta^6\text{-}C_5R^1_4CR^2R^3)$ (M = Ti, Zr, Hf, Ta, Cr, Mo, W, Re, Ru; L = Cp, Cp*, Ar, CO; R^1 = H, Me; R^2, R^3 = H, Me, Ph) and cationic $[Cp'M(\eta^6\text{-}C_5R^1_4CR^2R^3)]^+$ An^- (Cp′ = Cp, Cp*; M = Fe, Ru, Os; R^1 = H, Me; R^2, R^3 = H, Ph) transition metal complexes with a fulvene ligand (metallocenylmethyl cations) studied to date (Tables 3, 4), one cannot but notice that they are closely similar. Only a few structurally characterised neutral allyldiene (or dimethylenecyclopentenyl) complexes with the $\eta^7\text{-}C_5Me_3(CH_2)_2$ ligand have been reported. Indeed, only one publication has been devoted to the X-ray diffraction study of the Ta complex — $(Me_3P)_2H_2Ta[\eta^7\text{-}C_5Me_3(CH_2)_2]$,[33] and one study [82] reports the structures of three related Ti complexes (see below).

Table 3 presents the X-ray diffraction characteristics of neutral and cationic η^6-fulvene metal complexes $[L_nMC_5R^1_4CR^2R^3]^{m+}An^-_m$ (M are Group 4–10 metals; L_n = Cp, Cp*, Ar, CO, PR^3_3, H; R^1 = H, Me; R^2, R^3 = H, Me, Ph; m = 0, 1, 2) studied to date.



The data for Ti complexes have been collected in a separate Table (Table 4), as they require separate consideration. It can be seen from Table 3 that, despite the different ligand environments of the metal M (L_n ligands) and the substituents in the cyclopentadienyl ring, the M–C(11) and M–C(1) distances are usually commensurable. For compounds of elements of the third transition row (5d), they are somewhat smaller than the distances in complexes formed by metals of the second transition row (4d).

The shortest M–C(11) and M–C(1) distances were found for the 18-electron cationic complex $[Cp^*Os(C_5Me_4CH_2)]^+BPh^-_4$.

† The radii of 5d-metal atoms differ little from one another due to lanthanide contraction.

Table 3. X-Ray diffraction characteristics of transition metal complexes with the $\eta^6\text{-}C_5R^1_4CR^2R^3$ and $\eta^7\text{-}C_5R^1_3(CR^2R^3)_2$ ligands.

[a] The Ti–CHPh bond length.

These distances are somewhat longer in 16-electron neutral 'primary' (η^6-6,6-H,H-fulvene) tantalum complexes. Attention is attracted by somewhat greater (and virtually equal to each other) Ru–C(11) distances in the $[Cp'Ru(C_5R_4CH_2)]^+An^-$ cationic complexes (Cp′ = Cp, Cp*; R = H, Me) and the neutral Ru complex, $[\{Cl(\mu\text{-}Cl)C_5Me_4CH_2\}Ru]_2$. In the $[(cyclo\text{-}C_8H_{12})ClRu(C_5Me_4CH_2)]$ complex, the Ru–C(11) distance is somewhat longer.

The data of Table 3 indicate that for 16-electron compounds of Group 4 metals, $[Cp^*ZrPh(C_5Me_4CH_2)]$ and $[Cp^*Hf(CH_2Ph)(C_5Me_4CH_2)]$, and for 18-electron compounds of Group 6 metals, $[(C_6H_5Me)Mo(C_5H_4CPh_2)]$ and $[(C_6H_6)W(C_5H_4CPh_2)]$, the M–C(11) distance tends to increase on going up along the group (5d → 4d). An increase in the M–C(11) and M–C(1) distances in the 18-electron complexes

of Group 8 metals is observed on passing from 4d (Ru) to 3d metals (Fe), despite the smaller covalent radius of the iron atom.

A similar pattern is observed for the 18-electron η^6-6,6-diphenylfulvene cationic complexes of Group 8 metals $[CpM(C_5H_4CPh_2)]^+$ (M = Os, Ru, Fe), neutral complexes of Group 6 metals, $(C_6H_6)W(C_5H_4CPh_2)$, (C_6H_5Me).$Mo(C_5H_4CPh_2)$, $(CO)_3Cr$-$(C_5H_4CPh_2)$, and for two η^6-6-H,6-Ph-fulvene cationic complexes, $[Cp^*M(C_5Me_4CHAr)]^+$ (M = Os, Ar = C_6F_5; M = Ru, Ar = Ph). Thus, most often, for 18-electron complexes of Group 6 and 8 metals and for 16-electron compounds of Group 4 metals, the M–C(11) distances tend to decrease in the sequences Cr > Mo > W; Fe > Ru > Os; and Zr > Hf (5d → 4d → 3d). These regularities clearly attest to the increase in the degree of interaction of the lone electron pair (LEP) of the metal atom with the carbocationic centre in cationic complexes or with the appropriate vacant orbital of the fulvene ligand in neutral complexes along these sequences. It can also be seen from the data of Table 3 that for compounds of Group 8 metals and for Cr-containing complexes, the M–C(11) distance tends to increase with enhancement of steric restrictions in the fulvene ligand (the bulk or the size of substituents), *i.e.*, on passing from primary $[Cp^*M(C_5Me_4CH_2)]^+An^-$ cations to tertiary $[CpM(C_5H_4CPh_2)]^+$ An^- cations (M = Fe, Ru, Os). The corresponding neutral complexes behave in a similar way: the M–C(11) distance increases on passing from $(CO)_3Cr(C_5H_4CH_2)$ to $(CO)_3Cr(C_5H_4CPh_2)$.

More detailed analysis of structural data, both presented in Table 3 and absent from the Table but contained in original publications shows that in all neutral and cationic η^6-$C_5R_4CH_2$ complexes of Group 4 (Zr, Hf), 6 (Mo, W) and 8 (Ru, Os) metals of the second and third transition rows, the M–C(11) bond length barely differs from the lengths of the bonds between the metal and other atoms of the cyclopentadienyl ring of the fulvene ligand. Quantum-chemical calculations (see below) indicate that in the cationic $[Cp^*M(C_5Me_4CH_2)]^+An^-$ complexes (M = Ru, Os), the positive charge is concentrated almost entirely on the metal atom. In any of these compounds, one LEP of the metal atom (Fe and, especially, Ru and Os) is involved in substantial donor–acceptor interaction with the carbocationic centre. In the doubly charged Group 8 metal complexes, donor–acceptor interaction takes place between two LEP of the metal atom (Ru and Os and, to a lesser extent, Fe) and two carbocationic centres. Cationic compounds of this type have been termed metallonium compounds.[83] Apparently, the term 'neutral metallonium complexes' is applicable to neutral fulvene or allyldiene complexes in which the M–C(11) bond length does not differ much from the bond lengths between the metal atom and the carbon atoms of the Cp or Cp^* ring and which are characterised by a substantial donor–acceptor interaction between one or two LEP of the metal atom (Ti, Zr, Hf, Ta, Mo, W, Ru and, to a lesser extent, Cr) and one or two vacant orbitals of the fulvene or allyldiene ligand (see below). Their formation from the starting cyclopentadienyl complexes is actually accompanied by an increase in the hapticity of the metal atom ($\eta^5 \rightarrow \eta^6 \rightarrow \eta^7$). The structure of these complexes is best described by resonance forms **B** (σ,η^5) and **D** (σ,σ,η^5), respectively. Recall that the formation of cationic onium complexes, ER_n^+ (E = N, P, As, O, S, I; R = H, Me), anionic ('inverted') onium complexes, ER_n^- (E = B, Al; R = H, F, Cl), or neutral 'onium' $Me_3N\cdot BH_3$ or $Et_3N\cdot BF_3$ complexes (these are also characterised by interaction of the donor LEP with an acceptor vacant orbital) of organic or organoelement compounds of non-transition elements from the corresponding precursors is also accompanied by an increase in the coordination number of the central atom by unity.

In the case of Ti complexes, it is possible to compare directly structures with the η^6-$C_5R_4^1CR_2^2$ and η^7-$C_5R_3^1(CR_2^2)_2$ ligands. The first characteristic feature that can be noted when comparing the data of Tables 3 and 4 is the shorter M–C(11) distances for Ti complexes compared to similar Zr and Hf complexes; apparently, this is a consequence of the smaller covalent radius of Ti. The Ti–CH_2 bond length in the 15-electron $Cp^*Ti(C_5Me_4CH_2)$ complex is virtually equal to or even somewhat greater than that in the 16-electron complexes with the η^7-$C_5Me_3(CH_2)_2$ and η^7-$C_5Me_3(CHPh)CH_2$ ligands. In the $Ti(C_5H_4CPh_2)_2$ complex, the Ti–CPh_2 bonds (as in the Cr, Fe, Ru and Os complexes) are longer than the Ti–CH_2 bonds in other compounds. An increase in the Ti–CH_2 distance in the *ansa*-$(C_5Me_4SiMe_2)Ti$.$(C_5Me_3PhCH_2)$ complex and the $Cp^*Ti\{C_5Me_3(OCMePh)CH_2\}$ complex containing a TiC(Me)(Ph)O fragment should also be noted.

VI. Spectral characteristics of complexes

1. Chemical shifts

The number of fulvene and allyldiene complexes studied by NMR spectroscopy is much greater, as this does not require growing the crystals. In view of the fact that preparation of suitable crystals for some compounds is either difficult or impossible, the significance of the NMR spectroscopy can hardly be overestimated. The NMR spectral data are complementary to X-ray diffraction data. These data allow one (subject to some restrictions) to elucidate the same features as X-ray diffraction data.

The degree of interaction between the metal atom and the carbocationic centre or a vacant orbital in all the cationic and neutral complexes studied can be estimated by analysing the ^{13}C NMR chemical shifts (δ) of the C(11) nuclei. Of course, certain regularities of the variations of chemical shifts can also be followed in the ^1H NMR spectra but they are usually much less vivid than the corresponding changes in the ^{13}C NMR spectra and are not considered in this review. Tables 5–7 present the chemical

Table 5. Chemical shifts $\delta(^{13}C)$ of the C(11) nuclei in the 'primary' neutral and cationic η^6-6,6-H_2-fulvene and η^7-allyldiene metal complexes.

shifts in neutral and cationic $[L_nM(\eta^6\text{-}C_5R^1_4CR^2R^3)]^{m+}$ and $[L_nM\{\eta^7\text{-}C_5Me_3(CH_2)_2\}]^{m+}$ complexes ($m = 0, 1$).

It can be seen from the data of Tables 5–7 that for most primary, secondary and tertiary cationic and neutral complexes, shielding of ^{13}C nuclei in the CR^1R^2 (CH_2, CHMe, CHPh, CHMes, CHC_6F_5, CMe_2 and CPh_2) groups increases (δ values decrease) from top to bottom along the Groups. Thus, the results obtained by NMR are correlated with X-ray diffraction data, which attest to a decrease in the M–C(11) distance and an increase in the angle α along the same sequences (*i.e.*, Ti–Zr–Hf, Cr–Mo–W and Fe–Ru–Os). Thus, both physical methods provide the same conclusion: the donor–acceptor interaction of the LEP of the metal atom with the carbocationic centre or with the vacant orbital increases on going from top to bottom along the Groups of elements.

The effect of the metal atom [an increase in the shielding (a decrease in the δ values) of the C(11) carbon nuclei from top to bottom along the Group] is often manifested in the fact that the δ values for elements of different Groups but of the same Period are fairly similar. The effect of the metal often counterbalances not only the influence of the charge (see below) but also the degree of substitution at C(11).

The similarity of the δ values for Ru and, especially, Os cationic complexes to those for neutral fulvene complexes with a similar structure (Ti, Zr, Mo, W, *etc.*), apparently, indirectly confirms the conclusion based on extended Hückel (EHT) calculations,[97] according to which the major positive charge in these complexes is concentrated on the metal atom rather than on the CR^1R^2 group. However, it should be noted that the comparison of the carbon δ values for the CR^1R^2 groups is more or less legitimate only in the case of isostructural compounds or compounds with similar structures, because in the general case, the influence of other ligands (ligand environment) cannot be neglected.

Table 7. Chemical shifts $\delta(^{13}C)$ of the C(11) nuclei in the 'tertiary' neutral and cationic η^6-6,6-R_2-fulvene metal complexes.

Table 8. Chemical shifts $\delta(^{13}C)$ of the C(11) nuclei in the complexes $[(\eta^5\text{-}Cp^*)M\{\eta^7\text{-}C_5Me_3(CH_2)_2\}]^{n+}$ ($n = 0, 1, 2$).

M	$\delta(^{13}C)$ /ppm	Charge	Ref.
Mo	56.2	0	16
Ru	88.4	2+	87
W	45.9	0	16
Re	53.8	1+	16
Os	71.1	2+	87

It can be seen from Table 5 that in the case of 18-electron complexes of Group 6, 7 and 8 metals with η^7-dimethylenecyclopentadienyl ligands, the δ values decrease with a decrease in the overall charge of the complex, *i.e.*, in the series: doubly charged > singly charged > neutral. This can be seen in Table 8.

Therefore, for 18-electron complexes of Group 6, 7 and 8 metals (W, Re, Ru, Os), deshielding (an increase in the δ values) is typically observed on passing from η^6-monomethylene (neutral or singly charged) complexes to η^7-dimethylene compounds (singly or doubly charged). However, for neutral 16-electron Ti complexes, no regularities in the variation of chemical shifts on passing from η^6-monomethylene to η^7-dimethylene compounds, nor changes in the X-ray diffraction characteristics can be revealed.

It should be noted that for primary CH_2 derivatives, it is easier to elucidate regular features in the variation of the δ values depending on the nature of the metal atom, the charge or other electronic effects than for secondary CHR^1 and tertiary CR^1R^2 complexes due to the spatial and electronic effects of the substituents R^1 and R^2. The observed decrease in the δ values following the migration from top to bottom along the Groups appears to be quite natural, because the diffuseness of atomic orbitals of transition metals tends to increase from top to bottom along the Subgroups. On the basis of EHT calculations[95] for the cationic complexes of Group 8 metals, $[Cp^*M(C_5Me_4CH_2)]^+$ (M = Fe, Ru, Os), it was shown that the M–C(11) bond order increases ($0.01 < 0.16 < 0.22$) in the sequence Fe $\ll$ Ru < Os. It is common knowledge that the bond length increases following a decrease in the bond order. The shielding constant σ (or its paramagnetic component σ_p, which makes the greatest contribution to this constant), is a function of a charge density and the M–C(11) bond order. This clarifies the observed decrease in the δ values of the C(11) nuclei for the $[Cp^*M(C_5Me_4CH_2)]^+$ cations in the sequence Fe > Ru > Os. Apparently, similar regularities are also typical of cationic and neutral $\eta^6\text{-}C_5R^1_4CR^2R^3$ complexes formed by metals of other Groups.

2. The spin–spin coupling constants $^1J_{CH}$ for η^6 and η^7 neutral and cationic complexes

Apart from the data on chemical shifts, the spin–spin coupling constants ($^1J_{CH}$) of the carbon atom of the CHR groups are often used to determine the structures of cationic and neutral fulvene complexes. Unfortunately, no systematic research into the spin–spin coupling constants of isostructural cationic and neutral η^6-complexes of Group 4–8 metals has been carried out. A fairly large number of scattered $^1J_{CH}$ values have been reported in the literature. They are summarised in Table 9.

It can be seen that the spin–spin coupling constants ($^1J_{CH}$) for the CH_2 group in the series of the primary $[Cp^*M(C_5Me_4CH_2)]^+$ (M = Fe, Ru, Os) and for the CHR group in the series of the secondary $[Cp^*Os(C_5Me_4CHC_6F_5)]^+$ and $[CpM(C_5H_4CHPh)]^+$ (M = Ru, Os) cationic nonmethylated complexes of Group 8 metals and their neutral analogues barely depend on the nature of the metal.

Meanwhile, the coupling constants of the studied doubly charged dimethylene complexes, $[Cp^*M\{C_5Me_3(CH_2)_2\}]^{2+}$ (M = Ru, Os), and their neutral analogues (Table 10) show that these values increase somewhat on passing from neutral complexes to doubly charged ones. However, generally, the presented

data indicate that the spin–spin coupling constants for cationic and neutral compounds, unlike the tilt angles of the $C_{Cp}-CHR$ bond relative to the metal (α), the $M-C_\alpha R$ distances, or the chemical shifts δ, are little dependent on the degree of interaction of the metal with the carbocationic centre or a vacant orbital.

VII. Quantum-chemical description of complexes

The electronic structure of the α-ferrocenylmethyl cation (the cationic fulvene complex), $[CpFe(C_5H_4CH_2)]^+$, was first calculated by the EHT method with charge self-consistence.[96] Gleiter and Seeger[96] have predicted the most typical feature of the structure of complexes of this type, namely, distortion of the planarity of the fulvene ligand, which is manifested as a deviation of the carbon atom of the CH_2 group toward the metal atom (the angle α) through 40°. The researchers also showed that the charge on the Fe atom in this monocation is 0.5, while the rest of the charge (0.5) is delocalised over all carbon atoms of the ligands. Subsequently, it has been shown that neutral and cationic complexes, $[L_nM(C_5H_4CR^1R^2)]^{m+}$ [$L_nM = (CO)_3Cr$, $m = 0$; L_nM = CpFe, $m = 1$] with a fulvene ligand have a similar structure.[97] In a more recent study,[95] EHT calculations for a number of monocations, $[Cp'M(C_5R_4CH_2)]^+$ (M = Fe, Ru, Os; Cp′ = Cp, Cp^*; R = H, Me), were used to calculate the angles α, the energy gaps ($\Delta E = E_{LUMO} - E_{HOMO}$), the charges on the metal atoms (Q) and the CH_2 groups (q), and Mulliken bond orders (Table 11).

It is of interest that the minimum total energy (*i.e.*, the most effective $Mo-CH_2$ interaction) in the neutral fulvene complex $(C_6H_6)Mo(\eta^6\text{-}C_5H_4CH_2)$ corresponds to the angle $\alpha = 35°$ (see Ref. 54), which is well correlated with the experimental values for the angle α (37–39°) found for $(C_6H_5R^1)M(\eta^6\text{-}C_5H_4CR^2_2)$ (M = Mo, W; R^1 = H, Me; R^2 = Me, Ph). Similar calculations for the neutral fulvene complex, $(CO)_3Cr(\eta^6\text{-}C_5H_4CH_2)$, give $\alpha = 21°$ (according to X-ray diffraction data, the angle α in this complex equals 35°).[75]

Table 11. Energy and charge characteristics of the $[(C_5R_5)M(C_5R_4CH_2)]^+$ cations according to EHT calculations.[95]

R	M	α /deg	ΔE /eV	Q(M)	q(CH_2)
H	Fe	5.0	1.28	0.25	0.36
H	Ru	41.5	1.68	1.48	0.04
H	Os	35.0	0.85	0.85	0.12
Me	Fe	26.0	1.33	0.10	0.31
Me	Ru	40.3	2.53	1.35	−0.13
Me	Os	41.8	3.32	0.84	−0.08

The molecular orbital energies for a number of neutral Ti complexes, $(\eta^5\text{-}Cp^*)TiMe(\eta^6\text{-}C_5Me_4CH_2)$, $(\eta^5\text{-}C_5HMe_4).TiMe(\eta^6\text{-}C_5HMe_3CH_2)$, $(\eta^5\text{-}Cp^*)Ti(\eta^6\text{-}C_5Me_4CH_2)$ and $(\eta^5\text{-}Cp^*)TiMe\{\eta^7\text{-}C_5Me_3(CH_2)_2\}$ have been calculated by the EHT method.[98] For the cationic complexes, $[(\eta^5\text{-}Cp)Os(\eta^6\text{-}C_5H_4CH_2)]^+$ and $[(\eta^5\text{-}Cp)Os\{C_5Me_3(CH_2)_2\text{-}\eta^7\}]^{2+}$, the angles α (40 and 35°, respectively) calculated by EHT[87] were compared with the values obtained experimentally for the $[(\eta^5\text{-}Cp^*)Os(\eta^6\text{-}C_5Me_4CH_2)]^+$ complex ($\alpha = 41.8°$).[95] The calculated $Os-CH_2$ bond length in the $[CpOs\{C_5Me_3(CH_2)_2\}]^{2+}$ complex is 2.33 Å.[99]

The M–C(11) and M–C(1) bond lengths and the tilt angles α in 18-electron singly and doubly charged cationic $\eta^6\text{-}C_5Me_4CH_2$ and $\eta^7\text{-}C_5Me_3(CH_2)_2$ complexes of Group 8 metals calculated using the density functional theory (DFT)[100] are listed in Table 12. It can be seen that the calculated M–C(11) bond lengths tend to increase on passing from η^6-complexes to η^7-complexes. This is indicative of some decrease in the metal–carbocation centre interaction in doubly charged complexes with respect to similar singly charged ones. Comparison of the data of Tables 3 (X-ray diffraction data) and 12 (DFT calculations) shows that the structures of the complexes in the crystal and in the gas phase are somewhat different. A more detailed consideration of the data published in original publications[100,101] permits the conclusion that transition from the gas phase to a condensed (crystalline) state induces the most pronounced change in the M–C(11) bond length, while the lengths of the metal bonds with other atoms of the ligand change insignificantly. Similar conclusions were drawn in another study[70] in which X-ray diffraction analysis and DFT calculations for the $[CpRu(C_5H_4CH_2)]^+$ cationic complex have been performed. Doubly and especially triply charged complexes (see below) also tend to undergo structural changes on passing from the gas phase into a condensed state (solution).

Table 12. Calculated geometric parameters in the cationic complexes of Group 8 metals with the $\eta^6\text{-}C_5Me_4CH_2$ and $\eta^7\text{-}C_5Me_3(CH_2)_2$ ligands.[23,100]

Compound	M–C(11) /Å	M–C(1) /Å	The angle α /deg

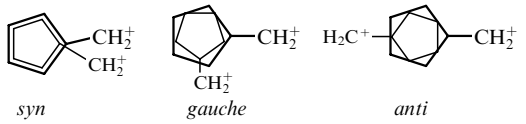
The angles α and other geometric parameters, charge characteristics and the rotation energies for the *syn*, *gauche*- and *anti*-conformers of the $[M(C_5Me_4CH_2)_2]^{2+}$ cationic complexes (M = Fe, Ru, Os) have been reported.[99, 100] The EHT calculations showed [99] that of the three possible conformers (*syn, gauche* and *anti*), *gauche*-conformers are thermodynamically most stable in the gas phase and in solutions.



syn *gauche* *anti*

The calculated α values for the *gauche*-conformers of the Fe, Ru and Os complexes are 30, 40 and 40° (EHT data [99]), and the M–C(11) bond lengths are 2.43, 2.20 and 2.22 Å, respectively.

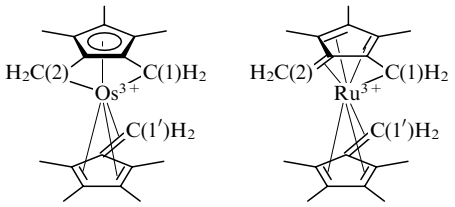
In the *gauche*-conformer, the overlap energy of the corresponding orbitals of the metal atom and the ligands exceeds the Coulomb repulsion energy (which is the lowest in the *anti*-conformer). This is not surprising, because, according to the same calculations, the CH_2 groups bear virtually no positive charge, the charge being concentrated almost entirely on the metal atom. The results of EHT calculations for the structures of doubly charged complexes (predominance of *gauche*-conformers) were confirmed by ^{1}H NMR spectra.[99]

The higher thermodynamic stability of the *gauche*-conformers for the ruthenium complexes was confirmed by subsequent calculations (DFT *ab initio*).[100] Meanwhile, for the osmium analogue, the energies of the *anti*- and *gauche*-conformers are equal.[23] Density functional theory calculations indicate higher thermodynamic stability of 1,2-dimethylene complexes compared to 1,1′-dimethylene complexes.[100] It follows from the results of the same calculations (see Table 12) that in the $[Cp^*Ru\{C_5Me_3(CH_2)_2\}]^{2+}$ and $[Os(C_5Me_4CH_2)_2]^{2+}$ complexes, the distances from the metal atom to both carbocation centres are identical, while in $[Cp^*Os\{C_5Me_3(CH_2)_2\}]^{2+}$ and $[Ru(C_5Me_4CH_2)_2]^{2+}$, these distances are different. In the condensed state (in solution), the interaction of the metal atom with both carbocation centres is the same in any of the four complexes, as indicated by the ^{13}C NMR data [the presence of only one signal from C(11) nuclei]. Thus, in this case, too, the structures of the cationic species in the gas phase and in solution are somewhat different.

VIII. Trimethylene complexes

The representation of η⁶-fulvene and η⁷-allyldiene complexes as a 'specific' resonance hybrid of structures **A** ↔ **B** or **C** ↔ **D** (see Section II) is especially significant for describing the structures of complexes containing three methylene groups in the molecule. It is noteworthy that the whole set of chemical, structural and calculated data available until recently did not allow one to distinguish clearly and unambiguously the structures of mono- and dimethylene complexes. Apparently, it should be stated that forms **B** (σ,η⁵) and **D** (σ,σ,η⁵) are characterised by more substantial donor–acceptor interaction between the metal LEP and the vacant orbitals of carbon atom(s) and, hence, by shorter M–C(11) bonds and greater tilt angles of the C(1)–C(11) bond toward the metal atom than forms **A** and **C**. These shorter bonds can be called metallonium.[101]

The complexes containing three methylene groups in the molecule have been prepared by oxidation of decamethylmetallocenes or monocations **8** (M = Ru, Os) with molecular oxygen in a CF_3SO_3H solution.[20, 39] Their structure has been described in the literature.[22, 101] The Group 8 metal atoms (Fe, Ru, Os) are known to contain three lone electron pairs in three non-bonding orbitals. The LEP are able to interact with three vacant orbitals of the carbon atoms of three carbocation centres or, in other words, they can stabilise the compounds containing three CH_2 groups. According to calculations, in these compounds, the major portion of the positive charge is concentrated on the metal atom.[22, 101] However, it should be noted that, as shown by DFT calculations, in the $[Cp^*M\{\eta^7\text{-}C_5Me_3(CH_2)_2\text{-}1,2\}]^{2+}$ and $[M(\eta^6\text{-}C_5Me_4CH_2)_2]^{2+}$ dimethylene complexes (M = Ru, Os), the lengths of both M–CH_2 bonds in the gas phase are either equal or do not differ much (see Table 12).[100] However, in trimethylene osmium complex **46**, the Os–C(1′)H_2 bond length is much longer (2.768 Å) than the other two lengths, Os–C(1)H_2 and Os–C(2)H_2 (2.431 and 2.435 Å , respectively) and the angles α are 27.2, 26.2 and 20.4°, respectively, *i.e.*, this complex can be described by structure **D**(σ,σ,η⁵),**A**(η²,η⁴). For the Ru analogue **47**, the Ru–C(1)H_2 bond is markedly shorter (2.442 Å) than the Ru–C(2)H_2 and Ru–C(1′)H_2 bonds (2.925 and 2.950 Å, respectively) and the angles α are 20.8, 13.4 and 11.7°, respectively, *i.e.*, the trication has structure **C**′(σ,η²,η⁴),**A**(η²,η⁴). In other words, osmium complex **46** is characterised by the presence of two metallonium bonds and one fulvene fragment, and the ruthenium analogue **47** has only one metallonium bond and two fulvene fragments. The spatial structure of both complexes is similar to that for the *gauche*-conformers of the corresponding complexes **13**.



46 (**D**,**A**) **47** (**C**′,**A**)

Thus, according to DFT calculations, the trimethylene ruthenium and osmium complexes have different structures in the gas phase, the Os compound having two short bonds and the Ru analogue containing one short bond. This circumstance indicates that the interaction between the metal atom and the carbocation centres is enhanced from top to bottom along the Group. This trend has been noted above for mono- (**8**) and dimethylene (**12**) complexes; however, in the case of complexes **46** and **47**, it is most pronounced.

The presence of three methylene groups in the molecules of complexes **46** and **47** was proved unambiguously by ^{1}H and ^{13}C NMR spectroscopy (Table 13).[20, 22, 39, 101] According to NMR

Table 13. ^{1}H and ^{13}C NMR spectral data for mono-, di- and trimethylene complexes of ruthenium and osmium.

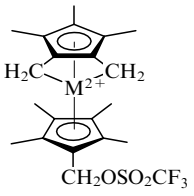
Note. s is singlet, d is doublet, t is triplet.

spectral data, the structures of Ru- and Os-containing derivatives are similar. It should be noted that the DFT calculations also confirm the existence of three methylene groups in these compounds. The enthalpies of formation (ΔH) of complex **8a** from Cp^*_2Ru, complex **12a** from **8a** and complex **47** from **12a** in the gas phase are -232.2, -124.5 and -13.6 kcal mol^{-1}, respectively,[101] *i.e.*, complex **47** is thermodynamically stable, although its stability is an order of magnitude lower than that for complex **12a**. Thus, according to these calculations, there is a certain probability that trimethylene complexes would be formed in solutions. Indeed, upon the reaction of metallocenes or monomethylene complexes with oxygen in a solution of a strong acid (superacid), three methyl groups are oxidised to give three carbocation centres. However, the ways of stabilisation and, correspondingly, the forms of existence of these unusual species in solution may differ from those of the previously studied analogues **8** and **12**, which have a smaller charge. Thus the ^{1}H and ^{13}C NMR spectra of trimethylene compounds exhibit a number of specific features, which call for discussion. Table 13 presents the chemical shifts (δ) and the spin–spin coupling constants observed in the ^{1}H and ^{13}C NMR spectra of compounds $[Cp^*M(\eta^6\text{-}C_5Me_4CH_2)]^+$ (**8a**,**b**), $[Cp^*M\{\eta^7\text{-}C_5Me_3(CH_2)_2\text{-}1,2\}]^{2+}$ (**12a**,**b**) and $[(\eta^6\text{-}C_5Me_4CH_2)M\{\eta^7\text{-}C_5Me_3(CH_2)_2\text{-}1,2\}]^{3+}$ (**48a**,**b**) formed in solution.



48a,**b**

M = Ru (**a**), Os (**b**).

The ^{1}H NMR spectra of trimethylene cations **48a**,**b** exhibit two doublets and one singlet (the ratio of integral intensities is 1 : 1 : 1). Thus, the species obtained in solution really have three methylene groups and a plane of symmetry[20,39] that passes through one of these groups half way between the other two. Presumably, the structure of molecules in solution is analogous, to an extent, to the structure in the gas phase. Meanwhile, the data of the ^{13}C NMR spectra clearly indicate that in Ru- and Os-containing molecules, the metal atom interacts differently with the three carbocation centres and that in both species, the interaction with two of these centres markedly differs from the interaction with the third one. Thus, the structure of the osmium complex in solution does not contradict its structure in the gas phase (according to DFT calculations), whereas the structures of the Ru analogue in solution and in the gas phase are different, *i.e.*, transition from the gas phase to a solution induces more pronounced structural changes in the case of less stable Ru species.

It follows from the data of Table 13 that on passing from compounds **8a**,**b** to **12a**,**b**, the resonance carbon signals substantially shift downfield and the spin–spin coupling constants slightly decrease. Conversely, in the ^{13}C NMR spectra of complexes **48a**,**b**, the δ values and spin–spin coupling constants of the signals for the CH_2 groups of the η^7-$C_5Me_3(CH_2)_2$-1,2 ligand virtually coincide with those for complexes **12a**,**b**. However, the signals for the CH_2 groups of the η^6-$C_5Me_4CH_2$ ligand are shifted upfield, this signal for ruthenium complex **48a** being located in even higher field than in compound **8a**. The coupling constants of the CH_2 group in the trimethylene complex also decrease somewhat with respect to those observed for the monomethylene complex. In addition, the δ values for the carbon nuclei of the CH_2 groups of the η^7-$C_5Me_3(CH_2)_2$-1,2 ligand in complexes **12** and **48** decrease substantially on passing from Ru to Os (higher shielding), whereas the signals for the CH_2 groups of η^6-$C_5Me_4CH_2$ in complexes **48a**,**b** almost coincide (*i.e.*, the chemical shift does not depend on the nature of the metal).

Of course, it cannot be stated with full confidence that on passing from dimethylene complexes to trimethylene complexes, the NMR spectra should show the same trends (a decrease in shielding) as those observed (as has been shown above for numerous examples) on passing from neutral fulvene complexes to singly and doubly charged ones. In the general case, there is no direct correlation between the charge on the carbon atom and the ^{13}C NMR chemical shift of this atom; however, for singly, doubly and triply charged compounds (almost isostructural or with similar structures), the regularities we found in the variation of spectral characteristics allow one to ascribe structures **46** and **47** to the trimethylene species in the gas phase.

The stabilisation of the trimethylene complexes formed in solutions differs from that for complexes **8a**,**b** and **12a**,**b**. Apparently, complexes **8** and **12** in solutions of acids tend to form solvent-separated ion pairs and the nature of the anion (counterion) virtually does not influence the structure of the cations. For the triply charged trimethylene complexes, the interion (cation–anion) interaction is so pronounced that it seems to result in contact ion pairs or, more likely, a covalent bond. According to X-ray diffraction data (see above), the monomethylene cations **8a**,**b** and the BPh_4^- anions[68,72] are arranged in the crystal lattice fairly far from each other. The mono- (**8a**,**b**) and dimethylene cations (**12a**,**b** and **13a**,**b**) occur in solutions of CF_3SO_3H as kinetically independent species with the $CF_3SO_3^-$ anion, and trimethylene species **46**, **47** are partially esterified (at one methylene group) under these conditions to give esters **48a**,**b**.[22] In the ^{13}C NMR spectra, the signals of the CH_2 groups linked covalently to the O_3SCF_3 group are manifested as triplets (δ 65.7 and 65.8, J 157 Hz), while the ^{1}H NMR signals (δ 5.50 and 5.49) are singlets. The observed spin–spin coupling constants and chemical shifts are typical of CH_2 groups linked to two electron-withdrawing substituents, $[Ru]^{2+}$ and $CF_3SO_3^-$, which implies structure **48a**,**b**.[102]

IX. Conclusion

The data presented in this review show that the chemistry of neutral and cationic tetramethylfulvene and trimethylallyldiene complexes of transition metals is of substantial interest. These complexes have been obtained for almost any of Group 4–10 transition metals; they contain a non-planar six- (η^6) or seven-electron (η^7) ligand with a substantial deviation of one or two carbon atoms from the plane of the Cp ring toward the metal atom. This is indicative of the interaction of the LEP of the metal atom with the carbocation centre in cationic complexes or with the corresponding vacant orbital of the fulvene ligand in neutral complexes. The degree of this interaction increases from top to bottom along the Subgroups of the Periodic Table. These structural features (relatively low symmetry) of tetramethylfulvene and trimethylallyldiene complexes determine their properties and distinguish them from η^6-arene or η^7-cycloheptatrienyl complexes with a higher symmetry. The tetramethylfulvene and trimethylallyldiene transition metal complexes are characterised by (i) general methods for the synthesis (mainly, from η^5-pentamethylcyclopentadienyl precursors); (ii) essential similarity in the chemical behaviour [many reactions involving these complexes occur *via* the formation of odd-electron (17- and 19-electron) intermediates]; (iii) rupture of the M–C(11) bond on treatment with nucleophiles (more rarely, electrophiles) to give η^5-derivatives with the C(11)–Nu bond; (iv) similarity of the structural and spectral characteristics, which often do not depend on whether or not the complex is charged. Apparently, these properties allow one to classify tetramethylfulvene and trimethylallyldiene complexes, to a certain approximation, as a separate class of chemical compounds.

Abstract. Data on substitution reactions at boron atoms in 10 – 12-vertex metallacarboranes, which are of fundamental and applied significance, are generalised. The possible mechanisms of substitution reactions and the influence of the metal fragment on substitution positions in the polyhedron are discussed. The bibliography includes 161 references.

I. Introduction

For many years, metallacarboranes † were of only academic interest.[2 – 7] Most studies of this period were devoted primarily to the construction of unusual chemical structures and investigation of their structural features. Metallacarboranes, whose polyhedral cage contains both transition and main-group metals of all groups of the periodic table, have already been synthesised. In recent years, practical aspects of the use of metallacarboranes have attracted increasing interest [8] because some compounds of this class were found to possess useful properties. For example, particular metallacarboranes show promise as catalysts,[9 – 12] extractants for nuclear waste processing,[13 – 18] new materials for microelectronics [19 – 23] or drugs in nuclear medicine.[24 – 28]

The synthesis of new compounds and materials possessing desired properties is associated with the necessity of changing the structural parameters responsible for the qualitative and quantitative characteristics of compounds. In the case of metallacarboranes, such changes can be achieved by varying either components of the molecule (metal atoms and organic ligands involved in the metal coordination sphere) or the structure and electronic properties of the carborane fragment. The latter can be achieved by introducing various substituents, which are responsible for the final properties of the compounds synthesised, into the carborane fragment.

Therefore, the synthesis and investigation of substituted metallacarboranes are of both fundamental and applied importance.

In this connection, studies of substitution reactions in metallacarborane systems and elucidation of the characteristic features of these processes are of particular interest.

There are two approaches to the synthesis of substituted metallacarboranes: (1) the synthesis from substituted carborane ligands and metal complexes (salts), (2) substitution in the already available metallacarborane molecule. The first approach is used primarily for the construction of metallacarboranes containing substituents at carbon atoms [5, 6, 29 – 32] and is virtually the only procedure for the synthesis of such derivatives. Examples of substitution at carbon atoms in metallacarboranes are scarce.[33, 34] Metallacarboranes containing substituents at boron atoms are synthesised primarily with the use of the second procedure.

The present review surveys data on substitution in metallacarboranes, which were published primarily in the last 15 years, some earlier investigations being also included.

The published data are classified according to the types of carborane ligands. Substitution reactions in small metallacarboranes, *viz*., *nido*-C_2B_4-carborane derivatives, are beyond the scope of our review because the chemistry of the latter has been covered in the excellent review by Grimes [35] (see also recent studies [36 – 40]).

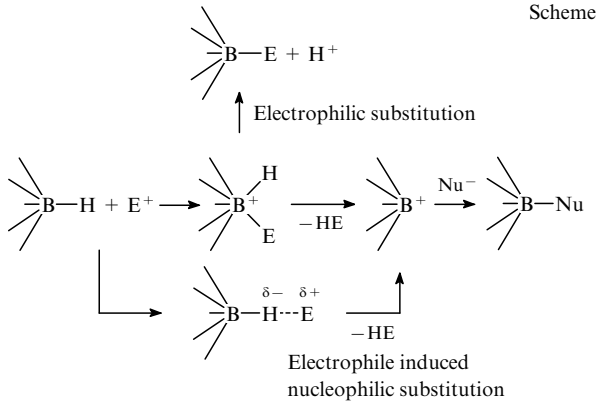
II. Mechanisms of substitution in metallacarboranes

At pesent, polyhedral boron hydrides are commonly considered as three-dimensional aromatic systems.[41] In particular, halogenation and mercuration of carboranes are adequately described within the framework of the mechanism of electrophilic aromatic substitution. Since metallacarboranes are derivatives of polyhedral boron hydrides, it is reasonable to assume that this mechanism is one of the main mechanisms of substitution in metallacarboranes. Apparently, most substitution reactions considered below proceed according to this mechanism.

At the same time, taking into account the hydride character of hydrogen atoms in polyhedral boron hydrides, another possible mechanism may involve the attack of an electrophilic agent resulting in elimination of the hydride hydrogen atom to form a pseudoelectrophilic centre on the boron atom, which is then subjected to the attack of a nucleophilic species (Scheme 1). This mechanism is called Electrophile Induced Nucleophilic Substitution (EINS).[42, 43] The nature of the intermediate generated upon the attack of the electrophilic agent remains unclear. Probably, this is the arenium ion (Wheland intermediate), from which both

† First representatives of this class were synthesised in 1965.[1]

Scheme 1



the electrophilic species and the hydride hydrogen atom are simultaneously eliminated. Another possible intermediate is an ion pair formed by the electrophilic species and the hydride hydrogen atom.

Electrophile induced nucleophilic substitution is the mechanism of numerous reactions of polyhedral boron hydrides with solvent molecules accompanied by the formation of numerous charge-compensated derivatives, in which the solvent molecule (tetrahydrofuran, 1,4-dioxane or tetrahydropyran) serves as a substituent bound to the boron atom.[44–47] Acid-catalysed nucleophilic substitution reactions, in particular, the formation of acetoxy and hydroxy derivatives, also proceed according to this mechanism.[48–50]

It should be noted that many substitution reactions can occur by two competitive mechanisms to form mixtures of products of both electrophilic and nucleophilic substitution. An example is acylation of the dodecahydro-*closo*-dodecaborate anion $[B_{12}H_{12}]^{2-}$ giving rise both to the acyl derivative $[B_{12}H_{11}COR]^{2-}$ (product of electrophilic substitution) and the hydroxy derivative $[B_{12}H_{11}OH]^{2-}$ (product of electrophile induced nucleophilic substitution).[51] The ratio between the products of electrophilic and nucleophilic substitution is determined by the strength of the attacking electrophilic agent.

In addition to substitution reactions typical of all polyhedral boron hydrides, substitution reactions involving the metal atom occur in metallacarboranes containing labile ligands in the metal coordination sphere.

It is of importance to determine the substitution position in metallacarboranes. Earlier studies of electrophilic substitution of hydrogen atoms in icosahedral *o*- and *m*-carboranes $C_2B_{10}H_{12}$ have demonstrated that the reactions proceed primarily at the boron atoms, which are most spatially remote from carbon atoms, *i.e.*, at the boron atoms in position 9.[52,53] The presence of the metal fragment has a substantial effect on the direction of substitution in the metallacarborane moiety.

III. Substitution in 12-vertex metallacarboranes

1. Derivatives based on the 7,8-dicarbollyl ligand $[7,8\text{-}C_2B_9H_{11}]^{2-}$

Since the 7,8-dicarbollyl ligand $[7,8\text{-}C_2B_9H_{11}]^{2-}$ is readily accessible, substitution in icosahedral metallacarboranes based on this ligand has been well studied. This ligand is prepared by partial destruction of the icosahedral carborane cage *o*-$C_2B_{10}H_{12}$ with bases.[52] Among numerous metallacarboranes, cobalta-, ferra- and nickelacarboranes $[3\text{-L-}3,1,2\text{-}MC_2B_9H_{11}]^{n-}$ based on the 7,8-dicarbollyl ligand (Fig. 1) were studied in most detail.[5,6]

Bromination of bis(1,2-dicarbollyl)cobalt [*commo*-3,3′-Co(1,2-$C_2B_9H_{11})_2]^-$ (**1**) (the atomic numbering scheme is shown in Fig. 1 *d*)[54] was the first example of substitution in metallacarboranes. Later on, halogenation of anion **1** was studied by different research groups of chemists. Substitution was demonstrated to proceed stepwise. Initially, the hydrogen atoms at

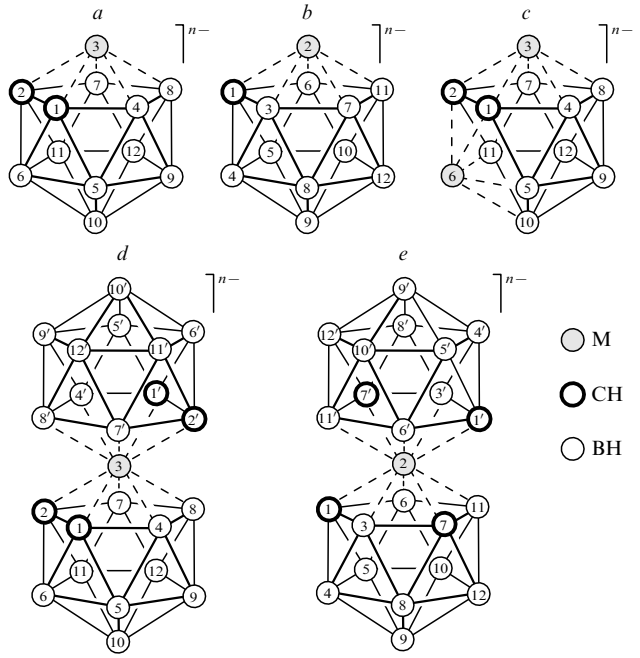


Figure 1. Atomic numbering schemes for different types of icosahedral metallacarboranes.
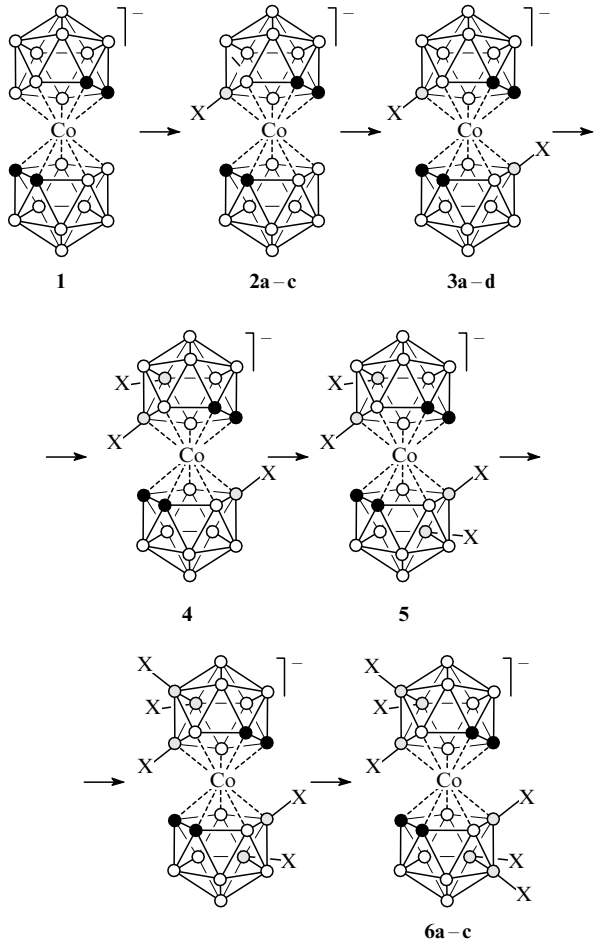
(*a*) 1,2-dicarba-3-metalla-*closo*-dodecaborane, (*b*) 1-carba-2-metalla-*closo*-dodecaborane, (*c*) 1,2-dicarba-3,6-dimetalla-*closo*-dodecaborane, (*d*) *commo*-3,3′-metallabis(1,2-dicarbollide), (*e*) *commo*-2,2′-metallabis(1,7-dicarbollide).

positions 8 and 8′ adjacent to the metal atom are replaced. In the next step, the hydrogen atoms at positions 9, 9′ and 12, 12′, which are most remote from the carbon atoms, are replaced. Examples are chlorination of *o*- and *m*-carboranes (Scheme 2). For instance, when passed through a solution of Cs[*commo*-3,3′-Co(1,2-$C_2B_9H_{11})_2$] (Cs[**1**]) in an EtOH – CCl_4 or $PhNO_2$ – CCl_4 mixture, chlorine successively replaces the hydrogen atoms at the B(8), B(8′), B(9), B(9′), B(12) and B(12′) atoms to form Cs[8-Cl-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] (Cs[**2a**]), Cs[8,8′-Cl_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$] (Cs[**3a**]), Cs[8,8′,9-Cl_3-3,3′-Co(1,2-$C_2B_9H_9$)(1′,2′-$C_2B_9H_{10}$)] (Cs[**4**]), Cs[8,8′,9,9′-Cl_4-3,3′-Co(1,2-$C_2B_9H_9)_2$] (Cs[**5**]) and Cs[8,8′,9,9′,12,12′-Cl_6-3,3′-Co(1,2-$C_2B_9H_8)_2$] (Cs[**6a**]).[55]

The reaction of Cs[**1**] with bromine in methanol at room temperature affords either Cs[8-Br-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] (Cs[**2b**]) or Cs[8,8′-Br_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$] (Cs[**3b**]) depending on the reagent ratio.[55] The reaction of [Me_3NH][**1**] with bromine in boiling tetrahydrofuran produces the dibromo derivative [Me_3NH][**3b**].[56] The reaction of Rb[**1**] with an excess of bromine in boiling acetic acid yields the hexabromo derivative Rb[8,8′,9,9′,12,12′-Br_6-3,3′-Co(1,2-$C_2B_9H_8)_2$] (Rb[**6b**]).[54]

The reaction of Cs[**1**] with iodine in methanol at room temperature produces the monoiodo derivative Cs[8-I-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] (Cs[**2c**]),[55] whereas the reaction with a small excess of iodine in ethanol[55] or in acetic acid (at 100 °C)[57] gives rise to the diiodo derivative Cs[8,8′-I_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$] (Cs[**3c**]). The latter can also be prepared by refluxing Cs[**1**] with iodine chloride.[58] The cross-coupling reactions of the monoiodo-substituted derivative Cs[**2c**] with organomagnesium and -zinc compounds in the presence of a Pd catalyst afford the corresponding alkyl and aryl derivatives [8-R-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]$^-$ (R = Me, Et, Ph, CH_2CH_2Ph, C_6H_4Bu-4, C_6H_4OMe-4, C_6H_4Ph-4, 9-anthracenyl, 2-thienyl).[59,60] The reactions of Cs[**3c**] with RMgBr (R = Me or

Scheme 2



Here and below ● CH ○ BH ⊙ B;
X = Cl (**a**), Br (**b**), I (**c**), F (**d**).

Et) form Cs[8,8′-R_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$] along with [8-R-8′-OH-3,3′-Co(1,2-$C_2B_9H_{10})_2$]$^-$ as a by-product.[58]

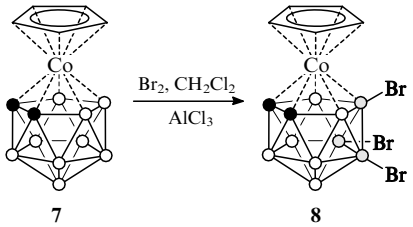
The reaction of Cs[**1**] with a high excess (more than sixfold) of iodine in the presence of $AlCl_3$ in benzene made it possible to prepare the hexaiodo derivative Cs[8,8′,9,9′,12,12′-I_6-3,3′-Co(1,2-$C_2B_9H_8)_2$] (Cs[**6c**]).[55] The compound Cs[**6c**] can also be synthesised with the use of iodine chloride.[61] The iodine atoms in Cs[**6c**] are readily replaced with methyl groups by the reaction with MeMgBr in the presence of $PdCl_2(PPh_3)_2$ and CuI in boiling THF. The corresponding hexamethyl derivative [8,8′,9,9′,12,12′-Me_6-3,3′-Co(1,2-$C_2B_9H_8)_2$]$^-$ was isolated as the triphenylmethylphosphonium salt.[61]

The difluoro derivative [Bu_4N][8,8′-F_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$] ([Bu_4N][**3d**], the yield was 80%) was prepared by the reaction of [Bu_4N][**1**] with an excess of 4-chloromethyl-1-fluorobicyclo[2.2.2]octane-1,4-diazonium bis(tetrafluoroborate) in acetone at 50 °C.[62]

The structures of the compounds Cs[**2c**],[63] K[**3a**],[64] [$(Ph_3P)_2N$][**3a**],[56] Cs[**3c**],[65] [Bu_4N][**3d**],[62] [Me_4N][**6b**][66] and Cs[**6b**][67] were established by X-ray diffraction analysis. In the di- and hexahalogen-substituted derivatives, the dicarbollyl ligands adopt a transoid conformation.

It should be noted that the replacement at other positions of bis(dicarbollyl)cobalt (**1**) does not occur even under severe conditions. Such derivatives can be synthesised by the direct assembly of the metallacarborane fragment from $CoCl_2$ and the corresponding substituted carboranes. This procedure was used for the preparation of [9,9′-Cl_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$]$^-$,[55] [9,9′,12,12′-Cl_4-3,3′-Co(1,2-$C_2B_9H_9)_2$]$^-$,[55] [9,9′-Br_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$]$^-$,[68] [9,9′,12,12′-Br_4-3,3′-Co(1,2-$C_2B_9H_9)_2$]$^-$,[68] [4,4′,7,7′-Cl_4-3,3′-Co(1,2-$C_2B_9H_9)_2$]$^-$,[69] [4,4′,7,7′-Br_4-3,3′-Co(1,2-$C_2B_9H_9)_2$]$^-$ (see Ref. 69) and [9,9′-I_2-3,3′-Co(1,2-$C_2B_9H_{10})_2$]$^-$.[70]

Halogenation of unsymmetrical cobaltacarborane 3-Cp-3,1,2-$CoC_2B_9H_{11}$ (**7**) was studied in less detail. Depending on the reagent ratio, the reaction of compound **7** with bromine in dichloromethane in the presence of $AlCl_3$ affords mono-, di- and trisubstituted products. It is assumed that the first step of the reaction involves the replacement of the hydrogen atom at position 8 [like in the case of bis(dicarbollyl)cobalt] followed by the replacement of the hydrogen atoms at positions 9 and 12 of the dicarbollyl ligand. In the presence of an excess of bromine, the reaction yields the tribromo derivative 8,9,12-Br_3-3-Cp-3,1,2-$CoC_2B_9H_8$ (**8**).[71,72]



Refluxing of compound **7** in benzene with an excess of AlX_3 (X = Cl, Br, I) affords the corresponding monohalogen-substituted derivatives.[73] It is assumed that the substitution occurs at position 8. However, no evidence for this structure of the halogenation product was reported.

Due to the paramagnetic nature of Fe^{III}-based metallacarboranes, substitution in these compounds was studied in much less detail compared to substitution in Co^{III}-based metallacarboranes. Nevertheless, it can be assumed that these reactions proceed analogously. For example, chlorination of [*commo*-3,3′-Fe(1,2-$C_2B_9H_{11})_2$]$^-$ (**9**) affords the dichloro derivative [8,8′-Cl_2-3,3′-Fe(1,2-$C_2B_9H_{10})_2$]$^-$ (**10**). The structure of its potassium salt was established by X-ray diffraction analysis.[64]

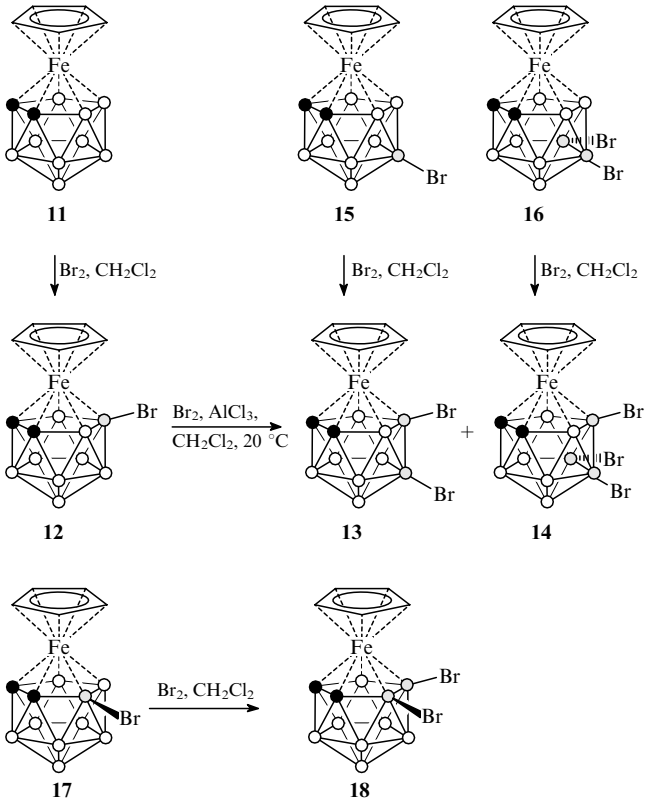
Halogenation of ferracarborane 3-Cp-3,1,2-$FeC_2B_9H_{11}$ (**11**) was studied more thoroughly. Bromination of compound **11** in dichloromethane at room temperature in the absence of a catalyst gives rise to the monobromo derivative 8-Br-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**12**) (Scheme 3). In the presence of $AlCl_3$, the substitution occurs less selectively and affords monobromide **12** along with dibromo [8,9-Br_2-3-Cp-3,1,2-$FeC_2B_9H_9$ (**13**)] and tribromo [8,9,12-Br_3-3-Cp-3,1,2-$FeC_2B_9H_8$ (**14**)] derivatives. Bromination in acetic acid and nitromethane proceeds analogously. The dibromo derivative **13** can also be prepared by bromination of 9-Br-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**15**) and the tribromo derivative can be synthesised by bromination of 9,12-Br_2-3-Cp-3,1,2-$FeC_2B_9H_9$ (**16**), which was prepared by direct synthesis from the corresponding substituted *nido*-carborane (Scheme 3).[74]

Bromination of 4-Br-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**17**) derived from the corresponding *nido*-carborane produces 4,8-Br_2-3-Cp-3,1,2-$FeC_2B_9H_9$ (**18**).[74]

The published data on mercuration of anion **1** are contradictory. The reaction of the mercury salt Hg[**1**]$_2$ with mercury acetate in boiling acetic acid forms the disubstituted product Hg[9,9′-$(AcOHg)_2$-3,3′-Co(1,2-$C_2B_9H_{10})_2$]$_2$. It was hypothesised that the hydrogen atoms most remote from the carbon atoms, *viz.*, those at positions 9,9′, are replaced.[75]

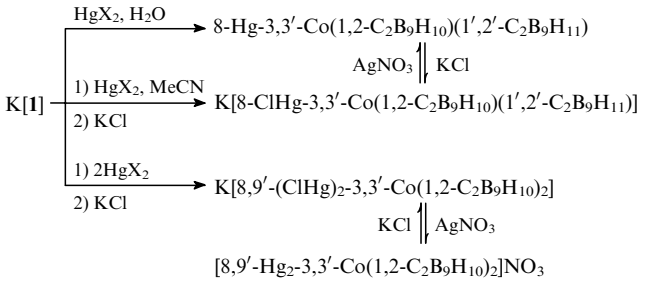
By contrast, mercuration of K[**1**] in an aqueous–organic medium leads to the replacement of one dicarbollyl ligand at position 8 followed by the replacement of another ligand at position 9′ (Scheme 4).[76] However, it should be noted that the proposed structures of the reaction products were not supported by rigorous evidence.

Scheme 3



The reaction of bis(dicarbollyl)nickel(IV), *viz*., *commo*-3,3′-Ni(1,2-$C_2B_9H_{11})_2$ (**19**), with mercury oxide in boiling trifluoroacetic acid followed by the replacement of the trifluoroacetate group with the chlorine atom gave rise to the disubstituted derivative $(ClHg)_2$-3,3′-Ni(1,2-$C_2B_9H_{10})_2$ (substitution positions were not established).[77]

Scheme 4

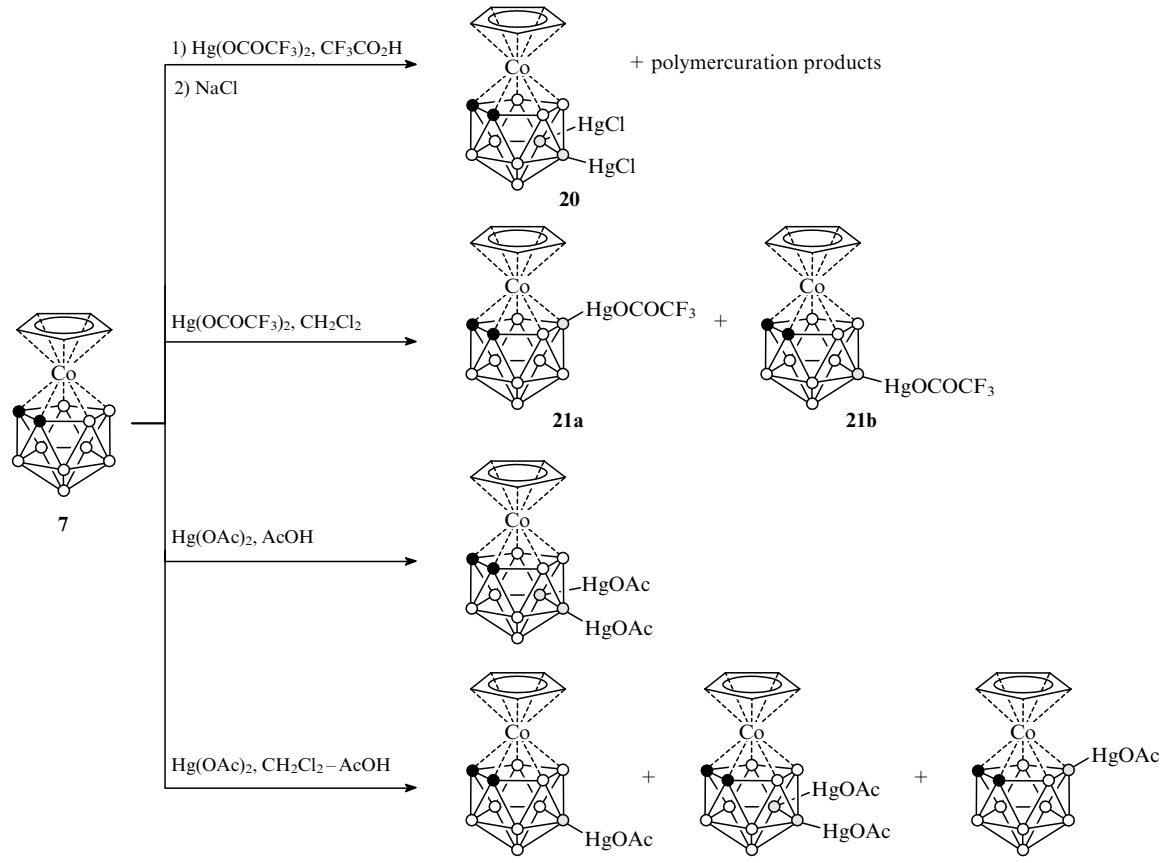


X = BF_4, AcO, CF_3CO_2.

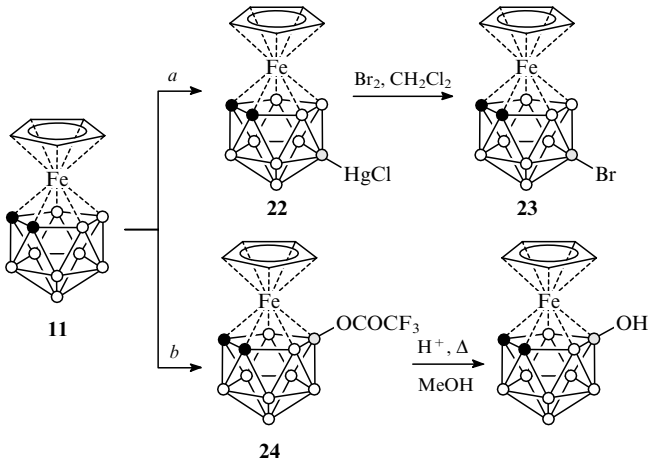
Mercuration of compound **7** was examined in the studies.[75,78] It was noted that different products can be prepared by varying the reaction conditions. For example, mercuration under severe conditions, *i.e*., the reaction of cobaltacarborane **7** with mercury trifluoroacetate in trifluoroacetic acid followed by treatment with NaCl in a water–acetone system, afforded the disubstituted derivative 9,12-$(ClHg)_2$-3-Cp-3,1,2-$CoC_2B_9H_9$ (**20**) and polymercuration products (Scheme 5). The reaction with the use of a softer system (mercury trifluoroacetate in dichloromethane) yielded a mixture of two isomeric 8- (**21a**) and 9-substituted (**21b**) monomercury derivatives in a ratio of 1 : 5. The structure of the 9-substituted monomercury derivative was confirmed by X-ray diffraction analysis.[78] A diacetomercury-substituted derivative was prepared by the reaction of compound **7** with mercury acetate in acetic acid, whereas the reaction in the CH_2Cl_2–AcOH system gave rise to a disubstituted complex along with two isomeric 8- and 9-substituted monomercury derivatives.

The 9-chloromercury derivative 9-ClHg-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**22**) was synthesised by mercuration of ferracarborane **11** with mercury trifluoroacetate in a trifluoroacetic acid–

Scheme 5



Scheme 6



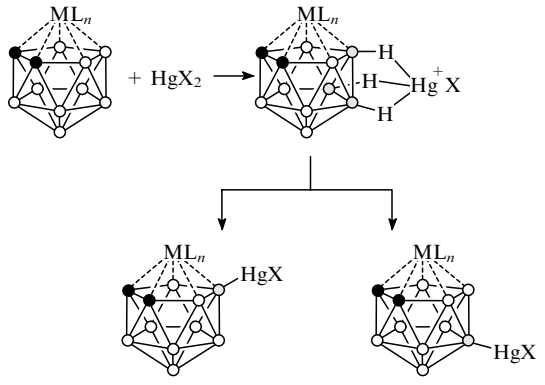
(*a*): 1) $Hg(OCOCF_3)_2$, $CF_3COOH - CH_2Cl_2$, 2) NaCl, H_2O;
(*b*): $Tl(OCOCF_3)_3$, Δ, CF_3COOH.

dichloromethane mixture followed by the replacement of the trifluoroacetoxy group with chlorine (Scheme 6). The reaction of compound **22** with bromine in dichloromethane afforded the corresponding bromide, *viz*., 9-Br-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**23**).[79]

In attempting to prepare a thallium derivative by heating ferracarborane **11** with thallium(III) trifluoroacetate in trifluoroacetic acid, the 8-trifluoroacetoxy derivative 8-CF_3COO-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**24**) was isolated instead of the expected thallation product. The structure of this reaction product was established by X-ray diffraction analysis.[80] The reaction with cobaltacarborane **7** proceeds analogously. However, this reaction afforded the 8-trifluoroacetoxy derivative 8-CF_3COO-3-Cp-3,1,2-$CoC_2B_9H_{10}$ along with a small amount of the 8-hydroxy derivative 8-OH-3-Cp-3,1,2-$CoC_2B_9H_{10}$.[80]

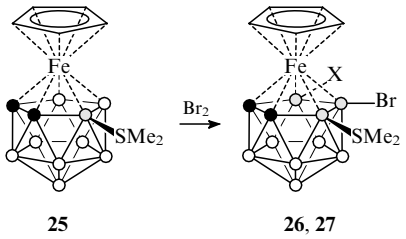
The mechanism of formation of trifluoroacetoxy derivative **24** remains unclear. Apparently, it may involve both the electrophilic substitution followed by elimination of thallium and the electrophile induced nucleophilic substitution with the initial attack of the thallium reagent followed by the attack of the trifluoroacetate anion (see below). The ricochet mechanism also cannot be ruled out.

Analysis of the above data shows that halogenation of metallacarboranes $[3\text{-L-}3,1,2\text{-}MC_2B_9H_{11}]^{n-}$ occurs first at position 8 and then at positions 9 and 12 of the metallacarborane moiety. Unlike halogenation, mercuration generally gives rise to a mixture of 8- and 9-substituted metallacarboranes with the 9-substituted isomer predominating. This anomaly is attributable to the fact that the first step of the process gives rise to an intermediate, in which the mercury atom coordinates the B(8)B(9)B(12) face of the metallacarborane moiety. The subsequent substitution can occur at both positions 8 and 9(12), and the product ratio depends on the electronic properties of the intermediate.



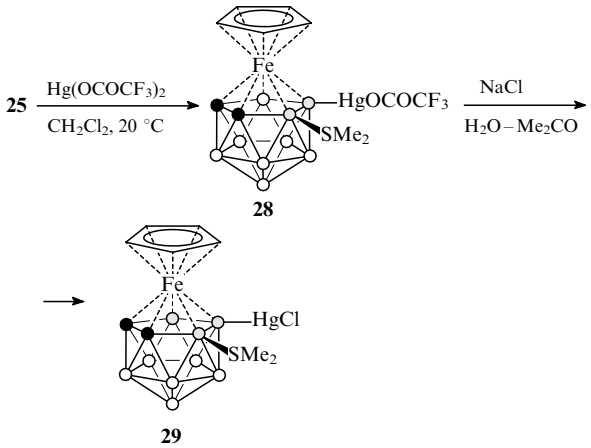
The formation of such boron hydride complexes with various transition metals is well known. The mercury complex $[Ph_4P][1,2,3\text{-}PhHg\text{-}1,2,3\text{-}(\mu\text{-}H)_3B_6H_3]$ was isolated and characterised by X-ray diffraction analysis.[81]

The influence of the *exo*-polyhedral substituents on the direction of substitution in metallacarborane systems is of interest. Let us consider the effect of the Me_2S^+ substituent in the carborane cage of diamagnetic ferracarborane 4-Me_2S-3-Cp-3,1,2-$FeC_2B_9H_{10}$ (**25**) on the mechanism of substitution. The reaction of compound **25** with 1 equiv. of bromine in dichloromethane affords the monobromo derivative 8-Br-4-Me_2S-3-Cp-3,1,2-$FeC_2B_9H_9$ (**26**), whereas the reaction with two or more equivalents of bromine gives rise to the disubstituted derivative 7,8-Br_2-4-Me_2S-3-Cp-3,1,2-$FeC_2B_9H_8$ (**27**). The use of $AlCl_3$ as the catalyst does not allow one to introduce more than two boron atoms into the ferracarborane moiety and the reaction forms dibromo derivative **27** as the final product. The structure of complex **27** was confirmed by X-ray diffraction analysis.[82]



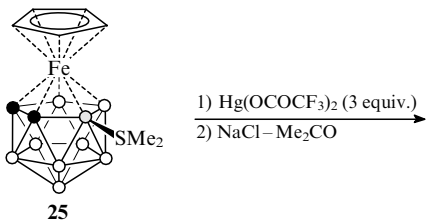
X = H (**26**), Br (**27**).

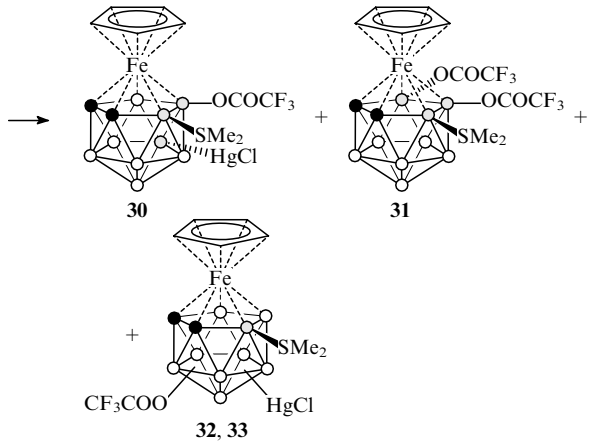
The reaction of compound **25** with mercury trifluoroacetate in a ratio of 1 : 1 in dichloromethane at room temperature yields 8-CF_3COOHg-4-Me_2S-3-Cp-3,1,2-$FeC_2B_9H_9$ (**28**) as the only product.[82]



The position of the substituent in ferracarborane **28** was determined by ^{11}B and $^{11}B-^{11}B$ COSY NMR spectroscopy and confirmed by X-ray diffraction study of its chloro derivative **29**.

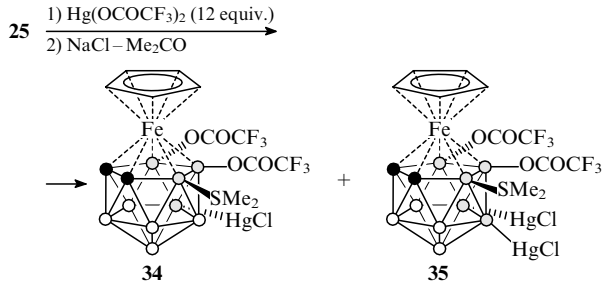
The reaction of ferracarborane **25** with a threefold excess of mercury trifluoroacetate gave a mixture of four products,[83] which were isolated as HgCl derivatives after treatment with sodium chloride in acetone.





This reaction afforded 8-CF_3COO-12-HgCl-4-Me_2S-3-Cp-3,1,2-$FeC_2B_9H_8$ (**30**) as the major product in 52% yield. In addition, the reaction produced small amounts of 7,8-$(CF_3COO)_2$-4-Me_2S-3-Cp-3,1,2-$FeC_2B_9H_8$ (**31**) containing three substituents at the open face and two isomers **32** and **33** each bearing one HgCl group and one CF_3COO fragment, the positions of which were not unambiguously determined.

The reaction with a 12-fold excess of the mercurating agent followed by treatment of the reaction mixture with NaCl gave a mixture of complexes **34** and **35**. The structures of the reaction products were determined by spectroscopic methods. The structure of ferracarborane **35** was confirmed by X-ray diffraction analysis.[83]



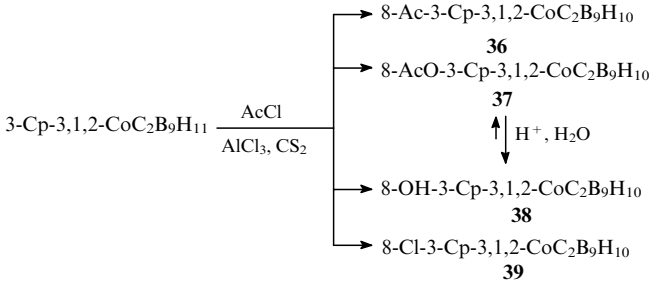
Therefore, from one to four substituents can be introduced into the carborane moiety depending on the ratio between the starting ferracarborane **25** and the mercurating agent (mercury trifluoroacetate).[82, 83]

It should be noted that further substitution in ferracarboranes depends on the nature of the substituents. For example, like in the case of unsubstituted derivative **11**, bromination of bromine-substituted ferracarboranes **15**, **16** and **17** leads to substitution at position 8. The introduction of the Me_2S^+ substituent has a much more substantial effect on the direction of substitution. Mercuration of unsubstituted ferracarborane **11** results in the replacement of the hydrogen atom at position 9(12), whereas mercuration of its 4-Me_2S^+-substituted derivative **25** leads to substitution of the hydrogen atom at position 8. Substitution at position 9 or 12 requires an excess of the mercurating agent, substitution at position 9 being attained only in the presence of a large excess of mercury trifluoroacetate due, apparently, to the deactivating effect of the Me_2S^+ group.

An analogous situation was observed earlier in the study of substitution in the *closo*-dodecaborate anion $[B_{12}H_{12}]^{2-}$. In this compound, the effect of *exo*-polyhedral substituents on the replacement of hydrogen atoms with electrophilic reagents is much less pronounced compared to carboranes and is manifested only in the presence of strong electron-withdrawing substituents (R_2O^+, R_2S^+ or R_3N^+).[84, 85] Unfortunately, data on the influence of the *exo*-polyhedral substituents on substitution in metallacarboranes are insufficient to give an unambiguous answer to this question. This problem requires additional investigation.

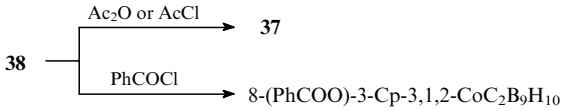
The reactions of metallacarboranes $[3\text{-L-}3,1,2\text{-}MC_2B_9H_{11}]^{n-}$ with arylsulfenyl chlorides provide yet another typical example of electrophilic substitution in this class of compounds. For instance, the reaction of 4-nitrophenylsulfenyl chloride with ferracarborane **11** in acetonitrile affords 8-(4-$NO_2C_6H_4S$)-3-Cp-3,1,2-$FeC_2B_9H_{10}$, whereas the analogous reaction with K[**1**] yields $[8,8'\text{-}(4\text{-}NO_2C_6H_4S)_2\text{-}3,3'\text{-}Co(1,2\text{-}C_2B_9H_{10})_2]^-$. Interestingly, the reactions of phenylsulfenyl and 2-nitrophenylsulfenyl chlorides with K[**1**] form the monosubstituted derivatives $[8\text{-ArS-}3,3'\text{-}Co(1,2\text{-}C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})]^-$ (Ar = Ph or $C_6H_4NO_2$-2) as the final products even in the presence of an excess of ArSCl. This difference in the behaviour of sulfenyl halides was accounted for by the difference in the basicity of the sulfur atoms in the monosulfides that formed. In the case of phenylsulfenyl and 2-nitrophenylsulfenyl chlorides, protonation of sulfur with HCl that is eliminated affords the sulfonium salt, whose positive charge deactivates the molecule and hinders the replacement in the second dicarbollyl ligand.[86]

The use of other electrophilic reagents can give unexpected results. For instance, the reaction of cobaltacarborane **7** with acetyl chloride in carbon disulfide in the presence of $AlCl_3$ produced a complex mixture of acetyl (**36**), acetoxy (**37**), hydroxy (**38**) and chlorine derivatives (**39**).[73]



The substitution positions in 8-Ac-3-Cp-3,1,2-$CoC_2B_9H_{10}$ (**36**) and 8-AcO-3-Cp-3,1,2-$CoC_2B_9H_{10}$ (**37**) were determined by X-ray diffraction analysis.[73]

Acid hydrolysis of acetoxy derivative **37** gives the corresponding hydroxy derivative **38**. The reactions of the latter with acetic anhydride, acetyl chloride and benzoyl chloride afford the corresponding acyloxy derivatives.



Reduction of acetyl derivative **36** with zinc in hydrochloric acid gives the corresponding ethyl derivative 8-Et-3-Cp-3,1,2-$CoC_2B_9H_{10}$.[73]

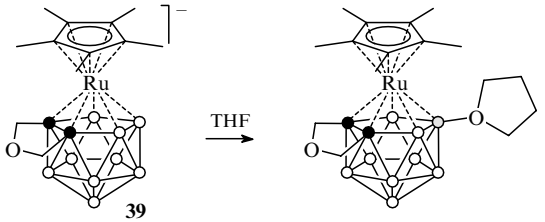
The reactions of cobaltacarborane **7** and its methyl- [1-Me-3-Cp-3,1,2-$CoC_2B_9H_{10}$ (**7a**)] and phenyl-substituted derivatives [1-Ph-3-Cp-3,1,2-$CoC_2B_9H_{10}$ (**7b**)] with acetyl chloride in dichloroethane in the presence of $AlCl_3$ form the corresponding hydroxy derivatives, *viz.*, 8-OH-3-Cp-3,1,2-$CoC_2B_9H_{10}$ (**38**), 1-Me-8-OH-3-Cp-3,1,2-$CoC_2B_9H_9$ (**38a**) and 1-Ph-8-OH-3-Cp-3,1,2-$CoC_2B_9H_9$ (**38b**).[29] Heating of compound **7** and CrO_3 in a mixture of acetic anhydride, acetic acid and sulfuric acids affords a mixture of hydroxy, acetoxy and diacetoxy derivatives.[29]

The above results provide evidence that the substitution in carbon disulfide occurs by competitive mechanisms of electrophilic and electrophile induced nucleophilic substitution, whereas substitution in dichloroethane occurs predominantly by the latter mechanism.

Analogously, the reactions of Cs[8,8′,9-Cl_3-3,3′-Co(1,2-$C_2B_9H_9$)(1′,2′-$C_2B_9H_{10}$)] (**4**) with alkyl halides in the presence of $AlCl_3$ afford complex mixtures of halogen- and alkyl-substituted derivatives.[87] In our opinion, this fact can also be attributable to competition between two substitution mechanisms.

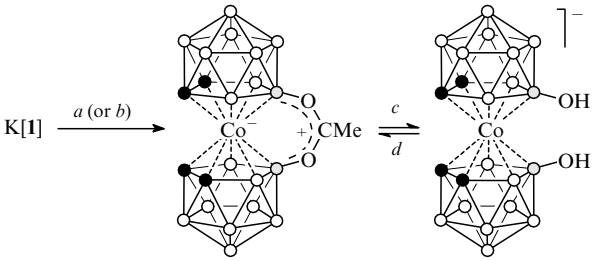
We believe that the formation of nitrates 8-NO_3-3-Cp-3,1,2-$CoC_2B_9H_{10}$, 1-Ph-8-NO_3-3-Cp-3,1,2-$CoC_2B_9H_9$ and 8-NO_3-3-(η^5-$C_5H_4C_6H_4NO_2$)-3,1,2-$CoC_2B_9H_{10}$ by nitration of the compounds **7**, **7b** and 3-(η^5-C_5H_4Ph)-3,1,2-$CoC_2B_9H_{11}$ with a mixture of nitric and sulfuric acids in dichloromethane [87] also occurs by the mechanism of electrophile induced nucleophilic substitution. Reduction of these nitrates with tin in hydrochloric acid affords the corresponding hydroxy derivatives.[87]

The reaction of the [3-C_5Me_5-3,1,2-$RuC_2B_9H_{11}$]$^-$ complex with [CpFe(C_6H_6)]$^+$ in tetrahydrofuran under UV irradiation produces 8-$(CH_2)_4O$-3-C_5Me_5-3,1,2-$RuC_2B_9H_{10}$, which is a product of electrophile induced nucleophilic substitution.[88] An analogous result was obtained in the reaction of [1,2-(μ-CH_2OCH_2)-3-C_5Me_5-3,1,2-$RuC_2B_9H_9$]$^-$ (**39**) with [(C_5Me_5)RuCl]$_4$ in tetrahydrofuran.[88]



39

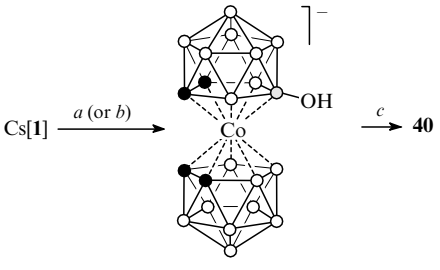
The reaction of acetic anhydride with K[**1**] in sulfuric acid or in acetic acid in the presence of $HClO_4$ proceeds in an unusual way.[89,90] Apparently, this reaction also occurs by the mechanism of electrophile induced nucleophilic substitution but gives 8,8′-(μ-AcO)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$ (**40**) in which two dicarbollyl ligands are linked by the bridging acetate group through the B(8) and B(8′) atoms.[89,90] The structure of compound **40** was established by X-ray diffraction analysis.[90] Hydrolysis of the acetate derivative in boiling aqueous ethanol affords the corresponding diol [8,8′-(HO)$_2$-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$]$^-$ (**41**).[89,90]



40 **41**

(*a*) Ac_2O, H_2SO_4, 80 °C; (*b*) Ac_2O, AcOH, $HClO_4$;
(*c*) H^+, 50% EtOH, 80 °C; (*d*) Ac_2O, H_2SO_4, 80 °C.

Dihydroxy derivative **41** can also be prepared by heating Cs[**1**] in 80% sulfuric acid to 140 °C. Heating of Cs[**1**] in 60% sulfuric acid at 120 °C affords the monohydroxy derivative [8-OH-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]$^-$ (**42**). The latter was prepared also by heating Cs[**1**] with acetic anhydride in a mixture of acetic and sulfuric acids.



42

(*a*) 60% H_2SO_4, 120 °C; (*b*) Ac_2O, AcOH, $HClO_4$; (*c*) Ac_2O, H_2SO_4, 80 °C.

The reactions of both mono- and dihydroxy derivatives with acetic anhydride in sulfuric acid produce bridged acetate derivative **40**.[90]

The reaction of Cs[**41**] with $POCl_3$ in chloroform in the presence of triethylamine yields the bridged [Et_3NH][8,8′-(μ-OPO(Cl)O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] derivative (**43**). Hydrolysis of the latter affords acid [8,8′-(μ-OPO(OH)O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$]$^-$.

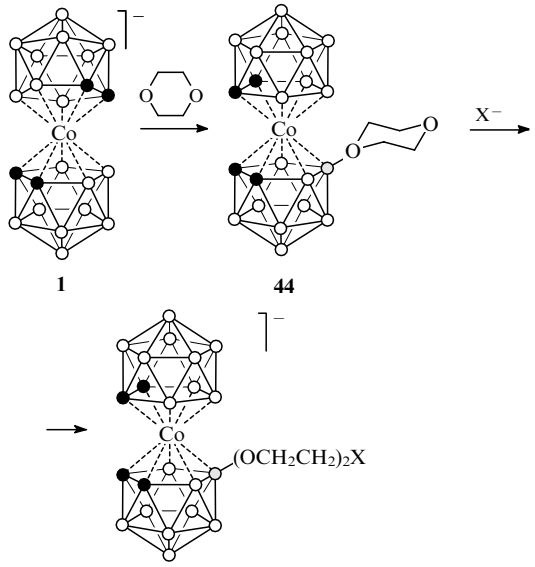
The reaction of compound **43** with diethylamine produces the corresponding amide [Et_3NH][8,8′-(μ-OPO(NEt_2)O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] (**43a**).[91] The structures of compounds **43** and **43a** were established by X-ray diffraction analysis.[90] The reactions of monohydroxy derivative **42** with $POCl_3$ and $PhPOCl_2$ followed by hydrolysis afford [8-PO_2(OH)$_2$-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]$^-$ and [8-HO_2P(Ph)O-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]$^-$, respectively.[91]

It should be noted that the formation of bridged derivatives is typical of the chemistry of cobalt and iron bis(dicarbollyl) complexes, although the latter complex was studied to a much lesser extent.

The reaction of Cs[**1**] with dimethyl sulfate in the presence of $AlCl_3$ at 80 °C forms the sulfate-bridged derivative [8,8′-(μ-OSO_2O)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$]$^-$. The structure of its tetramethylammonium salt was determined by X-ray diffraction analysis.[92]

Heating of Cs[**1**] with dimethyl sulfate and sulfuric acid in 1,4-dioxane affords the oxonium derivative 8-O(CH_2CH_2)$_2$O-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$) (**44**).[92] This compound was also prepared by heating Cs[**1**] with $BF_3 \cdot OEt_2$ in 1,4-dioxane.[93] It should be noted that monosubstituted bis(dicarbollyl)cobalt derivatives are generated primarily by introducing onium substituents, whose involvement in the carborane ligand gives rise to neutral charge-compensated products. The presence of the positive charge on the onium substituent causes a substantial electron density redistribution in the metallacarborane moiety and deactivation of the second dicarbollyl ligand.

The reactions of compound **44** with various nucleophilic agents are accompanied by the dioxane-ring opening to form various functional derivatives with composition [8-X(CH_2CH_2O)$_2$-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]$^-$ [X = OH, OR, CN, NH_2, $CH(NH_2)COOH$, P(O)$(OBu)_2$, P(O)(OBu)OH, NEt_3, Py].[18,27,93,94]

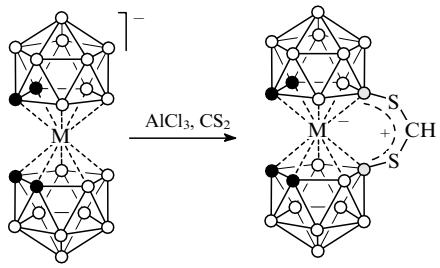


1 **44**

Analogously, the reaction of Cs[**1**] with dimethyl sulfate in the presence of sulfuric acid in tetrahydropyran yields 8-$C_5H_{10}O$-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$) (**45**). The tetrahydropyran-ring opening in the reactions of derivative **45** with nucleophiles made it possible to prepare a series of derivatives of the [8-X(CH_2)$_5$O-3,3′-

$Co(1,2\text{-}C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})]^-$ type (X is 1-pyrrolyl, 1-indolyl or 9-carbazolyl).[95]

Thioformate-bridged bis(dicarbollyl) derivatives of cobalt and iron, 8,8′-(μ-HCS_2)-3,3′-M(1,2-$C_2B_9H_{10})_2$ (**46** and **47**), were prepared by the reactions of K[**1**] and K[**9**], respectively, with carbon disulfide in the presence of aluminium chloride.[89,96] The structure of compound **46** was determined by X-ray diffraction analysis.[96]



1, **9** **46**, **47**

M = Co (**1**, **46**), Fe (**9**, **47**).

Hydrolysis of compound **46** in boiling 50% ethanol affords the dimercapto derivative [8,8′-$(HS)_2$-3,3′-Co(1,2-$C_2B_9H_{10})_2]^-$ (**48**). Oxidation of the latter with hydrogen peroxide gives [8,8′-(μ-S_2)-3,3′-Co(1,2-$C_2B_9H_{10})_2]^-$ (**49**), in which the dicarbollyl fragments are linked by the disulfide bridge.[89,96] Derivative **49** was also prepared by heating Cs[**1**] with S_2Cl_2 in dichloromethane.[97]

Refluxing of $[(Me_2SO)_2H]^+$[**1**]$^-$ with acetic anhydride in benzene gives rise to the monosubstituted dimethylsulfonium derivative 8-Me_2S-3,3′-Co(1,2-$C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})$ (**50**),[97] which can also be prepared by assembly from $CoCl_2$ and the corresponding dicarbollyl ligands.[98] The analogous diethylsulfonium derivative 8-Et_2S-3,3′-Co(1,2-$C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})$ (**51**) was synthesised by the reaction of [Ph_3PMe][**1**] with diethyl sulfide in a strongly acidic medium.[99]

Treatment of a suspension of ferracarborane [Ph_3PMe][**9**] with gaseous HCl in diethyl sulfide yields a mixture of 8-Et_2S-3,3′-Fe^{III}(1,2-$C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})$ (**52**) and 8,8′-$(Et_2S)_2$-3,3′-Fe(1,2-$C_2B_9H_{10})_2$ (**53**).[99] The charge-compensated complex **52** can also be synthesised by oxidation of the [8-Et_2S-3,3′-Fe^{II}(1,2-$C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})]^-$ anion.[99]

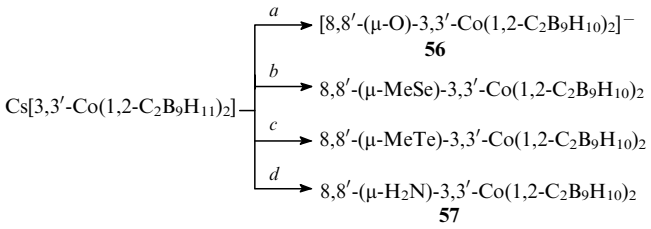
The carborane derivative [8,8′-(μ-S)-3,3′-Co(1,2-$C_2B_9H_{10})_2]^-$ (**54**) containing a one-atom sulfide bridge was synthesised[100] by refluxing $[(Me_2SO)_2H]$[**1**] with S_2Cl_2 in dichloromethane followed by methanolysis and reprecipitation. Complex **54** can also be prepared by refluxing compound **1** with sulfur in benzene in the presence of $AlCl_3$.[97]

The reaction of complex **54** with dimethyl sulfate produces the neutral complex 8,8′-(μ-MeS)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ (**55a**).[97,100] The latter can also be prepared by intramolecular cross-linking of compound **50** in boiling benzene in the presence of $AlCl_3$ [the reaction gives 8-Me_2S-8′-Cl-3,3′-Co(1,2-$C_2B_9H_{10})_2$ as the second product].[97]

The sulfonium derivatives 8,8′-(μ-RS)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ [R = Et (**55b**), Bu (**55c**), Bn (**55d**), $CH_2CH{=}CH_2$ (**55e**), $CH_2C{\equiv}CH$ (**55f**) and CH_2COOH (**55g**)] were prepared by the reactions of compound **54** with the corresponding halides.[15,97] Protonation of derivative **54** with sulfuric acid in benzene affords very active acid 8,8′-(μ-HS)-3,3′-Co(1,2-$C_2B_9H_{10})_2$, which readily reacts with acrylonitrile and formaldehyde to form 8,8′-(μ-RS)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ [R = CH_2CH_2CN (**55h**), CH_2OMe (**55i**)].[97,101] The reaction of complex **54** with bromine in acetic acid gives unstable bromide 8,8′-(μ-BrS)-3,3′-Co(1,2-$C_2B_9H_{10})_2$, which immediately reacts with benzene in the presence of $AlCl_3$ to form 8,8′-(μ-PhS)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ (**55j**).[97]

Oxygen, selenium, tellurium and nitrogen atoms can also serve as bridges linking the dicarbollyl ligands (Scheme 7).[42]

Scheme 7



(*a*) HCHO, H_2SO_4, Ac_2O; (*b*) 1) SeO_2, H_2SO_4, Ac_2O, C_6H_6, 2) KOH – Me_2SO_4; (*c*) 1) Te, H_2SO_4, Ac_2O, 2) KOH – Me_2SO_4; (*d*) $NaNO_2$, H_2SO_4, C_6H_6.

Heating of cobaltacarborane Cs[**1**] with formaldehyde in acetic anhydride in the presence of sulfuric acid affords the [8,8′-(μ-O)-3,3′-Co(1,2-$C_2B_9H_{10})_2]^-$ complex (**56**)[42,102] [in the absence of formaldehyde, 8,8′-(μ-EtO)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ was obtained[42]]. Derivative **56** was also prepared by refluxing [8-Me-8′-HO-3,3′-Co(1,2-$C_2B_9H_{10})_2]^-$ with iodine in ethanol.[58]

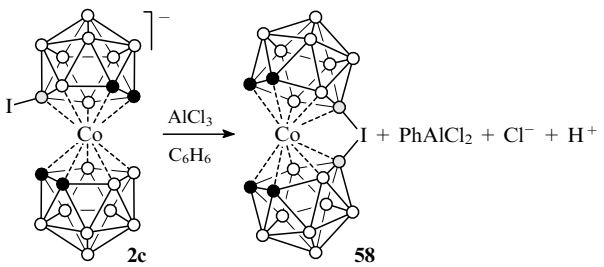
The reaction of ferracarborane **9** with formaldehyde in the presence of HCl produces 8,8′-(μ-MeO)-3,3′-Fe(1,2-$C_2B_9H_{10})_2$. Its structure was established by X-ray diffraction analysis.[103] By contrast, the reaction of nickelacarborane **19** with formaldehyde in a strongly acidic medium affords a mixture of the methoxy derivatives 8-MeO-3,3′-Ni(1,2-$C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})$ and 8,8′-$(MeO)_2$-3,3′-Ni(1,2-$C_2B_9H_{10})_2$ (the structure of the disubstituted derivative was established by X-ray diffraction analysis[104]) rather than the bridged derivative.

The reaction of Cs[**1**] with H_2SeO_3 in a mixture of benzene, acetic anhydride and sulfuric acid followed by treatment of the intermediate with dimethyl sulfate yields 8,8′-(μ-MeSe)-3,3′-Co(1,2-$C_2B_9H_{10})_2$, whereas heating of Cs[**1**] with tellurium in a mixture of acetic anhydride and sulfuric acid followed by treatment of the intermediate with dimethyl sulfate gives 8,8′-(μ-MeSe)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ (see Scheme 7).[42]

The reaction of Cs[**1**] with $NaNO_2$ in a $C_6H_6 - H_2SO_4$ mixture produces a mixture of 8,8′-(μ-H_2N)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ (**57**) (47%), 4,8′-(μ-H_2N)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ (6%) and 8,8′-(μ-NH_2O)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ (21%).[42,105,106] Methylation of compound **57** with dimethyl sulfate in a benzene – water mixture in the presence of KOH gives rise to the *N*-methyl derivative 8,8′-(μ-MeNH)-3,3′-Co(1,2-$C_2B_9H_{10})_2$, whereas methylation in an aqueous solution affords the *N*,*N*-dimethyl derivative 8,8′-(μ-Me_2N)-3,3′-Co(1,2-$C_2B_9H_{10})_2$.[87] The reaction of compound **57** with chloroacetic acid in methanol in the presence of KOH yields 8,8′-(μ-$HOOCCH_2NH$)-3,3′-Co(1,2-$C_2B_9H_{10})_2$.[107]

Refluxing of Cs[**1**] with white phosphorus in benzene in the presence of $AlCl_3$ followed by alkylation with dimethyl sulfate in alkaline ethanol affords a mixture of 8,8′-(μ-Me_2P)-3,3′-Co(1,2-$C_2B_9H_{10})_2$ and 8-Me_3P-3,3′-Co(1,2-$C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})$ in low yields.[107]

The iodonium-bridged derivative Cs[8,8′-(μ-I)-3,3′-Co(1,2-$C_2B_9H_{10})_2$] (**58**) was synthesised by refluxing Cs[**2c**] in benzene in the presence of $AlCl_3$.[108]



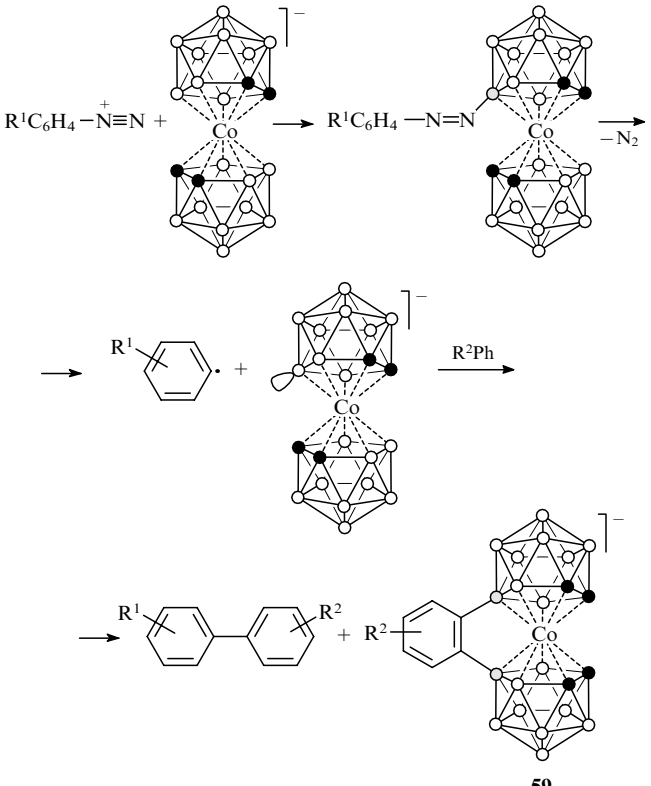
2c **58**

Compound **58** is highly reactive and is readily transformed into the corresponding bifunctional derivatives 8-I-8′-L-3,3′-$Co(1,2\text{-}C_2B_9H_{10})_2$ under the action of Lewis bases L, such as SMe_2, C_5H_5N, Me_3N and NH_3. An analogous bromonium-bridged derivative is very unstable due to which it was not isolated in the individual state. However, products of its reactions with dimethyl sulfide and dioxane with composition 8-Br-8′-L-3,3′-$Co(1,2\text{-}C_2B_9H_{10})_2$ (L = Me_2S and 1,4-$O_2C_4H_8$, respectively) were isolated.[109]

An interesting result was obtained when performing the reaction of an aqueous solution of K[**1**] with phenyldiazonium borofluoride. The reaction was accompanied by cation exchange to form the phenyldiazonium salt of bis(dicarbollyl)cobalt [PhN_2][**1**] instead of the expected arylation or coupling products.[110] At room temperature, this salt is virtually insoluble in benzene, but it completely dissolves on heating above 60 °C with elimination of N_2 to give biphenyl and the [8,8′-(μ-1,2-C_6H_4)-3,3′-$Co(1,2\text{-}C_2B_9H_{10})_2]^-$ complex (**59**).

Refluxing of the unstable phenyldiazonium salt of bis(dicarbollyl)iron [PhN_2][**9**] in benzene also affords the 1,2-phenylene-bridged [8,8′-(μ-1,2-C_6H_4)-3,3′-$Fe(1,2\text{-}C_2B_9H_{10})_2]^-$ compound.[111]

Decomposition of the phenyldiazonium salt in toluene and decomposition of the tolyldiazonium salt in benzene give rise to tolyl- and phenylene-bridged complexes, respectively, and methylbiphenyl (this is evidence that the aryl group of the diazonium cation is not involved in the reaction product).[110, 111]

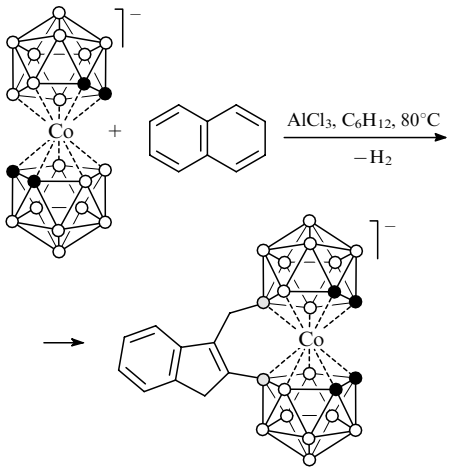


59

R^1, R^2 = H, Me.

The reaction of cobaltacarborane **1** with benzene in the presence of aluminium chloride produces bridged compound **59** (R^2 = H) and cobaltacarborane [4,8′-8,4′-(μ-1,2-C_6H_4)$_2$-3,3′-$Co(1,2\text{-}C_2B_9H_9)_2]^-$ containing two bridging 1,2-phenylene groups. The structures of these compounds were confirmed by X-ray diffraction analysis.[111, 112]

The reaction of compound **1** with naphthalene at 80 °C yields a 1-methyleneinden-2-yl-bridged derivative (which was proved by X-ray diffraction analysis).[113]

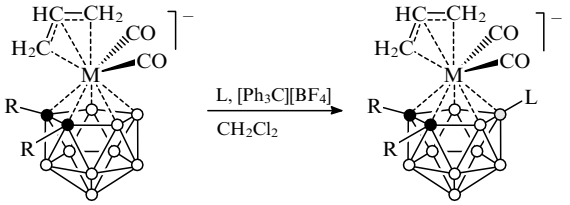


An interesting result was obtained in the reaction of $Me_3SiC{\equiv}CH$ with the complex Cs[**2c**] in the presence of a Pd catalyst (under conditions of the Sonogashira reaction). This reaction gives the ethene-bridged derivative [8,8′-(μ-CH = CH)-3,3′-$Co(1,2\text{-}C_2B_9H_{10})_2]^-$ instead of the expected addition product of acetylene with composition [8-$Me_3SiC{\equiv}$C-3,3′-$Co(1,2\text{-}C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})]^-$. The structure of the caesium salt of the reaction product was established by X-ray diffraction analysis.[114] The synthesis of the alkyl and aryl derivatives [8-R-3,3′-$Co(1,2\text{-}C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})]^-$ by Pd-catalysed cross-coupling of the complex [**2c**] with organomagnesium and -zinc reagents was mentioned above.[59, 60]

The phenyl derivative [8-Ph-3,3′-$Co(1,2\text{-}C_2B_9H_{10})(1',2'\text{-}C_2B_9H_{11})]^-$ was also prepared by the direct reaction of Cs[**1**] with dimethyl sulfate in benzene at 80 °C in the presence of concentrated sulfuric acid.[92] The diphenyl derivative [6,6′-Ph_2-3,3′-$Co(1,2\text{-}C_2B_9H_{10})_2]^-$ was synthesised by the reaction of Na_2[3-Ph-7,8-$C_2B_9H_{10}$] with $CoCl_2$ in tetrahydrofuran followed by precipitation as the tetramethylammonium salt.[115]

Metallacarborane complexes containing labile ligands in the metal coordination sphere are characterised by diverse chemistry because the presence of labile ligands increases the probability of substitution reactions involving the metal atom. In addition, such metallacarboranes can be involved in the above-mentioned electrophilic and electrophile induced nucleophilic substitution reactions.

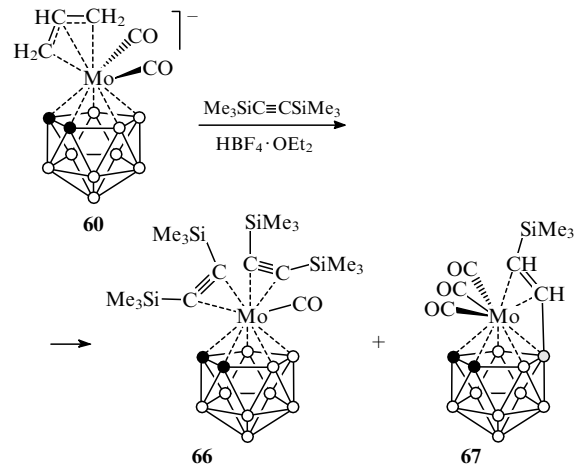
For example, the reaction of [Et_4N][3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$MoC_2B_9H_{11}$] (**60**) with [Ph_3C][BF_4] and Et_2O in dichloromethane affords 8-Et_2O-3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$MoC_2B_9H_{10}$ (**61**), which is a typical product of electrophile induced nucleophilic substitution. The reactions of [Et_4N][1,2-Me_2-3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$MoC_2B_9H_9$] (**62**) with various donor molecules L proceed analogously. This procedure was used for the synthesis of various charge-compensated complexes 8-L-1,2-Me_2-3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$MoC_2B_9H_8$ (**63a**–**f**) (L = OEt_2, THF, SMe_2, PPh_3, Py, 4,4′-bipy). The reaction of [Et_4N][1,2-Me_2-3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$WC_2B_9H_9$] (**64**) with [Ph_3C][BF_3] and Et_2O also yields the 8-substituted derivative 8-Et_2O-1,2-Me_2-3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$WC_2B_9H_8$ (**65**).[116]



60, **62**, **64** **61**, **63a**–**f**, **65**

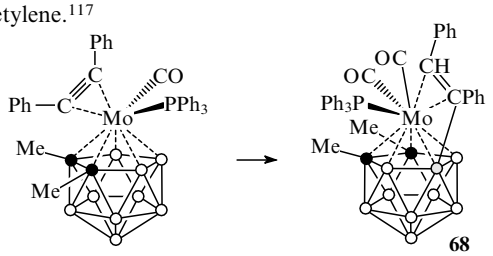
Compound	M	R	L	Compound	M	R	L
60	Mo	H	–	**63d**	Mo	Me	PPh_3
61	Mo	H	OEt_2	**63e**	Mo	Me	Py
62	Mo	Me	–	**63f**	Mo	Me	4,4′-bipy
63a	Mo	Me	OEt_2	**64**	W	Me	–
63b	Mo	Me	THF	**65**	W	Me	OEt_2
63c	Mo	Me	SMe_2				

Treatment of compounds **63a** and **65** with nucleophilic agents ($K[HBBu^s_3]$ and Et_4NX, where X = Cl or F) leads to elimination of one ethyl group to form $[Et_4N][8\text{-EtO-1,2-Me}_2\text{-3-}(\eta^3\text{-C}_3\text{H}_5)\text{-3,3-(CO)}_2\text{-3,1,2-MC}_2\text{B}_9\text{H}_8]$ (M = Mo, W), whereas treatment of the tetrahydrofuran derivative $8\text{-(CH}_2)_4\text{O-1,2-Me}_2\text{-3-}(\eta^3\text{-C}_3\text{H}_5)\text{-3,3-(CO)}_2\text{-3,1,2-MoC}_2\text{B}_9\text{H}_8$ (**63b**) with the R_4NF salt (R = Et, Bu) results in the tetrahydrofuran-ring opening to give $[R_4N][8\text{-F(CH}_2)_4\text{O-1,2-Me}_2\text{-3-}(\eta^3\text{-C}_3\text{H}_5)\text{-3,3-(CO)}_2\text{-3,1,2-MoC}_2\text{B}_9\text{H}_8]$.[116] By contrast, the reaction of complex **60** with $Me_3SiC{\equiv}CSiMe_3$ in the presence of $HBF_4\cdot Et_2O$ gives rise to a mixture of $3,3\text{-}(\eta^2\text{-Me}_3\text{SiC}{\equiv}\text{CSiMe}_3)_2\text{-3-CO-3,1,2-MoC}_2\text{B}_9\text{H}_{11}$ (**66**) and $8,3\text{-}(\sigma,\eta^2\text{-Me}_3\text{SiCH}{=}\text{CH})\text{-3,3,3-(CO)}_3\text{-3,1,2-MoC}_2\text{B}_9\text{H}_{10}$ (**67**).[117] It is assumed that the first step involves the replacement of the labile (allyl and carbonyl) ligands with the alkyne molecule $Me_3SiC{\equiv}CSiMe_3$. The second step involves, apparently, the formation of the vinylidene fragment $Mo{=}C{=}CHSiMe_3$ followed by its insertion into the B–H bond of the pentagonal face of the dicarbollyl ligand.



60 **66** **67**

An analogous complex with composition $8,3\text{-}(\sigma,\eta^2\text{-PhCH}{=}\text{CPh})\text{-1,2-Me}_2\text{-3,3-(CO)}_2\text{-3-Ph}_3\text{P-3,1,2-MoC}_2\text{B}_8\text{H}_8$ (**68**) was prepared by the rearrangement of $1,2\text{-Me}_2\text{-3-CO-3-Ph}_3\text{P-3-}(\eta^2\text{-PhC}{\equiv}\text{CPh})\text{-3,1,2-MoC}_2\text{B}_9\text{H}_9$ in dichloromethane at room temperature, which is evidence for the formation of the acetylene complex in the first step of the reaction of metallacarborane with acetylene.[117]



68

Ruthenacarborane $3,3\text{-(CO)}_2\text{-3-THF-3,1,2-RuC}_2\text{B}_9\text{H}_{11}$ (**69**) reacts with $Bu^tC{\equiv}CH$ to give a mixture of isomeric derivatives (Scheme 8), *viz.*, $4,3\text{-}(\sigma,\eta^2\text{-Bu}^t\text{CH}{=}\text{CH})\text{-3,3-(CO)}_2\text{-3,1,2-}$

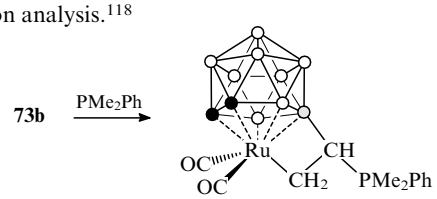
75 (R = Bu^t), **76** (R = $SiMe_3$)

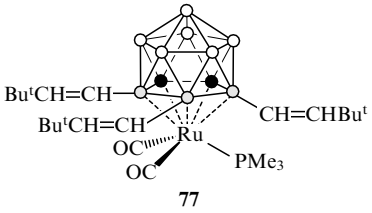
$RuC_2B_9H_{10}$ (**70**)‡ and 8,3-(σ,η^2-Bu^{t}CH = CH)-3,3-$(CO)_2$-3,1,2-$RuC_2B_9H_{10}$ (**71**).[118] The reaction of compound **69** with $Me_3SiC{\equiv}CH$ is accompanied by partial elimination of the $SiMe_3$ group to form a mixture of isomers 4,3-(σ,η^2-RCH = CH)-3,3-$(CO)_2$-3,1,2-$RuC_2B_9H_{10}$ (**72a**,**b**) and 8,3-(σ,η^2-RCH = CH)-3,3-$(CO)_2$-3,1,2-$RuC_2B_9H_{10}$ (**73a**,**b**) (R = $SiMe_3$, H), respectively, with the 4-isomer **72a** predominating.

Compound **73b** reacts with $PhMe_2P$ in heptane to give the ylide complex 8-[σ-$CH_2CH(PMe_2Ph)$]-3,3-$(CO)_2$-3,1,2-$RuC_2B_9H_{10}$ (**74**). Its structure was determined by X-ray diffraction analysis.[118]

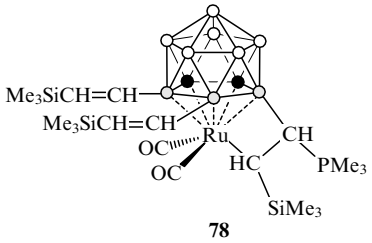


74

The reactions with an excess of alkyne RC≡CH (R = Bu^t, Me_3Si) produce the 4,3-(σ,η^2-RCH = CH)-7,8-(RCH = CH)$_2$-3,3-$(CO)_2$-3,1,2-$RuC_2B_9H_8$ complexes (**75**, R = Bu^t; **76**, R = $SiMe_3$) containing three alkene fragments in the open face of the dicarbollyl ligand. Treatment of complex **75** with trimethylphosphine leads to the replacement of the vinyl substituent from the metal coordination sphere to form 4,7,8-(Bu^{t}CH = CH)$_3$-3,3-$(CO)_2$-3-Me_3P-3,1,2-$RuC_2B_9H_8$ (**77**), whose structure was established by X-ray diffraction analysis. The reaction of PMe_3 with trimethylsilyl derivative **76** yields ylide 4-[σ-CH($SiMe_3$)CH(PMe_3)]-7,8-(Me_3SiCH = CH)$_2$-3,3-$(CO)_2$-3,1,2-$RuC_2B_9H_8$ (**78**).[118]



77



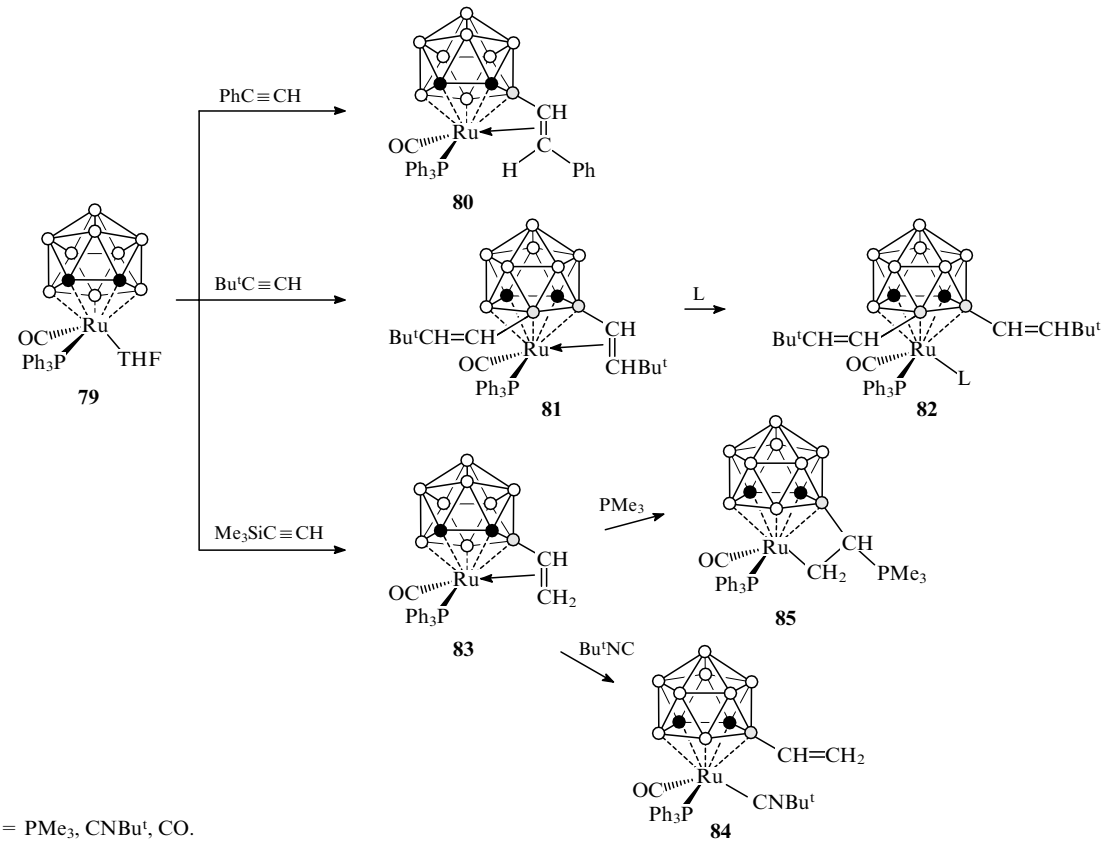
78

Interestingly, the reaction of ruthenacarborane 3-CO-3-Ph_3P-3-THF-3,1,2-$RuC_2B_9H_{11}$ (**79**) containing the triphenylphosphine ligand with a threefold excess of PhC≡CH is accompanied by the selective replacement of the hydrogen atom at position 4 nearest to the carbon atom of the dicarbollyl ligand to form the 4,3-(σ,η^2-PhCH = CH)-3-CO-3-Ph_3P-3,1,2-$RuC_2B_9H_{10}$ complex (**80**), whose structure was established by X-ray diffraction analysis.[119] By contrast, the reaction with a threefold excess of Bu^{t}C≡CH gives the disubstituted derivative 4,3-(σ,η^2-Bu^{t}CH = CH)-8-(Bu^{t}CH = CH)-3-CO-3-Ph_3P-3,1,2-$RuC_2B_9H_9$ (**81**) (Scheme 9). The reactions of the latter with PMe_3, CNBu^t and CO are accompanied by the displacement of the vinyl substituent from the metal coordination sphere to form 4,8-(Bu^{t}CH = CH)$_2$-3-CO-3-Ph_3P-3-L-3,1,2-$RuC_2B_9H_9$ (**82**) (L = PMe_3, CNBu^t and CO, respectively). The reaction of compound **79** with $Me_3SiC{\equiv}CH$ yields the 4,3-(σ,η^2-H_2C = CH)-3-CO-3-Ph_3P-3,1,2-$RuC_2B_9H_{10}$ isomer (**83**) as the only product. The latter reacts with CNBu^t and Me_3P to form 4-(H_2C = CH)-3-CO-3-Ph_3P-3-Bu^{t}NC-3,1,2-$RuC_2B_9H_{10}$ (**84**)§ and ylide 4-[σ-$CH_2CH(PMe_3)$]-3-CO-3-Ph_3P-3,1,2-$RuC_2B_9H_{10}$ (**85**), respectively.[119]

‡ The structure of complex **70** was established by X-ray diffraction.[118]

§ The structure of compound **84** was established by X-ray diffraction.

Scheme 9



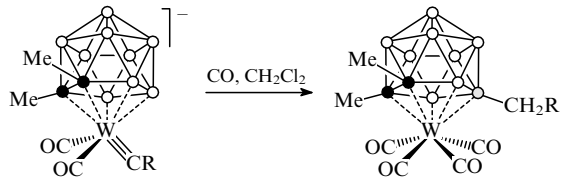
79 **80** **81** **82** **83** **85** **84**

L = PMe_3, CNBu^t, CO.

In most of the above-described examples, the reactions with the use of an excess of alkyne lead to the replacement of the H atoms in the band of the dicarbollyl ligand nearest to the metal atom; the degree of substitution may be as high as 3 (compounds **75** and **76**). The assumed mechanism of substitution involves the replacement of the labile ligand (for example, THF or CO) with the alkyne group η^2-RC≡CR, the rearrangement of the latter to form the vinylidene fragment Ru=C=CHR, its subsequent insertion into the B–H bond of the dicarbollyl ligand, and the displacement of the vinyl substituent from the metal coordination sphere with the next alkyne molecule. However, the degree of substitution in ruthenacarborane **79** containing the PPh_3 ligand in the presence of an excess of alkyne is no higher than 2, which is attributable to steric hindrance caused by the bulky triphenylphosphine substituent. However, the influence of the electronic properties of the ligands involved in the coordination environment about the metal atom on the depth of substitution cannot also be ruled out.

Recently, it has been demonstrated that metal-induced activation of the B–H bond can occur not only in metallacarboranes but also in metal complexes containing substituted *o*-carborane derivatives as a ligand. For example, the reaction of the Cp*Rh(1,2-S_2-1,2-$C_2B_{10}H_{10}$) complex with HC≡CCOOMe affords the substituted Cp*Rh(3,6-(μ-MeOOCCH=CH)$_2$-1,2-S_2-1,2-$C_2B_{10}H_8$) complex.[120, 121]

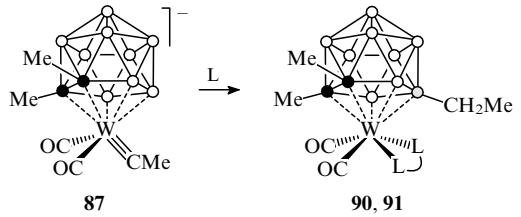
The rearrangement of the alkylidyne complexes belong to another type of reactions involving metal. The reaction of [Et_4N][1,2-Me_2-3-(≡CR)-3,3-$(CO)_2$-3,1,2-$WC_2B_9H_9$] [R = C_6H_4Me-4 (**86**), Me (**87**)] with $HBF_4 \cdot Et_2O$ in a saturated CO solution in dichloromethane is accompanied by the migration of the alkylidyne group to the carborane moiety to form the 8-RCH_2-1,2-Me_2-3,3,3,3-$(CO)_4$-3,1,2-$WC_2B_9H_8$ complexes (**88**, **89**).[122]



86, **87** **88**, **89**

R = C_6H_4Me-4 (**86**, **88**), Me (**87**, **89**).

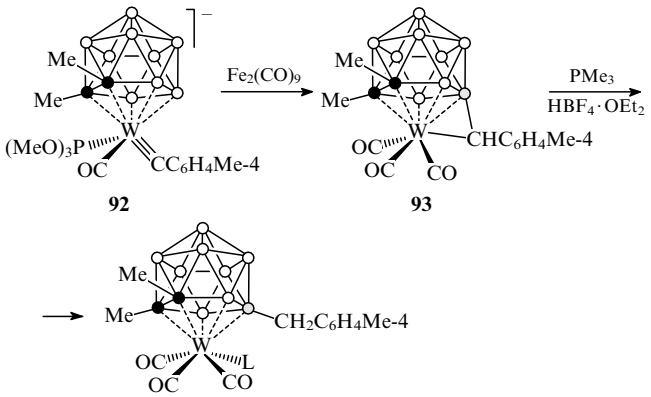
The reactions of compound **87** with $HBF_4 \cdot Et_2O$ and $Ph_2PCH_2CH_2PPh_2$ (dppe) or $Me_2PCH_2CH_2PMe_2$ (dmpe) in dichloromethane produce 8-Et-1,2-Me_2-3,3-$(CO)_2$-3,3-(μ-L_2)-3,1,2-$WC_2B_9H_8$ [L_2 = dppe (**90**) or dmpe (**91**)].[123]



87 **90**, **91**

L–L = dppe (**90**), dmpe (**91**).

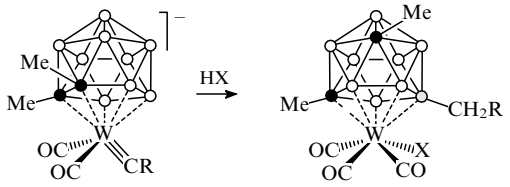
The reaction of [Et_4N][1,2-Me_2-3-(≡CC_6H_4Me-4)-3-CO-3-$P(OMe)_3$-3,1,2-$MoC_2B_9H_9$] (**92**) with $Fe_2(CO)_9$ proceeds through the intermediate formation of 8-[σ-CH(C_6H_4Me-4)]-1,2-Me_2-3,3,3-$(CO)_3$-3,1,2-$MoC_2B_9H_8$ (**93**), which was isolated in the individual state. Treatment of compound **93** with $HBF_4 \cdot Et_2O$ and PMe_3 afforded a mixture of 8-(4-$MeC_6H_4CH_2$)-1,2-Me_2-3,3,3,3-$(CO)_4$-3,1,2-$MoC_2B_9H_8$ (**94**) and 8-(4-$MeC_6H_4CH_2$)-1,2-Me_2-3,3,3-$(CO)_3$-3-Me_3P-3,1,2-$MoC_2B_9H_8$ (**95**).[124]



92 **93**

94 (L = CO), **95** (L = PMe_3)

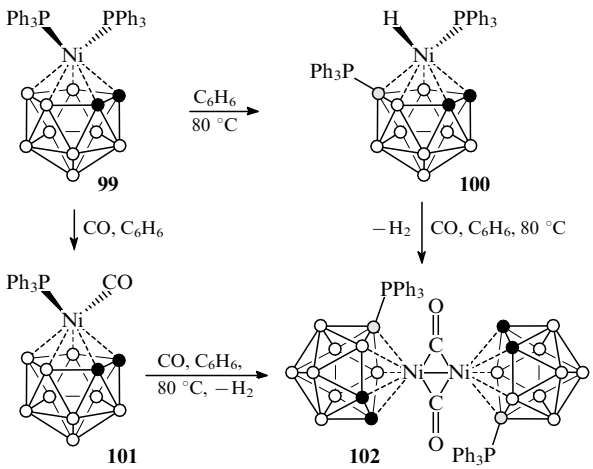
The reaction of the complex Y[**86**] (Y = $(Ph_3P)_2N$ (PPN), Ph_4P or Et_4N) with 1 equiv. of HX (X = Cl or I) proceeds in a more complex way and is accompanied not only by migration of the alkylidyne group from metal to the boron atom but also by the skeletal rearrangement of the dicarbollyl ligand to form Y[11-(4-$MeC_6H_4CH_2$)-1,8-Me_2-2-X-2,2,2-$(CO)_3$-2,1,8-$WC_2B_9H_8$] [X = Cl (**96**) or I (**97**)]. The reaction of the complex [Et_4N][**87**] with HI proceeds analogously to give [Et_4N][11-Et-1,8-Me_2-2-I-2,2,2-$(CO)_3$-2,1,8-$WC_2B_9H_8$] (**98**).[124, 125]



86, **87** **96**–**98**

R = C_6H_4Me-4 (**86**, **96**, **97**), Me (**87**, **98**); X = Cl (**96**), I (**97**, **98**).

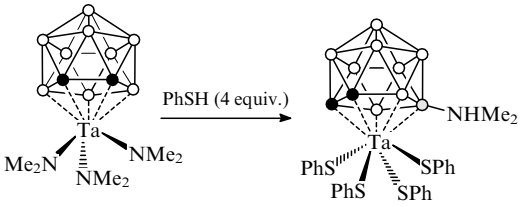
The rearrangement of 3,3-$(Ph_3P)_2$-3,1,2-$NiC_2B_9H_{11}$ (**99**) into 3,8-$(Ph_3P)_2$-3-H-3,1,2-$NiC_2B_9H_{10}$ (**100**) in boiling benzene[126] provides another example of substitution caused by migration of a ligand from the metal atom to the carborane moiety. The reaction of nickelacarborane **99** with CO is accompanied by the replacement of one Ph_3P ligand with the carbonyl group to form complex **101**. Refluxing of the latter in benzene under CO pressure results not only in migration of the triphenylphosphine ligand to the carborane moiety but also in dimerisation to give *closo*-[3-(μ-CO)-8-Ph_3P-3,1,2-$NiC_2B_9H_{10}$]$_2$ (**102**) containing the Ni–Ni bond. The structure of complex **102** was established by X-ray diffraction analysis.[127, 128] Compound **102** can also be prepared by refluxing compound **100** in benzene under CO pressure.



99 **100**

101 **102**

The reaction of tris(dimethylamino)-*closo*-tantalacarborane **103** with four equivalents of thiophenol producing the charge-compensated 8-Me_2HN-3,3,3,3-$(SPh)_4$-3,1,2-$TaC_2B_9H_{10}$ complex (**104**) is yet another example of migration of a ligand from the metal atom to the carborane cage. The structure of compound **104** was determined by X-ray diffraction analysis.[129]

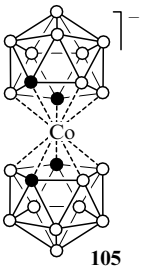


103 **104**

It should be noted that the primary substitution in all metallacarboranes containing the 7,8-dicarbollyl ligand (except for mercuration reactions) occurs at the position adjacent to the metal atom, *i.e.*, the hydrogen atoms at the boron atoms belonging to the open pentagonal face of the ligand are replaced. In the case of both electrophilic and electrophile induced nucleophilic substitution, the primary attack occurs at position 8 of metallacarborane, whereas the substitution with the direct involvement of the metal atom proceeds less selectively.

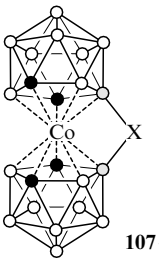
2. Derivatives based on the 7,9-dicarbollyl ligand $[7,9\text{-}C_2B_9H_{11}]^{2-}$

Substitution in metallacarboranes based on the 7,9-dicarbollyl ligand was exemplified by the only metallacarborane, *viz.*, bis(1,7-dicarbollyl)cobalt [*commo*-2,2′-$Co(1,7\text{-}C_2B_9H_{11})_2]^-$ (**105**) (the atomic numbering scheme is shown in Fig. 1 *e*). Substitution in complex **105** resembles that in analogous complex **1** (see p. 435) and is accompanied by the formation of compounds containing various bridges between two dicarbollyl ligands. For instance, the reaction of complex **105** with carbon disulfide in the presence of $AlCl_3$ and HCl affords (μ-HCS_2)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ (**106**) with the three-atom SCS bridge.[89]



105

The reaction of complex **105** with formaldehyde in an HCl(conc.)–$CHCl_3$ mixture at 60 °C gives rise to the bridged 6,6′-(μ-MeO)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ compound (**107**) in high yield. The latter is readily demethylated with Lewis bases in methanol to form [6,6′-(μ-O)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2]^-$.[130]



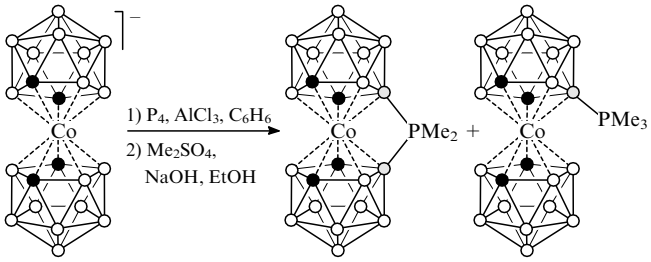
107–**119**

X = OMe (**107**), NH_2 (**108**), NMe_2 (**109**), NHMe (**110**), S (**111**), SEt (**112**), SPr^n (**113**), SPr^i (**114**), SBu^n (**115**), SC_6H_{13} (**116**), $SCH_2CH{=}CH_2$ (**117**), $SCH_2C(O)OMe$ (**118**), PMe_2 (**119**).

The reaction of compound **105** with $NaNO_2$ in benzene in the presence of sulfuric acid produces the corresponding derivative 6,6′-(μ-H_2N)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ (**108**) with a one-atom nitrogen bridge. Treatment of the latter with dimethyl sulfate in 30% NaOH affords the *N*,*N*-dimethylation product 6,6′-(μ-Me_2N)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ (**109**). The monoalkylated complex 6,6′-(μ-MeNH)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ (**110**) was prepared by treatment of a benzene suspension of [Me_4N][6,6′-(μ-HN)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$] with diiodomethane in 10% aqueous alkali.[130]

The reaction of complex **105** with sulfur in benzene in the presence of $AlCl_3$ at 80 °C yields the [6,6′-(μ-S)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2]^-$ complex (**111**),[131] whose alkylation with various alkyl halides in isopropyl alcohol affords the corresponding alkylsulfonium derivatives 6,6′-(μ-RS)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ [R = Et (**112**), Pr^n (**113**), Pr^i (**114**), Bu^n (**115**), C_6H_{13} (**116**) or $CH_2CH{=}CH_2$ (**117**)].[130, 132] The reaction of complex **105** with chloroacetic acid in an aqueous Na_2CO_3 solution gives an acid, whose esterification in methanol in the presence of $SOCl_2$ affords 6,6′-(μ-$MeOC(O)CH_2S$)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ (**118**).[130]

The reaction of compound **105** with phosphorus in benzene at 80 °C followed by reaction with dimethyl sulfate in the presence of sodium hydroxide in ethanol gives rise to a mixture of 6,6′-(μ-Me_2P)-2,2′-$Co(1,7\text{-}C_2B_9H_{10})_2$ (**119**) and 6-Me_3P-2,2′-$Co(1,7\text{-}C_2B_9H_{10})(1',7'\text{-}C_2B_9H_{11})$ (**120**).[108]



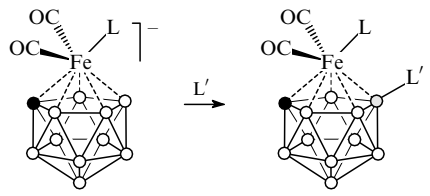
105 **119** **120**

It should be noted that in all the above-described reactions, substitution in metallacarboranes occurs at position 6 adjacent to the metal atom.

3. Derivatives based on the carbollyl ligand $[CB_{10}H_{11}]^{3-}$

There are abundant data on substitution in metallacarboranes based on the carbollyl ligand $[CB_{10}H_{11}]^{3-}$. As in the case of metallacarboranes based on the 7,8-dicarbollyl anion, substitution in metal complexes with carbollyl ligands can occur involving both the metal and boron atoms (by the mechanism of electrophilic or electrophile induced nucleophilic substitution).

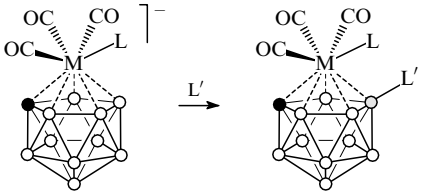
The reactions of ferracarboranes [PPN][2,2-$(CO)_2$-2-L-2,1-$FeCB_{10}H_{11}$] [L = SMe_2 (**121**) or PPh_3 (**122**)] with sulfuric acid in dimethyl sulfide or tetrahydrofuran produce charge-compensated products of electrophile induced nucleophilic substitution with composition 7-L′-2,2-$(CO)_2$-2-L-2,1-$FeCB_{10}H_{10}$ [L = SMe_2: L′ = SMe_2 (**123**), $O(CH_2)_4$ (**124**); L = PPh_3: L′ = SMe_2 (**125**), $O(CH_2)_4$ (**126**)] containing the L′ substituent in the open face at position 7, which is one of the most remote from the carbon atom.[133]



121, **122** **123**–**126**

L = SMe_2 (**121**, **123**, **124**), PPh_3 (**122**, **125**, **126**);
L′ = SMe_2 (**123**, **125**), $O(CH_2)_4$ (**124**, **126**).

The reactions with the [PPN][2,2,2-(CO)$_3$-2-L-2,1-MCB$_{10}$H$_{11}$] complexes [L = Ph$_3$P: M = Mo (**127**), W (**128**); L = Bu^{t}NC: M = Mo (**129**), W (**130**)] proceed analogously. For example, the reactions of compounds **127** – **130** with CF_3SO_3Me or sulfuric acid in the presence of the donors of L′ [L′ = SMe$_2$, OEt$_2$, O(CH$_2$)$_4$, S(CH$_2$)$_4$, cyclo-1,4,7-S$_3$(CH$_2$)$_6$, NCBu^t, CNBu^t, CNC$_6$H$_3$Me$_2$-2,6] give rise to the corresponding zwitterionic 7-L′-2,2,2-(CO)$_3$-2-L-2,1-MCB$_{10}$H$_{10}$ complexes (**131** – **134**).[134] The structure of molybdacarborane 7-CNBu^t-2,2,2-(CO)$_3$-2-Ph$_3$P-2,1-MoCB$_{10}$H$_{10}$ (**131g**) was confirmed by X-ray diffraction analysis.[134]



127 – **130** **131a** – **h**, **132a** – **h**, **133**, **134**

L = PPh$_3$: M = Mo (**127**, **131a** – **h**), W (**128**, **132a** – **h**); L′ = SMe$_2$ (**a**), OEt$_2$ (**b**), O(CH$_2$)$_4$ (**c**), S(CH$_2$)$_4$ (**d**), cyclo- 1,4,7-S$_3$(CH$_2$)$_6$ (**e**), NCBu^t (**f**), CNBu^t (**g**), CNC$_6$H$_3$Me$_2$-2,6 (**h**);
L = CNBu^t: M = Mo (**129**, **133**), W (**130**, **134**); L′ = OEt$_2$ (**133**, **134**).

Treatment of compounds **132b** and **132c** with trimethylamine oxide in the presence of Ph$_4$PBr in tetrahydrofuran affords the corresponding alkoxy derivatives [Ph$_4$P][7-RO-2,2,2-(CO)$_3$-2-Ph$_3$P-2,1-WCB$_{10}$H$_{10}$] (R = Et, (CH$_2$)$_3$CHO).[134]

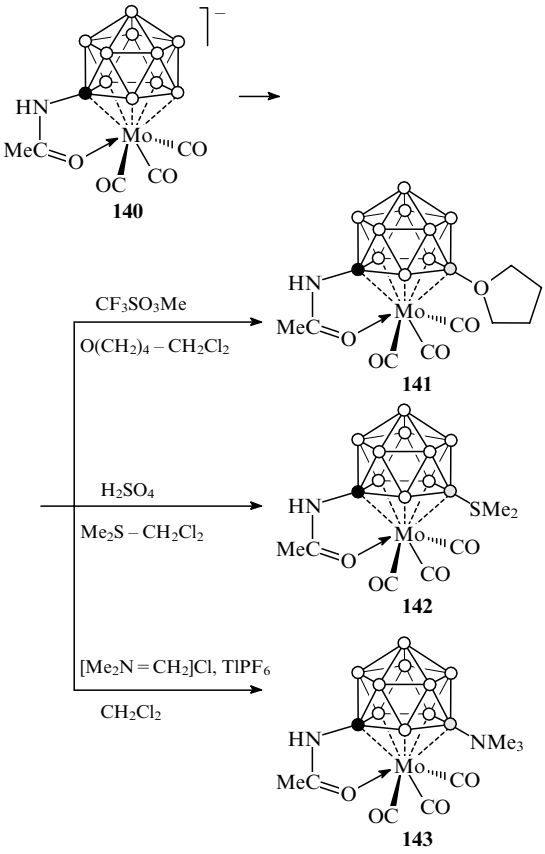
The reaction of cobaltacarborane [PPN][2-Et$_3$P-2-NO-2,1-CoCB$_{10}$H$_{11}$] with methyl triflate in a mixture of CH_2Cl_2 and THF yields the corresponding charge-compensated derivative 7-(CH$_2$)$_4$O-2-Et$_3$P-2-NO-2,1-CoCB$_{10}$H$_{10}$,[133] whereas the reaction in a mixture of CH_2Cl_2 and acetonitrile affords 7-MeCN-2-Et$_3$P-2-NO-2,1-CoCB$_{10}$H$_{10}$ with an impurity of *closo*-7-(NMe=CHMe)-2-Et$_3$P-2-NO-2,1-CoCB$_{10}$H$_{11}$.[135]

The reactions of ferracarboranes [PPN][2,2-(CO)$_2$-2-L-2,1-FeCB$_{10}$H$_{11}$] [L = PPh$_3$ (**122**), CO (**135**), Bu^{t}NC (**136**)] with methyl triflate in acetonitrile produce 7-[(*E*)-MeCH=NMe]-2,2-(CO)$_2$-2-L-2,1-FeCB$_{10}$H$_{10}$ (**137** – **139**) [L = PPh$_3$ (**137**), CO (**138**), Bu^{t}NC (**139**)] (Scheme 10).[133] It is assumed that acetonitrile is initially methylated with methyl triflate to form the *N*-methylnitrilium cation [MeC≡NMe]$^+$,[136] which is involved in electrophile induced nucleophilic substitution (Scheme 10).

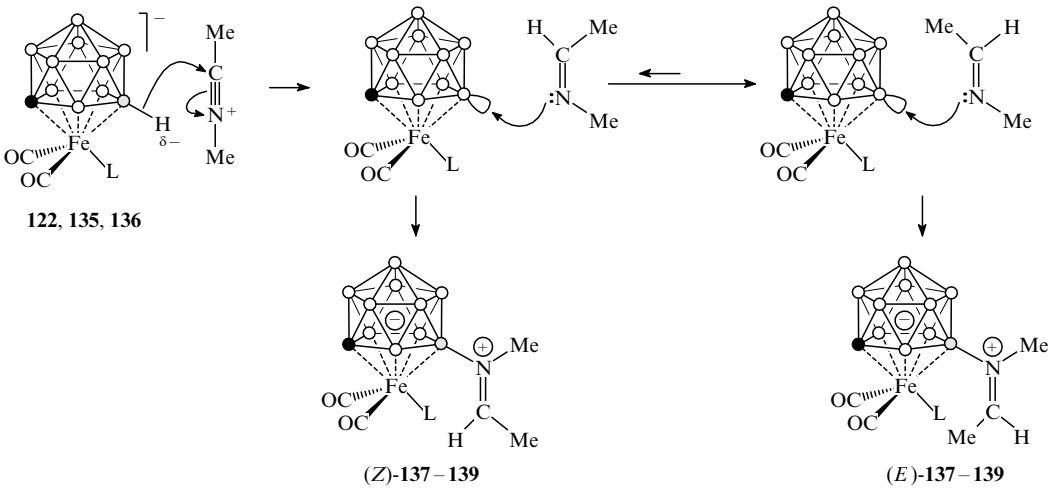
The *E* form of an imine is, apparently, more stable due to which only one isomer is formed. Complex **138** is readily hydrolysed in the presence of bases as catalysts to give 7-MeH$_2$N-2,2,2-(CO)$_3$-2,1-FeCB$_{10}$H$_{10}$ and is reduced to 7-Me(Et)HN-2,2,2-(CO)$_3$-2,1-FeCB$_{10}$H$_{10}$ in the presence of Na[BH$_3$CN].[133]

As in the case of analogous iron complexes, the reactions of compounds **127** and **128** with CF_3SO_3Me in acetonitrile produce the iminium derivatives 7-[(*E*)-MeCH=NMe]-2,2,2-(CO)$_3$-2-Ph$_3$P-2,1-MCB$_{10}$H$_{10}$ (M = Mo, W). The reaction with the use of Bu^{t}NC instead of acetonitrile gives rise to a mixture of *E* and *Z* isomers of 7-(MeCH=NBu^t)-2,2,2-(CO)$_3$-2-Ph$_3$P-2,1-MCB$_{10}$H$_{10}$.[134]

Substitution in *C*-substituted molybdacarborane [PPN][1,2-[μ-MeC(O)NH]-2,2,2-(CO)$_3$-2,1-MoCB$_{10}$H$_{10}$] (**140**) occurs analogously. The reaction of complex **140** with CF_3SO_3Me in a mixture of THF and dichloromethane yields the charge-compensated 7-(CH$_2$)$_4$O-1,2-[μ-MeC(O)NH]-2,2,2-(CO)$_3$-2,1-MoCB$_{10}$H$_9$ complex (**141**). The reaction of complex **140** with concentrated sulfuric acid in a CH_2Cl_2 – SMe$_2$ mixture affords the



Scheme 10



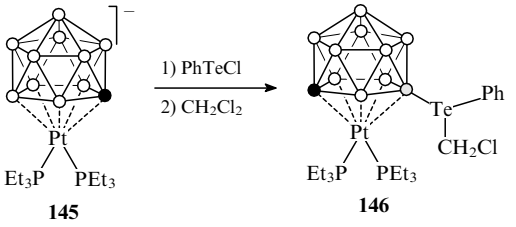
122, **135**, **136** (*Z*)-**137** – **139** (*E*)-**137** – **139**

L = PPh$_3$ (**122**, **137**), CO (**135**, **138**), Bu^{t}NC (**136**, **139**).

dimethylsulfonium derivative 7-Me_2S-1,2-[μ-MeC(O)NH]-2,2,2-$(CO)_3$-2,1-$MoCB_{10}H_9$ (**142**), whereas the reaction of this complex with $[Me_2N=CH_2]Cl$ and $TlPF_6$ in dichloromethane gives the corresponding trimethylammonium derivative 7-Me_3N-1-[μ-MeC(O)NH]-2,2,2-$(CO)_3$-2,1-$MoCB_{10}H_9$ (**143**).[137]

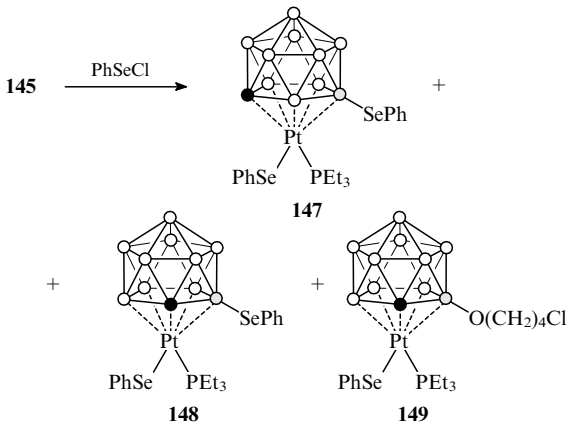
Interestingly, the reaction of [PPN][2,2-$(CO)_2$-2-(η^2-Bu^{t}C≡CH)-2,1-$MCB_{10}H_{11}$] (M = Mo, W) with CF_3SO_3Me in a $CH_2Cl_2-Et_2O$ mixture produces the corresponding charge-compensated derivatives 7-Et_2O-2,2-$(CO)_2$-2-(η^2-Bu^{t}C≡CH)-2,1-$MCB_{10}H_{10}$ rather than leads to the rearrangement of the Bu^{t}C≡CH ligand followed by the insertion of the alkene fragment at the B—H bond (which occurs in the reactions of alkyne dicarbollyl complexes).[134] By contrast, the reaction of ferracarborane **135** with *tert*-butylacetylene in THF in the presence of Me_3NO forms 3-[η^2-(*E*)-Bu^{t}CH = CH]-2,2,2-$(CO)_3$-2,1-$FeCB_{10}H_{10}$ (**144**), *i.e.*, substitution (as in the case of metallacarboranes based on the dicarbollyl ligand) occurs at the position adjacent to the carbon atom in the open face of the carborane ligand. The reaction of complex **144** with CF_3SO_3Me in acetonitrile affords 3-[η^2-(*E*)-Bu^{t}CH=CH]-7-(MeCH=NMe)-2,2,2-$(CO)_3$-2,1-$FeCB_{10}H_9$, in which the imine fragment is located in the open face of the carborane ligand occupying the position most remote from the carbon atom and the boron atom bearing the alkene substituent.[133]

Under similar conditions, the reactions of platinacarborane Na[2,2-$(Et_3P)_2$-2,1-$PtCB_{10}H_{11}$] (**145**) with PhSeCl and PhTeI in tetrahydrofuran proceed differently. The reaction with PhTeI proceeds according to the electrophilic mechanism to give (after chromatography with the use of CH_2Cl_2 as the eluent) the charge-compensated 7-$ClCH_2$(Ph)Te-2,2-$(Et_3P)_2$-2,1-$PtCB_{10}H_{10}$ complex (**146**), whose structure was established by X-ray diffraction analysis. By contrast, the reaction with PhSeCl proceeds with the participation of the metal atom to give a mixture of 7,2-$(PhSe)_2$-2-Et_3P-2,1-$PtCB_{10}H_{10}$ (**147**), 3,2-$(PhSe)_2$-2-Et_3P-2,1-$PtCB_{10}H_{10}$ (**148**) and 3-$Cl(CH_2)_4O$-2-PhSe-2-Et_3P-2,1-$PtCB_{10}H_{10}$ (**149**).¶ It is assumed that complex **149** is generated as a result of the tetrahydrofuran-ring opening in the oxonium derivative under the action of the chloride ion.[138]



145 **146**

¶ The structure of complex **149** was established by X-ray diffraction.

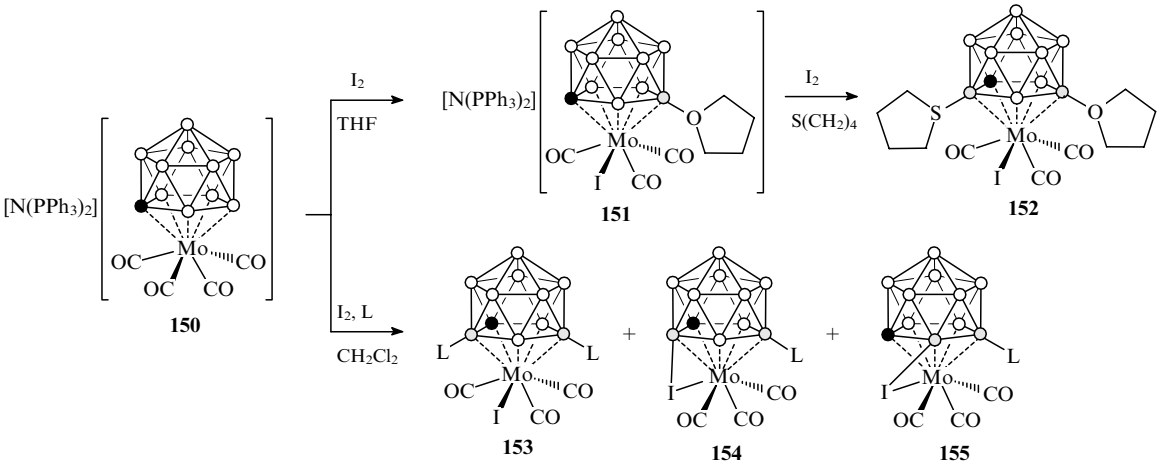


147 **148** **149**

The reactions of metallacarboranes, which contain labile ligands in the metal coordination sphere, with halides proceed in an unusual way. For example, treatment of the molybdenum complex [PPN][2,2,2,2-$(CO)_4$-2,1-$MoCB_{10}H_{11}$] (**150**) with iodine in tetrahydrofuran leads not only to the replacement of one of the carbonyl ligands with iodine but also to the replacement of the hydrogen atom at position 7 of the carborane moiety with tetrahydrofuran to form [PPN][7-$(CH_2)_4$O-2,2,2-$(CO)_3$-2-I-2,1-$MoCB_{10}H_{10}$] (**151**) (Scheme 11). The structure of complex **151** was determined by X-ray diffraction analysis. The reaction of a solution of compound **151** in tetrahydrothiophene with iodine is accompanied by the replacement of one more hydrogen atom in the open face of the carborane ligand with tetrahydrothiophene to give the neutral 3-$(CH_2)_4S$-11-$(CH_2)_4O$-2,2,2-$(CO)_3$-2-I-2,1-$MoCB_{10}H_9$ complex (**152**). The reaction of complex **150** with iodine in CH_2Cl_2 in the presence of cyclic thioesters (L) also affords two types of substituted molybdacarboranes. In both cases, the substitution involves the metal atom (one of the carbonyl groups at the Mo atom is replaced with the iodide ion). Derivatives of one type, *viz.*, 3,11-L_2-2,2,2-$(CO)_3$-2-I-2,1-$MoCB_{10}H_9$ (**153**), contain two sulfonium substituents in the open face of the monocarbollyl ligand, whereas derivatives of another type, *viz.*, 7-L-2,3-(μ-I)-2,2,2-$(CO)_3$-2,1-$MoCB_{10}H_9$ (**154**) and 11-L-2,3-(μ-I)-2,2,2-$(CO)_3$-2,1-$MoCB_{10}H_9$ (**155**), bear the sulfonium substituent along with the bridging iodine atom between Mo and the boron atom at the position nearest to the carbon atom.[139]

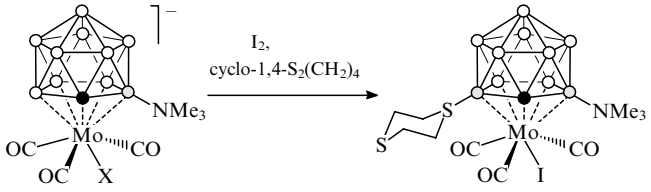
The reactions of the molybdenum complexes [PPN][3-Me_3N-2,2,2-$(CO)_3$-2-X-2,1-$MoCB_{10}H_{10}$] [X = I (**156**) or Br (**157**)] with 1,4-dithiane and iodine in dichloromethane afford the 3-Me_3N-6-$S(CH_2CH_2)_2S$-2,2,2-$(CO)_3$-2-I-2,1-$MoCB_{10}H_9$ complex containing substituents in the pentagonal face of the monocarbollyl ligand at the positions adjacent to the carbon atom. Interestingly,

Scheme 11

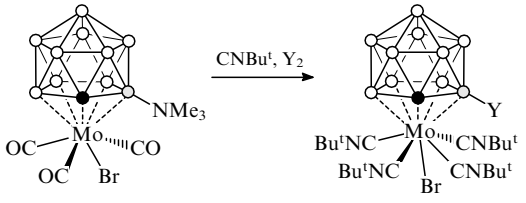


150 **151** **152** **153** **154** **155**

the reaction of [PPN][3-Me_3N-2,2,2-$(CO)_3$-2-Br-2,1-$MoCB_{10}H_{10}$] (**157**) with Bu^tNC and iodine (or bromine) in dichloromethane leads to the replacement of the trimethylamino group in the monocarbollyl ligand with the halogen atom to form 3-Y-2,2,2,2-$(Bu^tNC)_4$-2-Br-2,1-$MoCB_{10}H_{10}$ [Y = Br (**159**) or I (**160**)].[140]



156 (X = I), **157** (X = Br) **158**



157 **159** (Y = Br), **160** (Y = I)

Y = Br, I.

It should be noted that in none of the above-considered reactions does the replacement of the hydrogen atom with halogen occur through the mechanism of electrophilic substitution.

4. Dicobaltacarborane derivatives

The reaction of dicobaltacarborane 3,6-Cp_2-3,6,1,2-$Co_2C_2B_8H_{10}$ (**161**) containing two CpCo fragments with mercury acetate in boiling dichloromethane (Scheme 12) followed by the replacement of the acetate group with chlorine gives rise to a mixture of 3,6-Cp_2-8-HgCl-3,6,1,2-$Co_2C_2B_8H_9$ (**162**)† and 3,6-Cp_2-9-HgCl-3,6,1,2-$Co_2C_2B_8H_9$ (**163**) in a ratio of 1 : 1.2.[141]

† The structure of 8-monomercury derivative **162** was confirmed by X-ray diffraction.[126]

The reaction with an excess of mercury acetate in acetic acid allows one to introduce up to four substituents into the carborane moiety to form the 3,6-Cp_2-8,10,9,12-$(HgCl)_4$-3,6,1,2-$Co_2C_2B_8H_6$ complex (**164**).

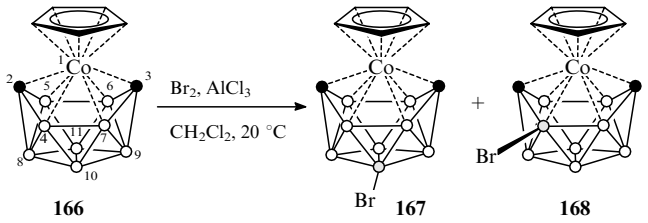
An attempt to prepare a thallium derivative by the reaction of complex **161** with thallium(III) trifluoroacetate in trifluoroacetic acid failed; instead, this reaction gave 8,9-bistrifluoroacetate derivative **165**.[141]

IV. Substitution in non-icosahedral metallacarboranes

Substitution in non-icosahedral metallacarboranes has received less study because these compounds are less readily accessible. Substitution in 10- and 11-vertex metallacarboranes was studied only for CpCo carboranes.

1. Substitution in 11-vertex cobaltacarboranes

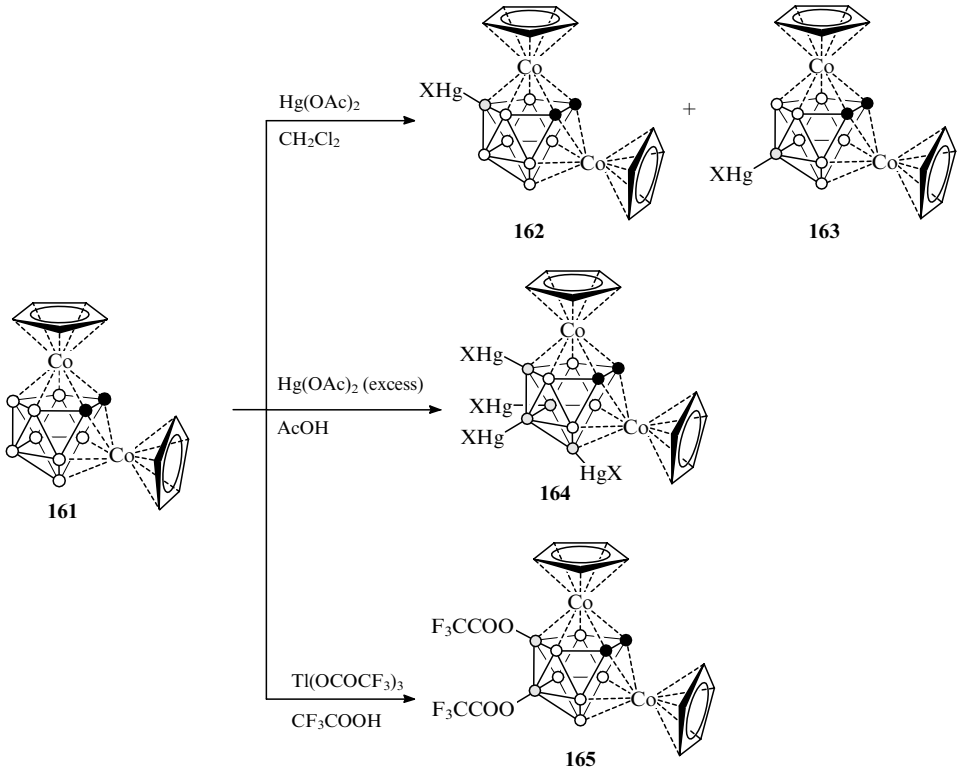
Zakharkin *et al.*[142] studied bromination of 1-Cp-1,2,3-$CoC_2B_8H_{10}$ (**166**). The reaction of complex **166** with 1 equiv. of bromine in dichloromethane in the absence of a catalyst or in the presence of $AlCl_3$ produces a mixture of the isomeric bromine derivatives 10-Br-1-Cp-1,2,3-$CoC_2B_8H_9$ (**167**) and 4-Br-1-Cp-1,2,3-$CoC_2B_8H_9$ (**168**). The reaction with the use of glacial acetic acid as the solvent gives a mixture of the same monobromides with an impurity of dibromo derivatives. The ratio between the 10- and 4-isomers is (4.5 – 6) : 1. The structure of complex **166** was established by X-ray diffraction analysis.[142]



166 **167** **168**

The reactions of complex **166** with two, three or four equivalents of bromine in the presence of $AlCl_3$ yield a mixture of di-,

Scheme 12

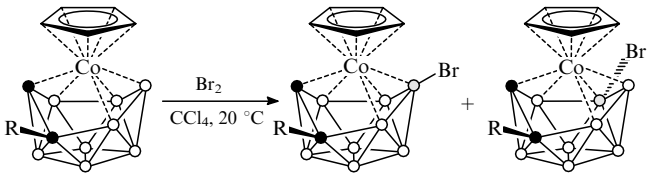


161 **162** **163** **164** **165**

tri- and tetrabromo derivatives. Attempts to separate these derivatives failed. The pentabromo derivative 4,5,6,10,11-Br_5-1-Cp-1,2,3-$CoC_2B_8H_5$ was synthesised by refluxing compound **166** with 8 equiv. of bromine in the presence of $AlCl_3$ in dichloromethane.[142]

Based on the above results, it was hypothesised that the electron density on the boron atoms of the π-carborane ligand decreases in the series B(10, 11) > B(4, 5, 6, 7) > B(8, 9).

The reaction of cobaltacarborane *isonido*-1-Cp-1,2,4-$CoC_2B_8H_{10}$ (**169**) (which is isomeric to compound **166**) with 1 equiv. of bromine in CCl_4 produces two isomeric monobromides, *viz*., 3-Br-1-Cp-1,2,4-$CoC_2B_8H_9$ (**170**) and 6-Br-1-Cp-1,2,4-$CoC_2B_8H_9$ (**171**), in a ratio of 1 : 10.[143]



169, **172** **170**, **173** **171**, **174**

R = H (**169**, **170**, **171**), Me (**172**, **173**, **174**).

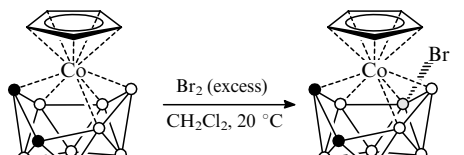
The reaction of complex **169** with *N*-bromosuccinimide also gives rise to a mixture of monobromides **170** and **171**, but in much lower yields.

At room temperature, each isomer in a benzene solution slowly (during two days) undergoes rearrangement to form an equilibrium mixture of monobromides **170** and **171** in a ratio of 1 : 1.3. This suggests that isomer **171** is a kinetic substitution product, whereas isomer **170** is a rearrangement product.

Only 6-Br-4-Me-1-Cp-1,2,4-$CoC_2B_8H_8$ (**174**) was isolated as a product of bromination of the *C*-methyl derivative *isonido*-4-Me-1-Cp-1,2,4-$CoC_2B_8H_9$ (**172**). This product underwent partial rearrangement into complex **173** (presumably) upon prolonged storage in a benzene solution. However, the percentage of **173** (according to the ^{11}B NMR spectroscopic data) was no higher than 10%.[143] Evidently, the introduction of the methyl substituent at the C(4) atom hinders the rearrangement of the substitution product.

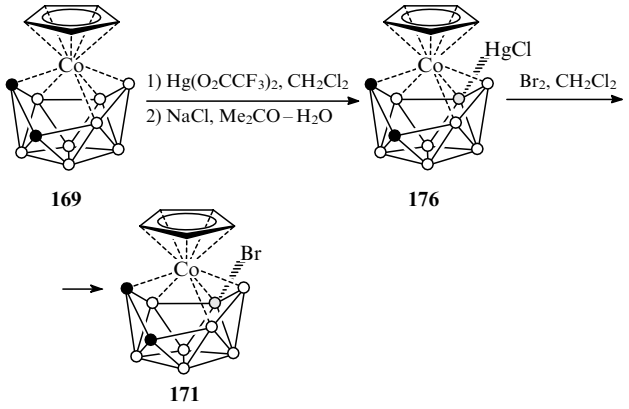
It should be noted that chloro-substituted derivatives of isostructural metallacarboranes 3-Cl-1-(η^6-Ar)-1,2,4-$RuC_2B_8H_9$ and 6-Cl-1-(η^6-Ar)-1,2,4-$RuC_2B_8H_9$ (Ar = C_6H_6, PhMe, 1,4-$Me_2C_6H_4$, 1-Me-4-$Pr^iC_6H_4$, 1,2,4-$Me_3C_6H_3$, 1,3,6-$Me_3C_6H_3$, 1,2,4,5-$Me_4C_6H_2$, C_6Me_6) were prepared by the reactions of $RuCl_2(PPh_3)_3$ with *nido*-5,6-$C_2B_8H_{12}$ in benzene and other aromatic solvents.[144] The reaction of *nido*-7-Br-5,6-$C_2B_8H_{11}$ with $[(\eta^6\text{-}C_6Me_6)RuCl_2]_2$ also produces a mixture of isomers 5-Br-1-(η^6-C_6Me_6)-1,2,4-$RuC_2B_8H_9$ and 7-Br-1-(η^6-C_6Me_6)-1,2,4-$RuC_2B_8H_9$.[145] The formation of such pairs of halogen derivatives indicates that the rearrangements of various metallacarboranes with the 1,2,4-MC_2B_8 skeleton occur by a similar mechanism.

The reaction of compound **169** with a tenfold excess of bromine produces exclusively the dibromo derivative 6,9-Br_2-1-Cp-1,2,4-$CoC_2B_8H_8$ (**175**). Derivatives containing the bromine atom at position 3 of the cobaltacarborane moiety were not found.[143]



169 **175**

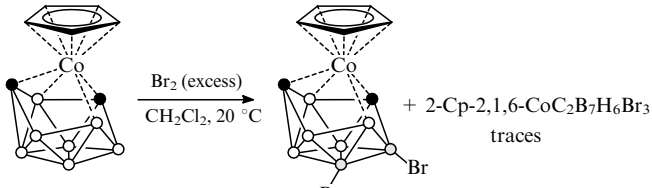
The chloromercury derivative 6-HgCl-1-Cp-1,2,4-$CoC_2B_8H_9$ (**176**) was synthesised by mercuration of complex **169** with mercury trifluoroacetate followed by treatment of the resulting complex with NaCl. The structure of compound **176** was established by X-ray diffraction analysis. The reaction of compound **176** with bromine in dichloromethane at room temperature affords monobromide **171**.[143]



169 **176** **171**

2. Substitution in 10-vertex cobaltacarboranes

Hawthorne and co-workers [146] studied bromination and acylation of 2-Cp-2,1,6-$CoC_2B_7H_9$ (**177**). The reaction of compound **177** with an excess of bromine in CCl_4 produces dibromo derivative **178**, in which the bromine atoms occupy positions 8 and 10, with a small impurity of tribromide.



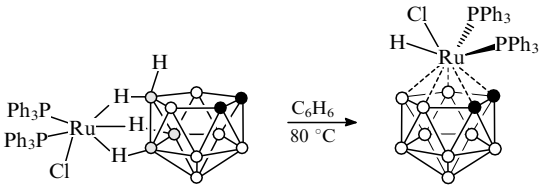
177 **178**

Acylation of complex **177** with acetyl chloride in the presence of $AlCl_3$ in dichloromethane gives the monoacetyl derivative 8-Ac-2-Cp-2,1,6-$CoC_2B_7H_8$.[146]

It should be noted that the above results agree well with the data on substitution in purely polyhedral boron hydrides devoid of the metal fragment. For example, electrophilic substitution in the ten-vertex polyhedra $[B_{10}H_{10}]^{2-}$ and $[1\text{-}CB_9H_{10}]^-$ occurs predominantly at the five-coordinate boron atoms.[147, 148] In the case of structurally flexible eleven-vertex polyhedral boron hydrides, which readily undergo rearrangement (for example, $[B_{11}H_{11}]^{2-}$), the substitution position is determined by the relative stability of intermediate and substitution products.[149–151]

V. Substitution in *exo-nido*-metallacarboranes

Interesting results were obtained in the study of substitution in ruthenacarboranes containing the hydride ligand in the metal coordination sphere. Metallacarboranes with the hydride ligand can exist as two isomers, *viz*., *closo*- and *exo-nido*-metallacarboranes. Stability of a particular form depends on the nature of the metal atom and substituents in the carborane ligand.[152] For example, ruthenacarborane *exo-nido*-5,6,10-[$Cl(Ph_3P)_2Ru$]-5,6,10-(μ-H)$_3$-10-H-7,8-$C_2B_9H_8$ (**179**) [153] undergoes isomerisation into *closo*-3,3-$(PPh_3)_2$-3-H-3-Cl-3,1,2-$RuC_2B_9H_{11}$ (**180**) [154] on heating in benzene at 80 °C

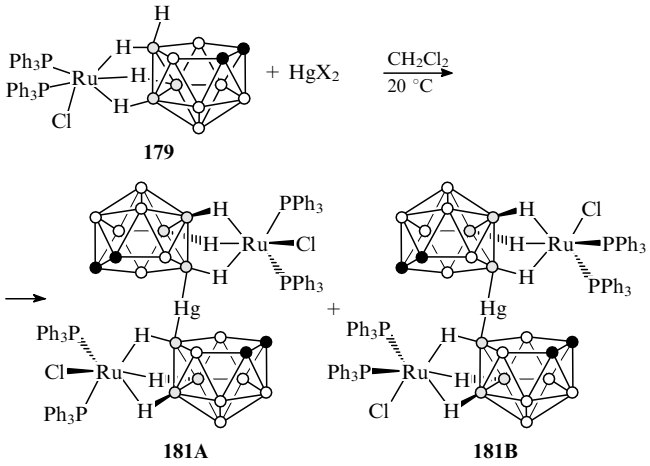


179 **180**

Isomers **179** and **180** differ in chemical behaviour. For example, isomer **180** does not react with $Hg(OAc)_2$ in CH_2Cl_2 or acetone and decomposes in acetic acid, whereas isomer **179** is involved in substitution reactions with various mercurating agents to form *exo-nido*-ruthenacarboranylmercury derivatives.[155]

It should be noted that ruthenacarborane **179** exists in solution as an equilibrium mixture of two geometric isomers (*cis* and *trans*) due to isomerism of the ligands at the six-coordinate ruthenium atom. The *cis* : *trans* isomer ratio is $\sim 1:1$.[156]

The reaction of complex **179** with mercury acetate or trifluoroacetate in dichloromethane at 20 °C affords the symmetrical mercury derivative 10,10′-Hg-[*exo-nido*-5,6,10-$(Cl(Ph_3P)_2Ru)$-5,6,10-$(\mu\text{-}H)_3$-7,8-$C_2B_9H_8]_2$ (**181**) in 46% yield. The latter was prepared as a mixture of geometric isomers, *viz*., *cis* (**A**) and *trans* (**B**). According to the ^{31}P NMR spectroscopic data, the **A** : **B** ratio was 5 : 1.[155]



179

181A **181B**

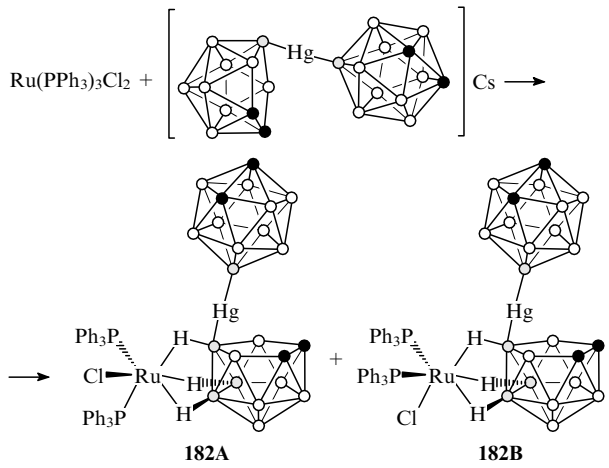
X = AcO, CF_3COO.

In the isomers **A** and **B**, the hydrogen atom at B(10) in the open face of the *exo-nido*-carborane ligand and the chlorine atom at the ruthenium atom are in the *cis* and *trans* positions, respectively.

An analogous mixture of isomers was prepared by the reaction of $Ru(Ph_3P)_3Cl_2$ with the symmetrical mercury derivative of the *nido*-7,8-dicarbaundecaborate anion $Cs_2[10,10'\text{-}Hg\text{-}(7,8\text{-}C_2B_9H_{11})_2]$.[157] Here, as in the first case, the isomer **A** prevails.[155]

In the study,[155] it was proposed to use trifluoroacetoxy-*o*-carboranylmercury 9-$CF_3COOHgC_2B_{10}H_{11}$ (see Ref. 158) along with mercury salts. The reaction of complex **179** with this reagent affords mercurated ruthenacarborane *exo-nido*-5,6,10-$[Cl(Ph_3P)_2Ru]$-5,6,10-$(\mu\text{-}H)_3$-10-$(C_2B_{10}H_{11}Hg)$-7,8-$C_2B_9H_8$ (**182**) containing both the *closo*- and *nido*-carborane moieties.[155] It should be noted that, unlike complex **181**, compound **182** is generated predominantly as the *trans* isomer (**182B**). According to the ^{31}P NMR spectroscopic data, the *cis* : *trans* ratio is 1 : 2.

The independent synthesis of compound **182** by the reaction of $Ru(PPh_3)_3Cl_2$ with $Cs[10\text{-}(9\text{-}HgC_2B_{10}H_{11})(7,8\text{-}C_2B_9H_{11})]$ gave an analogous result.[159]

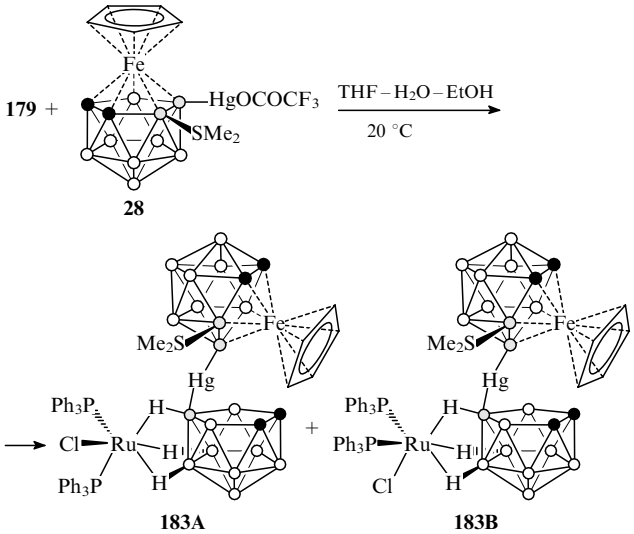


182A **182B**

Isomers **182A** and **182B** were isolated in the individual state. The structure of isomer **182B** was confirmed by X-ray diffraction analysis.

Refluxing of complexes **181** and **182** in benzene does not lead to their *exo-nido* → *closo* rearrangement. Carbon-substituted *exo-nido*-ruthenacarboranes behave analogously.[154] The B—Hg bond in compounds **181** and **182** is resistant to the action of HCl and $HgCl_2$ in acetone or THF at room temperature.

In the studies,[160, 161] mercurated ferracarborane **28** and cobaltacarborane **21** were used as mercurating agents for the first time.‡ The reaction of complex **179** with 1 equiv. of ferracarborane **28** affords the only product, *viz*., *exo-nido*-5,6,10-$[Cl(Ph_3P)_2Ru]$-5,6,10-$(\mu\text{-}H)_3$-10-$(3'\text{-}Cp\text{-}4'\text{-}SMe_2\text{-}8'\text{-}Hg\text{-}3',1',2'\text{-}FeC_2B_9H_9)$-7,8-$C_2B_9H_8$ (**183**), as a mixture of geometric isomers.

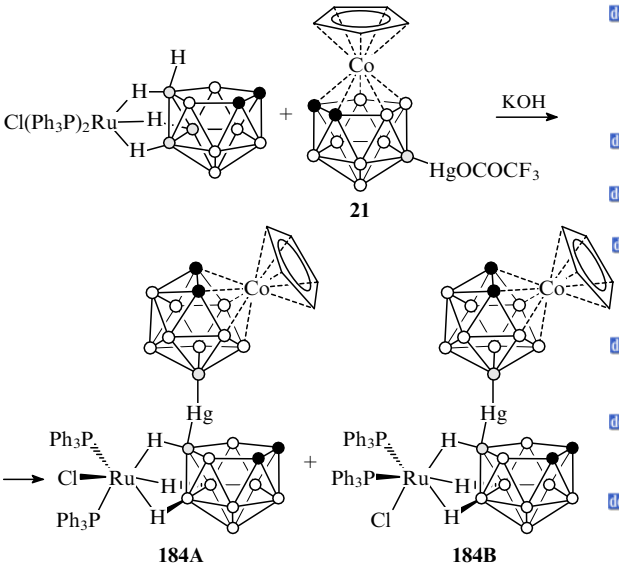


28

183A **183B**

Analogous results were obtained when performing mercuration of complex **179** with cobaltacarborane **21**. Like the above-described complexes **181**, **182** and **183**, complex **184** exists as a mixture of geometric (*cis* and *trans*) isomers (due to isomerism of the ligands with respect to the six-coordinate ruthenium atom). The structure of complex **183B** was confirmed by X-ray diffraction data.

‡ The synthesis of derivatives **21** and **28** was described in the studies.[78, 83]



Analysis of the published data on substitution in metallacarboranes makes it possible to compare these reactions with analogous reactions of other polyhedral boron hydrides and draw a conclusion about the influence of the metal atom and the coordinated ligands as well as of the substituents in the polyhedral moiety on the direction of substitution and possible mechanisms of the process.

The above-considered data provide evidence in favour of three major mechanisms of substitution: electrophilic aromatic substitution, electrophile induced nucleophilic substitution and substitution with direct involvement of the metal atom. In some cases, the reactions proceed simultaneously through several competitive mechanisms to give a mixture of substitution products.

The direction of substitution in metallacarboranes often differs from that in carboranes. For example, electrophilic substitution in *o*- and *m*-carboranes occurs at the boron atoms most remote from carbon atoms, whereas the influence of the metal fragment in metallacarboranes is manifested in that the replacement of hydrogen atoms generally occurs at positions adjacent to the metal atoms.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-32192), the Chemistry and Materials Science Division of the Russian Academy of Sciences (Project No. 591-07, the Program of Basic Research) and the INTAS (Grant 99-00806).

Abstract. The state-of-the-art in the structural investigations into fullerene derivatives is surveyed. The crystal structures of individual fullerenes and of their derivatives determined experimentally by single-crystal X-ray diffraction are systematised. The results of powder X-ray diffraction and EXAFS spectroscopy are overviewed for those classes of derivatives that have been insufficiently studied by single-crystal X-ray diffraction. Patterns of packing of the fullerene spheres encountered in crystal structures are described and representative examples of the most typical motifs are given. Reasons for the rotational disorder, which often hampers structure determination for fullerene derivatives, and its classification are considered. A model of the 'rubber cavity' is introduced, which allows prediction of typical mutual orientations of disordered molecules. The redistribution of bond lengths upon σ- and π-functionalisation of the carbon core is analysed based on the information retrieved from the Cambridge Structural Database. Factors affecting the molecular packing density in crystalline derivatives of fullerenes are discussed in relation to the quality of the diffraction data attainable for them. The bibliography includes 282 references.

I. Introduction

Fullerenes are a family of allotropic forms of carbon, the crystals of which are built up of hollow spheroidal molecules C_n united by van der Waals interactions. The C_{60} (also referred to as buckminsterfullerene) and C_{70} fullerenes and their derivatives are the most studied. To date, the C_n fullerenes, where $n = 60, 70, 76, 78, 80, 82, 84, 88$, and 92 (see Ref. 1) have been isolated as individual substances.

Received 15 December 2003
Uspekhi Khimii **73** (5) 492 – 525 (2004); translated by Ya V Zubavichus

The overall number of publications on fullerenes by the end of 2001 exceeded 10 000, however, the fraction of those devoted to single-crystal X-ray diffraction studies remains relatively small (*i.e.*, < 400 structures by the end of 2003). A large concentration of defects and twinning are very common for single crystals of fullerenes and their derivatives. Furthermore, the quasi-spherical C_n molecules were found to be rotationally disordered in the crystal structures of many fullerene derivatives. The co-existence of different orientations of a fullerene molecule similar in energies in one crystal results in a deterioration of the experimental diffraction pattern. The problem of the rotational disorder is of special importance in the van der Waals complexes comprising chemically non-modified fullerene molecules. On the other hand, co-crystallisation of different difficult-to-separate addition isomers becomes a serious issue for the chemically modified fullerenes. For higher fullerenes, the overall structural disorder may be increased due to the presence of different geometrical isomers statistically occupying equivalent crystallographic positions of the crystal lattice. All these factors hamper diffraction studies and decrease the accuracy of structure elucidation. However, it is these methods and, primarily, single-crystal X-ray diffraction, that are the most important in the studies of fullerene derivatives because of their structural complexity.

Several reviews on the crystal structures of particular groups of fullerene derivatives have been published,[2–6] but the general regularities of molecular and crystal structures within the whole class of compounds are still lacking. In the present review, the results of single-crystal X-ray diffraction studies of fullerene derivatives are surveyed and distinctive features of their structures are analysed. Special attention is paid to the crystallographic data retrieved from the Cambridge Structural Database (CSD) and original journal papers. The available information still admits a comprehensive coverage within one review paper, thus making it possible to reveal the most general tendencies in the crystallography of fullerene derivatives. For certain compounds closely related to the subject of the present review, the results of other experimental techniques (such as gas electron diffraction, neutron diffraction, powder X-ray diffraction, and XAFS spectroscopy) are also considered.

II. The molecular structures of fullerenes

The stability of a C_{60} molecule having the symmetry of a truncated icosahedron was predicted in the early 1970s independently by Osawa [7] and by Bochvar and Gal'pern.[8] Experimentally, C_{60} has been registered for the first time as a molecular ion in a mass-spectral analysis of gaseous species produced by laser ablation of graphite.[9] The nonequilibrium cooling of carbon vapour gives rise to formation of various C_n clusters with C_{60} being the dominant. Clusters with even smaller n have been detected in mass spectra of graphite sublimation products, however, the respective individual substances have not been isolated so far.

Later, a method for production of fullerenes in macroscopic quantities has been elaborated based on graphite evaporation in an electrical arc plasma with graphite electrodes performed in an inert atmosphere (He or Ar at a pressure of 10–100 mbar).[10] The soot produced in this process contains up to 15%–20% of fullerenes that are further extracted and separated by column chromatography. C_{60} (85%) and C_{70} (14%) are the dominant products while the remaining 1% falls within higher fullerenes, such as C_{76}, C_{84}, C_{90}, and so on.

The molecules of fullerenes represent convex polyhedra with carbon atoms in their vertices, which have only penta- and hexagonal faces, *i.e.*, the carbocycles characterised by the minimum steric strain. According to the Euler theorem, such polyhedra have exactly twelve pentagonal and any number of hexagonal faces.† The simplest fullerene-like polyhedron is a pentagondodecahedron, which has no hexagonal faces. The respective saturated hydrocarbon (*i.e.*, dodecahedrane $C_{20}H_{20}$) was prepared in the 1980s by a complex multistage organic synthesis.[11] Non-modified fullerene C_{20} is, most likely, unstable due to the large steric strain in the unsaturated carbon core. Nevertheless, C_{20} clusters have been detected in the gas phase upon thermal decomposition of brominated dodecahedrane.[12] The isolation of the C_{36} fullerene has been reported [13] but its crystal structure has not been determined. Probably, this structure involves C_{36} units covalently bound to each other rather than independent molecules.

Virtually all fullerenes, for which molecular structures have been determined experimentally, obey the so called Isolated Pentagon Rule, or IPR:[14] the pentagonal rings in their molecules must not have shared vertices. Taking this rule as a requisite, the simplest fullerene is buckminsterfullerene C_{60} (Fig. 1 *a*) and the next one is C_{70}. Furthermore, any fullerenes with even numbers of carbon atoms are allowed. The isolated pentagon rule substantially reduces the number of allowed fullerene structures. For instance, theoretically, the IPR-forbidden C_{66} cluster will have 4478 geometrical isomers if this rule is not taken into account.[15] Note, however, that metallofullerenes such as $Sc_2@C_{66}$ and $Sc_3N@C_{68}$ (see Refs 15, 16) have been isolated. Apparently, this means that the IPR is not stringent and may be violated, at least, in the case of chemically modified carbon cages.

For every fullerene starting from C_{76}, there are several geometrical isomers complying with the IPR. Some of them are chiral and may occur as enantiomers. The number of the fullerene-type polyhedra (M) complying with the IPR as a function of the number of atoms in the carbon cage (n) is given below:

n	60	62–68	70	72	74	76	78	80	82	84	86	90	96
M	1	–	1	1	1	2	5	7	9	24	35	46	187

A topological nomenclature of fullerenes taking into account their probable chirality has been suggested.[17] The relative stabilities of different fullerenes have been thoroughly studied theoretically by methods of quantum chemistry.[18, 19] In particular, the calculations predicted instability of C_{72} and C_{74} fullerenes (complying with the IPR) as neutral molecules.[20] These 'quantum chemistry-forbidden' fullerenes should be highly reactive biradicals. However, they can be stabilised as dianions, in particular, in endohedral derivatives, in which such a stabilisation is achieved owing to charge transfer from the metal atom located inside the carbon cage.[21]

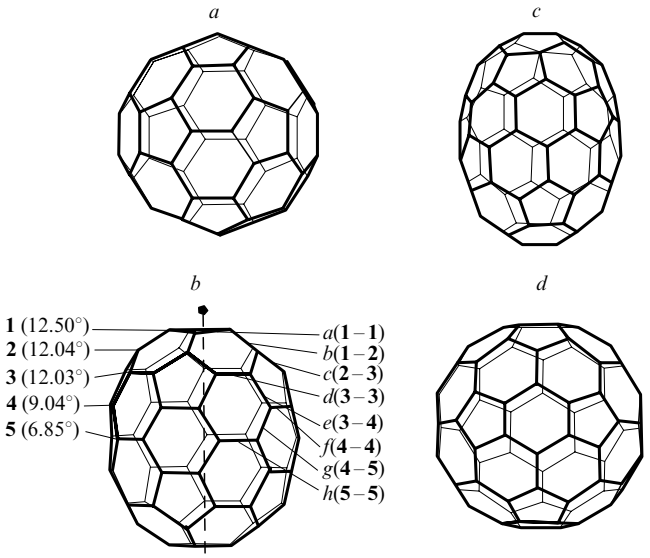

Figure 1. Molecular structures of C_{60} (*a*), C_{70} (*b*), C_{76} (*c*) and I_h isomer of C_{80} (*d*);
(*b*) (to the left): types of symmetrically nonequivalent carbon atoms and their spherical excesses; (to the right): types of bonds and atoms forming these bonds.

The molecular structures of best studied carbon cores are shown in Fig. 1. Buckminsterfullerene C_{60} having the icosahedral symmetry (I_h) is the most abundant fullerene. Its molecular structure has been first established based on the ^{13}C NMR data (the spectrum comprises only one singlet).[22] All carbon atoms in the C_{60} molecule are symmetrically equivalent (*i.e.*, they are transferred to each other by symmetry operation describing the molecule). Meanwhile, there are two nonequivalent types of bonds: those joining pentagons and hexagons and those joining two hexagons (referred to as 5/6 and 6/6 bonds, respectively). The latter bond is characterised by a larger π-contribution and thus is shorter. The CC distances in C_{60} are 1.40 Å (6/6) and 1.46 Å (5/6) according to the gas electron diffraction data.[23] The corresponding mean values for 52 ordered molecular complexes of C_{60} calculated by us based on the crystallographic data retrieved from the CSD are 1.39 Å (6/6) and 1.45 Å (5/6). The bond angles are 108° in pentagons and 120° in hexagons. The spherical excess φ, defined as a difference between 360° and the sum of the bond angles at a certain carbon atom, is, in the case of C_{60}, 12° for all carbon atoms.

After C_{60}, the non-centrosymmetrical C_{70} (see Fig. 1 *b*) having the D_{5h} symmetry is the next most studied fullerene. It differs from C_{60} by an additional equatorial belt of hexagons. In C_{70}, there are 5 symmetrically nonequivalent carbon atoms and 8 different bond types, which is consistent with the NMR data.[24] For the free molecule, the bond lengths have been determined using gas electron diffraction [25] coupled with the quantum chemistry optimisation of the molecular geometry within the density functional theory. The bond lengths in C_{70} from the electron diffraction data and from the single-crystal X-ray diffraction data for the molecular complex $C_{70} \cdot 6S_8$, which has been determined with the highest accuracy,[26] are listed in Table. 1. In C_{70}, the longest bond is the equatorial bond *h* (type 6/6) (see Fig. 1 *b*). All

† The Euler theorem states that for any convex polyhedron, $V - E + F = 2$, where V, E and F are the numbers of vertices, edges and faces of the polyhedron, respectively. Let a polyhedron be composed of n pentagonal and m hexagonal faces. Then, $F = n + m$, $E = (5n + 6m)/2$, since each edge is shared by two faces and $V = (5n + 6m)/3$, since each vertex resides in the intersection of three edges. After substitution of F, E and V in the above equation and simplification thereof, one gets $n = 12$.

Table 1. Bond lengths in the molecule of fullerene C_{70} (for notations, see Fig. 1 *b*).

Bond	Type	Number of bonds	Length (Å) determined using	
			gas electron diffraction [25]	single-crystal X-ray diffraction [26]
a	5/6	10	1.46	1.45
b	6/6	10	1.39	1.38
c	5/6	20	1.45	1.45
d	6/6	10	1.39	1.37
e	5/6	20	1.47	1.45
f	5/6	10	1.42	1.43
g	6/6	20	1.40	1.41
h	6/6	5	1.54	1.47

other 5/6 and 6/6 bonds are similar in length and character to the respective bonds in C_{60}. The spherical excess is the largest for the carbon atoms located at the pole positions of the molecule and the smallest for the equatorial atoms.

The molecular structures of higher fullerenes are less studied. The C_{76} fullerene, which has been isolated as a pure substance, represents a chiral isomer with D_2 symmetry (see Fig. 1 *c*) according to the single-crystal X-ray diffraction data of its molecular complex with sulfur $C_{76} \cdot 6\,S_8$.[27] The crystal contained a racemic mixture of enantiomers statistically occupying the same crystallographic positions.

The C_{78} fullerene is a mixture of two isomers with C_{2v} and D_3 symmetry in a ratio of 5 : 1, according to the NMR data.[28] The dominant isomer of the C_{80} fullerene has D_{2d} symmetry,[29] though an isomer with D_{5h} symmetry has also been isolated.[30] An isomer of C_{80} with icosahedral symmetry I_h (see Fig. 1 *d*), which is the least stable in the free form according to the quantum chemistry calculations, has been prepared and structurally characterised as an endohedral derivative. In these substances, the carbon cage is stabilised due to a charge transfer from the metal atoms to the carbon core. In contrast to C_{60}, which possesses regularly alternating 6/6 and 5/6 bonds in each hexagon, this I_h isomer of C_{80} comprises perylene fragments with five fused hexagons.

The structural study of higher C_{76} and C_{82} fullerenes as solvates with toluene using synchrotron radiation (SR) powder X-ray diffraction [31] has been conducted but not yielded reliable geometry of their carbon cores.

According to the quantum chemistry calculations,[19] the relative stabilities of isomeric fullerene cages C_n^{q-} change depending on the charge q (Fig. 2). The results of single-crystal X-ray diffraction studies of the endohedral derivatives $M_n@C_{82}$ and $M_n@C_{84}$ are discussed below (Section X).

According to the IR data,[32] pure C_{84} fullerene represents a mixture of two major isomers with D_{2d} and D_2 symmetry. Its π-complex with iridium, which has been isolated and structurally characterised,[33] contains a carbon cage having D_{2d} symmetry with a contribution of other unidentified isomers. The NMR data on the C_{88} fullerene have been interpreted [34] as a superposition of spectra attributable to three isomers. This spectral assignment has been made on the basis of the quantum chemistry calculations of all possible isomers complying with the IPR.

Among even larger fullerenes, C_{92} has been isolated and partially separated into fractions. One of them contained the only isomer with C_{2v} symmetry (according to the ^{13}C NMR data), whilst the other fraction represented a mixture of isomers.[35] Furthermore, there has been a report on a preparation of an individual cluster-'onion' (not studied structurally) with a C_{60} internal core and a C_{240} outer shell.[36]

Upon partial substitution of boron or nitrogen atoms for the carbon atoms, various heterofullerenes are produced. One of them with the stoichiometry $C_{59}N$ has been isolated and studied by means of powder X-ray diffraction using Rietveld refinement. This substance was identified as a molecular crystal containing dimeric molecules $(C_{59}N)_2$.[37] A cationic derivative of this heterofullerene, $[(C_{59}N^+CB_{11}H_6Cl_6)_2Ag] \cdot 3(o\text{-}C_6H_4Cl_2)$, has been studied by single-crystal X-ray diffraction.[38] In the crystal structure of this compound, the nitrogen atom is disordered over two positions in the $C_{59}N^+$ cluster, which is isolectronic and isostructural to buckminsterfullerene.

The energy diagram of the molecular π-orbitals for C_{60} has been calculated for the first time by the simple Hückel method.[8] The energy level diagrams for C_{60} and C_{70} are shown in Fig. 3. Due to the high symmetry of the buckminsterfullerene molecule, its lowest unoccupied molecular orbital (LUMO) is triply degenerate and its highest occupied orbital (HOMO) is quintuply

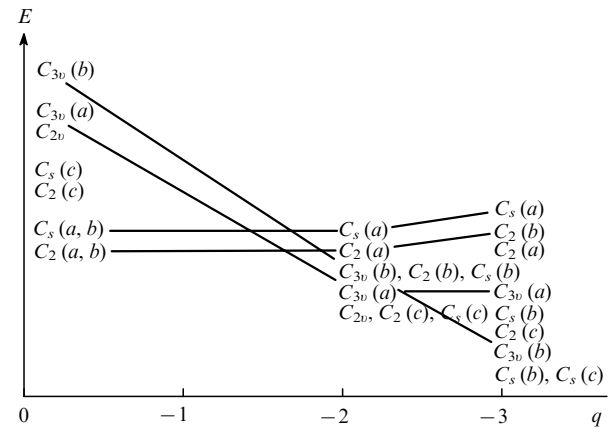

Figure 2. The relative stabilities of different geometrical isomers of C_{82}^{q-} (see Ref. 19).

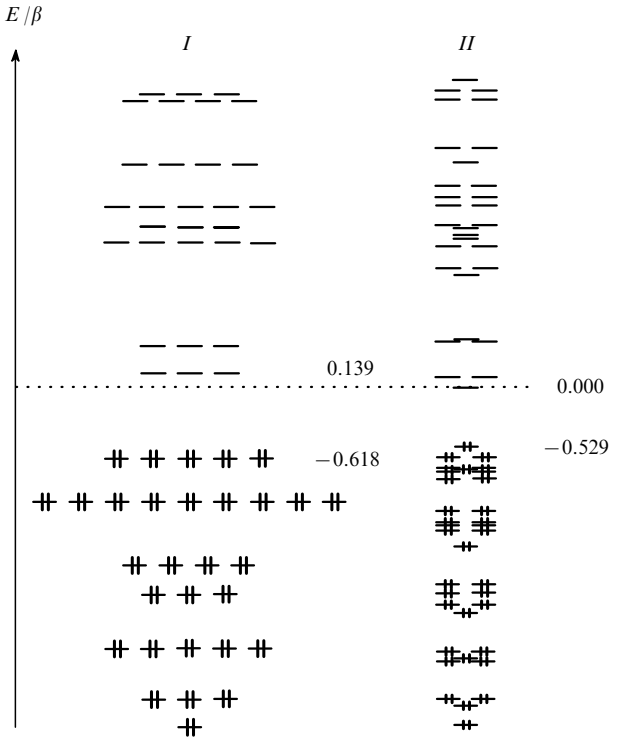

Figure 3. The energy diagram of π-orbitals in C_{60} (*I*) and C_{70} (*II*) in units of the resonance integral (β). The dotted line corresponds to the energy of 2p-AOs of an isolated carbon atom.

degenerate (see Fig. 3 *I*). The less symmetrical C_{70} molecule has only nondegenerate and doubly degenerate levels (see Fig. 3 *II*). On average, the energy difference (LUMO – HOMO) in stable C_n fullerenes, as determined by the quantum chemistry calculations, decreases with an increase in n approaching ultimately zero (as in graphite [39]).

Thus, polyhedral molecules of fullerenes retain important features of planar π-conjugated systems, such as low-energy π-bonding and stabilisation of alternant structures. As a result, energies of their frontier orbitals can be fairly reproduced using the simple Hückel method. Meanwhile, the C_n molecules themselves manifest many properties of unsaturated hydrocarbons, *e.g.*, addition reactions to 'double' 6/6 bonds and π-complexation to metals are typical of them. On the other hand, non-modified fullerenes do not contain fully delocalised π-systems, similar to those in aromatics, and their double bonds remain partially localised.

III. Crystal structures of individual fullerenes

The fullerene-containing substances, crystal structures of which have been deposited into CSD (2003 version) are listed in Table 2. The overall number of related CSD entries is 382 (including repeated studies). In several cases, no coordinates of carbon atoms have been deposited into the CSD. All the compounds are subdivided into classes according to the extent of the chemical modification of the corresponding fullerene molecule. Table 2 also contains single-crystal X-ray diffraction results published in scientific journals but not included in the CSD version of October, 2003, as well as some substances studied by powder X-ray diffraction.

Pure crystalline buckmisterfullerene C_{60} prepared by resublimation *in vacuo* possesses a face-centred cubic (fcc) lattice.[53] At room temperature, the fullerene molecules in this structure are rotationally disordered. Upon a decrease in the temperature down to 258 K, a phase transition occurs, which is accompanied by partial ordering of the molecules and lowering of the symmetry of the cubic lattice from $Fm3m$ to $Pa\bar{3}$. Upon further cooling, the dynamic disorder is gradually replaced by the static disorder.[54] At even lower temperatures (*e.g.*, at 5 K),[55] the crystal reveals a statistical mixture of only two molecular orientations (neutron diffraction data), however, no complete 'freezing' of this degree of freedom has been reached. The shortest interatomic C···C contacts between the neighbouring C_{60} molecules (3.00 Å) are almost 0.2 Å shorter than the interlayer C···C distances in graphite,[56] *i.e.*, they are likely to correspond to the van der Waals repulsion compensated by the mutual attraction of more distant atoms from the neighbouring molecules. Most probably, no local charge transfer within the carbon cage is involved, which would have given rise to the electrostatic attraction of the neighbouring molecules mutually oriented so as to expose oppositely charged sides (initially proposed as an explanation for the shortened C···C distances, see Ref. 57). Physical investigations into the dynamics of the disordered fullerene clusters in crystals will not be addressed in any detail here since this review is focused primarily on the structures of fullerene derivatives in their relation to chemical properties.

Under special conditions, it is possible to prepare polycrystalline powder of the metastable hexagonal modification of C_{60} in which the fullerene molecules make up a two-layer close packing of spheres.[58, 59] Earlier reports [60] on another hexagonal modification of buckminsterfullerene with the parameters $a = 33.54$ Å and $c = 10.11$ Å have not been confirmed. Probably, these parameters correspond to a fullerene-rich solvate rather than pure fullerene.

The C_{70} fullerene composed of molecules that may be approximated as ellipsoids has a more complex phase diagram. The high-temperature fcc phase, which is characterised by isotropic rotations of the molecules, converts, upon a decrease in the temperature down to 340 K, into a trigonal (rhombohedral) phase, in which the long axes of the ellipsoids are oriented along the crystallographic three-fold axis, and the rotational disorder appears only due to revolution around them (Fig. 4). At even lower temperature (*viz.*, 280 K), the molecules get completely ordered forming a monoclinic phase similar to the trigonal one as regards the lattice parameters ($a \approx c$, $\beta \approx 120$). As for C_{60}, a metastable modification of C_{70} with the hexagonal close packing (hcp) of isotropically disordered molecules is known. Upon a decrease in the temperature, this phase undergoes two phase transitions accompanied by an ordering of the molecular rotations, analogous to those described above. Apart from the two regular high-temperature modifications, *viz.*, fcc and hcp, there exists a series of intermediate phases characterised by irregular layer sequences.[61]

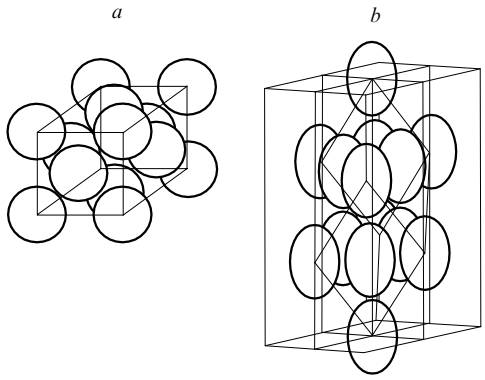

Figure 4. Schematic representation of the crystal structure of the fcc phase of C_{60} (*a*) and rhombohedral phase of C_{70} (*b*).

For some of the higher fullerenes with rather spheroidal molecules, only high-temperature fcc phases have been detected, while information on the phase transitions at low temperatures is lacking.[62] For the C_{84} fullerene, two phase transitions at 235 K and 181 K have been revealed by powder X-ray diffraction, although the structures of the low-temperature phases have not been determined.[63]

IV. Molecular complexes

Numerous derivatives of fullerenes may be classified as molecular complexes with non-polar molecules. Sometimes, they are also referred to as mixed or van der Waals crystals. As was first pointed out by A I Kitaygorodsky,[64] the most energetically favourable molecular packing in a crystal formed exclusively by van der Waals interactions normally coincides with the densest one. Any close packing of large spheroidal C_n molecules contains cavities of an appreciably large size. Therefore, fullerenes readily form molecular complexes (clathrates, inclusion compounds) with many 'guest' molecules. The structures and properties of such substances have been reviewed by several authors.[2, 3, 6] Many crystallographic regulations observed for this class of compounds may be extended to include fullerene derivatives.

The cavities in the parent close packing of fullerene 'spheres' can accomodate only single atoms, for instance, of alkali metals (see Section V). The majority of crystalline fullerene molecular complexes contain looser structural motifs of the C_n clusters formed as a result of incorporation of larger molecules or ions. It is convenient to characterise these motifs with the 'partial' molecular coordination number (MCN), which is the number of neighbouring fullerene clusters forming the van der Waals C···C contacts in the range 3.2 – 3.5 Å with the central cluster. For

derivatives of C_{60}, this is equivalent to distances of 9.9 – 10.3 Å between the centres of the adjacent molecules. As a semiquantitative measure of the density of the fullerene packing, it has been proposed [65] to use the dilution parameter defined as

$$\rho = \frac{V_{\text{cell}} - V_{\text{full}}}{V_{\text{full}}}, \qquad (1)$$

where V_{cell} is the unit cell volume and V_{full} is the volume occupied by fullerene molecules within the unit cell. The dilution parameter ρ ranging from 0.33 (for an fcc packing) to ∞ is linked to the commonly adopted partial packing coefficient of fullerene spheres in a crystal

$$\kappa = \frac{V_{\text{full}}}{V_{\text{cell}}}$$

through a simple relation

$$\frac{1}{\kappa} = \rho + 1.$$

An increase in ρ, which corresponds to progressive 'dilution' of fullerene clusters with other (non-fullerene) molecular components in the crystal, typically leads to a change in the packing motif of the carbon clusters $(C_n)_\infty$ at specific threshold values of ρ. For C_{60} derivatives, the typical ranges of various motifs can easily be estimated based on simple geometrical considerations.[65]

Since the overall structure in this type of compound is kept by non-specific van der Waals interactions, many 'guest' molecules that are similar in size and shape to the van der Waals surfaces form analogous structural motifs with similar values of ρ in the fullerene complexes. The crystal structures of the corresponding complexes may belong to different systems and differ significantly in the unit cell parameters. The packing motif $(C_n)_\infty$ in these structures plays the role of a flexible van der Waals matrix thus justifying the utilisation of MCN and ρ as classification criteria.

Solvent molecules often act as 'guests' in molecular complexes of C_n fullerenes. Crystal solvates are often formed upon growth of fullerene crystals from solutions. Some solvents form several solvates with different compositions. For instance, in the case of CCl_4, two solvates with C_{60} : solvent ratios of 1 : 2 (see Ref. 66) and 1 : 13 (see Ref. 67) have been isolated and characterised; $CBrCl_3$ behaves similarly (see Ref. 68).

Buckminsterfullerene is characterised by a relatively good solubility in aromatic hydrocarbons and their non-polar derivatives, but is virtually insoluble in polar solvents (alcohols, esters, *etc*.).[69] Aliphatic hydrocarbons are poor solvents for C_{60}, but nevertheless also form solvates. Solubility curves of fullerene in many solvents manifest a characteristic inflection, sometimes expressed as a distinct maximum. This phenomenon is known as the 'anomalous temperature dependence',[69] although a number of inorganic systems, *e.g*., $Na_2SO_4 - H_2O$, manifest similar changes in the solubility.[70] Initially, this peculiarity of C_{60} was suggestively

Table 4. Structural motifs of fullerene molecules in fullerene molecular complexes.

Type	MCN	Example	Ref.
'Almost dense' three-dimensional frameworks	9–11	$C_{60}\cdot 2/3\,C_8H_{10}$, $C_{60}\cdot C_5H_{12}$	76, 77
Double layers	7–10	$C_{60}Mpc\cdot 0.5\,C_6H_6$	78
Hexagonal layers with trigonal prismatic cavities in-between	6–8	$C_{60}\cdot 2\,P_4$	79
Loose three-dimensional frameworks (spatial honeycombs with channels or diamond-like frameworks)	4–6	$C_{60}\cdot 4\,C_6H_6$	80
Spatially separated closely packed layers	4–6	$C_{70}\cdot 6\,S_8$	26
Loose layers, including graphite-like	3–6	$C_{60}\cdot PdOEP\cdot 1.5\,C_6H_6$	81
Columnar motifs	2–4	$C_{70}\cdot CoOEP\cdot CHCl_3\cdot C_6H_6$	82
Island motifs	0–1	$C_n\cdot 13\,C_6H_{12}$ (n = 60, 70)	67

associated with a phase transition in pure fullerene[69] or with a formation of multi-molecule clusters in solution.[71] Nowadays, it is widely accepted that it is caused by formation of solvates.[72] At a specific temperature T^* (which, for aromatic solvents, typically lies below the boiling point of the solvent), the solvates incongruently melt, *i.e.*, decompose into fullerene and the solvent. According to the calorimetric studies on a number of fullerene–solvent systems, the enthalpy of the incongruent melting is normally 10–50 kJ per mole of fullerene.[73, 74] Properties of solutions of higher fullerenes are, in general, similar to those of C_{60}, but the solubility of, for example, C_{70} in organic media is usually slightly higher than that of buckminsterfullerene.[75]

The major motifs $(C_n)_\infty$ formed by chemically unbound fullerene spheres encountered in structurally characterised molecular complexes of fullerenes are listed in Table 4. For all the substances, the values of the MCN for fullerene molecules are given. The major motifs of the fullerene–'guest' packings are depicted schematically in Fig. 5.

Packing $(C_n)_\infty$, the least diluted by 'guest' molecules, is found in C_{60} solvates with *m*-xylene,[76] mesitylene,[83] and other small molecules of 1,3- and 1,3,5-substituted benzenes (A). These solvates have the stoichiometry $3\,C_{60}\cdot 2\,A$ and reveal an hcp motif of fullerene spheres with 'excised' columns (MCN = 9–10); the solvent molecules are located in the channels (see Fig. 5 *a*).

Among three-dimensional frameworks of fullerene spheres, the motif found in a series of 1:1 C_{60} solvates with pentane, hexane, dichloroethane, trichloroethane and trichloroethylene, is quite typical. In this structural motif, tetragonal dense layers $(C_{60})_\infty$ are stacked in such a way that the close and the closest stacking arrangements are regularly alternating; the solvent molecules occupy cavities (Fig. 6). The formation of characteristic polysynthetic twins with an approximate 10-fold symmetry axis has been reported for all of these solvates.[84] Higher fullerenes C_{82} and $M@C_{82}$ form toluene solvates of the same structural type.[31, 85] Furthermore, a 1:1 bromoform solvate of C_{60} with the closely packed framework structure is known, in which the disordered solvent molecules are located in cavities.[40]

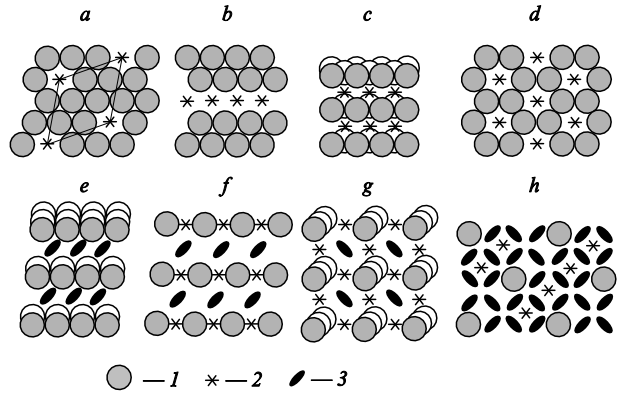

Figure 5. The main packing motifs in molecular complexes of C_{60}.
Motifs: (*a*) 'almost dense', (*b*) double layers, (*c*) closely packed layers, (*d*) framework, (*e*) separated closely packed layers, (*f*) loose layers, (*g*) columns, (*h*) islands (for examples of structures, see Table. 4); (*1*) fullerene, (*2*) solvent molecule, (*3*) 'guest' molecule.

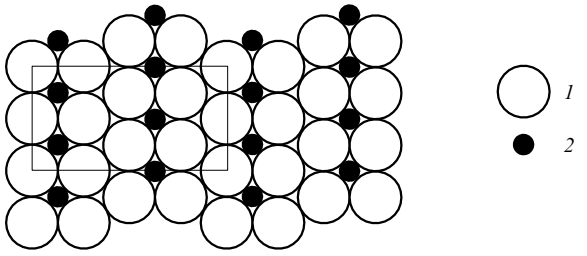

Figure 6. The molecular packing motif in the 1:1 pentane solvate of fullerene.[77]
(*1*) C_{60} molecule, (*2*) pentane molecule; projection of the unit cell is indicated by the rectangle.

Buckminsterfullerene forms an extended series of solvates and molecular complexes with the composition 1:2 [$C_{60}\cdot 2\,A$, where A = P_4,[79] CCl_4,[66] PhBr,[86] Cp_2Fe (see Ref. 87), *etc.*] built up of closely packed hexagonal layers of the fullerene molecules with the 'guest' molecules A in the interlayer space (see Fig. 5 *c*). Such a motif is characterised by the values of MCN = 6–8 and ρ = 0.7–0.8. It is encountered in crystal structures belonging to different systems from hexagonal (*e.g.*, $C_{60}\cdot 2\,P_4$) to triclinic (*e.g.*, $C_{60}\cdot 2\,Cp_2Fe$). In benzene solvates of the fullerene molecular complex with sulfur nitride with the variable composition $C_{60}\cdot 0.67\,S_4N_4\cdot 1.33\,C_6H_6$, half of the 'guest' positions is occupied by the ordered benzene molecules while the other half is statistically occupied by disordered C_6H_6 and S_4N_4 molecules.[88] It is noteworthy that in 1:2 fullerene solvates with bromobenzene and iodobenzene, which are characterised by similar packings but twice larger unit cells, the C_{60} molecules are rotationally disordered in the bromobenzene solvate and fully ordered in the iodobenzene solvate. The distances between the centres of the adjacent C_{60} molecules in the two solvates are 10.16 Å and 9.89 Å, respectively.[41]

A number of 'closely packed' molecular complexes can be prepared by direct intercalation of small molecules into solid fullerene at elevated pressure. In particular, the insertion of oxygen molecules into the octahedral cavities of the fcc packing of fullerene at room temperature and 1 kbar has been detected by NMR.[89] However, the main method of preparation of molecular complexes consists of co-crystallisation of the components from a suitable solvent. Co-crystallisation of buckminsterfullerene with tetrahedral molecules of white phosphorus P_4 from a solution yields the complex $C_{60}\cdot 2\,P_4$ (ρ = 0.82), which has closely packed hexagonal layers of C_{60} molecules. With larger sulfur molecules,

the complex $C_{60} \cdot 2\,S_8$ ($\rho = 1.08$) is formed,[90] which contains a three-dimensional framework of the fullerene molecules with channels. Meanwhile, C_{70} forms a molecular complex with sulfur with the composition 1 : 6 ($\rho = 2.13$)[26] in which layers of the C_{70} molecules are separated by layers of the sulfur molecules (see Fig. 5 *e*). The latter structural motif is also observed in $C_{76} \cdot 6\,S_8$ (see Ref. 27). All the molecular complexes with sulfur reveal short C···S contacts with lengths in the range of 3.20 – 3.50 Å, which apparently stabilise the crystal structures.

Loose layers $(C_{60})_\infty$ (which may be regarded as approximately tetragonal with the MCN = 4) are formed upon insertion of relatively small solvent molecules (C_6H_6, CS_2) from the 'guest' layers into the fullerene layers. For instance, this type of structure is observed for two buckminsterfullerene molecular complexes with tetramethyltetraselenafulvalene, $C_{60} \cdot TMTSeF \cdot 2\,(CS_2)$,[91] and with 9,10-[9,10]-anthracenoanthracene (DAN), $C_{60} \cdot DAN \cdot 3\,C_6H_6$.[92] The latter complex is remarkably stable thus making it possible to isolate buckminsterfullerene from a benzene solution of a mixture of C_{60} and C_{70}. Graphite-like layers with the MCN = 3 are revealed in two benzene solvates of molecular complexes $C_{60} \cdot PdOEP \cdot 1.5\,C_6H_6$[81] and $2\,C_{60} \cdot H_2TPP \cdot 3\,C_6H_6$.[93] Note that another fullerene – tetraphenylporphyrin molecular complex differing from the latter only in the benzene content, *viz*., $2\,C_{60} \cdot H_2TPP \cdot 4\,C_6H_6$ is characterised by a totally different molecular packing involving a three-dimensional framework of the C_{60} molecules with hexagonal channels.

As an example of the columnar motifs, the complex $C_{60} \cdot 2\,(CuTPP)$[93] may be taken, which contains linear chains $(C_{60})_\infty$ with the MCN = 2. In several compounds, more complex one-dimensional motifs are observed, in particular, zigzag chains (*e.g*., in $C_{60} \cdot CTV$, see Ref. 94) or double columns of the fullerene molecules with the MCN = 4 (*e.g*., in $C_{60} \cdot 2\,BEDT\text{-}TTF$, see Ref. 95).

The island packings are typical of complexes with predominating non-fullerene components that separate and isolate the fullerene molecules from each other. In the crystal structures of such complexes, the interaction between fullerene molecules is not a structure-forming factor. Fullerene solvates $C_{60} \cdot 13\,(Solv)$ with cyclohexane, CCl_4 (see Ref. 67) and $CBrCl_3$ (see Ref. 68) are typical examples of such substances. In several cases, the islands are formed by two fullerene cages ('the van der Waals dimers'), which corresponds to the MCN = 1 {*e.g*., in $2\,C_{70} \cdot 9\,[p\text{-}C_6H_4(OH)_2] \cdot 2\,C_6H_6$, see Ref. 96}.

Fullerene forms complexes with inorganic compounds. In the case of molecular inorganic 'guests', such complexes have a normal van der Waals character. As examples, two complexes $C_{60} \cdot 3\,TiCl_4$ and $C_{60} \cdot 3\,C_6H_6 \cdot 2\,Pd_6Cl_{12}$ can be mentioned. The former contains a diamond-like framework,[97] while the latter comprises columns built up of rotationally disordered C_{60} molecules.[98] In some substances, the 'guest' component is represented by charged species of ionic salts, as in $C_{60} \cdot 5\,(Ag^+NO_3^-)$, which reveal a distorted simple cubic packing of the fullerene spheres.[99]

The following large donor molecules forming molecular complexes with fullerenes are worth a special note: derivatives of tetrachalcogenafulvalenes, polyaryl and fused aromatic hydrocarbons, macrocyclic tetraaza-compounds and their complexes with metals, bulky cage molecules (*i.e*., calixarenes, cyclodextrins) with the cavities large enough to accomodate a fullerene sphere. A mismatch in the dimensions of the cavity and the 'guest' in the latter type of compounds results in a decrease in the density and an increase in the structural disorder, which additionally diminishes the accuracy of the structure determination.

Substituted tetrathiafulvalenes (TTF) are prototypical components of radical-ionic salts with aromatic molecules functionalised by strong electrophilic substituents as anions. Planar geometry of both the cation and anion favours their regularly alternating parallel arrangement formed due to the stacking interactions. Nevertheless, systematic single-crystal X-ray diffraction studies have shown that such stacking motifs are not typical

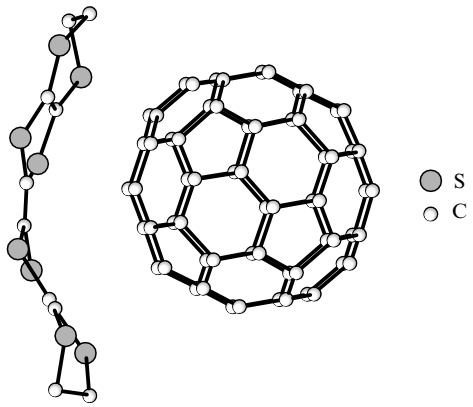

Figure 7. The mutual arrangement of bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) and fullerene molecule in the crystal structure of $C_{60} \cdot 2\,BEDT\text{-}TTF$.[95]

of fullerene molecular complexes with TTF derivatives. Vibrational spectroscopy data support a lack of significant charge transfer from the donor molecules to fullerene.[100] A distinctive feature of the molecular packing in such crystals is that the TTF derivatives forming the van der Waals contacts with adjacent fullerene molecules are non-planar (Fig. 7).

An analysis of structural data from the CSD regarding TTF-based molecular complexes (> 300 unique structures) shows that the molecules of TTF derivatives with bulky substituents or in the van der Waals crystals with large non-planar acceptors are often bent. Bending of the TTF moiety observed in almost all fullerene complexes with tetrachalcogenafulvalenes provides closer adjacency to a spheroidal C_n molecule and thus has purely van der Waals character (see Fig. 7). The complex $C_{60} \cdot (BEDT\text{-}TTF^+I_3^-)$ may be considered as an exception. It contains planar fulvalene as a radical cation.[101] Doping of the molecular complex $OMTTF \cdot C_{60} \cdot C_6H_6$ with alkali metals (K, Rb) gives rise to superconducting phases with relatively high temperatures of the transitions into the superconducting state T_c (17 K in the case of potassium and 23 K in the case of rubidium).[102]

Fused aromatic hydrocarbons and polyarenes, which are complementary to fullerenes in terms of the van der Waals shapes of their molecules, also form molecular complexes with fullerenes. Apart from the aforementioned buckminsterfullerene complex with 9,10-[9,10]anthracenoanthracene (DAN) $C_{60} \cdot DAN \cdot 3\,C_6H_6$,[92] the solvated complex with triptycene $C_{60} \cdot 2\,Trip \cdot 2\,(o\text{-}C_6H_4Me_2)$ may be taken as an example.[103] In many crystal structures, such polyarene derivatives adopt a conformation 'encompassing' the fullerene cage, thus increasing the number of energetically favourable van der Waals contacts.

The metal atoms in the coordination compounds with macrocyclic tetraazaligands (that form molecular complexes with fullerenes) have a square-planar coordination environment and thus are prone to additional coordination. In this class of compounds, zigzag chains of alternating fullerene and porphyrin molecules (Fig. 8) with shortened metal···fullerene contacts are frequently found. Such complexes are often regarded as supramolecular matrices capable of fixing a fullerene molecule in a specific orientation and therefore decreasing the rotational disorder of the crystal structure. In particular, the 'cage' molecule containing two zinc porphyrinate moieties linked in a way similar to that in paracyclophane strongly binds fullerene C_{60} in a complex with the composition 1 : 1, which is stable in solution. This complex has been isolated by chromatography[104] and studied by single-crystal X-ray diffraction.[105] Yet another complex, where one buckminsterfullerene molecule is embraced by two palladium porphyrinate units linked through a bridging group (Fig. 9), has also been characterised by single-crystal X-ray diffraction.[106] However,

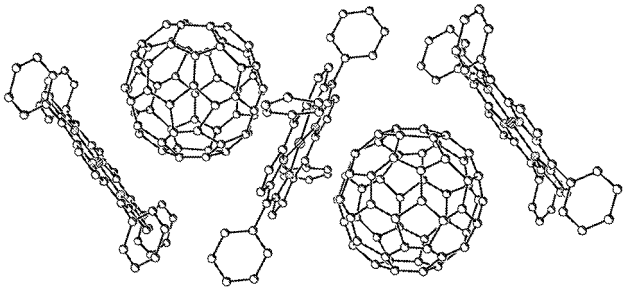

Figure 8. Zigzag chains in the crystal structures of fullerene complexes with metal porphyrinates.[47]

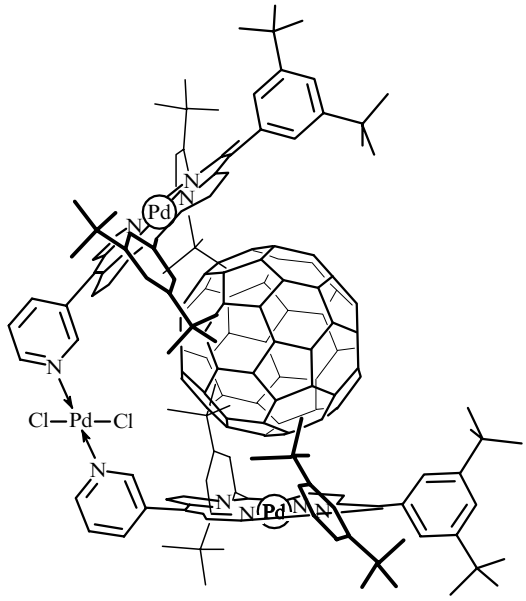

Figure 9. The molecular structure of a C_{60} complex with PdBPPyP containing two chemically bound Pd porphyrinate fragments.

both ordered and disordered fullerene molecules are revealed in the structurally characterised complexes with metal porphyrinates. Probably, the secondary metal···fullerene bonding is quite weak and does not exert decisive influence on the general molecular packing, though it can affect the degree of ordering of the fullerene molecules at specific favourable mutual arrangements of the porphyrin and fullerene molecules.[45]

The 'secondary' interactions of metalloporphyrins or related compounds with carbon cages, LM···C_n (L is a macrocyclic ligand), are characterised by the M···C distances intermediate between typical π-coordination (~2.0–2.3 Å) and van der Waals contacts (≥ 3.0 Å). For instance, the Fe···C distances are 2.70 Å in $C_{60}\cdot FeTPP^+\cdot(C_6F_5)_4B^-\cdot 2.5(o\text{-}C_6H_4Cl_2)$ complex.[107] In many cases, the secondary metal–fullerene interactions stabilise unique orientation of the fullerene cage preventing disorder. Nevertheless, in several substances of this class, for example, in the C_{60} complex with cobalt tetrakis(3,5-di-*tert*-butylphenyl)porphyrinate, both the short Co···C distances (2.59 Å) and disordering of the fullerene molecules are observed.[108]

Yet another class of fullerene molecular complexes includes cycloveratrylene and calixarenes. Some of these complexes contain molecules of water or alcohol in a crystal. This is quite nontypical for other classes of fullerene derivatives, which are most often hydrophobic. In the complexes with calixarenes, spheres of the fullerene molecules are laid on the bowl-shaped organic molecules. To date, sixteen different C_{60} complexes with substituted calixarenes starting from calix[3]- to calix[6]arenes have been characterised structurally (see Table 2). Water-soluble cyclodextrin also forms a complex with fullerene thus making it possible to transfer fullerene into an aqueous solution with a concentration of up to 10^{-5} mol litre^{-1}. The crystal structure of this complex has not been determined so far.[109]

Since the structural motifs $(C_n)_\infty$ in fullerene molecular complexes and chemically modified fullerenes are similar, it is convenient to analyse them in parallel. Figure 10 shows the numbers of all known crystalline fullerene derivatives as functions of the dilution parameter, MCN and the *R*-factor. The histogram of the dilution parameter distribution (see Fig. 10 *a*) manifests two maxima corresponding to $\rho = 0.8$ and 2.0. The former value is typical of layered hexagonal close packings and the latter, of loose framework structures. The values of $\rho \geqslant 3$, as a rule, correspond to chain or island motifs.

The distribution according to the MCN (see Fig. 10 *b*) of all fullerene structures deposited into the CSD indicates a large fraction of loose dilute structural motifs and a gradual decrease in the number of structures for the MCN ≥ 6. It is noteworthy that even molecular coordination numbers prevail over the odd ones, which may be explained by the frequent occurrence of the centrosymmetric motifs $(C_n)_\infty$.

The distribution according to the *R*-factor (see Fig. 10 *c*) is shifted to $R \geqslant 0.05$ and manifests a characteristic 'tail' at $R \geqslant 0.10$; the latter indicates a somewhat decreased accuracy of single-crystal X-ray diffraction for this specific class of crystalline compounds. Defects, stacking faults and very typical rotational disorder of spheroidal C_n clusters (dominated in the crystal structures with $R \geqslant 0.10$) are the reasons for the relatively low accuracy of the structure determination. For some fullerene

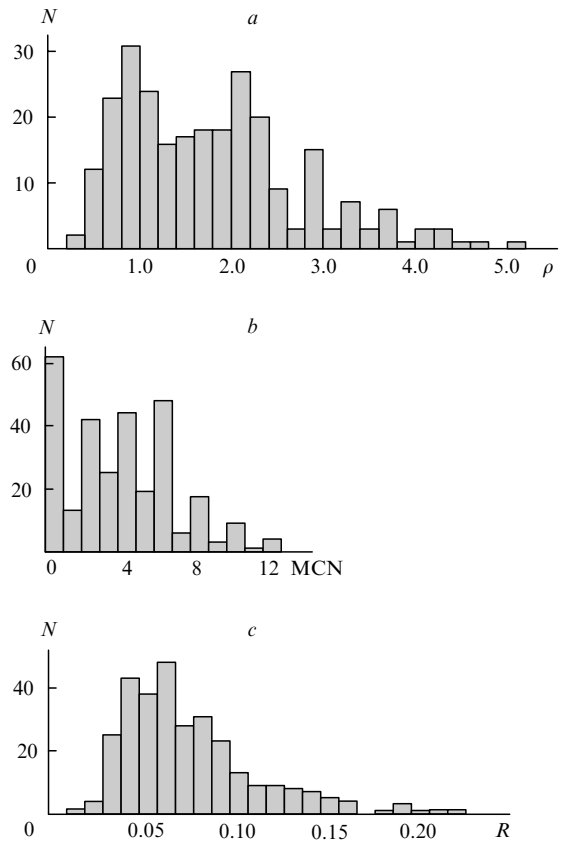

Figure 10. The number of fullerene structures from the CSD as a function of the dilution parameter (*a*), MCN (*b*) and *R*-factor (*c*).

molecular complexes, the 'guest' component is also disordered, which additionally reduces the quality of the crystallographic data.

In certain cases, it proves possible to approximate the rotational disorder of the fullerene molecules by superposition of C_n molecules in two orientations leading to coincidence of some of the atomic positions from the two orientations and partial occupancies of the remaining positions. In order to reduce correlations between fittable atomic positions in the least-squares refinement, a carbon cage with a fixed idealised geometry is often used. For C_{60}, two types of the rotational disorder occur most frequently (Fig. 11), *viz*., two orientations related to each other through a rotation by 90° around a molecular two-fold axis and two orientations related to each other through a rotation by 60° around a three-fold axis. In the former case, common positions determine 48 pairs of closely located carbon atoms from the two orientations, while the disordered part of the molecule (formed by spatially separated atomic positions with partial occupancies) forms characteristic 'crosses' at the vertices of an octahedron over the fullerene sphere. In the latter case, the disordered C_{60} molecule may be described as the ordered 'poles' and a disordered equatorial belt. For C_{70}, no similar regular superpositions of different molecular orientations have been revealed. Therefore, disordered structures are normally approximated by a superposition of two molecules with a fixed idealised geometry devoid of common atomic positions.

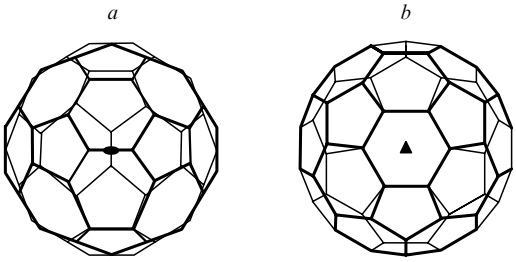

Figure 11. The major types of rotational disorder of the buckmisnterfullerene molecules in crystal structures (the two orientations are shown with bold and normal lines, respectively).
(*a*) rotation by 90° around the two-fold axis, (*b*) rotation by 60° around the three-fold axis.

To predict the preferred mutual orientations of rotationally disordered fullerene molecules, a model of the 'rubber cavity' has been proposed.[110] According to this model, all carbon atoms of the fullerene molecule residing in an equilibrium orientation occupy minima of the shallow van der Waals potential. To a first approximation, an increase in the interaction energy upon rotation of a molecule is proportional to the sum of squared radial stretches of the fullerene's van der Waals surface in the vicinity of atomic positions with respect to the initial equilibrium surface corresponding to the minimum interaction energy

$$\Delta U = k \sum \Delta r_i^2, \qquad (2)$$

where the summation is performed over radius-vectors of all carbon atoms. The most probable alternative orientations occurring in the case of a rotational disorder should correspond to the local minima of ΔU, *i.e*., to the least deformed van der Waals shape of molecule. A calculation based on the 'rubber cavity' model well reproduces both experimentally observed types of the rotational disorder for C_{60} as well as the lack of characteristic disorder types for C_{70}. Furthermore, this allows predictions of probable types of the rotational disorder for other highly symmetric spheroidal molecules (Fig. 12).

In some fullerene molecular complexes, as in pure fullerene, the second order phase transitions of the order–disorder type

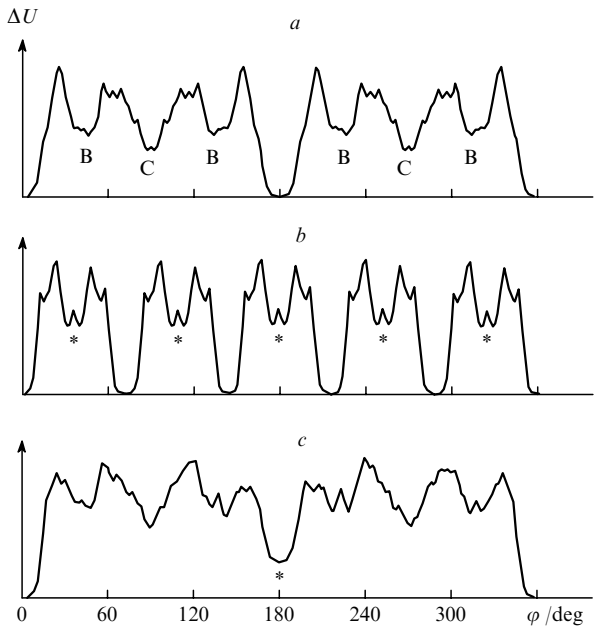

Figure 12. Profile of the interaction potential ΔU calculated within the model of the 'rubber cavity' for C_{60} (*a*), C_{80} (*b*) and $C_{60}F_{48}$ (*c*).
(*a*) Rotation by an angle φ around a two-fold axis; angles corresponding to the orientations giving rise to 'crosses' (C) and 'belt' (B) with partial occupancies of the atomic positions; (*b*) rotation by an angle φ around a five-fold axis; (*c*) rotation by an angle φ around a two-fold axis passing through the centres of two opposite 6/6 bonds; asterisks mark the second preferred orientations.

have been observed. For instance, such a phase transition takes place for the complex $C_{60} \cdot (C_6H_5)_2$ [111] where both the fullerene and biphenyl molecules are disordered. Upon a decrease in the temperature, two consecutive phase transitions occur resulting in the ordering of the two constituents: the biphenyl and fullerene molecules become ordered at 212 K and 147 K, respectively.

Fullerene-containing salts with bulky ions constitute a separate group, which is close to molecular complexes as regards their crystal chemistry. In such salts, fullerene may either be neutral [*e.g*., in $C_{60} \cdot$ BEDT-TTF$^+ \cdot I_3^-$ (see Ref. 110)] or charged [*e.g*., in $C_{60}^- \cdot 2\,Ph_4P^+ \cdot Cl^-$ (see Ref. 112)]. Both organic and metal-containing species can act as counterions. The latter can be exemplified by a series of isomorphous salts solvated by ammonia, *viz*., $C_{60}^{2-} \cdot M(NH_3)_6^{2+} \cdot 6\,NH_3$ [M = Mn, Cd (see Ref. 113), Co, Zn (see Ref. 114), Ni (see Ref. 115)]. These structures are built up of flat tetragonal layers of fulleride dianions and metal ammines with the octahedral coordination of the metals. Two other examples are the tetrahydrofuran solvate of potassium fulleride, $C_{60}^{3-} K_3^+ \cdot 14\,THF$ (see Ref. 116), and the toluene solvate of potassium 2,2,2-cryptand fulleride, $C_{60}^{2-} \cdot 2\,CryptK^+ \cdot 4\,PhMe$ (see Ref. 117) (both compounds are characterised by the island packing of the fullerene anions).

The properties of fulleride anions in the solid state and in solution have been recently reviewed.[118] As evidenced by cyclic voltammetry, buckminsterfullerene can undergo reversible reduction in solution yielding mono-, di- and trianions. Since the LUMO of fullerene is triply degenerate, the anions possess one, two and three unpaired electrons, respectively, and thus produce characteristic ESR spectra. Reduction of C_{60} to a diamagnetic hexaanion is possible in aprotic media.[119]

In this class of fullerene derivatives, as in molecular complexes, the structural motifs are determined primarily by van der Waals potential of the large C_n molecules. The packing of fulleride anions is somewhat denser than that in molecular complexes due to the electrostatic interactions with the cations. However, the

negative charge is evenly distributed over the fullerene molecule and does not prevent its rotation. Therefore, both ordered and disordered structures are found among anionic fullerene derivatives.

The low-temperature ferromagnetism has been observed for the fullerene radical-ionic salt with tetrakis(dimethylamino)ethylene, $C_{60}^{-} \cdot TDAE^{+}$, with the transition temperature of $T_c = 16$ K.[120] Some other analogous salts of buckminsterfullerene with donor amines (which have not been characterised structurally) also exhibit different types of ferromagnetic or antiferromagnetic ordering.[3] Attempts have been undertaken at the correlation of the magnetic properties of such compounds with rotation of the negatively charged fullerene cage.[121]

The fulleride anion carrying a negative charge from 1 – to 5 – is subject to Jahn – Teller distortions that result in deviations from the idealised I_h symmetry of the molecule. In the crystal structure of $C_{60}^{2-} \cdot 2(Ph_3P)_2N^{+}$, which has been determined with the highest accuracy, the completely ordered C_{60} molecule occupies the inversion centre.[122] The lengths of the 6/6 and 5/6 bonds lie in the ranges of 1.39 – 1.41 Å and 1.43 – 1.46 Å, respectively. The radial distortions of the carbon cage, calculated by us for this anion based on the atomic coordinates from the CSD, are shown in Fig. 13.

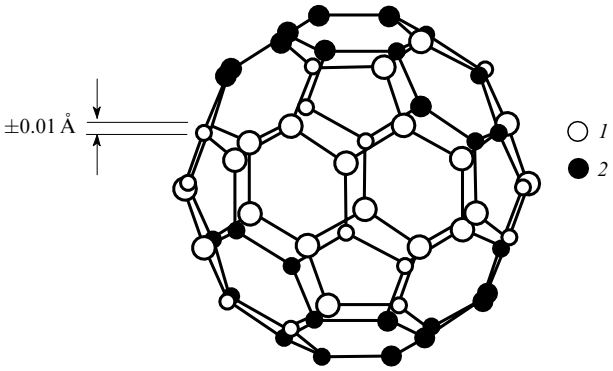

Figure 13. Radial Jahn – Teller distortions of the molecule C_{60} in the crystal structure of $C_{60}^{2-} \cdot 2(Ph_3P)_2N^{+}$ caclulated based on the atomic coordinates from the CSD.
(*1*) Atoms pushed out, (*2*) atoms pressed in. The magnitudes of the deviations from the idealised sphere are proportional to the radii of the circles (the scale is indicated).

Two ionic salts containing C_{60} dications, *viz*., $C_{60}(SbF_6)_2$ and $C_{60}(AsF_6)_2$, have been reported but not characterised structurally.[123] According to the ^{19}F NMR data, the hexafluoride anions therein freely rotate. Photoelectron spectra of the C_{60}^{+} ions in a molecular beam measured using SR have indicated dynamic Jahn – Teller disortions.[124]

V. Metal fullerides

The packing of carbon cages in ionic fullerene compounds with bulky inorganic or organic cations deviates from the close one and thus obeys the same regularities as in molecular complexes. In addition to these compounds, fullerene forms binary and ternary phases with metals that are similar to binary inorganic ionic salts. The majority of these phases have been characterised structurally using SR-based powder X-ray diffraction augmented with the Rietveld crystal structure refinement.

An interaction of solid buckminsterfullerene with alkali metals yields crystalline metal fullerides. A filling of, first, octahedral and then tetrahedral cavities in the fcc packing of the carbon spheres by alkali metal atoms gives rise to fullerides with stoichiometries MC_{60} and M_3C_{60}.[125, 126] Further doping results in substantial rearrangement of the whole structure. The final

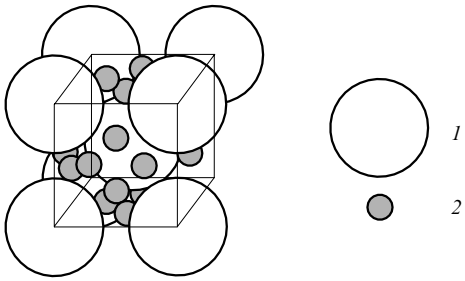

Figure 14. The crystal packing in metallofullerenes M_6C_{60}.
The unit cell is shown with thin lines; (*1*) C_{60}^{-}, (*2*) metal atom.

doping product is the M_6C_{60} phase[127] that is composed of the fullerene spheres forming a body-centred cubic packing and the squares of four metal cations situated in the centres of the faces of the cubic lattice (Fig. 14). An intermediate phase with the composition M_4C_{60} also exists. In its crystal structure, a part of the cavity is filled by 2 rather than 4 metal atoms so that the symmetry is lowered from cubic to orthorhombic.[128] Deeper doping is possible only in the case of lithium. It results in a product with the stoichiometry $C_{60}Li_{15}$, which is characterised by an fcc packing of the fullerene cages.[129]

Alkali metal fullerides containing buckminsterfullerene trianions (the LUMO of which is half-filled) are conductors at room temperature and transit into the superconducting state at low temperatures (18 K for K_3C_{60}).[130] As a result of systematic studies of phases with varied metallic component composition, a positive correltation between the critical temperature and the cubic lattice parameter has been established.[131] For the $Cs_xRb_{3-x}C_{60}$ salt, a value of $T_c = 33$ K has been obtained (see Ref. 132), while doping with a rubidium – thallium mixture has given rise to even higher temperature $T_c = 45$ K (see Ref. 133), which is the current record for fullerene derivatives. In a series of studies, Schön *et al.*[134] reported substantially higher critical temperatures achieved for the hole-doped fullerene and its solvates but these results were later disproved.[135] According to the calorimetric studies of M_3C_{60} salts, the orientational phase transition, typical of pure C_{60}, is also observed for them, but at higher temperatures (299 K for Na_2CsC_{60}, 313 K for Na_2RbC_{60} and 305 K for Na_2KC_{60}).[136]

The $KCsBaC_{60}$ and KBa_2C_{60} fullerides, which are characterised by similar structures but the higher charge of the fullerene anion, are relatively poor metallic-type conductors and do not manifest superconductivity.[137]

The fullerides containing the C_{60}^{6-} anions are dielectrics. A substitution of bications for a part of metal monocations resulting in an increase in the formal negative charge of the fullerene cage to nine (as in $K_3Ba_3C_{60}$), restores electroconductivity. A phase transition into the superconducting state has also been observed for the latter substance but at a lower temperature (5 K).[138] Fullerides of calcium Ca_5C_{60} (see Ref. 139) and barium Ba_6C_{60} (see Ref. 140) have crystal structures analogous to those of the M_6C_{60} salts (in the case of calcium derivative, one sixth of the metal atom sites remains vacant). They are conductors and show a supercondivity with the critical temperatures in the range of 4 – 8 K.

The crystal structure of ytterbium fulleride with the composition $Yb_{2.75}C_{60}$ can be described as an analogue of K_3C_{60}, in which 1/8 of all octahedral cavities is vacant, while the cations are shifted from the centres of the cavities. Due to ordering of the vacant sites, the lattice parameters of the original cubic cell are doubled and the lattice symmetry is lowered to orthorhombic.[141] Fullerides $M_{2.75}C_{60}$ similar to those discussed above and M_6C_{60} with a structure of K_6C_{60} have also been found in the systems C_{60} – Eu (see Ref. 142) and C_{60} – Sm (see Refs 143, 144). The orthorhombic phase $Sm_{2.75}C_{60}$ manifests an anomalous temperature dependence of the lattice constants (see Fig. 15): at $T < 32$ K, the thermal

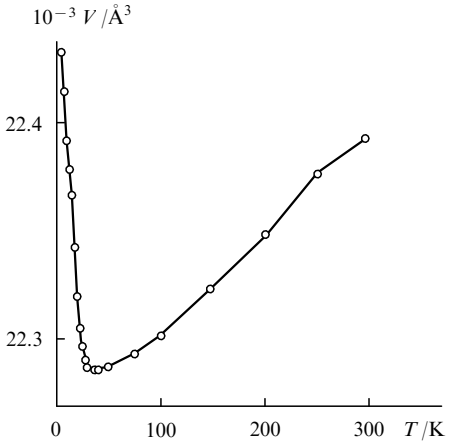

Figure 15. The temperature dependence of the unit cell volume for $Sm_{2.75}C_{60}$.[145]

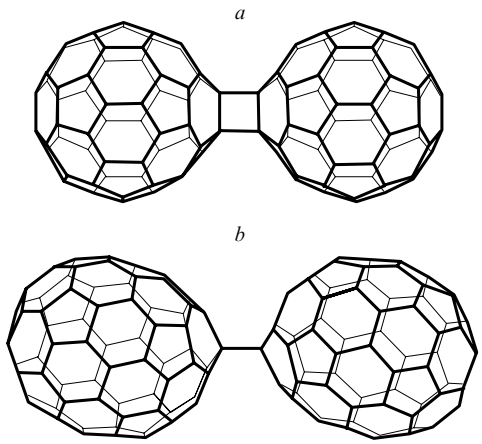

Figure 16. The molecular structures of the dimer $(C_{60})_2$ (*a*) [154] and dimeric anion $(C_{70}^-)_2$ (*b*).[155]

expansion coefficient becomes negative due to ordering of sites occupied by samarium di- and trications in the crystal lattice.[145]

With palladium and platinum, buckminsterfullerene forms crystalline compounds with the variable stoichiometry $C_{60}M_x$ ($1 \leqslant x \leqslant 7$) where formally zerovalent metal atoms are, probably, coordinated by double bonds of the fullerene molecules.[146, 147] This structural model has not been supported by diffraction techniques but it agrees well with the results of EXAFS on the palladium derivatives,[148] and gives a plausible explanation for the conversion of the palladium and platinum fullerides into the respective π-complexes with the η^2-C_{60} ligand upon action of organic phosphines PR_3.[6] The existing data on the structure of metallofullerenes have recently been surveyed by Ivanova.[149]

The C_{70} fullerene forms a series of fullerides with alkali metals characterised by stoichiometries MC_{70}, M_4C_{70} and M_6C_{70}.[150] The M_3C_{70} phase with an fcc lattice is stable only at elevated temperatures and readily converts upon cooling into the trigonal phase or disproportionates. Nevertheless, it can be stabilised by a proper selection of cations with suitable sizes (*e.g.*, sodium and caesium in Na_2CsC_{70}) so that the two smaller sodium cations occupy the tetrahedral cavities while the larger caesium cation is in the octahedral cavity.[151] An fcc phase with the composition Ba_3C_{70} has also been prepared.[152] Since the LUMO of the C_{70} molecule is nondegenerate and the next-in-energy orbital is doubly degenerate (see Fig. 3), the HOMO of the C_{70}^{4-} anion is half-filled. Respectively, salts M_4C_{70}, like M_3C_{60}, manifest superconductivity. A series of rare earth metal [70]-fullerides have also been described. In particular, two europium fullerides with stoichiometries $Eu_{3-x}C_{70}$ and $Eu_{9-x}C_{70}$ have been isolated.[48] According to powder X-ray diffraction, the former phase is antiferromagnetic and has a monoclinic structure, which is similar to $M_{2.75}C_{60}$ in the arrangement of the guest atoms. The latter phase is ferromagnetic and similar in structure to face-centred cubic M_6C_{60} fullerides. However, in the europium derivative, small metal clusters rather than single atoms occupy the octahedral cavities.[48]

Fullerides of higher fullerenes are less explored. The final product of doping of C_{84} with potassium is the salt $K_{8+x}C_{84}$, which is structurally similar to K_6C_{60} and contains fully ordered fullerene anions. Yet another fulleride, K_3C_{84}, is characterised by a rotational disorder of fullerene molecules and a lower metal content due to partial occupancies of potassium sites.[153]

VI. Fullerene-based oligo- and polymers

Due to the presence of double bonds, fullerenes form oligo- and polymers upon irradiation, under pressure, upon heating or action of chemical anionic or radical initiators. Transformations of fullerenes at elevated pressures have recently been reviewed.[5]

Pure buckminsterfullerene forms dimers under conditions of anionic catalysis.[154] According to the single-crystal X-ray diffraction studies of the dimer C_{120} solvate with *o*-dichlorobenzene, the dimerisation proceeds as a [2 + 2] cycloaddition at the 6/6 bond (Fig. 16 *a*). In the four-membered ring composed of the sp^3-hybridised carbon atoms (the corresponding spherical excesses are 26.2 – 26.7°), the C – C bond lengths are 1.581 Å and 1.575 Å for the 6/6 bonds within the fullerene core and exopolyhedral bonds, respectively. Synthesis of the C_{60} dimer from the molecular complex $(BEDT\text{-}TTF)_2C_{60}$ in which the 6/6 bonds of the adjacent fullerene molecules are mutually oriented to each other at a pressure of 5 GPa has been described.[156] Several isomeric C_{60} trimers have been produced as evidenced by mass spectrometry and high-resolution electron microscopy; however, these species have not been isolated as individual substances.[157]

A cross-dimer of C_{60} and C_{70} with an unknown structure has been prepared by means of mechanochemistry.[158] According to the quantum chemistry calculations, this may represent a [2 + 2] cycloaddition product to the C_{70} moiety at the *b*-type 6/6 bond (see Fig. 1 *b*).

Buckminsterfullerene forms several polymer phases at elevated pressures. Some of them have been obtained as single crystals and studied by single-crystal X-ray diffraction. At early stages of the modification, the phase contains linear polymeric chains of fullerene cores and is characterised by an orthorhombic lattice.[159] A deeper modification at a pressure of 2 – 5 GPa yields rhombohedral [160] and tetragonal [161] phases composed of hexagonal and tetragonal layers of covalently bound C_{60}, respectively. A detailed single-crystal X-ray diffraction study of the tetragonal phase [162] has revealed that it is rather orthorhombic with a tetragonal pseudosymmetry ($a \approx b$), though in another work, the lattice has been interpreted as being tetragonal.[163] The interfullerene C – C bond in the polymer is 1.60 Å. According to the powder X-ray diffraction, polymerisation at higher pressures (13 GPa) results in a quite irregular three-dimensional network of bound fullerenes.[164] Polymerisation of C_{60} and C_{70} at a pressure of 8 GPa and 800 – 900 °C is accompanied by partial destruction of the carbon clusters and formation of amorphous carbon materials. Densities of some of these materials were reported to approach that of diamond.[164, 165]

Polymerisation of fullerene anions occurs more easily. In particular, a linear polymer is formed from the cubic fulleride Na_2CsC_{60} at 0.7 GPa.[166] Alkali metal fullerides with the stoichiometry MC_{60}, in which fullerene anions are rotationally disordered at room temperature, form polymers with the C_{60} units joined into infinite chains by single C – C bonds upon lowering tempertures.[167] The radical-ionic salt $Cp'_2Cr \cdot C_{60} \cdot 2C_6H_4Cl_2$ ($Cp' = C_5Me_5$) at room temperature contains the $(C_{60})_2^{2-}$ dimers

linked by one C–C bond with a length of 1.60 Å.[168] Another radical-ionic salt, $(C_6H_5Me)_2Cr^+ \cdot C_{60}^- \cdot CS_2$, represents, according to single-crystal X-ray diffraction data, a linear polymer with unusually short non-bonding intermolecular C–C contacts of 2.24 Å.[169] In the $(C_6H_5Me)_2Cr-C_{60}$ system, a solvent-free molecular complex with the composition 1 : 1 has been found, in which C_{60} clusters exist as independent rotationally disordered anions at high temperatures (> 250 K) and as dimeric dianions bound by one σ-bond at low temperatures.[170]

The C_{70} fullerene also undergoes polymerisation both as a neutral molecule and an anion. The crystal structure of a polymer prepared from pure hexagonal C_{70} (a calculation within the atom–atom potential approach has shown that the mutual orientation of the molecules in cubic C_{70} is unfavourable for a formation of polymeric chains) has been determined.[171] In the polymer, the C_{70} molecules are joined in chains as a result of a [2 + 2] cycloaddition at the *b*-type 6/6 bonds (see Fig. 1 *b*). In the dimethylformamide–benzene solvate of a molecular complex of the radical-ion salt $Cs_2(C_{70})_2 \cdot CTV \cdot (DMF)_5 \cdot C_6H_6$ with cycloveratrylene (see Table 2), the fulleride anion exists as a dimer $(C_{70}^-)_2$. Two fullerene moieties are linked through one bond with the length of 1.56–1.58 Å (for different symmetrically independent dimers) involving the type **1** carbon atoms (see Fig. 1 *b*). The C_{70} core is non-symmetrically distorted so that the pentagonal 'pole' of the molecule acquires an envelope conformation with the C(sp^3) atom at the top point (Fig. 16 *b*).[155] In ammonia-solvated fullerides $MC_{70} \cdot n\,NH_3$ (M = Ca, Sr, Ba, Eu, Yb), the C_{70}^{2-} anions are bound into infinite chains by the exopolyhedral C–C bonds.[172]

VII. 'Binary' compound

In terms of chemical reactivity, fullerenes are similar to conjugated polyalkenes. The stable fullerene core may be considered as a large pseudoatom in reactions of addition and substitution involving exopolyhedral fragments. In this section, fullerene 'binary' compounds C_nX_m where X is an external atom or a stable substituent (CH_3, CF_3) covalently bound to the fullerene core C_n are discussed.

Structural studies of polyadduct mixtures C_nX_m are hindered by the multitude of addition isomers. For instance, a symmetrical addition of two functional groups to one of the 30 equivalent 6/6 bonds in buckminsterfullerene divides the remaining 6/6 bonds into nine nonequivalent classes. The number of theoretically possible isomers increases tremendously with an increase in the number of groups attached (*e.g.*, 6×10^{14} for $C_{60}H_{36}$, see Ref. 173), which makes impossible a comprehensive quantum chemistry analysis with a search for the global minimum.

Upon exposure of buckminsterfullerene to air, traces of C_{60} oxides are formed. For purposeful preparation of oxides, *m*-chloroperoxybenzoic acid is used, which is a standard reagent for the oxidation of alkenes into epoxides. Monoxide $C_{60}O$ (see Ref. 174) and dioxide $C_{60}O_2$ (see Ref. 175), which have been isolated and characterised structurally, form single crystals isomorphous to pure buckminsterfullerene. Exopolyhedral oxygen atoms occupying cavities of the fcc packing have not been revealed due to rotational disorder. For the $C_{60}O$ oxide, an orientational phase transition has been registered at 278 K. According to the single-crystal X-ray diffraction study of oxyfullerene π-complexes, the oxygen atom in $(\eta^2\text{-}C_{60}O)Ir(CO)Cl(PPh_3)_2$ is attached to the 6/6 bond of the fullerene cage while the iridium atom is coordinated to another 6/6 bond of the same hexagon.[176] In the $C_{60}O_2$ core of another complex, *viz*., $(\eta^2\text{-}C_{60}O_2)Ir(CO)Cl(PPh_3)_2$, two oxygen atoms are attached to neighbouring 6/6 bonds; the complex represents a mixture of isomers with metal atoms coordinated to different 6/6 bonds.[177] In the $C_{70}O$ core of the complex $(\eta^2\text{-}C_{70}O)Ir(CO)Cl(PPh_3)_2$,[178] the oxygen and iridium atoms are attached to adjacent *b*-type 6/6 bonds (see Fig. 1 *b*).

The properties of fullerene hydrides have been reviewed by Goldshleger and Moravsky.[4] The principal buckminsterfullerene hydrogenation product is $C_{60}H_{36}$, which was suggested to be a mixture of D_{3d} and S_6 isomers based on the data from IR and Raman spectroscopy.[179] Meanwhile, a fullerene hydride with the same composition was attributed[180] to a mixture of two other isomers with the C_3 and C_1 symmetry (isostructural to isomers of fullerene fluoride $C_{60}F_{36}$, see below) using the ^1H, ^{13}C and ^3He NMR data for the endohedral derivative $He@C_{60}H_{36}$. Another hydride, $C_{60}H_{18}$, was also suggested to be isostructural to the respective fluoride[181] based on the ^3He NMR data for $^3He@C_{60}X_{18}$ (X = H, F).[182] To our knowledge, no single-crystal X-ray difraction studies of fullerene hydrides have been conducted so far. In a study of $C_{60}H_{36}$ using powder X-ray diffraction, a bcc lattice with a lattice parameter of 11.75 Å was determined.[183]

Iodine forms no covalent compounds with C_{60} but rather a molecular complex $C_{60} \cdot 2I_2$ belonging to a structural type with closely packed hexagonal layers $(C_{60})_\infty$.[184] An iodine-containing solvate $C_{60} \cdot PhMe \cdot I_2$ falling into the same type of molecular packing has also been characterised.[185] All other halogens react with fullerenes to form addition products.

A series of fluorinated buckminsterfullerenes from $C_{60}F_2$ (see Ref. 186) to $C_{60}F_{48}$ (see Ref. 187), in which the polyhedral C_{60} core is retained, have been prepared and characterised. The methods of synthesis of fluorofullerenes and reported data on their structures have been recently reviewed by Taylor.[188] To date, single-crystal X-ray diffraction data are available for $C_{60}F_{18}$ (see Refs 189, 190), $C_{60}F_{18}O$ (see Ref. 191), $C_{60}F_{17}CF_3$ (see Ref. 192), $C_{60}F_{36}$ (three isomers)[193, 194] and $C_{60}F_{48}$ (see Refs 195, 196). The Schlegel diagrams for the structurally studied fullerene fluorides and bromides are given in Fig. 17. The molecular structures of three C_{60} fluorides are shown in Fig. 18, and their basic geometrical parameters are listed in Table 5.

In the molecule $C_{60}F_{18}$ with the C_{3v} symmetry studied as a toluene solvate[189] and individual fullerene fluoride,[190] all eighteen fluorine atoms are attached to one hemisphere of the fullerene core around a flattened hexagonal ring (the spherical excess is $\varphi_i \leqslant 0.1^\circ$) isolated from the π-system of the remaining part of the molecule (see Fig. 17 *a*). All the sp^3-hybridised carbon atoms are pyramidised ($26.4^\circ \leqslant \varphi_i \leqslant 29.9^\circ$) while the atoms adjacent to them are flattened ($\varphi_i = 3–6^\circ$) with respect to pristine C_{60}. Consequently, the carbon cage acquires the shape of a 'tortoise shell' (see Fig. 18 *a*).

Table 5. Parameters of the molecular geometry of structurally characterised fluorofullerenes.

Formula	Symmetry	C–C bonds /Å				k [a]	*R*-factor	Disorder	Ref.
		$sp^3–sp^3$	$sp^3–sp^2$	aromatic	C=C				
$C_{60}F_{18} \cdot PhMe$	C_{3v}	1.54–1.67	1.47–1.53	1.37	–	0.74	0.049	no	189
$C_{60}F_{36} \cdot 1.75\,PhMe$	T	1.55–1.66	1.48–1.49	1.36–1.38	–	0.70	0.090	yes	193
$C_{60}F_{36} \cdot 3.5\,PhMe$	C_1	1.54–1.68	1.46–1.54	1.37–1.38	1.32	0.70	0.059	no	194
$C_{60}F_{48} \cdot C_6H_3Me_3$-1,3,5	S_6	1.54–1.61	1.49–1.58	–	1.29–1.30	0.71	0.051	yes	195

[a] k is the Kitaygorodsky molecular packing coefficient.[64]

The Schlegel diagrams for $C_{60}F_{18}$ (*a*), $C_{60}F_{36}$ (*b*), $C_{60}F_{48}$ (*c*), $C_{60}Br_6$ (*d*), $C_{60}Br_8$ (*e*), $C_{60}Br_{24}$ (*f*); (*b*) (to the right): the arrows show the 1,3-shifts of fluorine atoms giving rise to the C_3 isomer, the double arrow shows the shift transforming the C_3 isomer further to the C_1 isomer; (*a*, *b*): aromatic rings are shown; (*c*, *f*): positions of double bonds are shown.

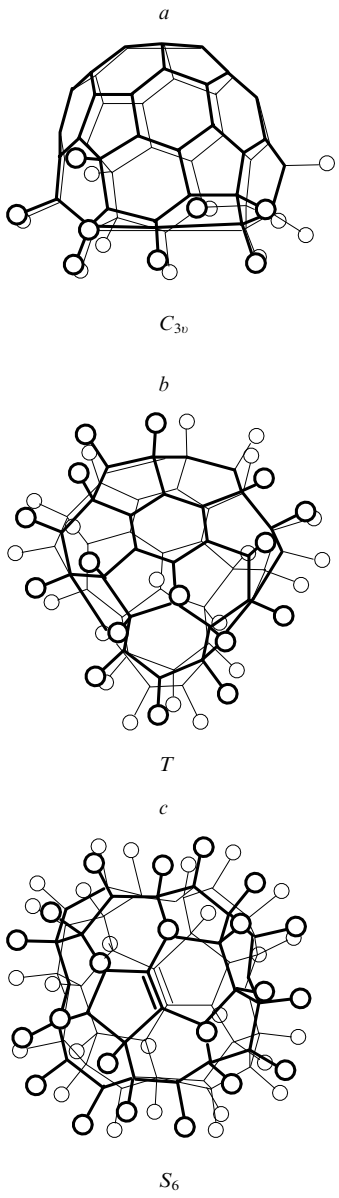

Figure 18. The molecular structures of $C_{60}F_{18}$ (*a*), $C_{60}F_{36}$ (*b*) and $C_{60}F_{48}$ (*c*).

Three symmetrically equivalent 5/6 $C(sp^3)-C(sp^3)$ single bonds in the molecule $C_{60}F_{18}$ are elongated to 1.67 Å. The addition of an oxygen atom at one of these bonds (to give $C_{60}F_{18}O$) results in its cleavage.[191] Three fluorine atoms the most remote from the isolated aromatic hexagon can be substituted by phenyl groups (using the Friedel – Crafts reaction) to give $C_{60}F_{15}Ph_3$ [197] and undergo nucleophilic substitution.[198] In the crystal structure of $C_{60}F_{17}CF_3$, the trifluoromethyl group occupies one of the peripheral fluorine sites; the crystal contains a mixture of two substitution isomers in different orientations.[192]

The molecular structure of the fluoride $C_{60}F_{20}$ (not studied by single-crystal X-ray diffraction) has been determined by NMR spectroscopy. According to Boltalina *et al.*,[199] all fluorine atoms in $C_{60}F_{20}$ are located at the equatorial belt of the molecule, *i.e.*, this fluoride does not include a fragment of the $C_{60}F_{18}$ structure. This suggests that, under the reaction conditions, the fluorine atoms migrate over the surface of C_{60}.

Several isomers of $C_{60}F_{36}$ are known. The major isomer with the exceptionally rare point symmetry *T* has been isolated and structurally characterised as a toluene solvate. This molecule contains four aromatic rings with equal bond lengths analogous to the single aromatic ring in $C_{60}F_{18}$. All other carbon atoms are sp^3-hybridised and bound to fluorine atoms. The strongly distorted carbon core acquires a shape resembling a tetrahedron with rounded edges and vertices (see Fig. 18 *b*). The crystal is statistically disordered and represents a racemic mixture of enantiomers.[194] The C_3 symmetry has been attributed to the isomer second in abundance based on the NMR data. The third isomer having the C_1 symmetry has been isolated and studied by single-crystal X-ray diffraction. Its molecular structure can be derived from that of the C_3 isomer by a 1,3-shift of one of the fluorine atoms in the five-membered ring [194] (see Fig. 17 *b*).

The fluorine-rich fullerene fluoride, $C_{60}F_{48}$, has been characterised by single-crystal X-ray diffraction as a solvate with mesitylene.[195, 196] The molecule occupies a special position of the $\bar{3}$ symmetry in a pseudocentred cubic lattice (space group $Pa\bar{3}$) and is rotationally disordered. It can be interpreted as a superposition of the D_{3d} and S_6 isomers in an overall ratio of 0.61 : 0.39.[195] In another study,[196] the unit cell was erroneously attributed to a bcc lattice and the molecule $C_{60}F_{48}$ was described as an S_6 isomer.

The $C(sp^3)-C(sp^3)$ bond lengths in $C_{60}F_{48}$ lie in the range 1.54 – 1.61 Å.[195] Six double carbon – carbon bonds (1.29 – 1.30 Å) situated at vertices of an octahedron (see Fig. 17 *c*), which belong to the 5/6 type (in contrast to respective bonds in the pristine fullerene), are noticeably pressed inside the molecule (the spherical excesses are from -2° to -9°).‡ This is consistent with the impossibility of further fluorination of C_{60} derivatives without disruption of the carbon cage.[200]

Due to the strong electrostatic dipole – dipole interactions (the dipole moment is 12 – 15 D, according to *ab initio* quantum chemistry calculations), both components of the $C_{60}F_{18}\cdot PhMe$ solvate are ordered. The Kitaygorodsky density coefficient[64] of the molecular packing for $C_{60}F_{18}\cdot PhMe$ is 0.74 (the packing of pure $C_{60}F_{18}$ is significantly looser since the lattice cavities cannot be filled with the solvent molecules). Meanwhile, solvates of the high-symmetry fluorides $C_{60}F_{36}$ and $C_{60}F_{48}$, which are characterised by zero dipole moments, are looser and more disordered ($k = 0.70 – 0.71$, see Table 5). The pattern of the rotational disorder of the molecules $C_{60}F_{48}$ observed in the crystal structure of $C_{60}F_{48}\cdot 2(1,3,5\text{-}C_6H_3Me_3)$[196] can be reproduced within the model of the 'rubber cavity'[110] (see Fig. 12).

Chlorination of fullerene yields a mixture of products $C_{60}Cl_n$, $n \leqslant 24$. These products have been studied by IR spectroscopy and mass spectrometry.[201] Using a mild chlorinating agent (ICl), the chloride $C_{60}Cl_6$ can be prepared. According to the NMR and IR data, its structure is similar to that of hexabromide (see Fig. 17 *d*).[202]

Six exopolyhedral fragments in hexamethylfullerene $C_{60}Me_6$ produced by methylation of $C_{60}Cl_6$ with methyllithium are arranged in the same mode as in hexachloride according to its single-crystal X-ray diffraction study.[203] Partial substitution of the methyl groups for the chlorine atoms to give $C_{60}Me_5Cl$ followed by a nucleophilic substitution of OH for Cl and epoxidation of the two C – C bonds in the isolated five-membered ring yields $C_{60}Me_5(OH)O_2$, the crystal structure of which has also been determined.[204] In this structure, the molecules are ordered and characterised by the C – C bond lengths of 1.52 – 1.57 Å for the $C(sp^3)-C(sp^3)$ bonds and 1.48 Å for the epoxy-rings. The C – O bond lengths lie in the range 1.44 – 1.46 Å. Five chlorine atoms around a five-membered ring in $C_{60}Cl_6$ can also be substituted by phenyl groups using the Friedel – Crafts reaction (in this reaction, $C_{60}Ph_4$ is produced as a by-product).[205] The electronic properties of the main product $C_{60}Ph_5Cl$ are similar to pentasubstituted cyclopentadiene. In particular, its two-electron electrochemical reduction gives rise to an aromatic anion,[206] and its chemical modification enables preparation of metal π-complexes of the η^5 type.

Nakamura *et al.*[50] isolated and studied structurally a fullerene derivative functionalised in a similar way at two opposite pentagonal faces. The equiatorial belt of such a fullerene cage is composed of sp^2-hybridised carbon atoms resembling a fragment of a [5,5]-nanotube (Fig. 19). Trifluoromethylation of C_{60} using silver trifluoroacetate on heating yields CF_3 addition products to the neighbouring 6/6 and 5/6 bonds, according to the NMR data.[207]

Single-crystal X-ray diffraction data for three buckminsterfullerene bromides $C_{60}Br_6$, $C_{60}Br_8$ and $C_{60}Br_{24}$ crystallised as solvates with liquid bromine have been published (the respective Schlegel diagrams are shown in Fig. 17 *b*). In the two latter molecules, the nearest bromine atoms occupy 1,3-positions to each other, which is, probably caused by steric reasons. In the molecule $C_{60}Br_{24}$, there are isolated double bonds belonging both to the 5/6 and 6/6 types. They are shortened to 1.33 – 1.34 Å, while the $C(sp^2)-C(sp^3)$ bonds are elongated to 1.46 – 1.51 Å. The packing of the molecules $C_{60}Br_{24}$ in the crystal lattice is close to fcc.

‡ Negative spherical excesses correspond to a pyramidal carbon atom with an apex directed towards the centre of the fullerene cage.

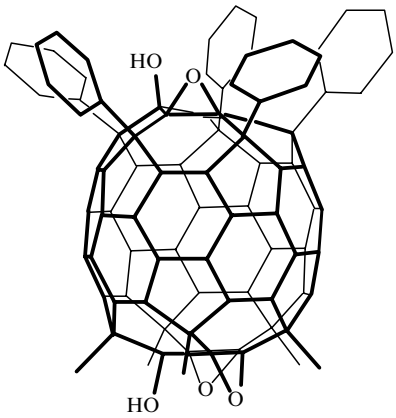

Figure 19. The molecular structure of $C_{60}Me_5Ph_5O_3(OH)_2$ with the fullerene core functionalised at two opposite pentagonal faces.[49]

Binary derivatives of C_{70} are less studied. The major hydrogenation products fall into the composition range $C_{70}H_{36} – C_{70}H_{44}$ (see Ref. 4). The fluorine-rich derivative is, likely, $C_{70}F_{56}$,[208] while chlorination stops at the $C_{70}Cl_{10}$ stage.[209] Substitution of methyl groups for chlorine atoms in this chloride is accompanied by partial reduction and yields $C_{70}Me_8$. The crystal structure of this substance has been determined.[210] The Me-fragments are attached to the type **4** carbon atoms (see Fig. 1 *b*) at both sides with respect to the equator of the molecule. In the bromide $C_{70}Br_{10}$, which has been also studied by single-crystal X-ray diffraction (Fig. 20), the bromine atoms are attached to the type **4** carbon atoms as well.[49] Synthesis of another bromide $C_{70}Br_{14}$ has been reported,[211] but its crystal structure has not been determined. Among binary derivatives of higher fullerenes, only one bromide $C_{78}Br_{18}$ has been studied, which contains statistically disordered molecules of two bromination isomers with the C_{2v} symmetry; no admixtures of probable bromination products of the D_3 isomer were detected.[212]

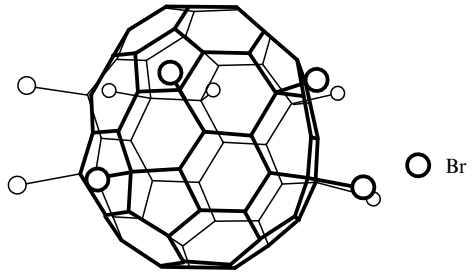

Figure 20. The molecular structure of $C_{70}Br_{10}$ from the single-crystal X-ray diffraction data.[49]

VIII. σ-Derivatives

Derivatisation of fullerene typically involves an addition to the 6/6 double C – C bond as the first stage. Thus, exocoordinated carbon atoms acquire the sp^3-character and protrude over the surface of the original C_{60} sphere due to an elongation of the C – C bond

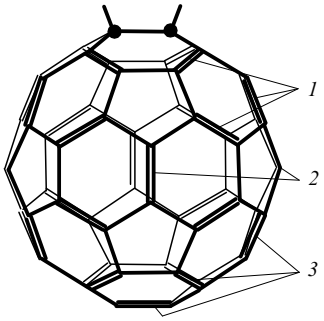

Figure 21. Symmetrically non-equivalent 6/6 bonds in the molecule C_{60} chemically modified at one of the 6/6 bonds.
Positions of bonds: (*1*) *cis*, (*2*) equatorial, (*3*) *trans*.

linking them and an increase in the spherical excesses φ_i from 12° to 16–32° ($\varphi = 31.7°$ for an unstrained sp^3-hybridised carbon atom). Such an addition to one of the 6/6 bonds divides the remaining 6/6 bonds in the fullerene molecule into 9 symmetrically nonequivalent types. Three of these types are conventionally referred to as *cis*-positions, four — *trans*-positions and two — equatorial positions (Fig. 21).

The main types of the σ-addition products to the molecule C_{60} are shown in Fig. 22. The binary products $C_{60}X_n$ produced by multiple σ-addition of one-electron fragments X to C_{60} were discussed in the previous section.

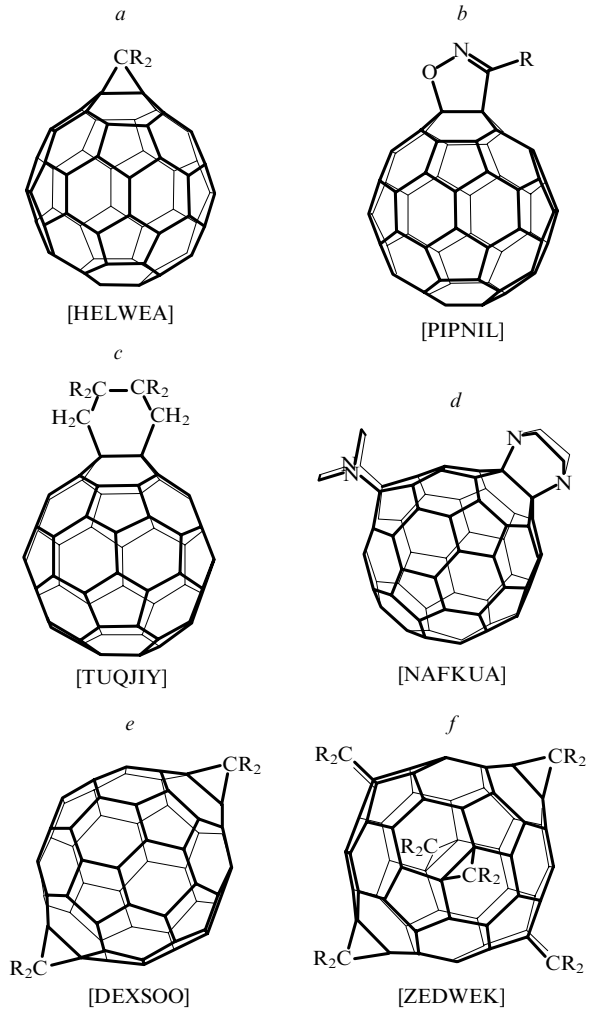

Figure 22. The possible types of σ-functionalisation of the fullerene molecule (CSD Refcodes are given).

The addition of carbene to a double carbon–carbon bond within the fullerene molecule yields a three-membered ring (see Fig. 22 *a*,*e*,*f*). On average, the key $C(sp^3)-C(sp^3)$ bond in these compounds is elongated to 1.59 Å, which is 0.04–0.05 Å longer than a typical single C–C bond. This clearly indicates substantial steric strains around the sp^3-hybridised carbon atoms in the fullerene core. Four-membered rings have been found only in derivatives of the dimeric molecule $(C_{60})_2$. Numerous derivatives with five- and six-membered rings (see Fig. 22 *b*–*d*) are formed in the reactions of [2 + 3] and [2 + 4] cycloaddition. As a result, the mean length of the C–C bond involved in the attachment increases to 1.60 Å and 1.61 Å, respectively.

Functionalisation of a double bond activates the five other 6/6 bonds, which form together an octahedron over the C_{60} core (see Fig. 22 *d*,*e*), towards further addition. Subsequent addition proceeds predominantly at these bonds giving rise ultimately to a hexaadduct with the T_h symmetry of the carbon cage (see Fig. 22 *f*). For instance, the crystal structure of the adduct containing six malonate groups $C_{60}[C(COOEt)_2]_6$ has been determined.[213] However, a hexaaduct violating this addition pattern is known, which is characterised by the composition $C_{60}(Tmp)_6 \cdot Solv$ and D_3 symmetry.[214]

Homofullerenes (*i.e.*, the addition products to the 5/6 bonds) are less abundant. Formally, this bond is single, and the attachment to it results in its cleavage and removal of the two carbon atoms to a distance ~2.1 Å from each other.[191,215]

The fullerene C_{70} possesses 8 non-eqivalent C–C bonds, which are characterised by different steric accessibilities. In the majority of structurally characterised derivatives, the addition occurs at the *b* type double bond (see Fig. 1 *b*), which is characterised by the largest sum of spherical excesses of its two carbon atoms among all the 6/6 bonds. Two exceptions to this rule are the adduct $C_{70}C_{10}H_{12}O_2$ [216] in which the *d* type bond is affected and a homofullerene produced by the addition of CCl_2 to the *f* type single bond, which results in its cleavage.[215]

Crystal packing of certain functionalised fullerenes is affected to a great extent by the external groups attached to the C_{60} or C_{70} core (which, for instance, link two fullerene cores or coordinate metal atoms). In particular, OsO_4, which is often used in organic synthesis for oxidation of alkenes to diols, reacts with buckminsterfullerene yielding an osmate ester of fulleren-1,2-ol. Note that the complex $C_{60}O_2OsO_2(4\text{-}BuPy)_2$ is the very first C_{60} derivative studied by single-crystal X-ray diffraction.[217] There are several other complexes, in which metal atoms are coordinated to exopolyhedral fragments attached to a fullerene core. As an example, a solvate of $C_{60}S_2Fe_2(CO)_6$ may be mentioned, in which two sulfur atoms attached to the fullerene core in 1,2-positions additionally coordinate the binuclear $Fe_2(CO)_6$ fragment.[218]

In addition to the aforementioned fullerene dimer, there are other molecules containing two fullerene cages bound to each other. Some typical examples are given in Fig. 23. Oxybifullerene $C_{120}O$ (its radical cation $C_{120}O^+$ is readily formed upon oxidation of solutions of C_{60} in air giving rise to a characteristic ESR signal, see Ref. 118) has been characterised by single-crystal X-ray diffraction as a molecular complex with octaethylporphyrin. Despite the positional disorder of the oxygen atoms, it was established that the molecule represents a dimer, in which one of the interfullerene C–C bonds is replaced by the C–O–C bridge.[82] In $C_{60}C(C{\equiv}CSiPr^i_3){-}C{\equiv}CC{\equiv}C(C{\equiv}CSiPr^i_3)CC_{60}$ (see Fig. 23 *a*), two 1,2-disubstituted fullerene cores are linked by a four-atomic butadiynediyl bridge.[219] A derivative of the dimer C_{60} where each of the fullerene cages is additionally functionalised at five bonds giving the addition pattern similar to C_{60} hexaadducts has been studied (see Fig. 23 *b*).[220] Yet another metallocomplex involving two fullerene fragments functionalised to hexaadducts and acting as bidentate σ-ligands has been synthesised and structurally characterised. The fullerene fragments in this complex

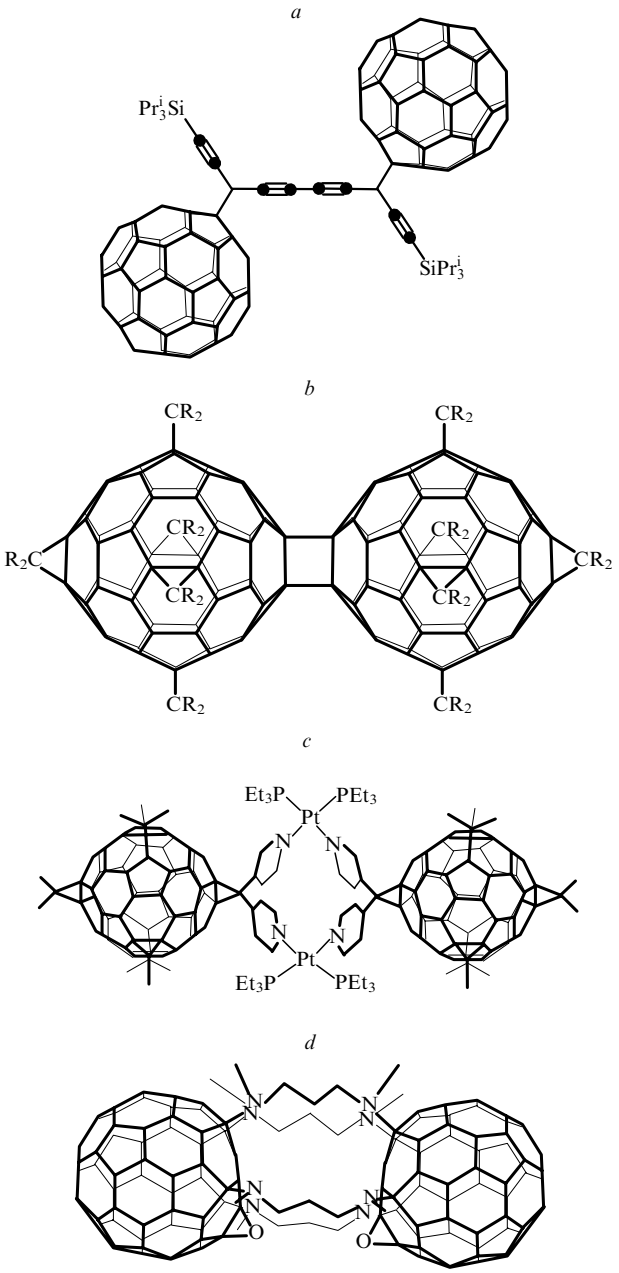

Figure 23. The structures of molecules containing two C_{60} moieties; (*a*) 1,4-bis{(1,2-dihydro-61-[(triisopropylsilyl)ethynyl]-1,2-methano-C_{60}-fullerene-61-yl}buta-1,3-diyne,[219] (*b*) bis[decakis(ethoxycarbonyl)pentacyclopropa(1,9 : 16,17 : 44,45 : 52,60)-C_{60}-fullerenediyl],[220] (*c*) bis{[μ^2-66,66-bis(4-pyridyl)-1,2 : 18,36 : 22,23 : 27,45 : 31,32 : 55,56-hexakis(methano)-C_{60}-fullerene-61,61,62,62,63,63,64,64,65,65-decakis(ethylcarbonate)-*N*,*N*′] bis(triphenylphosphino) platinum(II)},[221] (*d*) tetrakis(*N*,*N*′-dimethylpropanediamine-*N*,*N*′)bis(epoxy-C_{60}-fullerene).[222]

are linked by two bridging platinum atoms (see Fig. 23 *c*).[221] In 2000, the first fullerene-containing cryptand $(C_{60}O)_2 \cdot [NMe(CH_2)_3NMe]_4$ was synthesised, which may be regarded as a derivative of fullerene hexachloride, in which two chlorine atoms are substituted by an epoxy oxygen atom, while the other four atoms are substituted by propanediamine bridges joining two $C_{60}O$ moieties (see Fig. 23 *d*).[222]

The changes in the C–C bond lengths in the C_{60} core upon σ- and π-functionalisation are illustrated in Figs 24 and 25. It is clearly seen that the addition of any exopolyhedral fragment to a 6/6 bond results in its elongation and a specific redistribution of lengths of the neighbouring C–C bonds. The distortions of the

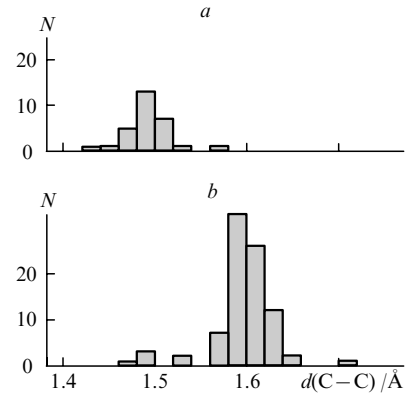

Figure 24. The distribution of lengths of the coordinated 6/6 C–C bonds in π- (*a*) and σ-derivatives of buckminsterfullerene (*b*).

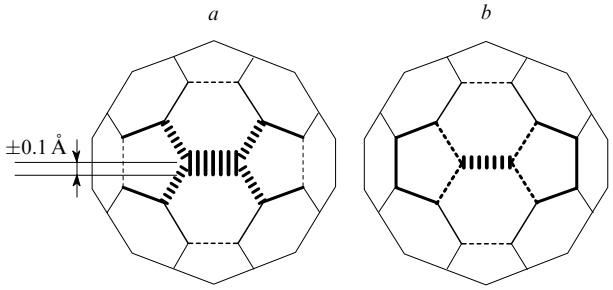

Figure 25. The elongation (dashed lines) and shortening (solid lines) of bonds in the fullerene molecule upon σ- (*a*) and π-addition (*b*). The magnitude of the bond length changes is proportional to the line width (the scale is shown).

C_{60} core due to coordination to a η^2-ML fragment (where M denotes a transition metal atom and L is its ligand shell) are substantially weaker as compared to those in σ-adducts, including $C_{60}CR_2$ derivatives. Note that the geometrical distortions of the cluster C_{60} are localised in the immediate proximity to the modified 6/6 bond both in σ- and π-derivatives, *i.e.*, the fullerene cage 'poorly transmits' the influence of attached fragments. As for chemically modified derivatives of C_{70}, structural data available for them are too sparse to derive reliable correlations.

A deeper chemical modification can result in opening and rearrangement of the carbon core. In particular, the molecule of a fullerene diketo derivative with an open 11-membered face admits penetration of small molecules, such as H_2, inside the fullerene core.[223] Another way to modify fullerene consists in 1,2-addition leading to the opening of the carbon cage and formation of a new fullerene with a four-membered carbocycle and two extra carbon atoms.[50] The cobalt complex σ,η^2,σ-$C_{64}H_4CoCp$, which contains an open fullerene core with a C_4H_4 fragment attached can be taken as an example.[224]

The crystal packings in chemically modified fullerenes obey the same regularities as molecular complexes. If a small externally attached fragment (*e.g.*, an oxygen atom) is present, a packing similar to the structure of pure C_{60} is formed. Covalently bound exopolyhedral fragments smaller than the van der Waals diameter of the fullerene sphere perform as 'diluents' in the standard structural motifs $(C_{60})_\infty$ (see Table 4). For instance, the crystal structure of the carbene monoadduct $C_{60}C(COOEt)_2 \cdot CHCl_3$ (ρ = 0.81)[225] may be classified as a three-dimensional framework with the MCN = 8 (here, the term MCN applies only to the fullerene subunit rather than to the whole molecule). At the same time, 3-benzyloxycarbonyl-(60)fullereno[1,2-*d*]isoxazole with the

bulkier five-membered isoxazole ring attached to the fullerene molecule, is composed of hexagonal layers of the C_{60} cores with the MCN = 6.[226] Bulkier exopolyhedral fragments together with solvate molecules result in looser packings down to motifs comprising isolated fullerene cores, such as the one encountered in the hexaadduct $C_{60}[C(COOEt)_2]_6$.[219] Note that fragments chemically attached to the fullerene core suppress rotational disorder, which typically leads to higher accuracy of the structure determination.

IX. π-Derivatives

The chemical properties of fullerenes as π-ligands are closer to polyalkenes rather than aromatic hydrocarbons. Chemically non-modified buckmisnterfullerene coordinates a few metal atoms by its 6/6 bonds acting exclusively as a η^2-ligand. As for σ-addition, η^2-coordination to one of the 6/6 bonds in buckminsterfullerene activates five analogous bonds forming together an octahedron over the fullerene cage (T_h symmetry, see Fig. 22 *f*). Upon π-coordination, the elongation of the affected 6/6 bond is not as significant as in the case of σ-addition (see Fig. 24). As a rule, the second group is π-coordinated at a *trans*-position with respect to the first one. The maximum number of metal-containing groups ML_n attached in this way is 6 (realised in the case of platinum), and the metal atoms are located in the vertices of an octahedron.[227]

Closely spaced double bonds enable fullerenes to act as polydentate η^2:η^2- and η^2:η^2:η^2-ligands in complexes with clusters of the platinum-group metals (Fig. 26). Such a coordination type is typical of arene ligands, *e.g.*, $C_6H_6Os_3(CO)_9$.[228] In a series of fullerene complexes with osmium and ruthenium, three metal atoms forming a triangular cluster are coordinated by three double bonds of one hexagonal face of the fullerene molecule.[229] A few complexes with buckminsterfullerene acting as a η^2-ligand for a triangular osmium carbonyl cluster have been reported.[230] In a series of closely related complexes described by Park *et al.*,[231] the osmium triangle coordinates fullerene as a η^2:η^2:η^2-, σ:η^2:σ- or η^2:η^2-ligand, depending on the non-fullerene ligand environment of the metal atoms.

In total, the CSD contains 30 entries, in which fullerene cages are π-coordinated to a single metal atom, 10 entries — to two metal atoms, 14 — to three, 2 — to four, 9 — to five and 6 — to six metal atoms. Furthermore, π-complexes containing two fullerene ligands coordinated to one cluster unit, such as Rh_6,[232] and even to one metal atom (Mo or W, see Fig. 26 *e*) [233] are known. For the π-complex $(\eta^2\text{-}C_{60})Ir(o\text{-}C_2B_{10}H_{10}CH_2PPh_2)(Bu^tNC)_2$, which contains the carborane and fullerene moieties coordinated to one iridium atom, insertion of an O_2 molecule at the metal–carbon bond upon oxidation in air has been confirmed by single-crystal X-ray diffraction. The resultant five-membered peroxide metallacycle has an Ir–C σ-bond with a length of 2.24 Å (Fig. 27).[52]

A η^2-coordination of an ML fragment to the fullerene core results in a redistribution of the C–C bond lengths, which is similar to that observed upon σ,σ-addition, but is less pronounced. Upon π-coordination, the 6/6 bond involved is elongated, on the average, to 1.48 Å (as compared to 1.60 Å in $C_{60}X_2$). The adjacent 5/6 bonds are elongated to 1.49 Å and a redistribution of the lengths of the adjacent bonds takes place (see Fig. 25). As in the case of σ-derivatives, the influence of the η^2-coordination on neighbouring bonds quickly attenuates with increasing distance from the coordinated bond and the 'rear' hemisphere of the fullerene core remains virtually unaffected.

In a series of structurally similar mononuclear fullerene complexes with iridium (fullerene)·$[Ir(CO)Cl(PPh_3)_2]_n$, n = 1, 2 (fullerene = C_{60}, $C_{60}O$, C_{70}, $C_{70}O$, C_{84}), the iridium atoms have approximately trigonal bipyramidal coordination environment. Essential geometrical parameters of these complexes are given in Table 6. Note that the volume occupied by the fullerene ligand in the coordination environment of iridium is larger than that of the triphenylphosphine ligand (the P–Ir–P bond angle is less than 120°, see Table 6).

Penta-functionalised fullerene derivatives $C_{60}R_5$, in which the attached groups are located around a five-membered ring, are similar in terms of their electronic structure to pentasubstituted cyclopentadiene and thus can be involved into the η^5-coordination. In the structurally chracterised thallium salt $C_{60}Ph_5^-$,[238] which is analogous to cyclopentadienyl complexes of alkali metals with the essentially ionic metal–ligand bonding of the η^5-type, the

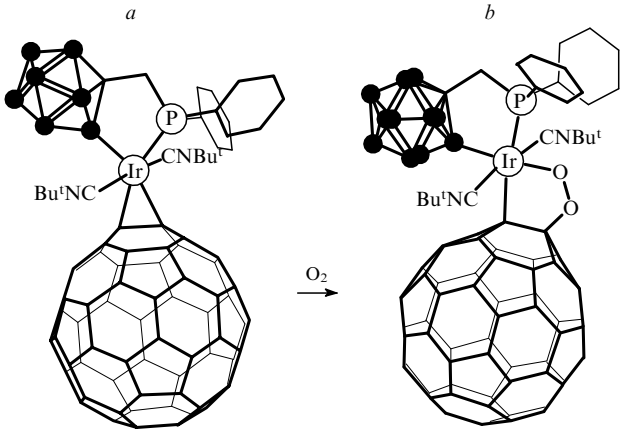

Figure 27. The molecular structures of the carborane–fullerene π-complex of iridium η^2-C_{60}Ir(*o*-$C_2B_{10}H_{10}CH_2PPh_2$)(Bu^{t}NC)$_2$·4 PhMe (*a*) and the product of its air oxidation (*b*) (single-crystal X-ray diffraction data).[52]

Tl–C lengths lie in the range 2.83–2.89 Å. The thallium atom is additionally coordinated to an oxygen atom of the THF solvate molecule at a distance of 3.16 Å. In another rhodium-based complex $C_{60}Me_5Rh(CO)_2$, the $C_{60}Me_5$ core acts as a real η^5-ligand coordinated to a metal atom[239] with the bonding Rh–C distances in the range of 2.12–2.27 Å.

As in the case of σ-addition, the fullerene C_{70} π-coordinates external metal atoms most typically by the *b* type bonds or, in complexes with metal clusters or several independent metal atoms, by *b* and *d* type bonds (see Fig. 1 *b*). In the thallim derivative $C_{70}(C_6H_4CF_3)_3Tl\cdot o$-$C_6H_4Cl_2$, the $C_{70}(C_6H_4CF_3)_3$ fragment acts as a cyclopentadienyl-like anion.[240] The molecular structures of the η^5-coordinated derivatives of C_{60} and C_{70} are depicted schematically in Fig. 28.

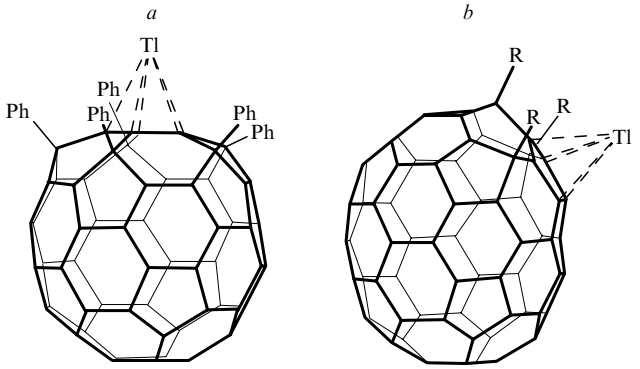

Figure 28. Examples of the η^5-coordination fullerene–metal. (*a*) $C_{60}Ph_5Tl\cdot 2.5\,THF$, Tl–C = 2.83–2.89 Å (see Ref. 238), (*b*) $C_{70}(C_6H_4CF_3)_3$ $Tl\cdot C_6H_4Cl_2$, Tl–C = 2.84–3.08 Å (R = *p*-$C_6H_4CF_3$).[240]

The D_{2d} isomer of C_{84} in the structurally investigated complex $C_{84}\cdot Ir(CO)Cl(PPh_3)_2$ is coordinated to iridium through the 6/6 bond located at the intersection of two symmetry planes. The coordinated bond is elongated to 1.45 Å, and the spherical excesses of its carbon atoms are increased to 21° and 18°.[33]

Of particular interest are the structures and chemical properties of fullerene metallocomplexes containing metal atoms bound to strongly modified 'open' carbon cages and involving attached exopolyhedral functional groups. For instance, the cobalt atom in the crystal structure of $C_{60}C_4H_4CoCp\cdot C_7H_8$ is coordinated to bishomofullerene acting as a (η^2,σ,σ)-ligand (see Fig. 26 *f*).[82] In this compound, the fullerene cage is open due to the formation of an 11-membered ring.

Bulky and sterically flexible molecules of fullerene π-complexes often form several different solvates with the same solvent. A typical example is two benzene solvates of the complex $C_{60}[Ir(CO)Cl(PPhMe_2)_2]_2$ (Fig. 29).[235] In one of the solvates with the composition $C_{60}[Ir(CO)Cl(PPhMe_2)_2]\cdot C_6H_6$ (ρ = 2.21), the fullerene cores are isolated from each other while in the second complex, which is characterised by the stoichiometry $C_{60}[Ir(CO)Cl(PPhMe_2)_2]\cdot 2\,C_6H_6$ (ρ = 2.45), the packing of fullerene fragments may be described as separated columns.

It is convenient to describe the crystal packings encountered in fullerene π-complexes (as well as in other derivatives) in terms of motifs formed by fullerene spheres. A distinctive feature of the π-complexes is an appreciable volume of the non-fullerene part. This often gives rise to loose and isolated motifs. Fullerene π-complexes with palladium and platinum having the composition $C_{60}M_n$ (attributed in the present review to fullerides) represent an exception from this tendency.

X. Endohedral fullerenes

Endohedral fullerenes, *i.e.*, compounds containing different 'guests', such as metal or nonmetal atoms (including atoms of inert gases) or small cllusters, inside the carbon cage, take a special place among diverse fullerene derivatives. The regularities of the formation of these compounds have been reviewed by Shinohara[241]. Endohedral metallofullerenes (EMFs) have been detected by mass spectrometry for the first time simultaneously with the 'empty' fullerenes,[242] and later were isolated in microgram quantities.[243] However, structural studies of these species are impeded to a great extent by their high reactivity and the multitude of isomers (see below).

A heating of 'empty' fullerenes C_n in the atmosphere of an inert gas A under pressure allows preparation of endohedral§ derivatives A@C_n in trace amounts.[244] In particular, endohedral compounds of C_{60} with ^{3}He (see Ref. 245) and ^{129}Xe (see Ref. 246) were prepared and studied by NMR. In the case of C_{70}, endohedral derivatives $A_2@C_{70}$ [A = He (see Ref. 247) and Ne (see Ref. 248)] with two inert gas atoms inside the fullerene cage were produced using this route. The ratio between the products A@C_{70} and $A_2@C_{70}$ suggests the 'classical' mechanism of the synthesis involving cleavage of a C–C bond with subsequent closure of the

§ In chemical formulas, the endohedral component is denoted with the sign @.

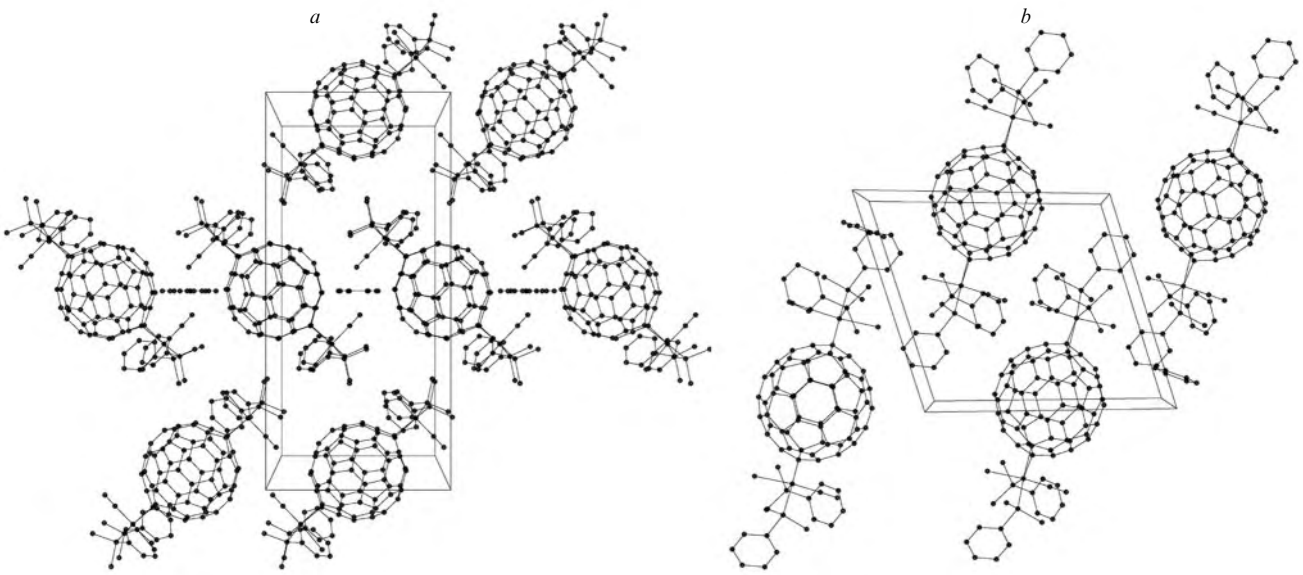

Figure 29. The molecular packings in the crystal structures of $C_{60}\cdot[Ir(CO)Cl(PPhMe_2)_2]\cdot C_6H_6$ (*a*) and $C_{60}\cdot[Ir(CO)Cl(PPhMe_2)_2]\cdot 2\,C_6H_6$ (*b*).[235]

cage. The single-crystal X-ray diffraction study of a solid solution of $Kr@C_{60}$ in crystalline $C_{60}\cdot NiOEP\cdot 2\,C_6H_6$ has shown that the krypton atom is located in the centre of the fullerene cage at distances of 3.54 Å from carbon atoms (which is 0.2 Å shorter than the sum of their van der Waals radii). The fraction of $Kr@C_{60}$ in the single crystal was estimated to be 9% based on the refinement of the Kr position occupancy.[249] A series of endohedral derivatives $X@C_{60}$ [where X = Li (see Ref. 250), N (see Ref. 251) and P (see Ref 252)] have been synthesised using an ion bombardment of C_{60} films *in vacuo* and studied with ESR. For the two latter cases, it was shown that the atoms of the fifth-group elements do not bind to the walls of the carbon cage and thus are in the quadruplet state, *i.e.*, have three unpaired electrons.

The standard method of the synthesis of endohedral metallofullerenes consists of a plasma-induced sublimation of graphite impregnated with the corresponding metal oxide (1 at.% – 2 at.%) in a helium atmosphere (10 – 100 Torr). Mass spectra of the products synthesised, in addition to C_{60}^+ and C_{70}^+, reveal peaks attributable to MC_n^+ ions ($n = 60-100$) with the predominance of MC_{60}^+ and MC_{82}^+.[241] Using extraction with polar organic solvents or CS_2 followed by chromatographic separation, the endohedral derivatives $M@C_{82}$, $M@C_{84}$ and $M_2@C_{80}$ moderately stable in air can be isolated while pure $M@C_{60}$ is very difficult to isolate due to its high reactivity. Individual EMFs of more than 20 metals (predominantly, lanthanides) have been synthesised to date in milligram quantities.[253 – 256]

One of the factors hampering the structural studies of EMFs (as well as of 'empty' higher fullerenes) is the isomerism of their carbon cores.[253] Quantum chemistry calculations on EMFs revealed a substantial charge transfer from the metal atoms to the carbon cage, which stabilises higher-symmetry isomers and can even result in a violation of the isolated pentagon rule.[257] Quantum chemistry optimisation of the geometry of mononuclear endohedral metallofullerenes $M@C_n$ predicts a shift of the metal atom from the centre of the cavity towards the walls giving rise to the bonding intrapolyhedral M···C contacts with lengths ~ 2.5 Å and a large molecular dipole moment (4 – 5 D). Furthermore, quantum chemistry calculations and spectroscopic data show the easiness of the metal atom migration inside the carbon cage, which poses additional difficulties for the structural studies.[19, 253, 257, 258]

The most studied mononuclear lanthane derivative $Ln@C_{82}$ represents, according to the spectral data,[256] a mixture of isomers with the C_{2v} (isomer I, content 70% – 80%) and C_{3v} symmetry (isomer II, content 20% – 30%) (Fig. 30). For derivatives of some other metals, the isomers III (Er, Dy, Tm, Ca) and IV (Ca) were

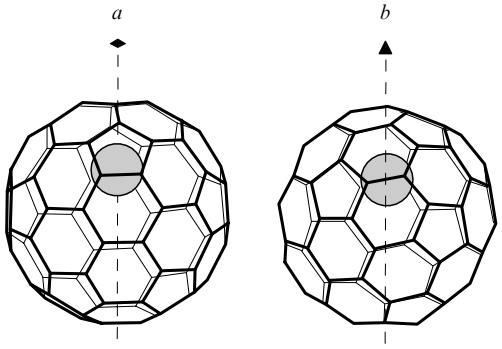

Figure 30. The molecular structures of endohedral metallofullerenes having the isomeric C_{82} cores with the C_{2v} symmetry (*a*) and the C_{3v} symmetry (*b*) (quantum-chemistry calculations).[253]

additionally found.[256, 259] Therefore, in order to avoid a thorough statistical disorder in single crystals, preparation of endohedral metallofullerenes for structural studies should always involve a time-consuming stage of the chromatographic separation of isomer mixtures.

For the majority of endohedral fullerenes, experimental data on their structures have been obtained by means of XAFS spectroscopy [260 – 264] and powder X-ray diffraction utilising synchrotron radiation. The position and overall shape of the X-ray Absorption Near-Edge Structure (XANES) spectra confirm the intramolecular charge transfer from the 'guest' metal atoms to the carbon cage. A shift of the metal atom from the centre of the fullerene cage and its coordination to carbon atoms have been established experimentally for the first time in the EXAFS studies of $Y@C_{82}$ (see Ref. 261) and $La@C_{82}$ (see Ref. 262). In mononuclear actinide-based (Th, U and so forth) endohedral derivatives of fullerenes $C_{82}-C_{84}$, the charge of the metal ions was estimated as 3+ according to the results of XANES.[265]

The most essential details of the molecular and crystalline structures for a series of polycrystalline EMFs were determined in an extended series of diffraction studies [85, 264 – 270] based on the maximum entropy method (MEM). For all the studied phases, the insertion of metal atoms into carbon cages was objectively revealed. Preparation of the binuclear derivative $Sc_2@C_{66}$ has been reported, in which the geometry of the carbon cage does not obey the IPR, in agreement with the quantum chemistry calcu-

lations.[15] In the strongly disordered crystal structure of $Sc_2C_2@C_{84}$ (see Ref. 271), a carbide cluster with two carbon atoms at a distance of 1.42(6) Å has been revealed inside the fullerene cage. The metal–metal distances in binuclear $La_2@C_{80}$ (3.90–3.94 Å)[271] and $Sc_2@C_{84}$ (3.91 Å)[268] derivatives imply that there is no direct metal–metal bonding. On the other hand, the Sc–Sc bonds with a length of 2.89 Å are revealed in $Sc_2@C_{66}$, which has a smaller carbon cage.[15] Furthermore, abnormally short Sc–Sc bonds with the length of 2.3(3) Å (see Ref. 270) (as compared to 3.20–3.30 Å in bulk scandium[272]) were found in the (1 : 1) toluene solvate of the three-nuclear derivative $Sc_3@C_{82}$. This result contradicts to the quantum chemistry calculations[257] and is probably caused by a rotational disorder of the EMF molecule. Estimates of charges of the endohedral fragments obtained by integrating the electron density distribution reconstructed from the powder X-ray diffraction data[15,85,270,272] are doubtful since they lie far beyond the standard accuracy of the technique. Notwithstanding, these studies report very important structural information concerning EMFs at a semiquantitative level.

A series of endohedral fullerenes, $M_3N@C_n$ (M = Sc, Er; n = 78, 80, 68), which have been synthesised and characterised by single-crystal X-ray diffraction,[16,273–275] contain triangular nitridometal clusters inside the respective carbon cages. They were produced through the plasma evaporation route in a dynamical N_2-containing atmosphere and crystallised as (1 : 1) molecular complexes with cobalt octaethylporphyrinate CoOEP also contaning solvent molecules. Despite the presence of short intermolecular Co···C (fullerene) contacts in the range of 2.71–2.78 Å, fullerene moieties and endohedral M_3N 'guest' fragments are strongly rotationally disordered. The molecular structures of two high-symmetry isomers of C_{78} (D_{3h}) and C_{80} (I_h) stabilised by a charge transfer from the metal atoms were established. The geomertry of the endohedral M_3N fragment (Fig. 31) was determined and a lability of the M···C (fullerene) bonding was pointed out. The same group of authors reported the preparation and crystal structure study of the dimethoxyxylylene derivative $Sc_3N@C_{80}$Dmxy.[276] In this structure, the fullerene cage is chemically modified from the outer side through a [4 + 2] cycloaddition to a 5/6 bond, which results in its elongation to 1.63 Å, but the endohedral group is nevertheless disordered. As has been determined, in the case of the C_{78} core, endohedral metal atoms are located above the 6/6 bonds of the pyracylene fragment, in agreement with the quantum-chemical predictions.[277] Meanwhile, in the case of the C_{80} core, which has no pyracylene fragments, the endohedral M_3N group is chracterised by a stronger rotational disorder. A smaller endohedral fullerene isolated and studied by single-crystal X-ray diffraction as a complex with the analogous composition, likely contains the C_{68} core that violates the isolated pentagon rule.[16] Both the fullerene cage and the endohedral fragment in this substance are strongly disordered, its stoichiometry was confirmed by mass spectrometry.[16]

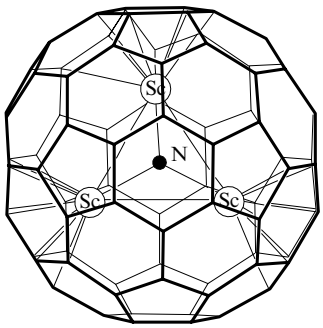

Figure 31. The molecular structure of $Sc_3N@C_{80}$ (single-crystal X-ray diffraction data).[273]
Interatomic distances: Sc–N 2.00–2.01 Å, Sc–C 2.15–2.73 Å, Sc–Sc 3.48 Å.

A single-crystal X-ray diffraction study of another endohedral metallofullerene molecular complex $Er_2@C_{82}\cdot CoOEP\cdot(C_6H_6)_{2-x}\cdot(CHCl_3)_x$ revealed[278] a carbon cage of the C_s symmetry and a strong disorder of the erbium atoms over numerous positions. The second isomer of this substance with the C_{3v} symmetry of the carbon core and the disordered endohedral fragment was also prepared and characterised.[279]

Solvent-free EMFs at room temperature are characterised by an fcc lattice[280] isomorphous to that of high-temperature modifications of C_{60} and C_{70}. Upon slow cooling, $La@C_{82}$ single crystal undergoes two phase transitions due to orientational ordering of the ellipsoid EMF molecules giving rise to the rhombohedral (180–150 K) and metastable triclinic (150–20 K) modifications. Rapid cooling of the rhombohedral polymorph yields a disordered simple cubic phase, which is stable below 132 K.[280] In strongly disordered EMF solvates $M@C_{82}\cdot 1.5\,CS_2$, the carbon disulfide molecules occupy cavities within a bcc lattice. This phase undergoes a magnetic phase transition at 150 K, which was suggestively attributed to the ordering of the metal-containing fullerene cores.[281] Endohedral fullerene derivatives, like pure fullerenes, are able to polymerise at elevated pressures.[282]

According to the powder X-ray diffraction data, monoclinic toluene solvates $M@C_{82}\cdot PhMe$ are isomorphous to the respective solvates of 'empty' higher fullerenes $C_{82}\cdot PhMe$ and $C_{76}\cdot x\,PhMe$.[31] The molecular packing motif in these structures conforms to that found earlier in the (1 : 1) solvates of buckminsterfullerene with n-pentane, dichloroethane and other solvents[84] (see Fig. 6) but the intermolecular electrostatic interactions favour the 'head-to-tail' arrangement of neighbouring molecules in the case of the endohedral derivatives.[267] The crystal structures of the $M_3N@C_{80}\cdot CoOEP\cdot Solv$ complexes discussed above contain zigzag chains of fullerene cages similar to those in molecular complexes of C_{60} and C_{70} with metalloporphyrins (see Fig. 8). The shortest distance between the centres of fullerene cores in the EMFs with known crystal structures lie in the range of 11.00–11.22 Å.

XI. Conclusion

The distinctive features of crystal chemistry of fullerenes summarised above are defined primarily by the involvement of bulky spherical-like carbon clusters and the predominance of non-bonding intermolecular interactions. The results of structural investigations into various derivatives of fullerenes including chemically modified and endohedral ones demonstrate the typical rotational disorder of carbon cores (which can be attenuated down to a complete ordering at low temperatures), high affinity of fullerenes towards formation of molecular complexes and diversity of their crystalline phases. Patterns of the rotational disorder typical of C_n molecules in crystals can be conveniently described within the model of the 'rubber cavity', which postulates occurrence of specific orientations corresponding to local minima of the shallow interaction potential. In all the considered classes of compounds, similar motifs of arangement of fullerene cores are observed, which are defined by the volume fraction occupied by the fullerene component in the total unit cell volume. Non-fullerene molecules and exopolyhedral fragments fill cavities of these motifs thus acting as a flexible van der Waals matrix.

Coulomb attraction (in ionic fullerides) and specific intermolecular interactions stabilise the crystal packing and increase the degree of ordering, which enables collection of more accurate crystallographic data for the corresponding substances. Some authors suggest weak Jahn–Teller distortions in mono- and dianions of buckminsterfullerene and proneness of anionic fullerenes to polymerisation. Chemical bonding between two or more fullerene molecules gives rise to dimers and trimers as well as to infinite motifs composed of chain, layer and framework polymeric structures.

The presence of 'guest' atoms inside the fullerene cages in the case of endohedral derivatives can, on the one hand, stabilise the crystal packing due to the polarisation of the carbon clusters and, on the other hand, increase structural disorder due to multiple positions of the endohedral atoms and/or dynamical transitions inside the carbon cage. According to the quantum chemistry calculations and experimental spectral data, endohedral metallofullerenes are characterised by a metal → carbon cage charge transfer stabilising the higher-symmetry isomers. Additional degrees of freedom in endohedral metallofullerenes, such as molecular dipole moment or magnetic moment of the 'guest' atoms, increase the number of possible ordering types and respective phase transitions.

The most typical way of a chemical modification of fullerenes (to form either σ- or π-derivatives) consists of an addition to one of the 6/6 bonds, which is accompanied by its elongation and a specific distortion of the carbon cage localised in the proximity to the exopolyhedral coordinated atoms. In the case of C_{70}, a functionalisation preferably occurs at the stereochemically strained and the most 'pyramidised' *b* type 6/6 bond. For several C_{60} and C_{70} derivatives, the addition occurs at a 5/6 bond and results in its cleavage and formation of 'open' homofullerene cages. As compared to crystals of non-modified fullerenes, functionalised derivatives are typically better ordered owing to the nonsphericity of their molecular shapes.

The multiple σ,σ- or η^2-addition of exopolyhedral fragments not interacting with each other proceeds at the most distant 6/6 bonds ultimately yielding (in the case of C_{60}) hexadducts with six exopolyhedral fragments octahedrally surrounding the fullerene core. If a metal cluster is taken as the exopolyhedral fragment, the fullerene molecule can act as a polydentate π-ligand coordinating the cluster through one of its hexagonal faces. In the case of σ-modified fullerenes, the η^5-coordination to single metal atoms is possible and even η^6-bonding can be realised in the future. Multiple σ-addition of small exopolyhedral fragment X leads to 'binary' fullerene derivatives C_nX_m (n = 60, 70; X = H, O, F, Cl, Br, Me, CF_3). When the number of attached fragments m is small (up to 5–6), they are typically localised in the same specific part of the carbon cage. Meanwhile, a more profound modification is accompanied by spreading of the attached groups X over the fullerene hemisphere (*e.g.*, in $C_{60}F_{18}$ and its analogues) or the entire sphere (*e.g.*, in $C_{60}Br_{24}$, $C_{60}F_{36}$ and $C_{60}F_{48}$). A deep chemical modification induces substantial distortions of the fullerene polyhedral cage and can even result in its opening.

The present structural data survey is in part a result of our own research activities, which have been conducted starting from the second half of the 1990s. We are grateful to all our colleagues who provided us with single crystals of new substances synthesised in their laboratories and shared with us the most recent structural results of their own (sometimes even prior to publication). We thank Corresponding Member of RAS M Yu Antipin (INEOS RAS, Moscow), Profs. G Saito (University of Kyoto, Japan), O Kashino and I Kubozono (Okayama University, Japan), R N Lyubovskaya (IPPC RAS, Chernogolovka), M V Korobov and O V Boltalina (Department of Chemistry, MSU, Moscow), J Howard (University of Durham, UK), R Taylor (University of Sussex, UK) and Dr. D V Konarev (IPCP RAS, Chernogolovka). Very interesting and useful information was collected owing to our participation in the series of the biannual international conferences IWFAC (International Workshop 'Fullerenes and Atomic Clusters') held in St Petersburg.

This review has been prepared and written with financial support of the Russian programme 'Fullerenes and Atomic Clusters' and the Russian Foundation for Basic Research (Project No. 02-03-33225).

II.	Novel types of polycondensation	487
III.	Macromolecular design of condensation polymers	491
IV.	Conclusion	497

Abstract. New trends in the development of polycondensation methods, elucidation of the main principles of macromolecular design of polymeric chains and preparation of novel promising condensation polymers are considered and analysed. The bibliography includes 152 references.

I. Introduction

Polycondensation is one of the most important methods for the synthesis of polymers. This is based on an elementary substitution reaction and opens up access to an immense variety of polymers — from linear aliphatic compounds to complex fused aromatic and heterocyclic systems including highly branched dendritic polymers.

Starting from 1833,[1] polycondensation has invariably attracted the keen attention of investigators. At present, this branch of polymer chemistry is being intensely developed owing to the discovery of hitherto unknown reactions leading to the formation of high-molecular-mass compounds. However, a search for alternative polycondensation routes and their intensification, elaboration of principles of macromolecular design, preparation of novel promising polymeric materials and detailed analysis of their properties still remain topical problems. These trends are considered in the present review.

II. Novel types of polycondensation

Studies aimed at the search for ways of involvement of less reactive starting compounds and new types of monomers in known polycondensation processes have been carried out since the 1980 – 1990's. These processes include carbonylation polycondensation,[2–12] polycondensation of monomers that undergo ring–chain isomerisation,[13–19] polynitrosubstitution,[20–22] radical-ion polycondensation in the presence of samarium iodide,[23–29] catalytic polycondensation of arylene halides, [30–43] *etc*. Some of these processes will be considered in the subsequent sections.

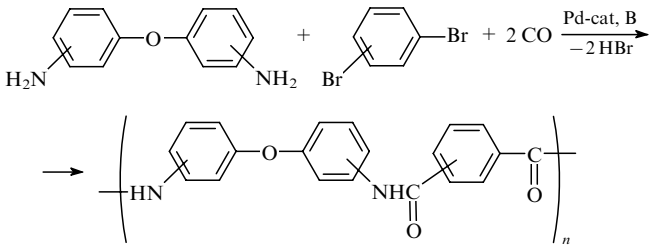
1. Carbonylation polycondensation

The recently discovered carbonylation polycondensation reaction [2–12] is based on the use of carbon monoxide and aromatic dihalogen derivatives instead of conventionally employed dicarboxylic acids or their activated derivatives (most commonly, dichlorides). These compounds react with dinucleophiles (*e.g.*, diamines, dihydrazides, diphenols, aminophenols, *etc*.) in the presence of palladium catalysts to yield the corresponding high-molecular-mass products, *viz*., polyamides, polyhydrazides, polyarylates, *etc*. This approach to the synthesis of polymers directly from CO and aryl halides is attractive, since the latter are readily available by direct halogenation of aromatic compounds and are rather stable, and carbon monoxide is very cheap. In contrast, aromatic dicarboxylic acid chlorides are hydrolytically unstable and the acids themselves are synthesised in many steps. This approach was used in the synthesis of, *e.g.*, polyamides (Scheme 1).

Scheme 1



B is a base.

Carbonylation polycondensation was used in the synthesis of aromatic, aliphatic-aromatic and silicon-containing polyamides. Using polycondensation of *m*-dibromobenzene, 4,4′-diaminodiphenyl oxide and CO as an example, it was shown that the best results were obtained if the reaction was carried out in *N*,*N*-dimethylacetamide (DMA) (115 °C, 1.5 h) using the $[PdCl_2(Ph_3P)_2]-Ph_3P$ complex as a catalyst and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as a base.[4] The reaction rate and the length of the polymeric chain increase if diiodoarenes are used instead of dibromides.[5] Thus the polycondensation of *m*-diiodobenzene with 4,4′-diaminodiphenyl oxide at a CO pressure of 0.1 MPa yields a polyamide with a molecular mass (*M*) of 24 000 at 90 °C in 2 h, whereas the molecular mass of a polymer prepared from *m*-dibromobenzene does not exceed 14 000 after 6 h. Moreover, the molecular mass of the polymer formed is even higher (up to 91 000 kDa) if the reaction is carried out in the presence of a 5% excess of the diamine.

Carbonylation polycondensation was used in the synthesis of polyarylates and aliphatic-aromatic polyesters.[4–6] In the former case, the solutions of the polymers formed had a logarithmic viscosity of up to 0.69 dl g^{-1} in *o*-chlorophenol, in the latter case, the viscosity was 0.18–0.36 dl g^{-1} (see Refs 6 and 7). The polycondensation of 4,4′-dibromodiphenyl oxide with 2,2-bis(4-hydroxyphenyl)propane in an atmosphere of CO in chlorobenzene as a solvent was carried out at 115 °C using a DBU–K_2CO_3 mixture as a base and various palladium derivatives {*e.g.*, the $[PdCl_2(Ph_3P)_2]$–PPh_3 complex} as catalysts and was complete within 3 h. The M_n and M_w values for the polyacrylate were equal to 70 000 and 88 000, respectively; the logarithmic viscosity (η_{log}) in chlorobenzene was 0.51 dl g^{-1}.

The best results in the synthesis of polyhydrazides from dibromoarenes, dicarbohydrazides and CO were obtained when the polycondensation was performed in DMSO or DMF (T = 95 °C) in the presence of $Pd(Ph_3P)_4$ and DBU.[8] A polymer with η_{log} = 0.65 dl g^{-1} was prepared starting from 4,4′-dibromodiphenyl oxide, CO and terephthalohydrazide.[8]

High-molecular-mass polyether ketoamides were synthesised using Pd-catalysed polycondensation of dibromoarenes containing etheroxo groups with aromatic diamines and CO.[9] Reactions of diiodoarenes with bis(*o*-aminophenols) and CO yield polyhydroxyamides with molecular masses M_w = 34 000–49 000 and M_n = 13 000–31 000; their thermal polycyclisation (T = 250–300 °C) gave the corresponding polybenzooxazoles.[10]

Tetraiodobenzene, tetraiodo-*p*-xylene, 3,3′,4,4′-tetraiododiphenyl sulfone and 1,4-dibromo-2,5-diiodobenzene were used as the halogen derivatives in the synthesis of polyimides.[4, 11] Thus a polyimide with M_w = 28 000 and M_n = 17 000 was synthesised in 95% yield from 1,2,4,5-tetraiodobenzene and 5-amino-3-(4-aminophenyl)-1,1,3-trimethylindane under CO pressure of 0.78 MPa in the presence of DBU, 6 mol.% of the complex $[PdCl_2(Ph_3P)_2]$ and 12 mol.% of triphenylphosphine (DMA, 115 °C, 24 h).
High-molecular-mass polyamidoimides were prepared from 4-chloro-*N*-(4-iodophenyl)phthalide, bis(aminophenyl) oxide and carbon monoxide using carbonylation polycondensation in DMA or *N*-methylpyrrolidone (*N*-MP) (T = 100 °C) in the presence of a palladium catalyst.[12]

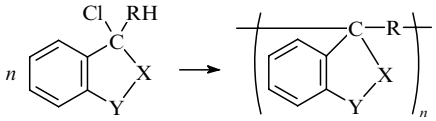
However, the attempts to replace expensive palladium catalysts by nickel catalysts [2] were unsuccessful. Obviously, the search for inexpensive efficient catalytic systems for the carbonylation polycondensation is a problem for future studies.

Thus, carbonylation polycondensation opens up new prospects for the synthesis of diverse polymers. It may be hoped that in the near future it will be used not only for preparation of novel polymers, but also for optimisation of synthetic procedures.

2. Polycondensation of monomers that undergo ring–chain isomerisation

Electrophilic substitution of monomers that undergo ring-chain isomerisation (or tautomerisation) is a new approach to the synthesis of aromatic polymers. Carboxylic acid pseudochlorides are examples of such non-traditional monomers.

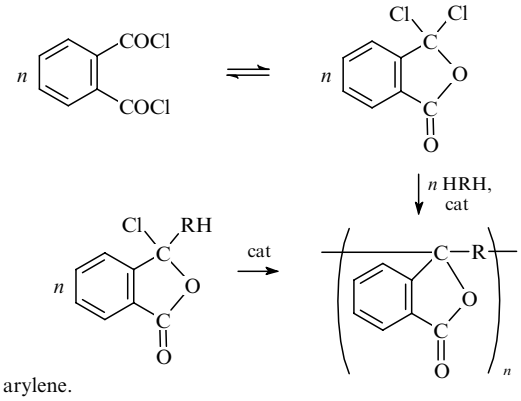
According to the scheme:



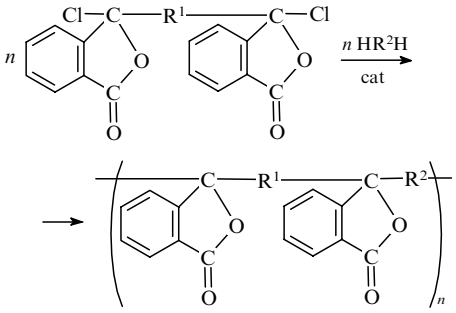
R is arylene; X = O, NAlk, NAr; Y = CO, SO_2

the growth of the polymeric chain results from the formation of a C–C bond between the carbon atoms of aromatic and heterocyclic (phthalide, phthalimidine and sulfophthalimide) nuclei. Such a polycondensation can be used for the preparation of polyarylenephthalides (X = O, Y = CO), polyarylenephthalimidines (X = NAr, Y = CO) and polyarylenesulfophthalides (X = O, Y = SO_2).

The synthesis of polyarylenephthalides from carboxylic acid pseudochlorides and their properties have been studied in much detail.[13–19]



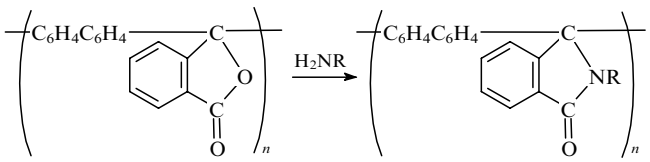
R is arylene.



R^1,R^2 are arylenes.

Chlorinated hydrocarbons (dichloromethane, dichloroethane, *etc.*) or nitrobenzene were used as solvents; the latter proved to be the most versatile. The temperature was varied from 770 to 140 °C; metal halides (*e.g.*, $ZnCl_2$, $AlCl_3$, $AlBr_3$, $FeCl_3$, $InCl_3$, $SbCl_5$, *etc.*) (0.01–1.5 mol per chloride group) were used as catalysts.[13] For example, the reaction occurs selectively and yields a polymer with M = 46 000–60 000 under conditions that are optimum for the synthesis of poly-*p*-diphenylenephthalide from 4-(3-phthalyl-3-chloro)biphenyl (monomer concentrations, 2–3 mol $litre^{-1}$, $SbCl_5$ (7 mol.%–10 mol.%) or $InCl_3$ (3 mol.%–10 mol.%) as a catalyst, nitrobenzene, 100–110 °C. The same reaction was performed in the so-called 'precipitation system', *i.e.,* in the presence of $AlCl_3$ in dichloroethane (20 °C, 24 h).[15] In the early steps, this reaction occurs in a homogeneous medium and then the polymer formed is precipitated to give a product with a higher molecular mass.

The presence of reactive groups in polyarylenephthalides opens up broad prospects for further chemical modifications at the lactone ring. Thus reactions of these polymers with amines yield *N*-substituted polyarylenephthalimidines:[17, 18]

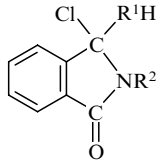


R = Me, Bu^n, C_8H_{17}, $C_{18}H_{37}$, Ph, C_2H_4OH, *etc.*

The properties of these compounds depend on the nature of the substituent at the nitrogen atom. With an increase in the length of the aliphatic substituent (from C_1 to C_{18}), the softening temperatures of the polymers decrease from 390 to 80 °C and the decomposition temperatures decrease from 360 to 260 °C. The possibility of thermal dehydration of polybiphenylene-*N*-(β-hydroxyethyl)phthalimidine, which yields an insoluble structurised polymer, has been demonstrated. A polymer which contains

phenyl substituents at the nitrogen atom manifests the best thermal characteristics: its softening temperature and the temperature of the onset of decomposition are equal to 450 and 475 °C, respectively. Thermolysis of polyterphenylenephthalide at 390–450 °C results not only in the cleavage of its polymeric chain but also in its structurisation.[16]

Polyarylenephthalimidines can also be synthesised by direct polycondensation of monomers of appropriate structures.



R^1 is arylene; R^2 = Alk, Ar.

It has been noted that, unlike the synthesis of polyarylenephthalides, the polycondensation in nitrobenzene cannot be realised with $SbCl_5$ and $InCl_3$ as catalysts. High-molecular-mass polyarylenephthalimidine could only be prepared in a reaction catalysed by $AlCl_3$ (2.5–3.5 equiv.).[18]

The synthesis of high-molecular-mass polyarylenesulfophthalides with phenylene fragments alternating with sulfophthalide groups in the main chains of the macromolecules has been carried out.[19] High reactivity of the sulfophthalide groups is a characteristic feature of these polymers. For example, the opening of the sulfophthalide ring under the action of aqueous solutions of alkalis results in quantitative formation of the corresponding polysulfonic acid salts. Such sulfonic acids can be regarded as a special type of polyelectrolyte, *viz*., aromatic polymers with side ionogenic sulfonate groups. In addition, the presence of triphenylmethane fragments determines the unusual optical properties of these compounds.[19]

Thus, the use of monomers of carboxylic acids of the pseudochloride type, which undergo ring-chain isomerisation, in the synthesis of polymers opens up attractive prospects for the development of novel polymers. The materials thus prepared combine high thermal and chemical stabilities with excellent solubilities in organic solvents, good physicomechanical characteristics and various unique properties.

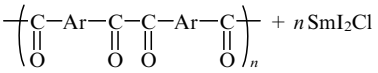
Studies in this area were begun in the 1990's and are ongoing. They are aimed predominantly at the in-depth analysis of specific (thermal, electrical, optical, *etc*.) properties of these polymeric systems.

3. Radical-ion polycondensation in the presence of samarium iodide

The efficient syntheses of organic compounds using bivalent metal halides of the lanthanide family, which are known to be potent reductants, have been documented relatively recently.[23] The use of such compounds as reaction initiators and coreactants ensures highly selective reactions under mild conditions and at high rates. SmI_2, which possesses an unusually high redox potential (for compounds soluble in organic solvents) is the most reactive amongst bivalent lanthanide halides.

Thus α-diketones are synthesised from aromatic acid chlorides and SmI_2 within several minutes in THF at room temperature (yields 70%–80%).[24] The use of aromatic dicarboxylic chlorides in such reactions is a relatively simple route to the synthesis of poly-α-diketones.[25–27]

$$n\,\mathrm{ClOCArCOCl} + n\,\mathrm{SmI_2} \longrightarrow$$



Ar = *m*-C_6H_4, *p*-C_6H_4, $C_6H_4OC_6H_4$, $C_6H_4C(CF_3)_2C_6H_4$, *etc*.

Based on the literature data of the mechanism of condensation of acid chlorides in the presence of SmI_2,[25] it may be supposed that it is radical ions generated under the action of compounds with high redox potentials that are the reactive species in the polycondensation. Their dissociation yields acyl radicals which are rapidly reduced into acyl anions; the latter react with the second acid chloride group to give α-diketone fragments:

$$\mathrm{a-A-a} + \mathrm{SmI_2} \longrightarrow [\mathrm{a-A-a}]^{\bullet -}\mathrm{SmI_2^+},$$

$$[\mathrm{a-A-a}]^{\bullet -}\mathrm{SmI_2^+} \longrightarrow [\mathrm{a-A-a}]^{\bullet -} + \mathrm{SmI_2^+},$$

$$[\mathrm{a-A-a}]^{\bullet -} \longrightarrow \mathrm{a-A^{\bullet}} + \mathrm{a^-},$$

$$\mathrm{a-A^{\bullet}} + \mathrm{a-A^{\bullet}} \longrightarrow \mathrm{a-A-A-a},$$

$$\mathrm{SmI_2^+} + \mathrm{a^-} \longrightarrow \mathrm{SmI_2a},$$

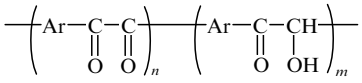
$$\mathrm{a-A^{\bullet}} + \mathrm{SmI_2} \longrightarrow \mathrm{a-A^-SmI_2^+},$$

$$\mathrm{a-A^-SmI_2^+} + \mathrm{a-A-a} \longrightarrow \mathrm{a-A-A-a} + \mathrm{SmI_2a}.$$

a = Cl, F; A = −C(O)ArC(O)−.

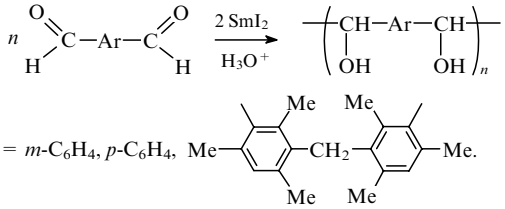
Thus, such a polycondensation can be termed as radical-ion polycondensation.

Studies of the pattern of this process have shown that the structures and yields of the polymers formed strongly depend on the reaction conditions, *viz*., the order of addition of the reagents, their ratios, concentrations and reaction time.[27] The units in these polymers often possess different structures; they contain hydroxymethylene groups along with α-diketone groups as a result of partial reduction of the carbonyl group by samarium iodide.



Polymers devoid of hydroxy ketone groups could be prepared only by adding a solution of SmI_2 in a THF–methyl iodide mixture to a solution of a dicarboxylic acid dichloride in THF (0.3–0.03 mol litre^{-1}, SmI_2 : substrate = 2.8 : 1.0, 30 °C, 20 min). The addition of a dicarboxylic acid dichloride to a solution of SmI_2 (4 : 1) yielded polymers with different-unit structures, the content of the diketone and hydroxyketone groups being the same.[27]

Radical-ion polycondensation in the presence of SmI_2 was also used in the synthesis of polypinacones from aromatic dialdehydes.[28]



In this case, the polymers had relatively low molecular masses (12 000–15 000).

The presence of reactive functional groups, *viz*., keto and hydroxy groups, in poly-α-diketones and polypinacones, opens prospects for their further chemical modification. For example, zirconocene dichloride reacts with the hydroxy ketone groups of the polymer to form covalent bonds owing to the presence of the hydroxy groups and coordination compounds due to interaction with the keto groups. Such polymers hold promise as catalysts for certain organic reactions.[29]

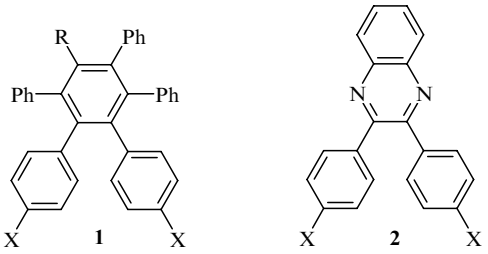
4. Polycondensation with arylene halides catalysed by palladium and nickel complexes

Since the 1990's, the need for polymeric materials with specific properties, such as electroconductivity, photo- and electroluminescence, third-order nonlinear optical activity, *etc*., has stimu-

lated studies on polycondensation of aromatic dihalides with alkenes and alkynes, aromatic diboronic acids, aromatic organometallic compounds, *etc*. Dehydrohalogenation and dehalogenation reactions, which are catalysed by palladium and nickel complexes and result in the formation of the C–C bond, are usually referred to as cross-coupling reactions. They were used in the synthesis of polyaryleneethynylenes $(-Ar-C\equiv C-)_n$,[30–36,42] polyconjugated polyarylenevinylenes $(-Ar-CH=CH-)_n$[30,32,34,37–40] as well as carbo- and heterocyclic polyarylenes.[32,41]

The use of aromatic halides, which are much more accessible than the monomers used in conventional polycondensation processes, is the advantage of this method. As a rule, polyconjugated polymers are poorly soluble in organic solvents due to high rigidity of their macromolecules, which significantly restricts their practical applications. Pd- and Ni-catalysed polycondensation circumvents this limitation, since side substituents or bulky groups can easily be introduced into the starting aromatic halides or ethynyl derivatives, which favour their solubility.[30,33,34]

Thus relatively short-chain polyaryleneethynylenes (M = 5800–8000) readily soluble in amide solvents were prepared from dibromides and diiodides derived from branched aromatic heterocyclic compounds (hexa- and pentaphenylarylenes, compounds **1**), quinoxalines, compounds **2**, phenylimidazoles



R = H, Ph (**1**); X = Br, I.

and diethynyl aromatic compounds in the presence of palladium catalysts (DMA, 90 °C, 6–8 h).[30,33]

Pd-Catalysed polycondensation was used in the synthesis of some novel regular polyaryleneethynylenes from dibromides and substituted diethynyloligothiophenes, -anthracenes and -benzenes. Such polymers (especially those containing anthracene fragments) are characterised by high quantum yields of luminescence.[31]

The synthesis of polyarylenevinylenes was carried out using ethylene and divinylbenzene as the starting monomers.[37,38]

The reaction of *p*-divinylbenzene with dialkoxy-substituted *p*-diiodobenzene derivatives gave polymers (M_w = 32 000–62 000) of the general formula

$$-\!\left(CH{=}CHC_6H_4CH{=}CHC_6H_2(OR)_2\right)_n-,$$

R = C_mH_{2m+1}, m = 4, 7, 8, 12, 16,

which are readily soluble in organic solvents and manifest liquid crystalline properties.[40]

Homopolycondensation of dibromotetraarylethylenes in the presence of a Ni(0) complex prepared *in situ* from anhydrous $NiCl_2$, Ph_3P, bipyridyl and Zn in a dipolar aprotic solvent (100 °C, 2 h) resulted in polyarylenevinylenes containing phenyl substituents in the vinylene group:[43]

$$-\!\left[C_6H_4C(Ar){=}C(Ar)C_6H_4\right]_n-,$$

Ar, phenyl; 2,4,6-triphenylphenyl; 2,4,6-tris(biphenylyl)phenyl.

Polymers that contain branched polyphenyl substituents usually possess fairly high quantum yields of luminescence (22%–23%).

A series of unsaturated polymers of the polycinnamide type

$$-\!\left(ArCH{=}CHCONHAr'NHCOCH{=}CH\right)_n-$$

have been synthesised[30] from aromatic *N*,*N*′-arylenediamides and arene dihalides in the presence of palladium catalysts. Thus a high-molecular-mass polymer with M_n = 93 000 and M_w = 488 000 has been synthesised from 4,4′-diiododiphenyl oxide and bisacrylamide with Ar′ = *p*-$C_6H_4OC_6H_4$-*m*.

Polycondensation cross-coupling with the use of transition metal complexes as catalysts allows preparation of various carbo- and heterochain polymers (*e.g*., substituted polyphenylenes, polyimides, polyether ketones, polythiophenes, *etc*.) (for review, see Ref. 41).

The above-described polycondensation, which occurs under relatively mild conditions, opens up new prospects for the synthesis of structurally diverse polymers. However, it demands further investigation, especially as regards the synthesis of polymers with high molecular masses, primarily of linear polyconjugated polymers possessing valuable electrical and optical properties. Systematic development of this approach aimed at the design of branched conjugated dendritic polymers and investigation of their optical properties is of special interest. And, of course, special attention should be given to the search for, and development of, novel efficient catalytic systems for cross-coupling reactions including catalytically active and selective metal–polymer composites.

5. Polycondensation in non-traditional media

It is known that many polycondensation processes demand large amounts of toxic or flammable organic solvents which are often nonrecoverable. In this context, a search for alternative reaction media is a topical ecological and economical problem. Therefore, supercritical carbon dioxide[44] and the so-called 'ionic liquids'[45,46] have attracted considerable attention in recent decades.

Supercritical carbon dioxide is interesting in that it manifests the properties of an inert solvent for numerous substances, on the one hand, and can be completely removed from the reaction mixture as a gas upon depressurisation, on the other hand.[44]

Ionic liquids usually represent organic salts or mixtures of organic and inorganic salts which exist in a liquid ionic state at, or close to, room temperature. Their main characteristic features include low vapour pressure, non-inflammability and the possibility to be repeatedly regenerated. Other advantages include high chemical and thermal stability; they are also good solvents for a broad range of compounds. Their melting points vary over a wide range — from −90 to 200 °C; in addition, these compounds manifest catalytic activity and other valuable properties.[45,46]

From the above, it follows that supercritical carbon dioxide and ionic liquids are promising media for polycondensation, however, their application is still poorly explored.[46,47] In contrast to polymerisation, there are very few examples of the use of supercritical carbon dioxide in polycondensation.[44] A recently published paper[47] is devoted to the use of this compound as a medium in the synthesis of polyimides based on a 4,4′-(hexafluoropropane-2,2-diyl)diphthalic dianhydride and 4,4′-(hexafluoropropane-2,2-diyl)aniline or diaminofluorene. This reaction was carried out at 130–180 °C for 3–6 h and under a CO_2 pressure of 32.5 MPa. It is noteworthy that polycondensation in CO_2 of a very high degree of purity [>99.997%, $c(H_2O)$ = 0.001%] yielded a polymer with a logarithmic viscosity as low as 0.14 dl g^{-1}, whereas polycondensation in the presence of small amounts of water gave higher-molecular-mass polymers. This suggests that in this case CO_2 plays a dual role of a solvent and a catalyst. Indubitably, polycondensation in supercritical CO_2 demands further investigation.

Some recently published papers describe polycondensation in ionic liquids.[48,49] These studies were the first to demonstrate the possibility in principle to perform the synthesis of condensation

polymers (polyimides and polyamides) in ionic solvents which are alternative to conventional organic solvents, and sometimes manifest catalytic activity, as in the synthesis of polyimides. 1,3-Dialkylimidazolium [bromide (**1**) and tetrafluoroborate], 1,3-dibutylimidazolium salts, *etc*., were used as the reaction media. The polycondensation of 1,4,5,8-naphthalenetetracarboxylic dianhydride with 5-amino-2-(4-aminophenyl)benzoimidazole in ionic liquid **1** at 180 °C with the concentrations of the starting compounds varying from 0.4 to 0.6 mol litre^{-1} afforded high-molecular-mass polynaphthoyleneimides (the logarithmic viscosity of a solution of the polymer in sulfuric acid was $\sim$ 0.6 dl g^{-1}). Polycondensation in an ionic liquid was successfully employed in the synthesis of high-molecular-mass aromatic polyamides. It is noteworthy that the rate of the polycondensation and the molecular mass of the polymer formed strongly depend on the nature of the ionic liquid cations. Using the synthesis of polyterephthalamide of 5-amino-2-(4-aminophenyl)benzoimidazole as an example, it was demonstrated that the ionic liquid used can be repeatedly regenerated.[48]

These data should be regarded as an initial step in the study of polycondensation in ionic liquids, which proved to be highly promising and deserving of further investigation.

* * *

On the whole, the novel types of polycondensation considered in this section significantly extend the range of its applications in the synthesis of high-molecular-mass compounds. Such methods open up new ways to the preparation of important special-purpose polymers needed in small amounts to suit the specific areas of their application.

III. Macromolecular design of condensation polymers

1. Construction of a polymeric chain in the course of polycondensation

A search for ways to a directed design of polymeric chains is the main challenge in polycondensation, since it is the only possibility to obtain materials with predetermined properties. This problem can be solved using different approaches. One of them is variation of the chemical structure of the monomers, which is widely employed at present (see Section III.3). The other consists of synthesis of copolymers or polymers from non-symmetrical monomers. This route is especially important, since it allows broad variations of specific characteristics of polymeric systems. However, this approach requires directed design of a polymeric chain, which is impossible without knowledge of the fundamental principles of formation of such chains in the course of polycondensation, *i.e*., the principles of macromolecular design.

Non-equilibrium acceptor-catalytic polyesterification was used as a model system. It is a detailed study of this type of polycondensation that has made it possible to establish the basic principles of macromolecular design, particularly with respect to different mechanisms of alternation of co-monomers and non-symmetrical monomers along the polymeric chain.[50–53] Copolycondensation of two co-monomers, *viz*., $y-M_2-y$ and $y-M_3-y$, *e.g*., 2,2-bis(4-hydroxyphenyl)propane, hexamethylene glycol, *etc*., with an intermonomer $x-M_1-x$ (*e.g*., terephthalic dichloride, *etc*.) entails different alternations of monomers along the polymeric chain in regularly alternating (RA), block (BL) and statistical (ST) modes.

$$2\,x-M_1-x + y-M_2-y + y-M_3-y \longrightarrow$$

$$\longrightarrow -(M_1-M_2-M_1-M_3)_n- \quad \text{RA}$$

$$\longrightarrow -(M_1-M_2-M_1-M_2-M_1-M_3-M_1-M_2-M_1-M_3)_n- \quad \text{ST}$$

$$\longrightarrow -(M_1-M_2)_n-(M_1-M_3)_m- \quad \text{BL}$$

x, y are terminal functional groups.

If polycondensation involves two monomers, one of which has a non-symmetrical 'head' and 'tail' structure (*e.g.,* β-hydroxyethyl ether of a diphenol), the limiting cases entail either regular alternation of the 'head-to-tail', 'head-to-tail' (HTHT) or 'head-to-head', 'tail-to-tail' (HHTT) types or statistic alternation.

$$x-M_1-x + y-M_2M_3-y \longrightarrow$$

$$\longrightarrow -M_1-M_2M_3-M_1-M_3M_2-M_1-M_2M_3-M_1-M_3M_2- \quad \text{HHTT}$$

Prior to these studies, there was an erroneous concept that blocks built up of a more reactive monomer are formed in the initial steps of the reaction, provided the co-monomers possess different reactivities, which results in block-copolymers. If the reactivities of non-symmetrical monomers are different, it is the more reactive groups that react in the first step thus leading to the formation of 'head-to-head' or 'tail-to-tail' structures, which favours the formation of regular polymers consisting predominantly of these fragments.[54, 55] However, this hypothesis does not take into account the violation of the rule of non-equivalence of the functional groups, which is extremely important for polycondensation. This has led to formulation of improper rules.

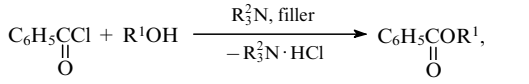
The generalisation of numerous experimental results, which take into account kinetic theory,[50–53] has made it possible to formulate the basic principles of a macromolecular design for non-equilibrium polycondensation. The presence of all monomers (irrespective of their reactivities) in the initial steps of the reaction favours the formation of statistical polymers, and deviation from this type of structure is related to a change in the reactivities of the functional groups of the intermonomer (symmetrical monomer). Gradual introduction of co-monomers into the reaction zone is not sufficient for the synthesis of block-copolymers.

In the case of one-step reactions, gradual addition of a symmetrical intermonomer into the solution of co-monomers favours the formation of block-copolymers (*i.e*., regular polymers of the HHTT type); the lengths of the blocks (*i.e*., the ratios of the 'head-to-head', 'tail-to-tail' fragments) reflect the differences in the reactivities of the co-monomers used. The prerequisites for the formation of block-copolymers by one-step non-equilibrium copolycondensation in a homogeneous system include noticeably different reactivities of co-monomers and the introduction of the intermonomer into the reaction zone at a rate lower than its reaction with the more reactive co-monomer. The passage of a one-step polycondensation to two-step and multistep processes significantly extends the potential of macromolecular synthesis and allows preparation of block-copolymers made up of blocks of required lengths. Using this approach, one can control the microstructure of a polymeric chain and thus regulate the properties of the polymers formed.

Further progress in the development of novel types of polycondensation, of non-equilibrium matrix polycondensation in

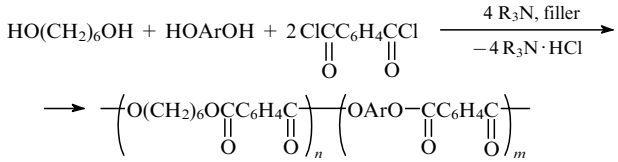
particular, has established a number of characteristic features, *e.g.*, the effect of a heterogeneous matrix on the formation of copolymer microstructure and other properties of polymeric systems.[3, 56–60] In contrast to polymerisation in the presence of fillers, which has been studied in great detail,[61, 62] polycondensation and polyaddition in the presence of a dispersed solid phase were first described in the 1970's. The subjects of these studies were polysiloxanes,[63] polyurethanes [64] and epoxide oligomers.[65] It was not until the 1990's that systematic studies of non-equilibrium polycondensation in the presence of fillers, such as graphite and molybdenum disulfide, were begun.[3, 56, 57]

Studies of model esterification



R^1 = Bu^n, Ph; R^2_3N = Et_3N, Py.

and copolyesterification



have shown that polyesters prepared in benzene in the presence of graphite had much higher molecular masses than polymers synthesised in the absence of graphite (Table 1), because the filler plays the role of a heterogeneous matrix. This influences the reactivities of functional groups and the ratios of chain propagation and termination rates.

Table 1. Effect of a matrix (graphite) on the molecular mass of a polyarylate prepared from 2,2-bis(4-hydroxy-3-chlorophenyl)propane and terephthalic dichloride.[56]

Matrix (mass %)	S [a] /m^2 g^{-1}	$[\eta]$ [b] /dl g^{-1}	$M \times 10^{-3}$
–	–	0.68	30
30	9.5	0.87	53
30	14.0	0.92	60
60	14.5	1.15	70

[a] Specific surface of the matrix. [b] The viscosity η was measured in THF at 25 °C.

In the absence of a filler in non-polar solvents (*e.g.*, benzene), the reactivity of phenol exceeds that of n-butanol 200-fold. The copolymers formed upon gradual introduction of terephthaloyl dichloride into the reaction zone have a block structure and are characterised by a microheterogeneity coefficient $K_m = 0.23$.†

In the presence of graphite (80 mass%), which has a specific surface of 14 m^2 g^{-1}, the activity of phenol in the acylation by aromatic acid chlorides is 3 times lower than in the absence of a filler, while that of butanol increases nearly 1.5-fold under similar conditions. As a result, the difference in the activities of phenolic and alcoholic groups decreases from 200- to 40-fold, *i.e.*, the difference in the reactivities of aromatic and aliphatic hydroxy groups is levelled off. As a result, the K_m value of copolymers of hexamethylene glycol and 2,2-bis(4-hydroxy-3-chlorophenyl)propane with terephthaloyl dichloride obtained in the presence of a filler is 0.53 rather than 0.23, *i.e.,* the structure of the copolymer becomes more statistical.

† The microheterogeneity coefficient K_m reflects the degree of orderliness of the copolymer units. At $K_m = 1$, the units of a macromolecular chain are distributed statistically, whereas at $K_m \neq 1$ the copolymer has a block structure, the size of its blocks increasing with a decrease in K_m.

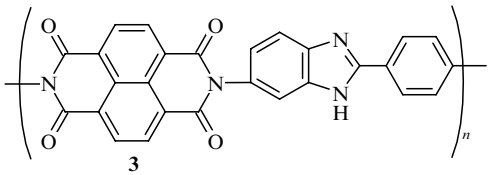
The changes in the reactivities of these components are caused by sorption, by the filler, of the active complexes formed. Since the acylation mechanisms of phenol and butanol are different, *viz.*, general basic (phenol) and nucleophilic (butanol),[66] the effects of graphite on each of these catalytic pathways are oppositely directed. It is this factor that influences the microstructure of the copolymers formed. The polycondensation in the presence of graphite also has a beneficial effect on the properties of the filled compositions formed. Apparently, this is due to the fact that the growth of macromolecules in a non-polar solvent in the presence of the filler largely occurs on its surface, which ensures more uniform distribution of graphite within the polymer in comparison with an analogous mixture prepared by simple mechanical blending of the components.[56]

As can be seen from Table 2, the 'synthetic' composition of a copolyester surpasses the corresponding 'mechanical' mixture in softening temperature, thermal stability, specific impact strength and specific electroconductivity. In addition, it has lower values of friction and wear factors.[56]

Table 2. Properties of compositions based on 2,2-bis(4-hydroxy-3-chlorophenyl)propane polyterephthalate prepared using different methods.[56]

Characteristics	Mechanical blending	Synthesis in the presence of a filler (graphite, 30 mass %)
Softening temperature /°C	220	260
Thermolysis (350 °C, vacuum),		
[CO] /10^3 mol $unit^{-1}$	9	1
[CO_2] /10^3 mol $unit^{-1}$	63	2
Specific impact strength /kJ m^{-1}	45	118
Specific electroconductivity /10^{13} Ω^{-1} m^{-1}	1	500

Interesting results were obtained when non-equilibrium acceptor-catalytic copolyesterification was carried out in the presence of hetero- and carbochain polymeric matrices.[58–60] These included 'active matrices', *i.e.*, polymers containing oxygen or nitrogen atoms in the main chain which can form hydrogen bonds with hydroxyl-containing monomers, such as polyphenylquinoxaline (a polyether based on 2-phenylquinoxaline), polynaphthoyleneimidobenzoimidazole **3** [a polyimide based on naphthalene-1,4,5,8-tetracarboxylic dianhydride and 5-amino-2-(4-aminophenyl)benzoimidazole], polyethylene oxide



3

and 'inert matrices', which do not react with monomers (*e.g.*, hyper-cross-linked polystyrene). The latter had a well-developed internal surface of their granules and differed from one another in pore size and structure of the cross-linking reagent (the cross-linking bridges are $-CH_2-$ or $-CH_2C_6H_4CH_2-$ groups, the pore sizes vary from 10 to 850 Å).

The results obtained suggest that the microstructures of the copolyesters formed with polymeric matrices introduced into the reaction system depend on the following factors, *viz.*, the presence and accessibility of nucleophilic sites which influence the kinetic parameters of intermonomer–co-monomer interactions, the convergence of reactivities of bisphenol and glycol, the presence and

sizes of pores in matrices and the ratios of sizes of pores and co-monomer molecules.

If porous matrices are used, two processes may occur simultaneously, which have opposite effects on the formation of the copolymer microstructure, *viz*., gradual desorption from the surface of the matrix, which results in an increase in K_m, and selective desorption of monomers from matrix pores, which decreases K_m (the so-called 'sponge effect'). Depending on the ratios of pore sizes of polymeric matrices to the molecular sizes of the co-monomers, one of these processes will predominate, which is reflected on the degree of the block structure of the copolymer formed. The use of polymeric matrices differing in the physicochemical properties of their particles opens up new possibilities for the synthesis of copolymers, since this allows purposeful variation of the microstructure of the chain formed and, correspondingly, the properties of the target product.

Thus it was found that copolymers having different microstructures [*e.g*., block ($0.3 < K_m < 1$) or statistical ($K_m = 1$)] can be prepared by copolycondensation of terephthaloyl dichloride with 2,2-bis(4-hydroxy-3-chlorophenyl)propane and hexaethylene glycol in the presence of triethylamine (benzene, 40 °C) at different concentrations of polyphenylquinoxaline or hypercross-linked polystyrene.[58, 59] Some examples of microstructures of copolyterephthalates prepared with the use of polymeric matrices are given in Table 3.

Table 3. Microheterogeneity coefficients of copolyterephthalates obtained in the presence of polymeric matrices (62 mass % Et_3N, benzene, 40 °C).[59]

Co-monomers	Matrix	K_m
DCD – HMG	PPQO	1.11
DCD – HMG	PEO	0.50
DCD – HMG	PS 10	0.89
DCD – HMG	PS 75	0.25
DMD – HMG	PS 10	0.92
DMD – HMG	PS 850	0.26
PP – DCD	PS 10	0.89
PP – DCD	PS 850	0.72

Notes. Abbreviations: HMG, hexamethylene glycol; DCD, 2,2-bis(4-hydroxy-3-chlorophenyl)propane; DMD, 2,2-bis(4-hydroxy-3-methylphenyl)propane; PP, bis(4-hydroxyphenyl)fluorene; PPQO, polyphenylquinoxaline; PS 10, polystyrene (pore size 10 – 15 Å); PS 75, polystyrene (pore size 75 – 85 Å); PEO, polyethylene oxide; PS 850, polystyrene (pore size 850 – 950 Å).

It may thus be expected that the use of polymeric matrices in polycondensation can in principle result in the manifestation of such effects as changes in the local concentrations of functional groups of reactants and 'sponge effects', *i.e*., initial sorption of monomers by the matrix with subsequent gradual desorption over the course of the reaction. This accounts for the changes in the reactivities of functional groups and conformations of molecules and for enhanced interactions of the macromolecules formed with the matrix.

In predicting the further fate of matrix-assisted polyesterification, one may suppose that one of the trends will be directed towards increasing the conformational specificity of this reaction. This will enable improvement of the microstructure of the polymeric chain if conformationally regular polymers are synthesised.

Polymeric matrices were also used for polycyclocondensation of tetracarboxylic dianhydrides with diamines.[67] In this case, amorphous cardo polyimides prepared from pyromellitic dianhydride and 3,3-bis(4-aminophenyl)phthalide or diphenyl oxide-3,3′,4,4′-tetracarboxylic dianhydride and 9,9-bis(4-aminophenyl)-fluorene, which are readily soluble in organic solvents and in reaction media, were used as matrix polymers.

Polyimides based on diphenyl oxide-3,3′,4,4′-tetracarboxylic dianhydride and 4,4′-diaminodiphenyl oxide or 5-amino-2-(4-aminophenyl)benzoimidazole and a polyimide from pyromellitic dianhydride and 9,9-bis(4-aminophenyl)anthrone were the target polymers. Their processability into films from solutions or into moulded articles from melts is difficult (or virtually impossible) because of their insolubility and high softening temperatures.

Sequential polycyclisation of these monomers in fusible catalytic media containing *p*-nitrotoluene (or diphenyl sulfone) and benzoic acid together with matrix cardo polyimides synthesised in previous steps in the same medium yielded novel polymeric systems. The latter differ from the corresponding crystalline polyimides synthesised by standard methods both in structures and properties (solubility, thermal stability, strength, *etc*.), which extends the range of their processability and practical applications. The data obtained demonstrate a high degree of control over the properties of these polymer – polymeric systems. Copolymers having both block and statistical structures should be formed, although this suggestion needs further verification.

The widening of the scope of these investigations is of indubitable interest. First of all, one should pay attention to the formation of systems from other classes of polymers and soluble matrix polyimides and the use of other polymers as matrices. It can be expected that the rate of formation of such polymers, their molecular masses and structures will be controlled, which will enable the preparation of finely dispersed homogeneous products and, if necessary, molecular composites. This offers an opportunity to improve the properties and processabilities of incompatible or partly compatible polymers in comparison with mixtures obtained by simple mechanical blending of the corresponding components.[67]

2. Polycondensation – polymerisation systems

The good solubility of polyheteroarylenes containing cardo and fluorine-containing groups in both common organic solvents and some unsaturated monomers has prompted an interesting route to the synthesis of novel polycondensation – polymerisation systems. Radical polymerisation and copolymerisation of (meth)acrylates, fluoro(meth)acrylates, styrene, acrylonitrile and other monomers in the presence of variable amounts of polyheteroarylenes (cardo and fluorine-containing polyimides, polyarylates, *etc*.) were used for the synthesis of novel soluble high-molecular-mass products.[68 – 72]

Together, the results obtained suggest that the transfer of a growing chain to the benzene nuclei of polyheteroarylenes in the radical polymerisation of unsaturated monomers in the presence of soluble polyheteroarylenes is not the only way to the synthesis of copolymers.[71] The mechanism of formation of such condensation – polymerisation systems is not finally elucidated, although the very fact of their synthesis is extremely important. The copolymers formed differ significantly from the corresponding carbochain polymers in solubility and enhanced thermal, mechanical, thermofrictional, *etc*., characteristics even at low concentrations of a polyheteroarylene[69 – 71] (Table 4). Such polymeric systems are distinguished for better solubility, and, in some

Table 4. Some properties of polymeric systems prepared upon polymerisation of methyl methacrylate in the presence of a polyarylate from 4,4′-hexafluoropropane-2,2-diyldiphenol and terephthalic acid.[70]

Concentration of polyarylate (mass%)	η_{log} /dl g^{-1}	T_g /°C	Characteristics of films		
			σ /MPa	ε (%)	$10^3 E$ /mPa
0	3.85	110	40	20	1.08
4	5.80	130	60	4	2.20
100	0.60	215	55	75	1.83

Note. σ, breaking strength; ε, relative elongation at breaking point; E, elasticity modulus.

cases, enhanced strength properties in comparison with starting polyheteroarylenes.

The possibility in principle to perform anionic polymerisation of ε-caprolactam in the presence of aromatic polyimides as macromolecular activators has been demonstrated.[72] The involvement of five-membered imide rings of polyheteroarylenes in the reaction enables the synthesis of novel polycondensation–polymerisation systems, *e.g.*, partly cross-linked graft copolymers with enhanced thermal and tribological characteristics and high water resistance as compared with ordinary polycaprolactam.

The design of novel polymeric systems based on polyheteroarylenes and epoxide polymers can also be related to such 'symbiotic' polymer formation.[73,74] In particular, a combination of cardo polyheteroarylenes [*e.g.*, poly(phenolphthalein terephthalate)] with epoxide oligomers upon moderate heating is a promising approach to their reprocessing into monolithic articles. The chemical reaction of an epoxy oligomer with a polyarylate, which occurs by the insertion (and opening) of the oxirane ring into the ester bond, results in the formation of a network structure, which manifests a set of specific properties. Enhanced (in comparison with classical compositions based on oligoepoxides) thermal durability is the main advantage of such compositions. Reactions of cardo polyimides with oligoepoxides favour the synthesis of novel polymeric materials which manifest good thermal, strength and electroinsulating properties.[74]

It may be hoped that the above-described processes hold great promise in the directed control of the properties of carbo- and heterochain polymers.

The polymer formation described above should more correctly be referred to as a 'symbiotic' process, since the reactants eventually complement the useful properties of each other. There is no doubt that this trend requires further development and perfection.

3. Variations of chemical structures of monomers

Rapid progress in high-tech branches of modern industry and growing demands for novel materials pose the problem to the polymer chemist of design of high-molecular-mass compounds possessing enhanced specific properties, such as thermal stability, high working capacity under extreme operating conditions and excess loads, photochemical stability, optical conductivity, low permittivity, *etc*. The variability and versatility of polycondensation opens new ways to the synthesis of such polymeric materials. The use of monomers with appropriate chemical structures leading to directed variation of the structures of the polymeric chains of condensation polymers is a promising approach to the macromolecular design of the latter.

a. Ring–chain polyheteroarylenes

The structures of ring–chain polyheteroarylenes possessing a set of useful properties have been much attended to in the past decade. Preparation of modified polyheteroarylenes which, contrary to infusible and insoluble polymers, manifest better solubility in organic solvents, thus favouring their processing into finished articles, is a topical problem in this area.

Studies carried out in the 1980's have shown that introduction of cardo groups into various polyheteroarylenes using the corresponding monomers is an effective route to improve their solubility.[3,75] This can also be attained due to the presence of 'hinge' and side groups in the resulting macromolecules and the nonsymmetrical structure of the polymeric chain.[3,75,76] Of particular interest is construction of a polymeric chain structure which combines the enhanced solubility of a polymer with advanced thermal characteristics and, in some cases, new specific properties conferred on the polymer.

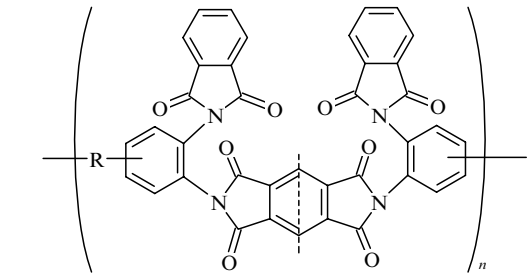
The introduction of phenyl substituents into the macromolecules of ring–chain polyheteroarylenes has proved a promising approach to increase their solubility, thermal plasticity and resistance against thermooxidation.[77] For example, polymers prepared from 5,6-diphenylbenzene-1,2,3,4-tetracarboxylic dianhydride and *p*- and *m*-phenylenediamines or 4,4′-diaminodiphenyl oxide soften at temperatures above 400 °C and lose 5% of their mass in air at 487, 523 and 591 °C, respectively. These polymers are soluble in a broad range of organic solvents, *e.g.*, *sym*-tetrachloroethane (TCE), *N*-MP, DMSO, DMA, DMF and *m*-cresol.

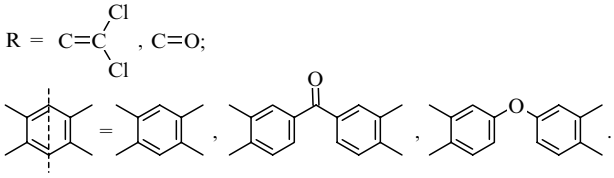
A series of novel soluble phenylated polyimides have been prepared starting from 4-(4-benzoylphenyl)-3,5,6-triphenylbenzenedicarboxylic dianhydride and various aromatic diamines. These polymers are amorphous, have glass transition temperatures (T_g) of 345–395 °C and lose 10% of their mass in air at 565–624 °C. The significant interval between their decomposition and glass transition temperatures enables their successful processing by pressing. Strong films prepared from polymer solutions are characterised by dielectric constants varying from 2.72 to 3.00.[78] Starting from 1,4-bis[2,3,4,5-tetraphenyl-6-(4,5-dicarboxy-1-naphthyl)phenyl]benzene dianhydride and benzidine or 3,3′,4,4′-tetraaminobiphenyl, soluble thermostable polynaphthylimide and the so-called polynaphthoylenebenzoimidazole, respectively, which manifest high luminescence efficiency due to the presence of aromatic groups, have been synthesised.[79] Methoxy- and phenoxy-substituted polyimides were synthesised based on 3,5-diaminoanisole,[80] 3-amino-5-(4-aminophenoxy)diphenyl ether,[81] 3,5-diaminodiphenyl oxide[82] and aromatic tetracarboxylic dianhydrides.

In the majority of cases, phenoxy-substituted polyimides manifest better solubilities in comparison with methoxy-substituted and unsubstituted analogues. A phenoxy-substituted polyimide containing hexafluoroisopropylidene groups manifests the best solubility.[82] Phenoxy-substituted polyimides based on tetracarboxylic dianhydrides containing 'hinge' groups are also easily soluble in common organic solvents. They are characterised by a large interval between the decomposition and glass transition temperatures and high thermal stabilities.[83] Polynaphthylimides and polyperylenimides possessing enhanced solubilities were synthesised from phenoxy-substituted diamines.[84]

The reaction of 2,6-diamino-4-hydroxytoluene and bis(3,5-diamino-4-hydroxyphenyl) oxide with tetracarboxylic dianhydrides gave a series of novel hydroxy-containing polyimides possessing good thermal characteristics. These polyimides are subject to further chemical modification. For example, the action of acryloyl chlorides yields photosensitive polymers.[85,86] Some soluble film-forming sulfur-containing polyimides[87–89] were synthesised from aromatic diamines containing phenylsulfonyl, phenylthio and benzothiazole-3-ylthio groups.

An interesting case of a chemical modification of polyimides has been described which includes incorporation of side phthalimide fragments into the polymer. These polymers were synthesised based on bis(phthalic anhydrides), bis(*o*-phenylenediamines) and chloral derivatives followed by reaction with phthalic anhydride.[90]





Polyimides with these structures are easily soluble in organic solvents, they manifest high thermal characteristics and fire-resistance. Polymers containing 1,1-dichloroethylene groups undergo structurisation upon thermal treatment, which renders them insoluble.

Polyimides containing phthalimide substituents were also prepared starting from 2,4-diamino-6-phthalimidotoluene and bisphthalic anhydrides[91] as well as from 2,4,6-triaminotoluene by sequential treatment with equimolar amounts of phthalic and bisphthalic anhydrides.[92] All the polymers thus modified are readily soluble in *N*-MP, DMF and a TCE–phenol mixture. Their softening temperatures are 270–360 °C; 10% mass loss temperatures are 400–450 °C.

The presence of side functional substituents has a beneficial effect on the properties of other polyheteroarylenes as well having ring–chain structures. For example, polyquinoxalines containing diarylether substituents[93,94] combine good processability with high thermal stability and low (in comparison with phenylquinoxaline) dielectric permittivity.[94]

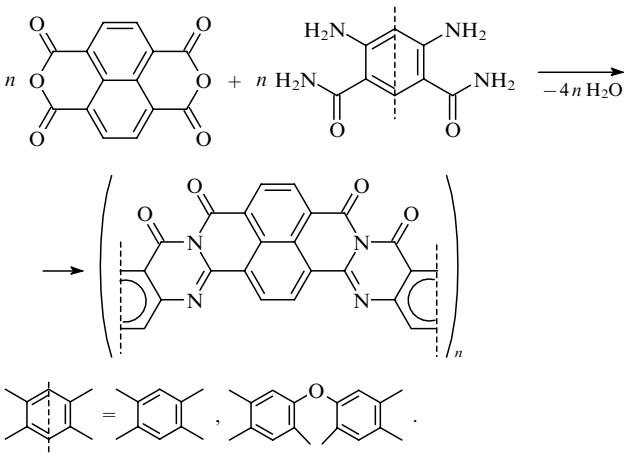
The presence of fluorine-containing (*e.g.*, trifluoromethyl, hexafluoroisopropylidene, trifluoromethylphenoxide, *etc.*) groups is also beneficial as regards the properties of different polyheteroarylenes.[95–102] Thus polyimides based on 2,2-bis[4-(3,4-dicarboxyphenoxy)phenyl]hexafluoropropane and aromatic diamines[87] are easily soluble not only in *m*-cresol, but also in chloroform, dichloromethane, DMF, DMA and *N*-MP. Their softening temperatures are 200–220 °C, while their 5% mass loss temperatures in air are around 500 °C. These polyimides are readily processed into strong monolithic articles and films by moulding, extrusion and casting from solutions. Apart from high solubility, heat resistance, thermal stability and easy processability, phenyl-substituted polyimides of 4,4′-bis[tetraphenyl(4,5-dicarboxy-1-naphthyl)phenyl]benzophenone containing trifluoromethyl and hexafluoroisopropylidene groups have low dielectric constants (2.85 and 2.8, respectively).[96]

There is evidence that electric conductivities of these polymers change on going to fluorine-substituted polyimide derivatives. Thus substitution of fluorine for four hydrogen atoms in the benzene nuclei of polyimides decreases their dielectric permittivities, whereas substitution of one atom increases them.[100] Substitution of a methyl group for a trifluoromethyl group decreases the dielectric permittivity. Dielectric permittivities of fluorine-containing polyimides vary from 2.58 to 2.85, whereas those of ordinary polyimides are equal to 2.9–3.4.

A search for new routes to the synthesis of novel promising low-permittivity polymeric materials for microelectronics has been a challenge to polymer chemists in the past decade. The main approaches to the design of polymeric film materials manifesting low permittivities on the basis of various condensation polymers are considered in a recent review.[98] According to computer prognoses,[101] significant advances in this area can be achieved through the use of phenylated polyphenylenes devoid of polar groups. Different modifications of such polymers can result in materials with dielectric constants of 2.50–2.60.

Significant progress has been achieved in recent years in the synthesis of soluble polynaphthyl- and polyperylenimides containing six-membered imide rings. These polymeric systems possess enhanced thermal and chemical stabilities, optical conductivity, unusual electrographic properties and easy processability into articles by conventional methods.[103]

In addition to the broad potential of chemical modification of the known classes of ring–chain polyheteroarylenes by changing the framework of their polymeric chains, attempts are being made to modify the polymers through the formation of new heterocycles in the chain. For example, the use of bisnaphthalic anhydrides and bisanthranylamides in the synthesis of polymers has made it possible to prepare a novel class of thermostable polyheteroarylenes, *viz.*, polynaphthoylenequinazolones with six-membered heterocycles.[104]



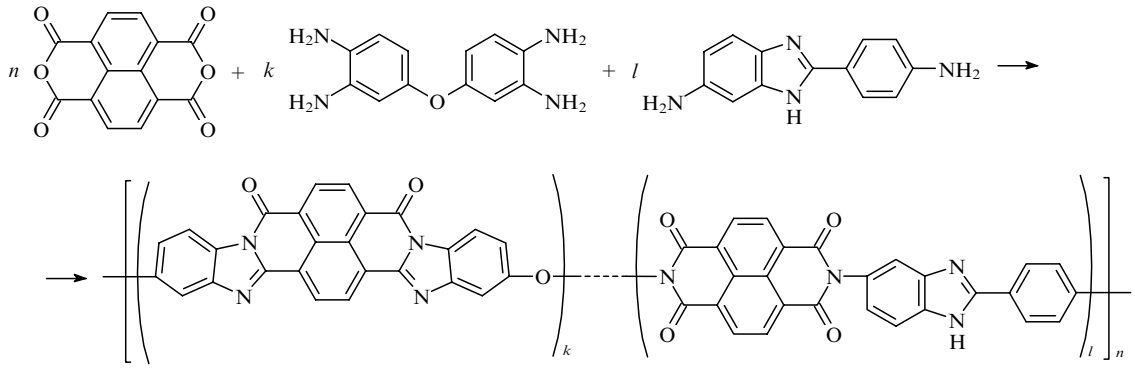
Properties of ring–chain polyheteroarylenes strongly depend on the composition of the basic polymeric chain, which determines its rigidity and flexibility.[105] The design of polymeric chains with high thermodynamic rigidity (*i.e.*, containing maximally straightened polymeric chains) is determined by the necessity to create thermostable, high-strength and high-modulus materials. Rigid-chain (the Kuhn segment is 320×10^{-8} cm) high-molecular-mass ($M = 1\,200\,000$) polynaphthoyleneimidobenzoimidazole **3** (see above) presents special interest in this respect.

Isotropic films of this polymer, which have been given the name 'iplon', are endowed with unique deformation characteristics: their breaking stress at specific elongation of $\varepsilon = 40\%$ and the elasticity modulus of $E = 46\,000$ kilogram-force cm^{-2} is $\sigma = 4700$ kilogram-force cm^{-2} (see Ref. 106). Their orientation (60%) gave anisotropic films with $\sigma = 9300$ kilogram-force cm^{-2}, $\varepsilon = 10\%$ and $E = 200\,000$ kilogram-force cm^{-2}.

With regard to these parameters, 'iplon' has no analogues among other heterocyclic non-composite polymeric materials. Approaches to further enhancing the strength characteristics of polynaphthoylenebenzoimidazole films have already been outlined. These include additional incorporation of rigid rod-like fragments into their polymeric chains. To meet this goal, a series of copolymers based on 1,4,5,8-naphthalenetetracarboxylic dianhydride, 5-amino-2-(4-aminophenyl)benzoimidazole and rod-like aromatic diamines have been synthesised.[107] The breaking strengths of oriented films of a copolymer based on 4,4′-diaminobiphenyl (30 mol.%) reaches 1.5×10^4 kilogram-force cm^{-2}, the elasticity modulus being 38×10^4 kilogram-force cm^{-2}.

Molecular composites, which represent mixtures of rigid-chain and flexible-chain polymers, are promising materials with enhanced physicomechanical characteristics. In such composites, rigid-chain components play the role of a reinforcing filler, which is dispersed at the molecular level in a flexible-chain polymer, which represents a permanent matrix. This allows fine attenuation of the microstructures of these polymeric systems (in comparison with mechanical mixtures) by synthesising block-type molecular composites with the corresponding structures. A series of block copolymers including those based on rigid-chain polynaphthoyleneimidobenzoimidazole with a Kuhn segment of 320×10^{-8} cm and flexible-chain polynaphthtoylenebenzoimidazole with a Kuhn segment of 50×10^{-8} cm have been synthesised specially for this purpose (Scheme 2).[108] These polymers manifest high physicomechanical characteristics ($\sigma = 4100$ kilogram-force cm^{-2}, $\varepsilon \approx 20\%$, $E = 82\,000$ kilogram-force cm^{-2}). Electron-microscopic studies have shown that at the molecular level the flexible matrix is reinforced by a rigid-chain block. The data on the molecular composites based on rigid-chain polybenzobisazoles have been generalised in a review.[109] It is reported that these composites are the most promising materials for those fields where low mass, high strength, thermal and chemical stability, and transparency with respect to radio waves are critical.

Scheme 2



Publications of the past decade consider miscellaneous properties of ring–chain polyheteroarylenes and various aspects of their applications in diverse branches of modern engineering, such as antifriction and self-lubricating plastics, composite materials, films, membrane and foamed materials, fibres, wave guides, adhesives, photoresists, *etc*.[3, 77, 79, 98, 103, 104, 109–115]

b. Polyarylenes

Recent investigations into the synthesis and chemical modification of polyarylenes,[116–119] polyaryleneethynylenes and polyarylenevinylenes[30–32, 120–124] attract considerable attention. In particular, the Diels–Alder homocondensation of 2,5-diphenyl-3,4-bis[4-(phenylethynyl)phenyl]cyclopentadienone was used for the preparation of a highly branched thermostable polyphenylene with M_w 160 000 that was readily soluble in organic solvents.[116] Polycyclocondensation of 4,4′-bis(4-acetylphenoxy)diphenyl sulfone was used in the synthesis of polyphenylenes containing acenaphthyl groups. Their subsequent dehydrogenation to acenaphthylenyl fragments gave a structurised polymer. The polymers containing reactive acenaphthylene groups are promising for production of thermostable plastics.[113]

The Diels–Alder reaction was used in the synthesis of hexafluoroisopropylidene-containing phenyl-substituted polyphenylenes which combine high thermal stability with solubility in organic solvents and have low dielectric constants.[119] Diethynylarenes and tolanes containing phenylated cyclopentadiene substituents[120–122] and other similar starting reagents[123, 124] were used, as in the synthesis of a series of thermostable thermoset phenylated polyphenylenes containing acetylene fragments under similar conditions. Some representatives of this class are easily soluble in organic solvents, have low dielectric constants[120] and manifest strong fluorescence.[121]

Polyconjugated polyaryleneethynylenes were synthesised by reaction of the corresponding dibromoarylenes and diethynylarenes in the presence of palladium or nickel complexes.[30–32] The fluorescence maxima of the polymers formed lie in the yellow-to-blue region.

A series of investigations of various physical characteristics of phenyl-substituted polyphenylenes, such as electrical birefringence,[125] hydrodynamic, optical and conformational characteristics[126] and radiation-induced conductivity,[127] have been carried out. No doubt, further development of the synthesis of high-molecular-mass polymers and in-depth study of their specific properties are topical.

The progress in investigations aimed at the synthesis of condensation polymers considered above would be impossible without further achievements in the chemistry of monomers based on readily available raw materials, *e.g*., 2,4,6-trinitrotoluene and chloral. Thus a series of aromatic diamines have been synthesised from 2,4,6-trinitrotoluene in order to obtain the corresponding ring–chain polyheteroarylenes containing methoxy-, fluoromethoxy-, phenoxy-, hydroxy-, sulfur-containing and other side groups.[80, 82, 83, 87–89] Diverse polyarylenes are accessible from arylene dihalides that can be prepared from chloral.[33, 128, 129]

c. Polyarylene ethers

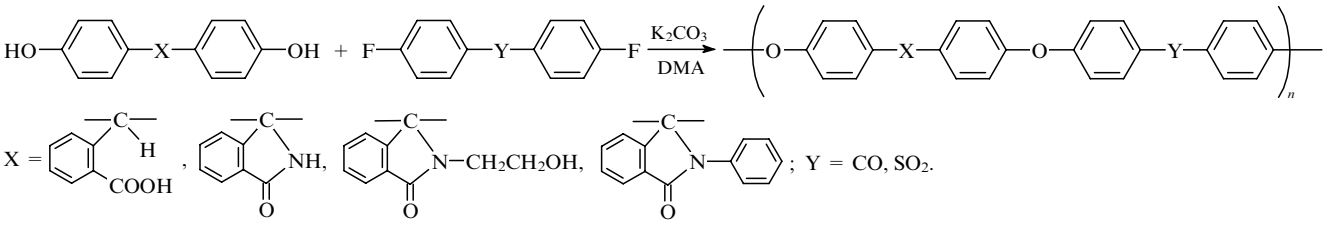
A series of recently published papers are devoted to the directed design of polymeric chains of polyarylene ethers. These polymers have attracted much attention since the 1960–1970's and are considered to be promising themoplastic materials owing to their high thermal stabilities and numerous valuable construction properties.[130] However, these compounds are not very heat-resistant, which inevitably poses the problem of their further modification. An analysis of the main regularities of their formation and effect of their molecular masses (*i.e*., the lengths of the polymeric chains) on their physicochemical properties is yet another central task.

Polyarylene ethers are usually synthesised by nucleophilic substitution of arylene dihalides with alkali metal phenolates or by electrophilic substitution (*e.g*., by reaction of aromatic dicarboxylic acid dichlorides with diaryl ethers in strongly acidic media). A recent study[131] aimed at the synthesis of polyarylene ether ketones from 4,4′-difluoro- or 4,4′-dichlorobenzophenone and cardo-type bisphenolates (phenolphthalein, phenolfluorene, phenolanthrone, phenolphthalein anilide) has significantly extended the knowledge of the pattern of this polycondensation process, enabled its optimisation and estimation of the effects of the chemical structures of the monomers on the properties of the polymers. In addition, it has enabled the synthesis of polymers with controllable molecular masses from 10 000 to 100 000 and above.[131]

The introduction of bulky cardo groups into macromolecules enhances considerably their thermal stabilities, so that glass transition temperatures of the above-mentioned polymers are 230–240 °C. They are amorphous, readily soluble and thermostable. The presence of the constituent cardo groups also favours the enhanced breaking stress and elasticity moduli of the films prepared from them.[132] The physicomechanical properties of polymers prepared from phenolphthalein and 4,4′-difluorobenzophenone were virtually unchanged starting from M = 40 000–60 000. In this range, poly(ether ketones) are easily molded from melts owing to their good fluidity. Such polymers were used for the preparation of unfilled monolithic materials as well as fiber glass and black-reinforced plastics possessing uniquely high specific impact strength. Thus the impact strength of an unfilled uncut specimen was 92 kJ m^{-2}.

Phthalide groups were also introduced into polyarylene ether ketones using an alternative procedure which employs a highly reactive difluoroderivative, *viz*., {3,3-bis[4-(4-fluorobenzoyl)phenyl]phthalide}.[133] This compound and various bisphenolates were used as starting materials in the synthesis of novel polyarylene ether ketones with softening temperatures up to 250 °C. It is noted that monolithic samples of cardo copolyarylene ether ketones containing 4,4′-propane-2,2-diyldiphenol fragments manifest uniquely high impact strength with incision (up to 44 kJ m^{-2}).[134]

Scheme 3

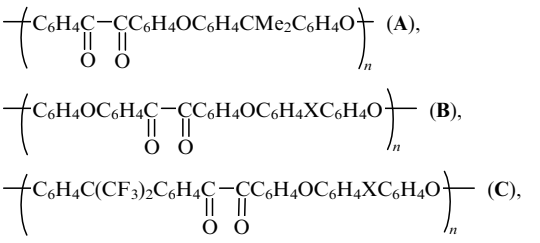


A series of crystallisable cardo copolyarylene ether ketones have been synthesised; their crystallisation is determined by the simultaneous presence of cardo bisphenols and hydroquinone (or 4,4′-dihydroxybiphenyl) fragments.[135,136] The glass transition temperatures of these compounds reach 250 °C, whereas the melting temperatures lie in the range of 300–350 °C.

Further developments in the field of chemistry of polymers will be directed at the incorporation of reactive groups into polymeric chains.[137–145] The development of methods for the synthesis of monomers containing functional groups (carboxy, alcoholic and phthalimide) is currently under way (Scheme 3).[137–139] Side groups in polyarylene ethers synthesised from these monomers allow their further chemical modification.

The polymers obtained have high softening temperatures (up to 260–290 °C); derivatives containing free carboxy groups are soluble in DMA, pyridine, cyclohexanone, THF and dioxane, and insoluble in chlorinated hydrocarbons. It is noted that the range of solvents for these polymers is wide and includes non-polar or low polarity solvents owing to the ability to form hydrogen bonds and to be involved in intra- and intermolecular interactions.[140] Polyarylene ethers containing free carboxy groups present interest as polyelectrolytes and polymeric composites.[139]

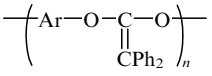
The use of difluoroarylenes containing α-diketone fragments as monomers has enabled the synthesis of the corresponding polyarylene ether ketones:[26,140–143]



X = CMe_2, $C(CF_3)_2$, *etc.*

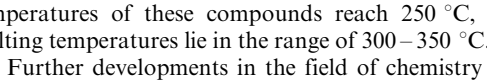
The glass transition temperatures of the polymers **B** and **C** vary in the range 165–245 °C, their 10% mass loss temperatures in air lie around 460–540 °C, and their dielectric constants vary from 2.90 to 3.25. These polymers are soluble in organic solvents.[142,143] The presence of α-diketone fragments in these macromolecules opens up new ways to their further conversion into, *e.g.*, linear polymers containing quinoxaline and triazine fragments or into cross-linked polymeric structures containing interchain quinoxaline fragments. It may be expected that the thermal and mechanical characteristics of these polymers will be enhanced in comparison with the original ones.

Chemical modification of polyarylene ethers can also be achieved through the introduction of double and triple bonds into their structures. The reaction of 1,1-dichloro-2,2-diphenylethylene with bisphenols was used in the synthesis of oligomers of the general formula:



Ar = $C_6H_4CMe_2C_6H_4$, $C_6H_4C(O)C_6H_4$,

which are promising candidates for thermoset fire-resistant materials.[144] Polycondensation of various bisphenols with difluoroarylenes containing acetylene groups was used for the preparation of unsaturated polyarylene ether ketones.[145]



X = CO, COCO; Ar = $C_6H_4CMe_2C_6H_4$, $C_6H_4CMePhC_6H_4$, *etc.*

Their thermal treatment is accompanied by structurisation at the triple bonds and results in enhancement of their thermal characteristics.

Thus, the studies of polyarylene ethers are mainly directed at the perfection of their synthesis and the design of novel promising polymeric structures. A search for hitherto unknown activators of electrophilic monomers employed in the synthesis of polyarylene oxides is currently under way. Thus it was found that the acyclic and heterocyclic groups present in arylene dihalide molecules activate halogen atoms. This line of research, which holds much promise both for the optimisation of nucleophilic substitution and for the preparation of novel polymeric systems possessing valuable properties, has been considered in a special review.[146]

IV. Conclusion

Because of the limited size of the present review, we cannot dwell further on all recent achievements in polycondensation and encompass the whole range of novel polymers synthesised by this method, since such examples are too numerous. The advances in the study of carborane-[147] and sulfur-containing[148] condensation polymers and polyorganophosphazenes[149,150] have been adequately covered in recently published papers. Suffice it to mention yet another promising trend which has been successfully developed over the past decade, *viz.*, design and investigation into highly branched dendritic polymers which are considered in detail in special reviews.[151,152]

In conclusion, it should be noted that polycondensation is still a very diverse and intensively explored area of research which is being further developed, being aimed at a search for novel polymer-forming reactions, methods for macromolecular design in polycondensation processes and purposeful design of polymeric chains for the most promising classes of polymers with the ultimate goal of conferring novel useful properties to existing polymers and of preparing new polymer systems. There is every reason to believe that future studies will provide interesting new data in this field of polymer chemistry.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 03-03-07011).

Abstract. The review concerns the syntheses of polymeric nanocomposites containing encapsulated nanoparticles formed in nanostructured polymeric systems including block copolymers, dendrimers, nanoporous polymers, polyelectrolyte gel – surfactant complexes and multilayered films. Nanostructures in amphiphilic block copolymers can form spontaneously both in the bulk (block microsegregation) and in solution (block copolymer micelle). In polymeric systems, nanostructures play the role of nanoreactors for the growing nanoparticles. The nanoparticle size, shape and size distribution are controlled by the nanostructure characteristics and synthesis conditions. The catalytic, magnetic and optical properties of these nanostructured polymeric nanocomposites are discussed. The bibliography includes 131 references.

I. Introduction

At present, increasing interest in the synthesis of nanoparticles and nanosystems and in the studies on their properties has been expressed.[1–3] Various methods for the synthesis of nanoparticles and the properties of these systems have been thoroughly reviewed (see Refs 4, 5 and 6 – 8, respectively). However, no systematic review of nanoparticle formation in nanostructured polymeric systems has been reported so far.

Nanostructures in a polymeric composite are defined as regular nanosized heterogeneous domains (*i.e.*, certain regions of the polymeric material that are separated by some interface). Due to the presence of nanostructures one can control the growth of nanoparticles, the particle size distribution and interfacial interactions. These factors are to a great extent responsible for the unique catalytic, magnetic, semiconductor, nonlinear optical, *etc.* properties of nanocomposites and, finally, for the fields of their application. Nanostructured matrices are quite promising for being used for nanoparticle formation. This is indicated by the tremendous progress achieved during the decade that has passed since the first use of block copolymers (the first representatives of nanostructured polymeric systems) for the formation of metal nanoparticles. At present, it is possible to obtain nanoparticles of different shape and size (*e.g.*, nanotubes, nanowires and other nanoscale objects) in nanostructured polymeric environment using various polymeric systems and different approaches.

II. Nanoparticle formation in amphiphilic block copolymers

A feature of amphiphilic block copolymers is the ability to undergo microsegregation in the bulk and to form micelles in dilute solutions in selective solvents.[9–11] To synthesise nanoparticles, one block of a diblock or triblock copolymer must contain functional groups that can be involved in reactions with metal compounds.

1. Nanoparticles in microsegregated blocks

Block copolymers containing incorporated complexes or encapsulated nanoparticles in a specified block can be prepared in several ways. These are, *e.g.*, copolymerisation of organometallic monomers followed by corresponding transformations of the system; reactions of metal complexes with functional groups of block copolymers in solutions followed by microsegregation of the organometallic block copolymers (either in the form of films or in the bulk); and sorption of organometallic compounds into microdomains of block copolymer films. The sorption of metal complexes into diblock and triblock copolymers causes significant changes in the properties of polymeric systems (first of all, in the Flory – Huggins interaction parameter χ_{AB}). One can expect the greatest changes in χ_{AB} for non-polar flexible blocks, *e.g.*, polyisoprene (PI) or polybutadiene (PB) due to the appearance of polar groups and to the change in the chain conformation.

A typical example is provided by the introduction of $Fe(CO)_3$ groups into the PB block of a polystyrene – PB – polystyrene triblock copolymer (Kraton) containing 30 mol.% of polystyrene (PS) *via* complexation.[12] Complexation leads to a considerable increase in the force of adhesive binding of the polymer film to polar surfaces (glass, metals) and in the rigidity of the PB block (the higher the iron concentration, the higher the glass transition temperature of the PB block) and causes reduction of the PB block mobility. At the same time, in spite of significant changes in the chemical structure, the material retains its morphology ('cylinders in matrix').

A similar mophological stability was also observed in highly assymetrical diblock ionomers in which the shorter polyacrylic

acid (PAA) block forms spherical microdomains encapsulated in the matrix of the major component (PS).[13] It was found that neither sorption of Cd^{2+} ions nor formation of CdS nanoparticles change the block copolymer morphology. Experiments with a diblock copolymer based on isoprene and 2-vinylpyridine (2VP) showed [14] that at low content of palladium nanoparticles the block copolymer retains its lamellar structure and that an increase in the palladium content causes distortion of the ordered (regular) structure. The growth of nanoparticles influences the block copolymer structure. The system is also characterised by feedback, namely, the interfaces between different domains and the free surfaces of the polymer films affect the formation of nanoparticles inside the block copolymer microphase. In particular, as was shown by transmission electron microscopy (TEM), the size of the growing silver,[15] palladium [14, 16] (Fig. 1) and other metal nanoparticles confined within microsegregated layers is limited to the corresponding layer thicknesses. Almost no penetration of the metal seeds and growing particles into adjacent non-polar layers was observed; *i.e.*, the block copolymer domain acts as a nanoreactor in the formation of metal nanoparticles. The synthesis of nanoparticles in thick homopolymer films led to uncontrolled growth of nanoparticles and resulted in large particles characterised by a broad size distribution.[15] As the thickness of the metal-containing homopolymer film decreased down to the characteristic lamella size in the block copolymer ($\sim$100 nm), the free surface of the thin film behaved as an interface.[15]

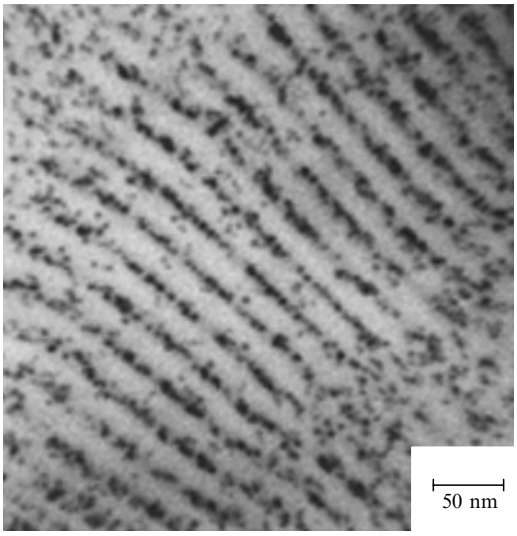

Figure 1. TEM image of a sample prepared by reduction of the system [polyisoprene-*block*-poly(2-vinylpyridine)] – $Pd(acac)_2$ – benzyl alcohol with a component ratio of 32.5 : 2.6 : 64.9 (mass %) after evaporation of the solvent.[16]

Metal nanoparticles encapsulated in multilayered thin films based on block copolymers were synthesised analogously.[17] The films were prepared by adsorption of symmetrical PS and poly(4-vinylpyridine) (P4VP), which form a lamellar structure, in the bulk, on a solid substrate. These films (they resemble multilayered films fabricated by adsorption of oppositely charged polyelectrolytes) were pre-loaded with a metal compound (*e.g.*, $HAuCl_4$) and then with the reducing agent. Nanoparticles were formed only within the P4VP block. It was shown that nanoparticles can affect the lamella size.[18] The best ordered arrangement of nanoparticles in multilayered block copolymer films was obtained for the films prepared under nonequilibrium conditions that provided the possibility for highly asymmetrical nanoparticles to be formed.[19, 20]

Sometimes, particle formation in the nanoreactor causes significant changes in the reaction conditions. For instance, cobalt ferrite ($CoFe_2O_4$) is usually obtained by high-temperature synthesis from corresponding hydroxides. If $CoFe_2O_4$ nanoparticles are formed inside the block copolymer domains,[21] the reaction can proceed at room temperature.

2. Metal nanoparticles in block copolymer micelles

a. Formation of metal nanoparticles in block copolymer micelle cores

Amphiphilic block copolymers dissolved in selective solvents (they dissolve only one block) form micelle. The size and shape of these objects depend on the nature of the blocks, the type of solvent (to a first approximation, a hydrophilic or hydrophobic one) and on the molecular mass of the blocks.[9, 11] If, in the case of diblock and triblock copolymers, the micelle core comprises a block containing certain groups capable of being involved in reactions with metal compounds to give metal complexes or salts, this core can be loaded with the corresponding metal constituent of the complex or salt and then used as a nanoreactor for metal nanoparticle formation. Appropriate block materials include, *e.g.*, poly(2-vinylpyridine) (P2VP) or P4VP, polymethacrylic acid (PMAA) or PAA, PB or PI and some other polymers. The micelle corona must be built of a block that contains no functional groups but provides the solubility and stability of micelles in corresponding solvents. Materials appropriate in this case include PS, poly(ethylene oxide) (PEO), polyisobutylene (PIB) and other polymers.

The synthesis of metal nanoparticles in block copolymer micelle cores was nearly simultaneously employed by several research groups.[13, 22–25] Studies on the formation of gold, palladium, platinum and other metal nanoparticles in PS-*block*-P4VP-based micelles revealed that the nanoparticle morphology strongly depends on the type of the reducing agent. With 'sluggish' reducing agents only one particle can be formed in the micelle core in the absence of inter-micellar exchange reactions. Using 'fast' reducing agents, the nucleation and growth of a large number of particles occur simultaneously; therefore, each micelle contains many small particles. This morphology is most preferable for catalysis (Fig. 2).[26] Both morphologies are schematically shown in Fig. 3. To prevent inter-micellar exchange, the micelle cores can be cross-linked. Then, variation of the reducing agent permits fine control of not only the particle morphology but also the particle size.[27] Using micelle cores as nanoreactors, both monometallic and bimetallic nanoparticles can be synthesised; their morphologies depend on the nature of the metal employed.[28] Adsorption of nanoparticle-containing micelles onto different substrates results

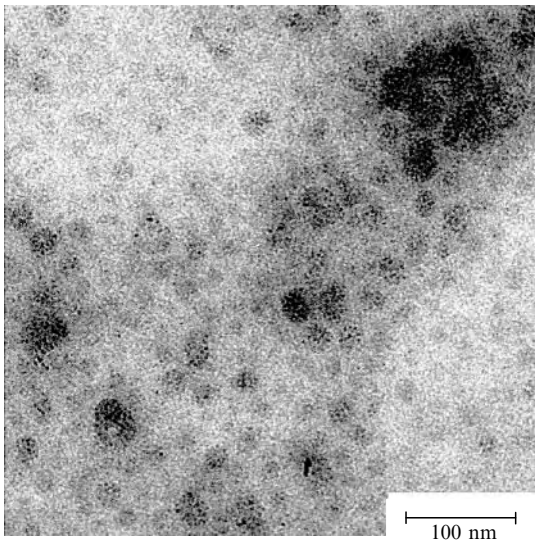

Figure 2. TEM image of bimetallic Pd – Pt nanoparticles formed in PS-*block*-P4VP-based micelles.[26]

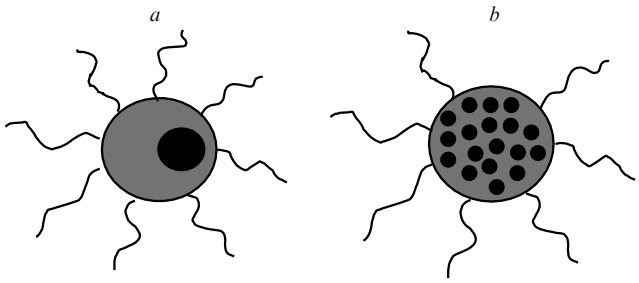

Figure 3. Schematic representation of nanoparticles with 'cherry' (*a*) and 'raspberry' (*b*) morphologies.

in the formation of monomolecular layers; this phenomenon is used in nanolithography.[29]

Nanoparticles confined within micelle cores can also be prepared using star-like block copolymers. For instance, block copolymer micelles based on star-like block copolymers with a P2VP core and PS shell were used [30] to form gold nanoparticles with a narrow size distribution. It is believed [30] that star-like polymer micelles are more stable, thus being responsible for the nanoreactor stability and improved control of particle growth.

When using a triblock copolymer in which only the middle block can be coordinated by metal compounds, and nanoparticles can be formed within the outer layer of the core rather than the entire core space when the middle block and one of the two terminal blocks are insoluble in the reaction medium. This can be exemplified by the synthesis of gold nanoparticles in PS-*block*-P2VP-*block*-PEO micelles in aqueous solutions.[31] Such systems can be of particular interest for catalysis, because nanoparticles present in the outer layer of the core are better accessible to substrates.

Analogously to the synthesis of nanoparticles in block copolymer micelle cores in organic media, metal nanoparticles can be produced in aqueous media; however, only a few block copolymers are available in this case, *e.g.*, PEO-*block*-P2VP and PEO-*block*-PB.[32, 33] In the former system, the situation is complicated by the fact that micellisation of the polymer depends on the pH value of the medium (at pH < 5, the PEO-*block*-P2VP micelles undergo disassembling). Nevertheless, in the presence of metal compounds or after formation of nanoparticles micelles are retained even in acid media; however, they become very loose. The reverse situation is observed in the case of PEO-*block*-PB. In water, this block copolymer forms very dense micelles that can act as both nanoreactors for the formation of palladium, platinum or rhodium nanoparticles and excellent templates for mesoporous silica formation.[33] Such systems are of great interest as promising heterogeneous catalysts of various reactions.

Not only micelle cores (see above) but also the inner micelle corona layer can be cross-linked to stabilise the nanoreactor. Triblock copolymers comprised of PEO, poly(glycerol monomethacrylate) (PGMA) and poly(diethylaminoethyl methacrylate) (PDEAEMA) blocks [poly(2-hydroxyethyl methacrylate), PHEMA, was also used as the middle block] completely dissolved in water at low pH values but formed multilayered onion-like micelles with PDEAEMA cores at pH > 7–8.[34] The middle block in the micelles was cross-linked by reaction with divinyl sulfone. These micelles were used as nanoreactors for the formation of gold nanoparticles. The authors [34] believe that the micelles cross-linked in the corona interior provide the stability of nanoparticles and prevent inter-micellar reactions. Yet another possible advantage of these micelles is a substantial increase in their loading without deterioration of sedimenting stability; however, this has not been confirmed so far.

Another approach was employed to form ferrous oxide nanoparticles in PI–poly(2-cinnamyl methacrylate)–poly(*tert*-butyl acrylate) (PI-*block*-PCM-*block*-PtBA) cross-linked triblock copolymer micelles in a THF–hexane mixture.[35] These micelles are comprised of a PI corona and two core layers with PCM as the outer layer and PtBA as the inner layer. The PCM layer was cross-linked by exposure to UV radiation, which resulted in the formation of stable nanospheres. Subsequent hydroxylation of the PI block to impart hydrophilic properties to the nanospheres was followed by removal of the *tert*-butyl groups to allow the nanosphere cores to react with metal compounds. The possibility of using such nanospheres as nanoreactors was demonstrated by taking the formation of magnetic ferrous oxide particles with a narrow size distribution as an example. However, this technique is very labour-consuming and seems to be of little promise.

We believe that targeted synthesis of block copolymer micelles opens up great prospects for the design of materials suitable for the fabrication of various devices. However, anionic polymerisation employed for the synthesis of most block copolymers is a quite expensive method. Besides, it is very sensitive to external factors, which hampers progress in this area of research. Another method, namely, charge transfer radical polymerisation, is thought to be a cheaper and more reproducible method of synthesis of block copolymers with a narrow molecular mass distribution.[36, 37]

b. Double hydrophilic block copolymers. Micellisation during complexation

In some cases, a metal compound incorporated into a polymer matrix can induce nanostructuring of the matrix. This is observed when using, *e.g.*, the so-called 'double hydrophilic' block copolymers comprised of blocks with similar hydrophilicities. One block must contain functional groups while the other block must be inert towards metal compounds. Dissolution of such a block copolymer in water results in a true solution, but the addition of some metal salts can induce micellisation due to coordination of the metal by one of the blocks (Fig. 4).[38] In this case micelles are formed and exist due to the coordination between the metal ions and functional groups of the polymer. Such block copolymers can be obtained by simply coupling two blocks after relevant functionalisation.[39] Another 'double hydrophilic' block copolymer, poly(ethylene oxide)-*block*-poly[(*N*-carboxymethyl)ethyleneimine] (PEO-*block*-PCMEI), was designed for controlled mineralisation (control of formation of $CaCO_3$ nanoparticles), because PCMEI can interact with calcium ions.[40]

Poly(ethylene oxide)-*block*-polyethyleneimine (PEO-*block*-PEI) was proposed for the synthesis of transition metal nanoparticles in aqueous media because the PEI block readily interacts with these metal ions affording coordination compounds.[38] The

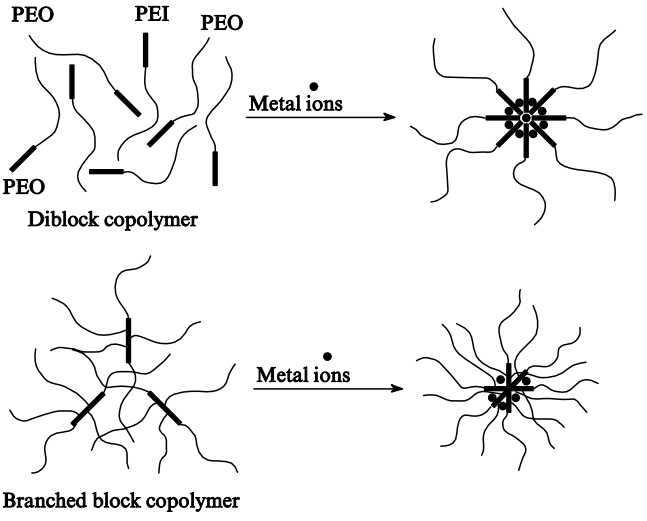

Figure 4. Scheme of micelle formation in PEO-*block*-PEI due to the interaction with metal ions in aqueous solution.[38]

PEI blocks undergo aggregation, thus formng the micelle core, while the PEO blocks form the micelle corona. These micellar systems can control the nucleation and growth of nanoparticles analogously to the amphiphilic block copolymer micelles described above. Moreover, a typical amphiphilic block copolymer, PEO-*block*-P2VP, also becomes soluble on the molecular level at pH < 5 and behaves like PEO-*block*-PEI in the reactions with metal compounds. Reduction of the metal ions is accompanied by the formation of nanoparticles, yet the PEO-*block*-PEI micelles do not decompose; only their hydrodynamic characteristics are changed (Table 1). This block copolymer was successfully used to form CdS nanoparticles [41] which exhibited oxidative stability for many months due to the polymeric environment. By varying the polymer concentration and the type of the solvent the nanoparticle size was varied from 2 to 4 nm.

Table 1. Hydrodynamic diameter (D_h) and its standard deviation (σ) for Pt-containing PEO-*block*-PEI micelles.[39]

Polymeric system	Molar ratio PEI : Pt	D_h /nm	σ (%)
PEO-*block*-PEI + H_2PtCl_6	8 : 1	138	32
	4 : 1	154	29
	2 : 1	176	32
	1 : 1	201	30
PEO-*block*-PEI + Na_2PtCl_6	8 : 1	210	29
PEO-*block*-PEI + K_2PtCl_4	8 : 1	578	115
PEO-*block*-PEI + H_2PtCl_6 reduced with $N_2H_4 \cdot H_2O$	4 : 1	110	24
PEO-*block*-PEI + H_2PtCl_6 reduced with H_2	4 : 1	149	27

To control the morphology of nanoparticles formed, one can use the relations described for amphiphilic block copolymer micelles. The nanoparticle morphology is affected by the nature of the reducing agent, the concentration of the metal compound and the pH value of the medium. Unlike amphiphilic block copolymer micelles, the micelles obtained *via* complexation are loose, which favours inter-micellar exchange of metal ions and prevents control of the growth of nanoparticles.

c. Nanoparticle formation in micelle coronas

Metal nanoparticles can be synthesised in coronas of amphiphilic block copolymer micelles. If the micelle corona contains no groups suitable to coordination by metal compounds, nanoparticles are stabilised only by the hydrophobic interactions with the core. This procedure was employed to synthesise palladium, platinum and gold nanoparticles stabilised in aqueous solutions of PS-*block*-PEO and PS-*block*-PMAA.[42, 43] It was shown that the reduction of metal compounds results in the formation of small nanoparticles and that stabilisation of the nanoparticles exclusively due to hydrophobic interactions with the PS micelle cores is insufficient for obtaining solutions with high sedimenting stability. At the same time, accessibility of the nanoparticles in the micelle corona can play an important role for applications of such systems in catalysis.

To make the nanoparticles located within coronas of amphiphilic micelles more stable, it was proposed to design hybrid systems comprising amphiphilic block copolymers and surfactants.[44–46] It was assumed that the hydrophobic surfactant 'tails' would penetrate hydrophobic PS-*block*-PEO micelle cores while the charged groups of the surfactant would be arranged at the core surface (Fig. 5). Exchange of the surfactant counterions by platinum, palladium or rhodium ions was assumed to enable the loading of the corona with metal ions.

Light scattering and ultracentrifugation experiments showed that hybrid systems PS-*block*-PEO–surfactant have a complex structure and comprise micelles, micellar clusters and supermicellar aggregates. The addition of positively or negatively charged

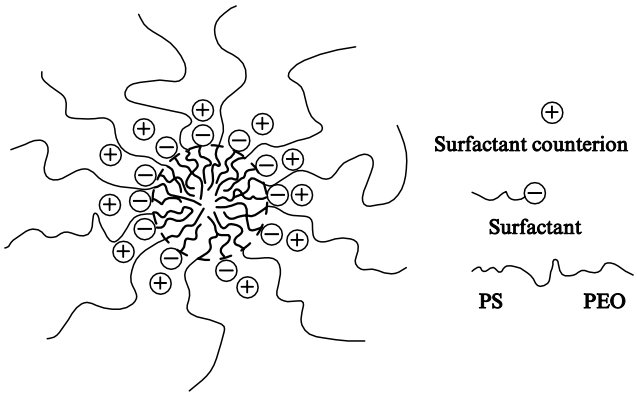

Figure 5. Schematic illustration of PS-*block*-PEO micelles containing anionic surfactant.[38]

surfactants to the PS-*block*-PEO micellar solutions causes an increase in the size and mass of micelles and micellar clusters. This holds until a certain surfactant concentration is reached, which depends on the type of the surfactant. An increase in the concentration [as a rule, above the critical micelle concentration (CMC)] causes a decrease in the size of micelles and micellar clusters. ^{1}H NMR studies revealed that the addition of surfactant significantly enhances the mobility in the PS core, which confirmes co-micellisation of the block copolymer and cationic (or anionic) surfactant molecules. Ion exchange of cetylpyridinium chloride (CPC) counterions by $PtCl_6^{2-}$ or $PdCl_4^{2-}$ ions in the system PS-*block*-PEO/CPC leads to saturation of the micellar structures with palladium or platinum ions. Subsequent reduction of the metal-containing systems thus obtained with sodium borohydride or dihydrogen is accompanied by the formation of (mostly) micelle-encapsulated metal nanoparticles. The morphology and stability of the palladium and platinum nanoparticles synthesised in these systems depend on the type of the reducing agent and on the metal salt concentration. Reduction with $NaBH_4$ results in breakdown of micellar clusters and formation of micelles containing encapsulated nanoparticles (Fig. 6). These systems exhibited very high stability for one year, provided that the metal salt concentration was at most 1.24×10^{-2} mol litre^{-1}. Reduction with dihydrogen results in the formation of metal nanoparticles both in micelles and in micellar clusters. In this case, colloid solutions were stable at the metal salt concentrations of at most 3.36×10^{-3} mol litre^{-1}. Platinum particles formed using the reducing agents

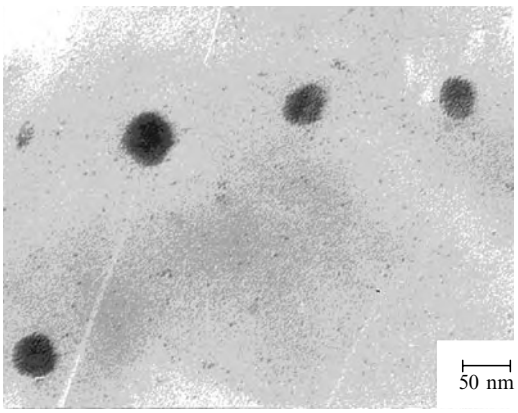

Figure 6. TEM micrograph of platinum nanoparticles obtained *via* reduction of $H_2PtCl_6 \cdot 6\,H_2O$ (1.24×10^{-2} mol litre^{-1}) with sodium borohydride and stabilised in the PS-*block*-PEO/CPC hybrid micelles in water.[44]

mentioned above were 2–4 nm in diameter, while palladium particles were somewhat larger (4 to 6 nm in diameter).

If the metal salt ions exist only in the form of cations, one can use hybrid systems containing an anionic surfactant, sodium dodecyl sulfate (SDS). For instance, the hybrid system PS-*block*-PEO/SDS allows sodium counterions to be exchanged with rhodium ions generated during dissociation of $[Rh(Py)_4Cl_2]Cl \cdot 6\,H_2O$. Reduction of the system thus obtained with sodium borohydride also leads to saturation of micelles with rhodium nanoparticles of sizes 2–3 nm. Thus, by adding surfactants to 'inert' (containing no functional groups) amphiphilic micelles, one can use them as a good stabilising system for the formation of metal nanoparticles of size 2 to 6 nm. The drawback of this approach is the absence of direct methods of varying the nanoparticle size.

An interesting method of transformation of core-embedded nanoparticles into corona-embedded ones has been reported.[47] When a solution of PS-*block*-P2VP–CdS micelles in an organic solvent was placed in an aqueous medium characterised by a low pH value, the PS block collapsed and a PS core was formed (in the organic medium, the core consisted of the P2VP block). Simultaneously, protonation-induced dissolution of the P2VP block occurred. Protonated (charged) P2VP formed the micelle corona and stabilised the CdS nanoparticles grown in the P2VP core in organic solvent. This permitted fine control of the growth of nanoparticles.

III. Formation of metal nanoparticles in polyelectrolyte systems with regular morphologies

1. Formation of nanoparticles in polystyrenesulfonate microgels

Microgels are spherical particles several nanometres in diameter.[48,49] Taking into account the structure-stabilising factors, *viz*., the size and cross-linked structure of microgels, they can be treated as nanoreactors, or molecular containers that allow the growth of nanoparticles to be controlled. Taking the reduction of gold compounds in these microgels as an example, the nanoparticle formation was studied.[50] The effects of the reduction rate and of the characteristics of the microgel on the nanoparticle parameters was studied. It was found that fast reduction of gold compounds with sodium borohydride in water results in the formation of small gold particles (4.5 nm in diameter according to X-ray diffraction data) in microgels. Slowing down the reduction using sodium borohydride in alkaline solution (0.1 M NaOH) changed the nanoparticle morphology, namely, long 'filaments' (according to X-ray diffraction and TEM data) were formed from the particles 7 nm in diameter. Very slow reduction with hydrazine hydrate led to the formation of large particles (25 nm), which were found only in 15% of the microgel (85% of the microgel contained no gold particles at all). Apparently, in the case of sluggish nucleation, small clusters and metal ions non-uniformly migrate towards disordered microgel domains and then easily undergo aggregation. Clearly, microgels with disordered morphologies cannot be used to control nanoparticle growth.

Yet another parameter, which strongly affects both the nanoparticle and the entire sample morphology, is the degree of cross-linking of the microgel. The larger this parameter, the higher the probability of formation of spherical metal nanoparticles encapsulated in microgels. A high resolution TEM study confirmed the fact that nanoparticles grew from the same core and that the exterior of the particles was governed by the microgel environment. In the experiments with $NaBH_4$, the particle growth was controlled by the elasticity of the surrounding gel matrix. This means that particles grow along a given direction until the surrounding polymer chains become completely aligned in this direction. Thus, the system ensures the 'cage' effect though the 'cage' itself is not rigid.

In addition to gold nanoparticles, this method was employed to synthesise palladium and platinum nanoparticles.[51] Microgel-grown nanoparticles and amphiphilic PS-*block*-PEO copolymers were used as templates for obtaining mesoporous silica. Hence, microgels can have two functions, namely, to act as nanoreactors for the formation of metal nanoparticles and to serve as pore-forming templates in the formation of mesoporous silica.

2. Polyelectrolyte gel–surfactant complexes as nanostructured media for the interaction with metal ions and formation of metal nanoparticles

Polyelectrolyte gel complexes with oppositely charged surfactants are highly ordered self-organised nanostructures. They have been the subject of intensive research in the last decade.[52–57] The SAXS spectra of the cationic gel–anionic surfactant and anionic gel–cationic surfactant complexes exhibit very sharp and intense peaks indicating the presence of large ordered surfactant domains in gel. Statistical disorder in gel has no effect on the regular ordered arrangement of surfactant aggregates. Moreover, at the same surfactant concentration the surfactant molecules in oppositely charged gels are better ordered compared to aqueous media.[57] Spatial ordering in the gel–surfactant complexes is of interest from the standpoint of preparation of a nanostructured medium for the formation of metal nanoparticles.

It was established that sorption of metal ions by hydrogel–surfactant complexes occurs when the charges of the ions and of the charged groups of the gel are opposite in sign.[58–60] The ions sorbed form metal compound clusters arranged between the charged groups of the polymer chain and the head groups of the surfactant molecules (Fig. 7). These clusters serve as the nucleation centres of metal nanoparticles. In the case of fast reduction, particles are formed in an ordered environment. Moreover, the surfactant molecules in the immediate vicinity of the growing particles are even more ordered (though generally the growth of nanoparticles makes the surfactant more disordered), thus providing an extra means for control of the particle growth, which results in a narrow particle size distribution (Fig. 8).[60] This effect is observed for various metal compounds and hydrogel–surfactant complexes. In the case of slow nucleation, small clusters and metal ions non-uniformly migrate towards the disordered region of hydrogel and then undergo aggregation into large particles characterised by a broad size distribution. Polyelectrolyte gels without nanostructured morphologies cannot be used to control the growth of metal nanoparticles.

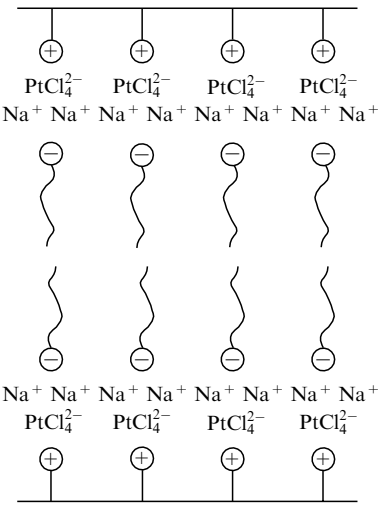

Figure 7. Schematic view of hydrogel–surfactant complexes with a sorbed metal salt.

R is the particle radius.

3. Nanoparticle formation in thin layers of supported polyelectrolytes

Thin polyelectrolyte layers are prepared by depositing a polyelectrolyte layer onto a charged substrate. This can be followed by layer-by-layer deposition of oppositely charged polyelectrolytes (Fig. 9).[61] Nanoparticles can also be used as 'substrates.' This permits preparation of various core – shell materials or hollow spheres.[62,63] These multilayered materials are treated as nanostructured systems in which each layer is a nanoreactor. For instance, cadmium sulfide nanoparticles were prepared[64] by sequential deposition of cadmium polystyrenesulfonate and polyvinylpyridine layers on PEI-modified silica or other substrates. Then, the multilayered film was exposed to H_2S for 30 min at room temperature, which resulted in a hybrid system containing CdS nanoparticles. Silver nanoparticles were produced in multilayered polyelectrolyte films based on PAA and protonated polyamine.[65] Repeated treatment with the silver salt (carboxyl groups are released after formation of nanoparticles on exposure to UV radiation) permitted an increase in the metal content in the film from 4% to 24%.

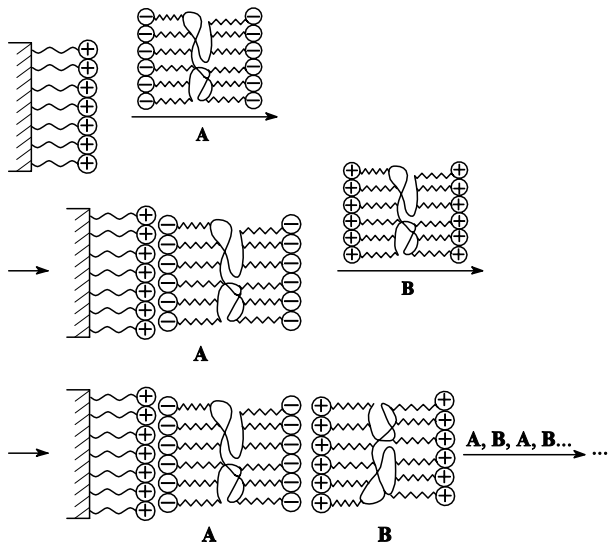

Figure 9. A scheme showing the formation of polyelectrolyte layers involving layer-by-layer adsorption of cationic and anionic polyelectrolytes (counterions are not shown).[61]

In order to provide better control of the particle growth, nanoparticles are sometimes prepared in surfactant micelles, which are then incorporated into polyelectrolytes to give multilayered films containing nanoparticles.[66] In this case, nanoparticles grow outside the polymeric system, which goes beyond the scope of this review. However, this approach is noteworthy. Indeed, recent studies revealed that, in contrast to amphiphilic block copolymers, multilayered composites are characterised by the presence of broad transient regions between each pair of electrolytes. As a consequence, the 'nanoreactor' size changes appreciably. In this case, it is difficult to synthesise particles with narrow size distribution, though their arrangement is governed by the particular polyelectrolyte layer.

Nanoparticles can also be formed using Langmuir – Blodgett polymer films, which resemble thin homopolymer films considered above. Only a few studies on the subject are available. Usually, nanoparticles were prepared separately and then mixed with an amphiphilic polymer before film formation.[67] Interesting results were reported in the article[68] concerned with the formation of CdS nanoparticles in the Langmuir – Blodgett film based on nonacosa-10,12-diyne acid after polymerisation of the acid on exposure to UV radiation. Exposure of the polymerised film containing cadmium ions to H_2S resulted in the formation of nanoparticles 10 nm in diameter. The photochemical and electrochemical properties of these films were described.[68] Another example of similar approach was also reported.[69] Here, cadmium sulfide nanoparticles of different size were prepared in Langmuir – Blodgett films formed by a polymer based on the octadecyl ester of polymaleic acid with different carboxyl group/hydrocarbon chain ratios. This permitted variation of the nanoparticle size and the photochemical properties of the films. Clearly, the systems developed cannot be used for fabrication of bulk materials or thick films, because ordered nanostructures in these amphiphilic homopolymers are formed under specific conditions (*e.g.*, at the air – water interface).

Controlled growth of nanoparticles can be performed in any thin homopolymer films. For instance, bimetallic Au/Cu nanoparticles of different composition were obtained by evaporation of metals in thin nylon-11 films.[70] The composition of bimetallic particles and their sizes were changed by varying the amount of metals evaporated. Experiments led to preparation of bimetallic nanoparticles of different composition with a narrow size distribution.

IV. Synthesis of dendrimer-encapsulated metal nanoparticles

The formation of dendrimer-encapsulated metal nanoparticles can be treated as a specific kind of nanoparticle synthesis in loose cores of block copolymer micelles. At the same time, there are significant differences between these processes (see below). In most cases researchers use commercially available poly(amidoamines) (PAMAM) dendrimers. By varying the dendrimer size (or dendrimer generation) and the metal compound loadings one can control the metal nanoparticle size. All publications on the subject are quite recent. It was Bar *et al.*[71] who pioneered the use of dendrimers as stabilisers in the formation of gold and silver nanoparticles. More recently,[72] it was shown that hydroxyl-terminated PAMAM dendrimers can be used as templates and stabilisers for the preparation of monodisperse transition metal nanoparticles possessing catalytic properties (Fig. 10). It is believed that the dendrimer macromolecule has an internal cavity, which is used for the formation (stabilisation) of a nanoparticle. However, broad nanoparticle size distribution when metal ions

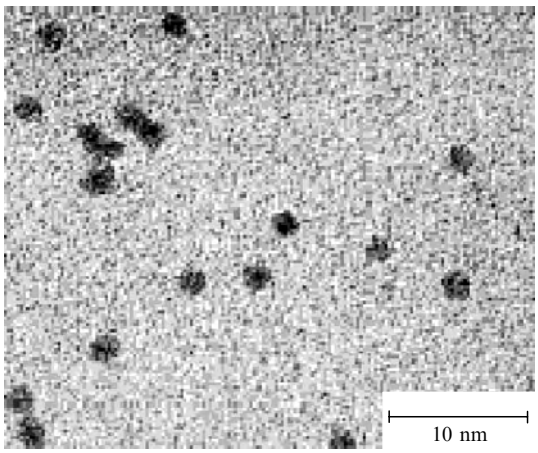

Figure 10. A HRTEM image of hydroxyl-terminated G4 dendrimer containing a total of 60 Pt atoms in each dendrimer.[72]
Platinum nanoparticles are monodisperse in size and shape.

exchange between dendrimer macromolecules (the metal compound migrates from one dendrimer to another) suggests that this cavity plays an insignificant role in the limitation of nanoparticle growth. These materials are prepared *via* sorption of metal ions into dendrimers followed by complexation with amino groups. Subsequent chemical reduction results in the formation of dendrimer-encapsulated metal nanoparticles comprising exactly the same number of atoms as that pre-'loaded' into the dendrimer. If no exchange of metal ions between dendrimer macromolecules occurs, the nanoparticle size distribution is narrow and fine control of the particle growth is possible. Nanocomposites thus obtained are water soluble and retain their stability for months. They exhibit a high catalytic activity towards alkene hydrogenation in water.[73] What is more, the catalytic activity can be controlled by varying the dendrimer size (generation), *i.e.*, the dendrimer acts as a nanofilter. Dendrimers are used as nanoreactors for the formation of not only monometallic but also bimetallic particles.[3]

When using PAMAM dendrimers containing amino groups at the surface, the size of the gold nanoparticles synthesised by exposing the dendrimer solutions to UV radiation was strongly dependent on the amino group/metal compound concentration ratio.[74,75] The particle size distribution was much broader than in the case of hydroxyl-terminated PAMAM dendrimers. Probably, the presence of the surface amino groups favours ion exchange between dendrimers during the formation of gold nanoparticles. By using penetration of hydroxyl-terminated PAMAM dendrimers into PHEMA followed by the formation of dendrimer-encapsulated nanoparticles one can prepare novel hybrid materials containing nanostructured polymer fragments and encapsulated nanoparticles.[76]

The effect of the dendrimer generation in systems with surface hydroxyl groups on the nanocomposite morphology has been studied in detail.[77] It was shown that low dendrimer generations undergo aggregation upon stabilisation of metal nanoparticles, whereas G6–G9 dendrimers can stabilise one nanoparticle per dendrimer and the particle size can be controlled with ease by varying the number of metal atoms. These results are consistent with the published data.[74] Experiments with G10 dendrimers revealed the formation of several small metal particles per dendrimer. To increase the stability of metal nanoparticles in various media, dendrimers can be modified by attaching PEO chains to the terminal amino groups of PAMAM macromolecules.[78] This has no effect on the ability of dendrimers to control the nanoparticle growth but provides better compatibility with a broad range of solvents and with a number of polymers. When using dendrimers with terminal glucose residues, the reduction of gold and silver ions and subsequent formation of nanoparticles from them is performed in an alkaline medium. Oxidation of hydroxyl groups does not require the use of additional amount of the reducing agent; however, nanoparticles thus obtained are characterised by a very broad size distribution.[79,80] Apparently, here we deal with facilitated exchange of metal ions between the dendrimer molecules because the terminal groups are involved in the reduction of metal ions.

Hydrophobically modified PAMAM dendrimers were used to form gold nanoparticles of size 2 to 4 nm in toluene and chloroform.[81] Recently, polypropyleneimine-based dendrimer modified by adamantyl groups have been reported.[82] The idea of these experiments was to involve hydrophobic groups in the interaction with amphiphilic block-cyclodextrin (the inner cavity of this molecule also possesses hydrophobic properties) and thus to prevent inter-dendrimers reactions during the sorption of metal ions and formation of nanoparticles. However, in spite of the complexity of this approach, the degree of control of nanoparticle growth was the same as that achieved using hydroxyl-terminated PAMAM dendrimers. Namely, no stabilisation of nanoparticles was observed with low-generation dendrimers, whereas higher-generation dendrimers permitted formation of nanoparticles with a narrow size distribution.

Another type of hydrophobic modification is to use polypropyleneimine-based dendrimers with stearyl terminal groups.[83] In toluene, they form inverse micelles with collapsed cores; however, sorption of metal salts causes the formation of cylindrical multi-dendrimer structures with swollen cores containing no metal salt. The action of the reducing agent leads to the formation of spherical gold nanoparticles and to the breakdown of cylindrical structures. These composite materials are thought to be of interest as catalysts and in the design of materials with specific optical properties (though these properties were not studied). Higher generation PAMAM dendrimers are commercially available but their synthesis is a multistage process. Because of this, the use of dendrimers seems to be no more promising compared to block copolymers.

Analogously to other nanostructured polymer matrices (*e.g.*, block copolymers or microgels), dendrimers containing encapsulated nanoparticles can be used as templates for the formation of mesoporous materials containing nanoparticles in pores. For instance, dendrimers containing Cu^{2+} ions were used[84] as templates for the formation of mesoporous silica. However, these templates provided no high SiO_2 porosity and ordered pore structure. Structural ordering is of great importance for the manifestation of optical properties while low porosity is inappropriate for catalytic applications (those materials containing encapsulated CuO nanoparticles were assumed to be efficient catalysts). We believe that only those templates that allow interpenetrating pores to be formed are promising for the fabrication of mesoporous materials containing encapsulated nanoparticles.

Introduction of metals and synthesis of nanoparticles can also be performed with carbosilane dendrimers[85] as well as nitrogen-containing and phosphorus-containing dendrimers[86,87] that offer the possibility of sorption of mixed transition metal clusters.

Thus, the use of dendrimers provides a means for fine control of nanoparticle growth under particular conditions. However, multistage synthesis of these macromolecules and the necessity of purification in each stage of the process complicate practical implementation of these systems as nanoreactors.

V. Metal nanoparticle formation in cavities (pores) of a polymer matrix

Controlled growth of metal nanoparticles in a polymer matrix is possible if it occurs in cavities or pores. In this case, the size of the growing particles can be limited to the cavity size. In the text below we consider two cases: (1) cavities contain no functional groups interacting with metal compounds and with the surface of nano-

particles and (2) cavities contain reactive groups favouring sorption of metal compounds into the polymer.

The first case can be illustrated taking the synthesis of metal nanoparticles in pores of crazed polymers [88] and in pores of hyper-cross-linked polystyrene (HPS) developed at the A N Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences.[89,90]

1. Nanoparticle growth in pores formed as a result of delocalised crazing of polymers

Delocalised crazing of polymers upon mechanical tension in adsorption active media (solvents) permits preparation of polymers containing reactant accessible open interpenetrating pores 3–6 nm in diameter. These pores can be used as templates for metal nanoparticle formation after introduction of corresponding reactants.[91,92] This procedure was employed to obtain nickel nanoparticles in porous polypropylene (PP) and poly(ethylene terephthalate) (PETP). A study of the reduction of nickel perchlorate with sodium borohydride in polymers with different morphologies and pore structures showed that the pore sizes govern the growth of nanoparticles. An interesting aspect of development of a crazed morphology is deformation of the polymer in a solution containing the corresponding metal complex. The synthesis of copper nanoparticles in high density polyethylene (HDPE) matrix was reported.[93] HDPE was crazed in monoethanolamine (MEA) solution containing complex copper salts and MEA. The formation of cavities in HDPE was accompanied by sorption of the copper compound into them. Subsequent heating of the composite material resulted in the formation of metal nanoparticles. However, this technique is inappropriate for preparation of nanoparticles with a narrow size distribution.

2. Metal nanoparticle formation in pores of hyper-cross-linked polystyrene

Hyper-cross-linked polystyrene is the first representative of a new class of cross-linked polymers characterised by unique topology and unusual properties. The internal morphology of HPS is schematically shown in Fig. 11.[94]

Hyper-cross-linked polystyrene has a rather large inner surface area (usually nearly 1000 $m^2\ g^{-1}$) and the ability to swell in any liquid medium including precipitating agents of the starting polymer. The HPS matrix used to form cobalt and platinum nanoparticles was characterised by a formal degree of cross-linking of 200%, an inner surface area of 833 $m^2\ g^{-1}$ and a narrow pore size distribution with a maximum at about 2 nm.

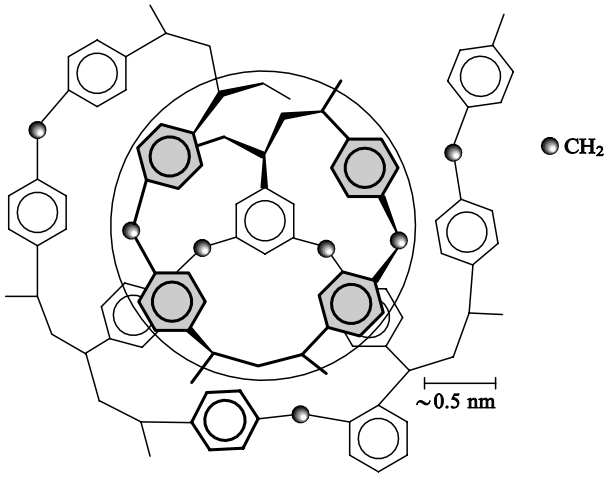

Figure 11. Schematic view of the HPS morphology.[94]
Shaded phenyl rings are in the foreground and bright phenyl rings are in the background. The circle denotes an individual pore of the hyper-cross-linked network.[94]

a. Cobalt nanoparticles in hyper-cross-linked polystyrene

The formation of metal nanoparticles in the HPS matrix was studied taking cobalt particles as examples, because the size and shape of cobalt nanoparticles are known to be related to their magnetic characteristics. Changes in the magnetic properties of the particles manifest themselves in changes in the spectral parameters of ferromagnetic resonance (FMR).[95] Particles of size less than 1 nm do not possess any magnetic properties. Particles 1 to 10 nm in diameter possess superparamagnetic properties. Larger particles are ferromagnetic. Moreover, the width of the signal of spherical particles in the FMR spectrum (ΔH) depends on the particle size while the position of the absorption maximum (H_0) is related to the shape of the cobalt nanoparticles.[95,96] Thus, information on the size and shape of cobalt nanoparticles can be extracted from their FMR spectra.

A cobalt compound, $Co_2(CO)_8$, was introduced into the HPS matrix from solutions in DMF and isopropyl alcohol. The reaction of $Co_2(CO)_8$ with DMF results in a relatively stable complex, $[Co(DMF)_6]^{2+}[Co(CO)_4]^{2-}$, while in isopropyl alcohol, a molecular solution is formed. Both materials were heat-treated at 200 °C. The H_0 and ΔH values for the HPS–Co samples prepared using the starting compound $Co_2(CO)_8$ in isopropyl alcohol and $[Co(DMF)_6]^{2+}[Co(CO)_4]^{2-}$ are listed in Table 2. As can be seen, an increase in the Co content to 8 mass % has little effect on the FMR spectral parameters and they are independent of the type of the starting Co-containing compound used in the experiments. The position of the absorption maximum, H_0, for all the samples under study indicated the formation of spherical cobalt nanoparticles.[95] According to TEM data, the average particle diameter was 2.1 ± 1.0 and 2.6 ± 1.6 nm for the samples with a cobalt content of 5.07 mass % and 10.08 mass %, respectively.[94]

Table 2. H_0 and ΔH values for HPS–Co samples prepared from different starting metal compounds.[94]

Co content (mass %)	H_0 /Œ	ΔH /Œ
Starting compound — $Co_2(CO)_8$ in isopropyl alcohol		
0.85	3100	125
2.58	3050	125
3.41	3100	200
5.69	3100	200
7.09	3125	200
Starting compound — $[Co(DMF)_6]^{2+}[Co(CO)_4]^{2-}$		
0.26	3100	125
1.85	3050	150
5.07	3075	160
8.22	3090	200
11.22	3105	350

Thus, it is the nanoscale voids in HPS that are responsible for controlled formation of Co nanoparticles in the relatively wide range of cobalt concentrations (from 0.9 mass % to 8.0 mass %). The most probable reason for controlled growth of Co particles in the HPS matrix is non-specific interaction between the phenyl rings and the metal surface, which must result in steric stabilisation of the cobalt nanoparticles. At cobalt concentrations exceeding a certain limiting value (> 8 mass %), growth of large nanoparticles begins. In this case, the particle size can reflect either the HPS pore size distribution statistics or the rearrangement of HPS morphology caused by the presence of the metal.

b. Formation of platinum nanoparticles in hyper-cross-linked polystyrene pores

Hyper-cross-linked polystyrene is an interesting object for the creation of novel catalytic systems. This compound can act as a

nanostructured matrix, which governs the particle growth, and as a carrier of catalytically active particles. Moreover, HPS can swell in almost all solvents. This can provide access to catalytic sites in virtually all reaction media.

A model study was carried out taking the formation of platinum nanoparticles in HPS pores as an example. Platinum was introduced into the polymer matrix by sorption of H_2PtCl_6 from solutions in THF or methanol. In contrast to the synthesis of cobalt nanoparticles, the formation of platinum nanoparticles involved the reduction of platinum compounds with hydrogen gas at moderate temperatures (the case of restricted migration of these compounds within the HPS matrix). In Fig. 12 we present a TEM micrograph of HPS containing encapsulated platinum nanoparticles (sorption of H_2PtCl_6 was conducted in THF) and a nanoparticle size distribution histogram. As can be seen, the average particle size is 1.3 ± 0.3 (*cf.* the average size of Co nanoparticles in HPS is ~ 2 nm). This difference can be explained by different mechanisms of formation of metal nanoparticles. At 200 °C, cobalt clusters can readily migrate into the HPS pores, thus forming particles that match the pore size. In the case of platinum, reduction with H_2 proceeds at room temperature (no migration of the platinum atoms or clusters or the molecules of the starting metal compound occurs); therefore, the nanoparticle size exactly matches the number of metal ions in the pores.[97] Thus, in the formation of cobalt nanoparticles the HPS matrix directly controls the metal nanoparticle size by physically limiting the particle size to the pore size (2 nm). In the case of platinum nanoparticles the pores impose restrictions on the amount of the starting metal compound that fills an individual pore; the reduction causes the volume of this compound to decrease (particle density increases) down to the volume of a single particle.

We believe that nanoporous polymers are promising as matrices for creation of efficient heterogeneous catalysts. However, they are inappropriate if the goal is to form thin films or homogeneous solutions.

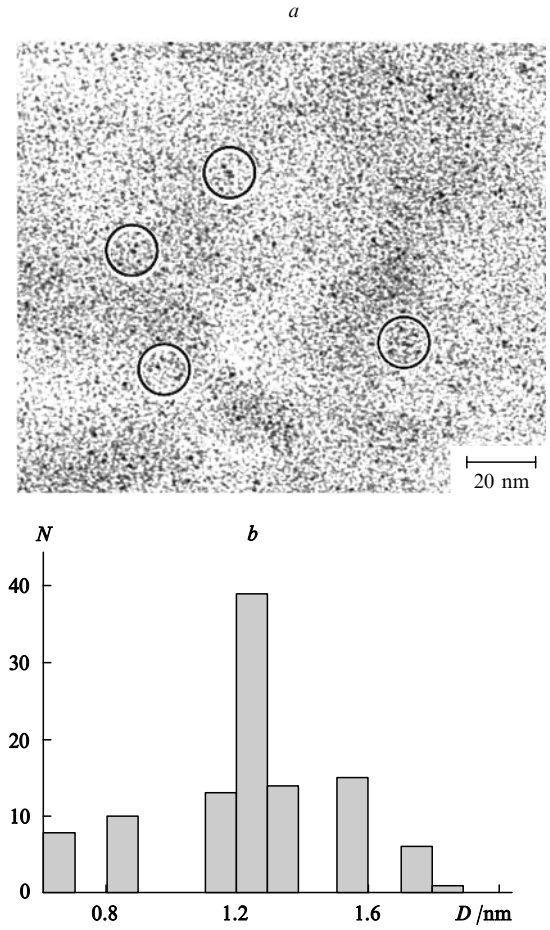

Figure 12. TEM micrograph of HPS containing encapsulated platinum nanoparticles (sorption of H_2PtCl_6 was conducted in THF) (*a*) and a histogram of nanoparticle size distribution (*b*).[97]
D is the particle diameter and *N* is the number of particles.

3. Formation of metal nanoparticles in cavities of nanostructured polyoctadecylsiloxane

Yet another example of control of the growth of metal particles confined in a cavity is provided by the formation of nanoparticles in the bisiloxane layers present in polyoctadecylsiloxane (PODS).[98, 99] This polymer is obtained by hydrolytic polycondensation of octadecyltrichlorosilane in water. The reaction results in a polymeric condensate comprising lamellar microcrystallites in which inorganic siloxane chains form periodically arranged layers separated by crystalline domains (alkyl chains). It was assumed that (i) placing the polymer in a metal salt solution would lead to the sorption of the salt into the hydrophilic layer of the polymer and (ii) subsequent reduction must result in the formation of metal nanoparticles regularly arranged within the material (see Fig. 13). However, it was found that sorption of metal compounds into this nanostructured polymer strongly depends on the type of the metal compound employed.[101] Ions with a planar structure (*e.g.*, $PtCl_4^{2-}$) easily penetrate into the interior of the thin layer (2–3 nm), while the penetration of octahedral ions $PtCl_6^{2-}$ is hindered. The penetration of metal ions is assumed to be entropy driven; namely, an increase in entropy results from the formation of hydrogen bonds between the Cl atoms of the salt anions and the silanol groups (each $PtCl_4^{2-}$ ion can replace up to four water molecules). The formation of nanoparticles in the siloxane double layer occurs upon the reduction of platinum and palladium compounds. The process is independent of the type of the reducing agent and the metal compound and on the concentration of the latter and is governed exclusively by the growth of the metal particles confined within the siloxy bilayer cavity. The particle size distribution for platinum particles obtained in this polymer is shown in Fig. 14. Figure 15 presents a TEM micrograph of a material containing palladium nanoparticles.[100] As can be seen, the metal particles are located exclusively within the siloxy bilayers.

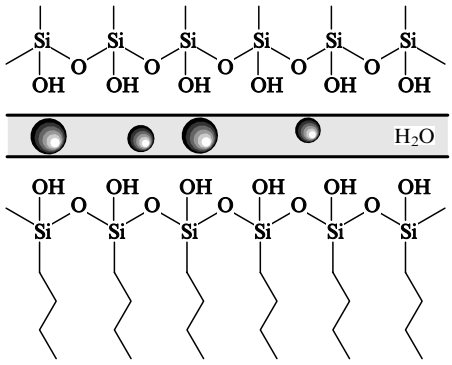

Figure 13. Scheme of nanoparticle formation in the siloxy bilayer of PODS.[100]

Thus, the presence of voids in nanostructured polymers permits control of the nanoparticle growth while the presence of functional groups ensures efficient and uniform sorption of metal compounds into the bulk material. At the same time, the metal content in these polymers is low because only the siloxy bilayers contain silanol groups.

The synthesis of novel highly functionalised colloidal polymer particles by hydrolytic condensation of *N*-(6-aminohexyl)aminopropyltrimethoxysilane was developed.[102] Polysilsesquioxane (PSSO) thus obtained is water soluble and has a structure

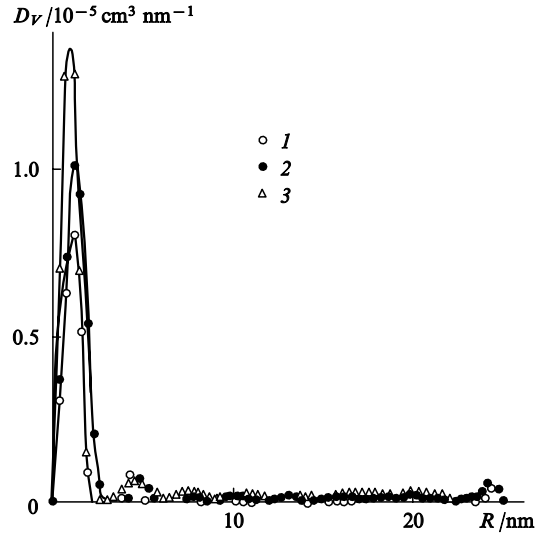

Figure 14. Volume distribution functions of platinum nanoparticles in PODS.[101]
Samples were prepared *via* sorption of K_2PtCl_4 after reduction with silanol groups of PODS (*1*) and *via* sorption of $H_2PtCl_6 \cdot 6\,H_2O$ after reduction with H_2 (*2*) and sodium borohydride (*3*).

Figure 15. TEM micrograph of palladium nanoparticles formed in PODS from Na_2PdCl_4 upon reduction with $NaBH_4$.[100]
Palladium nanoparticles were prepared in the siloxy bilayers of PODS with lamellar nanostructure. Palladium and silicon atoms provide a rather high contrast relative to the alkyl layers.

characterised by high degrees of cross-linking and functionalisation. Functionalised cavities in the PSSO structure act as nanoreactors for nanoparticle formation and provide a high metal loading (up to 35 mass %). The nanoparticles are 1–2 nm in diameter and do not undergo aggregation within the PSSO matrix. Colloidal PSSO particles filled with metals or metal compounds can form surface dendritic structures. We believe these systems are candidates for catalysts and chemical sensors.

VI. Properties of nanostructured polymeric systems containing metal nanoparticles

The unique properties of metal nanoparticles are mainly due to the large total surface area and to the considerable number of surface atoms. For instance, nearly 60% of the total number of atoms in a gold particle 2 nm in diameter are on the surface. In semiconductor and metal nanoparticles, this permits efficient charge transfer from the bulk of the material to the surface and *vice versa* (this manifests itself in, *e.g.*, changes in the optical absorption spectra). The surface of nanoparticles plays an important role in catalysis, being responsible for their selectivity and activity. Therefore, the characteristics of the stabilising polymer (its functionality and nanostructuring) and nanoparticles are of great importance, because they mainly determine the state of the surface of nanoparticles.[103]

1. Catalytic properties

Polymer-stabilised colloidal metal particles have been known to be hydrogenation catalysts for more than five decades. For instance, olefin hydrogenation catalysts based on palladium, platinum,[104,105] rhodium [106] and iridium [107] were prepared using poly(vinyl alcohol) and poly(vinyl acetate) as stabilisers. Most studies are concerned with the synthesis of nanoparticles inside homopolymer matrices that cannot provide a narrow particle size distribution (because of this, particles within the same sample can possess quite different catalytic properties). This reduces the selectivity and activity of a given catalyst.

Taking platinum nanoparticles stabilised by polymer surfactant micelles as an example, it was shown [108,109] that the state of the surface of metal nanoparticles plays an important role. These catalysts prepared within inverse micelles formed by cationic, anionic and non-ionic polymeric surfactants were employed in the isomerisation and hydrogenation of n-butene. The highest activity of the catalyst was achieved using a non-ionic surfactant; however, in all cases, the catalysts were an order of magnitude less active than conventional supported catalysts. Probably, the layer of the surfactant molecules adsorbed on the surface of a metal particle made the catalyst sites inaccessible to the substrate. At first glance, this negative conclusion is quite interesting from the standpoint of improvement of catalyst selectivlty. By choosing an appropriate stabiliser it is possible to achieve a great difference between the diffusion rates of different substrates towards the surface of the catalyst. The effect of surfactant micelles on the hydrogenation of long-chain unsaturated acids (*e.g.*, isomers of undecenoic acid and oleic acid) was studied taking platinum and palladium nanoparticles stabilised with a non-ionic surfactant poly(ethylene glycol monolaurate) as examples.[110] In these systems, the surface of the metal particle is protected by hydrophobic laurate chains while hydrophilic poly(ethylene glycol) chains form the micelle shell.

In this case, the position of the double bond in the substrate governs the hydrogenation rate because the substrate molecule is specifically arranged in the micelle wall. The ordered environment of the metal particle forces the acid molecule to be oriented in such a way that the polar carboxyl group is in the hydrophilic fragment of the micelle and the hydrophobic fragment of the molecule is surrounded by hydrophobic core-forming laurate chains. The acid hydrogenation rates obey the following pattern: undec-10-enoic acid > oleic acid > undec-2-enoic acid. This indicates that the terminal double bond is best accessible to the active sites of the catalyst, whereas the inner double bond has poorer access to the surface of the platinum particles. Platinum nanoparticles stabilised by poly(*N*-vinyl-2-pyrrolidone) (PVP) possessed no regioselectivity except in the cases where sodium salts of unsaturated acids were used. Here, the substrate behaved as a surfactant and the effect of PVP could be ignored.

Modification of the catalyst properties by forming a stabilising shell surrounding the particle is possible only in the case of metal nanoparticles. This is a great advantage of these particles over other catalysts of polyfunctional substrate hydrogenation. Thus, the use of nanostructured polymers permits not only control of nanoparticle growth but also further modification of the nanoparticle surface, which is of considerable value for catalytic applications.

A somewhat different approch was also developed.[42,43] As described above, corona-embedded metal nanoparticles were synthesised by the reduction of corresponding starting compounds of palladium and platinum in the presence of amphiphilic block copolymers (PS-*block*-PEO and PS-*block*-PMAA) in alcoholic and aqueous solutions. The catalytic activity of nanoparticles was assessed taking cyclohexene hydrogenation as a model

reaction. The particle activity was strongly dependent on the procedure for preparation and on the type of starting compounds. The formation of palladium and platinum nanoparticles in the presence of latex dispersions of different hydrophobicity was studied.[111, 112] In some cases, metal nanoparticles were adsorbed and immobilised on the latex surfaces, which was confirmed by TEM data. These dispersions exhibited catalytic activity in the model reaction of cyclohexene hydrogenation. Highly hydrophobic latexes caused such strong immobilisation of nanoparticles that they remained on the latex surface after performing catalytic cycles.

Silver and platinum nanoparticles synthesised in multilayered polyelectrolyte films[113] possessed electrocatalytic properties in methylene bromide reduction; however, these catalysts are less efficient than pure silver electrode because polymer films are insulators. These data are consistent with the results obtained by Zhao and Crooks[72] who used dendrimer-encapsulated platinum nanoparticles deposited on an electrode as a catalyst for an electrocatalytic reaction. Clearly, in spite of some catalytic activity these polymeric systems with encapsulated metal nanoparticles are of no promise as electrode coatings in electrocatalytic reactions, because the insulating properties of the polymer reduce the catalyst efficiency.

Hydrogenation of dehydrolinalool (DHL, oct-6-ene-1-yne-3-ol) is an industrially important reaction in fragrance chemistry. Using catalysts based on palladium nanoparticles synthesised in PS-*block*-P4VP micelles, a selectivity of 99.5% in hydrogenation of the triple bond in DHL to a double bond was achieved.[114] Probably, modification of the metal surface by pyridine units of the P4VP core also contributes to the reaction selectivity. The use of bimetallic nanoparticles Pd/Au, Pd/Pt and Pd/Zn causes a modification of the electronic structure and surface geometry of palladium, which additionally enhances the selectivity up to 99.8%.[28]

Palladium nanoparticles stabilised by PS-*block*-P4VP micelles were used as catalysts of cross-coupling reactions between aryl halides and alkenes (Heck reaction).[115] These hybrid systems exhibited nearly the same efficiency as low-molecular-mass palladium complexes (conventional catalysts of the Heck reaction), being at the same time much more stable.

Direct catalytic L-sorbose oxidation into 2-keto-L-gulonic acid is an intermediate stage of the synthesis of ascorbic acid (vitamin C). At present, direct sorbose oxidation is not used on industrial scale because of the low selectivity of the process. Another synthetic route involves transformation of sorbose into di-*O*-isopropylidenesorbose followed by oxidation of the latter to give di-*O*-isopropylidene-2-keto-L-gulonic acid and then 2-keto-L-gulonic acid. Direct L-sorbose oxidation into 2-keto-L-gulonic acid was performed using the HPS–Pt samples described above. They were obtained by sorption of H_2PtCl_6 from methanol and THF both before and after the reduction with H_2, and contained different amounts of platinum.[97] It was found that the yield of 2-keto-L-gulonic acid (*i.e.*, oxidation selectivity) is strongly dependent on the conditions for preparation of catalysts. In particular, the highest yield (nearly 98%) was achieved with the HPS–Pt(H_2PtCl_6 + THF) samples. Additional reduction of the samples with H_2 reduced the selectivity by 8%–10%. A study on the structure of HPS–Pt before the catalytic reaction, after the induction period and after the catalytic reaction revealed transformations of H_2PtCl_6 and THF in the HPS pores, which resulted in the formation of mixed clusters comprised of $Pt^0/Pt^{II}/Pt^{IV}$ and ligands. Reduction with H_2 increases the proportion of Pt^0 in the sample, which can upset the optimum composition of the complex.

The $\ln\tau_{0.1} - 1/T$ Arrhenius plot constructed using the experimental data obtained at different temperatures gave a value of 34 kJ mol^{-1} for the apparent activation energy, E_a. This is lower than the activation energy for the reaction conducted with the conventional catalyst Pt/SiO_2 ($\sim$45 kJ mol^{-1}).

Metal nanoparticles are widely used in the important catalytic reaction known as the Suzuki reaction. The effect of the stabiliser matrix on the catalytic properties and stability of transition metal nanoparticles in solution was studied.[116] Palladium nanoparticles were prepared *via* the reduction of metal salt in the presence of three different polymer stabilisers, namely, hydroxyl-terminated PAMAM dendrimers (Gn–OH, where Gn is the *n*th dendrimer generation), PS-*block*-PANa (PANa is sodium polyacrylate) and PVP. The nanostructured systems obtained were used to study the effect of the matrix type on their catalytic activity and stability in the catalytic cross-coupling reaction between phenylboronic acid (or 2-thienylboronic acid) and iodobenzene in aqueous medium. The stability of palladium nanoparticles was evaluated using the data on the formation of palladium black after catalytic cycles. The Suzuki reaction is a good test for the stability of nanoparticles, because it proceeds at 100 °C for 24 h. Palladium nanoparticles stabilised by PAMAM-G3 dendrimer and PVP were found to be efficient catalysts of the Suzuki reaction. The G4 dendrimer was found to be a very efficient stabiliser; however, strong encapsulation of palladium nanoparticles in the dendrimer led to reduction of the catalytic activity. The two properties were found to be interrelated, namely, the higher the stability, the lower the catalytic activity (due to inaccessibility of the nanoparticle surface to the substrate). Both palladium- and platinum-containing PAMAM exhibited catalytic activity in the electrochemical reduction of oxygen.[117]

2. Magnetic properties

If the critical distance responsible for a physical property becomes comparable with the nanoparticle size, the magnetic properties of the nanomaterials change significantly. Changes in the magnetisation of a material always require the overcoming of an energy barrier, while any physical mechanism proposed for the description of the corresponding energy barrier includes a relevant linear parameter (length or distance). The main linear parameters used to describe the magnetic properties are as follows: the linear crystalline anisotropy, l_k, the action range of the applied field, l_H, and the magnetostatic distance, l_s; they are defined by the respective equations[118]

$$l_k = \sqrt{\frac{J}{K}},$$

$$l_H = \sqrt{\frac{2J}{HM}},$$

$$l_s = \sqrt{\frac{J}{2\pi M^2}},$$

where J is the constant for intradomain exchange, K is the anisotropy constant, H is the magnetic field strength and M is the saturation magnetisation.

If there is more than one energy barrier, the magnetic properties are determined by the shortest characteristic distance. For the most widely used magnetic materials these values are of the order of 1 to 100 nm (*e.g.*, $l_H \approx 19$, $l_k \approx 45$ and $l_s \approx 8$ nm for nickel in a magnetic field of 1000 Œ at room temperature).

The most interesting magnetic properties of nanoparticles are manifested in the case of monodomain nanoparticles. (Remind that a domain is a group of aligned spins that act in a concerted way and are characterised by the total magnetic moment.) In bulk materials, domains are separated by domain walls characterised by their thickness and formation energy. The reversible magnetisation effect is due to the domain wall motion. The formation of domain walls in bulk metal is energetically favourable but a decrease in the particle size down to a certain critical value, R_c, makes the formation of domain walls energetically unfavourable. This is the case for monodomain particles.[119, 120] Here, the magnetisation changes are due to synchronous spin rotation

resulting in a large coercive force rather than domain wall motion. Further decrease in the particle size causes the spins to be more sensitive to the influence of thermally induced fluctuations. Finally, all spins become completely disordered as the external magnetic field is switched off. Such systems possess properties of superparamagnetics and are characterised by zero remanent magnetisation and zero coercive force.

If magnetic nanoparticles were formed inside a polymer matrix, the nanocomposites obtained possess unique magnetic properties and can be used for electromagnetic shileding and for creation of novel magnetic and magneto-optical devices.[118, 119]

Metallic cobalt is often used in the fabrication of various magnetic devices. Cobalt nanoparticles less than 60 nm in size are monodomain particles characterised by a nonzero total magnetic moment. If the particle size lies between 10 and 60 nm (these values are rough estimates and depend on the particle shape), the total magnetic moment dominates the thermal motion of particles and they form linear chains due to the dipole–dipole interaction. Such materials are the best candidates for production of permanent magnets, magnetic pigments, coatings for magnetic data storage devices, *etc*.[119, 120]

Nearly monodisperse cobalt nanoparticles with controlled morphology were synthesised [121] using PS-*block*-P4VP micelles in organic solvents. Metallic cobalt particles were produced in two ways, by the chemical reduction of $CoCl_2$ and by the thermal decomposition of $Co_2(CO)_8$. The amount of the block copolymer was kept constant but the concentration of the starting metal compound was varied. This permitted the preparation of non-magnetic, superparamagnetic or ferromagnetic materials. Experiments with the ferromagnetic samples allowed the conditions for obtaining very high specific coercive forces (with respect to the cobalt concentration in the sample) to be chosen. Apparently, this is mainly due to the very narrow size distribution of the cobalt nanoparticles. These particles are characterised by high magnetisation and extremely high stability in air, which can be explained by the high degree of adsorption of pyridine units on the particle surfaces.

The magnetic properties of γ-Fe_2O_3 nanoparticles formed inside microdomains of an optically transparent block copolymer based on $[NORCOOH]_{30}[MTD]_{300}$ (NORCOOH is 2-norbornene-5,6-dicarboxylic acid; MTD is methyltetracyclododecene) have been reported.[122, 123] The nanoparticle size was 5 nm. The magnetic properties of the material were strongly dependent on the quantum effects, *e.g*., co-operative magnetisation and superparamagnetic relaxation. It was shown that these nanocomposite films exhibit superparamagnetic properties and possess no remanent magnetisation and coercive force at room temperature. At low temperatures, the coercive force of these films was 530 Œ.

3. Optical properties

The synthesis of manganese- and terbium-doped ZnS nanoparticles in the microsegregated films of diblock copolymers containing carboxyl groups in one block has been reported.[124] The concentration of dopant ions in the microdomain containing the carboxyl groups was controlled by varying either the concentrations of aqueous solutions of the metal salt or the exposure time of the polymer film in solution. The doped ZnS nanoclusters were formed during subsequent treatment of the films with hydrogen sulfide. These films exhibit photoemission characteristic of the dopant ions (manganese and terbium). The synthetic procedure has no features and can be used for the preparation of doped semiconductor nanoparticles involving combinations of various metal salts.

Optically stable CdS nanoparticles were synthesised within a hydroxyl and amino group terminated G4 PAMAM dendrimer.[125] The UV spectra and luminescence spectra showed that the dendrimer stabilises nanoparticles whose optoelectronic properties differ from the corresponding properties of bulk CdS. Dendrimers are prone to aggregation, which depends on the temperature and particle concentration; however, the characteristics of the cadmium sulfide nanoparticles remained unchanged. Studies of the solutions stored at -10 °C revealed that the dendrimers did not undergo aggregation over a period of several months and that the solutions also possessed photoluminescent properties.

Another procedure for the formation of analogous nanocomposites involves PEI as the polymer stabiliser.[126] The optical properties of the particles thus obtained were similar to those of the particles described above (emission in the blue spectral region) but the quantum yield of luminescence was lower. The authors [126] believe that high local concentration of chelating nitrogen atoms (in the dendrimer or PEI) is the major factor affecting the formation of small nanoparticles with perfect morphology.

A XANES study of nanocomposites based on CdS nanoparticles and G4 PAMAM dendrimers was also reported.[127] Investigation of the structure of CdS nanoparticles revealed the presence of sulfates and oxides. A joint X-ray induced optical luminescence–XANES study also revealed correlations between the optical properties and the structure of CdS nanoparticles.

An interesting nanocomposite was obtained by incorporating CdTe nanoparticles into thin films prepared by layer-by-layer deposition of an anionic polyelectrolyte containing a poly(*para*-phenylenethynylene) (PFE) chain and poly(allylamine hydrochloride) (PAAHC) as the polycation.[128] The CdTe nanoparticles were stabilised by poly(ethylene glycol) (PEG)-containing reactive terminal groups. Nanoparticles were incorporated into the multilayered composite *via* chemical bonding to the stabiliser (PEG). The interaction between polyconjugated polymer and nanoparticles provided conjugation transfer, which manifested itself as changes in the optical properties. The luminescence spectrum exhibited a new peak at 600 nm due to the emission of CdTe nanoparticles. The excitation spectrum of CdTe–PEG-*block*-PFE recorded at 600 nm exhibited a new intense band at 400 nm corresponding to the absorption band of the multilayered composite. This is evidence of energy transfer between PFE and the nanoparticles. By varying certain structural parameters of the composite (*e.g*., the PEG chain length) one can change the optical properties. This system is expected to be suitable for fabrication of multilayered optical devices.

4. Electrical properties

A trend towards miniaturisation and high integration of elements of electric circuits has been a salient feature of modern microelectronics. As a rule, the shorter the distance between the elements of a device, the higher the performance of the device. Lithography techniques permit fabrication of working elements of size up to 100 nm, which has opened new prospects for their application using quantum effects. At present, using the Coulomb effect in electric circuits (including submicrometre-sized tunnelling junctions) allows one to control single charge carriers. Research in this field serves as the basis for fabrication of the so-called single-electron devices (SEDs).[129]

The Coulomb effect has long been known, however, studies on SEDs have been a particular avenue of scientific research only recently. Fifteen years have passed since the beginning of intensive studies into ultrasmall sandwich structures of the type metal–insulator–metal (tunnelling junctions).[130] It was shown that the electric charge discreteness becomes significant under particular conditions. Namely, quantum electron tunnelling in the system of tunnelling junctions is affected by the Coulomb inter-electron interaction, which can in turn be varied by applying an external voltage. This phenomenon is called single-electron tunnelling. It serves as the basis for the operation of any SED.

A practical implementation of the SED idea in systems with characteristic capacities of the order of 10^{-15} to 10^{-16} F (these values are typical of modern lithography techniques) requires that the samples be cooled down to a few thousandths of a Kelvin. Room-temperature operation of the SED dictates a reduction of the characteristic capacity by at least two orders of magnitude, which can be achieved using nanometre-sized metal nanoparticles.

Recent advances in lithography, made due to miniaturisation of electronic devices, cannot meet all the requirements from room-temperature operation of SEDs.[131] This problem can be solved by using ligand shell stabilised metal nanoparticles. These particles are thought to be promising as structural elements of novel nanoelectronic devices. A challenge is to develop novel methods for the fine adjustment of such elements in SED design at different scales of integration. Therefore, the use of the principles of self-organisation and controlled intermolecular interaction favours progress towards the design and fabrication of new electronic devices.

The use of dendrimers for the synthesis of metal nanoparticles can simplify some engineering aspects of SED fabrication. The dendrimer macromolecules are characterised by very narrow particle size distribution and an exact number of functional groups. This allows single nanoparticles to be synthesised within individual macromolecules. In contrast to low-molecular-mass ligands, dendrimers have particular chemical structures characterised by the absence of exchange and relaxation processes, provided that the surface functional groups are protected by hydrophobic groups. This permits fine control of the nanoparticle parameters and the thickness of the insulating layer, which is impossible in the case of conventional low-molecular-mass ligands. Dendrimer molecules can self-assemble in the course of, *e.g.*, adsorption from solutions onto appropriate surfaces. Block copolymer micelles with cross-linked cores or coronas can also be used for these purposes. In these systems, micelles are characterised by a very narrow size distribution, which allows a single nanoparticle per core to be generated under particular conditions.[27] A necessary condition for proper SED operation consists in self-organisation of such filled micelles on the surface (this is usually employed in nanolithography [29]). Because of this, we believe that the use of the unique properties of nanoparticles formed in nanostructured polymeric systems for fabrication of SEDs is a promising field of application.

* * *

There are a variety of nanostructured polymeric systems that can provide control of the formation of nanoparticles, stabilise nanoparticles and modify their surface due to the effect of the polymer chains. Among them, prospects for particular systems are determined by the possible fields of application. We believe that block copolymer micelles and dendrimers are the best candidates for use as nanostructured polymeric systems providing the possibility of nanoparticle formation in solutions. It should be noted that block copolymer micelles can form films and coatings, which is of particular importance for application in catalytic, magnetic and optical systems. Block copolymer micelles and dendrimers can adsorb on surfaces to form monolayers. Nanoporous materials are thought to be the most promising for the formation of nanocomposite catalysts of heterogeneous processes. These materials are simple and cheap, they permit control of particle growth, accessibility of reactive sites to substrates and do not require additional heterogenisation.

Contents

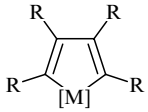
I.	Introduction	517
II.	Dinuclear complexes with the metallacyclopentadiene fragment	518
III.	Coordination of the metallaindene fragment	527
IV.	Trimetallic clusters with a pentagonal-bipyramidal geometry	529
V.	Coordination of the metallacyclopentadiene fragment to transition metal clusters	531
VI.	Conclusion	537

Abstract. Results of structural studies of polynuclear transition metal complexes containing the metallacyclopentadiene fragment are overviewed. The structural features of the complexes in relation to the nature of the substituents in the organic moiety of the metallacycles, the nature of the transition metals and their ligand environment are analysed. The main structural characteristics corresponding to different modes of coordination of metallacyclopentadienes to one or two additional metal centres are revealed. The bibliography includes 154 references.

I. Introduction

Metallacycles and their complexes occupy a special place in modern organometallic chemistry because of their higher stability compared to acyclic analogues (the so-called chelating effect) as well as the diverse applications of metallacyclic compounds in both fundamental and applied investigations. The formation of metallacyclic fragments is observed in many reactions of organic substrates with transition metal complexes, for example, in cycloaddition, insertion of metal atoms into C–H bonds, reactions accompanied by dimerisation of unsaturated molecules through C–C coupling or reactions involving carbonyl, nitrile and other ligands of the starting complex. Methods for the synthesis of compounds containing metallacyclic fragments and their chemical properties were described in general reviews [1,2] as well as in reviews devoted to special problems.[3–5] Transition metal complexes containing metallacyclic fragments play an important role in metal-catalysed chemical transformations, such as alkene and acetylene metathesis, isomerisation of strained rings, cycloaddition of alkenes, oligomerisation of dienes and polymerisation.

Coupling of alkenes or alkynes in the coordination sphere of metal atoms is widely used in the synthesis of metallacyclic compounds giving rise primarily to five-membered metallacycles.[1,2] Of particular interest are five-membered unsaturated metallacycles, the so-called metallacyclopentadienes (MCPs).



The MCP fragment is considered as an important intermediate in the synthesis of organic compounds from alkynes,[5–10] for example, in cyclotrimerisation of alkynes to form benzene derivatives and in the synthesis of quinones and tropones. Synthesis methods and studies of the chemical properties and structural features of transformation products of alkynes involved in transition metal complexes, including investigations of polynuclear complexes with the MCP fragment, were covered in the reviews.[11–14] In these complexes, the metallacycle generally serves as a π ligand with respect to transition metal atoms. Investigation of the coordination ability of the MCP fragment, particularly, taking into account its close analogy to the cyclopentadienyl ligand, is of interest not only for the development of the chemistry of certain systems but also for solution of more general problems of organometallic chemistry associated with a search for new 'non-classical' π ligands. Single-crystal X-ray diffraction is used as the main experimental method for studying the structures of MCP complexes.

Extensive experimental data on the structures of polynuclear transition metal complexes, in which the MCP fragment is involved in binding to one or several metal atoms, are available. According to the Cambridge Structural Database (CSD),[15] more than 350 structures of such compounds were characterised. For some series of related compounds, the results of structural studies were systematised (see, for example, the reviews [13,16,17]). However, abundant data on the structures of complexes with the MCP fragment have remained beyond the scope of these publications.

The present review covers the results of structural studies of polynuclear complexes containing the MCP fragment with special emphasis on comparative analysis of the structure of the MCP fragment and the modes of its coordination in transition metal complexes depending on the ligand environment, electronic state, the type and number of metal atoms, electronic and steric characteristics of substituents in the organic moiety of the metallacycle. We have restricted ourselves to complexes containing

† The present review completes a series of publications covering main fields of research of the A N Nesmeyanov Institute of Organoelement Compounds of the Russian Academy of Sciences [see *Russian Chemical Reviews* **73** (5) (2004)].

more than three metal atoms. Prominence is given to bi- and trinuclear complexes of metals for which most representative data are available in the CSD (metals of the iron and cobalt subgroups). The structure of the uncoordinated MCP fragment has been discussed in detail earlier.[2,18] Hence, we do not consider mononuclear complexes. Complexes with metallacycles, in which one or several carbon atoms are replaced with heteroatoms (N, O, S, *etc.*), are also beyond the scope of our review.

II. Dinuclear complexes with the metallacyclopentadiene fragment

The first structure of an MCP-containing dinuclear complex with composition $Fe_2(CO)_6\{C(OH)C(Me)C(Me)C(OH)\}$ (**1**) was published in 1961.[19] The structure of complex **1** is shown in Fig. 1. The authors believed that the Fe(1) and Fe(2) atoms are in different oxidation states (0 and 2+, respectively); the diene fragment is coordinated to the Fe(2) and Fe(1) atoms through two σ-bonds and two π-bonds, respectively. Equalisation of the C–C bond lengths in the ring is indicative of strong conjugation. One of the six carbonyl groups, *viz.*, C(10)O(10), is apparently semibridging with the Fe(1)–C(10)–O(10) angle of 168°. However, in the authors' opinion, the Fe(2)···C(10) distance (2.48 Å) is too large to be indicative of interaction between these atoms.

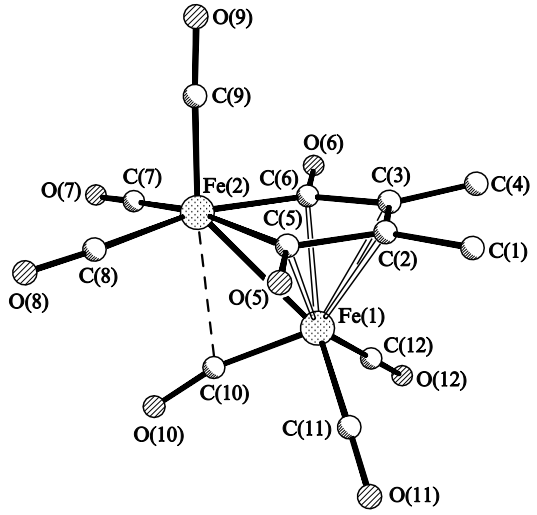

Figure 1. Structure of the $Fe_2(CO)_6\{C(OH)C(Me)C(Me)C(OH)\}$ complex (**1**).[19]
The hydrogen atoms are omitted, the atomic numbering scheme corresponds to that used in the original paper.

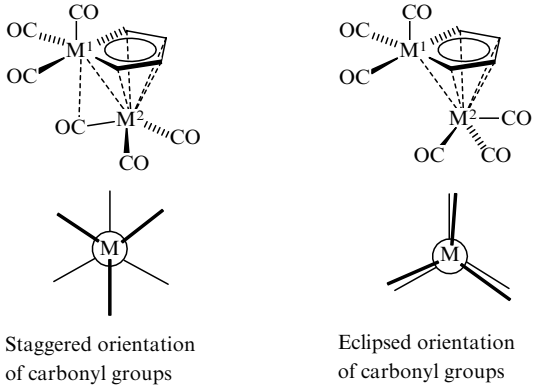
In the above-described compound, the structural motif, which proved to be typical of many bi- and polynuclear transition metal complexes, was found for the first time. Later on, the ferracyclopentadienyl fragment in complex **1** was given the short name ferrole. Nowadays all structurally similar dinuclear complexes are called complexes of the ferrole type regardless of the metal atoms involved in such complexes.

The structures of 158 dinuclear complexes of this type with different transition metals are included in the CSD. For convenience of comparison and discussion, typical compounds are shown in Fig. 2. The compounds are divided into five groups according to which subgroup of the Periodic Table the metal atom of the MCP fragment belongs. Each column in Fig. 2 begins with homometallic complexes with identical ligands (in most cases, these are carbonyl complexes) followed by heterometallic complexes (two different metal atoms, M^1 and M^2) and complexes with metal atoms in a non-equivalent ligand environment.

All compounds can formally be divided into two types according to the modes of distribution of electrons donated by an organic ligand between the metal atoms depending on the external ligand environment. In complexes of one type, the butadiene fragment forms two σ-bonds with one metal atom giving rise to a five-membered metallacycle, which is coordinated to the second metal atom through the metal–metal σ-bond and π-coordination of two alkene bonds of the diene fragment (η^1-η^4-coordination of the MCP fragment). For both metal atoms, the effective atomic number (EAN) rule is fulfilled, *i.e.*, the metal atoms have the filled 18-electron configuration (**A2**, **B1**, **B2**, **C4**, **D1** – **D3** in Fig. 2). In complexes of another type (**A1**, **C1** – **C3**, **D4**, **D5**, **E1**, **E2**), this description of coordination leads to non-equivalence of the electronic states of the metal atoms, which can be remedied by considering the metallacycle as a completely delocalised π-system (η^5-coordination of the MCP fragment). It should be emphasised that the use of these two limiting forms for the description of binding of the MCP fragments in dinuclear transition metal complexes of the ferrole type is based only on the formal application of the EAN rule. Nevertheless, as will be demonstrated below, the predominant contribution of one particular form was confirmed by the experimentally observed differences in the geometric parameters of ferrole complexes of different types.

1. Carbonyl complexes with metals of the iron subgroup

In crystals, dinuclear ferrole-type carbonyl complexes with metal atoms of the iron subgroup exist as one of two conformers, which differ in the orientation of the $M(CO)_3$ fragments with respect to the M–M bond. In most structures, like in complex **1**, the carbonyl groups have a staggered conformation giving rise to a shortened intramolecular contact between the endocyclic metal atom and one of the carbonyl groups at the exocyclic metal atom (this carbonyl group will be called semibridging). The second conformer is characterised by the eclipsed orientation of the carbonyl groups with the result that semibridging interaction is absent. In the general form, the structures of two conformers can be represented by the following scheme:



Dinuclear iron, ruthenium and osmium carbonyl complexes containing the MCP fragment are listed in Table 1 (structures available in the CSD and two compounds **31** and **32**, which were not deposited with CSD). Analogous complexes in which one or several carbonyl groups are replaced with other ligands (phosphine, alkene, *etc.*) are not considered. Polynuclear (containing more than two metal atoms) complexes bearing a ferrole-type fragment are also not included in Table 1. Selected compounds of this type are described below.

Analysis of the data from Table 1 shows that, first, isomers with a staggered conformation of carbonyl groups occur much more frequently than those with an eclipsed conformation of these groups (except for complexes of osmium for which only three structures of the type under consideration are known, and all these complexes have carbonyl groups in an eclipsed orientation). Second, for all compounds containing the semibridging carbonyl

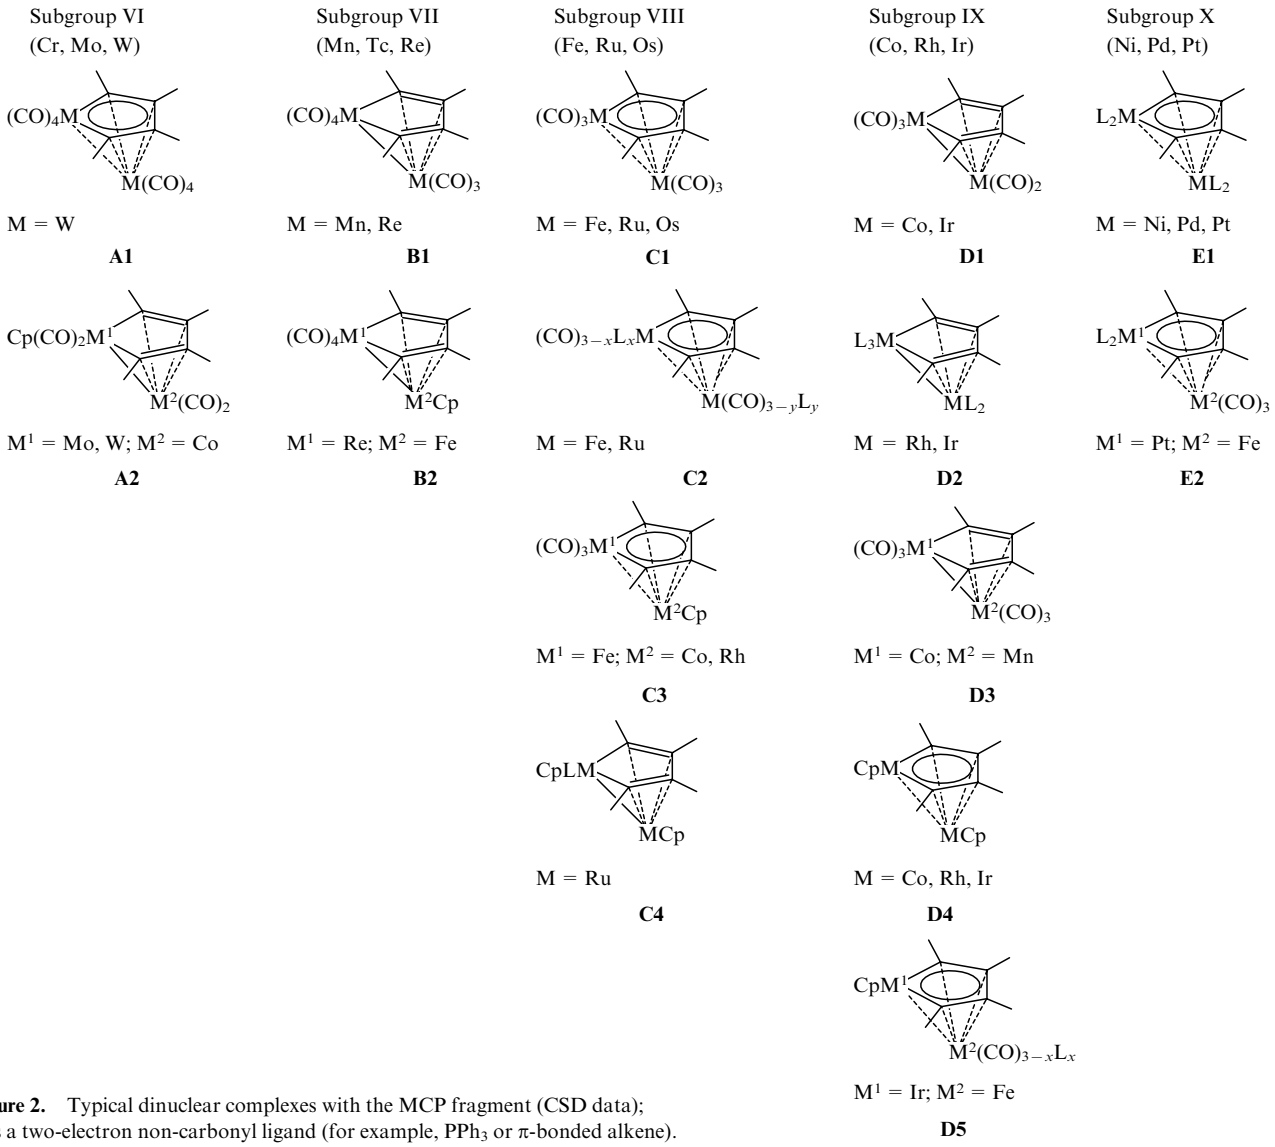


Figure 2. Typical dinuclear complexes with the MCP fragment (CSD data); L is a two-electron non-carbonyl ligand (for example, PPh_3 or π-bonded alkene).

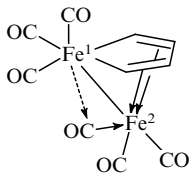
group, there is a clear correlation between the $M^1\cdots CO(4)$ distance and the deviation of the metal carbonyl group $M^2-C-O(4)$ from linearity. These parameters vary over rather wide ranges, whereas the M^1-M^2 bond lengths are in a relatively narrow range. For example, the $M^1\cdots CO(4)$ distances in the iron complexes with a staggered conformation of carbonyl groups vary from 2.281 to 2.596 Å, whereas the M^1-M^2 distances are in the range of 2.463–2.533 Å, which is apparently indicative of high mobility of the carbonyl ligands at the M^2 atom relative to the relatively rigid metal–metal bond and a very weak interaction between the M^1 atom and the semibridging carbonyl group. It should be noted that the iron complexes with an eclipsed conformation of carbonyl ligands (compounds **21**, **22** and **23**) are characterised by somewhat larger metal–metal bond lengths (2.538, 2.544 and 2.568 Å, respectively). However, such a correlation is not observed for ruthenium complexes.

The nature of the metal–semibridging CO group interaction, its role in stabilisation of the molecule, the reasons for the existence of one of two possible conformers and other problems associated with this interesting characteristic feature of dinuclear ferrole-type carbonyl complexes with metals of the iron subgroup were discussed in numerous structural and theoretical studies. In particular, the following scheme of charge redistribution in complex **2** with unsubstituted ferrole was proposed [20] (the formal description assumes a negative charge on the metal atom involved in the metallacycle and a positive charge on the second metal atom): back donation from the occupied d orbitals of Fe^1 to the π* orbital of the semibridging CO group, which, in turn, leads to an increase in σ-donation from this carbonyl group to the electron-deficient Fe^2 atom.



This scheme of charge density redistribution in transition metal complexes involving semibridging carbonyl ligands was proposed in the studies by Cotton (see, for example, Refs 50 and 51).

An alternative description was proposed in the publication,[46] where two ruthenium complexes (**31** and **32**) were considered. The authors of the cited study noted that the lengths of the $M^1-C(1)$ and $M^1-C(4)$ σ-bonds in these complexes and a number of other analogous compounds are close to the M=C double bond lengths in carbene complexes (the same fact was also mentioned in the study [20]). It is therefore concluded that there is a substantial additional π-contribution to binding of the metal atom M^1 in the ring. Hence, the charge redistribution in such complexes can occur as follows: $M^2 \rightarrow M^1 \rightarrow$ π electrons of the ring $\rightarrow M^2$. Therefore,

Table 1. Main geometric parameters for the dinuclear carbonyl complexes with general composition $(C_4R_4)M_2(CO)_6$ containing the MCP fragment (M^1, M^2 = Fe, Ru, Os; distances are given in Å, angles are given in degrees).

[a] M^2 = Fe (**1**–**24**), Ru (**25**–**33**), Os (**34**–**36**). [b] The C(1)−C(2)−C(3)−C(4) torsion angle. [c] The dihedral angle between the C(1)C(2)C(3)C(4) and C(1)M^1C(4) planes; the positive value corresponds to the deviation of the M^1 atom from the plane of the diene fragment in the direction opposite to the M^2 atom, the negative value corresponds to the deviation of the M^1 atom toward the M^2 atom. [d] Values are given for two independent molecules in the crystal. [e] The structures are unavailable in the CSD.

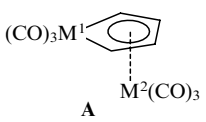
this process can take place without the involvement of a semibridging carbonyl group.

The contributions of Fe atoms and the diene fragment to the molecular orbitals of the ferrole complex $Fe_2(CO)_6(C_4H_4)$ were analysed in detail in the systematic study of the electronic structures of complexes containing the dinuclear fragment $M_2(CO)_6$, which is bound to various organic ligands.[52] It was demonstrated that there is an insignificant (0.2 eV) difference in the energy of two conformers of the complex with carbonyl ligands in eclipsed and staggered orientations. In the former case, there is a better overlap between the orbitals of the Fe^2 atom and the diene fragment. In the latter case, bonding interaction occurs between the Fe^1 atom and the semibridging carbonyl group.

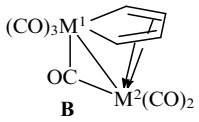
It should be emphasised that the interaction between the M^1 atom and the semibridging carbonyl group is weak in both cases. The results of ^{13}C NMR and IR spectroscopic studies of dinuclear complexes of the ferrole type at low temperatures (below −125 °C)[53–55] provide evidence for free rotation of the $M^2(CO)_3$ fragment in solution.

An interesting observation was made in the study of ruthenium complex **29**.[44] There are two independent molecules in the crystal. These molecules have similar geometry, except for the orientation of the semibridging carbonyl group (CO_{sb}); the $Ru(1)\cdots CO_{sb}$ distances in two independent molecules are 2.852(9) and 2.968(8) Å. An even larger difference in the $Ru(1)\cdots CO_{sb}$ distances [2.49(3) and 2.69(3) Å] was observed in two crystallographically independent molecules of complex **28**,[43] although the molecules differ only in the angle of rotation of the phenyl substituents with respect to the plane of the MCP fragment. Such substantial differences in the length of the $Ru(1)\cdots CO_{sb}$ contact, which are caused only by the crystal packing effects, confirm the conclusion as to a fine balance between forces responsible for the existence of one of two possible conformers.

Consequently, the structures of dinuclear ferrole-type carbonyl complexes with metals of the iron subgroup should be described with consideration for the contribution of two possible limiting forms (**A** and **B**):



A



B

In the first case (**A**), it is presumed that the endocyclic metal atom M^1 is completely integrated into the common π system of the MCP fragment through which the charge redistribution between two metal atoms occurs. For another limiting form (**B**), the charge redistribution occurs through the bridging carbonyl group, and the M^1 atom is not involved in the interaction with the π system of the butadiene unit of the metallacycle. However, the fact that the interaction between the endocyclic metal atom and the semibridging carbonyl group is weak as well as the flattened structure of the MCP fragment are indicative of the predominant contribution of the form **A**.

It can be assumed that the semibridging interaction characterises the degree of involvement of the endocyclic metal atom in the common π system of the MCP fragment. This assumption is supported by analysis of the structure of the MCP fragment in complexes **1**–**36** (see Table 1). With rare exceptions, the butadiene fragment in the metallacycles retains a planar structure (see the ω torsion angles in Table 1), whereas the endocyclic metal atom generally deviates from the plane of the butadiene system in the direction opposite to the second metal atom (parameter τ in Table 1). An interesting exception is compound **33**, which provides the only example of ruthenium complexes with carbonyl ligands in an eclipsed orientation.[47] The structure of this complex is shown in Fig. 3.

In the crystal, the molecule occupies a special position on the symmetry plane passing through both ruthenium atoms and the midpoint of the C(6)−C(6A) bond. Four carbon atoms of the metallacycle are coplanar, whereas the endocyclic Ru(1) atom deviates from the plane of the butadiene fragment by 0.134(1) Å toward the second metal atom Ru(2), *i.e.*, there is 'negative' folding ($\tau = -4.8°$) of the metallacycle along the C(5)···C(5A) line. It should be noted that the presence of two bulky ferrocenyl substituents in the α positions of the metallacycle in complex **33** has apparently only a slight effect on the structure of the MCP fragment, as evidenced by the absence of shortened intramolecu-

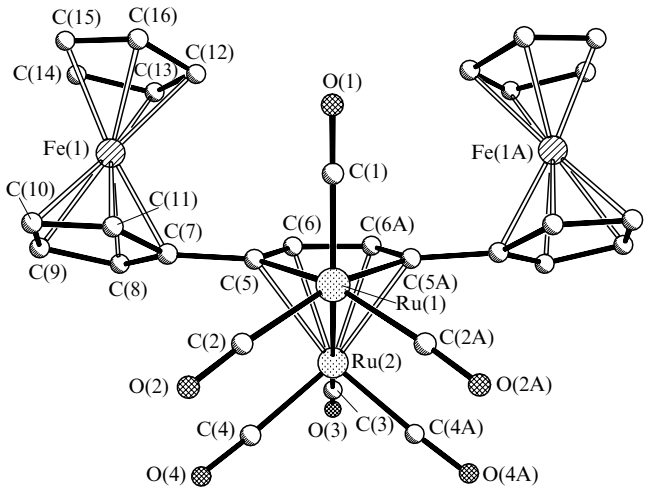


Figure 3. Structure of complex **33**.[47]

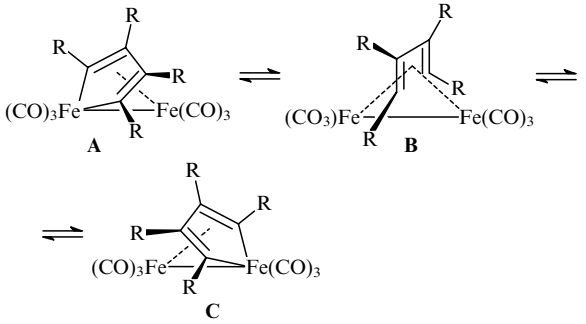
lar contacts. Besides, the negative value of the parameter τ is observed in two iron complexes (**21** and **23**), which also contain carbonyl ligands in an eclipsed orientation (see Table 1) and are devoid of sterically crowded substituents in the MCP fragment. In all other complexes with an eclipsed conformation of carbonyl ligands (**22**, **35** and **36**, see Table 1), the endocyclic metal atom deviates from the mean plane through four carbon atoms of the metallacycle in the direction opposite to the second metal atom. Nevertheless, in all complexes with eclipsed carbonyl ligands, folding of the MCP fragment is substantially smaller (the average angle $\tau = 4^\circ$) than that in complexes with staggered ligands and the semibridging carbonyl group (the average angle $\tau = 11^\circ$). Therefore, the MCP fragment is substantially flattened in complexes which contain carbonyl ligands in an eclipsed orientation and in which, correspondingly, additional interactions with the semibridging carbonyl group are absent.

The surprising thing is that the crystal structures of three dinuclear osmium complexes of the ferrole type (compounds **34**, **35** and **36**) are characterised by the eclipsed orientation of carbonyl ligands, whereas the staggered orientation (with the formation of the semibridging CO group) is typical of iron and ruthenium complexes. This fact was explained on the basis of *ab initio* calculations for $M_2(CO)_6(C_4H_4)$ (M = Fe, Ru, Os) complexes and comparison of these results with the data from UV photoelectron spectroscopy.[56] The authors proposed two mechanisms of charge redistribution in the dinuclear system: the direct metal–metal interaction and back donation from the d orbitals of the endocyclic metal atom to the π orbitals of the butadiene fragment and the semibridging carbonyl group. The absence of osmium complexes with staggered carbonyl ligands was accounted [56] for by substantial strengthening of the metal–metal interaction in the series Fe, Ru, Os, because the charge balance in such complexes can be established without the involvement of the semibridging carbonyl group.

It should be noted that derivatives containing only carbonyl ligands (**A1**, **B1**, **C1**, **D1**) were found for almost all dinuclear complexes with the MCP fragment (with the exception of Ni, Pd and Pt complexes; see Fig. 2). However, the existence of complexes as two conformers, *viz*., with the semibridging carbonyl group and without this group, is typical only of metals of the iron subgroup. In none of the complexes with other metals does a shortened contact between the endocyclic metal atom and one of the carbonyl groups coordinated to the second metal atom occur.

Yet another interesting characteristic feature of ferrole-type complexes is the rapid ferrole ring exchange **A** $\rightleftharpoons$ **C** characterised by the transition state **B** with the symmetry C_{2v}. This exchange was exemplified by optically active alkoxy- and hydroxy-substituted ferroles, which undergo racemisation at high temperatures.[57] The transformation from the hypothetical intermediate state **B** with the symmetry C_{2v} into ferrole was theoretically considered in the study.[52]



A remarkable example of the equilibrium transition between ferroles **A** and **C** was reported in the study,[58] where two isomers **37** and **38** (Fig. 4) were prepared in 18% and 57% yields, respectively, by thermolysis of the trimetallic cluster $Fe_3(CO)_9(N_2Et_2)$ with phenylacetylene. Heating of the pure isomers in solution afforded an equilibrium mixture of two complexes, which clearly confirms the occurrence of the dynamic transition **A** $\rightleftharpoons$ **C**. The enthalpy of isomerisation determined from the temperature dependence of the equilibrium constant is 90 ± 20 kJ mol^{-1} (low accuracy is related to slow decomposition of the compounds at high temperatures). The structures of both isomers were established by X-ray diffraction analysis.[59]

Both clusters contain the linear trimetallic core [the Fe(1)–Fe(2)–Fe(3) angle is 162° and 167° in isomers **37** and **38**, respectively]. The central iron atom is coordinated by both the

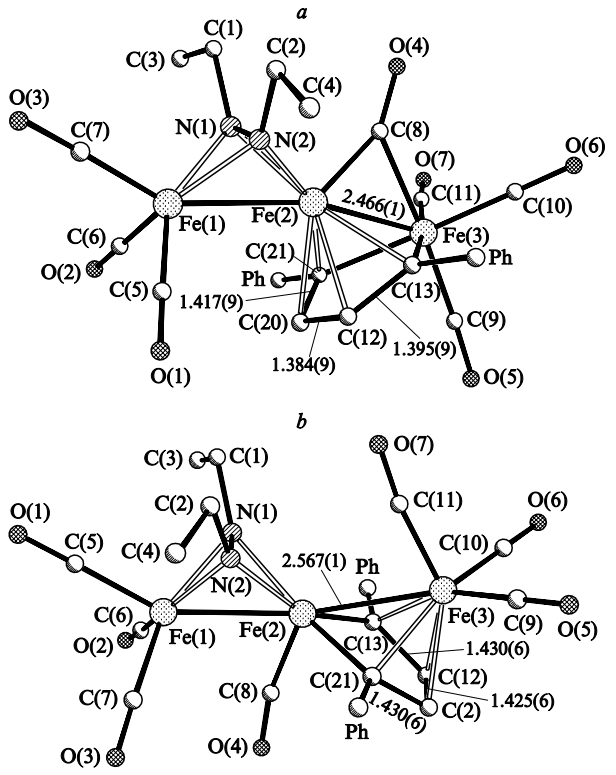


Figure 4. Structures of isomers **37** (*a*) and **38** (*b*) with composition $Fe_2(CO)_7(\mu\text{-}N_2Et_2)(\mu\text{-}HCCPh)_2$.[59]
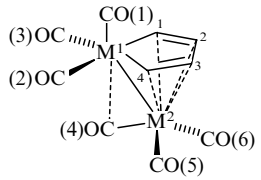
Hereinafter, the bond lengths are given in Å. The phenyl substituents at the C(13) and C(21) atoms are omitted. The average Fe–C distances in the metallacycle are 2.02 and 1.93 Å, the Fe–C_{MCP} distances (π-coordination) are 2.09 and 2.11 Å in isomers **37** and **38**, respectively.

μ-azoalkane and μ-butadienyl ligands, which are located on opposite sides of the metal chain. The MCP fragments in both isomers are structurally similar to those in dinuclear ferrole complexes. The C—C bond lengths are equalised and the endocyclic metal atom deviates from the plane of the butadiene fragment in the direction opposite to the π-coordinated metal atom [the folding angle along the C(13)···C(21) line in the metallacycle is 15.2° and 12.9° for complexes **37** and **38**, respectively].

An analogous structure was described also for several homo- and heterometallic trinuclear complexes [60–65] containing an open metal chain and the MCP fragment. Only in one complex,[60] is the central metal atom involved in the metallacycle (like in isomer **38**). In other cases, the metallacycle is formed by the terminal metal atom (analogously to isomer **37**). In all compounds, the structure of the dinuclear fragment with the metallacycle is similar to that observed in dinuclear complexes of the ferrole type.

2. Phosphine derivatives

A characteristic feature of dinuclear carbonyl complexes of the ferrole type (see Table 1) is a shorter bond between the metal atom M^1 and the carbonyl group CO(1) located perpendicular to the plane of the metallacycle compared to two other bonds [M^1—CO(2) and M^1—CO(3)] involving the carbonyl groups in *trans* positions with respect to the M^1—C(1) and M^1—C(4) σ-bonds. For example, the average M^1—CO(1) and M^1—CO(2,3) bond lengths in the iron complexes are 1.76 and 1.81 Å, respectively.



A noticeable shortening of the M^1—CO(1) bond can be explained by two alternative hypotheses:[17] (a) an increase in the electron density on the M^1 atom due to the $M^2 \rightarrow M^1$ dative bond, which, in turn, leads to an increase in back donation from the M^1 atom to the CO(1) group; (b) the electron deficiency on the metal atom M^1 is compensated by an increase in electron donation by the CO(1) group. The second hypothesis was confirmed by the fact that it is this carbonyl group that is replaced with a stronger σ-donor, for example, with the phosphine ligand.[54,66–68] For instance, prolonged refluxing of $(C_4Ph_4)Fe_2(CO)_6$ with triphenylphosphine in toluene afforded the only product $(C_4Ph_4)Fe_2(CO)_5PPh_3$ (**39**). Its structure was established by X-ray diffraction analysis [54] and is shown in Fig. 5 (prior to this study, it was believed that the phosphine ligand is coordinated to the exocyclic iron atom [69]).

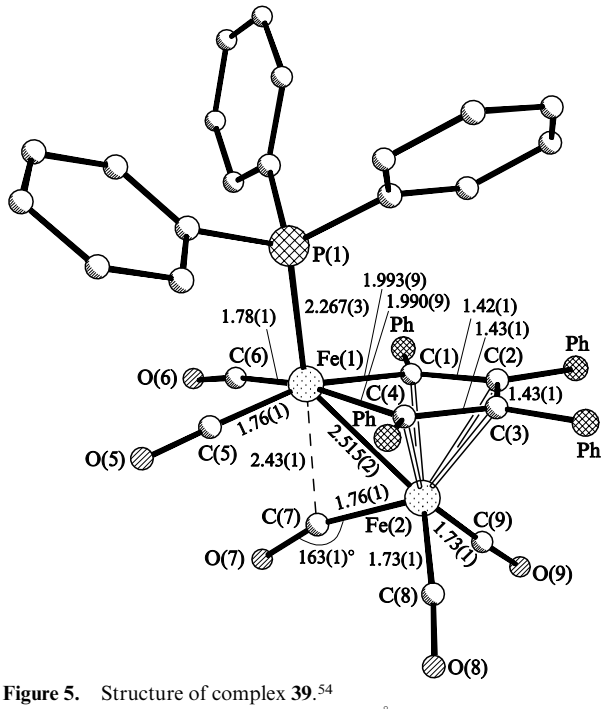


Figure 5. Structure of complex **39**.[54]
The average Fe(2)—C_{MCP} distance is 2.14 Å.

A comparison of the geometric parameters of complex **39** and its carbonyl analogue (compound **16**, Table 1) reveals no substantial differences in their structures. By contrast, the shortest $M^1 \cdots CO_{sb}$ distances [2.223(8) Å for Fe (see Ref. 66) and 2.236(3) Å for Ru (see Ref. 67)] in the series of ferrole-type carbonyl complexes (see Table 1) are observed in iron and ruthenium complexes with the trimethylphosphine ligand,[66,67] which is a stronger donor compared to the triphenylphosphine ligand.

It should be noted that in all monophosphine derivatives whose structures were established, the phosphine ligand is coordinated to the metal atom of the MCP fragment. Apparently, this isomer is thermodynamically more stable than the isomer in which this ligand is coordinated to the second metal atom (M^2). Coordination of the phosphine ligand to the M^2 atom was found only in diphosphine derivatives prepared by successive substitution of two CO groups in dinuclear hexacarbonyl complexes.[67,68]

3. Complexes with η^5- and η^1-η^4-coordination of the metallacyclopentadiene fragment

When describing complexes of the ferrole type, many authors (see, for example, Refs 61 and 63) invoked the analogy between the MCP fragment and the cyclopentadienyl ligand. This analogy is supported by the geometry of the metallacycle (a nearly planar structure, equalisation of the C—C bond lengths), the data from spectroscopic and electrochemical studies [70] and results of theoretical calculations.[18,52] A series of homo- and heteronuclear complexes of the ferrole type in which the exocyclic metal atom is coordinated simultaneously to the metallacycle and the cyclopentadienyl ligand (**B2**, **C3**, **C4**, **D4** in Fig. 2) belong to a peculiar type of metallametallocenes.[70–73] The structures of two ruthenium complexes **40** [74] and **41** [75] (see Fig. 6) are of interest.

Unlike homometallic dinuclear carbonyl complexes with metals of the iron subgroup characterised by η^5-coordination of the MCP fragment (**C1** and **C2** in Fig. 2), complexes **40** and **41** contain the η^1-η^4-coordinated metallacycle. This is related to the difference in the number of electrons donated to the metal atoms from the external ligand environment. In carbonyl complexes, each metal atom acquires six electrons, whereas the endocyclic ruthenium atom in complexes **40** and **41** has seven electrons and the exocyclic ruthenium atom has five electrons. Two different descriptions of the coordination modes of the MCP fragment in dinuclear complexes assume different electronic structures of the metallacycles. We proposed these descriptions based on the formal application of the EAN rule (see description of Fig. 2). The validity of this approach is supported also by the differences in the geometric structure of the complexes under consideration.

In complex **40**, the Ru(1)—Ru(2) bond is substantially elongated [2.831(1) Å)] compared to the Ru—Ru bonds in ruthenium carbonyl complexes **25**–**33** (the average bond length is 2.721 Å, see Table 1). In addition, the structure of the MCP fragment in complex **40** is non-planar, the folding angle of the metallacycle along the C(1)···C(4) line is 18.2°, which is also substantially larger than the average value (10.7°) for carbonyl complexes **25**–**33** (parameter τ in Table 1). It can be assumed that these changes in complex **40** are caused only by steric repulsions between the methyl groups of the pentamethylcyclopentadienyl ligands located in *cis* positions relative to the metal—metal bond. However, a comparison with complex **41**, in which the cyclopentadienyl ligands are in *trans* positions with respect to the metal—metal bond and steric hindrance is absent, provides

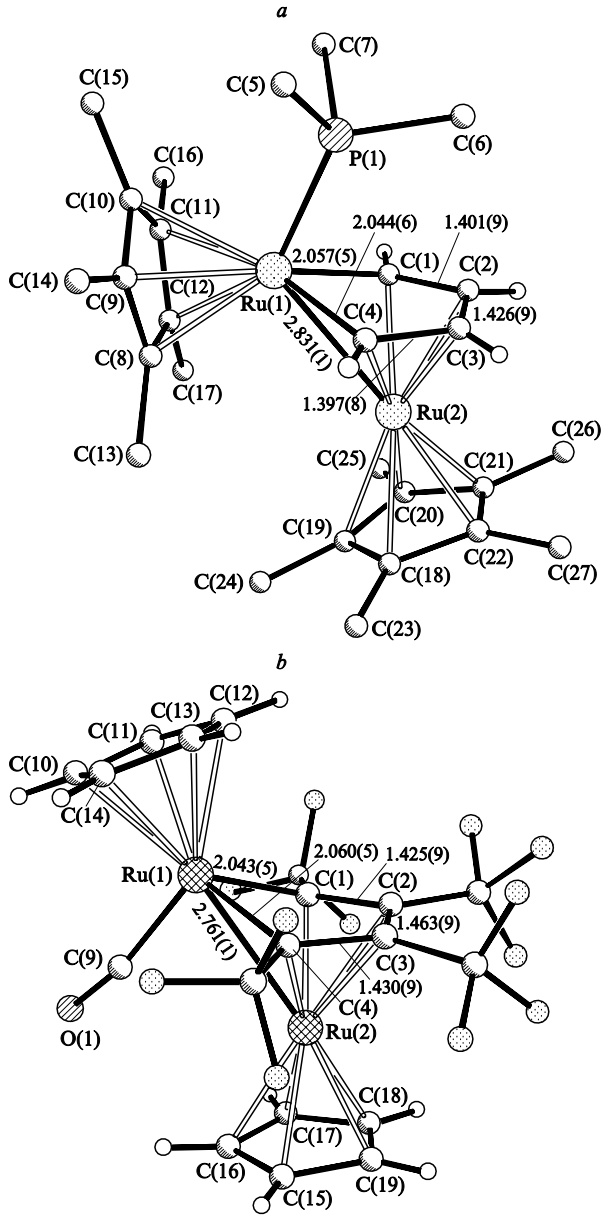

Figure 6. Structures of the complexes (η^5-C_5Me_5)Ru(PMe_3)(μ-η^4-C_4H_4)Ru(η^5-C_5Me_5) (**40**)[74] (*a*) and (η^5-C_5H_5)Ru(CO)(μ-η^4-$C_4(CF_3)_4$)Ru(η^5-C_5H_5) (**41**)[75] (*b*).

evidence for the predominant influence of the electronic properties of the ligand environment about the ruthenium atoms on the structure of the dinuclear fragment containing the metallacycle. The Ru(1)—Ru(2) bond length in complex **41** is smaller [2.761(1) Å] than that in complex **40** but it is noticeably larger than the average bond length in ruthenium carbonyl complexes **25**–**33**. The structure of the MCP fragment in complex **41**, where steric hindrance is absent, is analogous to that observed in complex **40**. The folding angle of the metallacycle is 23.1°. In both complexes, the C—C bonds are equalised. The Ru—C bond lengths in the metallacycles are close to the values typical of other ruthenacyclopentadienyl fragments.

In addition to complexes **40** and **41**, a number of analogous ruthenium compounds with cyclopentadienyl ligands and various ligands of another nature at the Ru(1) atom were also described.[76–78] In all complexes, the Ru—Ru bond is elongated and the MCP fragment shows greater deviations from planarity compared to those observed in ruthenium hexacarbonyl complexes of the ferrole type. In this connection, it is of interest to compare these compounds with the dinuclear cobalt carbonyl complexes $Co_2(CO)_5(C_4R_4)$ (**D1** in Fig. 2), whose formal consideration also reveals the η^1-η^4-coordination of the MCP fragment. The structures of all known dinuclear cobalt carbonyl complexes with the MCP fragment were described in the publication.[8] The authors noted that the structures of the complexes are independent of the nature of substituents in the organic moiety of the metallacycle and are characterised by equalisation of the C—C bond lengths in the diene fragment, a substantial deviation of the metallacycle from planarity (the average folding angle of the metallacycle is 16.5°) and a slight shortening of the Co—C bonds in the metallacycle (1.973 Å) compared to the values typical of the Co—C σ-bonds. Therefore, in the authors' opinion,[8] the use of the analogy between the MCP fragment and the cyclopentadienyl ligand in these complexes is not quite correct.

To compare complexes with different coordination modes of the MCP fragment (η^1-η^4- or η^5-coordination of the metallacycle) in more detail, we chose compounds with the same metal atoms and different ligand environments. In addition to the above-described ruthenium complexes, such pairs are known for cobalt and rhodium. The structures of these compounds are shown in Fig. 7 and their main geometric parameters are given in Table 2.

Table 2. Selected average geometric parameters for complexes with different coordination modes of the MCP fragment.

Metal	Coordination mode of the MCP fragment	M^1-M^2 /Å	$M^1-C(1,4)$ /Å	τ [a] /deg	Compounds
Ru	η^1-η^4	2.806	2.060	21.8	**40**–**44**
	η^5	2.725	2.073	9.3	**25**–**33**
Co	η^1-η^4	2.488	1.973	16.5	**45**–**49**
	η^5	2.451	1.889	5.7	**50**–**52**
Rh	η^1-η^4	2.708	2.048	16.5	**53**, **54**
	η^5	2.648	1.991	4.2	**55**–**58**

[a] The folding angle of the metallacycle along the C(1)···C(4) line.

The numbers of electrons donated by the external ligand environment to the metal atoms M^1 and M^2 are given in parentheses in Fig. 7. For complexes in which the numbers of electrons donated to the M^1 and M^2 atoms differ from each other (compounds at the left of Fig. 7), the fulfillment of the EAN rule assumes the formation of two σ-bonds between the organic ligand and the M^1 atom giving rise to the MCP fragment, which, in turn, is η^1-η^4-coordinated to the M^2 atom (the metal—metal σ-bond and π-coordination of the butadiene fragment). For complexes containing the M^1 and M^2 atoms in the same ligand environment (compounds at the right of Fig. 7), this consideration leads to non-equivalence of the metal atoms and, consequently, the electron density redistribution occurs apparently through the common π system of the metallacycle (η^5-coordination of the MCP fragment).

As can be seen from Table 2, the metal—metal bonds in the compounds with η^5-coordination of the MCP fragment are 0.03–0.08 Å shorter than those in the compounds with η^1-η^4-coordination. The structure of the MCP fragment also depends on its coordination mode. In the complexes with η^5-coordination, the metallacycle is more flattened than that in the complexes with η^1-η^4-coordination (parameter τ). In addition, the $M^1-C(1)$ and $M^1-C(4)$ bonds in the metallacycles are substantially shortened in the cobalt and rhodium complexes with η^5-coordination of the MCP fragment. This situation is not observed in ruthenium complexes.

Therefore, two coordination modes of the metallacycle occur in dinuclear complexes containing the MCP fragment depending on the number of electrons donated by the ligand environment

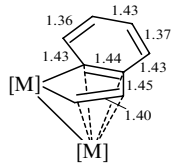
Figure 7. Dinuclear complexes with the η^1-η^4- and η^5-coordinated MCP fragment.

about each metal atom. These coordination modes differ in the geometric parameters (see Tables 1 and 2). Complexes with η^1-η^4-coordination of the MCP fragment are characterised by a non-planar structure of the metallacycle with the endocyclic metal atom deviating from the plane of the butadiene unit in the direction opposite to the second metal atom (the folding angle of the metallacycle is close to 20°). Complexes with η^5-coordination of the MCP fragment are characterised by a more flattened structure of the metallacycle with an insignificant deviation of the endocyclic metal atom from the plane of the butadiene unit (the folding angle of the metallacycle is close to 5°). In this case, it is apparently more reasonable to assign the metallacycle to aromatic heterocycles. Shortening of the metal–metal bond is also typical of complexes with η^5-coordination. In some cases, shorter metal–carbon bonds were found in the metallacycle. In dinuclear carbonyl complexes with metals of the iron subgroup and carbonyl ligands in a staggered orientation, the structure of the MCP fragments is intermediate between the η^1-η^4 and η^5-coordination modes (the average folding angle of the metallacycles is 11°). This is attributable to an additional interaction between the metal atoms through the semibridging carbonyl group. Apparently, this additional interaction provides an alternative electron density redistribution between the metal atoms and results in a smaller contribution of the π system of the metallacycle to this process. The above analysis demonstrates that the folding angle of the metallacycle, which characterises the deviation of the endocyclic metal atom from the plane of the butadiene fragment, is most sensitive to a change in the coordination mode of the MCP fragment in dinuclear transition metal complexes.

III. Coordination of the metallaindene fragment

Among transition metal complexes involving the MCP fragment, many bi- and polynuclear compounds contain the five-membered metallacycle fused to the benzene ring to form the metallaindene system.



The above scheme gives the average C–C bond lengths (in Å) in dinuclear complexes with the metallaindene fragment.[31,49,67,80,81,85–89] We did not take into account polynuclear complexes (because the presence of additional metal atoms complicates the consideration) as well as complexes in which the six-membered ring is fused at the C–C single bond of the MCP fragment or the five-membered metallacycle is fused to two six-membered rings (as, for example, in complex **18** [36]).

The distribution of the bond lengths in the metallaindene system is indicative of a noticeable difference in the double and single C–C bonds and also of a decrease in the order of the double bond at which two rings are fused. It should be noted that a planar structure is typical of the metallaindene fragments (the average dihedral angle between the planes of the five- and six-membered rings is 6.4°; if the metal atom is ignored, this angle is 3.6°).

The fact that the common π system of the metallaindene fragment is divided into two butadiene units was clearly demonstrated in the study,[90] where the structure of trinuclear complex **59** was described (Fig. 8).

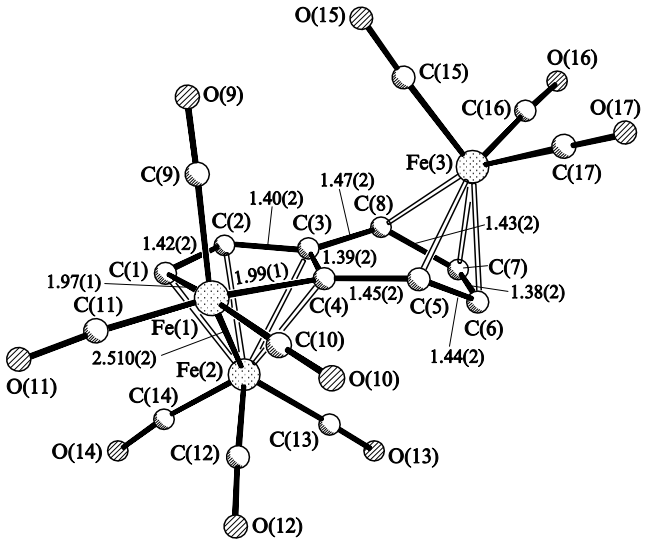


Figure 8. Structure of the ferraindene complex $Fe_3(CO)_9(C_8H_6)$ (**59**).[90]

As can be seen from Fig. 8, the Fe(2) and Fe(3) atoms are located on opposite sides of the bicyclic fragment, whose structure is essentially non-planar. There are two planar fragments, *viz*., C(1)C(2)C(3)C(4)C(5)C(8) and C(5)C(6)C(7)C(8). The dihedral angle between these planes is 32.5°. Hence, molecule **59** can be considered as consisting of two isolated fragments, *viz*., *cis*-butadienetricarbonyliron and the dinuclear ferrole complex. The latter has a structure typical of such complexes. The carbon–carbon bonds in the MCP fragment are equalised. The Fe(1) atom deviates from the plane through four carbon atoms by 0.16 Å in the direction opposite to the Fe(2) atom; the folding angle of the metallacycle along the C(1)···C(4) line is 8.0°. The carbonyl groups in the $Fe_2(CO)_6$ fragment are in a staggered orientation [the semibridging carbonyl group C(12)O(12) deviates from the linear coordination by 11°, the Fe(1)···C(12) distance is 2.53 Å]. The C(3)–C(8) and C(4)–C(5) bond lengths have values typical of the $C(sp^2)–C(sp^2)$ single bond within experimental error. Later on, an analogous complex containing the *p*-tolyl substituent at the C(2) atom and the methyl substituent at the C(7) atom was described.[91]

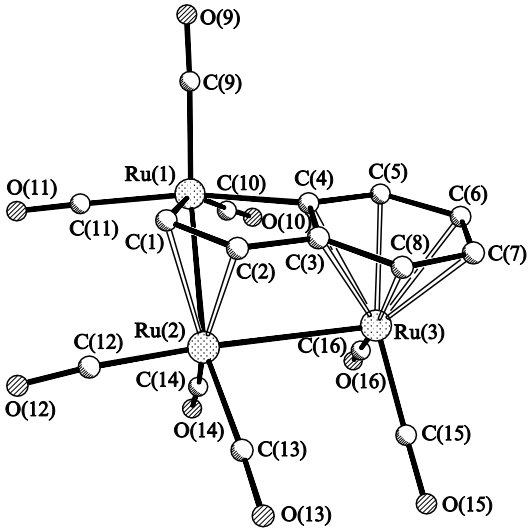

Figure 9. Structure of the ruthenaindene complex $Ru_3(CO)_8(C_8H_6)$ (**60**).[92]

Even more interesting results were obtained in the study,[92] where benzothiophene was subjected to desulfurisation in the reaction with $Ru_3(CO)_{12}$. The structure of trinuclear complex **60** (Fig. 9, Table 3) containing the metallaindene system was described. However, the coordination mode in this complex differs from that observed in compound **59**.

Table 3. Main geometric parameters for complexes **61**–**63** (bond lengths are given in Å, angles are given in degrees).

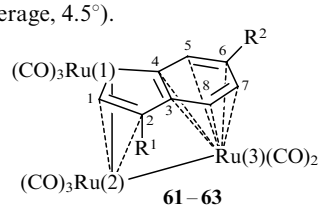
Parameter	Compound			
	60	**61**	**62**	**63**
Ru(1)–Ru(2)	2.781	2.774	2.781	2.783
Ru(2)–Ru(3)	2.946	2.951	2.951	2.958
Ru(1)–C(1)	2.058	2.042	2.052	2.057
Ru(1)–C(4)	2.088	2.093	2.106	2.096
Ru(2)–C(1)	2.237	2.246	2.252	2.233
Ru(2)–C(2)	2.257	2.266	2.280	2.249
Ru(3)–C(3)	2.351	2.374	2.342	2.352
Ru(3)–C(4)	2.322	2.335	2.316	2.356
Ru(3)–C(5–8)	2.248–2.295	2.244–2.305	2.261–2.299	2.275–2.280
C(1)–C(2)	1.400	1.394	1.394	1.394
C(2)–C(3)	1.458	1.445	1.478	1.453
C(3)–C(4)	1.454	1.450	1.449	1.440
C–C (in benzene ring)	1.399–1.430	1.384–1.432	1.400–1.438	1.392–1.438
Ru(1)–Ru(2)–Ru(3)	83.5	85.2	84.8	86.8

In complex **60**, both additional ruthenium atoms are located on the same side of the bicyclic system. The five-membered metallacycle coordinates the second ruthenium atom, Ru(2), through one C(1)=C(2) double bond, whereas two other carbon atoms of the metallacycle, *viz*., C(3) and C(4), are involved in η^6-coordination to the third ruthenium atom, Ru(3). Taking into account the planar structure of the metallaindene system (the dihedral angle between the mean planes of the five-membered metallacycle and the six-membered benzene ring is 7.6°), the

authors considered the $C_8H_6Ru(CO)_3$ fragment as the 8-electron ligand π-coordinated to the $Ru_2(CO)_5$ group.

Three structurally similar ruthenaindene complexes **61**–**63** were described in studies of the products obtained in reactions of $Ru_3(CO)_{12}$ with substituted benzenes.[93–95] Main geometric parameters of complexes **61**–**63** are given in Table 3.

The metallaindene system in complexes **61**–**63**, like that in complex **60**, is planar (the dihedral angle between the planes of the five-membered metallacycle and the six-membered ring is, on average, 4.5°).



61–**63**

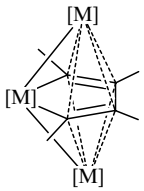
Compound	R^1	R^2	Ref.
61	Me	H	93
62	Me	$C(CH_2)Me$	94
63	H	Me	95

Evidently, the coordination mode of the MCP fragment in these four complexes differs radically from that observed in all the above-described compounds in which the metallacycle is symmetrically η^5-coordinated to one additional metal centre. In complexes **60**–**63**, the five-membered metallacycle is bound to two additional metal centres, one metal atom, Ru(2), being η^3-coordinated [the free C(1)=C(2) double bond and the Ru(1) atom are involved in coordination], whereas another metal atom, Ru(3), is η^2-coordinated [coordination by the C(3)=C(4) double bond involved in fusion to the six-membered ring]. The coordination is accompanied by localisation of the carbon–carbon bonds in the five-membered metallacycle. This is particularly clearly manifested in the C(2)–C(3) bond length. In all complexes, this bond corresponds to the length of the $C(sp^2)-C(sp^2)$ single bond. An interesting structural feature of the MCP fragment in complexes **60**–**63** is the deviation of the Ru(1) atom from the plane through four carbon atoms [C(1), C(2), C(3) and C(4)] toward two other metal atoms [Ru(2) and Ru(3)]. The mean folding angle of the metallacycle along the C(1)···C(4) line is 9.4°. The C(1)–C(2)–C(3)–C(4) torsion angle is 2.5°. It should also be noted that none of the complexes has an additional semibridging interaction between the ruthenium atoms involving carbonyl ligands, which is typical of ruthenium complexes of the ferrole type.

As is evident from the foregoing, the presence of the second additional metal centre in complexes containing the MCP fragment can lead to a substantial change in the coordination mode of the metallacycle. The main coordination modes of the MCP fragment in polynuclear transition metal complexes are described below.

IV. Trimetallic clusters with a pentagonal-bipyramidal geometry

In addition to the above-described dinuclear complexes with the MCP fragment, there is one more large class of related compounds with a pentagonal-bipyramidal geometry.



In these compounds, the MCP fragment is η^5-coordinated to two metal atoms located symmetrically on opposite sides of the plane of the metallacycle. Such complexes are often produced in reactions which also give dinuclear complexes of the ferrole type. This is particularly typical of reactions of metal carbonyls of the iron subgroup with alkynes.[12,13]

The first structure of the trinuclear iron complex $Fe_3(CO)_8(PhC_2Ph)_2$ characterised by pentagonal-bipyramidal geometry was described almost 40 years ago.[96] Later on, the structures of a series of analogous homonuclear iron and ruthenium clusters were studied. Their main geometric parameters are given in Table 4.

Table 4. Main geometric parameters (distances are given in Å, angles are given in degrees) of trinuclear iron and ruthenium complexes with a pentagonal-bipyramidal geometry.

[a] M = Fe (**64**–**74**), Ru (**75**–**80**). [b] The folding angle of the metallacycle along the C(1)···C(4) line. [c] Two crystallographically independent molecules.

Complexes **64**–**80** contain an open trimetallic core with two nearly equal-length metal–metal bonds; the angle between these bonds is close to 90°. Each metal atom is coordinated by two terminal CO groups. Two other carbonyl groups form bridges between the central and peripheral metal atoms. The bridging CO groups are slightly shifted to the peripheral metal atoms (the M^1-CO_M distances are, on average, 0.2 Å longer than the M^2-CO_M and M^3-CO_M distances). The central metal atom is involved in two σ-bonds with the butadiene moiety to form the MCP fragment, which is, in turn, symmetrically π-coordinated to both peripheral metal atoms at the vertices of the bipyramid.

The metallacycle is planar (parameter τ in Table 4) and dissects the structure into two equivalent moieties, each moiety being structurally similar to dinuclear iron and ruthenium complexes of the ferrole type. The common symmetry of these complexes is particularly pronounced in the crystal structures of compounds **67**, **78** and **79**. Molecules of these compounds occupy special positions on the mirror symmetry plane passing through the plane of the metallacycle. The carbon–carbon bonds in the MCP fragments of complexes **64**–**80** are equalised, whereas the metal–metal distances (the average values are 2.429 and 2.666 Å for the iron and ruthenium complexes, respectively) are noticeably shortened compared to the corresponding bonds in dinuclear complexes of the ferrole type (see Table 1).

The structures of the trinuclear complexes listed in Table 4 are often described using polyhedral clusters (see, for example, the

studies [26, 100] and the review [13]), for which the number of skeletal electrons (*i.e.*, electrons involved in bonding in the polyhedron) is counted according to the so-called Wade's rule (or the '$2n+2$' rule).[108]

In complexes **64**–**80**, the M_3C_4 system can be considered as a *closo*-pentagonal-bipyramidal structure. According to Wade's rules, 16 skeletal electrons are required for a seven-vertex polyhedron. It is easy to demonstrate that this rule is fulfilled for all compounds listed in Table 4. After the removal of one vertex of the bipyramid occupied by the $Fe(CO)_2$ or $Ru(CO)_2$ group, which donates no skeletal electrons, the seven-vertex *closo* system is transformed into a six-vertex pyramidal cluster with a *nido* structure, the total number of skeletal electrons remaining unchanged. The six-vertex clusters thus obtained represent the above-described dinuclear carbonyl complexes of the ferrole type. It should be noted that all dinuclear complexes which are presented in Fig. 2 and contain different transition metal atoms with different ligand environments, can be described as *nido*-pentagonal-pyramidal systems bearing 16 skeletal electrons.

The possibility of the transformation of trinuclear complexes with composition $M_3(CO)_8(RC_2R)_2$ into the dinuclear complexes $M_2(CO)_6(RC_2R)_2$ has been demonstrated in the pioneering studies on the chemical behaviour of these clusters [109, 110] and was subsequently confirmed in many investigations (see, for example, Refs 98 and 111). This transformation occurs in the course of thermolysis under severe conditions, no other products being formed, which is indicative of high stability of ferrole complexes and the MCP fragment. Investigation of the electronic structures of ferracyclopentadiene derivatives (dinuclear and trinuclear complexes) by photoelectron spectroscopy and *ab initio* calculations [112] demonstrated a high degree of electron density delocalisation in these clusters as well as the strong Fe–C σ-interaction in the metallacycle, which accounts for the stability of the MCP fragment in chemical reaction. Substantial delocalisation of the electron density in trinuclear iron and ruthenium clusters with a pentagonal-bipyramidal geometry is also evidenced by the data from spectroscopic (^1H and ^{13}C NMR and IR) and electrochemical studies of a large number of compounds containing various substituents at the carbon atoms of the metallacycles.[111, 113]

In addition to the above-mentioned pentagonal-bipyramidal trinuclear iron and ruthenium carbonyl complexes **64**–**80**, six structurally similar compounds with other transition metal atoms and/or with another ligand environment were described. These are two heteronuclear complexes with composition $Re_2Fe(CO)_9(CH=CHC_6H_4)$ (**81**)[114] and $Cp^*WRe_2(CO)_7$.$(\mu\text{-}H)(CH=CHC_6H_8)$ (**82**),[115] the trinuclear iridium complex $Ir_3(2\eta^2\text{-cod})_3(\mu\text{-}H)(C_4H_4)$ (cod is cyclooctadiene) (**83**)[82] and the trinuclear ruthenium complexes $Ru_3(CO)_6(dppm)(C_4H_2Ph_2)$ [dppm is bis(diphenylphosphine)methane] (**84**),[116] $Cp^*_3Ru_3$.$(H)(C_4H_3Et)$ (**85a**)[117] and $Cp_2Ru_3(CO)_3\{C_2(CF_3)_2$.$C_2(CO_2Me)_2\}$ (**86b**),[118] the latter two complexes having an unusual triple-decker sandwich structure. All complexes satisfy the '$2n+2$' rule for the number of skeletal electrons in the *closo*-pentagonal-bipyramidal polyhedron. The structure of the MCP fragments in complexes **81**–**85** is analogous to that observed in trinuclear iron and ruthenium carbonyl complexes **64**–**80**.

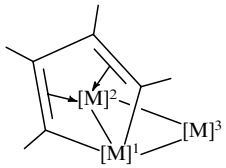
V. Coordination of the metallacyclopentadiene fragment to transition metal clusters

Many trinuclear and polynuclear complexes with the MCP fragment include the structural motif presented in the following scheme:



The lateral or $\mu_2\text{-}2\eta^1\text{-}\eta^4$-coordination of an organic ligand to the triangular metal core is typical of trimetallic iron, ruthenium and osmium clusters.[97, 119–137] The formation of such complexes was observed in the reactions of metal carbonyl clusters of the iron subgroup with alkynes and their functional derivatives. The complexes contain the dinuclear ferrole-type fragment and the third metal atom, which is not directly bound to the organic moiety of the metallacycle.

The structural formulae and selected geometric parameters of the triangular metal complexes of the iron subgroup with this coordination mode of the MCP fragment are given in Table 5. All complexes contain the MCP fragment, whose diene moiety is π-coordinated to the M^2 atom. Besides, in some complexes (**86**, **87**, **92**–**99** and **107**–**109**), the functional group at one of the α-carbon atoms of the metallacycle is coordinated to the third metal atom (M^3), which is not involved in a direct bond with the MCP fragment. This additional interaction results in inclination of the MCP fragment relative to the plane of the triangle formed by the metal atoms (the average angle between the planes is 63°). In complexes in which an additional coordination to the third metal atom is absent, the metallacycle is located almost perpendicular to the $M^1M^2M^3$ plane (the average angle between the planes is 83°).

In complexes listed in Table 5, the metal–metal bond lengths are non-equivalent. The M^1-M^2 bond lengths are close to the values observed in the dinuclear complexes of the ferrole type (see Table 1, complexes **1**–**36**). The M^2-M^3 bonds have similar or even somewhat larger lengths, whereas the M^1-M^3 bond between the endocyclic metal atom and the metal atom which is not directly bound to the MCP fragment, is noticeably elongated in most complexes. This tendency is most pronounced in complexes **91** and **100**–**103** bearing no bridging ligands, whose tightening effect may substantially influence the M–M bond lengths. For this reason, it is of interest to compare two related ruthenium complexes $Ru_3(CO)_8(PPh_3)\{C_4Ph_2(CH=CHPh)_2\}$ (**91**)[123] and $Ru_3(CO)_8\{C_4Ph_2(CH=CHPh)_2\}$ (**92**)[124] containing, along with the MCP fragment, only terminal two-electron ligands (CO or PPh_3). Complex **92** was prepared by the thermal reaction of enyne $PhCH=CHC\equiv CPh$ with $Ru_3(CO)_{12}$. The reaction of complex **92**

Table 5. Selected geometric parameters (bond lengths are given in Å, angles are given in degrees) for trinuclear iron, ruthenium and osmium clusters with the laterally coordinated MCP fragment.

[a] The C(1)–C(2)–C(3)–C(4) torsion angle. [b] The dihedral angle between the C(1)C(2)C(3)C(4) and C(1)M^1C(4) planes. [c] The dihedral angle between the mean plane of the MCP fragment and the plane of the $M^1M^2M^3$ triangle. [d] Two crystallographically independent molecules. [e] Two crystal modifications: monoclinic $P2_1/c$ and orthorhombic *Iba*2.

with triphenylphosphine led to the displacement of the alkenyl ligand π-coordinated to the Ru(3) atom giving rise to complex **91**.[123] The triphenylphosphine ligand in complex **91** occupies an equatorial position at the Ru(3) atom in the *trans* position with respect to the Ru(1)–Ru(3) bond.

The Ru(1)–Ru(2) bond length in complexes **92** and **91** [2.733(1) and 2.757(1) Å, respectively] remains virtually unchanged and is typical of the Ru–Ru bonds in dinuclear ruthenium complexes of the ferrole type (2.703–2.753 Å, see Table 1). This fact is indicative of structural rigidity of the fragment regardless of the type of the complex, the ligand environment about the metal atoms and substituents at the carbon atoms of the metallacycle.

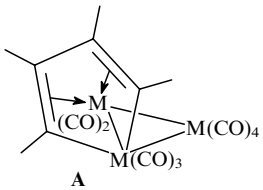
It is noteworthy that two other metal–metal bond lengths in complexes **92** and **91** are different. The Ru(1)–Ru(3) bond in complex **91** [2.927(1) Å] is substantially elongated compared to the analogous bond in complex **92** [2.823(1) Å]. Apparently, this is associated with the influence of the phosphine ligand in the *trans* position with respect to the Ru(1)–Ru(3) bond and can also be attributable to the lack of the tightening effect which occurs in the case of additional coordination by the alkenyl group of an organic ligand. The latter explanation seems to be more reasonable because an analogous change in the Ru(1)–Ru(3) bond length is observed in complexes **88**–**90** (2.982–3.073 Å) compared to complexes **93**–**99** (2.822–2.880 Å), in which an additional coordination to the Ru(3) atom is respectively absent and present (see Table 5).

The shortening of the Ru(2)–Ru(3) bond in complex **91** [2.732(1) Å] compared to that in complex **92** [2.802(1) Å] is less pronounced. A comparison of complexes **88**–**90** and **93**–**99** from Table 5 reveals no changes in the Ru(2)–Ru(3) bond length. Presumably, the mode of electron density redistribution in the cluster plays an important role in establishing electron balance on metal atoms. For example, the bridging ligands have a dominant role in complexes **88**–**90**, whereas the role of the direct metal–metal interaction increases significantly in complex **91** in which bridging interactions are absent (all carbonyl ligands are terminal). In this connection, it should be emphasised that the distribution of the bond lengths in the triangle formed by the metal atoms in analogous osmium complexes (**100**–**103**, Table 5), which also have no bridging ligands, is similar to that observed in complex **91**.

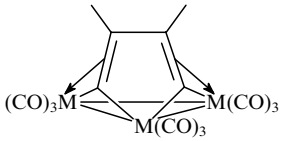
Reversible dissociation of the π-coordinated alkenyl group was exemplified by complexes **91** and **92**.[123] The transformation of one triruthenium cluster into another cluster is accompanied by migration of the MCP fragment relative to the plane of the Ru_3 triangle. In addition, the transformation is accompanied by the redistribution of the Ru(1)–Ru(3) and Ru(2)–Ru(3) bond lengths, which is indicative of high lability of the third metal centre bound to the dinuclear ferrole-type fragment. Apparently, it is this metal atom through which the electron density in the triangular clusters is redistributed to establish charge balance in a similar way to that observed in dinuclear ferrole-type complexes with staggered carbonyl ligands involving the semibridging carbonyl group. For example, the structure of complex **96** was described [125] as a result of the formal substitution of the semibridging carbonyl group in compound **29** (see Table 1) with the isolobal $Ru(CO)_3(PR_3)$ group. A comparison of complexes **96** and **29** demonstrates that there is a complete analogy in the structure of the dinuclear fragment with the metallacycle.

In addition to the triangular iron, ruthenium and osmium complexes with the laterally coordinated MCP fragment, there are also a number of heteronuclear complexes with more complicated structures (this is often associated with the presence of additional metal centres), which have a trimetallic core analogous to that of the metallacycle. The commonly used reactions of acetylide clusters with alkynes or alkyne complexes afford tri-, tetra- and polynuclear mixed complexes with the MCP fragment [WOs_3,[138–140] WRe_2,[115] Mo_2Re_2 (see Ref. 141)]. Since the structure of the metallacycle and its coordination are analogous to those described above for complexes **86**–**109**, we will not consider them in more detail.

An alternative mode of coordination of the MCP fragment to triangular transition metal clusters can be described as the μ_3-2η^1-2η^2 interaction between the organic ligand and the metal core. Symmetrical binding of the diene moiety to the triangle consisting of metal atoms is referred to as facial coordination, unlike the above-described lateral coordination. The assumption about the possibility of this coordination mode was made when studying the reactions between metal carbonyl complexes of the iron subgroup and an excess of alkynes giving rise to the $M_3(CO)_9(RC_2R)_2$ clusters, for which two structures (**A** and **B**) with the μ-2η^1-η^4- and μ_3-2η^1-2η^2-coordinated organic ligand were considered.[142, 143]



A



B

X-Ray diffraction study of one of the first $Os_3(PhC_2Ph)_2(CO)_9$ clusters demonstrated that it has the structure **A**.[129] Later on, analogous structures were assigned to all related compounds.[144, 145] Until recently, there was no convincing evidence for the existence of complexes with the structure **B**.

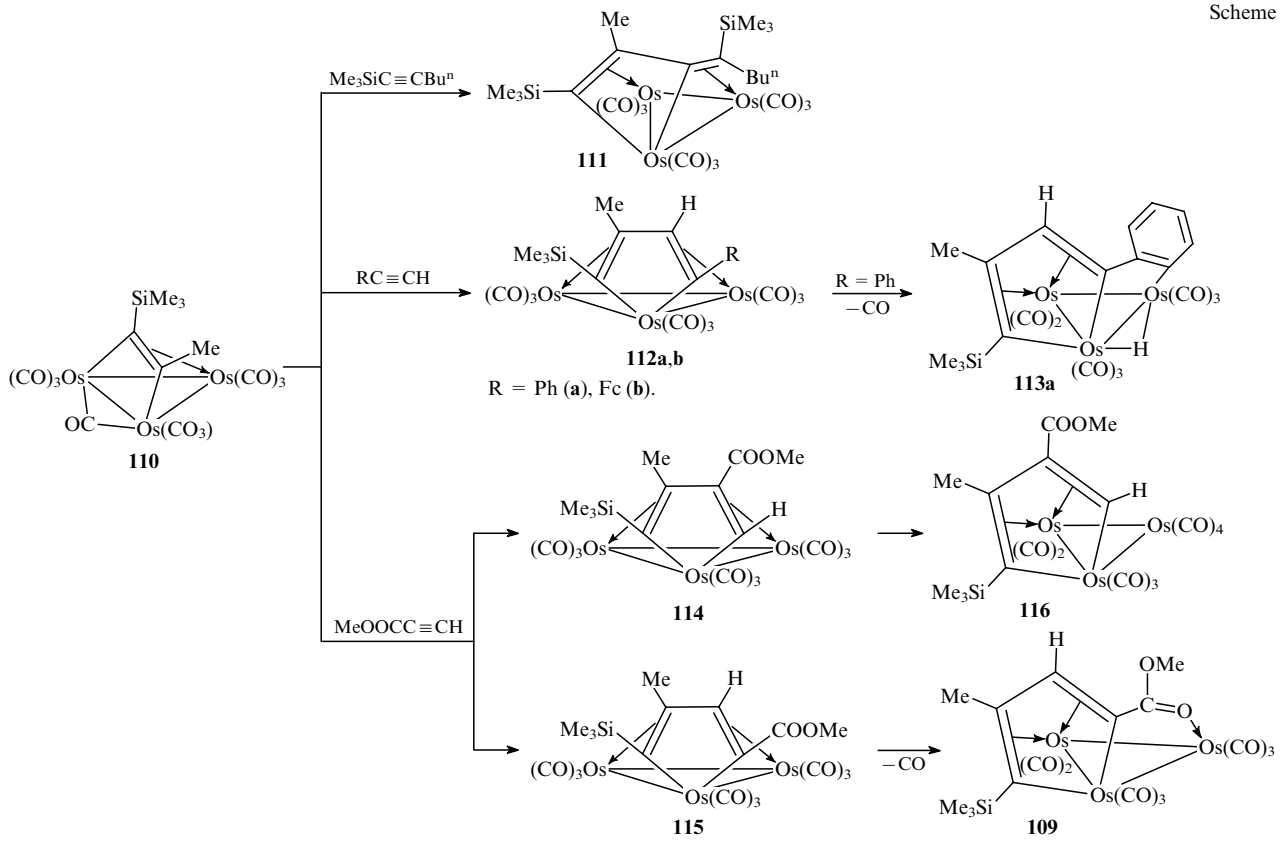
The experimental proof of the existence of isomers with the structure **B** was obtained for the first time in studies of the reactions of the alkyne cluster Os_3(μ-CO)$(CO)_9$(μ-2η^1-η^2-Me_3SiC_2Me) (**110**) with phenylacetylene [146, 147] as well as with other monosubstituted alkynes, *viz*., ferrocenylacetylene [148] and methyl propiolate.[137] The reactions involve alkyne–alkyne coupling and afford triosmium clusters with the facially coordinated osmacyclopentadiene fragment (complexes **112a**,**b**, **114** and **115** in Scheme 1). It should be noted that an analogous reaction with silyl-substituted alkyne $Me_3SiC{\equiv}CBu^n$ is accompanied by the acetylene–vinylidene rearrangement to give a cluster with the osmacyclobutadiene unit $Os_3(CO)_9\{\mu_3$-2η^1-2η^2-C$(SiMe_3)$=C.$(Me)C=C(SiMe_3)Bu^n\}$ (**111**).[149]

As can be seen from Scheme 1, thermolysis of the complexes with the facially coordinated MCP fragment gives rise to trinuclear complexes with the laterally coordinated MCP fragment. For example, complexes **112a**,**b** are transformed into hydride clusters with the *ortho*-metallated phenyl (**113a**) [146, 147] or ferrocenyl (**113b**) [148] fragment, respectively. The reaction of alkyne cluster **110** with methyl propiolate produces two isomeric complexes **114** and **115** with the facially coordinated MCP fragment, which differ in the mode of coupling of unsymmetrical alkynes.[137] Subsequent thermolysis of complex **115** containing the ester group in the α position of the osmacyclopentadiene ring affords complex **109**.[137]

Cluster **114** was studied by IR and NMR spectroscopy. In this cluster, the α position of the metallacycle contains no groups which are susceptible to *ortho*-metallation, or functional substituents capable of being coordinated to the metal atom. It was demonstrated that cluster **114** can undergo an intramolecular rearrangement and is a precursor of cluster **116**.[150] This previously unknown intramolecular rearrangement involves a change in the coordination mode of the dienediyl ligand (μ_3-2η^1-2η^2 → μ-2η^1-η^4) and the internuclear migration of one CO group. The trimetallic cluster with the facially coordinated MCP fragment, in which the hydrocarbon ligand forms η^2-bonds with two metal atoms, was demonstrated [150] to be thermodynamically less stable than the isomer in which the ligand forms the diene η^4-bond with one metal atom (lateral coordination of the MCP fragment).

The structures of three complexes (**112a**,[147] **112b** [148] and **114** [137]) with the facially coordinated MCP fragment were estab-

Scheme 1



lished by X-ray diffraction analysis. The molecular structure of complex **112a** is shown in Fig. 10. Main geometric parameters for complexes **112a**,**b** and **114** are given in Table 6.

The formation of complexes **112a**,**b** involves coupling of monosubstituted alkyne (phenyl- or ferrocenylacetylene, respectively) with the already coordinated silyl-substituted alkyne, which proceeds in such a way that the hydrogen atom is bound to the β-carbon atom of the MCP fragment. In complex **114**, the hydrogen atom is bound to the α-carbon atom of the MCP fragment. Otherwise complexes **112a**,**b** and **114** are structurally similar and the presence of different substituents in the MCP fragments has no noticeable effect on the geometry of the coordination unit of the complexes.

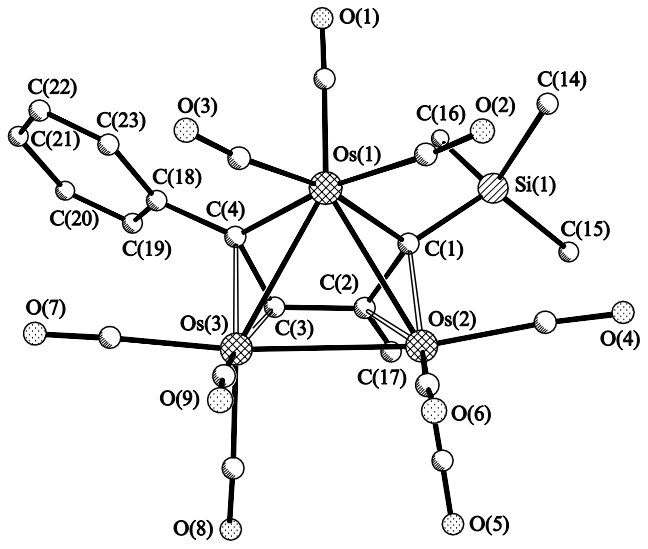


Figure 10. Molecular structure of the triangular osmium cluster $Os_3(CO)_9\{\mu_3\text{-}2\eta^1\text{-}2\eta_2\text{-}C(SiMe_3)C(Me)C(H)C(Ph)\}$ (**112a**) with the facially coordinated MCP fragment.[147]

In the complexes under consideration, the osmacyclopentadiene ring is substantially non-planar due to the deviation of the endocyclic osmium atom from the plane of the butadiene fragment toward two other metal atoms. The folding angle of the metallacycle along the C(1)···C(4) line is 30° (parameter τ in Table 6) and is substantially larger than the values typical of the MCP fragments coordinated to one metal atom (in dinuclear complexes of the ferrole type and trinuclear complexes with the laterally coordinated MCP fragment).

In complexes **112** and **114**, the C−C bond lengths in the butadiene moiety of the metallacycle are more differentiated than those in the complexes with the η^5-coordinated metallacycle. Although the differences in the bond lengths are only slightly larger than the experimental error, the tendency to an increase in the C(2)−C(3) bond length compared to the C(1)−C(2) and C(3)−C(4) alkene bond lengths is observed in all cases (the average values are 1.48, 1.41 and 1.42 Å, respectively). On the other hand, the lengths of the endocyclic σ-bonds involving the Os(1) atom are in the range typical of analogous bonds in complexes with the η^5-coordinated osmacyclopentadienyl fragment (2.01–2.25 Å; dinuclear complexes **35** and **36** listed in Table 1 and trinuclear complexes **100**–**109** presented in Table 5). However, it should be noted that the Os(1)−C(1) and Os(1)−C(4) bonds in complexes **112** and **114** are non-equivalent. In all cases, the distance to the C(1) atom bearing the trimethylsilyl substituent is somewhat larger than the Os(1)−C(4) bond length (the average values are 2.18 and 2.13 Å, respectively). The reasons for this non-equivalence are not quite clear. It can be assumed that an elongation of the Os(1)−C(1) distance eliminates unfavourable contacts between the trimethylsilyl group and the carbonyl groups at the Os(1) atom. It cannot also be excluded that some geometric distortions are related to the positive inductive effect of the trimethylsilyl group. Presumably, this is responsible for another structural feature of these complexes, *viz*., asymmetry of

Table 6. Selected geometric parameters for trinuclear osmium complexes with the facially coordinated MCP fragment (distances are given in Å, angles are given in degrees).[a]

[a] For the atomic numbering scheme, see Fig. 10. [b] The C(1)–C(2)–C(3)–C(4) torsion angle. [c] The folding angle of the metallacycle along the C(1)···C(4) line [the dihedral angle between the C(1)C(2)C(3)C(4) and C(1)Os(1)C(4) planes]. [d] The dihedral angle between the C(1)C(2)C(3)C(4) and Os(1)Os(2)Os(3) planes. [e] Two crystallographically independent molecules.

π-coordination of the Os(2) and Os(3) atoms to the corresponding alkene bonds in the metallacycle. One osmium atom [Os(3)] is located at virtually equal distances from the carbon atoms of the C(3)–C(4) alkene bond [the average Os(3)–C(3) and Os(3)–C(4) bond lengths are 2.27 and 2.23 Å, respectively], whereas another osmium atom [Os(2)] forms non-equivalent bonds with the carbon atoms of the C(1)–C(2) alkene bond [the average Os(2)–C(1) and Os(2)–C(2) bond lengths are 2.17 and 2.44 Å, respectively].

The osmacyclopentadiene ring in complexes **112** and **114**, unlike that in the trinuclear complexes with the laterally coordinated MCP fragment, is located above the plane of the triangular metal core (facial coordination of the MCP fragment). The averaged dihedral angle between the plane passing through four carbon atoms of the butadiene moiety of the metallacycle and the plane of the triangle formed by the osmium atoms (parameter θ in Table 6) is 34.5°.

The trinuclear complexes with the laterally coordinated MCP fragment differ from those with the facially coordinated MCP fragment also in that the metal–metal bond lengths in the latter are equalised. All Os–Os bond lengths in complexes **112** and **114** vary within a narrow range (2.793–2.834 Å).

In addition to the above-described compounds **112** and **114**, only one compound belonging to trimetallic clusters with the facially coordinated MCP fragment, *viz*., trinuclear molybdenum cyclopentadienyl complex **117**, was structurally characterised.[151] The structure of complex **117** is shown in Fig. 11.

The metal core in complex **117** is V-shaped. The bond between the Mo(1) and Mo(2) atoms is absent, although they are linked through the bridging chlorine atom. All Mo atoms are linked by the μ_3-bridging oxygen atom. In the study,[151] the μ_3-O, μ-Cl and $C_4(CF_3)_4$ groups in complex **117** were considered as four-, three- and six-electron ligands, respectively, and consequently, the complex as a whole has 46 valence electrons, which implies the presence of four metal–metal bonds (in this case, the molybdenum atoms have an 18-electron configuration). Based on this analysis and the results of theoretical calculations, the Mo(1)–Mo(3) and Mo(2)–Mo(3) bonds in complex **117** were assumed to be double and it was postulated that there is no direct interaction between the Mo(1) and Mo(2) atoms. The structure of the MCP fragment in complex **117** is analogous to that described for complexes **112** and **114** and differs substantially from that observed in complexes with η^5-coordination of the metallacycle. For example, the carbon–carbon distances in the metallacycle

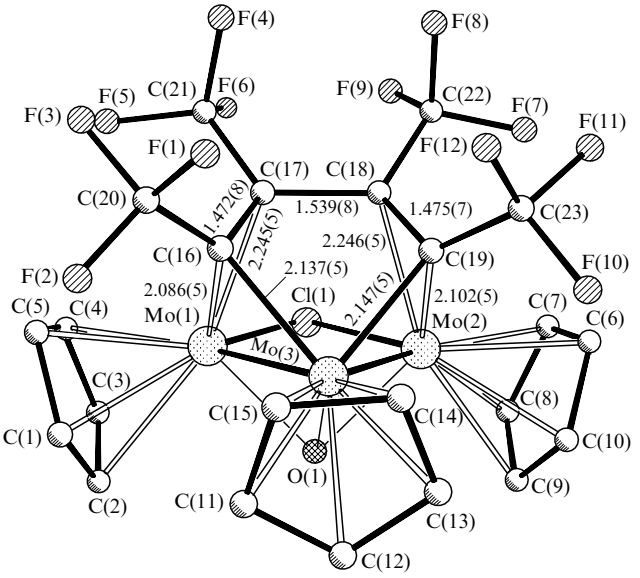

Figure 11. Structure of the $Mo_3(\mu\text{-Cl})(\mu_3\text{-O})(C_5H_5)_3\{C_4(CF_3)_4\}$ complex (**117**).[151]
The Mo(1)–Mo(3) and Mo(2)–Mo(3) bond lengths are 2.5723(7) and 2.5790(7) Å, respectively; the Mo(1)···Mo(2) distance is 2.8930(7) Å.

are noticeably differentiated (short–long–short) and the metallacycle is significantly folded (38.9°) along the C(16)···C(19) line.

VI. Conclusion

In conclusion of the description of complexes containing the MCP fragment, is should be emphasised once again that this metallacycle exhibits various coordination modes with transition metal atoms. The most commonly observed coordination mode is described as the symmetrical η^5-coordination to an additional metal centre (dinuclear complexes of the ferrole type and trimetallic clusters with the laterally coordinated MCP fragment). In these complexes, the MCP fragment is nearly planar. The equalisation of the carbon–carbon bond lengths in the diene moiety is indicative of strong conjugation in the carbon chain. The degree of deviation of the metallacycle from planarity can serve as a

criterion of the involvement of the endocyclic metal atom in the interaction with the π system of the diene moiety and, in the case of dinuclear complexes, corresponds to two different modes of coordination of the MCP fragment to an additional metal centre (η^1-η^4- or η^5-coordination). The symmetrical η^5-coordination of the MCP fragment to two additional metal centres is observed also in trimetallic clusters with a pentagonal-bipyramidal geometry. The presence of additional metal centres can substantially influence the coordination properties of the MCP fragment, as demonstrated for trimetallic complexes with the metallaindene system or clusters with the facially coordinated metallacycle. In the latter case, the MCP fragment is η^3-coordinated to two additional metal centres, which excludes the formation of the common π system. The structure of the MCP fragment is characterised by a substantial deviation from planarity and localisation of the carbon–carbon bonds in the diene moiety. However, it should be noted that complexes of this type are observed much more rarely than complexes with the η^5-coordinated MCP fragment.

Polynuclear complexes with the MCP fragment are most often formed in the reactions of metal derivatives with acyclic organic molecules, *i.e.*, the metallacyclic ligand is formed simultaneously with the complex as such. The analogy between the MCP fragment and the cyclopentadienyl ligand is invoked many times in discussions of the structures of particular compounds, *i.e.*, in the 'post-factum' analysis of the already formed MCP complexes. However, examples of the use of mononuclear complexes with the MCP fragment as ligands in reactions with other transition metal complexes are scarce (see, for instance, Ref. 152).

A growing number of publications devoted to investigations of metal-containing fragments as potential representatives of a new class of π ligands demonstrates that this problem has attracted increasing interest. Many aspects of these studies were covered in reviews on aromaticity of metallacycles [153] and investigations of the structures and chemical properties of six-membered metallabenzenes.[154]

Undoubtedly, the use of metallacyclic fragments, including metallacyclopentadienes, as non-classical ligands is a promising area of modern chemistry of transition metal π-complexes.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 02-07-90322 and 04-03-32371) and Grant from the President of the Russian Federation (the Federal Program for the Support of Leading Scientific Schools, Projects NSh-1060.2003.03 and MK-60.2003.03).

Abstract. The results of X-ray photoelectron spectroscopy (XPS) studies of the structures of the outer and inner electron shells of compounds of light actinides (Th, U, Np, Pu, Am, Cm, Bk, Cf) in the binding energy (E_b) range of 0 – 1250 eV are generalised. The regularities of formation of the fine structure in the X-ray photoelectron (XPS) spectra of these compounds are considered. The mechanisms of appearance of such structure are analysed, and the correlations between the fine structure parameters and actinide oxidation states and local environment, the magnetic properties of compounds, the nature of the chemical bond and secondary electronic processes that accompany photoemission of electrons are discussed. Experimental evidence for effective formation of the outer (E_b = 0 – 15 eV) and inner valence (E_b = 15 – 50 eV) molecular orbitals, in particular, from the fully occupied An6p and L*n*s orbitals of the neighbouring actinide (An) and ligand (L) atoms in the compounds in question is presented. The use of fine spectral structure parameters, together with the electron binding energies and line intensities extends significantly the scope of application of the XPS method in structural studies.
The bibliography includes 276 references.

I. Introduction

Actinides (An) are the An5f transition elements located after actinium in the Periodic Table with atomic numbers (Z) in the range $90 \leqslant Z \leqslant 103$. These elements can be conventionally subdivided into two groups, namely, light actinides (Th, Pa, U, Np, Pu, Am, Cm), which are readily accessible for X-ray spectral studies, and heavy actinides (Bk, Cf, Es, Fm, Md, No, Lr), less accessible for such studies, which is mainly due to the relatively short half lives of the longest-lived actinide isotopes (Table 1). The electronic configuration of actinide atoms can be expressed as $\{Rn\}5f^n6d^m7s^2$, where $\{Rn\}$ is the electronic configuration of radon, $0 \leqslant n \leqslant 14$, $m = 0, 1$. In the ground state, actinides, except for thorium, protactinium, uranium, neptunium, curium and, possibly, lawrencium have no An6d electrons ($m = 0$); however, transition of one or two An5f electrons to the An6d shell does not require much energy. In compounds, actinides can occur in various oxidation states.[1–4]

Currently, nuclear energy is widely used in science and engineering. The permanent growth of the demand for the raw materials stimulates the design of economical nuclear-chemical processes used in all stages of nuclear energy production ranging from ore mining to transmutation of the spent nuclear fuel [1–7] and for the solution of the concomitant environmental problems using X-ray spectral methods.[8–16] Despite the fact that a number of industrially important actinide (Th, U, Pu) compounds have been widely studied in the last decades, many aspects concerning the physicochemical properties of these compounds still remain unknown.[1–4] Therefore, study of the electronic structures of actinide compounds and elucidation of the relationship between

Table 1. Electronic configurations and half lives ($T_{1/2}$) of the longest-lived isotopes of actinides.[1–3]

Isotope	Electronic configuration	Z	$T_{1/2}$ (see [a])
^{227}Ac	$6d7s^2$	89	21.8
^{232}Th	$6d^27s^2$	90	1.41×10^{10}
^{231}Pa	$5f^26d7s^2$	91	3.28×10^4

its parameters and their properties is a fairly topical task. In addition, investigation routes for the electronic structures and properties of transactinide compounds with atomic numbers in the range of $104 \leqslant Z \leqslant 118$ have taken shape in recent years.[17,18]

In the last decades, the design of high-precision X-ray photoelectron spectrometers[19–23] and development of quick methods for the calculation of electronic structures such as X_α-methods[24–28] and spectral structure parameters[29–35] enabled X-ray photoelectron spectroscopy studies into the electronic structures of actinide compounds to be carried out at a qualitatively new level. The results show that not only the spectra of core electronic shells[29,36,37] or outer valence molecular orbitals (OVMO),[38–44] but also spectra of the inner valence molecular orbitals (IVMO)[38,45–48] provide information about the physical and chemical properties of these compounds. Not only the chemical shifts of electronic levels and line intensities can be used for analysis. Useful information concerning the physicochemical properties of compounds and secondary processes that accompany photoemission can also be drawn from fine structure parameters of the spectra of both the core and outer electrons.[20–23,49–56] This is especially important in those cases where reliable determination of electron binding energies and line intensities of some electronic levels is difficult. In the spectra of actinide compounds, a complex fine structure is observed for almost all electron shells in the binding energy (E_b) range of $\sim 0 \leqslant E_b \leqslant 1250$ eV. This energy range is normally used for XPS measurements. The fine structure provides information on the actinide oxidation states in compounds (Th,[23,57–64] U,[39,40,60–78] Np,[79–81] Pu,[29,64,79,81–86] Am,[29,79,87,88] Cm, Bk, Cf[79,81,87,88]), on the magnetic properties (Th,[44,58,89] U,[43,44,55,89–91] Np[44,55,89,90]), on the structures of compounds (Th,[55,58] U,[26,38,45,47,48,55,66,92–97] Np,[55,80] Pu,[29,55,82] Am,[29,79] Cm, Bk, Cf[79]), on the nature of the chemical bond (Th,[37,52,53,55,58,98–100] U,[26,40,47,48,52,53,55,66,92–94,98,101–112] Np,[41,51–53,55,80,81,87–90,113–115] Pu,[29,37,41,52,53,55,82,87–91,115,116] Am,[29,37,79,81,87–89,91] Cm, Bk, Cf[79,81,87,88]), on the secondary electronic processes that accompany the emission of photoelectrons (Th,[55,58,117–120] U,[47,55,56,103–105,117] Np,[55,56,79,80] Pu,[29,55,79,82,121] Am,[29,79] Cm, Bk, Cf[79]), and so on. Therefore, analysis of the reasons for the appearance of the fine spectral structure and identification of the correlation between its characteristics and the properties of the considered compounds, which represent key goals of this review, are fairly topical.

The XPS spectra of light actinide compounds clearly show the bands for the outer valence MO (Th,[39,58] U,[38,40,65,66,70,111,122] Np,[41,80,89] Pu,[41,82,83,89] Am,[79,88,89] Cm, Bk, Cf[79,88]); inner valence MO (Th,[53,58] U,[47,53,66,93,94,102,104,109,110,123] Np,[36,53,80,113] Pu,[36,53,82] Am,[29] Cm, Bk, Cf[53]); the multiplet line splitting due to the presence of unpaired An5f electrons in actinide ions (Th,[55,58] U,[55] Np,[80] Pu,[82] Am,[29] Cm, Bk, Cf[79]); a dynamic effect due to the giant Coster–Kronig transitions within the core and valence levels during the core electron photoemission (Th,[56,62,119,120,124] U,[47,56,66] Np,[55,56,80] Pu,[29,82] Am,[29] Cm, Bk, Cf[54,55]); many-body perturbation caused by simultaneous excitation of valence electrons during photoemission, which gives rise to satellites on the higher binding energy side from the basic XPS lines (so-called shake up satellites) (Th,[117,118,125] U,[52,66,105] Np,[79,80] Pu,[29,82,85,126] Am,[29,127,128] Cm, Bk, Cf[79]), and other effects.

Despite the fact that different mechanisms of the appearance of fine spectral structure occur simultaneously, for electrons of a particular shell, the probability of a particular mechanism is usually much higher than that of other mechanisms.[52,54,55] Therefore, to study particular mechanisms of the formation of fine spectral structure in actinide compounds, it is expedient to use compounds of those elements in the spectra of whose electronic shells this mechanism shows itself with the highest probability.

Most often, the fine structure of the XPS spectra of actinide compounds is interpreted based on the results of theoretical calculations (U,[24–26,31,32,42,55,93,129–137] Th,[124,125,129] Np,[33,36,136] Pu,[33,36,138] Am,[33,35,138] Cm, Bk, Cf[35,137,138]). However, such calculations are usually labour-consuming and are performed after the experimental spectra have already been measured. Therefore, in practice, spectra that have been thoroughly studied both theoretically and experimentally are often used as references to analyse the XPS spectra of new compounds.

X-Ray photoelectron spectroscopy is the most appropriate technique for the study of the physicochemical states of actinides. It is used to estimate the oxidation states of actinides, their electronic configurations, and the degree of participation of electrons in the chemical bond on the surface of solids (Th,[79] U,[139,140] Pu[141,142]), in alloys and other materials (Th,[143] U,[144–147] Pu,[82,146] Am, Cm, Bk, Cf[79]) and to determine radionuclides in the environment. This method is used in the quantitative elemental analysis of actinide materials;[148] in particular, it has been successfully used to determine the elemental and ionic composition of the reactor fuel melts from the Chernobyl nuclear power plant,[9,91,149,150] to study the nature and the structure of 'new-formed' materials grown on these melts,[10,150,151] to study the mechanisms of interaction of the uranyl group (UO_2^{2+}) with calcite and diabase,[12,152–157] humic acids,[11,157–160] apatite[161,162] and biosorbents,[91] to study the microbial reduction of the U^{6+} ions to U^{4+} (Refs 163, 164) and the effect of visible light on the decomposition of the uranyl citrate complex;[165] and to study the elemental and ionic composition of highly hazardous 'hot' particles[8] containing U, Cs,[15,166–169] Sr[15,170–172] and Ru,[13,14,173–175] which have been formed during the simulation of a nuclear power plant accident under laboratory conditions. Together with other X-ray spectral methods,[16] X-ray photoelectron spectroscopy[11,152,158,161] is efficiently used to solve problems related to radionuclide transfer in the environment.

For interpretation of XPS spectra, in particular, of actinide compounds, as has been shown previously for lanthanide compounds,[54] the binding energy range of the electrons (0–1250 eV) can be divided conventionally into three regions. The first one is from 0 to ~15 eV; this exhibits the spectral structure mainly caused by the An5f and OVMO electrons. The second region (~15 to ~50 eV) shows a structure that is largely related to the IVMO electrons and whose parameters correlate with the degree of participation of the An6p and L*n*s atomic orbitals (AO) in the chemical bond and with the structure of the local environment of the actinide ion. The third region (~50 to 1250 eV) reflects the fine spectral structure of the core electron levels; the mechanisms of its formation may be different.

This review mainly deals with the fine structure of the X-ray photoelectron spectra of compounds of light actinides (Th, U, Np, Pu, Am, Cm, Bk, Cf) observed in the binding energy range of 0–1250 eV, the mechanisms of formation of this structure and the dependence of its characteristics on the physicochemical properties of compounds and the nature of the chemical bond in them. We are going to answer the following questions.

1. What are the mechanisms and general regularities of the formation of fine XPS structure for actinide compounds?

2. How do the parameters of the fine structure in question correlate with the properties of actinide compounds and the nature of the chemical bond in them?

3. What new quantitative and qualitative information on the physicochemical properties of actinide compounds can be gained from the parameters of the fine XPS structure?

To simplify the discussion of the fine structure of XPS spectra in the region of valence electrons, we use atomic designations in addition to molecular ones.

II. Thorium compounds

Since the electronic configuration of thorium is $\{Rn\}6d^27s^2$ (see Table 1), the simplest structure of the XPS spectra should be expected of compounds formed by tetravalent thorium. This is due to the fact that Th^{4+} does not contain unpaired electrons (the electronic configuration is $\{Rn\}5f^0$). Filling of the An5f shell with

an increase in the atomic number of the actinide complicates the spectral structure due to the multiplet splitting, which is caused, as noted above, by the presence of unpaired valence electrons in the actinide ion; this results in a complex structure of the final state of this ion upon photoemission of an outer or an inner electron.

This Section presents the results of analysis of the XPS spectra of thorium [57, 120, 176, 177] and its compounds,[52, 55, 59–62, 64, 118, 119, 125, 177] in particular, ThO_2,[53, 58, 61, 98, 99, 117] ThF_4,[53, 58, 98, 99] $Th(NO_3)_4 \cdot 4H_2O$,[53, 58] $Th(SO_4)_2 \cdot nH_2O$, $Th(OH)_4$, $Th(CO_3)_2 \cdot nH_2O$,[55] $ThSiO_4 \cdot nH_2O$,[61, 63] mainly dealing with their fine structure and dependence of its characteristics on the oxidation state of thorium, the structure of compounds, and the nature of the chemical bond in them. This information is also necessary for interpretation of the XPS structure of heavier actinide compounds containing unpaired An5f electrons.

1. Spectral range of valence electrons

In the low binding energy range (around the Fermi level for metals), the XPS spectra of thorium compounds (Figs 1, 2) exhibit a poorly resolved band due to electrons of the OVMO. This band largely reflects the participation of the $Th6d^27s^2$ and L*n*p electrons of thorium and the surrounding ligands L in chemical bonds. The full widths at half maximum (FWHM) of these bands for ThO_2, $Th(NO_3)_4 \cdot 4H_2O$ and ThF_4 are 3.3, 2.5 and 3.7 eV, respectively [55, 58] (see Fig. 2).

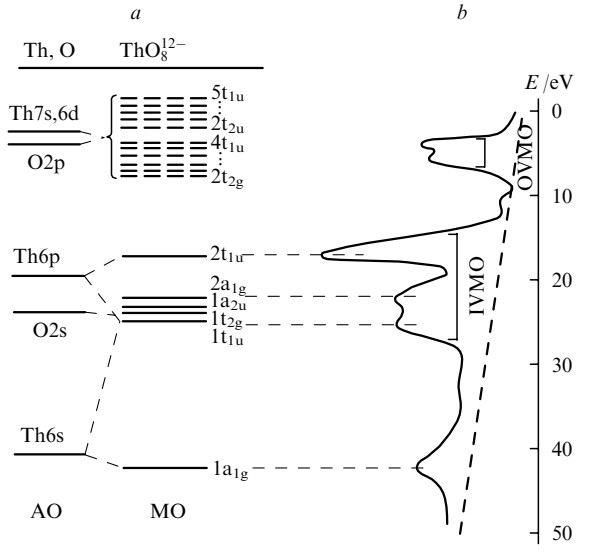

Figure 1. Scheme of MO formation in the ThO_8^{12-} cluster (O_h group of symmetry) (*a*) and X-ray photoelectron spectrum of the oxide ThO_2 (*b*).[58, 62] The dashed line in Fig. 1 *b* is the background.

In a binding energy range of ~10–50 eV, the spectra show a structure due to the Th6s, Th6p and L*n*s electrons. This structure is more complicated than that expected for the sum of the atomic spectra of the elements contained in the given compounds. Thus, the experimental spin–orbit splittings (ΔE_{sl}) for the Th6p electrons differ markedly for the oxide (9.0 eV), fluoride (7.2 eV), thorium metal (7.9 eV) and atomic thorium (9.2 eV) (Tables 2, 3).[55, 57, 58, 62, 178, 179] For ThO_2 and ThF_4, this binding energy difference between the $Th6p_{3/2}$ and $Th6p_{1/2}$ electrons cannot be attributed to the superposition of the Th6p line onto the neighbouring lines related to the ligands. In this case, the components of the thorium doublet would shift in the opposite direction, and apparent splitting of this level for ThO_2 would be lower than for ThF_4. It is known from numerous experimental data that in the low-energy range, the spin–orbit splitting of the core levels depends only slightly on the chemical environment.[21, 23]

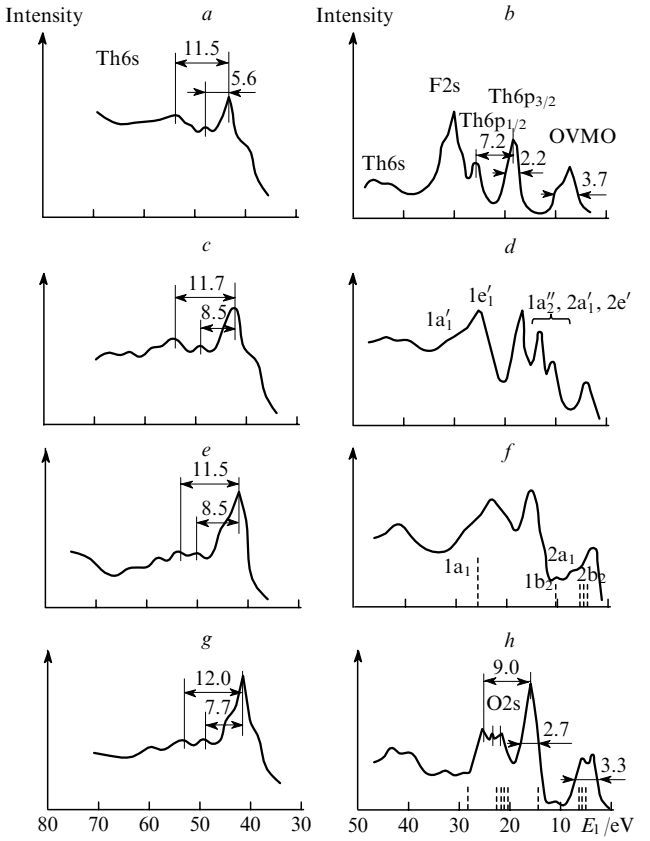

Figure 2. XPS spectra of thorium compounds in the range of weakly bound electrons
(*a*, *b*) ThF_4; (*c*, *d*) $Th(NO_3)_4 \cdot nH_2O$; (*e*, *f*) $Th(OH)_4$; (*g*, *h*) ThO_2. The Th6s spectra (*a*, *c*, *e*, *g*) show the dynamic effect with the formation of final states of the type $Th6s^16p^66d^0 \rightleftharpoons Th6s^26p^46d^1$; the vertical lines below the spectrum *h* show the MO energies for the ThO_8^{12-} cluster (O_h symmetry);[180] the vertical strokes below spectrum *f* show the experimental spectrum of H_2O;[19] the designations for the MO of the NO_3^- ligand (D_{3h} symmetry) are presented above spectrum *d*.

The extra structure present in the O2s and F2s binding energy range cannot be explained by the presence of ligand atoms in different oxidation states in ThO_2 and ThF_4. In this case, the corresponding structure would also be observed in the O1s and F1s spectra. This is due to the fact that the chemical shift does not depend significantly on the core electron binding energy in the E_b range up to ~1000 eV.[21, 23] The O1s and F1s spectra of ThO_2 and ThF_4 consist of single lines with FWHM of 1.4 and 1.7 eV, respectively.[58]

The most complicated fine structure is observed in the low-energy XPS range for thorium compounds containing organic ligands. In this case, the thorium spectrum is superimposed by a spectrum of the IVMO electrons of the ligands. (For some compounds, these MO are also shown in Fig. 2.)

On the basis of the XPS data, taking into account the results of theoretical calculations,[129, 137, 180, 181] it has been suggested [51, 55, 58, 59, 101, 102] that an important reason for the formation of the fine structure in the spectra of these thorium compounds is efficient (experimentally observed) formation of IVMO from the Th6p and L2s atomic shells.

The foregoing can be illustrated in relation to the spectrum of the low binding energy electrons of ThO_2. The local environment of thorium in this compound can be simulated by the ThO_8^{12-} cluster (O_h group of symmetry) in which the Th–O bond length (R_{Th-O}) equals 0.241 nm (Fig. 3, see Fig. 1).[54] The results of theoretical calculations performed for the ground state of this cluster in the non-relativistic spin-limited SCF X_α-DV approx-

[a] The binding energies corresponding to the most intense peaks in the Th6s spectra are used. [b] The ΔE_i differences for oxygen and fluorine are given.

imation[180] are presented in Fig. 3 for convenient qualitative comparison with the experimental data. It follows from Fig. 3 that the MO system can be conditionally subdivided into two groups, inner valence and outer valence MO.

The outer valence MO (OVMO) group consists of vacant $2t_{2u}-6t_{1u}$ orbitals and filled $2t_{2g}-4t_{1u}$ orbitals, which contain occupied Th5f states, whereas free thorium atoms contain no Th5f electrons. It has been shown experimentally [99, 100] that relatively high line intensity in the XPS spectra of ThO_2 and ThF_4 in the OVMO energy range is largely related to the presence of filled Th5f states in these compounds. This is consistent with the results of studies of $L_{\alpha 1,\beta 2,4}$(Th)-emission of thorium oxide and halides.[182]

The other group of molecular orbitals includes the $1a_{1g}$, $1t_{1u}$, $1t_{2g}$, $1a_{2u}$, $2a_{1g}$ and $2t_{1u}$ IVMO. Analysis shows that, whereas OVMO mainly consist of vacant valence Th5f, Th7s, Th6d, Th7p and O2p atomic orbitals, the IVMO are mainly composed of fully occupied inner valence Th6s, Th6p and O2s AO. For example, orbitals of the $1t_{1u}$ and $2t_{1u}$ IVMO pair, one of which can be considered as a bonding orbital ($1t_{1u}$) and the other, as an antibonding one ($2t_{1u}$), consist of 18% of Th6p plus 68% of O2s and 55% of Th6p plus 27% of O2s, respectively (see Fig. 3). Significant mixing of the Th6s and O2s AO takes place during formation of the $1a_{1g}$ and $2a_{1g}$ IVMO pair. However, for uranium oxides, it has been shown [123, 180] that inclusion of relativistic effects in the calculation leads to a lower degree of mixing. This is mainly due to splitting off of the Th6$p_{1/2}$ component from the Th6$p_{3/2}$ level (ΔE_{sl} = 7.9 eV), which allows the use of non-relativistic calculation results in interpretation of the low binding energy spectra of actinide compounds.

The energies of occupied OVMO electronic levels do not differ much (−11.21 to −9.39 eV) and fall within a range of 1.82 eV. The energies of the inner valence MO vary over a broader range and form an energy structure typical of this cluster. This makes it possible to construct qualitative structural schemes for the IVMO of various model clusters (see Figs 1, 3).

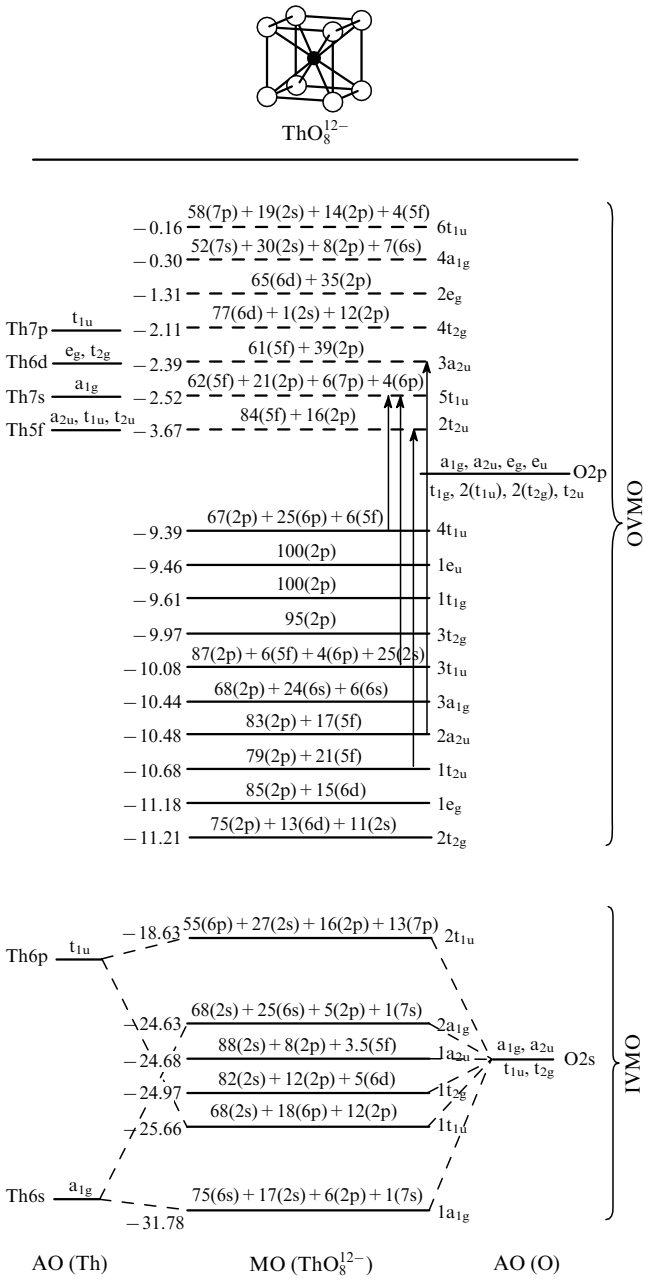

Figure 3. Composition (%) and the structure of MO of the ThO_8^{12-} cluster (O_h symmetry) for $R_{Th-O} = 0.241$ nm (X_α-DVM calculations).[180] The vacant MO are shown by horizontal dashed lines; here and below, AO and related IVMO are connected by dashed lines. The arrows show the most probable electronic shake up transitions which accompany the photoemission of a core electron (the energy scale is not maintained).

Experimental data for ThO_2 are presented in Fig. 4, which provides their qualitative comparison with the results of theoretical calculations and shows the binding energy differences between the valence and core electrons for separate atoms and the ThO_8^{12-} cluster, which can be determined experimentally.

It can be seen from Fig. 4 that the formation of molecular orbitals from the Th6p and O2s AO can induce a relative shift of the $2t_{1u}$ level toward lower binding energies compared to that of the Th6p electrons by a Δ_1' value. The formation of IVMO from the Th6s and O2s AO can entail a relative shift of the $1a_{1g}$ level toward higher binding energies compared to that of the Th6s electrons of the Th metal by a Δ_2 value. Note that MO formation can induce some other significant effects that influence the line shifts, for example, a change in the effective charge of the nucleus.

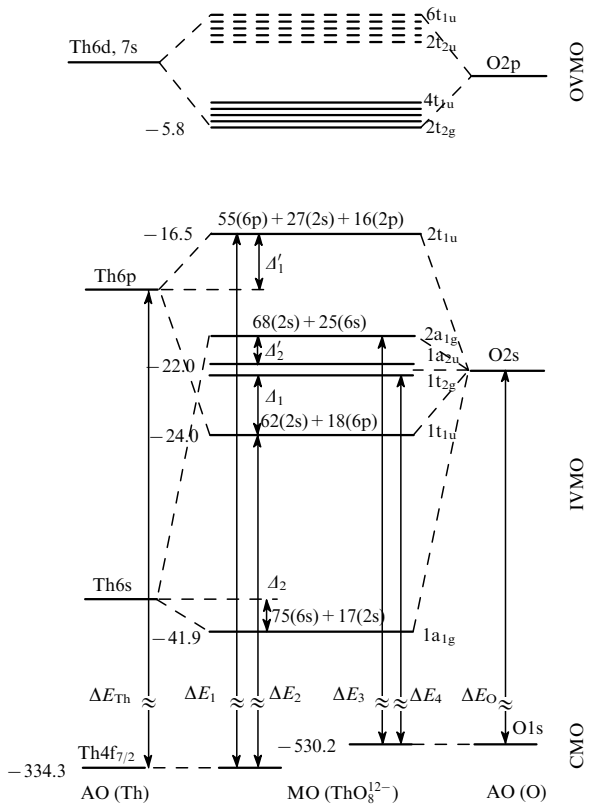

Figure 4. Diagram of MO of the ThO_8^{12-} cluster (O_h symmetry) reflect the structure of the nearest environment of the thorium atom in ThO_2. Chemical shifts induced by MO formation from AO are not reflected. The diagram is based on the XPS spectrum and calculation results.[180]

These shifts of the levels related to MO formation can be determined rather reliably by comparing the energy differences between various valence and core levels ΔE_i ($i = 1-4$), ΔE_{Th} and ΔE_O (see Fig. 4) found from the XPS spectra of thorium compounds (see Table 3).

It follows from the data of Table 3 that on passing from thorium metal to thorium compounds, the binding energy differences (ΔE_i) between the core $Th4f_{7/2}$ and $Th5d_{5/2}$ electrons change to the least extent. Substantial deviations in the ΔE_i energies are found for the formal $\Delta E_{sl}(Th6p_{3/2} - Th6p_{1/2})$ and $\Delta E_1(Th6p_{3/2} - Th4f_{7/2})$ values, which describe the energy shifts of valence electrons. These results are consistent with the assumption that at least the $Th6p_{3/2}$ and O2s atomic shells are involved in the $2t_{1u}$ IVMO, which is formally antibonding.

The formation of IVMO in the oxide ThO_2 and the fluoride ThF_4 is confirmed by X-ray $O_{4,5}$(Th) emission spectroscopy.[99,100,183–186] Additional information on the valence electron states of thorium dioxide and tetrafluoride can be gained from X-ray $O_{4,5}$(Th) [187–190] and $M_{3,4,5}$(Th) absorption spectra.[191]

2. Electronic structure of ligands

The low binding energy spectra of $Th(SO_4)_2 \cdot n\,H_2O$, $Th(NO_3)_4 \cdot n\,H_2O$, $Th(CO_3)_2 \cdot n\,H_2O$ and $Th(OH)_4$ [55] can be represented approximately as the summary spectra of clusters with a Th central atom surrounded by the ligands NO_3^-, SO_4^{2-}, CO_3^{2-}, OH^- and H_2O (see Fig. 2).

To estimate qualitatively the contribution of ligands to complication of the structure of the general low binding energy spectrum of thorium compounds, let us consider the spectral structure of the ligands taking the NO_3^- group as an example.

The low binding energy spectral range of $Th(NO_3)_4 \cdot n\,H_2O$ can be approximately regarded as a superposition of the spectra from thorium involved in the chemical binding with oxygen, the

NO_3^- ligand and H_2O (see Fig. 2 *c*,*d*). The experimental XPS spectrum of water (C_{2v} group of symmetry)[19,55] reflecting the system of its MO is shown in Fig. 2 *f* by vertical dashed lines. The spectral structure of the NO_3^- ligand (D_{3h} group of symmetry) with $R_{N-O} = 0.121$ nm is conveniently illustrated by the MO diagram (Fig. 5) constructed on the basis of results of semiempirical CNDO/2 calculations. These results are in satisfactory agreement with the data for $Ni(NO_3)_2 \cdot 6\,H_2O$ whose XPS spectrum exhibits, in the low binding energy range, only an OVMO band for nickel at low E_b values.[55] Except for the thorium line in the valence band, the spectral structures for nickel and thorium nitrates have much in common. The molecular orbitals of the NO_3^- ligand are shown in Fig. 2 *d* above the spectra of thorium nitrate. The contributions of the electrons from various MO to the covalent bonding in the NO_3^- ligand [58] were estimated based on the resonance energy value E^{α}_{N-O} (measured in au),[52,53] which characterises the fraction of covalent bonding in the chemical bond; the corresponding energy values are indicated in parentheses in Fig. 5.

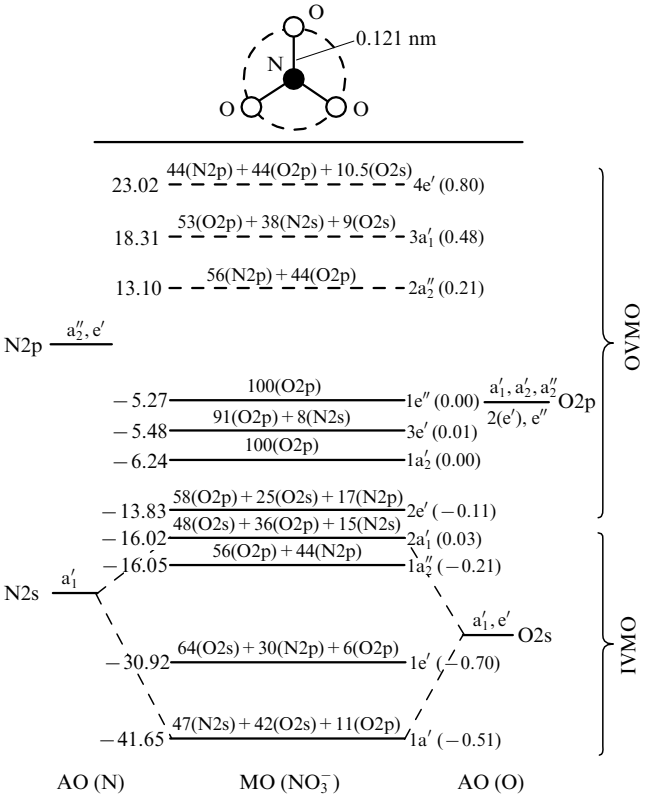

Figure 5. Composition (%) and structure of the MO of the NO_3^- ligand (D_{3h} symmetry) (CNDO/2 calculation).[58]
The values in parentheses are resonance energies (E^{α}_{N-O}, au; see Refs 52, 53). The vacant MO are shown by horizontal dashed lines (the energy scale is not maintained).

As can be seen from Fig. 5, the energies of occupied MO of the NO_3^- ligand are located within a 36.38 eV range, which almost overlaps the range of MO of the ThO_8^{12-} cluster; taking them into account provides a satisfactory description of the additional structure observed in the experimental XPS spectrum of thorium nitrate (see Fig. 2 *d*). This IVMO structure is expected to arise also in the spectra of compounds containing CO_3^{2-} and SO_4^{2-} groups (D_{3h} and T_d symmetry, respectively).[52]

The results indicate that the spectra of complex ligands of the thorium compounds studied have a characteristic structure caused by OVMO and IVMO electrons extended in a binding energy range of ~35 eV. This structure can be used to identify these substances. In addition, the low energy range of the spectra may display an additional structure caused by secondary electrons and other processes. Since these processes are also reflected in the core electron spectral structures, they can be studied more conveniently in the spectra of core levels.

3. Core electron spectra of thorium compounds

When performing quantitative elemental and ionic analysis using XPS spectra, the stoichiometric compositions of compounds and the oxidation states of ions are determined using the most intense single sharp lines for the core levels. The most suitable line for these studies of thorium compounds is a component of the doublet (caused by the spin–orbit splitting) of the $Th4f_{7/2}$ electrons.[58,60,117,121,125]

The core electron fine structure (shake up satellites) related to many-body perturbation reflects the composition and energy distribution of molecular orbitals. The many-body perturbation is due to the extra final states of thorium ion which arise upon the transition (excitation) of a valence electron to a vacant outer MO simultaneously with the photoemission of a core electron (shake up process[21–23,49]). This gives rise to shake up satellites on the higher binding energy side from the basic lines. Such satellites are observed in the spectra of all core and valence levels; however, as the electron binding energy decreases, their intensity diminishes (see, for example, the study[192] dealing with $LnNbO_4$). These satellites are more specific in the Th4f and Th5d spectra (Fig. 6). Since the excitation of ligand-related electrons from filled MO to vacant, mainly metallic AO can take place during the electron photoemission from a core metallic level (see Fig. 3), the corresponding satellites can be attributed to the charge transfer from the ligand L to the metal M: $Lnl \rightarrow Mn'l'$, where n (n') and l (l') are the principal and orbital quantum numbers, respectively.[23] These excitations, which satisfy the monopolistic selection rules, $\Delta l = \Delta s = 0$ (s is the spin quantum number) are shown for ThO_8^{12-} in Fig. 3 by arrows. A simple two-level theoretical model[22,23,118,193] makes it possible to calculate the satellite intensity, which is related to the change in the partial electron density on a filled AO of the metal caused by electron photoemission from a core level. On the basis of this model, it was shown that the satellite intensity diminishes as the metal electron density on a certain filled MO increases and the magnitude of its change upon the photoemission of the core electron decreases. The energy distance from a satellite to the basic line depends on the ionic–covalent nature of the chemical bond in the compound. In the case of 3d-metal compounds, this distance increases and the satellite intensity decreases with an increase in the ionic contribution to the bond.[193] The spectra containing shake up satellites are typical of a particular thorium compound and reflect the actinide oxidation

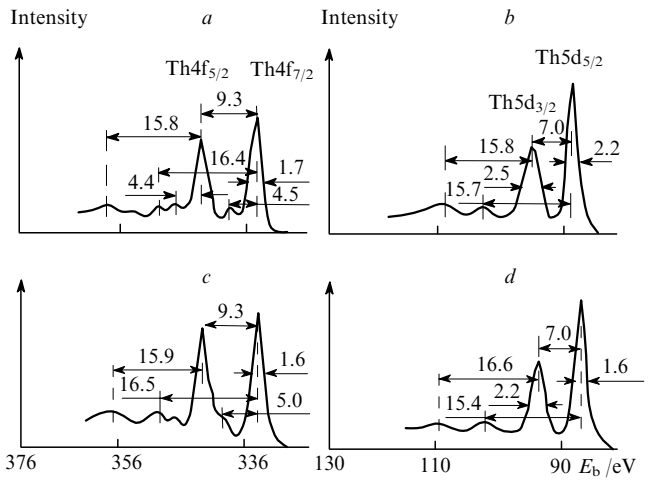

Figure 6. XPS spectra of thorium compounds in the Th4f (*a*, *c*) and Th5d (*b*, *d*) binding energy ranges.[55] (*a*, *b*) ThF_4; (*c*, *d*) ThO_2.

state and the stoichiometric composition. A similar satellite structure can also be followed in the Th5d spectra (see Fig. 6).

It is also noteworthy that, despite the complication of the Th4f and Th5d spectral structures due to many-body perturbation, the observed basic lines are relatively sharp. The intensity ratios of individual components of doublets are close to the theoretical values, while the spin–orbit splittings (ΔE_{sl}) are constant for different compounds, being equal to 9.3 and 7.0 eV for the Th4f and Th5d electrons, respectively. A similar spectral pattern for some shells of transition elements is usually observed when the multiplet splitting and dynamic effect are feebly manifested in the spectra of these electrons.[22, 23, 193]

The Th6s binding energies reported in several papers [20, 57, 58] are different. This discrepancy can be explained by the errors of measurements resulting from the relatively small Th6s photoionisation cross-section and unexpectedly wide energetic interval ($\sim$40 eV) in which the complex fine spectral structure arises. The most intense maximum in the Th6s spectrum from ThO_2 is observed at $E_b \approx 42$ eV (see Fig. 2 *g*).

On the basis of theoretical calculations, [129, 137, 180] it was suggested that the Th6s shell can markedly participate in the MO formation in thorium compounds. Therefore, for a number of thorium compounds, the low binding energy XPS spectra of Th6s electrons were recorded and analysed [55, 58] (see Fig. 2). In a range of $\sim$40 eV, the Th6s spectra show structure that cannot be attributed to the participation of Th6s in the chemical bond alone. This participation could result in the shift of the Th6s line or appearance of a fine structure with a width of several electron-volt. Since the compounds in question are diamagnetic and do not contain unpaired electrons, their XPS spectra are not expected to display multiplet splitting. The maxima observed at the same relative energies as the Th4f and Th5d spectra can probably be attributed to the shake up satellites in those cases where the corresponding line intensities do not exceed $\sim$10% of the basic lines.

Similar considerations are also valid for spectral structure of the Th5p electrons (Fig. 7). Instead of the expected doublet caused by the spin–orbit splitting, this spectrum exhibits a much more complicated fine structure. The spin–orbit splitting is given by ΔE_{sl}(Th5p) = 47 eV, while the binding energies (see Table 2) are as follows: $E_b(Th5p_{3/2}) = 182$ eV and $E_b(Th5p_{1/2}) = 229$ eV.[20] However, the spectra of thorium compounds exhibit a clear-cut additional line at $\sim$200 eV and the $Th5p_{1/2}$ lines are broadened (see Fig. 7). These structural changes in the spectra of relatively deep electron shells cannot be attributed to the crystal field splitting. Moreover, splittings of about several electron-volt are also observed in the $Th4p_{3/2}$ spectra.[55] These spectra are complicated due to the appearance of additional broad OKLL Auger bands. The most individual fine structure in the $Th4p_{3/2}$ spectra is found in the spectrum of thorium tetrafluoride containing no O atoms.[55]

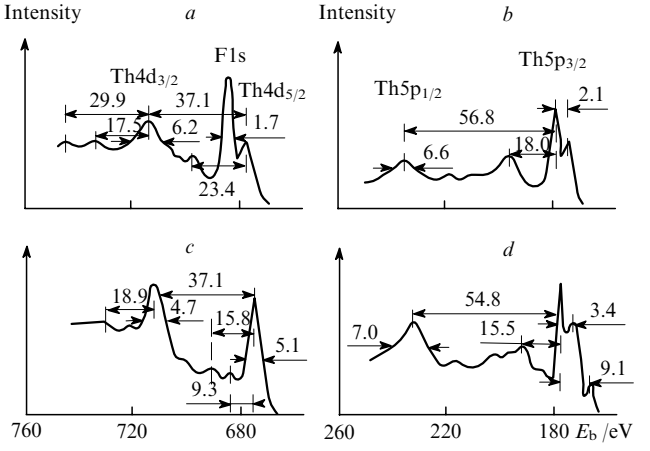

Figure 7. XPS spectra of thorium compounds in the Th4d (*a*, *c*) and Th5p (*b*, *d*) binding energy ranges.[58] (*a*, *b*) ThF_4; (*c*, *d*) ThO_2. The Th5p spectra for both compounds show the dynamic effect, resulting in the formation of final states of the type $Th5p^5 5d^{10}(6s^2 6p^6)5f^0 \rightleftharpoons Th5p^6 5d^8(6s^2 6p^6)5f^1$.

The XPS spectra of thorium and its compounds may clearly manifest the dynamic effect due to the giant Coster–Kronig transitions within the core and outer shells during the electron photoemission from an atom or an ion. This results in several final states of an ion and, as a consequence, a complicated fine structure is observed in the spectra instead of sharp single lines. For thorium compounds, the ratios of the binding energies of core and outer electronic levels are favourable for this effect to appear during the photoemission of core electrons from the Th atom. Indeed, since the binding energies of thorium levels obey the ratios $E_b(Th6s) \approx 2E_b(Th6p)$; $E_b(Th5d) \approx 2E_b(Th6s)$; $E_b(Th5p) \approx 2E_b(Th5d)$; $E_b(Th4f) \approx 2E_b(Th5p)$; $E_b(Th4d) \approx 2E_b(Th4f)$; $E_b(Th4p) \approx E_b(Th4d) + E_b(Th5s)$, and the dynamic effect has a resonance nature,[55] the probability of this effect for thorium compounds is rather high (see Table 2). The dynamic effect gives rise to an additional two-hole final state (apart from the ground one-hole state), due to the electron transition from an intermediate fully occupied level to a level with a hole that has appeared upon electron photoemission from the atom and to the nearest low-energy vacant level in the molecule under consideration. This two-hole state should have the same orbital quantum number L as the ground one-hole final state and a similar energy.[119, 120, 194] According to estimates,[119, 124] the following one-hole and two-hole final states are expected to appear with the highest probability for Th^{4+} compounds after photoemission of the core electron: $Th6s^1 6p^6 6d^0 \rightleftharpoons Th6s^2 6p^4 6d^1$ (see Fig. 2); $Th5p^5 5d^{10}(6s^2 6p^6)5f^0 \rightleftharpoons Th5p^6 5d^8(6s^2 6p^6)5f^1$ (see Fig. 7, Table 2); $Th5s^1 5p^6 5d^{10}(6s^2 6p^6) \rightleftharpoons Th5s^2 5p^5 5d^9(6s^2 6p^6)5f^1$. It is assumed [55, 58] that the dynamic effect can also be observed in the $Th4p_{3/2}$ spectra. This can be attributed, for example, to the formation of final states of the type $Th4p^5 4d^{10} 5s^2 . (5p^6 5d^{10} 6s^2 6p^6) \rightleftharpoons Th4p^6 4d^9 5s^1 (5p^6 5d^{10} 6s^2 6p^6) 7p^1$.

The structure of the Th5s spectra caused by the dynamic effect is difficult to observe, as it is superimposed by the C1s spectrum;[55, 58] however, it has been shown theoretically that this structure should occur in this binding energy range.[124, 194]

It follows from the above examples that, on the one hand, the fine spectral structure complicates gaining the traditional information concerning the binding energies and line intensities for the core electrons, but, on the other hand, this structure provides significant additional information on the electron structure, the nature of chemical bonds and the secondary electronic processes that accompany the electron photoemission from ions.

A number of industrially important thorium compounds have now been studied by XPS. Although thorium is formally tetravalent in each of the compounds studied, the binding energies imply that the thorium oxidation state increases in the following sequence: ThO_2, $Th(CO_3)_2 \cdot n H_2O$, $Th(OH)_4$, $Th(NO_3)_4 \cdot 4 H_2O$, $Th(SO_4)_2 \cdot n H_2O$, ThF_4.[55, 58] This results in an increase in the $Th4f_{7/2}$ binding energy by $\Delta E_b = 1.8$ eV. Thus, in the series of thorium compounds, the ionic nature of the chemical bond increases.

To conclude this Section, we would like to note that the understanding of the mechanism of fine structure formation in the XPS spectra of thorium compounds is highly favourable for gaining the most detailed and reliable information on the properties of these compounds and the nature of the chemical bond in them.

III. Uranium compounds

Solid-state uranium compounds have been studied by XPS in most detail.[45, 47, 53, 55, 57, 65, 66, 75, 78, 93, 94, 177, 195–198] The gaseous UF_6, $U(BH_4)_4$, $U(BH_3Me)_4$ and $U(C_8H_8)_2$ molecules have been

studied.[199–201] Photoelectron spectroscopy data for the UF_4, UCl_4 and ThF_4, $ThCl_4$ molecules in the gas phase have also been reported.[179, 202] Theoretical analysis of the electronic structures of these compounds has received much attention.[53, 55, 123, 129–132, 203–206] X-Ray photoelectron spectroscopy has proved to be the most adequate method for determining the oxidation states and ionic compositions of uranium in oxides and other compounds, in particular, in ores.[66] Knowledge of the uranium oxidation state in ores is especially important for underground leaching.[207, 208] In a number of studies,[47, 65, 66, 92–94] uranium compounds have been studied by XPS in order to develop a non-destructive method for determining the uranium oxidation states in compounds and minerals and the stoichiometric compositions of minerals on the basis of XPS fine structure parameters.

1. Uranium oxides

a. The U5f spectra

X-Ray photoelectron studies of uranium oxides have shown[38–40, 45, 53, 65–68, 76, 77, 93, 111, 190, 209, 210] that the fine structures of the low binding energy spectra ($E_b = 0-50$ eV) of UO_2 and UO_3 are substantially different (Fig. 8). Since the U^{6+} ion in the trioxide γ-UO_3 has the electronic configuration $\{Rn\}5f^0$, while the electronic configuration of U^{4+} in the dioxide UO_2 is $\{Rn\}5f^2$, the XPS spectrum of the latter,[40, 45, 65–68, 93, 209] unlike the spectrum of γ-UO_3, exhibits a rather narrow intense line at $E_b = 1.9$ eV, which belongs to the U5f electrons participating only slightly in the chemical bond. In addition, some differences in the structures of OVMO and IVMO bands for uranium dioxide and trioxide are also observed (see Fig. 8).

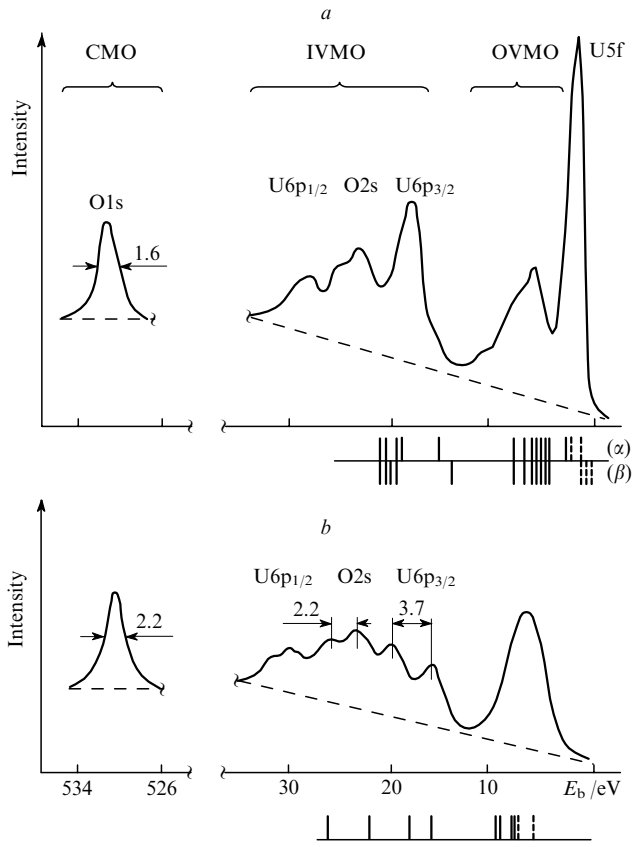

Figure 8. XPS spectra of uranium oxides UO_2 and γ-UO_3 in the low binding energy range and in the O1s range.[53, 93]
(*a*) UO_2, (*b*) γ-UO_3. The intensities of electrons from different shells are not normalised. The dashed lines show the background. The vertical lines under the spectra show the energy levels found by non-relativistic spin-unrestricted (*a*) and spin-restricted (*b*) SCF X_α-SW calculations.[93]

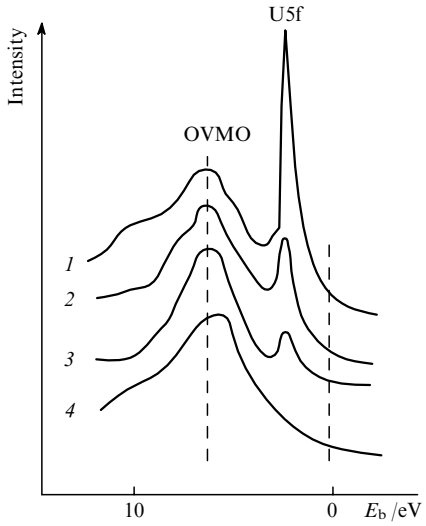

Figure 9. XPS spectra of synthetic uranium oxides in the U5f and OVMO binding energy ranges.[65]
(*1*) $UO_{2.06}$; (*2*) U_2O_5; (*3*) U_3O_8; (*4*) γ-UO_3.

X-Ray photoelectron spectra of low binding energy electrons (0 to $\sim$50 eV) which participate in the MO formation reflect the band structure and represent lines with a width of several electron-volt. The line around a zero binding energy observed in the spectrum of uranium dioxide containing unpaired U5f electrons has the FWHM $\Gamma \approx 1.4$ eV, which is typical of core electrons (see Fig. 8). In the spectra of the U_4O_9, U_2O_5 and U_3O_8 oxides, the intensity of the U5f line decreases (Fig. 9).

Since the ratio of photoionisation cross-sections $\sigma(U6d)/\sigma(U5f)$ is appreciably lower than unity,[203] the U6d line in the XPS spectra should be much less intense than the line for the unbound U5f electrons. For the U^{4+} ion with the electron configuration $\{Rn\}5f^2$, $\sigma(U5f_{5/2})/[3\sigma(U4f_{7/2})] = 0.0213$,[35] which is almost half the corresponding experimental relative intensity[65] $I = I(U5f)/I(U4f_{7/2})$ for UO_2, equal to 0.0383 (Fig. 10).

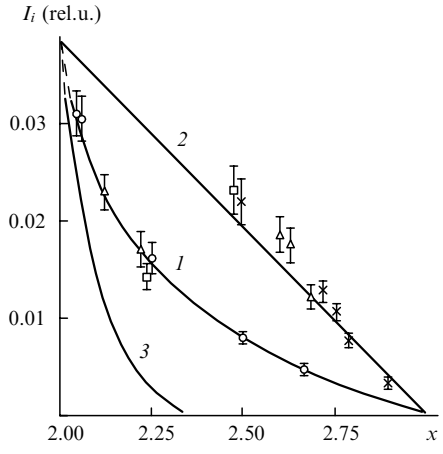

Figure 10. Relative intensity (I_i) of the U5f line in the XPS spectra of synthetic and natural uranium oxides UO_x *vs.* the oxygen coefficient x.[65, 66]
(*1*) I_1 calculated from Eqn (1); (*2*) I_2 calculated from Eqn (2), (*3*) I_3 calculated from Eqn (6); the dots correspond to experimental data: the circles show the data for synthetic oxides; triangles and squares, natural oxides; crosses, UO_2 and γ-UO_3 mixtures.

The energy difference between the U5f and OVMO lines is ~4.2 eV, which permits reliable determination of the intensity of the former. For elucidating the dependence of the intensity (I_1) of the U5f line on the number of oxygen atoms (oxygen coefficient x) in the UO_x oxides, found as the intensity ratio of the U5f lines to the $U4f_{7/2}$ lines without inclusion of the shake up satellites, a number of synthetic uranium oxides have been studied.[65,66] The dependence of the relative intensity I_1 of the line observed in the XPS spectra of the UO_x oxides around zero binding energy, which is caused presumably by the unbound U5f electrons, on the oxygen coefficient x for synthetic oxides can be described as follows (see Fig. 10):

$$I_1 = 5.4x^{-7.2}. \quad (1)$$

Extrapolation of the curve for the dependence of I_1 on x gave the relative intensity $I_1 = 0.0383$ for UO_2. This allows one to construct a similar dependence for mixtures of UO_2 and UO_3 obtained upon homogenisation. This dependence is given by[66]

$$I_2 = -0.0383x + 0.1148. \quad (2)$$

The values of the relative intensity I_2 of the U5f line for mechanical mixtures of the UO_2 and γ-UO_3 oxides fit satisfactorily into this straight line (see Fig. 10).

Since unpaired electrons are responsible for paramagnetism of molecules, it appeared pertinent to compare the dependences of the U5f line intensity in the XPS spectra and the magnetic susceptibility (χ) of the UO_x oxides on the oxygen coefficient x. An increase in x in the range $2 < x \leqslant 3$, entails a decrease in the magnetic susceptibility,[55,90,211] the corresponding dependence being described by the following relation (Fig. 11)

$$\chi = (55.8x^{-0.95} - 19.6) \times 10^{-6}\ g^{-1}. \quad (3)$$

Similar results as regards the magnetic properties have been obtained in another study.[212] It was concluded that $\{Rn\}5f^2$ or $\{Rn\}5f^16d^1$ is the most probable electronic configuration of uranium in the dioxide UO_2 ($\mu_{ef} = 3.2\ \mu_B$), while the trioxide UO_3 possesses a weak temperature-independent paramagnetism, which can be neglected.[212]

For synthetic oxides, the specific magnetic susceptibility χ correlates with the relative intensity I_1 in the following way[91] (Fig. 12):

$$\chi = 62.3 \times 10^{-6} I_1^{0.579}\ g^{-1}. \quad (4)$$

In this case, the I_1 grows faster than the magnetic susceptibility following a decrease in x (see Fig. 10–12).

It has been noted[212] that on a further decrease in the oxygen coefficient x from 2 to 1.835, the magnetic susceptibility of UO_x drops from 8.74×10^{-6} to $8.38 \times 10^{-6}\ g^{-1}$. Unfortunately, the change in the U5f line intensity upon the removal of an oxygen atom from the UO_2 surface, for example, by means of an argon gun, has not been studied quantitatively.

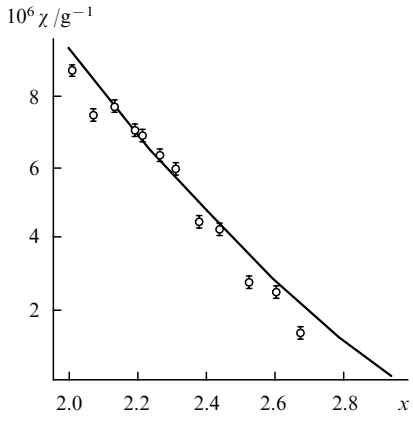

Figure 11. Specific magnetic susceptibility (χ) of synthetic oxides UO_x *vs.* the oxygen coefficient x [see Eqn (3)] plotted using the data of Ref. 211.

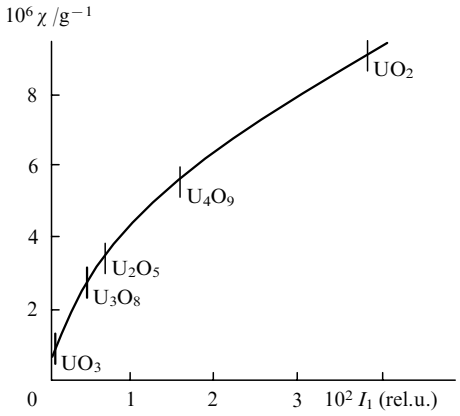

Figure 12. Specific magnetic susceptibility (χ) of synthetic oxides UO_x *vs.* relative intensity I_1 of the U5f line in the XPS spectrum [see Eqn (4)].[65,211] No correction for diamagnetism was done.

For oxide mixtures, the dependence of χ on the intensity I_2 is nearly linear[44,55] (Fig. 13):

$$\chi = 730 \times 10^{-6} I_2^{1.35}\ g^{-1}. \quad (5)$$

It is natural to expect that the magnetic susceptibility would grow proportionally to the intensity I_2 following an increase in the UO_2 concentration in the mixture provided that the intensity of the line under consideration is due to the unpaired unbound U5f electrons.

It follows from the above correlations that the line around the zero binding energy in the XPS spectra of UO_x can be assigned to the unpaired U5f electrons and the configuration of the U^{4+} ion in the dioxide UO_2 is given by $\{Rn\}5f^2$ (see Ref. 55). The relationship between the χ and I values is not as simple as would be expected if the magnetic properties of uranium oxides were governed only by the full spin of the U5f electrons. In addition, the results imply that synthetic oxides are not mere mixtures of UO_2 and UO_3. For example, the dependence of the intensity I_1 on the x value cannot be interpreted under the assumption that the oxides UO_x contain only U^{4+} and U^{6+} ions (see Fig. 10), but it can be explained with the assumption that these oxides contain also U^{5+} ions.[65,66] The presence of U^{5+} ions in complex oxides is consistent with the results of XPS studies[74] and the data of X-ray $L_{III}(U)$ near-edge absorption spectroscopy of the UO_{2+x} oxides.[182] In this case, the difference $\Delta I = I_2 - I_1$ describes the decrease in the content of U^{4+} ions and the formation of U^{5+} ions in UO_x following an increase in x. The approximate relation for the decrease in the

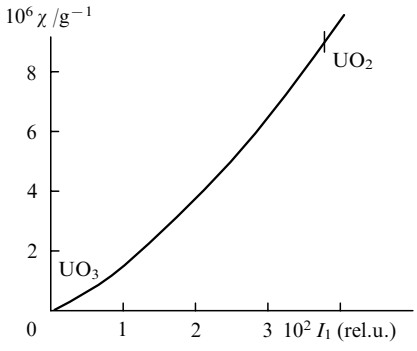

Figure 13. Specific magnetic susceptibility (χ) of synthetic oxides UO_x ($2 \leqslant x \leqslant 3$) *vs.* relative intensity I_2 of the U5f line in the XPS spectrum of oxide mixtures [see Eqn (5)].[55] No correction for diamagnetism was done.

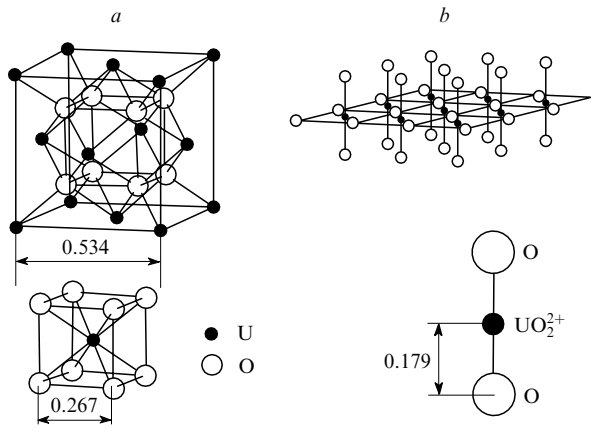

Figure 14. Crystal structure and the local environment of uranium ions in oxides.[5,7]
(*a*) UO_2, (*b*) γ-UO_3. The bond lengths are in nm.

relative intensity I_3 depending on the content of U^{4+} ions has the form

$$I_3 = I_2 - 2(I_2 - I_1) = 2I_1 - I_2. \quad (6)$$

It follows from Fig. 10 that upon an increase in x from 2 to 2.35, the U^{4+} ions disappear from UO_x. This is consistent with X-ray diffraction data indicating that synthetic uranium oxides with $x \to 2.38$, virtually do not contain a structure with the lattice parameters of UO_2 containing eight-coordinate uranium (Fig. 14).[213]

The above dependences (see Fig. 10) can be used to determine the relative contents of different uranium ions in oxides (Table 4). For example, it follows from the data of Table 4 that the oxides U_2O_5 and U_3O_8 mainly contain ions with spectral characteristics close to those of U^{5+} and U^{6+} in 1 : 1 and 1 : 2 ratios, respectively. This does not attest to any violation of the stoichiometric compositions of these oxides, as we are dealing with the formal ionic oxidation states determined from the spectral parameters that reflect the formal number of unbound U5f electrons. More information on the energy distribution of the uranium U5f electrons in oxides can be gained from $O_{4,5}(U)$,[187,189] $M_{III,IV,V}(U)$[191] and $L_{III}(U)$[214] near-edge X-ray absorption spectra. The U, UO and UO_2 species have been studied by high-temperature photoelectron spectroscopy in the gas phase;[215] the results of relativistic Hartree–Fock–Slater theoretical calculations of the electronic structures of these molecules were used to assign the spectral lines to the electrons of some shells.

b. Structure of the U6p–O2s spectra

In the U6p–O2s binding energy ranges (E_b = ~12–35 eV), a complex fine spectral structure is observed instead of the expected summary atomic spectrum due to the U6p doublet with the spin–orbit splitting ΔE_{sl}(U6p) = 10.0 eV and the O2s lines (see Fig. 8). This structure is more pronounced in the spectrum of γ-UO_3 than in the spectrum of uranium dioxide.[38,45,51,53,65,66,93] Unlike the spectrum of UO_2, the spectrum of γ-UO_3 in the U6p$_{3/2}$ binding energy range (~12–21 eV) displays two clear-cut components. In the U6p$_{1/2}$ spectral range (~27–~35 eV), two components are also observed for these oxides. For oxygen-containing U^{6+} compounds, the presence of two components in the U6p$_{3/2}$ spectrum was explained[45] by splitting of the U6p$_{3/2}$ level of the U^{6+} ion in the asymmetric electric crystal field of ligand ions present in the local environment, which arises on passing from the symmetric structure of the UO_2 dioxide to the asymmetric planar structure of γ-UO_3 (see Fig. 14 *b*).

A structure containing at least two peaks is also observed in the binding energy range of O2s electrons (~21–~27 eV). In the XPS spectrum of γ-UO_3, these peaks are separated by 2.2 eV. These have been attributed[45] to different oxygen ions located in the axial and equatorial positions with respect to the central atom in the uranyl compounds containing a U^{6+} ion. However, it has been noted[66,92,93,103,104] that this explanation does not work for the two peaks observed in this range in the case of UO_2 (see Table 4), because all the oxygen ions in this oxide are chemically equivalent (see Fig. 14 *a*). It should be expected[21,23] that the shifts of the O2s and O1s lines should be commensurable in magnitude. However, the spectrum of UO_2 exhibits a single relatively sharp O1s line, while in the spectrum of γ-UO_3, this line is broadened by 0.6 eV, due to the non-equivalence of two oxygen atoms (see Fig. 8). This single line is also present in the spectra of some uranium complexes.[216] This has led to the conclusion[66,92,93,103,104] that the two peaks observed in the spectrum of γ-UO_3 in the O2s binding energy range cannot be attributed to different types of oxygen ions present in this oxide, as was believed earlier.[45]

Comparison of the binding energy differences between the low-energy ($E_b \approx 12-35$ eV) and core electrons in uranium metal (which has a virtually atomic spectrum in this energy range) and uranium oxides shows that the formation of chemical bonds between uranium and oxygen atoms brings about significant differences between the XPS spectra of the metal and oxides (Table 5). Thus the energy level characteristic of the U6p$_{3/2}$ electrons in the UO_2 spectrum is shifted with respect to the U4f$_{7/2}$ level of uranium metal to lower binding energies by ΔE = 2.3 eV. In the case of γ-UO_3, the corresponding shift of the higher binding energy component equals 2.4 eV and that for the lower binding energy component is 6.1 eV. It is noteworthy that this allows one to observe the shifts of the low binding energy peaks not only for γ-UO_3 but also for UO_2 in which the environment of the uranium ion is symmetric.

Using the data on the causes and mechanisms of formation of the fine structure in the XPS spectra of actinides and other elements[38–40,45,52,65,79] and taking into account the results of theoretical calculations,[24,25,92,93,129–131,137,180,217] Teterin and coworkers[66,92,93,103,104,112] have suggested that the fine structure in the binding energy range $E_b \approx 12-35$ eV of the spectra of uranium oxides is due to IVMO electrons supplied mainly from the filled U6p and O2s AO of neighbouring atoms. This is consistent with the conversion electron spectroscopy data for uranium oxides in this energy range,[218–221] the

[a] The E_i values corresponding to the most intense peaks in the U6s spectra were used. [b] The ΔE_i differences for oxygen and fluorine are given.

structure of the XPS spectra of uranium halides [26, 43, 44, 47, 53, 55, 69, 70, 82, 98, 101, 102, 105, 109, 200, 201] and the results of theoretical calculations.[31, 122, 123, 132–134, 202, 222–233] The formation of IVMO in uranium oxides is confirmed by the X-ray $O_{4,5}$(U) emission [185, 234] and $OL_IL_{II,III}L_{II,III}$-Auger spectroscopy data.[235, 236]

The energetic spectral structure in the U6s, U6p and O2s binding energy range can be illustrated by a diagram reflecting the formation of IVMO in γ-UO_3 in the non-relativistic approximation (Fig. 15). This Figure shows the changes that take place in the IVMO system on passing from the UO_2^{2+} cluster ($D_{\infty h}$ group of symmetry) to the $[UO_2O_4]^{6-}$ cluster (D_{4h} group of symmetry). The spectrum of γ-UO_3 in the same binding energy range is given for comparison. It follows from this diagram that the XPS spectra in this binding energy range reflect the electron distribution in oxides over quasi-atomic and molecular orbitals. The partial contributions of the U6p AO and the O2s AO into each MO characterise the substantial overlap of these uranium and oxygen AO. Although these results were obtained in the non-relativistic approximation, they allow one to identify the spectral lines in the U6$p_{3/2}$ and O2s binding energy ranges. However, complete description of the electronic structure of γ-UO_3 requires performing relativistic calculations (see Section VI).

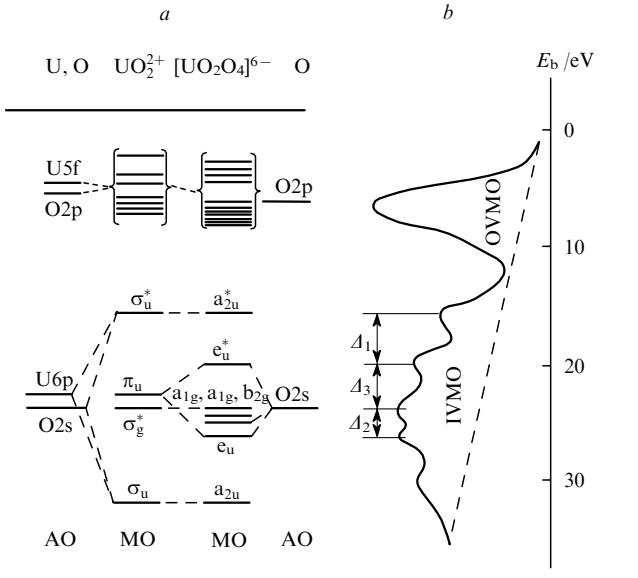

Figure 15. Diagram of MO formation in the UO_2^{2+} and $[UO_2O_4]^{6-}$ clusters ($D_{\infty h}$ and D_{4h} groups of symmetry, respectively) from the studies [25, 26, 102] (*a*) and X-ray photoelectron spectrum of the oxide γ-UO_3 (*b*).
The dashed line in Fig. 15 *b* corresponds to the background.

Analysis of the spectral structures of UO_2 and γ-UO_3 caused by MO electrons in the $\sim 0-35$ eV binding energy range suggests that the fine structure in the spectra of the U_4O_9, U_2O_5 and U_3O_8 oxides in this energy range can be considered to be a superposition of the spectra of simple oxides. It was shown [66] that the spectral structure in the U6$p_{3/2}$ energy range due to the UO_2^{2+} uranyl group becomes more pronounced as the oxygen coefficient x increases. Simultaneously, an additional line appears in the O2s energy range and the intensity of the U5f line diminishes.

c. XPS spectra of synthetic uranium oxides in the core electron binding energy range

The XPS spectra of UO_x oxides in the binding energy range of the core levels ($E_b \approx 40-1250$ eV), which exhibits the lines for U4p, U4d, U4f, U5s, U5p, U5d and U6s electrons, have been extensively studied.[47, 55, 66, 103, 105, 108, 109, 210, 215, 229]

The results are presented in Table 6 and in Figs 16–18. As the oxygen coefficient x for the synthetic oxides UO_x increases in the $2 < x \leqslant 3$ range, the core level binding energy grows by $\sim 0-1.5$ eV (see Table 6). This is due to the increase of uranium oxidation state on going from UO_2 to γ-UO_3. All of the spectra in this energy range show a complex fine structure; in some cases, this precludes precise determination of the binding energies and line intensities for some levels. Nevertheless, as has been mentioned above, the structure itself is characteristic of particular oxides and can be used for identification and for study of their properties.

Table 6. Binding energies (E_b /eV), line widths at half maximum (Γ /eV), spin–orbit splittings (ΔE_{sl} /eV), distances from the basic lines to satellites (ΔE_{Sat} /eV) and their relative intensities [I_{Sat}/I_0 (%)] for synthetic uranium oxides.[66]

d. The spectra of U4f electrons

The U4f XPS spectra of uranium oxides exhibit shake up satellites.[66, 105, 151, 237, 238] These spectra, like the spectra of U5f electrons, show that the U_2O_5 and U_3O_8 oxides contain two types of uranium ions.[66] However, these oxides are not mere mechanical mixtures of the simple oxides UO_2 and UO_3, they are complex phases whose lattices contain interrelated uranium and oxygen ions of two types.[55]

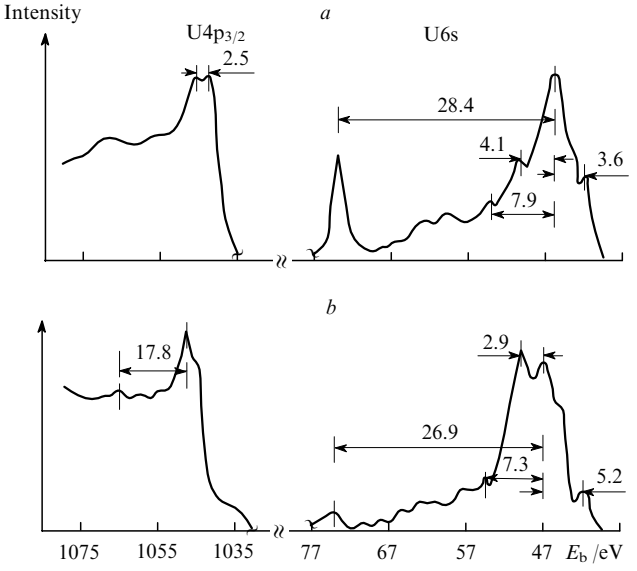

Figure 17. XPS spectra of uranium oxides in the U6s and U4p binding energy ranges.[56]
(*a*) UO_2, (*b*) γ-UO_3.

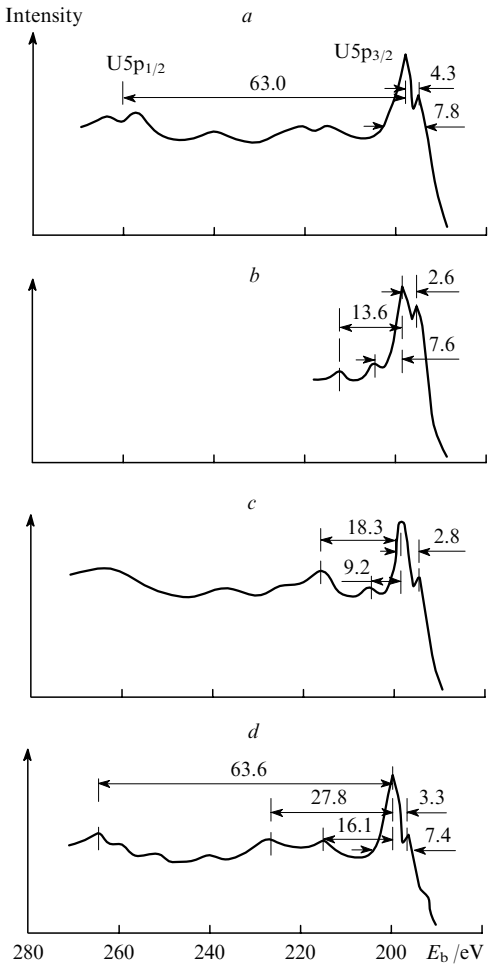

Figure 18. XPS spectra of uranium oxides in the U5p binding energy range.[56, 66]
(*a*) UO_2, (*b*) U_2O_5, (*c*) U_3O_8, (*d*) γ-UO_3; $\Delta E_{sl}(U5p) = 65$ eV.[20]

The spectral characteristics suggest that these complex oxides contain U^{5+} and U^{6+} ions. In this approximation, the $U4f_{7/2}$ lines of the given oxides were decomposed into two components (Fig. 16) and the contribution of each of the ions was quantitatively estimated.[55, 66] It was found that U_2O_5 and U_3O_8 contain U^{5+} and U^{6+} ions in 1 : 1 and 1 : 2 ratios, respectively, which agrees with the XPS spectra of the U5f electrons in these oxides. In addition, these conclusions are confirmed by the intensity ratio of the components of the $U4f_{7/2}$ lines and the corresponding $U4f_{7/2}$ binding energies found from decomposition of these lines (for U_2O_5, 381.5 and 382.3 eV; for U_3O_8, 381.5 and 382.4 eV).

The data on the contents of the two types of uranium ion in these oxides[55, 66] are in line with XPS data,[38, 60, 105] magnetic measurements,[211] and, in the case of U_3O_8, also with X-ray diffraction data.[5] The UO_2 and γ-UO_3 oxides contain U^{4+} and U^{6+} ions, respectively,[55, 66] which is also consistent with X-ray diffraction data.[5]

The binding energy distances between the satellites and the basic U4f lines in the XPS spectra reflect the MO structure and are characteristic of particular oxides (see Fig. 16). Thus in the spectrum of UO_2, the distance from the low energy satellite to the basic $U4f_{7/2}$ line is 6.9 eV, while the spectrum of γ-UO_3 exhibits two satellites spaced by 3.9 eV and 9.5 eV from the basic

$U4f_{5/2}$ component of the doublet. The spectra of other oxides exhibit more complicated satellite structures, which can be correlated to a certain approximation with the satellite structures in the spectra of UO_2 and γ-UO_3.

e. The spectra of the U5d and U4d electrons

The U5d binding energy range of the spectra of the oxides under study [55, 66, 103, 104] exhibits, instead of the expected doublet caused by the spin – orbit splitting, a more complicated fine structure. The $U5d_{3/2}$ component is broadened compared to the $U5d_{5/2}$ line, the binding energy difference between these electrons increasing on passing from UO_2 to UO_3. This is not related to the change in the spin – orbit splitting [(ΔE_{sl}(U5d) = 8.6 eV for U metal [57]] following the increase in the uranium oxidation number, but is due, first of all, to the multiplet splitting. Since the U^{6+} ion in γ-UO_3 does not contain unpaired electrons, this splitting should not be manifested in the XPS spectrum in the U5d binding energy range. Therefore, the value ΔE_{sl}(U5d) = 8.7 eV is closer to the true value of the spin – orbit splitting (see Table 6). Other reasons for broadening of the U5d doublet may include the superimposition of the shake up satellites onto the $U5d_{3/2}$ component and the dynamic effect.

In the spectra of deeper U4d electrons, the spin doublet lines are much broader than the U4f lines,[55, 238] which complicates decomposition of the U4d line of complex oxides into separate components. Nevertheless, the measured spin – orbit splittings for the U4d level for uranium dioxide and trioxide are equal and amount to 42.3 eV [ΔE_{sl}(U4d) = 42.3 eV for U metal [57]]. The observed change in the ΔE_{sl} value for complex oxides is attributable to the structure caused by the presence of uranium in different oxidation states.

f. The spectra of the U6s, U5p and U4p electrons

The XPS spectra of uranium and its compounds exhibit a complex structure in the U6s binding energy range.[55, 56, 106] Indeed, instead of the expected single relatively sharp line, the spectra of UO_2 and γ-UO_3 contain a complex fine structure in an energy range covering up to $\sim$40 eV (see Fig. 17).[56]

The spectral structure observed in the U6s range has much in common with the XPS structure observed for the Th6s electrons (see Fig. 2). Therefore, this structure has been suggested [55, 56] to be mostly due to the dynamic effect giving rise to the final states of the type $U6s^1 6p^6 5f^n 6d^m \rightleftharpoons U6s^2 6p^4 5f^n 6d^{m+1}$, because E_b(U6s) $\approx$ 2 E_b(U6p). This is in qualitative agreement with the results of calculation [32] of the U6s spectrum performed with the assumption that uranium occurs in the U^{6+} state.

A similar analysis of the reasons of formation of the fine spectral structure has also been carried out [56, 66] for the U5p and $U4p_{3/2}$ electrons (see Figs 17, 18). This structure in the spectra of uranium oxides in the U5p binding energy range induces splitting of the $U5p_{3/2}$ line and substantial smearing of the $U5p_{1/2}$ component of the doublet [(ΔE_{sl}(U5p) = 65 eV [20]. A similar situation is observed in the $U4p_{3/2}$ energy range [56] (see Fig. 17). Comparison of the magnitudes of splitting of the main components in the U6s, U5p and $U4p_{3/2}$ spectra has shown that these values change insignificantly as the electron binding energy increases from $\sim$50 to $\sim$1000 eV and, hence, the fine structure cannot be mainly due to the effect of the crystal field, as has been suggested [79] for the electrons of some shells.

Since the fine structure observed in the range of core levels for thorium dioxide containing no unpaired Th5f electrons has much in common with the corresponding spectral structure of UO_2, it has been suggested [56, 66] that this structure in the spectra of U5p and U4p electrons of UO_x cannot be related, to a large extent, to the multiplet splitting or many-body perturbation, but is mainly due to the dynamic effect, resulting in the final states of the types $U5p^5 5d^{10}(6s^2 6p^6)5f^n \rightleftharpoons U5p^6 5d^8(6s^2 6p^6)5f^{n+1}$ and $U4p^5 4d^{10}(4f^{14}).5s^2(5p^6 5d^{10} 6s^2 6p^6)5f^n np^0 \rightleftharpoons U4p^6 4d^9(4f^{14})5s^1(5p^6 5d^{10} 6s^2 6p^6).5f^n np^1$, respectively.[55, 56] This structure is superimposed by the satellites corresponding to many-body perturbation. This further complicates the spectral structure.

2. Uranyl compounds

Uranyl compounds contain the UO_2^{2+} group coordinated by four, five or six atoms of the ligand L (L = O, F, Cl, Br, *etc.*) in the equatorial plane.[239–241] The U – O bond length (R_{U-O}) in the UO_2^{2+} group of these compounds is usually smaller than the distances from the uranium atoms to the neighbouring ligand atoms located in the equatorial plane.[7, 53, 71–73, 240–243] In recent years, researchers' attention has been focused on the calculation of the electronic structures of uranyl derivatives (Refs 24, 26–28, 36, 42, 93, 102, 123, 130, 204, 233) which has been stimulated by the appearance of numerous publications devoted to X-ray photoelectron spectra of these compounds (Refs 26, 42–48, 55, 82, 94–97, 102, 109, 216, 244). It should be noted that only the actinyl group AnO_2^{n+} (An = U, Np, Pu, Am, *etc.*) has an almost linear structure, whereas a molecule of gaseous ThO_2 is bent at an angle of 122 $\pm$ 2° (see Ref. 245).

A number of uranyl compounds have been studied by XPS (Table 7) in order to establish the relationship of fine spectral structure parameters with the structure of these compounds and the nature of the chemical bond in them.[47, 55] To confirm the stoichiometric compositions and the structures of these compounds, the spectra of all elements contained in their molecules were analysed. For identification of XPS lines of uranyl compounds in the low binding energy range, the spectra of ligands based on $Ni(NO_3)_2$, NaOAc, Na_2CO_3 and CsCl have also been studied.

a. The spectra of uranyl compounds in the low binding energy range

As noted above, the XPS spectra of highly symmetric U^{4+} compounds (see Fig. 14), for example, UO_2 (see Fig. 8) and UF_4 (Fig. 19), containing U5f electrons not involved in the chemical bond, exhibit a sharp line at around a zero binding energy.

The spectra of uranyl compounds containing U^{6+}, for example, γ-UO_3 (see Fig. 8) and UO_2F_2 (see Fig. 19), do not exhibit this line. The absence of the U5f line in the XPS spectra of uranyl compounds directly confirms that the uranium oxidation state is

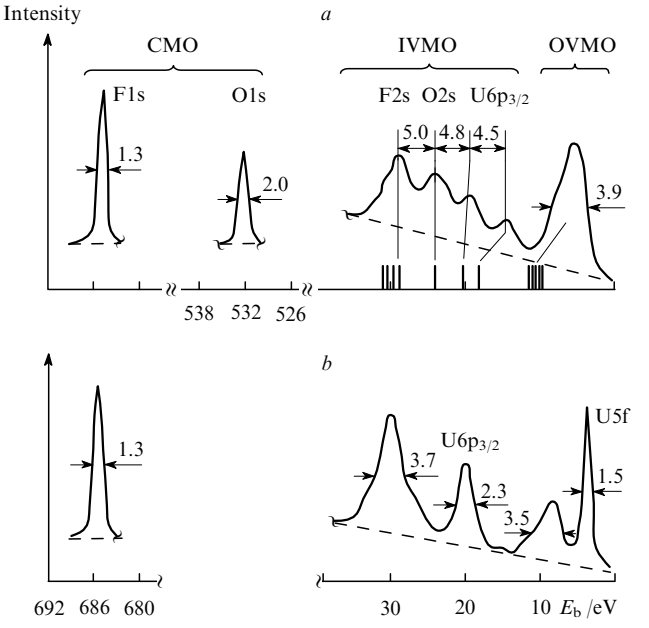

Figure 19. XPS spectra of uranium compounds.[98]

Note. The ΔE_1, ΔE_2, Δ'_1, Δ_1, Δ'_2, Δ_2 parameters are shown in Fig. 23. They have been found using the values ΔE_U [$\Delta E(U6p_{3/2}) = 360.6$ eV, $\Delta E(U6p_{1/2}) = 350.6$ eV], $\Delta E_O = 508.1$ eV, $\Delta E_F = 655.3$ eV, $\Delta E(U6p_{3/2} - O2s) = 2.1$ eV. The ΔE_1 and ΔE_2 values were measured to an accuracy of ±0.2 eV; the Δ'_1, Δ_1, Δ'_2, Δ_2 values, to an accuracy of ±0.3 eV. [a] Ratio of the number of oxygen atoms located in the axial position (O_{ax}) to the number of ligand atoms located in the equatorial plane. [b] Data of the studies [240–242] [c] The R_{U-O} values given in parentheses were measured to an accuracy of ±0.002 nm, the R_{U-L} values, to an accuracy of ±0.004 nm. [d] Experimental results. [e] Bond length between the closest uranium atoms in metallic γ-U.[243] [f] For UO_2 and UF_4, the ΔE_i and Δ_i differences are shown in Fig. 24. [g] The values in parentheses are ΔE_1 determined using relations (9) and (10). [h] The average R_{U-O} and R_{U-L} values are underlined.

six.[96,98] The presence of the UO_2^{2+} group may be indicated, in particular, by the structure of the XPS spectrum in the U6p and O2s ranges. Thus in the fluoride UF_4, the uranium ion occurs in a relatively symmetric environment formed by fluorine atoms (D_{4d} group of symmetry). In this case, as for UO_2, the XPS spectrum of the $U6p_{3/2}$ electrons exhibits a single line (see Fig. 19). The uranium environment in the UO_2F_2 molecule is less symmetric (D_{6h} group of symmetry), and the spectrum shows two components of the $U6p_{3/2}$ line. The spectra of UO_2F_2 and UF_4 exhibit fine structure over the whole U6p and O2s-, F2s binding energy ranges (see Fig. 19 [246–248]). The O2s and F2s lines in the XPS spectra of these compounds are much broader than the corresponding O1s and F1s lines and exhibit a fine structure. The binding energy difference $\Delta E_i(6p_{3/2} - 4f_{7/2}) = 362.6$ eV for UF_4 is much greater than the similar value $\Delta E_i = 360.6$ eV for uranium metal (Table 8, see also Table 5). This is consistent with the assumption that the $U6p_{3/2}$ line in the spectrum of UF_4 is not atomic, but is due to electrons of an antibonding MO. Therefore, it has been suggested [47,55,246–248] that the structure of low energy spectra of UF_4 and UO_2F_2 is mainly due to the effective formation of IVMO largely composed of U6p, O2s and F2s AO. In the case of UO_2F_2, this is in qualitative agreement with the results of calculation of the electronic structure of the $[UO_2F_6]^{4-}$ cluster (D_{6h} group of symmetry).[246–248]

The low binding energy region of the XPS spectrum of $Cs_2UO_2Cl_4$ shows a more complicated structure than the spectrum of UO_2F_2, due to the Cs5p and Cs5s lines present in this energy range (Fig. 20). The line for the Cl3s electrons that belong to chlorine atoms arranged in the equatorial plane occurs in the binding energy range of the U6p electrons, which implies a more essential involvement of the Cl3s AO, together with the $U6p_{3/2}$ AO, in the formation of IVMO than in the case of the F2s and $U6p_{3/2}$ fluorine and uranium AO.[26,47]

The results of non-relativistic SCF X_α-SW calculation [26] for the electronic structure of the $[UO_2Cl_4]^{2-}$ cluster (D_{4h} group of symmetry), which mimics the local environment of uranium in $Cs_2UO_2Cl_4$ molecules, provide a qualitative interpretation of the low binding energy spectrum of the compound under consideration (see Fig. 20). The energy range of OVMO, mainly consisting of the U5f, U6d, O2p and Cl3p AO, covers 3.9 eV, which is

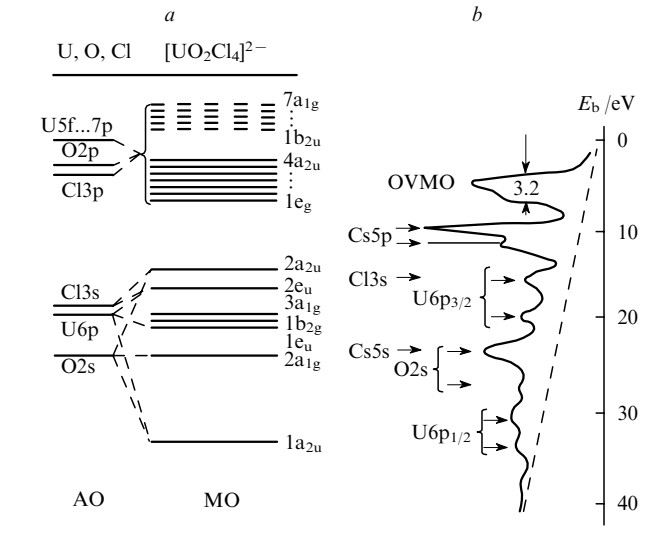

Figure 20. Diagram of MO in the $[UO_2Cl_4]^{2-}$ cluster (D_{4h} symmetry) based on the data of X_α-SW calculations (*a*) and XPS spectrum of $Cs_2UO_2Cl_4$ (*b*).[26,47] The dashed line in Fig. 20 *b* shows the background.

comparable with the experimental width of these lines in the spectrum, which equals 3.2 eV. In this compound, IVMO are formed efficiently from U6p, O2s and Cl3s AO.

The fine structure caused by the IVMO electrons is observed also in the XPS spectra of other uranyl compounds (Fig. 21).[47] The line near the binding energy zero also corresponding to U5f electrons not involved in chemical bonds is not detected for these compounds. This is in qualitative agreement with the known fact that the oxidation number of uranium in these compounds is six.

The OVMO-related bands in the spectra of uranyl compounds are characterised by FWHM of $\sim 3-4$ eV and by poorly resolved structures (see Fig. 21). The binding energies of these electrons in oxygen-containing uranium compounds measured as weight average values of the components lie in the range of $\sim 5-6$ eV (see Table 7). If fluorine or the NO_3 group are present as ligands, these values are somewhat greater (~ 7 eV).

The XPS spectra of the compounds in question in the IVMO region may become more complicated due to the overlap with the lines due to alkali metal ions. However, these lines can be interpreted rather easily

b. The IVMO spectral structure and the structure of uranyl compounds

In an early stage of the XPS studies of uranyl compounds, it was found[45,47,55,65,66,92,93,104] that the line splitting in the $U6p_{3/2}$ binding energy range [$\Delta E(U6p_{3/2})$] depends on the bond length R_{U-O} in the UO_2 group (Fig. 22). It has been suggested[45] that this splitting is due to the crystal field.

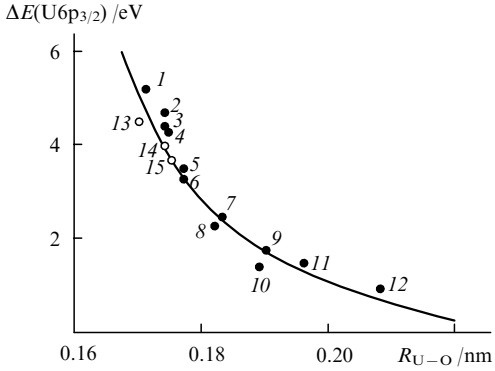

Figure 22. Dependence of splitting $\Delta E_b(U6p_{3/2})$ on the R_{U-O} bond length in the UO_2^{2+} group [see Eqn (7)] for a number of uranium compounds.
(*1*) UO_2CO_3, (*2*) $LiUO_2F_3 \cdot 2H_2O$, (*3*) $NaUO_2F_3 \cdot 2H_2O$, (*4*) $UO_2C_2O_4 \cdot 3H_2O$, (*5*) β-$UO_2(OH)_2$, (*6*) γ-$UO_2(OH)_2$, (*7*) $Li_2U_2O_7$, (*8*) LiU_3O_{10}, (*9*) Li_2UO_4, (*10*) α-Na_2UO_4, (*11*) $CaUO_4$, (*12*) Cr_2UO_6, (*13*) UO_2F_2, (*14*) $UO_2(NO_3)_2 \cdot 2H_2O$, (*15*) γ-UO_3; the light circles show the data from the study;[55] dark circles, from the study.[45]

The dependence of the $\Delta E(U6p_{3/2})$ value on R_{U-O} shown in Fig. 22 can be expressed as follows:

$$\Delta E(U6p_{3/2}) = -1.59 + 0.138(R_{U-O} - 0.149)^{-1}. \quad (7)$$

Hence, the expression for R_{U-O} has the form

$$R_{U-O} = 0.149 + 0.138[\Delta E(U6p_{3/2}) + 1.59]^{-1}. \quad (8)$$

Equation (8) can be used to estimate the R_{U-O} bond lengths in the UO_2^{2+} groups in these compounds (see Table 7).

A more profound understanding of the nature of the fine spectral structure in the low binding energy range of uranium compounds can be gained from theoretical and experimental results which allow one to consider the data on fine XPS spectral structure from a different standpoint.[94,96,97,107–109,245] Comparison of the E_b values for the outer electrons for various uranium compounds does not provide a vivid representation of the dependence of spectral characteristics on the properties and structures of these compounds. Indeed, the $U6p_{3/2}$ binding energies usually change little on passing from one compound to another (see Table 7). Therefore, for elucidating the regular features of the formation of IVMO structure, the binding energy differences between the valence and core electrons (ΔE_i) in these compounds have been considered (see Table 8). The data of Table 8 are illustrated by the MO diagram for the $[UO_2O_6]^{10-}$ cluster (D_{6h} group of symmetry), which reflect the local environment for a large number of oxygen-containing uranyl compounds (Fig. 23). The diagram shows the binding energy differences ΔE_U, $\Delta E_1 - \Delta E_6$, ΔE_O and ΔE_L. The ΔE_i values for uranium metal and its compounds can be measured experimentally. This provides the values Δ_1, Δ_2, Δ_3 and Δ'_1, Δ'_2, Δ'_3, which characterise quantitatively the type of MO (bonding, antibonding, non-bonding) and the degree of participation of the corresponding AO of the neighbouring atoms in the MO formation (see Fig. 23). Thus, the MO structure for uranium compounds can be determined experimentally.

The above results imply that, to a certain approximation, ligand atoms located in the axial positions and in the equatorial

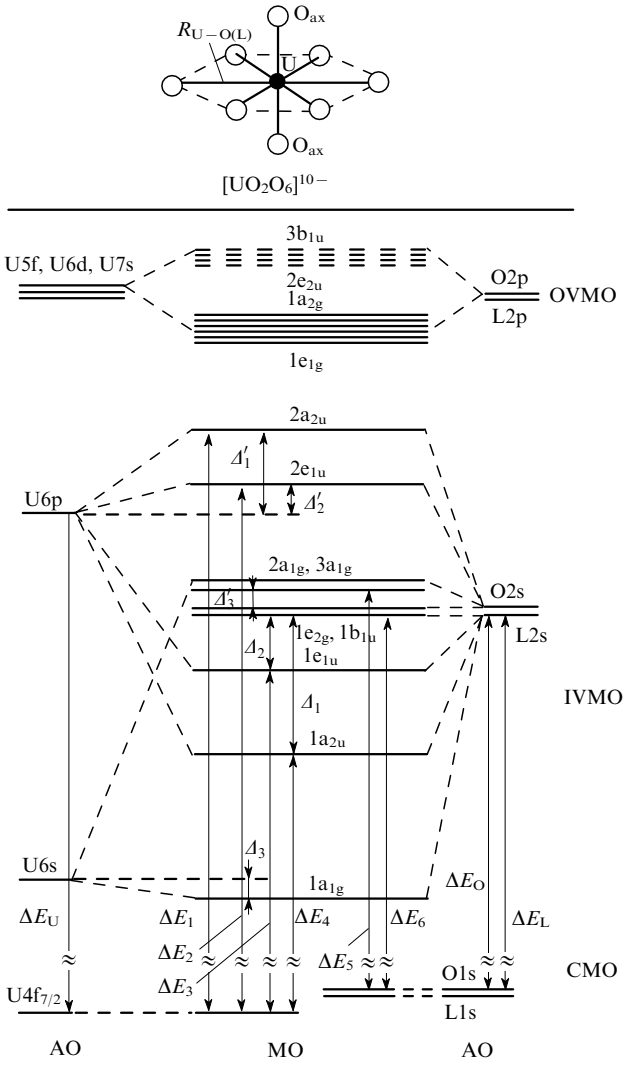

Figure 23. Diagram of MO energy levels in $[UO_2O_6]^{10-}$ (D_{6h} symmetry) constructed using experimental data and results of calculations.[26, 48]
The chemical shifts of the energy levels upon the formation of the cluster from single atoms are not shown. The arrows show the energy differences that can be derived from experimental spectra.

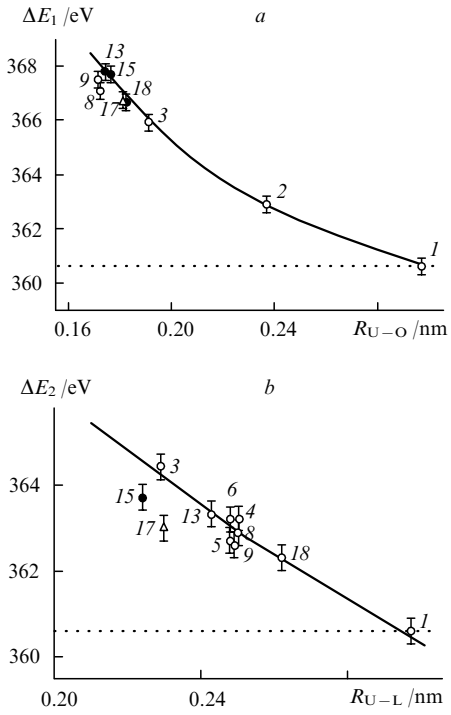

Figure 24. Dependences [see Eqns (9), (11)] of the relative binding energies ΔE_i ($U6p_{3/2} - U4f_{7/2}$) on the $R_{U-O_{ax}}$ bond lengths (*a*) and distances from the uranium atom to the ligand atom in the equatorial plane R_{U-L} (*b*) in the uranyl compounds (the dots are experimental data, the curves correspond to the calculation).[48, 94]
The theoretical curve in Fig. 24 *b* corresponds to oxygen-containing compounds (L = O) with D_{6h} symmetry. Here and in Fig. 25, the numbers of dots correspond to the numbers of compounds in Table 8; the light circles are oxygen-containing ligands; dark circles, F, Cl; triangle, γ-UO_3.

plane around a uranium ion influence in different ways the XPS spectral structure in the low binding energy range. Thus, it is possible to obtain experimental dependences of the spectral structure parameters in the given range on both the R_{U-O} bond length in the UO_2^{2+} group and the R_{U-L} distance between the uranium atom and the ligands L located in the equatorial plane (Fig. 24).

As an illustration of the efficiency of IVMO formation in uranium compounds, Fig. 24 shows also the ΔE_U and ΔE_1 values for the oxide UO_2. It can be seen that the formation of a chemical bond in uranium compounds is accompanied by a substantial relative shift of the upper $2a_{2u}$ IVMO towards lower binding energies (by more than 7.0 eV). This value is 1.5 orders of magnitude higher than the experimental error and can serve as a reliable and convincing proof for the effective formation of IVMO in uranium compounds. The dependence presented in Fig. 24 *a* has the form

$$\Delta E_1 = 356.07 + 0.55(R_{U-O})^{-1.75}, \quad (9)$$

hence,

$$R_{U-O} = \frac{0.55}{(\Delta E_1 - 356.07)^{0.571}}, \quad (10)$$

where ΔE_1 is expressed in eV, and R_{U-O}, in nm. Equations (9) and (10) have been used to determine the ΔE_1 values and bond lengths in the uranyl groups of some compounds (see Table 8).

When constructing the experimental dependence of the relative $U6p_{3/2}$ binding energy in the high energy spectral range on the R_{U-L} bond length for uranyl compounds, several points are to be borne in mind (see Fig. 24 *b*). First, the structure of the local environment of the uranium atom in these compounds should be described by the same cluster, specifically, $[UO_2L_6]^{10-}$ (D_{6h} group of symmetry). Second, the ligands should be identical. In this particular case, an oxygen atom acts as the ligand L and the influence of substituents is neglected.

For such compounds, the relative electron energy (ΔE_2) obeys the following dependence on the bond length R_{U-L}

$$\Delta E_2 = 343.84(R_{U-L})^{-0.039}; \quad (11)$$

this can be transformed into the expression

$$R_{U-L} = \left(\frac{383.84}{\Delta E_2}\right)^{25.71}, \quad (12)$$

which allows one to determine the average distance from the uranium atom to the equatorial oxygen atoms based on the ΔE_2 value. For comparison, Fig. 24 *b* shows the data for uranyl compounds with oxygen-free ligands in the equatorial plane (L = Cl, F). As was to be expected, some of the points markedly deviate from the basic curve (see Fig. 24 *b*). Figure 25 shows a more comprehensive dependence[96, 97, 109] of the ΔE_i values on R_{U-O} in the UO_2^{2+} group, which reflects the variation of the IVMO energies and agrees qualitatively with the results of theoretical calculations.[26, 102] Relations have been proposed[95] for determining the distances from the uranium ion to the nearest

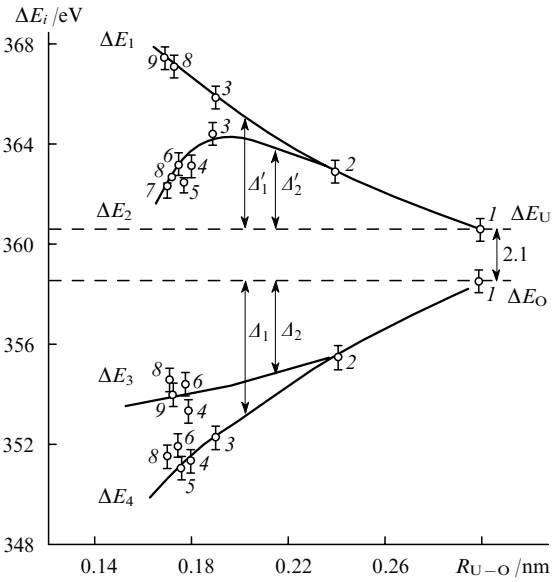

Figure 25. Experimental dependence of binding energy differences between the core and valence electrons corresponding to $\Delta E_1(2a_{2u})$, $\Delta E_2(2e_{1u})$, $\Delta E_3(1e_{1u})$ and $\Delta E_4(1a_{2u})$ for the $[UO_2O_6]^{10-}$ cluster (D_{6h} symmetry).[109] The designations of ΔE_i are given in Fig. 23.

ligand ion in the axial and equatorial positions in the uranyl compounds on the basis of U6p$_{3/2}$ line splitting ΔE:

$$R_{U-O} = b_1 \ln\left(\frac{a_1}{c_1 + \Delta E}\right), \quad (13)$$

$$R_{U-L} = b_2 \ln\left(\frac{a_2}{c_2 - \Delta E}\right), \quad (14)$$

where $a_1 = 157$ eV, $a_2 = 348$ eV, $b_1 = b_2 = 0.069$ nm, $c_1 = 8.57$ eV, $c_2 = 15.0$ eV.

Note that for uranyl difluoride (UO_2F_2), the formation of IVMO was confirmed by X-ray $O_{4,5}$(U) emission spectroscopy.[246–248]

c. XPS spectra of the core electrons

The XPS spectra of the core electrons of uranyl compounds resemble in many respects the corresponding spectra of uranium trioxide. The above considerations concerning the nature of the fine structure in the spectra of uranium oxides are largely valid for the spectral structure observed for uranyl compounds in the energy range of core electrons.

The U4f$_{7/2}$ line is used most often to determine the uranium oxidation state in compounds. The difference between the U4f$_{7/2}$ binding energies for the UO_2 and γ-UO_3 oxides equals 1.5 eV. Thus, the binding energies of the core electrons can, in principle, be used to draw conclusions about the oxidation state of uranium in a particular compound; however, this determination of the oxidation state is not always legitimate. For example, for $K_4UO_2(CO)_3 \cdot 5H_2O$ containing U^{6+}, the U4f$_{7/2}$ binding energy is lower than this value for the fluoride UF_4 in which the formal oxidation state of uranium is four (see Table 7). This indicates that for determining the oxidation state of uranium in compounds, one should resort to the whole set of data on the binding energies of the valence and core electrons and the relevant fine spectral structure.

As noted for oxides, the oxidation state of uranium can be derived from the structure of shake up satellites. The structure related to many-body perturbation is most pronounced in the U4f and U5d spectra.[47] It should be noted that in the spectra of uranyl compounds, the low-energy shake up satellites occur on the higher energy side (by $\sim$3–4 eV) of the basic lines of the U4f doublet and have a $\sim$20% intensity (see Table 7). The spin–orbit splitting of the U4f level is virtually constant for different uranyl compounds being equal on average to 10.9 eV [for uranium metal, ΔE_{sl}(U4f) = 10.8 eV].[57] The spectra of compounds containing U^{4+} ions display satellites at a distance of $\sim$7 eV from the basic lines.

Unlike the spectrum of UO_2, in the spectra of uranyl compounds, the U5d lines are sharp. This is probably due to the fact that the spectra of the UO_2 oxide, which contains U5f electrons, exhibit multiplet splitting in the U5d binding energy range. The average spin–orbit splitting of the U5d level found from the spectra of uranyl compounds [$\overline{\Delta E_{sl}}$(U5d) = 8.6 eV] is in good agreement with the corresponding value for uranium metal (8.6 eV).[57] The shake up satellites that arise in the U5d range complicate somewhat the spectra of these compounds but barely influence the spin–orbit splitting.

The U5p spectra exhibit a complex fine structure, which markedly suppresses the intensity of the U5p$_{1/2}$ component.[47] In the case of uranium oxides, the formation of this fine structure has been attributed[47,55,56] to the dynamic effect manifested in this range, which gives rise to final states of the type $U5p^55d^{10}(6s^26p^6)5f^0 \rightleftharpoons U5p^65d^8(6s^26p^6)5f^1$. The data obtained for uranyl compounds do not contradict this assumption.

The first detailed study of the U4p$_{3/2}$ spectra of uranyl compounds has been reported.[47] In all cases, the spectral structure was similar to the structure of the U5p spectra. These data are consistent with the assumption, based on the spectra of uranium oxides, stating that the structure in the U4p$_{3/2}$ spectra is due to the dynamic effect, resulting in the final states of the type $U4p^54d^{10}4f^{14}5s^2(5p^65d^{10}6s^26p^6)5f^0 \rightleftharpoons U4p^64d^94f^{14}5s^1(5p^65d^{10}.6s^26p^6)5f^0np^1$.

The U4d binding energy range also contains a fine structure, which is characteristic of particular compounds.[55] The doublet lines in the spectra are sharper than in the case of tetravalent uranium. The average spin–orbital splitting [$\overline{\Delta E_{sl}}$(U4d)] determined from the spectra of uranyl compounds is 42.4 eV, which is somewhat greater than the value of 42.1 eV found for uranium metal.[57]

On the basis of the U6s spectra of oxides, it was concluded that the final states described by the configurations $U6s^16p^65f^06d^0$ and $U6s^26p^45f^06d^1$ can arise with comparable probabilities upon photoemission of the U6s electrons from uranium compounds.[56] This gives rise to a spectral structure extending for $\sim$40 eV. The U6s spectral structure is characteristic of uranyl compounds and can be used for identification.

The experimental results on the binding energies of core and valence electrons and fine structure parameters of the XPS spectra altogether allow one to determine unambiguously the uranium oxidation states in compounds and to draw conclusions concerning the structure of the local environment of the central uranium atom and the nature of the chemical bond between this ion and the neighbouring ligand atoms. Procedure for quantitative elemental and ionic analysis of uranium compounds and for determination of the oxidation states of other ions involved on the basis of fine structure parameters of the XPS spectra of core and valence electrons has been elaborated.[47,53,55,94]

3. Natural uranium oxides

Determination of the relative contents of uranium ions in different oxidation states and the structural and phase compositions of natural uranium oxides (pichblendes) is very important for studying the conditions of formation of uranium deposits and for the exploration and development of the deposits.[208] Therefore, the possibility of using XPS studies for solving these problems has been evaluated.[65,66] The oxygen coefficients of the natural UO_x oxides were determined according to the standard procedure;[6] the specimens of minerals were taken from the collection of the researchers.[66]

The structure of the low binding energy XPS spectra of the natural oxides UO_x has much in common with the corresponding structure of complex synthetic oxides.[66] The spectra of all natural

oxide samples exhibit a relatively sharp line around a zero binding energy, which is assigned to the U5f electrons not involved directly in the chemical bond. The U6p and O2s spectral range exhibits a structure partially attributed to the IVMO electrons in natural uranium oxides. This spectral range can exhibit lines for the lead oxide PbO ($Pb5d_{5/2}$ and $Pb_{3/2}$ electrons, 19.5 and 21.8 eV, respectively; Pb6s electrons, 9.5 eV).[55] The possible occurrence of lead impurities in natural uranium oxides and complication of the structure caused by the Pb lines is taken into account in the identification of spectral peaks. The O2s energy range can also exhibit additional lines from oxygen atoms of the concomitant oxides and water molecules adsorbed on the oxide surface. Despite this possible complication of the spectra of natural uranium oxides, the most information-rich spectral ranges (0–4 and 10–20 eV) are almost free from impurity-related lines.

The line of the unbound U5f electrons in the spectra of natural uranium oxides is rather narrow and can be easily distinguished from the overall spectrum. The relative intensity of this line changes with an increase in the oxygen coefficient x in the range of $2.13 \leqslant x \leqslant 2.24$, as in the case of synthetic oxides (see Fig. 10). Then the intensity jumps up, and in the $2.47 \leqslant x \leqslant 2.68$ range, it decreases according to the same law as observed for UO_2 and γ-UO_3 mixtures (see Fig. 10).

The dependences of the lines for the U5f electrons not involved in the chemical bond on the x value established for synthetic oxides allow one to determine the ionic composition of the pitchblende studied (Table 9). This is done assuming that the natural oxides can contain three types of ions, U^{4+}, U^{5+} and U^{6+}. The results obtained in this approximation lead to the conclusion that an increase in the oxygen coefficient x in the range $2.13 \leqslant x \leqslant 2.24$ entails a sharp decrease in the U^{4+} content in the pitchblende. On further increase in x in the range $2.47 \leqslant x \leqslant 2.68$, the concentration of U^{4+} ions increases and the concentration of the U^{6+} ions decreases. No U^{5+} ions are present in the natural oxides in this x range.

The IVMO spectral range corresponding to the U6p and O2s AO (binding energy range 10–20 eV) exhibits a series of peaks. On the basis of binding energy differences between the core and inner valence electrons, one can distinguish lines corresponding to the IVMO of the U^{4+}, U^{5+} and U^{6+} ions. With allowance for relations (9) and (10), these data permit one to estimate the R_{U-O} bond lengths in natural oxides (see Table 9).

Analysis of the spectral structure of natural uranium oxides in the U6p–O2s binding energy range and the intensity of the line for the U5f unbound electrons shows that natural uranium oxides are composed of several structural phases containing U^{4+}, U^{5+} and U^{6+} ions (see Table 9). The same conclusion can be drawn on the basis of the data on the core electron spectra.[66] For example, it follows from the U4f spectral structure that natural uranium oxides contain uranium ions in different oxidation states. This can be seen from both the shapes of the U4f lines and the structure of shake up satellites, which cannot be described as a superposition of individual U4f satellites due to U^{4+} and U^{6+}, but is more complicated.

The decomposition of the $U4f_{7/2}$ line into components has made it possible to determine the relative concentrations of uranium ions in different oxidation states. The results were similar to those derived from the line intensities of unbound U5f electrons (see Fig. 10, Table 9). The $U4f_{7/2}$ binding energies presented in this Table were found as weight-average values for the electrons of the components, which characterise the uranium ions in different oxidation states. As expected, these values grow upon an increase in the U^{6+} concentration in the samples. The substantial broadening of the $U4f_{7/2}$ line compared to the narrower lines observed for individual UO_2 and γ-UO_3 oxides is itself an important

Table 9. Binding energies (E_b / eV), binding energy differences (ΔE_i / eV), line widths at half maximum (Γ / eV), relative contents of uranium ions [k (%)] and bond lengths [R_{U-O}, $R_{U-O(L)}$ / nm] in natural uranium oxides.[66]

indication of the fact that pitchblende contains uranium ions in different oxidation states.

The lines of the U5d and U4d doublets of natural oxides are broader than the corresponding lines in the spectra of synthetic uranium oxides. As the content of U^{6+} ions in the samples increases, the U5d and U4d binding energies measured as the weight average values for different states of ions increase by about 1.0 eV. A more complicated structure than that observed in the spectra of synthetic uranium oxides is also found in the $U4p_{3/2}$, U5p and U6s spectra of natural oxides. These data confirm that natural uranium oxides do not show complete similarity to either complex synthetic oxides or mixtures of simple uranium oxides but represent complex structural phases. It follows from the obtained results that at $2.13 \leqslant x \leqslant 2.24$, the natural oxides UO_x are closer in properties to berthollides, while at $2.47 \leqslant x \leqslant 2.68$, they are closer to daltonides.[5]

The XPS data obtained for a broad range of technologically important uranium compounds show that the fine structure parameters of their spectra reflect the properties of these compounds, the nature of the chemical bond in them and the secondary electronic processes which accompany the electron photoemission.

IV. Neptunium compounds

In recent years, studies of physicochemical properties of neptunium compounds have attracted considerable attention.[1, 3, 239, 249, 250] Neptunium dioxide NpO_2,[41, 79] single crystals of $Cs_3NpO_2Cl_4$ and $Cs_2NpO_2Cl_4$,[51, 53, 80] the compounds $Cs_2NpO_2(OAc)_3$, $NaNpO_2(OAc)_3$ and $RbNpO_2(NO_3)_2 \cdot 2\,H_2O$ [55] have been studied by XPS. A number of studies have been devoted to elucidation of correlations between the fine structure parameters of the XPS spectra of outer and core electrons and the neptunium oxidation states in compounds,[44, 80, 81] magnetic properties,[44, 89, 90] the nature of the chemical bond (Refs 36, 41, 51 – 53, 55, 81, 87 – 90, 115) and the secondary electronic processes.[55, 56] Non-relativistic X_α-SW calculations have been carried out for the electronic structure of the NpO_2^{2+} cluster ($D_{\infty h}$ group of symmetry) with $R_{Np-O} = 0.171$ nm,[115] while calculations for the $[NpO_2Cl_4]^{2-}$ cluster (D_{4h} group of symmetry) with $R_{Np-O} = 0.171$ nm and $R_{Np-L} = 0.262$ nm were carried out in the relativistic X_α-DV approximation.[36]

In a number of studies,[51, 53, 55, 56, 80, 114, 115] the XPS spectra of several neptunyl compounds (Table 10) have been analysed in order to establish the relationships of the spectral structure with the properties and structures of the compounds and the nature of the chemical bond in them. A key goal was to confirm the assumed formation of IVMO in neptunium compounds, which has been established for thorium and uranium compounds on the basis of the XPS spectral structure.

1. The low binding energy range of the spectra

The structure of the low binding energy XPS spectra of neptunyl compounds is fairly similar to that of the corresponding spectra of uranyl compounds. Since these compounds contain other elements apart from neptunium, the low binding energy range of the spectra exhibits an additional structure caused by electrons of these elements, which markedly complicates interpretation of the fine structure of the spectra of neptunium compounds. Thus the neptunium lines in this binding energy range in the spectra of the $Cs_3NpO_2Cl_4$ and $Cs_2NpO_2Cl_4$ single crystals are overlapped by caesium and chlorine lines and their satellites, which occur on the higher-energy side of the basic lines (Fig. 26). The spectra of other neptunium compounds also exhibit additional lines (Fig. 27). For comparison, Fig. 27 shows the spectra of NaOAc and $Ni(NO_3)_2$.

a. The spectra of the Np5f electrons

The spectra of the studied neptunium compounds exhibit a sharp line near a zero binding energy (the Fermi level for metals), like the spectra of U^{4+} (see Figs 26, 27). As the oxidation number of

$NaNpO_2(OAc)_3$	Np^{6+}	1.8 ± 0.2	2.2 ± 0.1	51.5

neptunium increases, the intensity of this line diminishes (Table 11). Hence, it has been suggested that this relatively narrow line near a zero binding energy is due to the Np5f electrons not involved in the chemical bond.[55, 80] As the neptunium oxidation state increases, the number of unbound Np5f electrons decreases, so does the effective magnetic moment μ_{eff} (see Table 11).

It follows from the XPS spectra [55, 79] and calculation results [137] that on passing from uranium compounds to neptunium compounds, the binding energy difference between the OVMO and An5f electrons decreases. This imposes some limitations on the accuracy of determination of the relative intensity of the Np5f line in neptunium compounds containing unbound Np5f electrons. Nevertheless, the intensity of this line can serve as not only a qualitative but also a quantitative measure of the neptunium oxidation state in compounds.

b. The spectra of the Np6p and O2s electrons

As noted above, the low binding energy range of the XPS spectra of the neptunium compounds studied contains, in addition to the

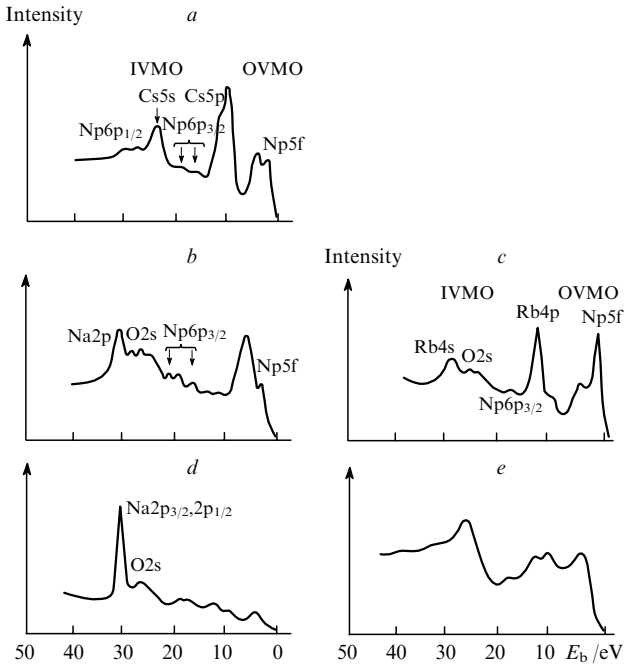

Figure 27. XPS spectra of neptunium compounds in the low binding energy range (for comparison, XPS spectra of sodium acetate and nickel nitrate are given).[55]
(*a*) $Cs_2NpO_2(OAc)_3$, (*b*) $NaNpO_2(OAc)_3$, (*c*) $RbNpO_2(NO_3)_2 \cdot 2H_2O$, (*d*) NaOAc, (*e*) $Ni(NO_3)_2$.

Np6p and O2s lines, some lines due to ligand electrons (Table 12, see Figs 26, 27), which complicate the spectrum. For example, the OVMO and IVMO spectra of the NO_3^- and AcO^- ligands exhibit a complex structure covering a range of approximately 35 eV. This structure [55] has been studied both experimentally and theoretically (for NO_3^-, it is shown in Figs 5 and 27 *e*).

Despite the complexity of the low binding energy XPS spectra of neptunium compounds containing an NpO_2^{n+} group, the structure of the $Np6p_{3/2}$ spectrum is similar to that observed in the $U6p_{3/2}$ spectra of uranyl compounds (see Fig. 26). In all cases, two components appear instead of the single $An6p_{3/2}$ line. The lower binding energy component is partially superimposed onto the Cl3s line.

The R_{An-O} bond lengths in the AnO_2^{n+} groups have been estimated using relation (8) with the assumption that the effect of the difference between the charges of the Np and U nuclei can be neglected.[80] This gave the following values: $R_{U-O} = 0.174$ nm, $R_{Np-O} = 0.180$ nm and $R_{Np-O} = 0.174$ nm for the UO_2^{2+}, NpO_2^{+} and NpO_2^{2+} groups in the compounds $Cs_2UO_2Cl_4$, $Cs_3NpO_2Cl_4$ and $Cs_2NpO_2Cl_4$, respectively. The appearance of two components in the $Np6p_{3/2}$ spectral range for neptunium compounds confirms the assumption that the XPS spectra of compounds containing AnO_2^{n+} groups should exhibit the structure typical of the IVMO.

The participation of low-energy occupied Np6p and L*n*s AO in the IVMO formation can be established on the basis of the binding energy difference between the core AO and valence MO. The researchers cited [80] could not carry out this comparison due to the lack of data for neptunium metal. However, comparison of these values for neptunium compounds shows that they are different. A reason for this discrepancy may be dissimilar participation of the Np6p and L*n*s AO in the IVMO formation in different compounds (Table 13).

2. The spectra of the core electrons

In the binding energy range of core electrons, XPS spectra of neptunium compounds exhibit a complex fine structure (Figs 28 – 31).[55, 56, 79, 80] The binding energies for the most intense lines are listed in Table 10. The most intense lines correspond to the Np4f electrons (see Fig. 28). The basic lines of these spectra are least distorted due to the additional structure; therefore, the Np4f spectrum is most suitable for quantitative elemental and ionic analyses and determination of the neptunium oxidation state. For compounds containing neptunium ions in only one formal oxidation state, the Np4f binding energy varies within a range of 0.6 eV (see Table 10).[55] The greatest change in the $Np4f_{7/2}$ binding energy on passing from compounds with formally pentavalent neptunium to hexavalent neptunium compounds equals 2.2 eV, while the smallest change is 1.0 eV. Hence, the chemical shifts can be used to draw conclusions concerning the formal oxidation state of neptunium and the relative ionic – covalent natures of the bond in compounds.

In caesium- and chlorine-containing neptunium compounds, the binding energies formed by these elements are somewhat greater than the corresponding binding energies in CsCl (see Table 12). This is due to the increase in the caesium and chlorine oxidation states upon their incorporation in the compounds considered. Thus, it can be concluded that the bonds between Cl and the AnO_2^{n+} group are more covalent than the Cs–Cl bond, while the bond between the caesium and chlorine atoms in a neptunium compound is more ionic than that in CsCl.

a. The spectra of Np4f electrons

The basic lines of the Np4f doublet related to the spin – orbit splitting [ΔE_{sl}(Np4f) = 11.8 eV [80]] are relatively narrow (see Fig. 28). In this binding energy range, satellites caused by many-body perturbation appear with the highest probability. The maxima corresponding to these satellites can also be seen in the spectra of other core electron levels. However, the Np4f range exhibits most characteristic shake up satellites. For example, for Np^{4+} (NpO_2),[79] Np^{5+} ($Cs_3NpO_2Cl_4$) and Np^{6+} ($Cs_2NpO_2Cl_4$), the ΔE_{Sat} values equal ~7.0, 9.4 and 3.5 eV, and the intensities of low-energy satellites are ~17%, 12% and 20%, respectively.[80] These values are correlated satisfactorily with corresponding values for U^{4+} (UO_2) and U^{6+} ($Cs_2UO_2Cl_4$): 6.9 and 3.8 eV, 25% and 20%, respectively. This indicates that the electronic structures of isostructural neptunium and uranium compounds have much in common, which also agrees with the results of theoretical calculations.[115, 137] It is noteworthy that the structure of the Np4f spectrum related to many-body perturbation can serve as a reliable characteristic of the neptunium formal oxidation state.

b. Spectra of the Np5d and Np4d electrons

In the Np5d binding energy range, the intensity of the $Np5d_{3/2}$ line is essentially suppressed and the line is broadened (see Fig. 29). This results in a seeming substantial change in the spin – orbit splitting. Thus the average value is given by $\Delta\bar{E}_{sl}$(Np5d) = 9.2 eV and the difference between these values for the studied neptunium compounds does not exceed 0.8 eV.

The change in the spin – orbit splitting is due to the formation of the complex structure of the Np5d spectral lines. This structure may arise due to the multiplet splitting caused by the presence of unpaired Np5f electrons. In addition, the Np5d spectra may exhibit a structure related to the dynamic effect, which gives rise to the final electronic states like $Np5d^96s^26p^65f^n np^0 \rightleftharpoons Np5d^{10}6s^06p^65f^n np^1$, because the relation E_b(Np5d) ≈ $2E_b$(Np6s) holds. However, this process is relatively unlikely ($\Delta n = 1$, $\Delta l = 2$). The value ΔE_{sl}(Np5d) = 9.7 eV should be considered to be most realistic.

The Np4d spectral structure is also complicated due to superposition of lines related to the many-body effects involving ligand atoms (see Fig. 29). The other observed maxima cannot be explained in this way. Presumably,[55] this structure is a consequence of the dynamic effect, resulting in final states like $Np4d^94f^{14}(5s^25p^65d^{10}6s^26p^6)5f^n \rightleftharpoons Np4d^{10}4f^{12}(5s^25p^65d^{10}6s^2.6p^6)5f^n6d^1$. This is one of the possible mechanisms for the formation of the fine structure in the Np4d spectra.

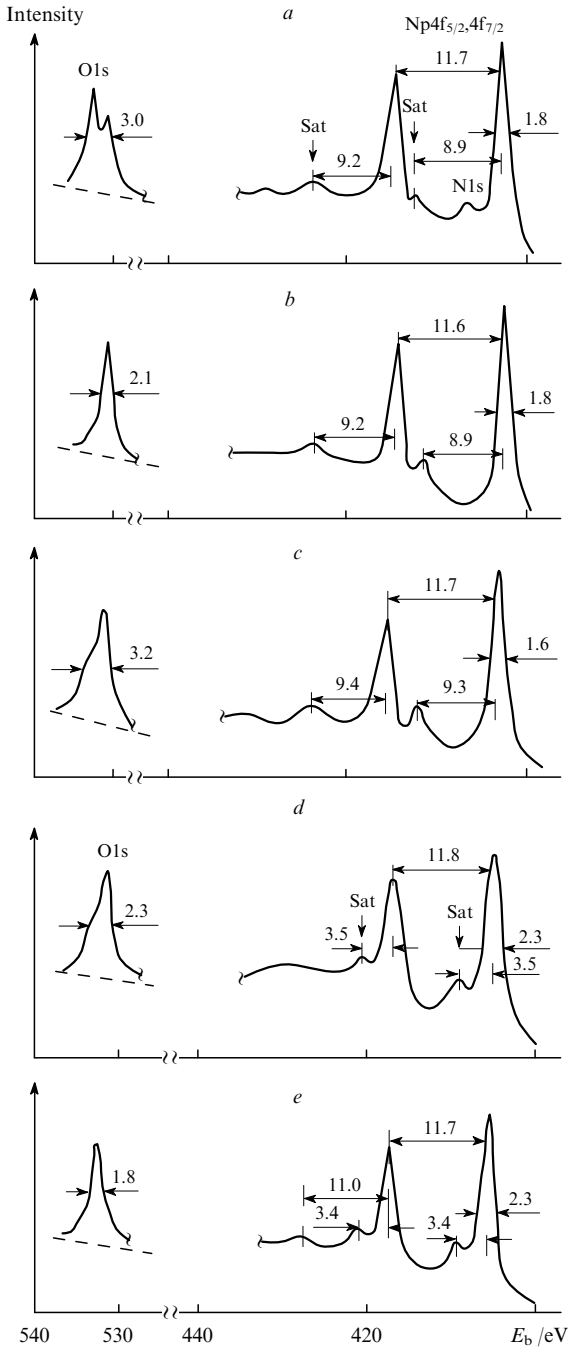

Figure 28. XPS spectra of neptunium compounds containing the NpO_2^+ (*a*–*c*) and NpO_2^{2+} (*d*, *e*) groups in the Np4f and O1s binding energy ranges.[55]
(*a*) $RbNpO_2(NO_3)_2 \cdot 2H_2O$, (*b*) $Cs_2NpO_2(OAc)_3$, (*c*) $Cs_3NpO_2Cl_4$, (*d*) $Cs_2NpO_2Cl_4$, (*e*) $NaNpO_2(OAc)_3$. The dashed lines show the background.

The appearance of the complicated fine structure in the Np4d spectra leads to a seeming change in the spin–orbit splitting on passing from one compound to another. The average value $\Delta\bar{E}_{sl}$(Np4d) is equal to 45.0 eV. This does not allow any accurate measurements of the binding energies on the basis of the Np4d spectra.

c. Spectra of the Np5p and Np4p$_{3/2}$ electrons

The Np5p binding energy range of the XPS spectra of neptunium compounds exhibits lines for the core electrons of the ligand atoms (see Fig. 30).[56] The structure of the Np5p$_{1/2}$ spectra cannot be observed, as the ΔE_{sl}(Np5p) value equals 77 eV; the binding

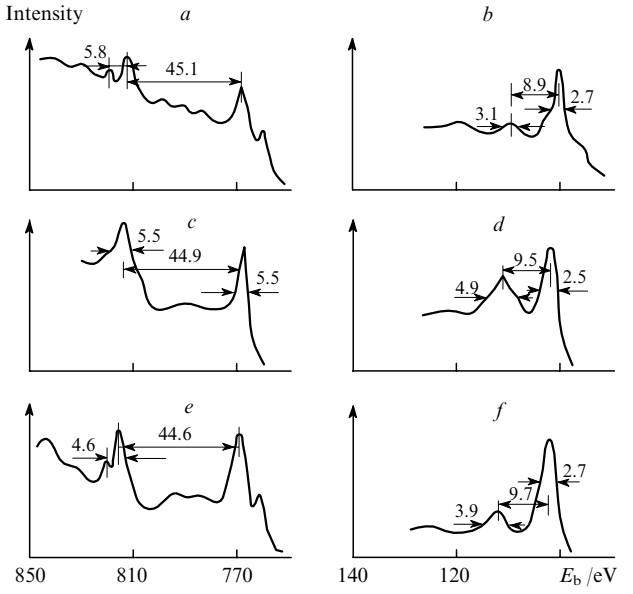

Figure 29. XPS spectra of neptunium compounds in the Np4d (*a*, *c*, *e*) and Np5d (*b*, *d*, *f*) binding energy ranges.[55, 80]
(*a*, *b*) $Cs_3NpO_2Cl_4$; (*c*, *d*) $NaNpO_2(OAc)_3$; (*e*, *f*) $Cs_2NpO_2Cl_4$.

energy of these electrons [E_b(Np5p$_{1/2}$] is approximately 283.0 eV,[20] their spectrum being superimposed onto the intense C1s lines of the AcO groups or the residual oil vapour molecules adsorbed on the sample surface. However, for some compounds, individual spectra of the Np5p$_{3/2}$ electrons can be observed (see Fig. 30).[56]

The reported[20] values for the neptunium binding energy E_b(Np5p$_{3/2}$) = 206 eV and E_b(Np5d$_{5/2}$) = 101 eV roughly satisfy the condition E_b(Np5p$_{3/2}$) $\approx 2\,E_b$(Np5d$_{5/2}$). This suggests[56] that the structure observed in the Np5p$_{3/2}$ spectra is largely caused by the dynamic effect, resulting in final states of the type $Np5p^5 5d^{10}(6s^2 6p^6)5f^n \rightleftharpoons Np5p^6 5d^8(6s^2 6p^6)5f^{n+1}$. Apparently, additional broadening of these lines can be due to multiplet

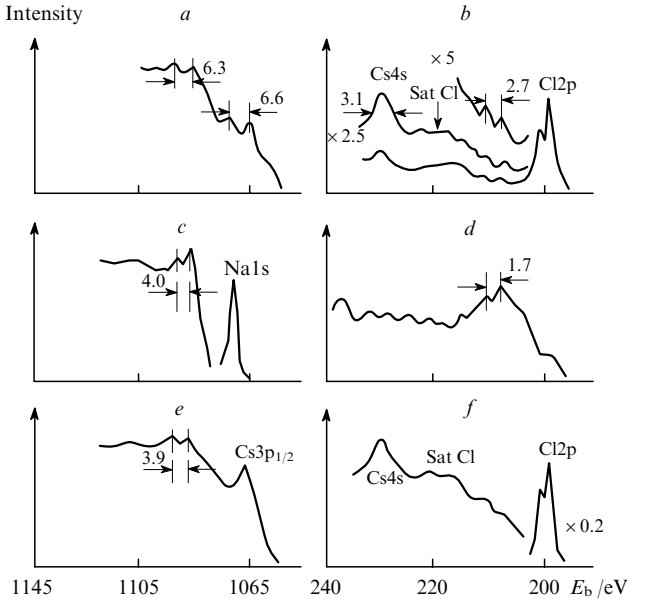

Figure 30. XPS spectra of neptunium compounds in the Np4p$_{3/2}$ (*a*, *c*, *e*) and Np5p (*b*, *d*, *f*) binding energy ranges.[56] (*a*, *b*) $Cs_3NpO_2Cl_4$; (*c*, *d*) $NaNpO_2(OAc)_3$; (*e*, *f*) $Cs_2NpO_2Cl_4$.

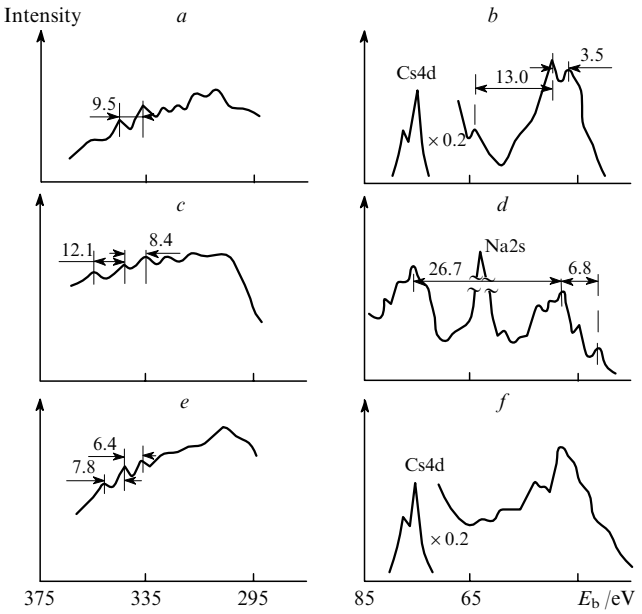

Figure 31. XPS spectra of neptunium compounds in the Np5s (*a*, *c*, *e*) and Np6s (*b*, *d*, *f*) binding energy ranges.[56] (*a*, *b*) $Cs_3NpO_2Cl_4$; (*c*, *d*) $NaNpO_2(OAc)_3$; (*e*, *f*) $Cs_2NpO_2Cl_4$.

splitting, because all the neptunium compounds considered contain unbound Np5f electrons. Some of the peaks can be attributed to shake up satellites (see Fig. 30).

The spectra of the $Np4p_{3/2}$ electrons of caesium-containing neptunium compounds are overlapped by satellites of the $Cs3p_{1/2}$ structure (see Fig. 30). The spectrum of the $Np4p_{3/2}$ electrons of $RbNpO_2(NO_3)_2 \cdot 2\,H_2O$ contains no ligand-related lines over a broad binding energy range; nevertheless, this range also displays fine structure. The binding energies of neptunium electrons reported in a study,[20] $E_b(Np4p_{3/2}) = 1087$ eV, $E_b(Np4d_{3/2}) = 773$ eV and $E_b(Np5s) = 338$ eV, roughly satisfy the relation $E_b(Np4p_{3/2}) \approx E_b(Np4d_{5/2}) + E_b(Np5s)$. Hence, one may suggest that the $Np4p_{3/2}$ spectral structure is due to the dynamic effect, resulting in final states of the type $Np4p^54d^{10}4f^{14}5s^26p^65f^n np^m \rightleftharpoons Np4p^64d^94f^{14}5s^16p^65f^n np^{m+1}$.

d. Structure of the Np6s and Np5s spectra

It is known that the Np6s electrons have a relatively small photoionisation cross-section [203] and their spectra exhibit a relatively complex fine structure. Nevertheless, the sample preparation and experimental procedures allowed researchers [55, 56] to measure the spectra of these electrons (see Fig. 31).[56] The fine structure of the Np6s spectrum extends over a binding energy range of ~40 eV. The electron binding energies found as the weight average values for electrons around the most intense band are listed in Table 10. The spectra of $RbNpO_2(NO_3)_2 \cdot 2\,H_2O$ and $NaNpO_2(OAc)_3$ exhibit a rather intense spectral structure in addition to the relatively broad bands at ~50 and ~75 eV. The spectra of these compounds reflect most fully the Np6s spectral structure over the whole binding energy range considered (see Fig. 31).

Presumably, the formation of the Np6s fine structure over this broad binding energy range may be due to the dynamic effect, resulting in final electronic states like: $Np6s^16p^65f^n6d^0 \rightleftharpoons Np6s^26p^45f^n6d^1$. The presence of unbound Np5f electrons in all of the studied neptunium compounds may give rise to an additional structure caused by multiplet splitting. Finally, shake up satellites should also be manifested in these spectra.[55, 56]

It should be noted that, without thorough theoretical analysis of the spectral structure in the Np6s binding energy range and without identification of individual lines, it is difficult to draw any qualitative conclusions concerning the involvement of the Np6s shell in the IVMO formation in neptunium compounds.

Attempted study of the Np5 spectral structure has been reported.[55, 56] In this energy range, against the relatively intense background of the broad C1s satellite band due to the OAc group or the residual vacuum oil, the spectrum exhibits an additional structure missing from the C1s spectrum of graphite (see Fig. 31). This structure always consists of two lines that cannot result from the multiplet splitting, because the corresponding binding energy difference does not exceed 2–3 eV. Therefore, it is assumed that the structure manifested in the Np5s spectra is due to the dynamic effect, which results in final states of the type $Np5s^15p^65d^{10}6s^26p^65f^n np^m \rightleftharpoons Np5s^25p^55d^{10}6s^16p^65f^n np^{m+1}$.

Thus, it can be concluded that parameters of the fine structure manifested in the spectra of neptunium compounds provide information on their magnetic properties, neptunium oxidation states and the degree of participation of the Np6p and L*n*s AO in the formation of the IVMO whose structure is determined by the local environment of the neptunium ion. The fine structure observed in the spectra of core electrons, which arises due to different mechanisms, is characteristic of particular neptunium compounds and can be used for identification.

V. Plutonium compounds

Plutonium oxides on the metal surface,[41, 64, 79, 83–86, 116, 121, 126] $Pu(NO_3)_4 \cdot n\,H_2O$,[29, 55] and the single crystal of $Cs_2PuO_2Cl_4$ [55, 82] have been studied by XPS. The correlations of fine structure parameters of the spectra of inner and outer electrons with plutonium oxidation states in compounds,[29, 64, 79, 81–86] the structures of compounds,[29, 55, 82] the types of chemical bond,[29, 37, 41, 44, 51–53, 55, 81, 82, 87–91, 115, 116] and secondary electronic processes that accompany photoemission of electrons [29, 55, 79, 82, 121] have been studied. The relativistic electronic structure parameters of plutonium were evaluated;[33, 35] nonrelativistic X_α-SW calculations were carried out for the electronic structure of the PuO_2^{2+} cluster ($D_{\infty h}$ group of symmetry) with $R_{Pu-O} = 0.171$ nm [115] and relativistic X_α-DV calculations were performed for the $PuO_2Cl_4^{2-}$ cluster (D_{4h} group of symmetry) with $R_{Pu-O} = 0.171$ nm and $R_{Pu-L} = 0.262$ nm.[36] On the basis of the XPS spectrum of outer valence electrons, the mechanism of formation of a PuO_2 film on the surface has been studied;[64] the dependence of valence and core level spectral parameters for metallic plutonium on the number of monolayers on the substrate has been analysed.[85]

For the single crystal of $Cs_2PuO_2Cl_4$ containing the PuO_2^{2+} group, the XPS spectra of various electron shells in the binding energy range from 0 to ~1250 eV have been studied [82] in order to determine the relationship between the fine spectral structure parameters and the structure of the local environment of the plutonium ion, plutonium oxidation state and the nature of the chemical bond in the compound. The spectral lines were identified using the spectra of plutonium metal [83, 116, 127] and plutonium dioxide,[41, 79, 84] the results of calculations for individual atoms [178] and model clusters,[36, 115] photoionisation cross-sections [203] and the XPS spectra of thorium, uranium and neptunium compounds and CsCl.[55] The procedure used for sample preparation and for recording made it possible to obtain the first spectra of the core and valence electrons for a bulky sample, which was a $Cs_2PuO_2Cl_4$ single crystal. This double salt contains a plutonium ion formally as Pu^{6+} with the electronic configuration $\{Rn\}5f^2$. Therefore, the fine spectral structure of the core and valence levels can be discussed conveniently using this compound as an example.

1. The spectra of valence electrons

The low binding energy XPS spectrum of $Cs_2PuO_2Cl_4$ largely resembles the spectra of isostructural uranium and neptunium compounds (see Figs 26, 31).

a. The spectrum of the Pu5f electrons

Comparison of the An5f spectra of uranium,[47] neptunium,[80] plutonium,[82] the oxides NpO_2 (see Refs 41 and 79) and PuO_2 (see Refs 41, 79 and 84) shows that on passing from uranium to plutonium, the difference between the weight-average An5f binding energy and the OVMO binding energy substantially decreases. This results in a significant overlap of the corresponding lines in the spectra of plutonium compounds (Fig. 32); this increases the error of determination of the relative intensity of the Pu5f lines.

It follows from the spectra of PuO_2 [41, 79, 84] and $Cs_2PuO_2Cl_4$ [82] that an increase in the plutonium oxidation state in compounds entails a decrease in the intensity of the Pu5f line. The magnetic properties of plutonium compounds have not been adequately studied, hence, they cannot be quantitatively correlated with the intensity of the Pu5f lines in the spectra; nevertheless, there exists some qualitative correlation. Thus on passing from the tetravalent plutonium in PuO_2 to hexavalent plutonium in the fluoride PuF_6, the specific molar susceptibility (χ) decreases from 536×10^{-6} to 170×10^{-6} mol^{-1} (see Ref. 251). This is in line with the fact that a decrease in the number of the unbound Pu5f electrons in the molecule induces both a decrease in the intensity of the Pu5f lines and a decrease in the paramagnetic term in the specific magnetic susceptibility of the compound. However, as follows from the data on the An5f line intensity and the published data on the magnetic behaviour of actinide compounds, no direct correlation can be followed between the magnetic moment and the number of unpaired An5f electrons for $n_f > 2$.[252–254]

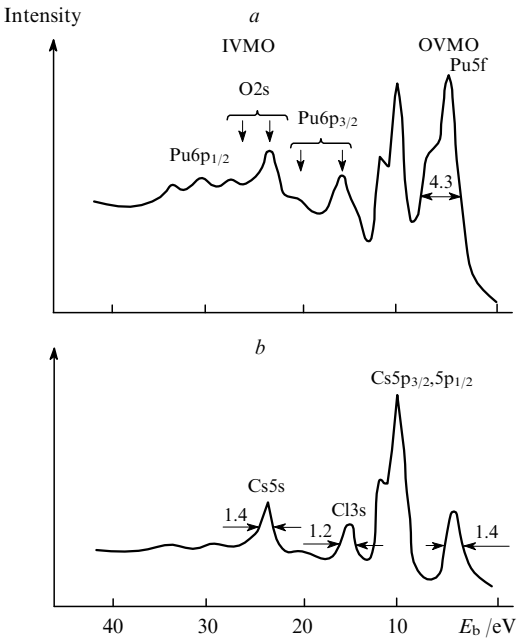

Figure 32. Low energy range of the XPS spectrum of the single crystal of $Cs_2PuO_2Cl_4$ (*a*).[82] For comparison, the XPS spectrum of caesium chloride is given (*b*).

b. The spectra of the Pu6p and O2s electrons

The $Pu6p_{3/2}$ spectrum of $Cs_2PuO_2Cl_4$, like the $An6p_{3/2}$ spectra of $Cs_2AnO_2Cl_4$ (An = U, Np), consists of two lines (see Figs 26, 32). The line characterised by the lower binding energy partially overlaps with the Cl3s line. In the spectrum of the O2s and $Pu6p_{1/2}$ binding energy range, a complex fine structure typical of compounds containing the actinyl group AnO_2^{n+} can be observed, in addition to the Cs5s peak.

Table 14. Binding energy differences (ΔE_i) between various plutonium and oxygen shells.

Compound, element	$E_i = E_k - E_l$ /eV				
	$6p_{3/2} - 6p_{1/2}$	$6p_{3/2} - 4f_{7/2}$	$5d_{5/2} - 4f_{7/2}$	$4f_{7/2} - 4d_{5/2}$	O2s – O1s
$Cs_2PuO_2Cl_4$ (see [82])	–	412.5, 408.2	321.1	374.8	506.5, 508.8
PuO_2 (see [79])	12.2	408.2	321.6	375.2	507.5
Pu_{metal} (see [83])	12.0	403.9	319.8	377.0	
Pu_{theor} (see [178])	11.9	403.8	319.3	379.8	

Comparison of the binding energy differences between the valence and core levels ΔE_i ($Pu6p_{3/2} - Pu4f_{7/2}$) for plutonium and its compounds (Table 14) shows that IVMO are formed effectively from the Pu6p and O2s AO not only in the case of $Cs_2PuO_2Cl_4$, containing the PuO_2^{2+} group, but also for the oxide PuO_2, which has a more symmetric structure. Indeed, the difference between the $Pu4f_{7/2}$ and $Pu6p_{3/2}$ binding energies for plutonium metal equals 403.9 eV. For PuO_2, this value is greater by 4.3 eV, and for the $Cs_2PuO_2Cl_4$ single crystals, these values are greater by 8.6 and 4.3 eV for the two components arising due to IVMO formation in these compounds (see, for example, Figs 4, 23).

These data also provide the conclusion concerning the nature (either bonding or antibonding) of some IVMO. The contribution of the IVMO electrons in the PuO_2^{2+} cluster to the covalent component of chemical bonding estimated on the basis of determination of the orbital forces (f^{α}_{Pu-O} /au) [53] amounts to 22% of the total contribution of the electrons of all MO.[115]

2. The spectra of core electrons of plutonium

The XPS spectra of $Cs_2PuO_2Cl_4$ for all core electron levels in the energy range from ~40 to ~1250 eV exhibit fine structure which is also typical of other plutonium compounds (Figs 33–37). The corresponding binding energies are given in Table 15. In those cases where a complex fine structure is present, instead of the expected single lines, the Table gives the weight average values for the binding energies corresponding to the most intense lines.

On passing from plutonium metal to PuO_2 or $Cs_2PuO_2Cl_4$, the core electron binding energies regularly increase (see Table 15). It can be seen that the core electron energies are correlated with the Pu oxidation states in the compound.

a. The spectrum of Pu4f electrons

The Pu4f spectrum consists of a spin doublet of sharp intense peaks accompanied by satellites on the higher binding energy side (see Fig. 33).

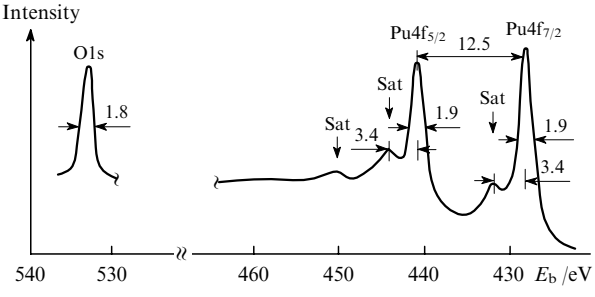

Figure 33. XPS spectra of the single crystal of $Cs_2PuO_2Cl_4$ containing the PuO_2^{2+} group in the Pu4f and O1s binding energy range.[82]

Table 15. Binding energies (E_b) and photoionisation cross-sections (σ) for plutonium compounds.

Orbital Pu, L (nl_j)	E_b /eV					σ [a]
	$Cs_2PuO_2Cl_4$ (see [82])	PuO_2 (see [79])	$Pu(NO_3)_4 \cdot n H_2O$ (see [29])	Pu_{metal} (see [83])	Pu_{theor} (see [178])	
Pu5f	5.0	–	4.1	–	4.7	0.81

$Cs5p_{3/2}$	10.4 (10.1) [b]					0.33
Cs5s	23.7 (23.4) [b]					0.18
Cl3s	16.1 (15.0) [b]					0.19

[a] Obtained at 1487 eV and expressed in 13.6 b per atomic shell.[203] [b] The electron binding energies for CsCl are given in parentheses.

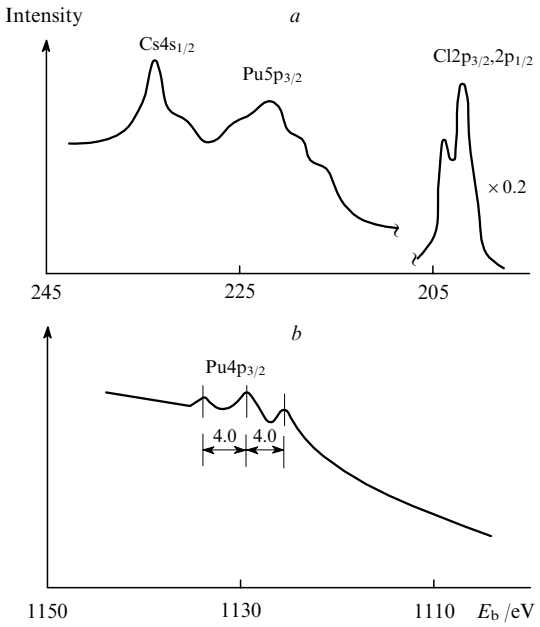

Figure 35. XPS spectra of $Cs_2PuO_2Cl_4$ in the $Pu5p_{3/2}$ (*a*) and $Pu4p_{3/2}$ (*b*) binding energy ranges.[55]

Comparison of the Pu4f lines in the spectra of $Cs_2PuO_2Cl_4$,[82] containing Pu^{6+}, and the dioxide PuO_2,[79] containing Pu^{4+}, shows that the binding energy distance from the basic lines of the doublet to the satellites (ΔE_{Sat}) can characterise, as in the case of uranium and neptunium compounds, the plutonium oxidation state. In the spectra of $Cs_2AnO_2Cl_4$ with An = Pu^{6+}, Np^{6+} and U^{6+}, the ΔE_{Sat} values equal 3.4, 3.5 and 3.8 eV, and the intensities I_{Sat} are 20, 20 and 20%, respectively. In the spectra of AnO_2 for An = Pu^{4+}, Np^{4+} and U^{4+}, the ΔE_{Sat} values amount to ~7,

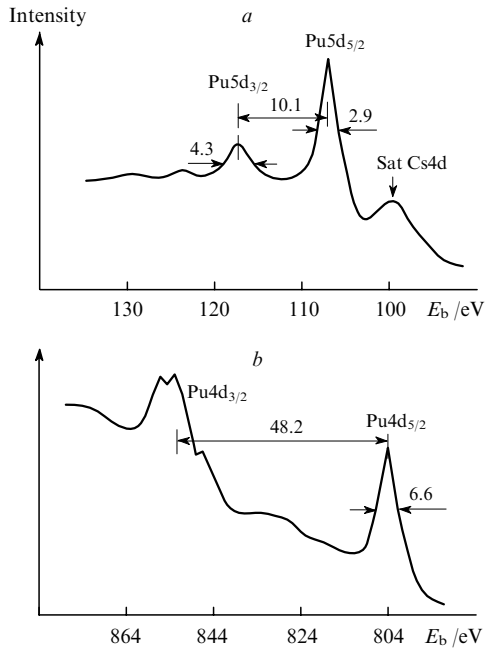

Figure 34. XPS spectra of $Cs_2PuO_2Cl_4$ in the Pu5d (*a*) and Pu4d (*b*) binding energy ranges.[82] A satellite arising on the higher binding energy side of the basic Cs4d line is shown.

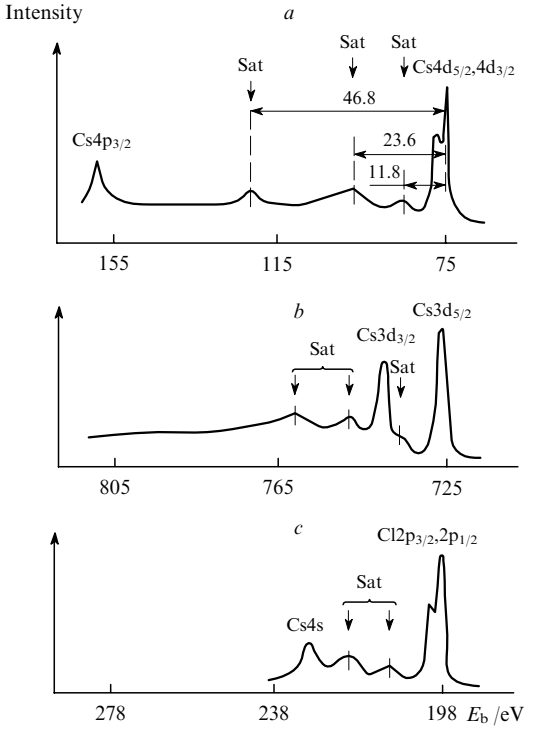

Figure 36. XPS spectra of caesium chloride in the binding energy range of core electrons.[55]
(*a*) $Cs4p_{3/2}$ and Cs4d electrons; (*b*) Cs3d-electrons, (*c*) Cs4s electrons.

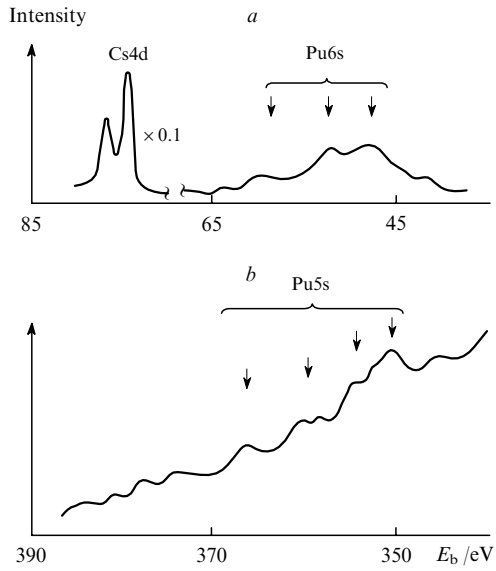

Figure 37. XPS spectra of $Cs_2PuO_2Cl_4$ in the Pu6s (*a*) and Pu5s binding energy ranges (*b*).[55]

~7 and 6.9 eV, while I_{Sat} are ~20, ~17 and 25%, respectively. The spin–orbit splitting ΔE_{sl}(Pu4f) values found by different researchers are 13.0, 12.7 and 12.5 eV for plutonium metal,[83] PuO_2 oxide[79] and $Cs_2PuO_2Cl_4$,[82] respectively. The observed differences in the ΔE_{sl}(Pu4f) values are related to the error of determination (see Table 15).

b. The spectra of Pu5d and Pu4d electrons

In the Pu5d binding energy range (see Fig. 34), an intense band with $E_b \approx 100$ eV due to the satellite of the Cs4d line is observed on the lower binding energy side of the basic $Pu5d_{5/2}$ line. The intensity of the $Pu5d_{3/2}$ component is largely suppressed, and it is broad compared to the basic $Pu5d_{5/2}$ line.

Despite the complicated spectral structure, the $Pu5d_{5/2}$ line can be used to determine the Pu oxidation state in compounds. Thus on passing from plutonium metal to the Pu^{6+} ion, the binding energy of these electrons decreases by $\Delta E_b(Pu5d_{5/2}) = 6.3$ eV (see Table 15). When the plutonium oxidation state changes from Pu^{4+} to Pu^{6+}, the corresponding energy difference is 2.6 eV. For individual compounds, these differences can be easily measured experimentally. The fine structure of the Pu5d spectra can also characterise the plutonium oxidation states in compounds. However, the exact energy of the spin–orbit splitting of the Pu5d line [ΔE_{sl}(Pu5d) = 11 eV][20] is difficult to determine due to the complex shape of this line (see Table 15).

The $Pu4d_{5/2}$ line for $Cs_2PuO_2Cl_4$ (see Fig. 34) is relatively broad ($\Gamma = 6.6$ eV) and symmetric. In the $Pu4d_{3/2}$ binding energy range, fine structure is observed. A structured band, possibly associated with Auger transition electrons, occurs at these energies. Against the background of this structure, a peak attributable to the $Pu4d_{3/2}$ electrons is observed. The spin–orbit splitting ΔE_{sl}(Pu4d) found from this spectrum is 48.2 eV. This coincides with the value $\Delta E'_{sl}$(Pu4d) = 48.2 eV obtained from the PuO_2 spectra,[79] but differs from the value $\Delta E''_{sl}$(Pu4d) = 46.7 eV, found from the spectrum of plutonium metal in the Pu4d binding energy range, by 1.5 eV.[83]

c. The spectra of $Pu5p_{3/2}$ and $Pu4p_{3/2}$ electrons

The Pu5p binding energy range of the XPS spectrum of $Cs_2PuO_2Cl_4$ contains several rather intensive peaks attributed to ligands and carbon atoms of the residual organic substances adsorbed on the surface in vacuum (see Fig. 35). For example, the $Pu5p_{1/2}$ line is superimposed by the C1s spectrum, which precludes drawing conclusions concerning its structure.

The spectra of various ligands have been analysed.[55] In particular, the spectrum of CsCl has been thoroughly studied (see Table 12, Fig. 36). This allowed researchers to identify the structure due to the $Pu5p_{3/2}$ electrons upon comparison of the spectra of $Cs_2PuO_2Cl_4$ and CsCl in the Cl2p and Cs4s binding energy ranges (see Fig. 35).

Comparison of the $Pu5p_{3/2}$ spectral structure for the studied compounds with the An5p spectra of other actinides shows that this structure can be attributed to the dynamic effect resulting in final states of the type $Pu5p^5 5d^{10}(6s^2 6p^6)5f^n \rightleftharpoons Pu5p^6 5d^8.(6s^2 6p^6)5f^{n+1}$. Indeed, the ratio of the Pu5p and Pu5d binding energies does not contradict this assumption. Thus for $Cs_2PuO_2Cl_4$, $E_b(Pu5p_{3/2}) = 218$ eV and $E_b(Pu5d_{5/2}) = 107.6$ eV (see Table 15), which approximately satisfies the condition $E_b(Pu5p_{3/2}) \approx 2\,E_b(Pu5d_{5/2})$.

The structure observed in the $Pu4p_{3/2}$ spectrum largely resembles that observed in the $Pu5p_{3/2}$ spectrum. The binding energies $E_b(Pu4p_{3/2}) = 1128.9$ eV, $E_b(Pu4d_{3/2}) = 851.7$ eV and $E_b(Pu5s) = 359.2$ eV approximately satisfy the condition $E_b(Pu4p) \approx E_b(Pu4d) + E_b(Pu5s)$. This suggests that, as for thorium, uranium and neptunium compounds, in this case, too, the structure observed in the spectrum of $Cs_2PuO_2Cl_4$ in the $Pu4p_{3/2}$ binding energy range may be due to a large extent to the dynamic effect, resulting in the formation of final states of the type $Pu4p^5 4d^{10}(4f^{14})5s^2(5p^6 5d^{10}6s^2 6p^6)5f^n np^m \rightleftharpoons Pu4p^6 4d^9(4f^{14})5s^1.(5p^6 5d^{10}6s^2 6p^6)5f^n np^{m+1}$.

d. The spectra of Pu6s and Pu5s electrons

Instead of the expected single peak for Pu6s electrons, the spectrum exhibits a complicated fine structure in an energy span covering ~30 eV.[55] A number of averaged peaks at 49.0, 54.5, 59.5 and 67.3 eV can be noted. The weight-average binding energy for these electrons E_b – (Pu6s) amounts to 51.2 eV (see Fig. 37).

Probably, the structure of the Pu6s spectrum is mainly due to the dynamic effect giving final states like $Pu6s^1 6p^6 5f^n 6d^m \rightleftharpoons 6s^2 6p^4 5f^n 6d^{m+1}$. Indeed, the values $\overline{E}_b$ (Pu6s) = 51.2 eV, $E_b(Pu6p_{3/2}) = 20.5$ eV and $E_b(Pu6p_{1/2}) = 30.4$ eV obey satisfactorily the condition $\overline{E}_b$ (Pu6s) $\approx 2\,E_b$(Pu6p), which is not at variance with the assumption concerning the dynamic effect. The spectral structure parameters can hardly allow a conclusion about the possible participation of the Pu6s shell in the OVMO and IVMO formation.

The Pu5s spectrum is expected to exhibit a fine structure in the region where the intensity of the C1s satellite corresponding to the carbon atoms of the adsorbed oil declines (see Fig. 37). Indeed, this range in the spectrum of $Cs_2PuO_2Cl_4$ contains peaks at 351.2, 354.9, 358.2 and 365.8 eV (see Fig. 37) for which the weight average binding energy is given by $\overline{E}_b$ (Pu5s) = 359.2 eV (see Table 15).

In the Pu5s binding energy range equal to ~35 eV, the XPS spectrum of Pu metal exhibits two peaks with the width $\Gamma \approx 10$ eV having a fine structure.[83] Hence, it can be suggested that the structure at 351.2 and 354.9 eV ($\Delta E_b = 3.7$ eV) (see Fig. 37) is partially due to the multiplet splitting. It is evident that the pronounced broadening (to ~35 eV) of the Pu5s binding energy range containing fine structure in the spectrum of $Cs_2PuO_2Cl_4$ cannot be attributed to the multiplet splitting alone.

For $Cs_2PuO_2Cl_4$, the binding energies $\overline{E}_b$ (Pu5s) = 359.2 eV, $E_b(Pu5p_{3/2}) = 218.0$ eV and $E_b(Pu5d_{5/2}) = 107.6$ eV satisfy the condition $\overline{E}_b$ (Pu5s) $\approx E_b$(Pu5p) + E_b(Pu5d). Thus, it can be suggested that the structure observed in the Pu5s binding energy range can also be attributed to the dynamic effect with the final states like $Pu5s^1 5p^6 5d^{10}(6s^2 6p^6)5f^n \rightleftharpoons Pu5s^2 5p^5 5d^9(6s^2 6p^6)5f^{n+1}$. The same conclusions have been drawn by other researchers,[83] who analysed the XPS spectral structure for plutonium metal.

It should be noted that, as for compounds of other actinides, this XPS spectral structure can be used to identify particular plutonium compounds.

VI. General rules of the formation of fine structure in the XPS spectra of actinide compounds

The fine structures of the XPS spectra of light actinide compounds have much in common. As noted above, this is due to the fact that actinides form a row of transition elements in which the An5f shell is gradually occupied by electrons with the increase in the atomic number. A complex fine structure is manifested to one or another extent in the XPS spectra of all electronic levels in the binding energy range of 0 – 1250 eV. On the one hand, the reasons for fine structure formation in the spectra of various electron shells of actinide compounds are largely similar, but on the other hand, parameters of the fine spectral structure are characteristic of particular compounds. Thus, the XPS spectral structure of the core and outer electron shells can be used to elucidate the physicochemical properties of actinide compounds. A typical feature of the An6p$_{3/2}$ and An5f valence electrons of actinides is relatively weak dependence of the binding energies (E_b) on the atomic number (Z) compared to analogous dependences for core electrons (Fig. 38). In the series of actinide dioxides, the binding energy for the valence An5f electrons increases by 3.1 eV, that of the An6p$_{3/2}$ electron, by 2.7 eV, and the core An5d$_{5/2}$ binding energy increases by 38.0 eV as the atomic number increases in the range of $90 \leqslant Z \leqslant 98$. The substantial increase in the An6p$_{1/2}$ binding energy is due to enhancement of the spin – orbit splitting ΔE_{sl}(An6p). Indeed, as noted above, the peaks in the An6p$_{3/2}$ and An6p$_{1/2}$ binding energy ranges observed in the spectra of actinide dioxides reflect the inner valence molecular orbitals rather than atomic levels. As a result, the An6p electrons are delocalised and shielded from the core charge, their energy depending only slightly on the atomic number Z. As was to be expected, the An5d, An4f and An4d binding energies of the core levels of actinides (Th, U, Np, Pu, Am, Cm, Bk, Cf), for example, in oxides,[79] increase appreciably with an increase in the atomic number (Table 16).

1. Spectra of the An5f electrons

The An5f electrons not involved in the chemical bond largely determine the magnetic properties of actinide compounds.[143, 255–257] The XPS spectra of compounds containing the An5f electrons exhibit a relatively narrow line around a zero binding energy (Fig. 39). The assumption that this line is due to free An5f electrons based on experimental data [38–40, 67, 68, 87, 127, 197, 252, 253] is consistent with the results of theoretical calculations.[93, 129, 137, 180] In particular, the correlation between the core An4f binding energy and the An5f line intensity observed for uranium and neptunium compounds confirms the assignment of the lines near a zero binding energy in the XPS spectra to the An5f electrons.[81, 88] Indeed, a decrease in the intensity of the line for the An5f electrons not involved in the chemical bond (*i.e.*, a decrease in the relative density of the An5f electrons on the actinide ions) brings about an increase in the actinide oxidation state and, hence, an increase in the core electron binding energies (Fig. 40).

It follows from the above results that the An5f electrons not involved in the chemical bond are largely accumulated on the actinide ions in compounds, and the corresponding orbitals are quasi-atomic (see Fig. 39).

Figure 41 shows that the slopes of the straight lines that reflect the dependence of the relative intensity of the An5f lines on the actinide oxidation state (Table 17) are equal to within the experimental error.[55] This allowed a group of researchers [81, 88–90] to find a general mathematical expression for the dependence of the relative intensity I_{5f}^{exp} on the number n_{5f} of free An5f electrons (Fig. 42).

It can be seen from Figs 41 and 42 that the An5f line intensity in the XPS spectra of the studied actinide compounds in the range of $0 \leqslant n_f \leqslant 7$ is proportional to the number of electrons not involved in the chemical bond. Within the framework of the approximations used, it can be inferred that the oxidation state of actinides changes discretely and that the An^{n+} ions have the electron configuration $\{Rn\}5f^n$.

The relative intensity of the An5f line was measured as the ratio of the area confined by the An5f line to the area confined by the $An4f_{7/2}$ line, $I_{5f}^{exp} = I(An5f)/I(An4f_{7/2})$. The satellite lines caused by the shake up process which accompanies the photo-

emission of the An4f electron were not taken into account.[81, 88–90] The area confined by the lines for such satellites can reach 20% of the area corresponding to the basic lines.[90] For example, the OVMO band in the spectra of actinide oxides located in the binding energy range from 0 to ~15 eV is mainly formed by the An5f, An6d and An7s electrons of the actinide and the O2p electrons of oxygen. For the X-ray excitation energy normally used in XPS studies (1486.6 eV), the photoionisation cross-sections (σ) for the O2s and $O2p_{3/2}$ electrons are equal to 0.00191 and 0.000263 Mb, respectively,[258] which is substantially lower than the value $\sigma \approx 0.02$ Mb for the An5f electrons. In addition, the photoionisation cross-sections for the An5f electrons of all actinides are much greater than the corresponding σ value for the $An6d_{3/2}$ (~0.0020 Mb) and An7s electrons (~0.00018 Mb).[258] Therefore, the intensity of the low binding energy XPS spectrum is mainly due to the An5f electrons.

The experimental data for the dependence of the relative intensity of the An5f line on the number of weakly bound electrons reported in several publications [81, 88–90] (see Table 17, Fig. 42) are described satisfactorily by the following equation:[90]

$$I_{5f}^{exp} = 0.0217\, n_{5f}. \qquad (15)$$

Equation (15) was derived with the assumption that the oxidation states of actinides in compounds are integers and the photoionisation cross-section barely depends on the atomic number (Z). This approximation is most adequate for light actinides since the energy gap between the E_b values for weakly bound An5f electrons and OVMO electrons determined from the XPS spectra of these actinides is rather narrow (see Table 17). Physically, this means that the An5f electron involved in chemical bonding passes from the localised state corresponding to a relatively narrow low binding energy XPS line to the delocalised state corresponding to the OVMO band. Despite the roughness of this approximation, the experimental dependence considered (see Fig. 42) can be effectively used for determination of actinide oxidation states in compounds.[90] For example, for AmO_2 (see Table 17, Fig. 42), this dependence suggests that either the oxide Am_2O_3 or another Am^{3+} compound is formed on the sample surface.

In the MO LCAO approximation, during the MO formation in actinide compounds, the An5f electrons can either directly participate in a chemical bond with retention of their nature ($l = 3$, where l is the orbital quantum number) [137] or be first excited, for example, to the An6d level, and participate in the chemical bond having the new d nature ($l = 2$). The relative intensity of the X-ray photoelectron lines of the OVMO electrons (I_{OVMO}^{theor}) in actinide oxides,[81] equal to the ratio of the intensities of the lines due to the OVMO (including An5f) and IVMO (including An6p and O2s orbitals) electrons, was estimated theoretically taking into account the corresponding photoionisation cross-sections [258] according to the equation

$$I_{OVMO}^{theor} = \frac{n_{5f}\sigma_{5f} + n_{6d}\sigma_{6d} + n_{7s}\sigma_{7s} + \nu n_{O2p}\sigma_{O2p}}{n_{6p}\sigma_{6p} + \nu n_{O2s}\sigma_{O2s}}, \qquad (16)$$

where n_{nl} and σ_{nl} are the numbers of electrons and the corresponding photoionisation cross-sections, and ν is the number of oxygen atoms ($\nu = 2$ for AnO_2 and 3 for AnO_3). Since all the considered lines fall in a binding energy range of ~35 eV, no corrections taking into account the binding energy differences between the electrons of different levels were introduced in relation (16).

The I_{OVMO}^{theor} values obtained in this approximation can be compared with the corresponding experimental data for actinide oxides (Table 18). The experimental values of I_{OVMO}^{exp} are presented in Table 18 for the electronic configurations acquired by the actinide ions in those cases where the An5f electrons involved in the chemical bond lose their f nature upon the formation of the bond. Although the error in the measurement of I_{OVMO}^{exp} can reach 20% and An5f and other valence electrons become delocalised upon chemical bonding and their photoionisation cross-sections should decrease, a number of qualitative conclusions have been reported.[81, 87, 88] Indeed, the fact that the I_{OVMO}^{exp} values (0.35 for ThO_2 and 0.72 for γ-UO_3) are substantially greater than the I_{OVMO}^{theor} values (0.20 and 0.30, respectively) can be related to the involvement of the An5f AO in the OVMO formation. As a result, An5f states occupied by electrons are present in the valence band of the oxides, ThO_2 and γ-UO_3; these states are missing, for example, for the thorium atom. This experimental result, although qualitative, is very important and agrees with the data of calculations of the electronic structures of these oxides.[137] It follows from the foregoing that upon the formation of chemical bond in actinide oxides, the An5f electrons can lose the f nature only partially.

In order to evaluate the validity of the assumption of localisation of weakly bound An5f electrons in actinide compounds made on the basis of experimental data, [35, 81, 87, 88] the experimental intensities of the An5f lines were compared with the corre-

Table 18. Theoretical [I_{OVMO}^{theor} (rel.u.)] and experimental [I_{OVMO}^{exp} (rel.u.)] relative intensities of the OVMO line in the XPS spectra for various occupancies of the shells (n_{nl}).[81]

sponding theoretical values determined from the photoionisation cross-sections of these electrons with allowance for the influence of spectroscopic and other factors on the An5f line intensity (see Fig. 42). The question of why the experimental dependence [see Fig. 42, Eqn (15)] is approximately linear was considered.

The dependences of the photoionisation cross-section $\sigma(An4f_{7/2})$ and $\sigma(An5f)$ on the number of An5f electrons n_{5f} (see Refs 53, 81) are shown in Fig. 43. It can be seen that these dependences are not linear. However, the variation of the $\sigma(An5f)/\sigma(An4f_{7/2})$ ratio as a function of n_{5f} is described by a smoother curve and, to a certain approximation, it can be regarded as linear. This explains qualitatively the course of the corresponding experimental dependence (see Fig. 42). However, the calculated $\sigma(An5f)/\sigma(An4f_{7/2})$ values are much smaller than the experimental values derived from the intensities of spectral lines.

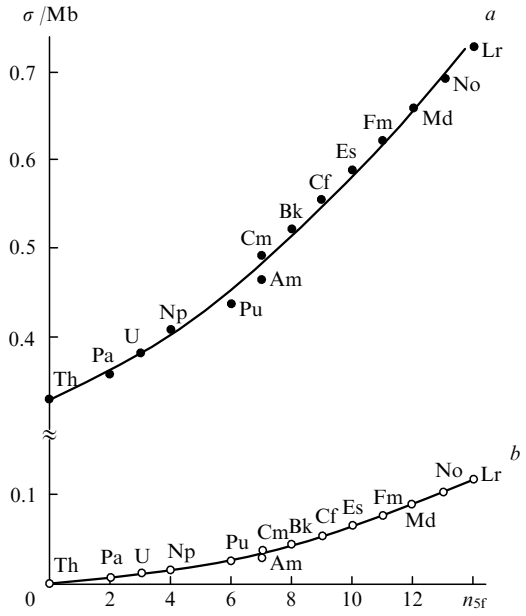

Figure 43. Photoionisation cross-sections (σ) for $An4f_{7/2}$ (*a*) and An5f shells (*b*) of actinide atoms *vs.* the number of An5f electrons (n_{5f}). The calculations were carried out in the Dirac – Fock approximation with precise calculation of the exchange integral.[35,81]

The theoretical values of the relative intensity I_{5f}^{theor} calculated using full photoionisation cross-sections and spectroscopic and other factors[81,88] for the basic configurations of actinide atoms are given in Fig. 42 in comparison with the corresponding experimental data. This comparison is qualitative, because the theoretical dependence was constructed without taking into account the participation of actinide atoms in the chemical bond. Nevertheless, it follows from Fig. 42 that the overall pattern of the theoretical curve following the increase in the number of An5f electrons is in qualitative agreement with experimental data.

The experimental relative intensity $I_{5f}^{exp} = I(An5f)/I(An4f_{7/2})$ of the An5f line was used[35] to estimate the non-formal number of these electrons (n_{5f}) in actinide ions. This was done according to the equation

$$n_{5f} = I_{5f}^{exp}\frac{f_{4f}n_{4f}\sigma'_{4f}\lambda_{4f}[1-\beta_{4f}(0.75\cos^2\theta-0.25)]F_{4f}}{f_{5f}\sigma'_{5f}\lambda_{5f}[1-\beta_{5f}(0.75\cos^2\theta-0.25)]F_{5f}}, \qquad (17)$$

where f is the spectroscopic factor, σ'_{nf} is the photoionisation cross-section per electron, λ is the electron free path, β is the asymmetry parameter, θ is the angle between the non-polarised radiation and the photoelectron escape (in this case, $\theta = 90°$), F is the transmittance of the analyser. Only the $An4f_{7/2}$ shell was considered, therefore the subscript 7/2 is omitted. The spectroscopic factor (the fraction of the basic peak without inclusion of satellites) has been calculated.[35]

It was shown[35] that for a neptunium oxidation state of 4+ the number of the Np5f electrons, equal to 4.25, differs little from the number of these electrons for the free atom. For pentavalent neptunium, the number of Np5f electrons is approximately 3, while for hexavalent neptunium, it is between 1 and 2. For UO_2, these data are consistent with the results presented in Table 18. Indeed, the value $I_{OVMO}^{exp} = 1.03$ for UO_2 corresponds to an n_{5f} value ranging from 2 to 3 (see Table 18). The data for other oxides indicate that the An5f orbitals take a significant part in chemical bonding.

Thus, for analysis of the electronic structure and quantitative ionic composition of actinides and for determination of actinide oxidation states in compounds, important information can be gained from the XPS spectral parameters for the An5f binding range. The quantitative correlation found between the relative intensity of the line for the weakly bound An5f electrons and the actinide oxidation state (U, Np, Pu, Am, Cm, Bk) in compounds is used to determine the ionic composition of actinides. The fact that the An5f electrons can directly participate in chemical bond formation is in line with the data of resonance X-ray $O_{4,5}$(U) emission spectra of uranium oxides measured using synchrotron radiation.[259–261] On the basis of chemical shifts of the X-ray $L_{\alpha1}$, $L_{\beta2,4}$, $L_{\beta1,5}$ and $L_{\gamma1}$ emission spectra, the conclusion about the existence of bound Th5f states in thorium oxide and halides has also been drawn.[262]

Despite the scantiness of the information on the magnetic behaviour of actinide compounds, a number of conclusions have been reached[44,89,90] from comparison of the data on their magnetic moments and magnetic susceptibilities with XPS data. During filling of the An5f shell in uranium and neptunium compounds, no direct proportionality between the effective magnetic moment (μ_{eff}) and the An5f line intensity can be followed (Fig. 44). The curve shown in the Figure is in good agreement with the dependence of molar magnetic susceptibility on the number of the Np5f electrons obtained previously.[254] The magnetic susceptibility data for the Pu^{4+} and Pu^{3+} ions also indicate that further filling of the An5f shell ($n_{5f} = 4, 5$) should entail a decrease in the

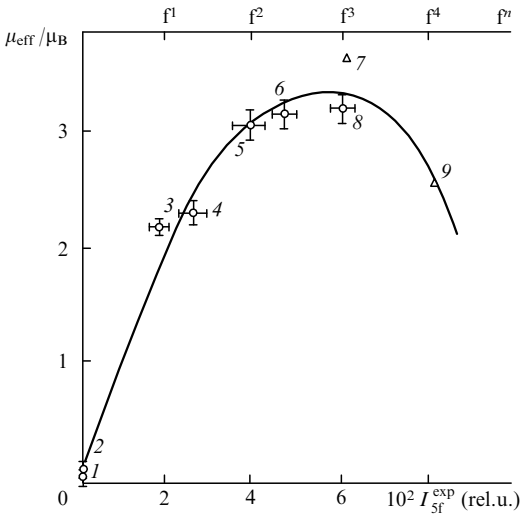

Figure 44. Relationship between the effective magnetic moments (μ_{eff}) of actinide compounds and relative intensity (I_{5f}^{exp}) of the XPS line for unbound An5f electrons.[89,90,253]
The μ_{eff} values were taken from Refs 211 and 251 (light circles) and from Ref. 263 (triangles). (*1*) ThO_2, (*2*) γ-UO_3, (*3*) $NaNpO_2(OAc)_3$, (*4*) $Cs_2NpO_2Cl_4$, (*5*) UO_2, (*6*) $Cs_3NpO_2Cl_4$, (*7*) $U(HCO_2)_3$, (*8*) NpO_2, (*9*) $Np(HCO_2)_3$. For $U(HCO_2)_3$ and $Np(HCO_2)_3$, the I_{5f}^{exp} values were not measured.

magnetic moment.[98, 254, 263] These results attest to a complex pattern of the influence of unbound An5f electrons on the magnetic properties of actinide compounds. Many problems are still to be solved in this field.

2. The spectra of the An6p and O2s, L*n*s electrons

Th comparison of binding energy differences between the core and valence electron levels of metals and compounds used in a number of studies [53–55] allowed the researchers to elucidate legitimately the MO structure, to construct the MO diagrams and to estimate the degree of participation of the low-energy occupied An6p and O2s L*n*s AO of the neighbouring atoms in the formation of the IVMO in actinide compounds. This approach provides the possibility of estimating the effect of IVMO formation not only in asymmetric actinide compounds containing AnO_2^{n+} actinyl groups, but also in highly symmetric compounds like AnO_2 (AnO_8^{12-}, O_h group of symmetry), whose XPS spectra exhibit less pronounced IVMO structure in the low energy XPS range. For example, the splitting between bonding and antibonding IVMO in uranium compounds can reach 15 eV,[109] which is comparable with the energy difference between IVMO in the nitrogen molecule (18.7 eV).[19] The method of 'differences' can also be used to evaluate the nature (bonding, antibonding or non-bonding) of individual IVMO, which is important for comparison with the results of calculations of the contribution of IVMO electrons to chemical binding. The use of this method, with allowance for the data of theoretical calculations of the electron structure, allows one to identify the IVMO structure based on the low binding energy XPS spectra and to correlate the parameters of this structure with the structure of the local environment of the actinide ion in the compound. The distances from the actinide to the nearest ligand atoms can often be estimated experimentally. For amorphous compounds, these data can hardly be obtained by X-ray diffraction.

Theoretical estimates have shown [52, 102, 115, 226] that the contribution of the IVMO electrons to the energy of chemical bonds in the AnO_2^{2+} clusters (An = U, Np, Pu) is approximately 25% of the contribution of the electrons from all MO. The experimental data on the natures of various IVMO do not contradict qualitatively these results. The XPS data on the OVMO and IVMO structures in actinide compounds are qualitatively in line with the results of non-relativistic X_α-DV calculation of the electronic structure of the $[UO_2F_5]^{3-}$ cluster (D_{5h} group of symmetry) [264] and relativistic X_α-DV calculation for the UF_6, NpF_6, PuF_6,[265] UF_6 [266–268] and $UO_2(NO_3)_2 \cdot 2H_2O$ [204, 269] molecules as well as with the data of X-ray emission,[100, 182, 185, 186, 188, 234, 246, 247, 259] Auger,[235, 236] X-ray absorption,[189, 191, 270] conversion electron spectroscopy,[218–221] *etc*.

3. The role of the An6p and An5f electrons in the formation of chemical bond

Since the XPS spectra of actinide compounds together with the ionisation cross-sections reflect the total valence electron density in a binding energy range of 0–50 eV, additional information for determination of the partial density, for example, of the An6p and An5f states, can be derived from other X-ray spectral methods.

While examining the XPS spectra of actinides, it has been noted [53, 55, 103, 104] that the lines observed in the low binding energy range (E_b = 0–50 eV) are usually several electron-volt wide, being often wider than the lines for deeper core electrons.[53, 55] For example, in the case of UO_2, the FWHM (Γ) of the O1s line (E_b = 531.4 eV) amounts to 1.6 eV, whereas the width of the O2s line ($E_b \sim 23.3$ eV) exceeds 4 eV, and this line is structured.[66] In conformity with the uncertainty principle $\Delta E \Delta\tau \sim h/2\pi$ (h is Planck's constant), the natural width (ΔE) of the level from which the photoelectron has been removed is inversely proportional to the hole lifetime ($\Delta\tau$) of the ion formed. Since the hole lifetime decreases as the absolute binding energy increases, the width of the XPS lines for some atoms is expected to decrease rather than increase, as is really the case in experiments (see, for example, Figs 8, 19). This served as the main reason for the thorough investigation of the spectral structure for actinide compounds in this energy range.[53, 55, 103, 104] It was found that, among other reasons, line broadening in the low energy range (0–50 eV) of the XPS spectra is due to the formation of OVMO and IVMO in actinide compounds (see, for example, the studies [51–55]). These spectra reflect the band structure and are observed as several electron-volt wide lines. In particular, in uranium compounds, the IVMO arise due to the significant overlap of the U6p and L(O,F,Cl)*n*s shells of neighbouring atoms and ligands.

Yet another important aspect vigorously studied in recent years is efficient participation of the An5f shell in the OVMO formation. Previously, it has been traditionally assumed that prior to chemical bonding, the An5f electrons are excited to, for example, the An6d AO. However, the calculation results show that the An5f shells can be directly involved in the formation of MO in actinide compounds.[129, 228] This basically important fact requires experimental corroboration.[81, 88] The commensurability of experimental and theoretical values for the partial density of the An5f and An6p electrons of actinide compounds can serve as a criterion for the consistency of calculations.

As an example of the information on the An6p and An5f electronic states of actinides that can be gained from X-ray spectral and theoretical data, we shall consider the results obtained for uranium trioxide. In particular, the fine structure of the low binding energy range of the XPS spectrum of uranium trioxide has been analysed taking into account the results of calculations of the electronic structure of the $[UO_2O_4]^{6-}$ cluster (D_{4h} group of symmetry) reflecting the local environment of the uranium atom in γ-UO_3 (first carried out in the relativistic X_α-DV approximation).[110, 123, 271] The fine structure of the X-ray $O_{4,5}$(U) emission spectrum of γ-UO_3, reflecting the partial densities of the U6p and U5f electronic states in the valence band, has been studied for the first time.[185, 234]

As noted above, the low energy range (0–40 eV) of the XPS spectrum of uranium trioxide can be divided conventionally into two parts (Fig. 45). The first part (0–13 eV) exhibits a structure caused by the OVMO, which are mainly formed from partially occupied outer valence U5f, U6d, U7s and O2p AO of neighbouring atoms. The fine structure observed in the second part of the spectrum (13–40 eV) is due to the IVMO, which mainly arise due to the substantial interaction of the electrons from completely occupied valence U6p and O2s AO of the neighbouring atoms. The OVMO spectral structure has three characteristic features and can be divided into three components. Eight clear-cut peaks can be observed in the IVMO range, and eight components can be distnguished (see Fig. 45). Despite the formalism of such subdivision, it allows one to perform qualitative and quantitative comparison of parameters of the XPS spectrum with the corresponding parameters of the X-ray O4,5(U) emission, Auger and other spectra and with the results of relativistic calculations for the electronic structure of the $[UO_2O4]^{6-}$ cluster (D_{4h} symmetry group).

The intensity of the OVMO band was found to contain a contribution of the outer valence U5f, U6d and O2p AO and a substantial contribution of the inner valence U6p AO of neighbouring atoms. Experimental evidence for the direct participation of the U5f electrons in the chemical bonding with partial loss of their f nature has been obtained. Indeed, the experimental intensity ratio of the OVMO and IVMO bands is 0.70,[81] which is comparable with the theoretical value (0.93).[123] Since the U5f AO almost does not participate in the formation of the IVMO, the difference between these values may be due to the decrease in the photoionisation cross-section of the U5f electrons involved in chemical bonding. However, if the intensity of the OVMO band in uranium trioxide is assumed to be formed only by the $U6d^47s^2$ and $3O^2p^4$ electrons, and the IVMO intensity, by $U6p^6$ and $3O2s^2$ electrons, the corresponding theoretical value would have been 0.30 (see Table 18), which is significantly smaller than the

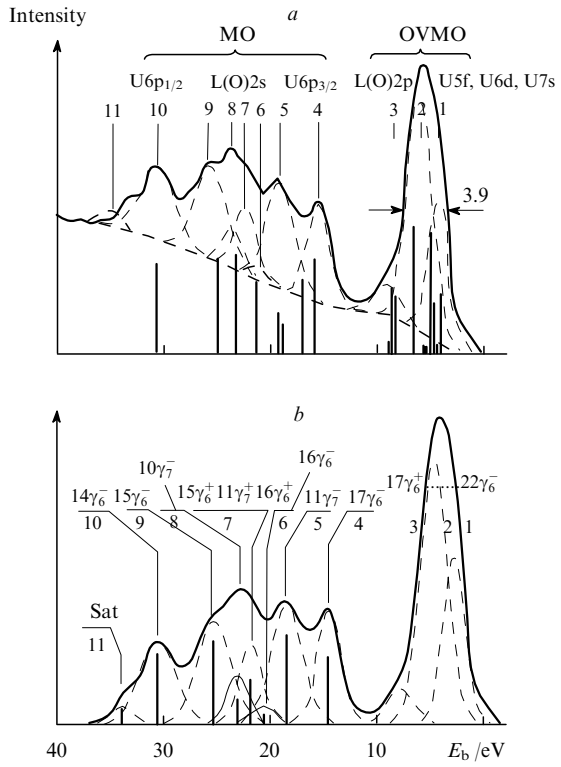

Figure 45. X-Ray photoelectron spectrum of γ-UO_3 with (*a*) and without (*b*) the background. The dashed lines show the spectral pattern of the subtracted background and thin lines show the conventional decomposition of the spectrum into components. The vertical segments in Fig. 45 *a* are the results of relativistic X_α-DV calculation for the $[UO_2O_4]^{6-}$ cluster (D_{4h} symmetry);[123] the vertical segments in Fig. 45 *b* show the expected correct spectrum simulated with allowance for calculations and experimental data;[110] $n\gamma_i^+$ and $n\gamma_i^-$ are designations of molecular orbitals; the digits are the numbers of peaks.

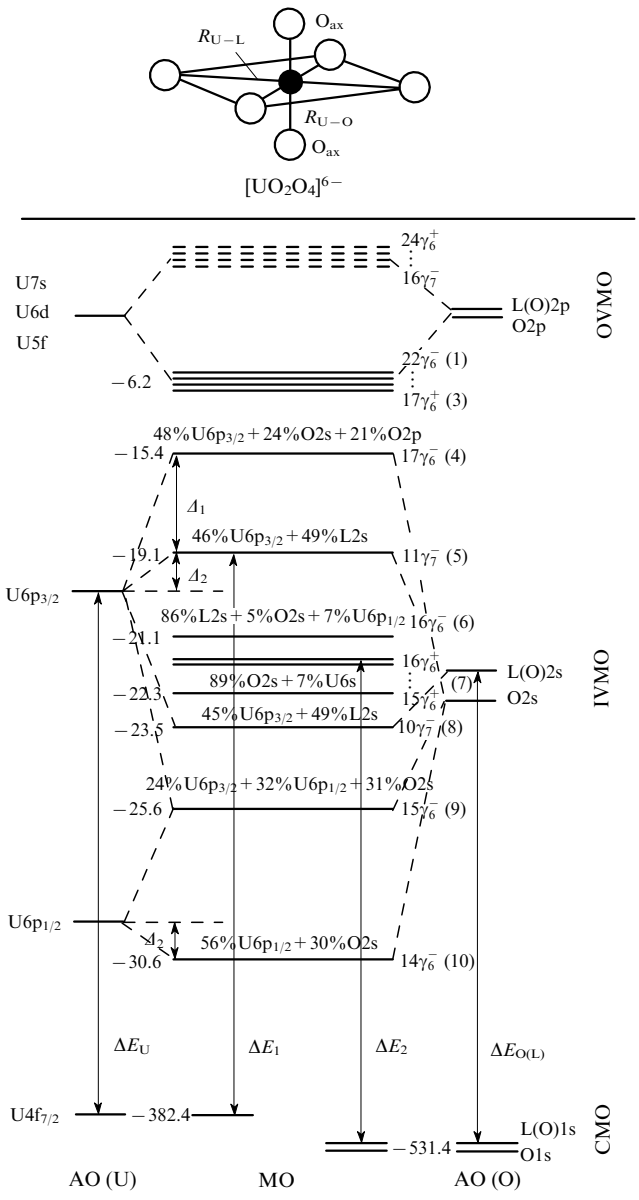

Figure 46. Diagram of MO energy levels in the $[UO_2O_4]^{6-}$ cluster (D_{4h} symmetry) constructed with allowance for calculations and experimental data.[271]
The chemical shifts of the energy levels upon the formation of the cluster from single atoms are not shown. The arrows show the energy differences that can be measured experimentally. The digits on the left are experimental E_b values, eV (the energy scale is not maintained).

experimental value.[81] This contradicts the traditional view that, before being involved in chemical bonding, the U5f electrons are excited to the U6d shell. Thus, the results of the relativistic calculation reflect rather reliably the partial electron density of the U5f states (see Fig. 45). This means that about two U5f electrons participate directly in the chemical bond, while the vacant U5f states are located in an energy range of 6 eV near the absorption edge.[123] This is in qualitative agreement with the X-ray $O_{4,5}$(U) emission spectroscopy [185] and X-ray near-edge $O_{4,5}$(U) absorption spectroscopy data for uranium trioxide.[189, 270]

In the IVMO binding energy range, the best agreement has been obtained for the $17\gamma_6^-$, $15\gamma_6^-$ and $14\gamma_6^-$ orbitals characterising the width of the spectrum of these electrons. Since the theoretical and experimental total relative intensities are comparable, the calculated energies of the $11\gamma_7^-$ – $10\gamma_7^-$ IVMO (see Fig. 45) may differ appreciably from the corresponding experimental values.

Using the data of relativistic calculations for the $[UO_2O_4]^{6-}$ cluster (D_{4h} group of symmetry) and experimental binding energy differences between the core and outer electron levels of uranium [57] and for uranium trioxide (see, for example, the studies [55, 109]), an MO diagram has been constructed in the MO LCAO approximation (Fig. 46).[123] This diagram provides understanding of the real XPS structure of uranium trioxide. In this approximation, one can distinguish conventionally the $17\gamma_6^-$ (4), $15\gamma_6^-$ (9) and $14\gamma_6^-$ (10) IVMO, which characterise the U – O bond length in the UO_2^{2+}; the $11\gamma_7^-$ (5) and $10\gamma_7^-$ (8) IVMO which characterise the U – L bond and its length in the equatorial plane of the cluster and the quasiatomic $16\gamma_6^-$ (6), $16\gamma_6^+$ (7), $11\gamma_7^+$ (7) and $15\gamma_6^+$ (7) orbitals formed from the O(L)2s AO of two types of oxygen atoms (O and L). Note that this separation of the IVMO has been experimentally substantiated.[55, 109] It follows from the experimental data that the energies of the quasi-atomic $16\gamma_6^-$ (6) – $15\gamma_6^+$ (7) IVMO should be similar to each other. Indeed, it follows from the parameters of the XPS spectrum of γ-UO_3 in the O1s binding energy range that the difference between the E_b values for these orbitals should not exceed 0.9 eV, as this line is asymmetric and its FWHM (Γ) equals 2.2 eV. The binding energy should be approximately 23.4 eV, because $\Delta E_{L,O}$ = 508 eV and the O1s binding energy for γ-UO_3 is 531.4 eV (see Fig. 46). In view of the fact that ΔE_U = 360.6 eV and ΔE_1 = 363.0 eV, one can find Δ_2 = 2.4 eV and Δ_1 = 3.7 eV.[55] Since the binding energy difference between the $14\gamma_6^-$ (10) and $17\gamma_6^-$ (4) IVMO equals 15.2 eV and the U6p spin – orbit splitting in the atom is given by ΔE_{sl}(U6p) = 10.0 eV,[57] it is possible to estimate the perturbation Δ_3 = 2.6 eV (*i.e.*, it is comparable with the value Δ_2 = 2.4 eV). These data led to the conclusion [123] that the contribution of U6p to the $11\gamma_7^-$ (5) and

$14\gamma_6^-$ (10) IVMO should be markedly higher, while that to the $10\gamma_7^-$(8) IVMO should be much lower than its contribution to the$17\gamma_6^-$ (4) IVMO. As expected, the width of lines corresponding to quasi-atomic orbitals, $16\gamma_6^-$ (6) – $15\gamma_6^+$ (7) is smaller than the corresponding values for other IVMO. The observed relative reduction of the $17\gamma_6^-$ (4) IVMO line width can be attributed to the partial loss of the antibonding nature of this MO resulting from a significant admixture of O2p AO (21%).[53]

It is noteworthy that a stricter comparison of the theoretical and experimental electron binding energies requires resorting to values calculated [272] for the transition state.

For qualitative and quantitative comparative analysis of the experimental and theoretical intensities of spectral lines, the spectra were decomposed into components with allowance for the data given in Fig. 46. The electron binding energies were derived from experiments, while the theoretical intensities were calculated. The results of identification of the XPS spectral structure are shown in Fig. 45. However, experimental IVMO intensities often differ significantly from the corresponding theoretical values. The closest agreement is observed for the electrons of the $17\gamma_6^-$ (4), $16\gamma_6^-$ (6) and $14\gamma_6^-$ (10) IVMO. It has been found[123] that $\sim$1.3 U6p electrons (mainly, the U6p$_{3/2}$ electrons) are involved in the formation of the OVMO. This is comparable with the theoretical value, equal to 1.0 e. Similar agreement is observed in some cases for the IVMO energy range. For example, the antibonding $17\gamma_6^-$ (4) IVMO contains 0.8 U6p$_{3/2}$ electrons, which does not differ much from the calculated value equal to 0.98 e. Similar agreement is observed for the bonding $14\gamma_6^-$ (10) IVMO. For the antibonding $11\gamma_7^-$ (5) and the corresponding bonding $10\gamma_7^-$ (8) IVMO, the calculated overlap of the U6p and O2s AO is approximately twice as great as the experimental value.

Since the pattern of variation of line intensities in the XPS spectra upon the change in the MO energy levels is known from quantum mechanics, it is possible to discuss whether the experimental and theoretical results agree with each other. As has been shown previously,[53, 55] the greater the participation (bonding or antibonding) of AO in the MO formation, the wider the MO lines. The sharpest lines are those corresponding to non-bonding or quasi-atomic MO. Therefore, the relatively small width of the $17\gamma_6^-$ (4) IVMO line can be attributed, as noted above, to the substantial content of the O2p AO in this MO, which also results in a significant decrease in its intensity and the loss of the antibonding nature (see Fig. 46). The observed discrepancy in the intensities of the $11\gamma_7^-$ (5) IVMO lines confirms the assumption that the degree of participation of the U6p AO in this MO is about twice as high as that in the $17\gamma_6^-$ (4) IVMO. The degree of participation of the U6p state in the corresponding bonding $10\gamma_7^-$ (8) IVMO is approximately the same. Unfortunately, it is difficult to determine reliably the line width corresponding to the $10\gamma_7^-$ (8) IVMO electrons.

The energy region of the $16\gamma_6^-$ (6) – $10\gamma_7^-$ (8) IVMO is most ambiguous for interpretation. As can be seen, the structure of this spectral range is mainly due to the O(L)2s electrons, which agrees with the results of calculations. However, the overlap of the uranium U6p AO with the oxygen L2s MO, which occurs in the equatorial plane upon the formation of the $11\gamma_7^-$ (5) and $10\gamma_7^-$ (8) IVMO, was apparently overestimated in the calculations; this resulted in a wrong order of the $16\gamma_6^-$ (6) – $10\gamma_7^-$ (8) IVMO. This may be due to the fact that the distances between the uranium and oxygen atoms in the equatorial plane used in the calculation of the $[UO_2O_4]^{6-}$ cluster were understated compared to the real values. In view of the foregoing, this spectral range has been decomposed.[123] The correct order of the IVMO is especially important for elucidation of their contribution to the covalent component of the chemical bond in uranium trioxide. The peak (11) observed in the spectrum (see Fig. 45) is apparently due to the shake up process which accompanies the emission of electrons from the sample. The expected theoretical spectrum is shown in Fig. 45 *b* by vertical segments.

In conclusion, we would like to note that, despite a number of approximations used in the calculation of the electronic structure of the $[UO_2O_4]^{6-}$ cluster, which models the nearest environment of uranium in γ-UO_3, the results obtained agree qualitatively with experimental data. This allowed the first reliable identification of a series of lines, at least, the upper and lower IVMO lines. These data can be used, in particular, to determine the structures and bond lengths in uranyl compounds [55, 109] and to interpret the structures of other X-ray spectra of uranium compounds. Since the electronic structures of actinide compounds are fairly similar, the results can be used for qualitative discussions of the electronic structures of compounds of not only uranium but also other actinides.

4. Parameters of the fine spectral structure of core electrons

Analysis of the fine XPS structure of the core electron shells of actinide compounds ($\sim$40 – 1250 eV) has shown that there exist general regularities of the formation of such structure and that its parameters depend on the physicochemical properties of compounds. For some actinide compounds, the fine structure parameters are characteristic and can be used for identification. For example, within the error of measurement, the spin – orbit splitting (ΔE_{sl}) of lines corresponding to the core electron levels of actinides does not change on passing from one compound to another. The observed apparent differences between the ΔE_{sl} values for actinides contained in various compounds are related, most often, to multiplet splitting and dynamic effect.

It was found that shake up satellites arise in the spectra of all electronic levels accessible for measurements, their intensity decreasing with a decrease in the electron binding energy. The parameters of these satellites were found to be correlated with the actinide oxidation state and the ionic – covalent nature of the bond.

For all actinide compounds studied, the structure of the An4f spectra is very sensitive to changes in the stoichiometric composition, the structure parameters being correlated with the oxidation state of the central actinide ion. Thus, the distance (along the energy scale) from the basic lines of the An4f doublet to the satellites related to many-body perturbation (ΔE_{Sat}) for An^{6+} lies in the range of 3 – 4 eV, while that for An^{4+} is 7 eV.

The An5d spectra of actinide compounds containing unpaired An5f electrons exhibit multiplet splitting, resulting in a substantial broadening of the An5d$_{3/2}$ line relative to the An5d$_{5/2}$ component of the doublet.

The XPS fine structure caused by the dynamic effect is most clear-cut for electrons whose binding energies are in a certain ratio to the binding energies of electrons less involved in the bonding, so that the energy conservation law and the selection rules hold. In particular, the dynamic effect results in substantial spreading of the An5s and An6s spectral lines; as a consequence, the An6s spectral structure covers a range of $\sim$40 eV. The intensity of the high binding energy component related to the An5p$_{1/2}$ electrons is strongly suppressed, and the An5p$_{3/2}$ component exhibits a complex fine structure. In all cases, fine structure is present in the An4p$_{3/2}$ spectra. It was shown experimentally that the structure in the XPS spectra of actinide compounds in the An4p, An5s, An5p and An6s binding energy range is mainly due to interaction of final state configurations of the type $An4p^54d^{10}(4f^{14})5s^2(5p^65d^{10}6s^26p^6)\ 5f^np^m \rightleftharpoons An4p^64d^9(4f^{14})5s^1.(5p^65d^{10}6s^26p^6)5f^np^{m+1}$; $An5s^15p^65d^{10}(6s^26p^6)5f^n \rightleftharpoons An5s^25p^5.5d^9(6s^26p^6)5f^{n+1}$; $An5p^55d^{10}(6s^26p^6)5f^n \rightleftharpoons An5p^65d^8(6s^26p^6).5f^{n+1}$; and $An6s^16p^65f^n \rightleftharpoons An6s^26p^45f^n6d^1$, respectively.

X-Ray photoelectron studies of the properties of actinide compounds and the nature of the chemical bond in them have provided a number of interesting results. It should also be noted that in recent years, X-ray photoelectron spectroscopy has been used more and more extensively for ecological studies to determine the physical and chemical state of radionuclides in the environment (see, for example, a series of studies [262, 273 – 276]).

VII. Conclusion

Thus, we have shown that knowledge of the parameters of fine XPS structure, together with the traditional information (line intensities and chemical shifts) significantly extends the potential of the XPS method for diverse studies in solid state physics and theoretical and physical chemistry, in particular, studies of the electronic structure and properties of actinide compounds and the nature of the chemical bond in them. The mechanisms of formation of this fine structure have been analysed using compounds with well-known properties. The understanding of the nature of the fine structure provides new information on the physicochemical properties of actinide compounds and the ions they contain. The three questions stated in the Introduction can be answered in the following way.

1. The XPS spectra of compounds of light actinides (Th, U, Np, Pu, Am, Cm, Bk, Cf) exhibit a complex fine structure for almost all electron shells in the energy range of 0 – 1250 eV. This structure may be due to many reasons, in particular, the formation of inner and outer valence molecular orbitals; multiplet splitting; spin – orbit splitting; splitting due to the induced charge; dynamic effect; many-body perturbation; overlap with the Auger spectral lines; the presence of actinide ions in different oxidation states and so on. General regularities of the formation of the fine spectral structure can be followed for particular electron shells.

2. It was found experimentally that particular mechanisms of fine structure formation are manifested in the spectra of different electron shells with different probabilities. This made it possible to establish qualitative and quantitative correlations of structure parameters with the physical and chemical properties of actinide compounds. For example, the line intensity around a zero binding energy is proportional to the number of An5f electrons not involved in the chemical bond. The structure of the low binding energy spectral range (0 – 50 eV) reflects the degree of participation of the An6p and An5f shells in the formation of outer and inner valence molecular orbitals, the nature and the sequence of these orbitals and the structure of the local environment of the actinide ion. The multiplet splitting of the core levels characterises the number of unpaired electrons in the compound. The spectral structures caused by the dynamic effect and many-body perturbation reflect the secondary many-body processes that accompany electron photoemission and the configuration of the final states of the electronic system.

3. The fine structure parameters of the spectra of actinide compounds can be used to determine the degree of delocalisation of the An5f electrons; the degree of their participation in the chemical bond; the electron configuration and oxidation state of the metal atom in these compounds; the density of unpaired electrons on paramagnetic ions; the degree of participation of the low-energy occupied An6p and L*n*s shells of neighbouring actinide atoms and ligand atoms in the formation of outer and inner valence molecular orbitals; the structure and the nature of these orbitals; and the structure of the local environment, in particular, uranium ions in amorphous substances. These data cannot be obtained directly by other methods.

Despite the substantial advances in the understanding of the electronic and crystal structures of actinide compounds and extension and deepening of the knowledge on the nature of the chemical bond in them, some points still remain obscure. For example, the structures of the IVMO spectra for compounds of most actinides still cannot be completely interpreted, due to the lack of results of proper relativistic calculations. The role of the IVMO electrons in the formation of the chemical bonds in compounds has not been ultimately clarified, because procedures for experimental and theoretical estimation of the contributions of particular orbitals to the binding energy have not been adequately developed.

The greatest success in solving the problems mentioned above can be attained by performing X-ray photoelectron spectral studies for diatomic gaseous molecules such as thorium and uranium monoxides using synchrotron radiation for excitation. In this case, relativistic calculations of the electronic structures can be done most easily as, for example, for the UF_6 molecule. No ultimate opinion on the role of IVMO in the formation and structures of actinide compounds has been formed as yet. However, there already exist a number of examples that imply that the concept of efficient IVMO formation allows one to interpret some experimental results, for example, the formation of the complex fine structure in the XPS spectra of actinide compounds in the $\sim 15-50$ eV binding energy range; the relationship between fine XPS structure characteristics in this region and the structure of the nearest environment and distances from the metal atoms to the closest ligand atoms in the compounds; the appearance of peaks and fine structure in the binding energy range of $\sim 15-50$ eV in the emission spectra of thorium oxide and fluoride and uranium oxides, Auger spectra of uranium oxide and conversion spectra of uranium oxides and fluorides. The formation of IVMO might also be a reason for the appearance of stable actinyl groups AnO_2^{n+}. In conclusion, it should be noted that the experimental and theoretical studies of the electronic structure of compounds and solids and the nature of the chemical bond carried out in recent years deal, most often, with the binding energy range of 0 – 50 eV rather than 0 – 15 eV studied traditionally. This is a recent and important achievement in chemistry, biology and solid-state physics.

IV.	Use of 1,3,2-oxazaborolidines in miscellaneous reactions	596
V.	Reduction by immobilised 1,3,2-oxazaborolidines	601
VI.	1,3,2-Oxazaborolidine analogues	603

Abstract. The use of chiral 1,3,2-oxazaborolidines in asymmetric organic synthesis, particularly, in enantioselective reduction of ketones, imines and oxime ethers, asymmetric Diels – Alder reactions, aldol condensation and atroposelective reduction of lactones is reviewed. Reactions of immobilised 1,3,2-oxazaborolidines are also considered. The bibliography includes 266 references.

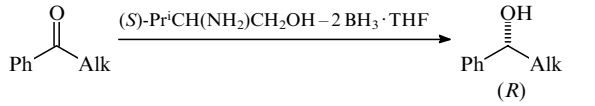
I. Introduction

Enantioselective reduction of ketones, imines and oximes by boranes in the presence of chiral catalysts, *viz*., 1,3,2-oxazaborolidines, is one of the most convenient methods for the preparation of enantiomerically enriched secondary alcohols and amines. This rapidly developing research area has been the subject of numerous reviews;[1–7] however, early papers [1–4] encompass the literature published before 1993, and the review of 1998 [5] and some selected chapters in monographs [6,7] are devoted exclusively to enantioselective reduction of ketones using Corey – Bakshi – Shibata catalysts (CBS catalysts).

A great number of papers concerned with this problem have been published recently. Some papers report on the possible use of chiral 1,3,2-oxazaborolidines as Lewis acids, which significantly expands the area of application of these derivatives in synthetic organic chemistry. We undertook an attempt to systematise the results of investigations carried out in this field in the past decade (references to earlier publications having fundamental significance are also given).

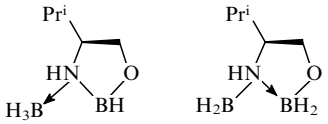
II. 1,3,2-Oxazaborolidines as catalysts of enantioselective reduction of ketones

This trend in asymmetric synthesis dates back to 1981 when Itsuno [6–10] reported the reduction of prochiral ketones by an (*S*)-valinol – $BH_3 \cdot THF$ mixture (1 : 2) to optically active secondary alcohols in up to 100% yields and with enantiomeric excess (*ee*) up to 73%.[8]



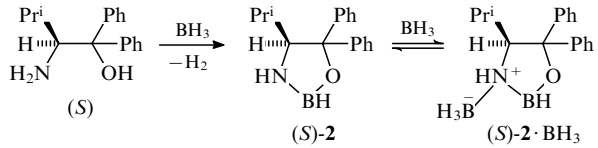
Alk = Me, Et, Pr, Bu. (*ee* 49% – 73%)

According to Itsuno, this reaction is catalysed by 1,3,2-oxazaborolidine (**1**) (form **A** or **B**).



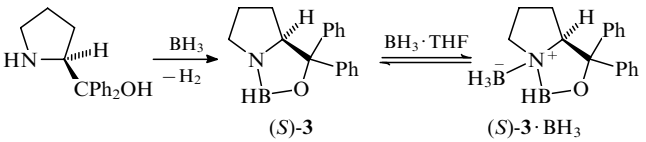
1A **1B**

Later, Corey showed [11] that hydrogen (2 equiv.) is released in the reaction of (*S*)-diphenylvalinol with 2 equiv. of borane in THF at 35 °C. On removal of residual amounts of borane and the solvent in vacuum and twofold distillation of the residue (105 – 130 °C, 0.05 Torr), a colourless crystalline compound with a molecular mass of 265.16365 (265.16379, according to the mass spectrometric data) was obtained. This compound was formulated as **2** · BH_3.



According to X-ray diffraction analysis data of this compound, this exists in the form **A**.

The same group of investigators have succeeded in obtaining 1,3,2-oxazaborolidine **3** · BH_3 and its *B*-methyl derivative.[12]



It was shown that (*S*)-perhydro-3,3-diphenylpyrrolo-[1,2-*c*][1,3,2]oxazaborolidine-borane [(*S*)-**3** · BH_3] and its

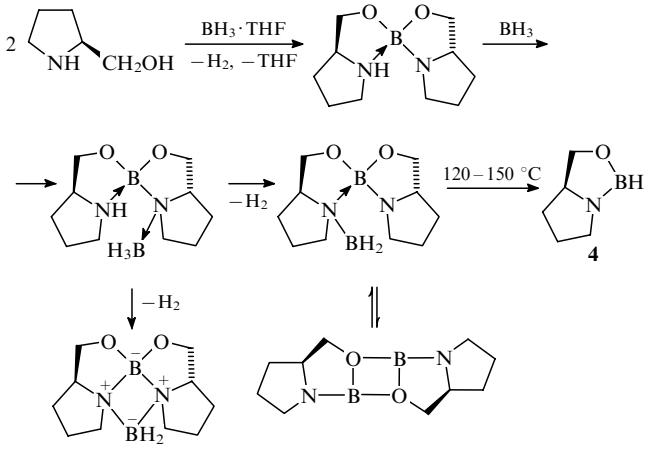
Received 27 February 2003
Uspekhi Khimii **73** (6) 632 – 661 (2004); translated by R L Birnova

B-methyl derivative catalyse enantioselective reduction of ketones even more efficiently than (*S*)-4-isopropyl-5,5-diphenyl-1,3,2-oxazaborolidine-borane [(*S*)-**2**·BH_3] and reduce acetophenone to (*R*)-1-phenylethanol in more than 99% yield and *ee* 97%.[12,13] The structure of the *B*-methyl derivative was studied by X-ray diffraction analysis.[14]

In the general case, synthesis of 1,3,2-oxazaborolidines containing a B–H bond is accompanied by the formation of various dimers (Scheme 1); this was confirmed by ^{11}B NMR spectroscopy (see Refs 15–17) and X-ray diffraction analysis.[16]

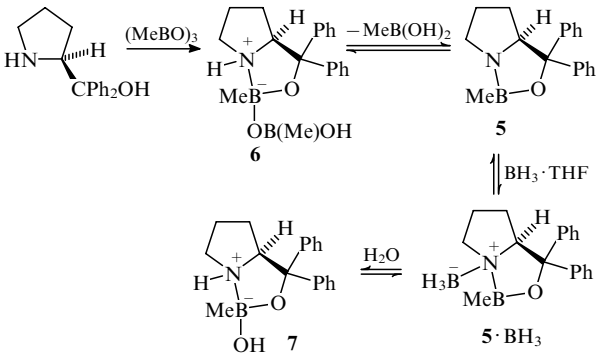
Scheme 1



Whereas the ^{11}B NMR spectrum of compound **2** (THF, 23 °C)[11] contains a broad signal at δ 28.1 (relative to $Et_2O \cdot BF_3$, external standard), the ^{11}B NMR spectrum of compound **3** (0.17 M solution in THF, 23 °C) contains signals at δ 28.3 and 7.6, which were assigned to the monomer and the dimer, respectively. The dimers are converted into monomers (*e.g.*, **4**) upon heating; therefore, the procedure used for the synthesis of substituted 1,3,2-oxazaborolidine plays a crucial role in the catalytic reduction of carbonyl compounds (for temperature regime and the solvent see below).

Methyl-substituted 1,3,2-oxazaborolidine **5** was prepared using two approaches, *viz*., starting from methylboronic acid[13] and from trimethylboroxine.[18] The presence of additional signals in the ^{11}B NMR spectra in 1,3,2-oxazaborolidine (*S*)-**5** prepared from (*S*)-diphenylprolinol and trimethylboroxin is explained by the formation of side products of the type **6** and **7** (Scheme 2).[18]

Scheme 2

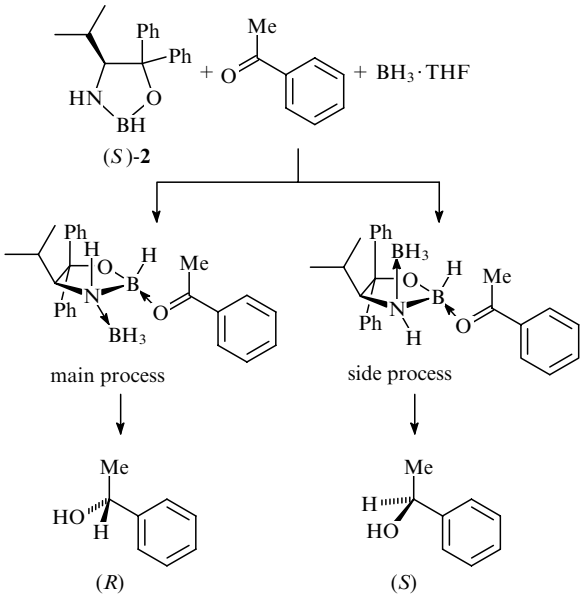


In contrast to compounds **2** and **3**, compound **5** is more resistant to the action of atmospheric oxygen,[13] but undergoes hydrolysis in the presence of moisture. It is of note that all 1,3,2-oxazaborolidines undergo hydrolysis, therefore, all manipulations with these compounds demand thorough dehydration of the solvents.

1. The reduction mechanism

The mechanism of reduction of acetophenone by the complex (*S*)-**2**·BH_3 is shown in Scheme 3.

Scheme 3



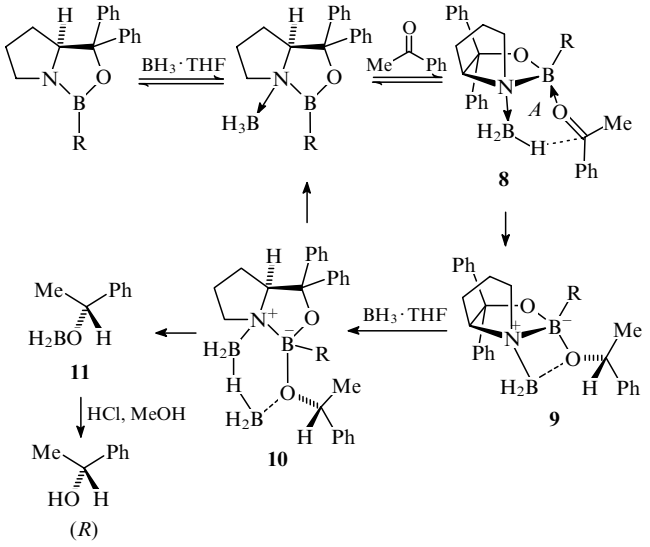
Of fundamental importance is the fact that 1,3,2-oxazaborolidine **2** itself does not reduce ketones and becomes active only after addition of the second equivalent of borane.[11] During the formation of a catalytic complex, borane coordinates the nitrogen atom of 1,3,2-oxazaborolidine in such a way that it itself comes to occupy the *trans*-position relative to the isopropyl group; the *cis*-position of borane results in a steric strain in the complex. Subsequent coordination of acetophenone and the hydride ion transfer also proceed in a stereospecific manner to afford (*R*)-1-phenylethanol with high *ee* (up to 99%). The stereospecificity of the CBS catalyst is comparable to that of enzymes; therefore, Corey termed it 'chemzyme' (a chemical catalytic system similar to an enzyme).[19] If a catalyst based on an (*R*)-amino acid is used, the reduction of a ketone results in an (*S*)-alcohol. The possibility of control over stereoselectivity is an attractive feature of reductions based on the use of the CBS catalysts.

A mechanistic model of the reaction of an active catalytic complex with a substrate has been developed in order to explain high stereospecificity of ketone reduction.[5–7] Let us consider the mechanism of ketone reduction in which (*S*)-diphenylprolinol is used as a catalyst in more detail (Scheme 4).

This model implies a multistep reduction mechanism of acetophenone. In the first step, a catalytically active complex of 1,3,2-oxazaborolidine with BH_3 is formed. The coordination of the nitrogen atom by borane strongly increases the Lewis acidity of the boron atom of the heterocycle[5] as a result of which it acquires the ability to coordinate the carbonyl group of acetophenone. This is followed by the hydride ion transfer from the boron atom of borane to the carbon atom of the carbonyl group (direct reduction).

It was suggested that coordination of a ketone affords a transition state (complex **8**) with a six-membered quasi-heterocycle *A* where the bulkier ketone substituent (the phenyl radical) occupies an equatorial position. In other words, the boron atom of the 1,3,2-oxazaborolidine ring coordinates the electron pair of the oxygen atom of the ketone occupying the *anti*-position relative to the phenyl group, which ensures high enantioselectivity of the reduction similar to that in enzyme systems.[5] This hypothesis was also confirmed by the results of quantum-chemical calculations.[20–25]

Scheme 4



R = H, Me.

The last step includes the decomposition of the complex **9** (presumably, *via* the intermediate complex **10**) resulting in the original catalytically active complex and the ester **11**. The latter is converted into the final product, *viz*., (*R*)-1-phenylethanol.

The conformation of the transition state was also considered. According to semi-empirical MNDO calculations, the transition state **8** where the heterocycle *A* acquires a chair conformation possesses much lower energy than in the case of a boat conformation.[20] A detailed analysis of *ab initio* quantum-chemical calculations of various conformations of all the transient species **8**–**11** in the basis sets 3-12G, 4-13G, 6-31G, 4-31G* and 6-31G* has been carried out.[23–27] The transition state **8** has two stable conformations, *viz*., *twist-boat* and *twist-chair*.[24]

According to quantum-chemical calculations,[21] the potential energy of the formation of the transition state **8** (coordination of the ketone) was similar to that of the transition state **9** (the hydride ion transfer), and the kinetic isotope effect k_H/k_D = 1.8 (23 °C) calculated for the reduction of acetone by the complex (*S*)-**5**·BH_3 virtually coincided with the experimental value k_H/k_D = 1.7 for the reduction of acetophenone.[28] It was therefore supposed that the hydride ion transfer is the rate-determining step.[28] The kinetics of reduction of *para*-substituted acetophenones was studied in order to establish the limiting step of the overall catalytic process. The rate ratios for the reduction of *p*-nitro- and *p*-methoxy acetophenones to that of non-substituted acetophenone were 3.4 and 1.8, respectively.[28] This suggests that the hydride ion transfer step, like the ketone complex formation with the catalyst, controls the rate of the overall process.[5]

The formation of the transient species of the types **8, 9** and **10** was also confirmed by ^{11}B NMR spectroscopy.[29]

2. Structural types of 1,3,2-oxazaborolidines

Further perfection of structures of catalysts of enantioselective reduction of ketones (CBS catalysts) followed several routes. These involved modification of the rigid skeleton of a chiral amino alcohol and selection of substituents in the alcoholic group of the starting amino alcohol † and at the boron atom of the borane. Thus Bu-substituted 1,3,2-oxazaborolidine (**12**) was synthesised along with the Me-substituted catalyst **5**.[30]

The dependence of enantioselectivity of the reduction using CBS catalysts on the nature of the substituent at the HO-bearing carbon atom of the amino alcohol has been reviewed.[5–7] Bulky substituents provide stereochemical control over the reaction, but hinder the complexation of the ketone with 1,3,2-oxazaborolidine. Besides, they decrease the optical yields due to competitive non-catalytic reduction. In some cases, bulky substituents 'reverse' the selectivity so that *S*-enantiomers are formed instead of *R*-enantiomers.

The dependence of enantioselectivity on the nature of the substituent R at the boron atom has been studied. It should be noted that in terms of the mechanistic model of the transition state **8** (see Scheme 4) the steric strain between the substituent R at the boron atom and the substituents at the carbonyl group of the ketone is critical for the discrimination between different types of ketone coordination. Thus the presence of bulky aromatic substituents at the boron atom favours their steric interactions with more remote fragments of a coordinated ketone molecule,[5] as a result of which the enantioselectivity of reduction increases considerably. Thus, in each concrete case the choice of an optimum substituent R at the borane B atom should depend on the nature of the substrate (ketone). However, it is 1,3,2-oxazaborolidines carrying H-, Me- and Bu-substituents at the boron atom that are commonly used as catalysts because of the ease of their preparation.

A representative set of CBS catalysts based on various chiral amino alcohols is listed in Table 1. Natural amino acids or their analogues served as starting compounds in the synthesis of many of these catalysts.[27,35–38] The results presented in Table 1 were obtained for catalytic variants of the reaction, *viz*., the reduction of a ketone by 0.6–1.0 equiv. of $BH_3 \cdot THF$ or $BH_3 \cdot Me_2S$ in the presence of 0.05–0.10 equiv. of a catalyst (1,3,2-oxazaborolidine), although in some cases the catalyst, the reducing agent and the substrate were used in equal amounts in order to ensure higher enantioselectivity. The amount of the reducing agent (borane) is usually 0.6–0.7 equiv. per carbonyl group of the ketone, since 2 equiv. of the hydride ion are transferred.[5–7] The chemical yields of secondary alcohols are usually > 90%.

The majority of papers devoted to enantioselective reduction of ketones describe the reduction of acetophenone. As can be seen from Table 1, 1,3,2-oxazaborolidines **26** and **30** based on prolinol derivatives are the best catalysts for the acetophenone reduction.

The use of catalysts based on phenylalanine in the enantioselective hydrogenation of acetophenone also gives good results, the catalyst based on *o*-chlorophenylalanine **15** manifesting somewhat higher enantioselectivity in comparison with its unsubstituted analogue **14**. Presumably,[36] this is due to the formation of an additional coordination bond between the boron and chlorine atoms.

1,3,2-Oxazaborolidines **13** and **51** based on two diastereomers of 2-amino-1,2-diphenylethanol effectively catalyse the reduction of many carbonyl compounds (see, *e.g*., Refs 34 and 71), whereas the catalyst **48** based on 2-amino-1,1,2-triphenylethanol (R = Me) was found to be suitable for the reduction of alkyl methyl ketones[66] (*ee* of the product is 70%).

The catalysts based on diastereomeric 1-aminoindan-2-ols (compounds **27** and **39**)[47–49,59,61,71] and 1-amino-2-hydroxy-1,2,3,4-tetrahydronaphthalene **41**,[60] as well as on spiro derivatives (**28**–**31**, **55**) also appeared to be highly efficient.[50,51,68,69]

As can be seen from Table 1, the use of the catalyst **49** based on norephedrine for the reduction of tetralone gives good results,[27,67] while its analogue **50** prepared from pseudo-ephedrine is ineffective.[27] The catalyst **46** containing a 1-naphthyl group is less active in the reduction of butyrophenone than the catalyst **47** containing a 2-naphthyl group.[65] It was noted that the stereoselectivity of the reaction increases upon introduction of the 2-naphthyl group into the carbon atom of the C–O fragment of 1,3,2-oxazaborolidine.[19] The catalysts **18** and **38** with aziridine[39] and azetidine[58] rings, respectively, manifested higher activities than the catalyst **19** with the pyridine ring.[40] The enantioselectivity of the reduction in the case of the catalyst **23** is lower than that

† The starting (*S*)- and (*R*)-diphenylprolinols commonly used in the synthesis of 1,3,2-oxazaborolidines can be prepared by different methods (see, *e.g*., Refs 13, 31–33).

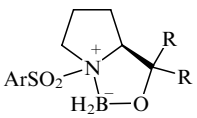
[a] The amount of the catalyst and the reducing agent is expressed in equiv. (equiv. of ketone)$^{-1}$; [b] The reaction is carried out in toluene; [c] The reaction is carried out in the presence of 0.2 equiv. of diethylaniline; [d] A mixture of (1*R*,2*R*,4*R*) and (1*R*,2*S*,4*R*) isomers (6 : 94) was obtained; [e] For other reactions with this catalyst, see Refs 72 and 73; [f] A mixture of *dl*- and *meso*-isomers with predominance of the *dl*-isomer (*dl* : *meso* > 99 : 1) was obtained.

with its diphenyl-substituted (**20**) and fully hydrogenated (**24**) analogues.

A search for cheap and renewable sources of raw materials for the commercial production of CBS catalysts has stimulated the synthesis of 1,3,2-oxazaborolidines **33**, **45** and **54** from chiral amino alcohols of the terpene series which gave encouraging results (*ee* 80%–93%).[27, 53, 54] An attempt to increase *ee* by replacing 1,3,2-oxazaborolidines by their chromotricarbonyl complexes [56] was unsuccessful (*cf*. *ee* obtained in the presence of the catalysts **35, 20** and **23**).

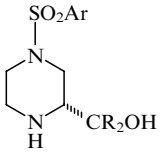
Considerable recent interest in sulfonylated 1,3,2-oxazaborolidines is explained by their higher stabilities and ease of purification and regeneration in comparison with the classical CBS catalysts. It is believed that these catalysts form more stable complexes owing to additional coordination of the hetero atom to the boron atom within the catalytic complex.[57] For example, *N*-arylsulfonylated (*S*)-diphenylprolinol is a good catalyst for the reduction of bromoacetophenone. When the reaction is carried out in boiling toluene, the yield of (*R*)-2-bromo-1-phenylethanol is 96% (*ee* is 91%).[74] This suggests that the amino alcohol reacts as the complex (**57**).



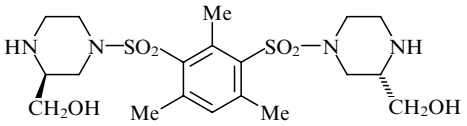
57

R = H: Ar = *p*-MeC_6H_4, 1-naphthyl, 2-naphthyl, 2,4,6-$Pr^i_3C_6H_2$;
R = Ph: Ar = *p*-MeC_6H_4.

It is believed that in the case of enantiomerically pure 2-hydroxymethylpiperazines (**58** and **59**) as catalysts, the formation of dimeric 1,3,2-oxazaborolidines takes place.[75]



58



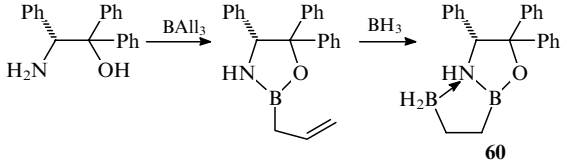
59

R = H, Ph; Ar = *p*-MeC_6H_4, 1-naphthyl, 2-naphthyl, 2,4,6-$Pr^i_3C_6H_2$.

1,3,2-Oxazaborolidine prepared from compound **59** catalyses the reduction of acetophenone to (*S*)-2-phenylethanol with *ee* 71%.

Dimeric 1,3,2-oxazaborolidines are presumably also formed in the reduction by (1*R*,4*R*,2*S*,3*S*)-1,4-diamino-1,4-dibenzylbutane-2,3-diol and BH_3.[76]

The formation of the original chelate 1,3,2-oxazaborolidine **60** has been reported:[66]



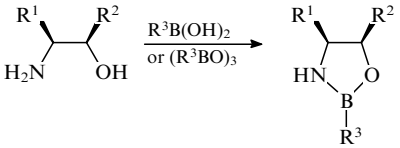
60

The reduction of acetophenone by borane in the presence of binary mixtures of homochiral amino alcohols (1*S*,2*R*)-1-amino-2-indanol, (*S*)-prolinol and (*S*)-phenylglycinol has been studied.[77]

On the whole, the analysis of literature data suggests that the relatively accessible catalysts for ketone reduction, 1,3,2-oxazaborolidines **3** and **5** based on (*S*)-diphenylprolinol recommended by Corey are the most efficient.[5, 11–13] The use of other boron-substituted (*S*)-diphenylprolinol-based 1,3,2-oxazaborolidine derivatives in the reduction of ketones has recently been reported. All these catalysts manifest high enantioselectivity in the reduction of various carbonyl compounds and are successfully used in asymmetric Diels–Alder reactions, aldol condensation, enantioselective cleavage of acetals, *etc*. (see below).

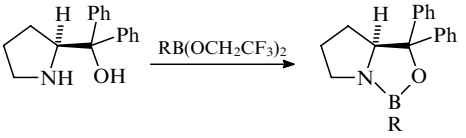
3. Effects of the catalyst preparation procedure, temperature, solvent and reducing agent on the enantioselectivity of the ketone reduction

The purity of a catalyst was shown [5, 7, 18, 33, 76] to be of crucial importance for obtaining high *ee* in the enantioselective catalytic reduction of carbonyl compounds. The presence of admixtures of starting amino alcohols and boronic acids decreases *ee*. Some CBS catalysts are available from Aldrich and Lancaster, but the catalysts do not always meet necessary requirements.[18, 78] Their application in laboratory practice gives irreproducible results due to high content of admixtures and poor storage stability.[78] Therefore, the preparation of a catalyst is a key step in the reduction. 1,3,2-Oxazaborolidines can be prepared using various approaches, *e.g.,* (a) by reactions of amino alcohols with 3 equiv. of $BH_3 \cdot THF$ or $BH_3 \cdot Me_2S$ in an argon atmosphere in boiling THF or toluene with a subsequent removal of the solvent *in vacuo* (the product formed is used without additional purification [7–10] or is purified by sublimation [11–13]); (b) boiling of an amino alcohol with the corresponding alkylboronic acid $RB(OH)_2$ in toluene with azeotropic distillation of water formed;[30] (c) boiling of an amino alcohol with boroxine $(RBO)_3$ [18, 27, 30] in toluene in the presence of molecular sieves 3–5 Å with azeotropic distillation of water formed.



R^1, R^2 = Alk, Ar; R^3 = Me, Bu, Ar.

In many cases, the catalyst is prepared *in situ* by mixing an amino alcohol with $Me_2S \cdot BH_3$ or $BH_3 \cdot THF$ at room temperature, which is especially convenient for the synthesis of 1,3,2-oxazaborolidines non-substituted at the boron atom based on non-cyclic amino acid derivatives. An express method for the synthesis of 1,3,2-oxazaborolidines with a substituted boron atom (1 h) has been developed.[79] In this approach, the amino alcohol is mixed with bis(2,2,2-trifluoroethyl) alkylboronate in toluene. Subsequent vacuum evaporation of toluene, trifluoroethanol and the excess of $RB(OCH_2CF_3)_2$ and heating (110 °C, 0.07 Torr) give pure 1,3,2-oxazaborolidine.



R = Alk, Ar. (*S*)

As mentioned above, special care should be taken over the removal of traces of moisture from the catalyst, reagents and solvents, since water decomposes the 1,3,2-oxazaborolidine ring.[33] It was found [61] that the addition of 2.5 mg of H_2O per g of bromoacetophenone decreases *ee* of the (*R*)-1-phenyl-2-bromoethanol formed from 96% to 85%, while the addition of 10 mg of H_2O per g of the substrate decreases it to 50%. The content of H_2O in the reaction mixture should not exceed 40 μg ml^{-1} at the ketone concentration of 70 mg ml^{-1} (see Ref. 78), while the maximum *ee* is reached at the H_2O content not exceeding 20 μg ml^{-1} (see Ref. 18). Contrariwise, the addition of propan-2-ol or any other aliphatic alcohol increases *ee*,[80, 81] which suggests its involvement in the decomposition of the intermediates **9** and **10** (see Scheme 4).

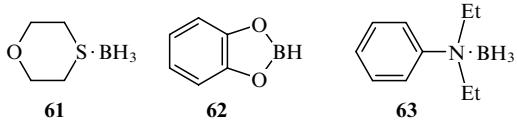
The effect of temperature on the enantioselectivity of the reduction has been considered in several publications.[76, 82, 83] The dependence of *ee* on temperature is usually described by a curve with a maximum at 30–50 °C, which is typical of catalysts prepared *in situ*. At temperatures below −30 °C, 1,3,2-oxazaborolidine is formed at a very slow rate, the reaction mixture contains many catalytically inactive components and non-selective reduction of the carbonyl compound by borane predominates.[5] The low values of *ee* observed at temperatures exceeding the optimum temperature corresponding to the maximum value of *ee* can be explained by thermal decomposition of the catalytic complex. Thus compound **5** is decomposed at 124–126 °C with liberation of B_2H_6.[18]

However, there is still no unambiguous answer to the question of the effect of temperature on the value of *ee*. In some cases, high values of *ee* were obtained when the reaction was carried out in toluene at temperatures below −10 °C with additional amounts of a freshly prepared catalyst $\mathbf{5} \cdot BH_3$ added to the reaction mixture in the course of the reduction.[18, 78] In others, the highest values were reached when the reaction was performed in boiling toluene.[15, 74] This suggests that the optimum temperature should be selected in each concrete case and for each concrete catalyst.

The value of *ee* also depends on the rate of addition of the ketone and the nature of the solvent. The lower the rate of ketone addition the higher the *ee*. In some solvents favouring coordination of borane (*e.g.*, THF) only 10% of the catalyst is involved in the complexation with BH_3. This factor should also be taken into consideration in the optimisation of reduction processes.[18]

As a rule, high enantioselectivity is attained in the presence of as little as 0.05–0.1 equiv. of the $BH_3 \cdot Cat$ complex (Cat is 1,3,2-oxazaborolidine) with respect to the substrate (ketone). However, in some cases the optical yield of the target product depends on the amount of the catalyst used. Thus the value of *ee* for (*R*)-1-phenylethanol in the reduction of acetophenone by the complex $BH_3 \cdot THF$ in the presence of the catalyst **4** increases from 63% and 89% to > 95% as the concentration of the catalyst is increased, correspondingly, from 2 mol.% and 4 mol.% to 10 mol.%.[15]

Other reducing agents, *e.g.*, the borane complex with 1,4-thioxane (**61**),[83] catecholborane (**62**) and the *N,N*-diethylaniline complex with borane (**63**), are used along with $BH_3 \cdot THF$ and $BH_3 \cdot SMe_2$ in the reduction of ketones. Compounds **61**–**63** are less reactive than $BH_3 \cdot THF$ and $BH_3 \cdot SMe_2$, however in some cases they give better results.



61 **62** **63**

Thus the use of catecholborane **62**, which does not require any additional ligands for its stabilisation, allows highly enantioselective reduction of ketones in non-coordinating solvents (*e.g.*, toluene, CH_2Cl_2).[5, 30] This reagent was used in the reduction of trihaloketones,[73, 84] α,β-enones [85] and oxophosphonates [86] as well as in the preparation of (3*S*)-2,3-epoxysqualene [87] and non-natural amino acids.[88] If the reaction is carried out at −78 °C and lower temperatures, the reduction of carbonyl compounds occurs without the involvement of other functional groups (C=C, C≡C) sensitive to hydroboration under ordinary conditions.[5]

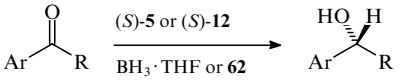
In some cases, enantioselectivity can be increased if tertiary amines are added to the reaction mixture.[38, 52, 70] The catalytic reduction of aromatic ketones by oxazaborolidines prepared *in situ* from amino alcohols and borane complexes with tertiary amines has been studied.[89] Thus the reduction of acetophenone by the complex **63** in the presence of the catalyst **3** has made it possible to increase *ee* of (*R*)-1-phenylethanol to 99% (see Refs 90 and 91).

The *ee* of the product also depends on the presence of admixtures in commercial reducing agents. According to most recent reports,[92] the admixtures of $NaBH_4$ added to the commercial reagent $BH_3 \cdot THF$ for its stabilisation favour non-catalytic reduction and thus decrease *ee* of the reduction product. It is recommended to use the reverse order of addition of reagents to increase *ee*, *e.g.*, to add ketone to the catalyst and the reducing agent.[92] This should also be taken into consideration in those

cases where borane is synthesised *in situ* using the $I_2 - NaBH_4$ (see Ref. 89) or the $Me_3SiCl - NaBH_4$ system.

4. Examples of reduction of carbonyl compounds

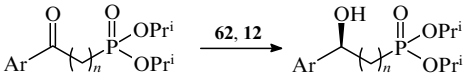
Let us consider some characteristic features of enantioselective reduction of carbonyl compounds (particularly those not listed in Table 1) in more detail. The reduction of aromatic ketones by $BH_3 \cdot THF$ or catecholborane (**62**) in the presence of catalysts [(*S*)-**5** or (*S*)-**12** based on (*S*)-diphenylprolinol] has been studied in especially great detail.



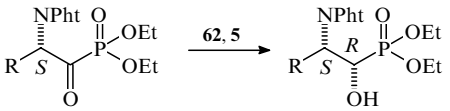
R = CH_2Cl,[82,90] CH_2Br,[90,93,94] CH_2OTHP (THP is tetrahydropyranyl),[95] CH_2N_3 (*ee* 91% – 100%),[96] $(CH_2)_nC(O)R$ (R = Me, Bu^t, Ph; *n* = 0 – 4, both carbonyl groups are reduced simultaneously),[97] CH_2SO_2Ar,[98] $(CH_2)_nP(O)(OPr^i)_2$ (*n* = 1, 2),[86,99] CF_3,[57,84] CCl_3;[28,84,88] Ar = Ph, *m*(*p*)-$R'C_6H_4$ (R′ = Alk, Hal),[100–103] α(β)-$C_{10}H_7$ *etc*.

A large body of experimental evidence has made it possible to formulate a general rule, *viz*., the greater the difference in the size (steric discrimination) between the Ar and R groups the higher the *ee* in enantioselective reduction of ketones.[5–7] The enantioselectivity of reduction of acetophenone, propiophenone and other alkyl aryl ketones by boranes is rather high (*ee* is 94% – 98%, see Table 1).

In the presence of the catalyst **12**, catecholborane reduces α-, β- and γ-oxophosphonates to α-, β- and γ-hydroxy phosphonates (*ee* 51% – 99%) depending on the nature of the substituents in the aromatic nucleus (it is of note that the phosphonate group is considered to be bulkier than the aromatic radical).[86] 1-Oxo-(2*S*)-phthalimidophosphonates are reduced by catecholborane exclusively to (1*R*)-hydroxy-(2*S*)-phthalimidophosphonates (yields 63% – 77%).[99]

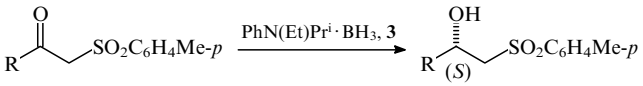


Ar = Ph, XC_6H_4 (X = Hal, Me, OMe); *n* = 0 – 2.



R = $PhCH_2$, Pr^iCH_2, Me, *p*-$BnOC_6H_4CH_2$; Pht is phthalimido.

In contrast to oxophosphonates, the arylsulfonyl group of β-oxosulfones is considered to be less bulky than the aromatic residue; such compounds are usually reduced by borane in the presence of the catalyst **3** to give (*S*)-enantiomers of β-hydroxy sulfones.[98]



(*ee* 97% – 99%)

R = Ar, Alk.

$BH_3 \cdot THF$ (in the presence of the catalyst **5**)[100] and catecholborane **62** [in the presence of the catalyst **3** generated *in situ* from (*S*)-diphenylprolinol and $NaBH_4 - Me_3SiCl$] were used for the reduction of 2-acetylnaphthalene.[101] The *ee* of naphthylethanol formed was 96% – 98%. Efficient reduction of cyclic ketones, such as 1-tetralone (see Table 1), 1-indanone[18] and 1-suberone, also occurs under similar conditions.[18]

If the substrate to be reduced contains a nitro group[104] or other functional groups able to coordinate the boron atom,[105] the reducing agent should be used in larger amounts, an additional equivalent should be added. Chiral alcohols containing a heterocyclic substituent were prepared from 2-acylfurans,[16,106] 3-acetylpyridine[5] and 2-acylthiophenes.[96,106]

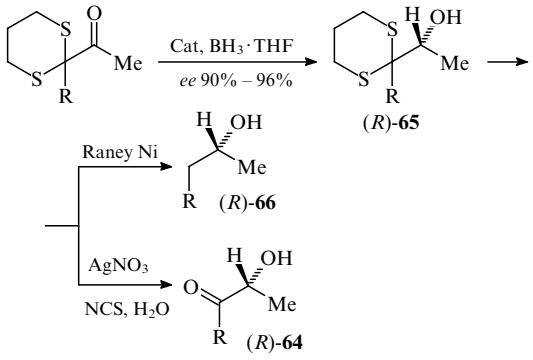
The reduction of substituted benzophenones[104] and 2-benzoylpyridinium triflates[107] yields optically active benzhydrols. It was found that the introduction of substituents into the *ortho*-position of the aromatic nucleus of alkyl aryl ketones (MeCOAr and EtCOAr) decreases the *ee* of the alcohols formed upon their reduction by the system $BH_3 \cdot Me_2S$ in the following order: Ph > *o*-Tol > Mes.[108]

Modest enantioselectivity was achieved in the reduction of aliphatic ketones: high values of *ee* were obtained only for sterically hindered ketones where the spatial difference between two alkyl substituents was high enough. Thus the reduction of isopropyl methyl ketone and *tert*-butyl methyl ketone gave the corresponding alcohols with *ee* 91% and 93% – 97.3%, respectively.[13,66,90] High values of *ee* (99%) were also obtained in the reduction of cyclohexyl methyl ketone by the complex **63**.[90]

It is of note that the reduction product of cyclopropyl isopropyl ketone has a configuration in which the cyclopropyl group plays the role of a bulky substituent (R_L) and the isosteric isopropyl group acts as a minor substituent (R_S).[5] This can be attributed to the fact that the cyclopropyl group is a more potent electron donor than the isopropyl group; therefore, the former increases the electron density of the free electron pair of the carbonyl group which is in the relative *anti*-position (the intermediate **8** in Scheme 4).[104]

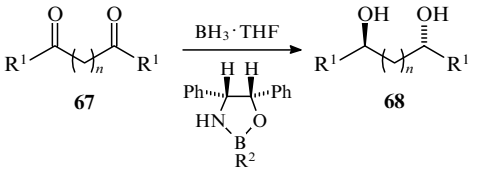
The use of 1,3,2-oxazaborolidines for the enantioselective reduction of alkanones does not give good results;[109,110] only alkyl methyl ketones containing alkyl substituents C_nH_{2n+1} ($n \geqslant 4$) are reduced with satisfactory enantioselectivity [*ee* of the alcohol (*R*)-MeCH(OH)Bu^n is 47% (see Ref. 34) or 66%,[105] *ee* of (*R*)-MeCH(OH)C_6H_{13}-n is 70%[66]]. The reduction of phenylacetone proceeds with moderate stereoselectivity, *viz*., in the presence of $Me_2S \cdot BH_3$ and the catalyst **48**, (2*R*)-phenylpropan-2-ol is formed with *ee* 61%,[66] whereas in the presence of $BH_3 \cdot THF$ and the catalyst **4** *ee* is 81%.[15]

The reduction of ketones containing alkyl and 1,3-dithianyl substituents is a convenient method for the synthesis of optically active ketols **64**.[72,111] The bulky 1,3-dithianyl substituent possesses a high discriminative ability which increases *ee* of ketols **64**. This reaction proceeds *via* the alcohols **65**. The desulfurisation of the alcohols **65** by Raney nickel yields the secondary alcohols **66**.



R = Alk, Ar; Cat =  ; NCS is *N*-chlorosuccinimide.

It is known that the non-catalytic reduction of dicarbonyl compounds by borane yields diols in the *meso*-form.[97] In the catalytic reduction of diphenyl diketones **67** (R^1 = Ph) (10 mol.% of the catalyst **51**), the *meso* : *R*,*R* (or *S*,*S*) ratio varies from 48 : 52 (*n* = 1) to 21 : 79 (*n* = 2), 9 : 91 (*n* = 3) or 2 : 98 (*n* = 4).[112–114]



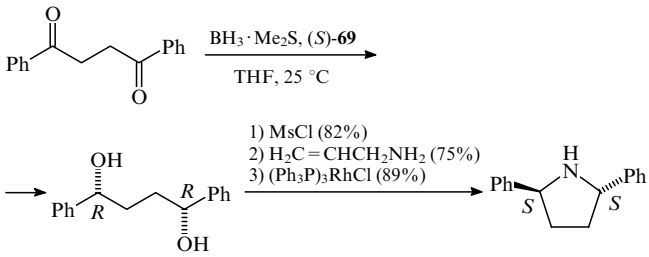
67 **68**

n = 1 – 4; R^1 = Me, Bu^t, Ph; R^2 = H, Me.

After crystallisation of the diol **68**, *ee* of the *S*,*S*-enantiomer was 99% (the content of the *meso*-form was < 1%). (For n = 1, the configuration of the diol formed was *R*,*R*).

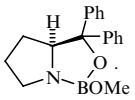
α-Diketones RC(O)C(O)Ph (R is a heterocyclic substituent) are reduced to (*S*,*S*)-RCH(OH)CH(OH)Ph by $BH_3 \cdot SMe_2$ in the presence of the catalyst (*S*)-**3** with *ee* 99%.[113]

The reduction of 1,4-diphenylbutane-1,4-dione by the $BH_3 \cdot SMe_2$ complex in the presence of 1,3,2-oxazaborolidine (*S*)-**69** proceeds with high selectivity. The diol **68** formed (*ee* 99%) is easily converted into chiral 2,5-diphenylpyrrolidine with high *ee*.[114] The catalyst (*S*)-**69** was obtained *in situ* from (*S*)-diphenylprolinol and trimethyl borate.



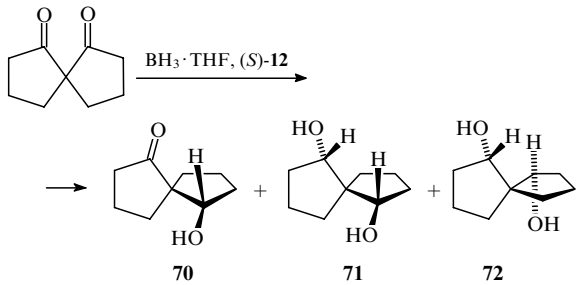
68 (96%, *ee* 99%) (55%, *ee* 99%)

(*S*)-**69** =



The reduction of hexane-2,5-dione under identical conditions yields the corresponding diol with *ee* 33%.[114]

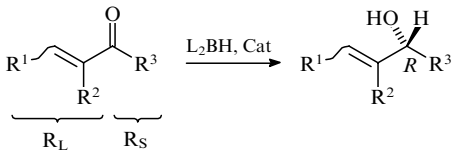
The reduction of spiro[4.4]nonane-1,6-dione (1.5 equiv. of borane, 0.1 equiv. of the catalyst (*S*)-**12**) at 78 °C gives ketol **70** (60%) and *trans*,*trans*-spirodiol **71** (40%). With an increase in temperature to 22 °C and of borane concentration to 2 equiv., a mixture of *cis*,*trans*-spirodiol **72** (83%) and the *trans*,*trans*-isomer **71** (17%) is formed.[115]



70 **71** **72**

A simple method for the synthesis of (1*S*,2*R*)-indenoxide with *ee* > 99% and (1*S*,2*S*)-*trans*-2-bromoindan-1-ol with *ee* 87% has recently been developed. The enantioselective reduction of 2-*p*-tolylsulfonyloxy-1-indanone was carried out using a borane complex with *N*-ethyl-*N*-isopropylaniline in the presence of the catalysts **5** and **39** (R = Me).[116]

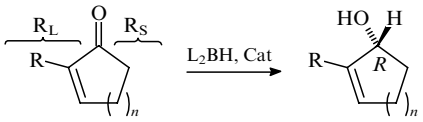
A detailed description of enone reduction is given in the reviews.[5–7] To prevent the non-catalytic reduction of the double bond, enones are usually reduced by catecholborane **62** at low temperatures in the presence of the catalysts **5** and **12**. It is of note that the alkene residue of acyclic enones plays the role of the larger substituent (R_L).[5–7, 112, 117] In conformity with this rule, the catalytic reduction of enones in the presence of 1,3,2-oxazaborolidines (*S*)-**5** and (*S*)-**12** yields (*R*)-enantiomers of substituted allylic alcohols.[5, 30, 103, 118–123]



(*S*)-Enantiomers are formed exclusively in the presence of α-substituents in R^2 and R^3 groups (see Ref. 117).

The enantioselective catalytic reduction of alk-2-ene-1,4-diones is documented in the studies.[112, 124]

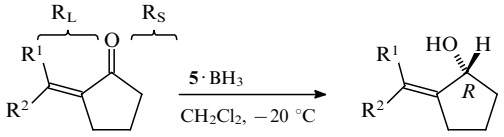
The catalytic reduction of cyclic enones containing an endocyclic double bond yields allylic alcohols with *ee* > 90%. In this case, the key role in the selectivity control is played by the nature of the substituent R at the α-carbon atom.[5]



n = 1, 2.

The reduction of enones with R = Me,[30] Br,[13, 125–127] Bu^{t}Me$_2$SiOCH$_2$ [128] and (MeO)$_2$CHCH$_2$ [129] in the presence of the catalysts (*S*)-**5** and (*S*)-**12** gave exclusively (*R*)-enantiomers of allylic alcohols.

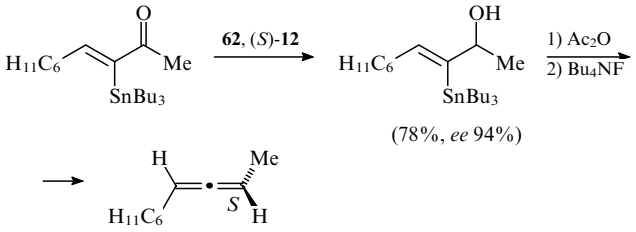
The alkene residue of cyclic enones containing an exocyclic double bond also plays the role of a bulky group R_L.[130]



73 **74**

The yield of the alcohol **74** in the reduction of the ketone **73** (R^1 = H, R^2 = Ph) was 84% and its enantiomeric excess was 96%. To ensure high selectivity, the reduction was performed in dichloromethane at low temperature by slowly adding the enone solution to the reducing agent ($BH_3 \cdot SMe_2$) (the enone : reducing agent : catalyst ratio was 1 : 1 : 0.2).[130]

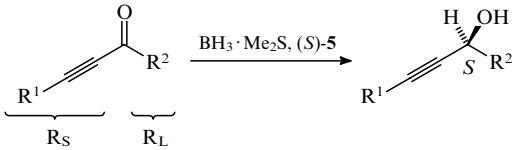
A method for the synthesis of chiral allenes from α-tributylstannylated allylic alcohols has been developed:[118]



(78%, *ee* 94%)

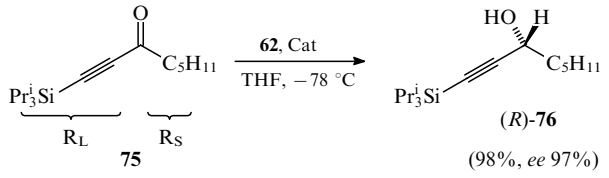
(*ee* 94%)

The reduction of acetylenic ketones gave unexpected results. It was found that the acetylene residue plays the role of a minor substituent R_S irrespective of the size of the substituent R^1 as a result of which the reduction of acetylenic ketones yields (*S*)-enantiomers of acetylenic alcohols.[124, 131]



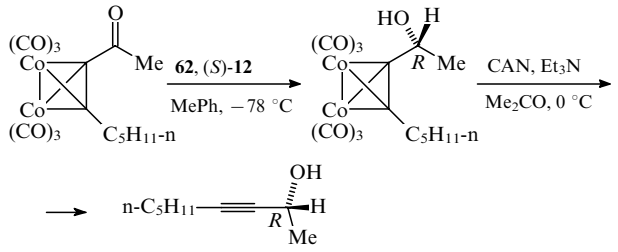
R^1 = H, Ph; R^2 = Me, Et, n-C_6H_{13}, Pr^i, cyclo-C_6H_{11}.

The introduction of a bulky $SiPr^i_3$ group into the acetylene residue converts it from R_S into R_L. Thus the reduction of the ketone **75** by catecholborane **62** in the presence of 1,3,2-oxazaborolidine based on (*S*)-diphenylprolinol having a trimethylsilyl substituent at the B atom results in the formation of the (*R*)-acetylenic alcohol **76**.[85]



75

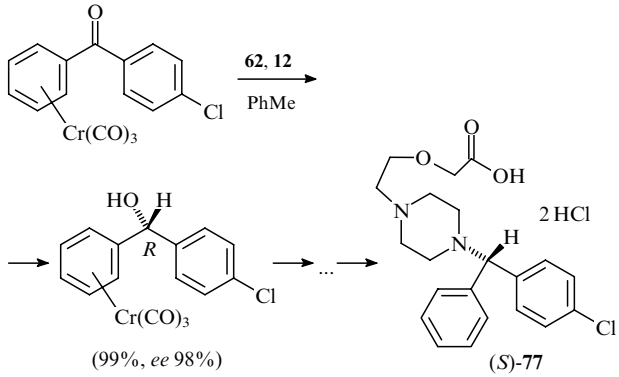
In order to make the acetylenic substituent play the role of a bulky R_L group, this can be converted into a π-complex with dicobalthexacarbonyl. Following the reduction, the complex is converted into an acetylenic alcohol by oxidative decomplexation.[104]



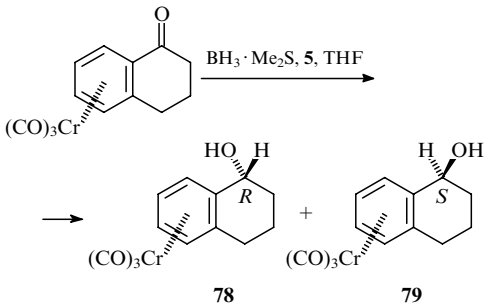
CAN = $(NH_4)_2Ce(NO_3)_6$.

The enantioselective reduction of acetylenic diketones and their π-complexes with dicobalthexacarbonyl has been described.[124]

The reduction of 4-(η^6-chromotricarbonylbenzoyl)chlorobenzene[104] was used in the synthesis of the second-generation histamine antagonist Cetirisine (**77**).[132]

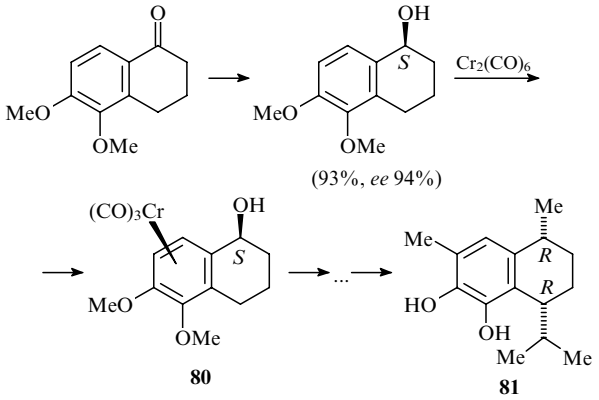


An attempt to perform the kinetic resolution of η^6-chromotricarbonyl complexes of 1-tetralone using CBS reduction failed.[133] It was expected that this reaction would result in the predominant formation of the *endo*-isomer **78** (which could correspond to the hydride ion transfer from the side opposite to the ligand $Cr(CO)_3$). However, under kinetic resolution conditions (*i.e.,* in the presence of 0.3 equiv. of the reducing agent) the reaction mixture contained the starting ketone (44% – 54%), the *endo*-isomer **78** (36% – 42%) and the *exo*-isomer **79** (10% – 14%); a mixture of the alcohols **78** and **79** (52 : 48) was formed in the presence of an excess of the reducing agent and after complete conversion of the original complex.



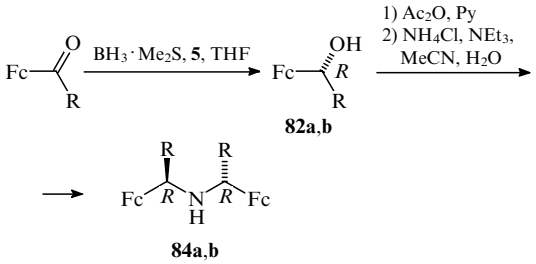
78 **79**

These results are rationalised as being due to the hydride ion transfer from the side of the $Cr(CO)_3$ group. An approach which includes primary catalytic reduction of the tetralone‡ and subsequent formation of the chromiumtricarbonyl complex **80** (the latter was used in the synthesis of (1*R*,4*R*)-7,8-dihydroxycalamenene **81**) appeared to be far more efficient.[134] The reduction of dimethoxytetralone by $Me_2S \cdot BH_3$ was carried out in THF in the presence of 0.2 equiv. of a catalyst based on (*R*)-proline which provided the (*S*)-configuration of the substituted tetralol. The stereospecific formation of the chromiumtricarbonyl *endo*-complex **80** is attributed to the regulatory effect of the hydroxy group which forms a complex with the chromium atom. Subsequent stereoselective alkylation of the complex **80** is well known in the chemistry of η^6-$Cr(CO)_3$ – arene complexes.



80 **81**

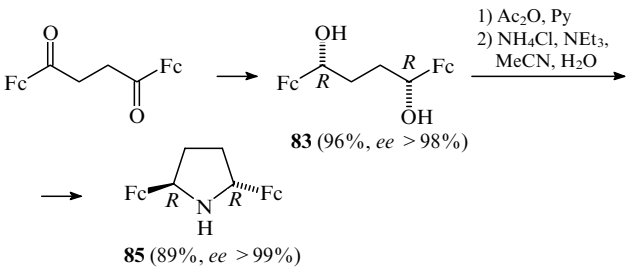
The catalytic reduction of the ferrocene derivatives[135–137] in the presence of 1,3,2-oxazaborolidines yields the chiral alcohols **82a**,**b** and **83** which were used in the synthesis of the chiral amines **84a,b** and **85**.§ The latter are used in enantioselective deprotonation and alkylation reactions.[136]



Compound	R	Yield (%)	*ee* (%)
82a	Me	97	98
82b	Ph	94	97
84a	Me	52	> 99
84b	Ph	90	> 99

‡ In this reaction, the enantiomeric excess of (*S*)-tetralol was 94%, while that after recrystallisation from EtOAc was 99%.

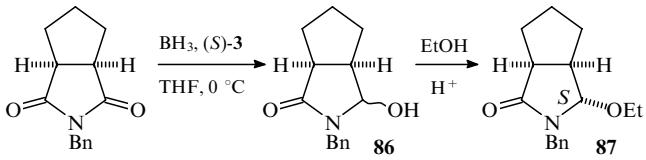
§ This reaction is similar to that involving the diols **68**.[114]



83 (96%, *ee* > 98%)

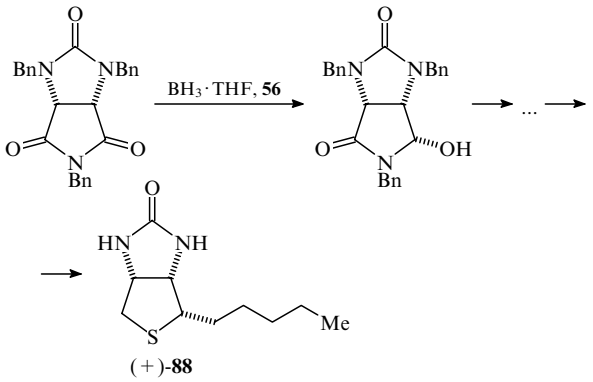
85 (89%, *ee* > 99%)

The reduction of cyclic *meso*-imides in the presence of the catalyst (*S*)-**3** yields a mixture of *cis*- and *trans*-5-hydroxypyrrolidones **86**; however, their rapid treatment with an EtOH – H_2SO_4 mixture yields predominantly *trans*-ethoxy lactam **87** in 73% yield (*ee* 75%).[138,139]



86 **87**

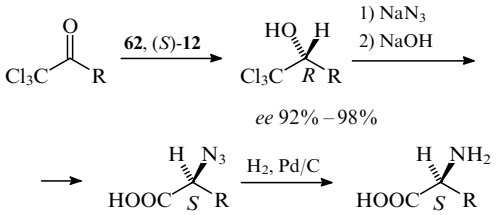
The reduction of imides in the presence of 1,3,2-oxazaborolidine **56** (R = H) was used in the synthesis of (+)-deoxybiotin **88**.[140]



(+)-**88**

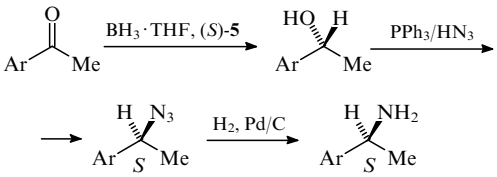
5. Synthesis of biologically active substances and natural compounds

The catalytic reduction of trichloromethyl ketones by catecholborane **62** in the presence of 0.1 equiv. of (*S*)-**12** can be used in the synthesis of both natural and non-natural (*S*)- or (*R*)-amino acids.[88]



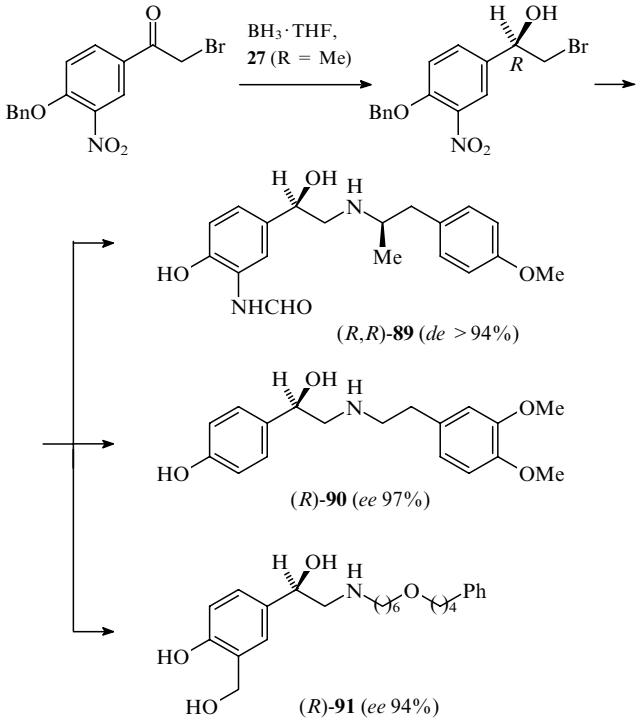
R = Alk, Ph.

A combination of enantioselective reduction with the Mitsunobu reaction opens up new routes to the synthesis of enantiomerically pure azides [141] and substituted 1-arylethylamines.[100]



Ar = C_6H_4Br-*m*, C_6H_4OH-*m*, C_6H_4OMe-*m*.

The reduction of α-haloacetophenones catalysed by 1,3,2-oxazaborolidines is the most promising approach to secondary amino alcohols: (*R*,*R*)-formoterol (**89**),[61,94] (*R*)-denopamine (**90**)[142] and (*R*)-salmeterol (**91**),[93] which represent β-adrenoreceptor agonists [the biological activity is manifested predominantly by (*R*)-enantiomers].

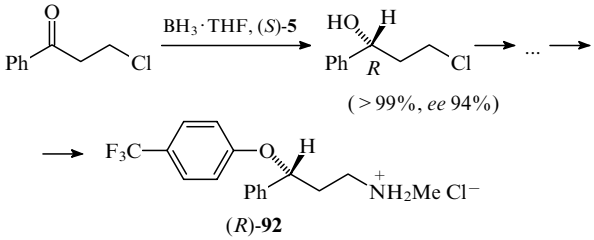


(*R*,*R*)-**89** (*de* > 94%)

(*R*)-**90** (*ee* 97%)

(*R*)-**91** (*ee* 94%)

The antidepressant fluoxetine (**92**) (Prozac©) is a potent selective serotonin uptake inhibitor and is widely used in medicine [143] (for the synthesis of fluoxetine and its metabolites see Ref. 144 and references cited therein). It was found that the (*R*)-enantiomer **92** possesses biological activity; the first step in its synthesis includes CBS reduction of β-chloropropiophenone.[143]



(> 99%, *ee* 94%)

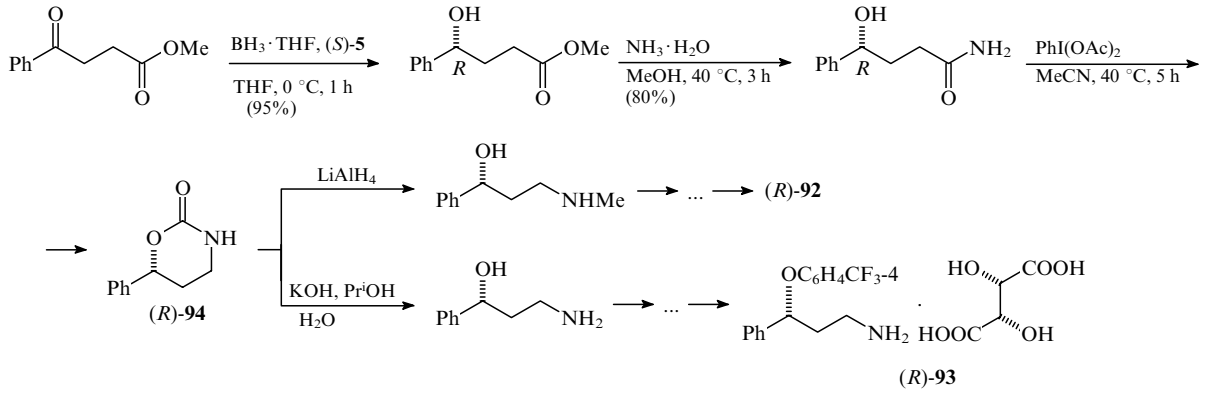
(*R*)-**92**

An improved method for the synthesis of (*R*)-fluoxetine **92** and its main metabolite (*R*)-norfluoxetine **93** (isolated as D-tartrate) includes CBS reduction, Hoffmann rearrangement induced by diacetoxyiodobenzene and cleavage of the intermediate cyclic carbamate **94** (Scheme 5).[144]

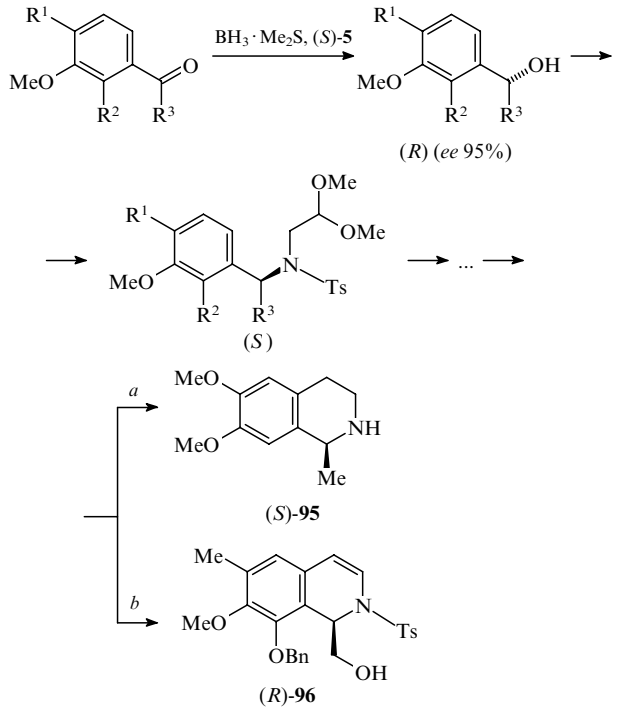
Catalytic CBS reduction was used by Kaufman for the synthesis of chiral 1,2,3,4-tetrahydro- and 1,2-dihydroisoquinolines, *viz*., (*S*)-(−)-salsolidine (**95**) [145] and the intermediate (*R*)-**96** used in the synthesis of the β-adrenoreceptor antagonist MY336-a (Scheme 6).[102]

The stereoselective (*ee* 94%) synthesis of (3*R*,4*E*)-19-methyleicos-4-en-1-yn-3-ol (**97**) (a metabolite from the sea sponge *Cribrochalina vasculum*), which possesses immunosuppressive and antitumour properties, has been described.[146] This example is interesting in that the molecule of the starting compound **98** contains simultaneously the C=C and C≡C bonds. In this case, the role of the minor substituent R_S is played by the acetylenic fragment. The borane – dimethyl sulfide complex (THF, 0 °C) was

Scheme 5

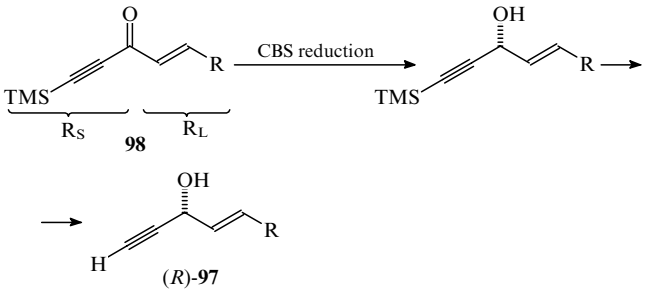


Scheme 6



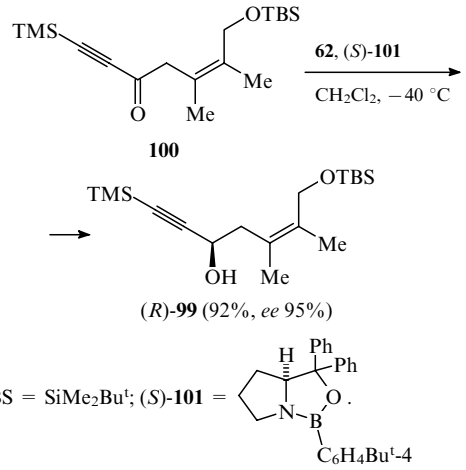
(*a*) R^1 = OMe, R^2 = H, R^3 = Me;
(*b*) R^1 = Me, R^2 = OBn, R^3 = CH_2OBn.

used as a reducing agent while (*R*)-**5** or (*R*)-**48** (R = Me) was used as a catalyst.

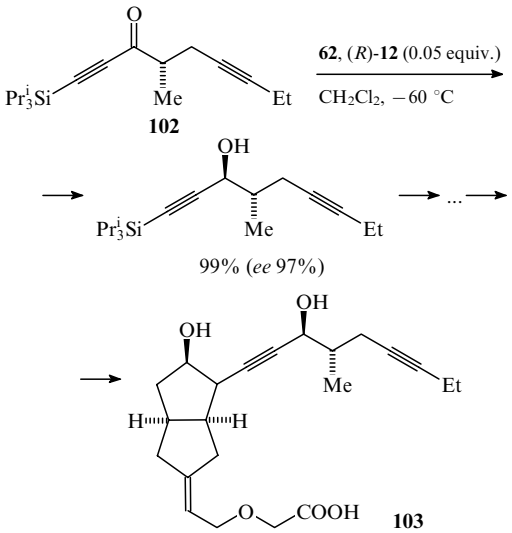


R = $(CH_2)_{13}Pr^i$, TMS = $SiMe_3$.

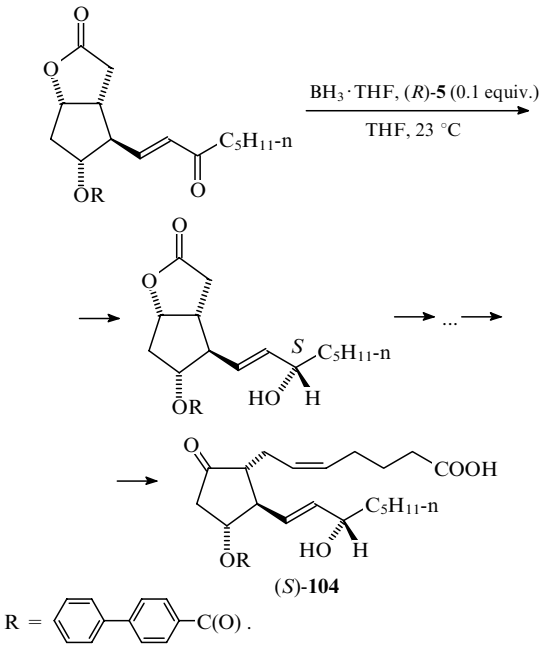
The key synthon (*R*)-**99** used in the synthesis of nicandrenones was prepared by CBS reduction of ketones **100** using (*S*)-**101** as a catalyst.[147]



The mild conditions of CBS reduction have made possible its wide application in the chemistry of prostaglandins. Thus the enantioselective catalytic reduction of diynone **102** by catecholborane (**62**) was used in the synthesis of the ω-chain of the orally active cicaprost **103**, a metabolically stable analogue of prostaglandin I_2.[5]



The stereoselective introduction of a hydroxy group into the C(15) atom in the synthesis of the protected prostaglandin PGE_2 **104** [(*S*) : (*R*) ≈ 10 : 1] is carried out in a similar way.[13]

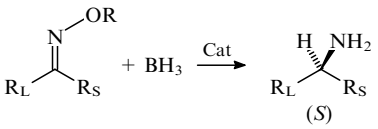


Other examples of the synthesis of biologically active and natural compounds by enantioselective reduction of carbonyl compounds can be found in the reviews.[5,6]

The above data suggest that CBS reduction of prochiral ketones has a number of advantages over other reduction procedures. These include versatility, *i.e.*, the possibility of reduction of different types of carbonyl compounds, predictable stereochemistry of the alcohol formed, relative availability of catalysts in any of their enantiomeric forms, easy regenerability of the catalyst precursor (an amino alcohol), low cost, high yields and relative simplicity of the experimental procedure.

III. Reduction of oximes and imines

The unflagging interest of investigators in optically active amines is due to the wide diversity of their practical applications, *e.g.*, in separation of enantiomers,[148] preparation of drugs[149] and as auxiliary reagents in asymmetric synthesis and catalysis.[150] It is therefore not surprising that the enantioselective reduction of ketones in the presence of chiral oxazaborolidines was extended to the synthesis of optically active amines. In this case, oxime ethers were used as the starting compounds.[10,151]



R = Me, Et, Bn, $SiMe_3$; R_L = Ph, 1(2)-naphthyl; R_S = Me, Alk.

On the whole, the product yields and the stereoselectivity of reduction of oxime ethers are lower than those of ketones.¶

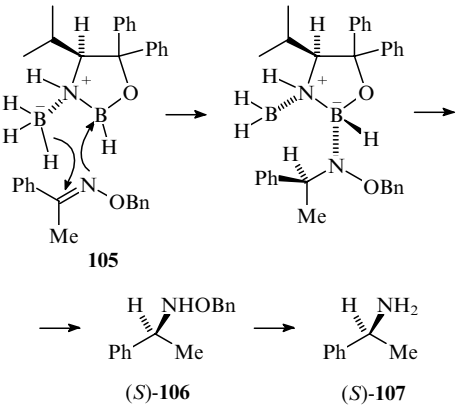
Let us point out the differences in the conditions of preparation of optically active alcohols and amines.

First, the synthesis of amines requires that the reaction is carried out with only individual geometrical oxime isomers, since the stereochemistry of the final product (an amine) depends on the configuration of the precursor [*e.g.*, the (*S*)-enantiomer of the amine is usually formed from the *E*-isomer of the oxime containing small R_L and R_S fragments].[2,152] Second, high efficiency of the catalytic reaction (high values of *ee*) requires usually an increase in the reaction time up to 20–70 h and the use of equivalent amounts of 1,3,2-oxazaborolidine[153] (only a few examples of effective catalytic reactions are known[154,155]). Third, in the case of oxime ethers the *ee* value of the reaction product depends on the nature of the substituent R [the reduction of oximes non-substituted at the oxygen atom is non-selective (*ee* 0.6%), the best results are achieved for R = Me or CH_2Ph] and the catalyst type.[10,75]

As a rule, 2 equiv. of borane and 1 equiv. of the catalyst (**2**,[151–153] **3**[151,153] or 1,3,2-oxazaborolidine based on norephedrine[152]) are used per 0.8–1 equiv. of the oxime ether;† the reaction is carried out in THF at 30 °C for 24 h.

Let us consider the mechanism of reduction of oxime ethers in more detail (Scheme 7).[152]

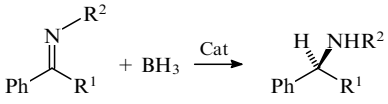
Scheme 7



As was shown above in the example of the Corey model for ketones[5] (see Section II), the addition of borane to chiral 1,3,2-oxazaborolidine **2** occurs from the side opposite to the isopropyl group. The nitrogen atom of the *E*-isomer of the oxime ether coordinates the endocyclic boron atom by the free electron pair to form a six-membered transition state **105** where the bulkier phenyl radical of the oxime occupies an equatorial position. Subsequent stereoselective hydride ion transfer yields protected (*S*)-hydroxylamine **106** which is reduced to the (*S*)-enantiomer of the amine **107**. In some cases, hydroxylamines (*S*)-**106** were isolated together with the amines (*S*)-**107**.[152]

A somewhat different, but essentially similar interpretation for the formation of the (*S*)-enantiomer was given by Itsuno[156] who suggested that the steric interaction of the *O*-benzyl group with the *trans*-phenyl group is critical for the stereoselectivity (the solid-phase enantioselective reduction of ketoxime ethers[157–158] will be considered in Section V).

The reduction of imines occurs in a similar way.



R^1 = Me, Et, Pr^i; R^2 = Ph, Bn, Alk.

The imines with R^2 = Ph are reduced best of all, the yields of the corresponding amines are 96%–98%, *ee* is 71%–88%.[153,159] The reduction of *N*-alkylketimines is less selective (*ee* 46%–52%), while the selectivity of reduction of dialkyl ketone imines is very low (*ee* 7.4%–24%).[153] The *ee* increases with an increase in the size of the radical R^1.

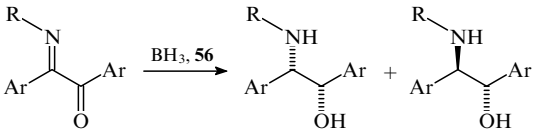
The structure of the catalyst is known to influence the course of the reduction of oxime ethers and imine.[75] It was found that the

¶ The early procedures[10,151] were further improved which enabled one to obtain semi-preparative amounts of substituted (*S*)-1-phenylethylamines with *ee* 90%–99%.[152] Hence, enantioselective reduction of oxime ethers and imines by boranes in the presence of chiral 1,3,2-oxazaborolidines is one of the most efficient methods for the synthesis of optically active amines.

† An experimental procedure for the regeneration of the catalyst **2** as a hydrochloride is reported.[152]

reduction of acetophenone *O*-methyloxime to 1-phenylethylamine by 1 equiv. of $BH_3 \cdot THF$ in the presence of *N*-arylsulfonylated 1,3,2-oxazaborolidine derived from **58** results in the formation of either an (*S*)- or an (*R*)-enantiomer depending on the nature of the substituents in compound **58**. Thus the (*S*)-enantiomer is formed with Ar = Tol-*p*, R = H (yield 61%, *ee* 84%), while (*R*)-2-phenylethylamine is formed with Ar = 1-naphthyl, R = H (yield 31%, *ee* 84%).[75] This is an illustrative example of a reversal of stereoselectivity due to replacement of a substituent in the arylsulfonyl group from tolyl to naphthyl. A similar dependence is observed in the reduction of prochiral ketones.[75]

The possibility of preparing chiral amino alcohols, which are valuable intermediates in asymmetric synthesis, by diastereoselective reduction of imino ketones and *O*-ethers of α-hydroxyimino ketones has also been studied.[154, 160–163] In the first experiments, the enantioselectivity and diastereoselectivity were rather low.[160] Thus the reduction of the imino ketone **108** (R = *p*-$MeOC_6H_4$, Ar = Ph) by the complex $BH_3 \cdot THF$ in the presence of 0.2 equiv. of the catalyst **56** (R = H) (see Table 1) gave a mixture of *syn*-(1*S*,2*S*)- and *anti*-(1*S*,2*R*)-isomers **109** (58 : 42) with the enantiomeric purity of the products < 14% (yield 88%).[162]

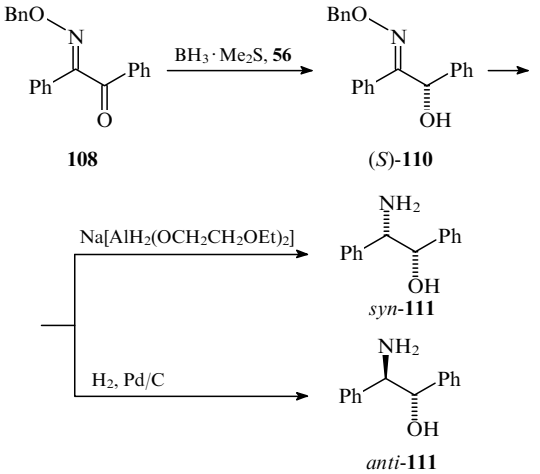


108 *syn*-(1*S*,2*S*)-**109** *anti*-(1*S*,2*R*)-**109**

R = *p*-$MeOC_6H_4$, BnO, *p*-$MeC_6H_4SO_2$;
Ar = Ph, *p*-$MeOC_6H_4$, *p*-MeC_6H_4, *p*-BrC_6H_4, 2-furyl.

The stereoselectivity increased on going from α-imino ketones (R = *p*-$MeOC_6H_4$) to ethers of α-hydroxyimino ketones (R = OBn): the enantiomeric purity of the target product reached 88%. In the presence of 1 equiv. of the catalyst **56** and $Al(OPr^i)_3$, the enantioselectivity increased to 90%, however, the diastereoselectivity was not changed (the *syn* : *anti* ratio was 47 : 53). It was thus concluded that under these conditions the catalytic reduction of the keto group was followed by non-selective reduction of the oxime group by borane.[162] This process was complicated by the formation of a side 1,3,2-oxazaborolidine from BH_3 and the amino alcohol formed, which catalysed the reduction in a non-selective manner.[160]

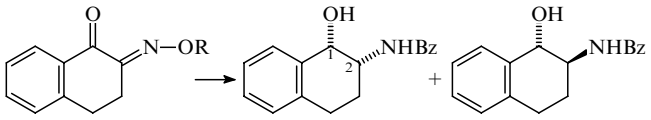
It was found experimentally that the keto group is reduced more easily than the oxime group.[154, 160] The stereoselectivity could be increased, if stepwise reduction was used under optimum conditions for each step.[162, 163] The reduction of the ether of hydroxyimino ketone **108** (R = OBn, Ar = Ph) in the presence of 1 equiv. of the catalyst **56** (R = H) at room temperature gave (*S*)-hydroxy oxime **110** (yield 78%, *ee* 98%).[162]



108 (*S*)-**110** *syn*-**111** *anti*-**111**

Subsequent reduction of the oxime function was carried out in the absence of 1,3,2-oxazaborolidine. The *syn*-isomer **111** was prepared by treatment of compound **110** with the complex hydride $Na[AlH_2(OCH_2CH_2OEt)_2]$, while the *anti*-isomer **111** was obtained by catalytic reduction of compound **110** with hydrogen in the presence of 10% Pd/C.[162, 163]

The reduction of ethers of α-hydroxyimino ketones **112** yields predominantly the *cis*-amino alcohols *cis*-(1*S*,2*R*)-**113**, *cis* : *trans* = 10 : 1 (for R = Bu^tPh_2Si, *ee* is 96%, after recrystallisation *ee* > 99%),[154] or 9 : 1 (for R = CPh_3, *ee* 90%).[160]

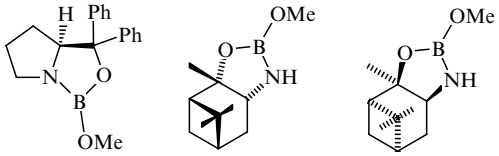


112 *cis*-(1*S*,2*R*)-**113** *trans*-(1*S*,2*S*)-**113**

R = Bu^tPh_2Si, Ph_3C.

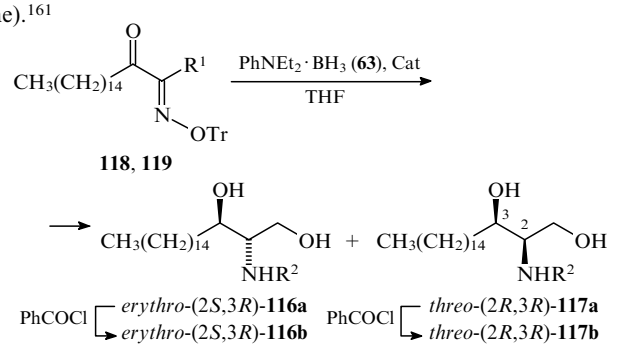
The reduction of compounds **112** containing less bulky groups in the ether moiety proceeds with lower selectivity.

The reduction of ketoxime ethers by a borane–dimethyl sulfide complex in the presence of chiral 1,3,2-oxazaborolidines **69**, **114** and **115** prepared from trimethyl borate and the corresponding alcohols has been described.[160]



69 **114** **115**

The introduction of a bulky *O*-trityl (Tr) group into oximes is yet another approach to increase the selectivity of reduction of α-hydroxyimino ketones.[160, 161] This approach was used in the diastereoselective synthesis of sphinganine (dihydrosphingosine).[161]



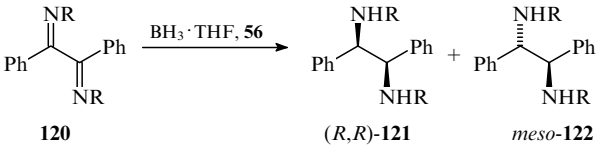
118, **119**

R^1 = CO_2Me (**118**), $CH_2OSiMe_2Bu^t$ (**119**); R^2 = H (**116a**, **117a**), PhCO (**116b**, **117b**); Cat = **69**, **114**, **115**.

Depending on the substrate, the catalyst and reduction conditions, one can obtain either the *erythro*-(2*S*,3*R*)-isomer **116** or the *threo*-(2*R*,3*R*)-isomer **117** [natural sphingosine has the *erythro*-(2*S*,3*R*)-configuration]. These conversions provide a typical example of so-called 'substrate control'.

Substrate	Catalyst	Reducing agent	*erythro* : *threo*	*ee* (%)
118	**69**	**63**	13 : 87	89 (*threo*)
119	**115**	**63** + $BH_3 \cdot SMe_2$	98 : 2	97 (*erythro*)

The catalytic reduction of diimines of the type **120** in the presence of 0.05 equiv. of the catalyst **56**, which yields substituted (*R*,*R*)-1,2-diphenylethylenediamines with *ee* 99% [the (*R*,*R*)-**121** : *meso*-**122** ratio is 95 : 5], has been described.[155]

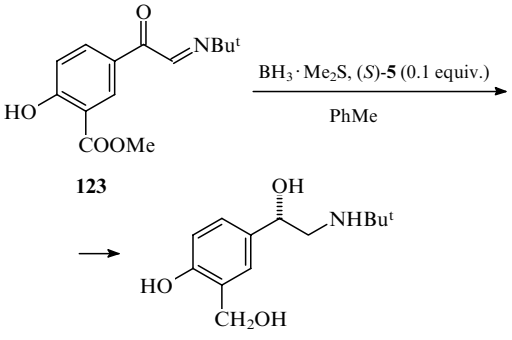


120 (*R*,*R*)-**121** *meso*-**122**

R = *p*-$MeOC_6H_4$.

An attempt to use this method for the reduction of 1,2-dioximes failed.[155]

The reduction of α-imino ketone **123** is the key step in the synthesis of the β-blocker (*S*)-albuterol (**124**).[164]



123

124 (90%, *ee* 93%–95%)

Despite the obvious success in the reduction of imines and oxime ethers, this reaction has a number of limitations. Thus no 1,3,2-oxazaborolidines able to catalyse effectively the reduction of 3,4-dihydroisoquinolines and carbolines have been found so far.[2] There are virtually no publications devoted to large-scale semi-industrial synthesis of chiral amines required for the synthesis of some medicinal drugs, *e.g.*, α- and β-adrenoblockers, antidepressants, *etc.*[149]

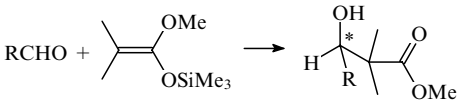
IV. Use of 1,3,2-oxazaborolidines in miscellaneous reactions

In addition to reduction of ketones, imines and oximes, chiral 1,3,2-oxazaborolidines find wide application in other branches of synthetic organic chemistry. Some applications of these catalysts in the Diels–Alder reaction, aldol condensation and some other reactions are considered in the review;[165] however, the articles cited therein were published before 1991. Therefore, we thought it expedient to systematise the literature data published in the past decade.

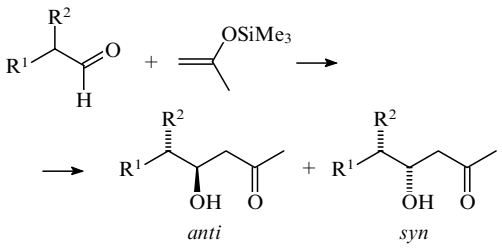
1. Aldol condensation

At the end of the 20th century, the efforts of many chemists were focused on the development of methods for enantioselective and diastereoselective aldol condensation [166–168] owing to the high versatility and wide applicability of this reaction in the synthesis of natural compounds, of macrolide antibiotics, in particular.

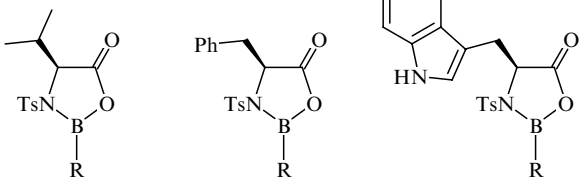
The aldol condensation of aldehydes with enol silyl ethers or ketone silyl acetals catalysed by Lewis acids (the Mukaiyama reaction) [169–171] can be implemented in an asymmetric version.[172]



If an aldehyde introduced into the reaction contains a chiral α-carbon atom, the condensation product will contain two chiral centres.[172, 173]



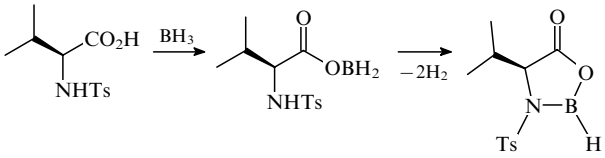
In the general case, this reaction yields a mixture of diastereomers. In a recent study,[174] the possibility of effective control over *syn*- and *anti*-selectivities by changing the spatial structure of the catalyst (the latter is used in amounts not exceeding 20 mol.%) has been demonstrated. It was found that high enantioselectivity (*syn* : *anti* > 98 : 2) can be achieved with a proper catalyst chosen with due regard to the nature of the substituents R^1 and R^2 in the starting aldehyde.[175, 176] This type of reaction can be referred to as a catalytically controlled process.[172] (Far from all reactions considered in this section can be carried out under conditions of catalytic control, often equimolar amounts of the catalyst are required.) The minor diastereomer formed is easily separated by chromatography.[172] Chiral *N*-acyl- and *N*-tosyl-1,3,2-oxazaborolidin-5-ones were found to be suitable catalysts for such conversions. The use of these compounds as catalysts was proposed simultaneously by Corey,[177, 178] Yamamoto,[179] Helmchen [180, 181] and Masamune.[182] Catalysts based on natural (*S*)-enantiomers of the amino acids **125a–e**,[172, 183] **126a–e** [184] and **127a–e** [185] are the most common.



(*S*)-**125a–e** (*S*)-**126a–e** (*S*)-**127a–e**

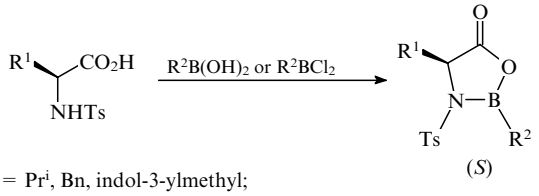
R = H (**a**), Me (**b**), Bu (**c**), Ph (**d**), 3,5-$(CF_3)_2C_6H_3$ (**e**).

Compounds **125a, 126a** and **127a** were prepared by treatment of the corresponding *N*-tosylated amino acid with borane.[186] For example:



(*S*)-**125a**.

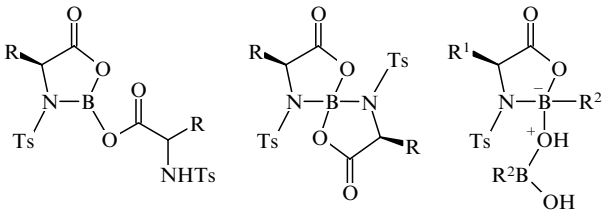
Esters of alkyl- or aryl-boronic acids were used instead of BH_3 in the synthesis of compounds **125b–e**, **126b–e** and **127b–e** containing B—Alk or B—Ar bonds.[184, 185]



(*S*)

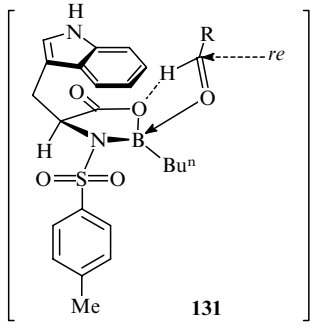
R^1 = Pr^i, Bn, indol-3-ylmethyl;
R^2 = Me, Bu, Ph, 3,5-$(CF_3)_2C_6H_3$, CH_2Bn.

Using negative ion mass spectrometry,[186, 187] it was shown that this reaction is accompanied by the formation of side products **128** and **129** (for R = H) or **130** (for R^1, R^2 = Alk, Ar).



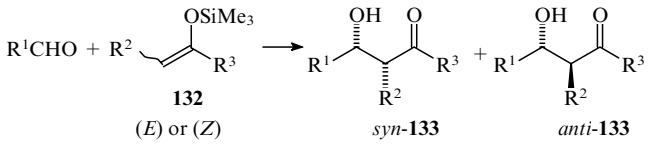
128 **129** **130**

Quantum-chemical methods were used to study the adducts formed upon coordination of formaldehyde with *N*-tosyl-1,3,2-oxazaborolidin-5-ones[183,188] and to determine the energies of their formation.[189] These calculations confirmed the previous assumption[190] on the possible formation of B–O···H–C and B···O=C bonds. The structures of the aldehyde adducts with *N*-tosyl-1,3,2-oxazaborolidin-5-ones were finally established only after the appearance of the publication by Corey *et al.*[191] devoted to X-ray diffraction analysis of some stable adducts where the existence of a hydrogen bond B–O···H–C between the oxygen atom of the 1,3,2-oxazaborolidine ring and the hydrogen atom of the aldehyde group was confirmed. According to Corey *et al.*,[191] the formation of such a non-trivial hydrogen bond is possible due to the high acidity of the hydrogen atom of the H–C(O) group upon coordination of its oxygen atom to the boron atom. This hydrogen bond is the structure-forming element in the rigid structure **131** resulting from the *re*-frontal attack of the nucleophile and governing the enantioselectivity of the aldol condensation and the Diels–Alder reaction (see below) catalysed by 1,3,2-oxazaborolidines (in this case, by compound **127c**).[191]



131

Other examples of the Mukaiyama-type aldol condensation of a series of aldehydes R^1CHO (R^1 = Ph, Pr^n, Pr^i, PhC≡C) with (*Z*)- and (*E*)-enol silyl ethers **132** are considered in the review.[185]

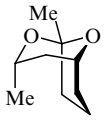


132 (*E*) or (*Z*) *syn*-**133** *anti*-**133**

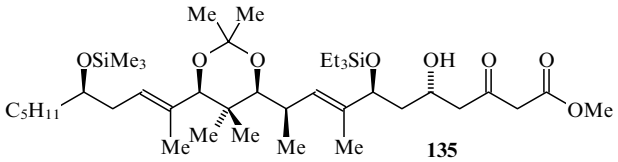
R^1 = Ph, Pr^n, Pr^i, PhC≡C; R^2 = Me, R^3 = Ph, $R^2–R^3$ = $(CH_2)_4$.

The predominant formation of the *syn*-isomers **133** in this reaction is in accord with the model of the transition state **131**. The ratio of the *syn*-**133**:*anti*-**133** products in the condensation of benzaldehyde with trimethylsilyloxycyclohexene [$R^2–R^3$ = $(CH_2)_4$, *E*-isomer] in the presence of the catalyst **127e** was 78:22 with the total yield 99% (*ee* of compound *syn*-**133** was 89%),[185] while that in the condensation of propanal with the (*Z*)-isomer of trimethylsilyl ether **132** (R^2 = Me, R^3 = Ph) was > 99:1 with the total yield 99% (*ee* of compound *syn*-**133** was > 99%). These reactions were carried out in propionitrile at −78 °C for 12 h in the presence of 5 mol.%–10 mol.% of the catalysts **127a–e** (the catalyst **127e** manifested the highest efficiency).

Kiyooka *et al.*[172,192–204] have carried out a comprehensive analysis of the 1,3,2-oxazaborolidin-5-one catalysed Mukaiyama reaction and applied this methodology to the synthesis of bicyclic acetals, *e.g.*, compound **134**[195] and some natural compounds, *e.g.*, compound **135** which is a precursor of the macrolide acutiphycin, the key intermediate of the polyene macrolide filipin and the non-proteinogenic *N*-benzyloxycarbonylgalantinic acid.[201,205–207]



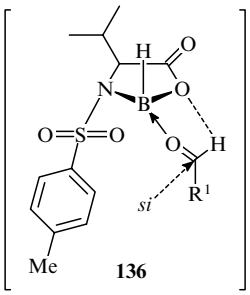
134



135

These reactions were carried out in the presence of stoichiometric amounts of 1,3,2-oxazaborolidine (*S*)-**125a** and its (*R*)-enantiomer (Schemes 8 and 9).

Three aldol condensations in the multistep synthesis of compound **135** (Scheme 9) were performed in the presence of the catalyst (*S*)-**125a** and the last one, in the presence of (*R*)-**125a**, which ensured the desired orientation of the asymmetric centres in the molecule **135**. It was found that the relative configuration of the stereocentres is governed by the stereochemistry of the oxazaborolidine and does not virtually depend on the nature of the substrate. According to Corey,[191] the structure of the transition complex formed in the Mukaiyama reaction catalysed by compound (*S*)-**125a** differs from that of the complex **131**. In this case, *si*-frontal attack of the nucleophile occurs resulting in predominant formation of *anti*-isomers.



136

The *anti*:*syn* ratio varies from 2:1 to 10:1 [the use of (*R*)-**125a** results in the predominant formation of *syn*-isomers].[172,204] The isopropyl group in the complex **136** is *trans* relative to the tosyl group and *cis* relative to the B–H bond; the hydrogen bond C–H···O–B formed ensures fixation of the addition of the aldehyde to the catalyst **125a** thus providing high diastereoselectivity of its condensation with enol silyl ethers.

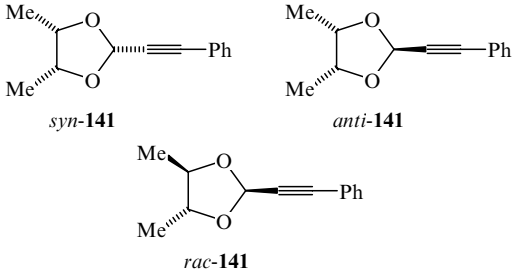
X = *p*-Me (**a**), *o*-NO_2 (**b**), *p*-NO_2 (**c**), *p*-OMe (**d**).

2. Enantioselective opening of the dioxolane ring

Desymmetrisation of *meso*-1,2-diols by asymmetric ring opening of 1,3-dioxolanes and other cyclic acetals under the action of chiral 1,3,2-oxazaborolidin-5-ones has been described by Harada *et al.*[210–215] In these reactions, 1,3,2-oxazaborolidin-5-one [*e.g.*, (*S*)-**126**] plays the role of a stereodifferentiating agent with respect to the enantiotopic oxygen atoms in the cyclic acetal and is predominantly coordinated to one of them. Treatment of this complex with a nucleophile results in the dioxolane ring opening.

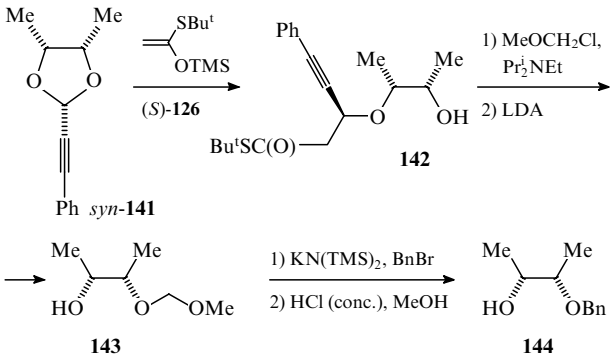
Treatment of commercial 2,3-butanediol, which represents a mixture of *meso*- and *dl*-isomers (~ 2 : 1), with 3-phenylpropynal yields 68% of a mixture of acetals, 2-phenylethynyl-1,3-dioxolane isomers, *viz.*, *syn*-**141**, *anti*-**141** and *rac*-**141** (63 : 3 : 34).[210]



syn-**141** *anti*-**141**

rac-**141**

Treatment of this mixture with $Me_2C{=}C(SBu^t)OSiMe_3$ in the presence of 10 mol.% of the catalyst (*S*)-**126** at –78 °C results in the opening of the acetal ring of *syn*-**141** and the formation of the product **142** (yield 64%, *ee* 96%) (the diastereomeric acetal *anti*-**141** is not cleaved under these conditions).‡ The *anti*-**141** – *rac*-**141** mixture (7 : 93) is isolated after termination of the reaction.



142

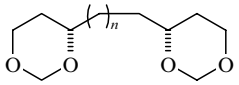
143 **144**

Thus a mixture of *meso*- and *dl*-forms of butanediol yields derivatives of optically active diols **143** and **144**.[210] Such desymmetrisation of *meso*-acetals is undoubtedly useful, since various 1,2-diols are available as mixtures of *meso*- and *dl*-forms (*e.g.*, they

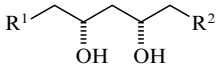
‡ The phenylethynyl substituent appeared to be a suitable functional group, which allows one to perform all transformations in the highest optical yield.

can be prepared by SmI_2-induced reductive dimerisation of aldehydes).[210]

The desymmetrisation of bisacetals **145**[212] and diols **146** has also been described.[213]



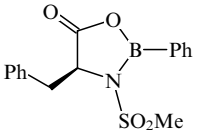
145 (n = 0, 1)



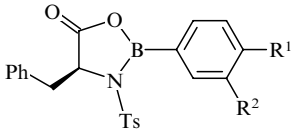
146

R^1 = OBn; R^2 = H, Me, Bu, OBn

(*S*)-**147** and (*S*)-**148a**,**b** can be used as catalysts along with (*S*)-**126.**[212,214]



(*S*)-**147**



(*S*)-**148a**,**b**

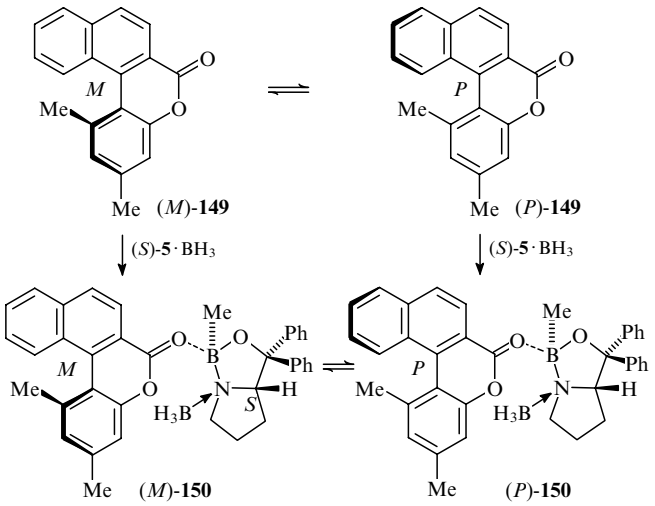
148a: R^1 = H, R^2 = Cl;
148b: R^1 = Cl, R^2 = H.

All these catalysts play the role of contact ion pairs in enantiodifferentiating coordination of acetals with chiral substituted 1,3,2-oxazaborolidin-5-ones.[215]

3. Atroposelective opening of the lactone ring

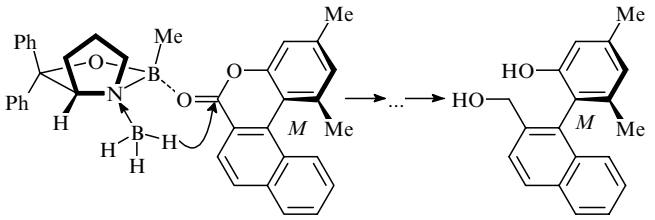
In developing methods for the synthesis of natural naphthyltetrahydroisoquinoline alkaloids, Bringmann *et al.*[216–221] proposed the use of atroposelective opening of the lactone ring of 1,3-dimethylbenzo[*b*]naphtho[1,2-*d*]pyran-6-one (**149**). This method is a convenient procedure for the synthesis of atropoisomers.

The atroposelective reduction of lactone **149** by the complex (*S*)-**5**·BH_3 was studied first.[216–218] This lactone exists in two forms, *viz.*, (*P*)-**149** and (*M*)-**149**§ which are configurationally unstable and are easily interconverted. They form (*P*)-**150** and (*M*)-**150** complexes with the catalyst (*S*)-**5**·BH_3, respectively.



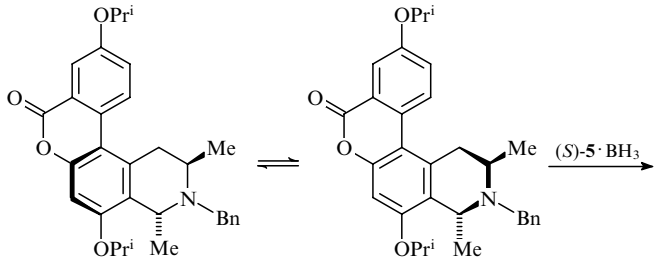
It was found that it is in the complex (*M*)-**150** that the enantioselective hydride transfer with subsequent formation of compound (*M*)-**151** takes place at −78 °C, which is due to the peculiarities of the spatial structure of the complex (*M*)-**150**. The isomeric complex (*P*)-**150** is not reduced under these conditions, it is first converted into (*M*)-**150** and then into (*M*)-**151**. Thus, the kinetic separation of two atropoisomers and their conversion into the same product, *viz.*, (*M*)-**151** (*ee* 97%), take place.[216–218]

§ For the (*P*) and (*M*) nomenclature of atropo-hindered biaryls, see Ref. 222.

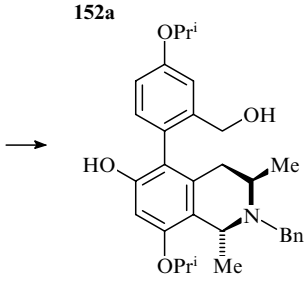


(*M*)-**150** (*M*)-**151**

This method was used by Bringmann for the total synthesis of naphthylisoquinoline alkaloids korupensamines. A mixture of lactones **152a** and **152b** (**152a** : **152b** = 4 : 96) was used as starting compounds, their reduction accompanied by kinetic resolution gives the key intermediate **153**.[219]

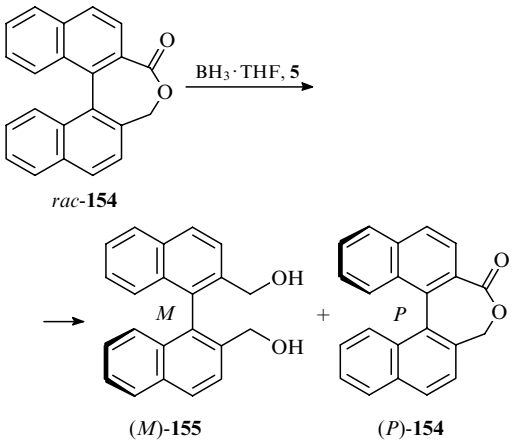


152a **152b**



153

The reduction of the racemic lactone **154** proceeds with high enantioselectivity in a similar way (k_{rel} = 50).[220] As in the case of compound **149**, only the (*M*)-isomer is reduced under these conditions; the configurationally stable isomer (*P*)-**154** remains in the reaction mixture and can be separated. A procedure was developed which allowed isolation of the product (*M*)-**155** and the starting compound (*P*)-**154** in 33% and 30% yields (*ee* 93% and 95%, respectively) at ~ 33% conversion.[220] After separation, the enantiomer (*P*)-**154** can be reduced to (*P*)-**155** using $LiAlH_4$. This conversion allows the preparation of both enantiomers of 2,2′-dihydroxymethyl-1,1′-binaphthyl **155**.



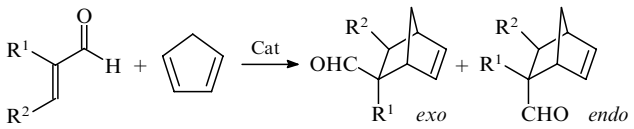
rac-**154**

(*M*)-**155** (*P*)-**154**

The reactions described in this section were also studied using quantum-chemical methods.[218,221]

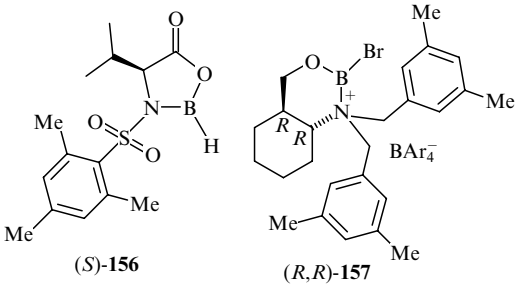
4. Cycloaddition reactions

The Diels–Alder reaction is one of the most popular reactions in organic synthesis. It is known that Lewis acids form complexes with the oxygen atom of the carbonyl group of dienophiles and thus increase its electrophilicity and facilitate the reaction. In this context, the idea of gaining control over the enantioselectivity of the Diels–Alder reaction using chiral 1,3,2-oxazaborolidines seems to be justified. One of the pioneering works [184] devoted to the use of 1,3,2-oxazaborolidines in the Diels–Alder reaction describes model reactions of acrolein, methacrolein and crotonaldehyde with cyclopentadiene.



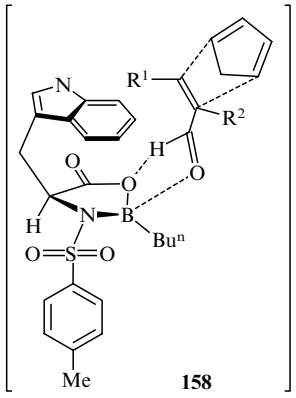
$R^1 = R^2 = H$; $R^1 = Me$, $R^2 = H$; $R^1 = H$, $R^2 = Me$.

The *exo* : *endo* ratio for methacrolein ($R^1 = Me$, $R^2 = H$) is 99 : 1 (*ee* of the *exo*-isomer is 86%), that for crotonaldehyde ($R^1 = H$, $R^2 = Me$) is 7 : 93 (*ee* of the *endo*-isomer is 59%). These reactions are catalysed by (*S*)-**125a** and (*S*)-**156**. The best results were obtained with the spatially hindered catalyst (*S*)-**156**. The use of (*S*)-**127a**–**c** and (*R*,*R*)-**157** as catalysts in the Diels–Alder reactions was first proposed by Corey.[223]



(*S*)-**156** (*R*,*R*)-**157**

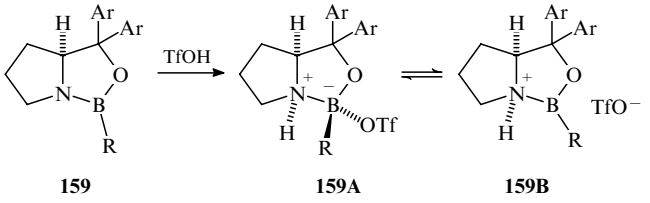
It has already been noted that high enantio- and diastereoselectivity of the Mukaiyama aldol condensations are determined by the complexation of 1,3,2-oxazaborolidin-5-ones with aldehydes and the formation of a stable intramolecular hydrogen bond C–H···O–B.[191] The same was observed for the reaction of the aldehydes $R^2CH=CR^1CHO$ with cyclopentadiene in the presence of the catalyst (*S*)-**127c** (the structure of the intermediate **158** formed is similar to that of the intermediate **131**).



158

The structure of the complex **158** determines the regio- and stereoselectivity of the Diels–Alder reaction.

An increase in the Lewis acidity of the catalyst increases the stability of the 1,3,2-oxazaborolidine–aldehyde complex and, correspondingly, the enantioselectivity of the reaction. Recent studies by Corey have shown [224] that this effect can be attained if 1 equiv. of CF_3SO_3H (TfOH) is added to the reaction mixture.

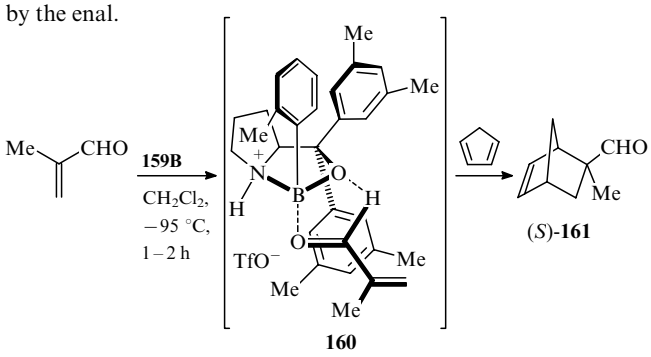


159 **159A** **159B**

R = Me, Bu, Ph, 2-MeC_6H_4, 1-naphthyl;
Ar = Ph, 2-naphthyl, 3,5-$Me_2C_6H_3$.

^{1}H NMR spectroscopy has shown that two forms of the catalyst **159**, *viz*., **A** and **B**, exist in solution at equilibrium at −78 °C in the presence of TfOH.[224]

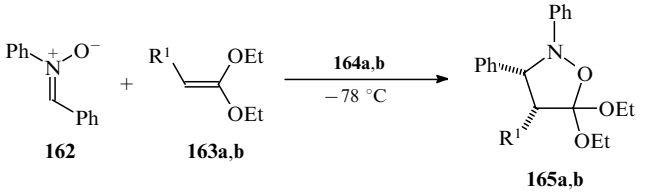
The coordination of the electron-deficient methacrolein in the complex **160** occurs in such a way that its donor–acceptor π–π interaction with the π-electrons of the aromatic ring of the Ar-substituent in the *cis*-position of the C(5) atom of 1,3,2-oxazaborolidine **159** is possible.[224] As a result, the enantioselectivity of the reaction increases. Thus the bulky 3,5-dimethylphenyl group (as an Ar substituent) effectively shields the rear-side attack by the enal.



160

The addition of 6 mol.% of TfOH is sufficient to obtain good results. The yield of the product **16** is 73%–98%, the *exo* : *endo* ratio varies from 83 : 17 to 93 : 7 and *ee* varies from 75% to 91%. The best results were obtained when the catalyst **159** where R = 2-MeC_6H_4 and Ar = 3,5-$Me_2C_6H_3$ was used. In this case, the yield of the product **161** was 99%, *ee* was 96%, the *exo* : *endo* ratio was 89 : 11. This reaction does not occur in the presence of the spatially hindered catalysts **159** (R = 2-$Pr^iC_6H_4$, 2,6-$Me_2C_6H_3$). The addition of $MeSO_3H$ instead of CF_3SO_3H does not favour the reaction (in this case, the yields of the products do not exceed 30%).

Along with [4 + 2]-cycloaddition 1,3-dipolar cycloaddition was also studied.[180, 183, 225–230] However, the use of 1,3,2-oxazaborolidin-5-ones in the 1,3-dipolar cycloaddition did not give any positive results. When the reaction of diphenylnitrone **162** with the ketene acetals **163a**,**b** was carried out in the presence of the catalysts (*S*)-**164a**,**b** (20 mol.%), the yields of the products **165a**,**b** did not exceed 10%, although the enantioselectivity of the reaction was rather high: *ee* was 74% (for **165a**) and 62% (for the *cis*-isomer of **165b**).[226, 227]



162 **163a**,**b** **165a**,**b**

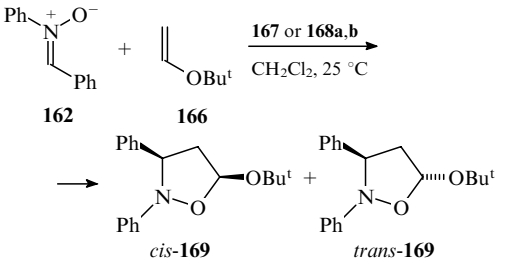
R^1 = H (**163a**, **165a**), Me (**163b**, **165b**);

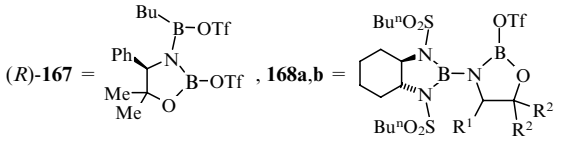
164a,**b** =  [R^2 = H (**164a**), Bu (**164b**)].

The 1,3-dipolar cycloaddition of the nitrone **162** to the electron-enriched alkene **163** is an example of a reaction with reverse electronic requirements. In this reaction, the catalyst **164** was used for the enantioselectivity control, since it was believed that a prominent role in such reactions is played by the donor–acceptor π–π interactions of the catalyst and the reagent in the transition state. The benzyloxy group of the catalyst **164** meets this requirement, since it interacts with the phenyl groups of the nitrone **162**.[227]

The enantioselectivity of this reaction drops drastically with an increase in temperature: at −78 °C, compound **165b** is formed with *ee* 62%, while at 25 °C *ee* is 38%. The product yields and reaction stereoselectivity also depend on the solvent.[227] Thus the reaction in THF catalysed by compound **164a** yields the isomer (−)-**165b** with *ee* 62%, whereas the reaction carried out in diphenyl ether, nitrobenzene or nitroethane gives the isomer (+)-**165b** with *ee* 79%. The yields of (−)- and (+)-**165b** are 33% and 60%, respectively.

The 1,3-dipolar cycloaddition of the nitrone **162** to the enal **166** in the presence of the catalyst (*R*)-**167** or **168a**,**b**[230] yields a mixture of isomers *cis*-**169** and *trans*-**169** in the *cis* : *trans* ratio of 1 : (8–9). In this case, the product yields are 44%–67%. The enantioselectivity of this reaction is rather low: the enantiomeric excess of *cis*-**169** in the reaction catalysed by (*R*)-**167** is 57%, while *ee* of *trans*-**169** in the presence of catalysts **168a** and **168b** are 8% and 19%, respectively.





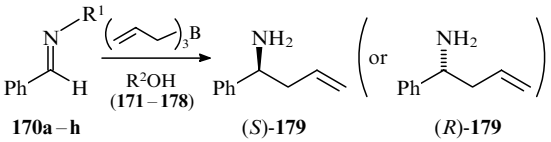
R^1 = Ph, R^2 = Me (**168a**);
R^1 = Bu^t, R^2 = H (**168b**).

The catalysis of the Diels–Alder reaction by 1,3,2-oxazaborolidines covalently bound to a polymeric matrix is also possible.[231, 232]

5. Miscellaneous reactions

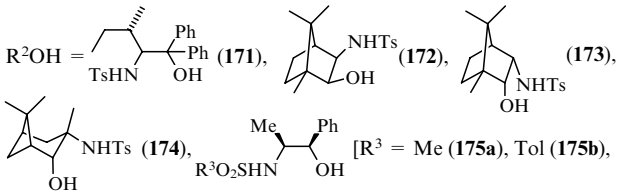
The asymmetric allylation of imines **170a**–**h** by triallylborane in the presence of chiral amino alcohols R^2OH (**171**–**178**) has been described by Itsuno *et al.*[233]

The yields of 1-phenylbut-3-enylamine (**179**) vary from 12% to 90%. Depending on the nature of the imine used, either the (*S*)- or the (*R*)-isomer **179** with *ee* 10%–72% is formed. The best yields of (*S*)-phenylbut-3-enylamine (**179**) (64%–93%, *ee* 78%–96%) were obtained if (1*R*,2*S*)-norephedrine derivatives

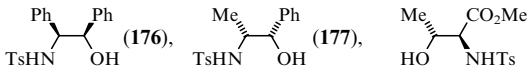


170a–**h** (*S*)-**179** (*R*)-**179**

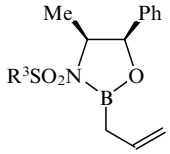
R^1 = *p*-MeOC$_6$H$_4$ (**170a**), Tr (**170b**), OMe (**170c**), OAc (**170d**), SPh (**170e**), Ts (**170f**), P(O)Ph$_2$ (**170g**), SiMe$_3$ (**170h**);



o-NO$_2$C$_6$H$_4$ (**175c**), 1-naphthyl (**175d**), 2-naphthyl (**175e**)],

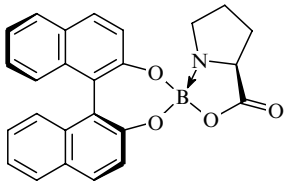


175a–**d** were used as catalysts. In the authors' opinion, this reaction occurs *via* the intermediate 2-allyloxazaborolidines of the type **180**.

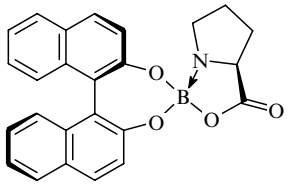


180

The chelate compounds **181** and **182** based on borates incorporating (*S*)-Pro were used for effective resolution of racemic 1,1′-bi-2-naphthol into enantiomers.[234]



181



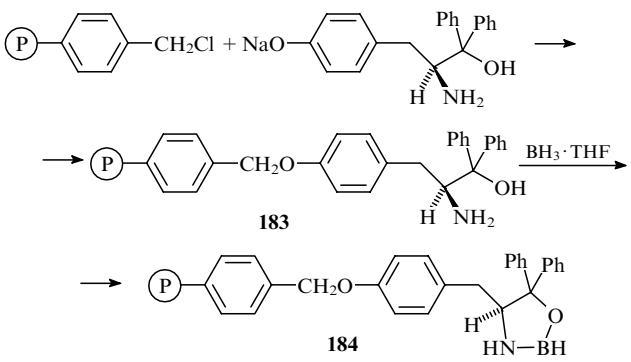
182

The use of oxazaborolidines for enantiomeric cleavage of epoxides by amines has been described.[235]

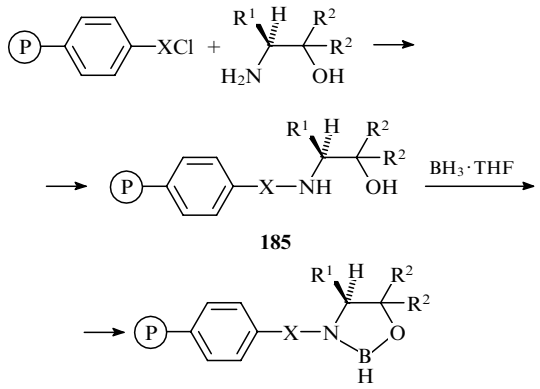
V. Reduction by immobilised 1,3,2-oxazaborolidines

Immobilised (polymer-bound or solid-phase) catalysts have a number of advantages over homogeneous catalysts, *e.g.*, they are easily separated from the reaction mass and can be used repeatedly.[158]

Several approaches to the synthesis of immobilised oxazaborolidines are known. First, the reaction of chloromethylated cross-linked polystyrene with amino alcohols containing phenol-type linkers (particularly, with tyrosine derivatives [156, 231, 236, 237]) yields the immobilised amino alcohol **183**, its reaction with $BH_3 \cdot THF$ affords the immobilised oxazaborolidine **184**.



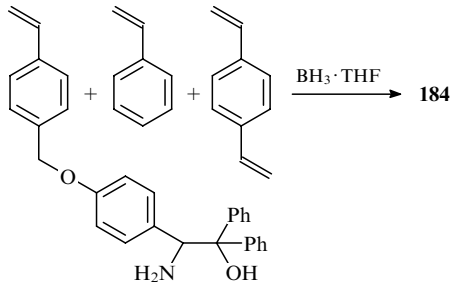
Second is *N*-alkylation or *N*-acylation of chiral amino alcohols by a reactive polymeric reagent with subsequent reaction of the intermediate **185** formed with $BH_3 \cdot THF$.[231, 232, 237–241]



185

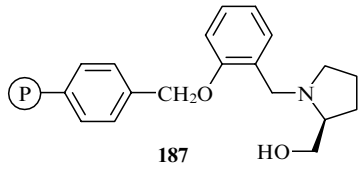
X = CH_2, SO_2; R^1 = Alk; R^2 = H, Alk, Ar.

The third approach entails suspension radical copolymerisation of the chiral monomer **186**, containing an amino alcohol fragment with styrene and divinylbenzene[156, 231, 242–244] in the presence of $BH_3 \cdot THF$.



186

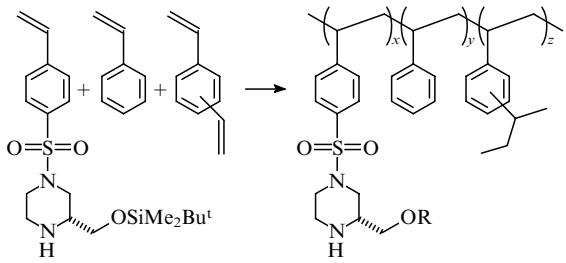
The enantiomeric excess in the reduction of butyrophenone by $BH_3 \cdot THF$ to (*R*)-1-phenylbutan-1-ol in the presence of the system **183** was 88%. The best results (*ee* 92% – 97%) were achieved in the reduction of acetophenone in the presence of the catalyst **187**.[156]



187

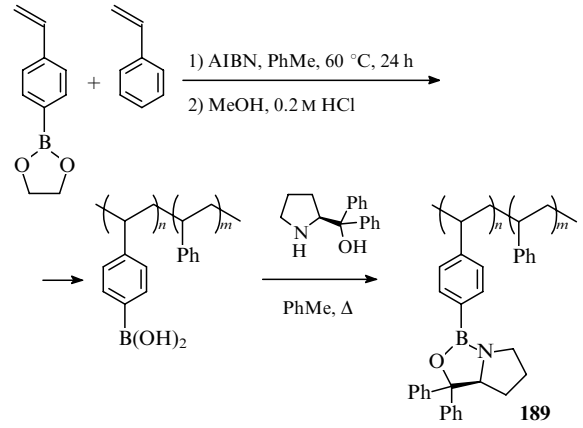
The immobilised reagent **184** was also used in the reduction of ketoxime ethers;[156] however, in this case the optical yields did not exceed 26%. The addition of Lewis acids ($AlCl_3$, $ZnCl_2$, $BF_3 \cdot OEt_2$) accelerated the reduction and increased the optical yields to 42% – 67%.[158]

Later,[158] a copolymer of a chiral monomer **188** with styrene and divinylbenzene was synthesised. With the molar content of the chiral ligand of 20% and of divinylbenzene of 10% (or 2%) (the degree of cross-linking), this compound catalysed the asymmetric reduction of acetophenone *O*-methyloxime to (*R*)-2-phenylethylamine by $BH_3 \cdot THF$ in 60% (or 65%) yield and *ee* 82% (or 96%). Repeated (5 times) use of the catalyst is possible without any loss of stereoselectivity (*ee* ~ 95%) for the divinylbenzene content of 2%.



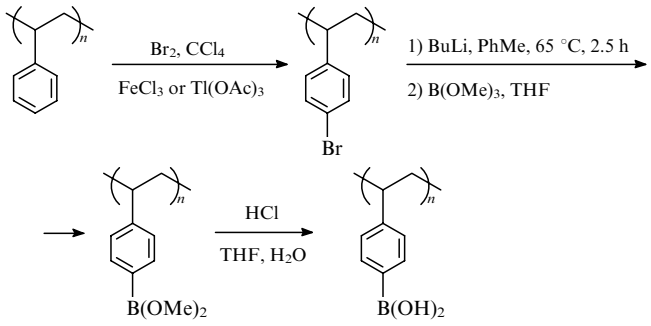
188 (R = $SiMe_2Bu^t$, H)

Immobilised 1,3,2-oxazaborolidines **189** can also be prepared from immobilised boronic acid.[237, 245–247]



AIBN is azobisisobutyronitrile.

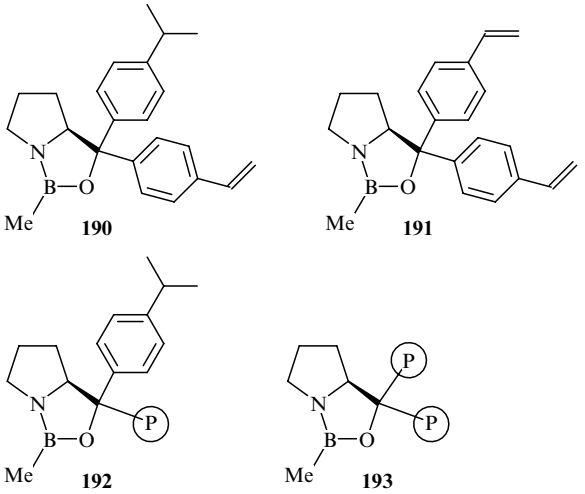
The boronic acid residue can be introduced into polystyrene using the following reaction sequence:[245–247]



Copolymerisation of a mixture of 2-vinylthiophene, styrene and *p*-divinylbenzene is also used for the synthesis of immobilised boronic acid.[247, 248] The resulting thiophene-containing polymer reacts smoothly with n-butyllithium to give the corresponding thiophene-lithiated product, which makes the bromination step unnecessary and increases the final yield of the catalyst. Subsequent synthesis of the polymer containing oxazaborolidine groups can be carried out *in situ* using the system $NaBH_4$ – Me_3SiCl (or $BF_3 \cdot OEt_2$).[239] Reduction of ketones in the presence of this catalytic system is carried out in THF[239–241, 247] or in toluene[241] (the optimum temperatures are 60 – 110 °C, the amount of the catalyst is 0.1 – 0.2 equiv. per equiv. of the substrate; the yields of the secondary alcohols are 87% – 98%, the optical purity is 86% – 96%).[240, 249] The reduction by heterogeneous polymeric catalysts is usually carried out in flow reactors; otherwise, the separation of the catalyst by filtration is necessary. Repeated use[250] and fivefold regeneration[241] of the catalyst with an insignificant (up to 5% *ee*) loss of enantioselectivity are possible.

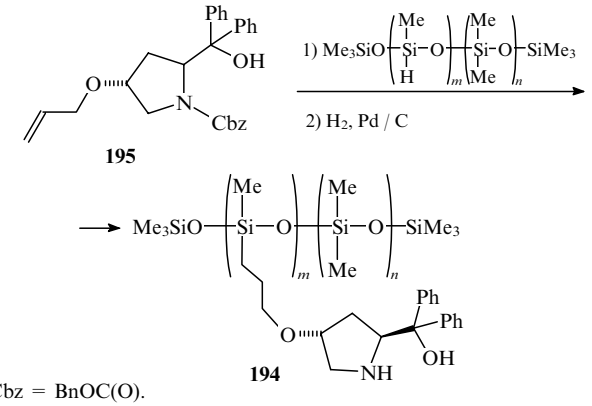
The synthesis of immobilised 1,3,2-oxazaborolidines by copolymerisation of compounds **190** or **191** with styrene and

p-divinylbenzene resulting in the polymeric catalysts **192** and **193** has recently been described.[249] The reduction of acetophenone by the $BH_3 \cdot THF$ complex in the presence of the catalyst **193** gave (*R*)-1-phenylethanol in 100% yield and with *ee* 84.8%, whereas the reduction of pinacoline affords the (*R*)-isomer of the corresponding secondary alcohol with *ee* 88.4%.



190 **191** **192** **193**

These data suggest that in some cases heterogeneous polymer-bound 1,3,2-oxazaborolidines compare well with homogeneous catalysts in efficiency.[240,245] It should be noted, however, that high values of *ee* were obtained only for polymers with a low (up to 2%) degree of cross-linking, *i.e.*, with low mechanical stability, which limits their industrial application.[238,241] An increase in the extent of cross-links hampers the diffusion of the substrate and the reducing agent within the polymer and thus increases the contribution of competitive non-catalytic reduction of the substrate and decreases its enantioselectivity.[245] This may account for the low selectivity of the reduction carried out in the presence of heterogeneous catalysts prepared by suspension copolymerisation.[245] This has prompted an idea to use homogeneous microgels soluble in organic solvents (THF, toluene) as carriers for oxazaborolidines.[237,245,251,252] To this end, the polymer **194** was prepared, which can be converted *in situ* into homogeneous immobilised oxazaborolidine manifesting a strong catalytic effect. The polymer **194** is formed upon palladium-catalysed hydrosilylation of the allyloxyprolinol derivative (2*S*,4*R*)-**195** by a copolymer of methylhydrosiloxane with dimethylsiloxane. In the presence of this catalyst, aromatic ketones are reduced to secondary alcohols with *ee* 89% – 98% (yields 83% – 89%).[251]



195 **194**

Cbz = BnOC(O).

Reaction products are separated from polymeric catalysts by nanofiltration in a membrane reactor.[237,252] Since the conversion of the ketone reaches ~ 100%, the solvent is distilled off at the outlet of the reactor; the reaction products are isolated by vacuum distillation.[252] The catalyst remains in the reactor and can be used in the next conversion cycle.

The preparation of a homogeneous polymeric microgel, which contains an oxazaborolidine fragment based on cheap (*S*)-diphenylalaninol, is a remarkable achievement of the Wulff group.[245] The radical polymerisation was carried out in strongly dilute solutions to prevent macrogel formation; ethylene dimethacrylate was used as a cross-linking agent. The reduction of aromatic ketones in the presence of this catalyst gives alcohols with *ee* 87% – 94%.[245] The weak spot of the given technology is the low activity of the microgels prepared using this method [the number of moles of the product per mole of the catalyst (turnover number) is 10 – 50]. The Kragl group[237] have succeeded in increasing the turnover number of the catalyst to 560. Later, the productivity of the membrane reactor was increased to 1.4 kg litre^{-1} day^{-1}; the deactivation rate of the catalyst was 1.8% per hour.[252] The efficiency of this catalytic system can be judged from the fact that the efficiency of enzymatic reduction of the same ketones by alcohol dehydrogenase is significantly lower (88 g litre^{-1} day^{-1}), which is attributed to low solubility of the enzyme in water.[252] On the whole, the use of homogeneous microgels in asymmetric catalysis is becoming more and more popular; considerable progress in this area should be expected in the near future.

A heterogeneous catalyst based on nickel boride nanoparticles coated with oxazaborolidine has been developed[253] aimed at combination of the advantages of a heterogeneous (easy separation of the catalyst) and homogeneous (high efficiency) catalysis. The catalyst with the formula $NiB_{2-0.1}$ (oxazaborolidine)$_{0.1}$ was synthesised *in situ* from (1*S*,2*R*)-(+)-2-amino-1,2-diphenylethanol or (1*R*,2*S*)-(−)-norephedrine and nickel salts $NiI_2 \cdot 6\ H_2O$ or $NiCl_2 \cdot 6\ H_2O$. This catalyst reduces acetophenone rapidly and with high enantioselectivity (*ee* of the alcohol is 90%) and can be used repeatedly. To ensure good selectivity, the ketone should be added to a catalyst – $BH_3 \cdot THF$ mixture at a very slow rate.

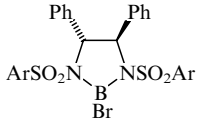
Catalytic reduction of aromatic ketones by the complex $BH_3 \cdot SMe_2$ in the presence of 0.1 equiv. of a chiral dendrimer based on 3,5-dihydroxybenzyl alcohol or 4,4-bis(4-hydroxyphenyl)pentanol with (*S*)-2-amino-3-(4-hydroxyphenyl)-1,1-diphenylpropan-1-ol linked through the phenolic group has been described.[254] The yields of the alcohols are 75% – 82%, *ee* is 82% – 96%. Homogeneous dendrimeric catalysts seem promising, since their application gives higher values of *ee* than the heterogeneous polymeric systems.[254]

The use of immobilised catalysts of the type **187** in enantioselective Diels – Alder reactions,[231,232] aldol condensation[242] and for addition of diethylzinc to aldehydes has been described.[247]

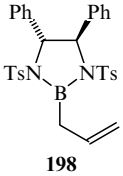
VI. 1,3,2-Oxazaborolidine analogues

1. 1,3,2-Diazaborolidines

1,3,2-Oxazaborolidine analogues, particularly diazaborolidines **196** – **198** recommended by Corey,[255,256] are widely used in asymmetric synthesis.



196, **197**

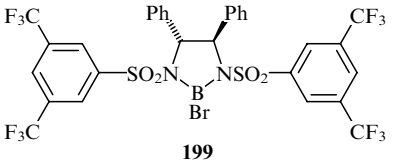


198

Ar = *p*-MeC_6H_4 (**196**), *p*-$NO_2C_6H_4$ (**197**)

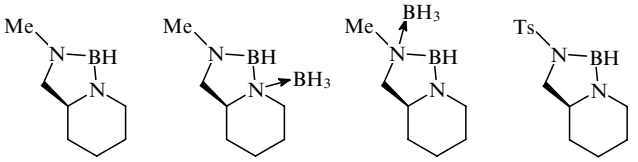
Compounds **196** and **197** catalyse stereoselective aldol condensation,[255] whereas compound **198** is a highly efficient enantioselective allylating reagent for the synthesis of chiral allylic alcohols with *ee* > 90%.[256]

It is known that the introduction of a trifluoromethyl group into the aromatic ring of the arylsulfonyl residue increases the Lewis acidity of the boron atom. This fact was used in the design of an effective catalyst of aldol condensation, **199**. Corey *et al.* used compound **199** for the enantioselective synthesis of aldehydes [257, 258] and D-*threo*-*N*-acetylsphingosine.[259]



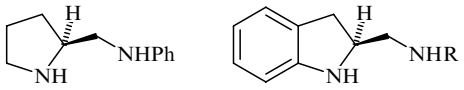
199

1,3,2-Diazaborolidine **200** was recommended as a catalyst for enantioselective reduction of prochiral ketones by boranes,[260] however, the *ee* in the reduction of acetophenone was low (40%). Two types of complexes of compound **200** with borane, *viz.*, **201a** and **201b**, were detected in THF by ^{11}B NMR spectroscopy; their competition accounts for low optical yields of the alcohol in this reaction. The use of compound **202** as a catalyst with a tosyl group at the nitrogen atom has made it possible to increase the enantioselectivity [the yield of (*S*)-1-phenylethanol was 95%, *ee* was 72%].



200 **201a** **201b** **202**

Chiral diamines **203**–**205** were recommended as an alternative to amino alcohols in the enantioselective reduction of prochiral ketones.[261]

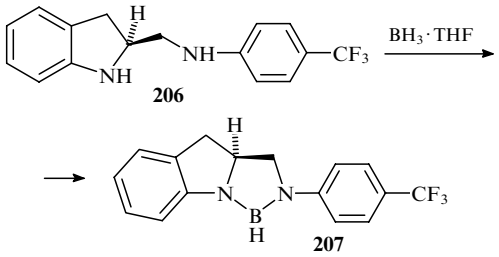


203 **204**, **205**

R = Ph (**204**), cyclo-C_6H_{11} (**205**).

Compound **204** appeared to be the most efficient of them.

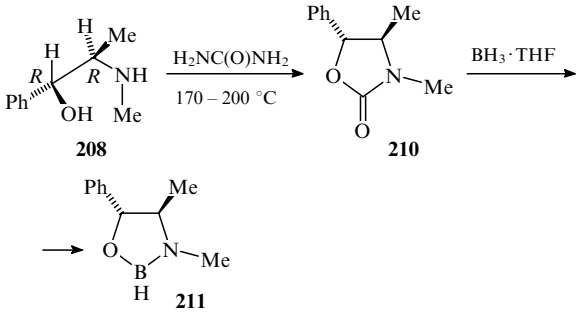
The introduction of electron-withdrawing groups (*e.g.*, CF_3) into the aromatic ring has led to more efficient catalysts; of those, compound **206** appeared to be the best in the reduction of acetophenone [the yield of (*S*)-1-phenylethanol was 88%, *ee* was 92%].



206 **207**

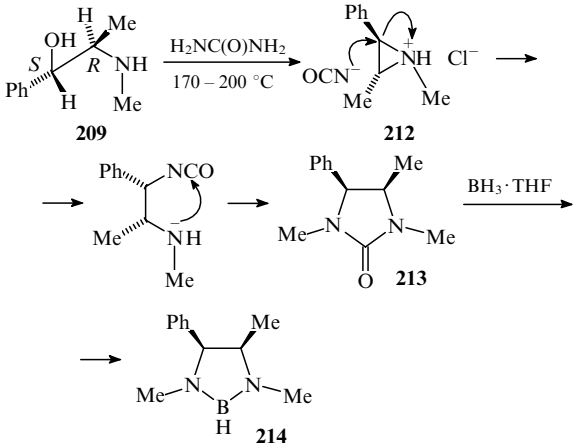
This reduction was carried out in THF at −15 °C in the presence of 0.15 equiv. of the chiral diamine and 1 equiv. of $BH_3 \cdot THF$, the reaction time was 2 h. This reaction is believed to proceed *via* 1,3,2-diazaborolidine **207** formed *in situ*. Other aromatic ketones were reduced in 88%–96% yields and with *ee* 82%–92%.[261] Thus, the electron-withdrawing groups increase the acidity of the boron atom, which results in its better coordination to the ketone carbonyl and, as a consequence, increases the optical yield of the final product.

Synthesis of heteroborolidines from pseudoephedrine (**208**) and ephedrine (**209**) has been described.[262–264] It was found that pseudoephedrine reacts with urea to give oxazolidinone **210**, which is converted into 1,3,2-oxazaborolidine **211** upon subsequent treatment with borane (this reaction is yet another method for the synthesis of 1,3,2-oxazaborolidines).



208 **210** **211**

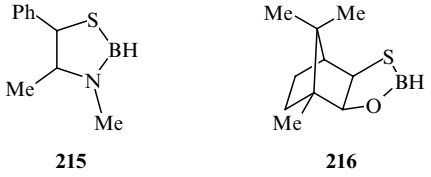
Ephedrine reacts with urea in a different way. Intramolecular cyclisation of ephedrine **209** and subsequent nucleophilic attack by the cyanate ion formed from urea at 170–200 °C on the intermediate **212** gives *cis*-imidazolidinone **213** which yields 1,3,2-diazaborolidine **214** after reduction with borane.[262] The stereochemistry of compounds **212** and **214** was established by heteronuclear $^1H/^{13}C$ NMR and that of compound **213**, by X-ray diffraction analysis.



209 **212** **213** **214**

2. 1,3,2-Oxathia- and 1,3,2-azathiaborolidines

1,3,2-Azathiaborolidines (*e.g.*, **215**) [263, 264] and 1,3,2-oxathiaborolidines (*e.g.*, **216**) can be used, along with 1,3,2-oxazaborolidines, as catalysts in enantioselective ketone reduction reactions.[265, 266] 1,3,2-Azathiaborolidine **215** was synthesised from pseudoephedrine.[263, 264]



215 **216**

Compound **216** catalyses the reduction of acetophenone by the complex $BH_3 \cdot SMe_2$ to (*S*)-1-phenylethanol with *ee* 92%.

* * *

The present review demonstrates that chiral 1,3,2-oxazaborolidines occupy a prominent place in the arsenal of modern reagents for asymmetric synthesis owing to their high efficiency in enantioselective reduction of prochiral ketones, imines and oxime ethers. Being representatives of chiral Lewis acids, 1,3,2-oxazaborolidines can also be used as effective catalysts in stereoselective Diels–Alder reactions, aldol condensation, cleavage of acetals and atroposelective resolution of spatially hindered lactones. This trend has been developing especially intensively in the past decade and entails a search for novel highly efficient catalysts, their application in the production of enantiomerically pure drugs, their modification by immobilisation on polymers and dendrimers and broadening of the range of reactions catalysed by them.

Abstract. The key methods for the synthesis of the acids HOF, HOCl, HOBr and HOI are considered. The results of investigations of the structures and properties of these acids are described. Possible participation of the HOHal acids in the destruction of stratospheric ozone is discussed. The bibliography includes 207 references.

I. Introduction

The aim of this review is to characterise a group of relatively little-known triatomic compounds of general formula HOHal belonging to the group of oxy acids of halogens. There are several types of oxy acids of halogens; however, only the triatomic acids HOHal are known for all halogens including fluorine, which forms hypofluorous acid. It is customary to use the suffix 'vatistaya' when naming the HOHal acids in the chemical literature written in Russian; its English equivalent is the suffix 'ous', which is used throughout the text of the review. Sometimes the compounds in question are called halogen hydroxides.

All the HOHal acids are unstable. They display a powerful oxidising action. The 'eldest' is hypochlorous acid, HOCl, whose salts have been known since the late 18th or early 19th century ('eau de Javelle', 'eau de Labarraque'). Salts of hypochlorous acid, *e.g.*, bleaching powder, calcium hypochlorite and sodium hypochlorite have found wide applications in the home and in industry as oxidants, bleaching agents, degassing agents and disinfectants. The chemistry of aqueous solutions of hypochlorous acid and its salts had been well studied by the mid-twentieth century. The acids of general formula HOHal have attracted considerable attention since the synthesis of hypofluorous acid and mainly in connection with the development of atmospheric chemistry. Possible involvement of halogen-containing small molecules† in the catalytic cycles of destruction of stratospheric ozone gave an impetus to investigations on the spectroscopic characteristics, photochemistry and reactivity (in particular, under conditions that simulate stratospheric conditions) of these species. Studies on the properties of hypofluorous acid and other hypohalous acids HOHal have also been reported. These new data are complementary to scarce information on these acids available from books on inorganic chemistry and handbooks.

II. Hypofluorous acid

Hypofluorous acid has long been considered a 'non-existent' compound [2] though its synthesis does not require hard-to-access starting compounds or unusual equipment.

Production of hypofluorous acid in the form of a complex with HF in the course of photolysis of a mixture of H_2O with F_2 in a low-temperature nitrogen matrix at 14 and 20 K was detected by IR spectroscopy in 1968.[3] The first synthesis of HOF was reported in 1971.[4]

HOF is synthesised from gaseous fluorine and liquid water or ice by bubbling fluorine through water one time at 223 – 233 K. Sometimes the reaction of fluorine with water is carried out in a recirculating system.

$$F_2 + H_2O \longrightarrow HOF + HF.$$

In spite of low reaction rate and low yield of HOF, the amount of the acid thus obtained can vary from several tens to several hundreds of milligrams.[2] The by-products of the reaction are oxygen difluoride, OF_2, and oxygen. It was assumed [5,6] that oxygen difluoride is produced in the reaction

$$F_2 + HOF \longrightarrow OF_2 + HF.$$

Later on, this assumption was confirmed experimentally. Using tracers (^{18}O and ^{18}F), it was shown that the OF_2 molecule contains one fluorine atom from the hypofluorous acid molecule and one fluorine atom from the F_2 molecule.[7] The reaction of fluorine with D_2O gave deuterated hypofluorous acid.

Noteworthy is that oxygen difluoride is not an anhydride of hypofluorous acid (no acid is produced upon dissolution of this compound in water). This differentiates OF_2 from dichlorine monoxide which gives hypochlorous acid upon dissolution in water.

Photolysis of a mixture of H_2O with F_2 in argon matrix produces HOF in the form of a complex with HF.[3] A thorough study of photolysis of $H_2O - F_2$ mixtures in solid argon at 12 K revealed the formation of complexes HF – HOF, FH – FOH and FH – OHF, the first-mentioned complex being the most stable.[8]

† The review [1] concerns tetraatomic compounds of halogens Hal_2O_2, which are of interest for atmospheric chemistry.

Hypofluorous acid is stable at the boiling temperature of liquid nitrogen but decomposes into HF and O_2 (sometimes, explosively) on heating. The half-life of HOF is $\sim$30 min at room temperature;[2] however, it increases to $\sim$3 h in a passivated IR spectroscopic cell.[9] The melting temperature of HOF is 156 K while its boiling temperature is somewhat lower than room temperature. The vapour pressure of HOF is at most 1 Torr at 194 K and nearly 5 Torr at 209 K (more accurate vapour pressure measurements are impossible because of the decomposition of the acid).[4]

The HOF molecule is a slightly asymmetrical prolate rotor characterised by the rotational constants $A_0 = 585\,628.93$, $B_0 = 26\,757.53$ and $C_0 = 25\,514.10$ MHz (see Refs 10, 11) and by the parameter $\kappa = 2[B-1/2(A+C)]/(A-C) = -0.9955$. The rotational constant values were repeatedly refined (see Refs 9, 12, 13). The rotational constants of the $H^{16}OF$ molecule are as follows: $A_e = 19.663796$, $B_e = 0.9003148$ and $C_e = 0.8608167$ cm^{-1}.[13]

An X-ray diffraction study [14] showed that the single crystal of HOF belongs to the orthorhombic crystal system. The lattice constants are $a = 4.075$, $b = 5.040$ and $c = 5.939$ Å; the space group is $P2_12_12_1$. The single crystal was grown by slow cooling of the HOF sample down to 113 K. Table 1 lists the experimental (obtained by X-ray analysis [14] and microwave spectroscopy [10, 11]) and calculated [15] bond lengths and bond angles in the HOF molecule.

Table 1. Bond lengths and bond angles in the HOF molecule.

[a] *Ab initio* calculations using the Triple-Zeta-Plus-Polarisation Coupled Cluster Method with Single and Double Excitations.

The HOF molecule has a large dipole moment, $\mu_{exp} = 2.23 \pm 0.10$ D.[16] *Ab initio* calculations gave the values of 2.18 D (see Ref. 17) and 2.032–2.182 D (see Ref. 15).

Hypofluorous acid forms no associates in the gas phase (at least at pressures below 160 Torr) [18] but undergoes association in the condensed phase. Initially, it was hypothesised [18, 19] that the HOF molecules are linked together through O–H...F bridges; however, this assumption was rejected.[20] Taking into account the fact that the oxygen atom in the HOF molecule bears a larger negative charge compared to the fluorine atom owing to withdrawal of the electron density from the hydrogen atom, one could expect the formation of O–H...O bridges. It was reported [20] that in self-association of hypofluorous acid involving O–H...O bridges the HOF molecules form zig-zag chains or large cycles, $(HOF)_n$.[20] An X-ray diffraction study [14] confirmed the presence of nearly linear bridges O–H...O [O–H...O 163°, r(H...O) = 2.895 Å] in the single crystal of HOF (Fig. 1).

An IR spectroscopic study of photochemical reactions of hypofluorous acid in low-temperature matrices revealed the formation of dimers, $(HOF)_2$, and, probably, other oligomers of HOF.[21] It was concluded [21] that the HOF molecules form dimers $(HOF)_2$ linked through the O–H...O bridge (acyclic dimer). *Ab initio* calculations [22] showed that the O–H...O bridge in the dimer is stronger than the O–H...F bridge. Other *ab initio* calculations [23] revealed two stable $(HOF)_2$ structures differing in orientation of the constituent HOF molecules, namely, a linear structure of C_1 symmetry (molecules are linked together through both O–H...O and O–H...F bridges) and a cyclic structure of C_2 symmetry (here, molecules form dimers involving two O–H...F bridges). The linear structure is more stable, though the energy of the cyclic structure is only 0.35 kcal mol^{-1} higher.

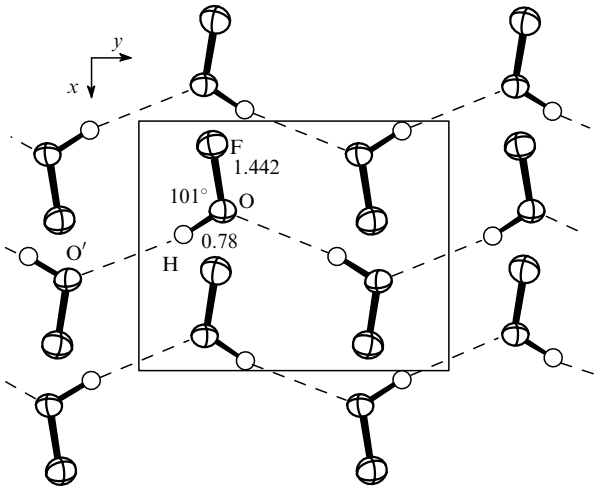

Figure 1. Crystal structure of HOF.[14]

The vibrational spectrum of HOF molecules has been thoroughly studied [9, 13, 18, 19, 21, 24, 25] (see Table 2).

Gaseous hypofluorous acid is characterised by intense absorption in the region $\lambda < 300$ nm; no pronounced absorption maximum is observed.[21] According to calculations,[26] the absorption spectrum of HOF exhibits two maxima, one in the region $\lambda < 200$ nm and the other in the region $\lambda > 200$ nm.

The ^1H and ^{19}F NMR spectra of hypofluorous acid were recorded [27] shortly after the pioneering synthetic study. The chemical shift of the F atom is 403 ppm (171 K) or 402 ppm (193 K) relative to gaseous fluorine at 298 K. The proton chemical shift is −16.0 ppm (193 K) or −12.1 ppm (293 K) relative to gaseous methane at 298 K. Fast proton exchange between HOF and HF present in the sample was demonstrated for the liquid phase.

The mass spectrum of HOF exhibits a peak of a molecular ion.[4] Photoionisation of hypofluorous acid at $\lambda = 77.5$ nm produces HOF^+, OH^+ and O^+ ions with the relative intensities of 100, 37 and 44 arbitrary units, respectively.[28] The first ionisation potential of the HOF molecule is 12.71 ± 0.01 eV [28] and nearly coincides with the adiabatic ionisation potential (12.69 ± 0.03 eV) determined from the HeI photoelectron spectrum of hypofluorous acid.[29] GAUSSIAN-2 (G2)‡ calculations [30] of the adiabatic ionisation energy of HOF gave a value of 12.71 eV.

The enthalpy of formation of hypofluorous acid determined in the study on photoionisation of HOF is -22.8 ± 1 (0 K) or -23.5 ± 1 kcal mol^{-1} (298 K).[28] A more accurate value is $\Delta H^\circ(HOF) = -19.9$ kcal mol^{-1} (0 K);[32] however, it was refined [33] and a new value of −19.5 kcal mol^{-1} (0 K) was reported. The results of some calculations very closely approach the experimental value of the enthalpy of formation of HOF (Table 3).

The adiabatic bond dissociation energy, $D_0(HO-F)$, of HO–F (50.4 kcal mol^{-1}) [28] was then recalculated. The refined $D_0(HO-F)$ value is 47.5 kcal mol^{-1} (see Ref. 32). Table 3 lists the bond dissociation energies reported in different studies. The atomisation energy of HOF obtained from G2 calculations [31] is 149.7 kcal mol^{-1}.

Proton affinity calculations for the HOF molecule were carried out for protonation at the O atom and at the F atom [routes (1) and (2), respectively].

$$HOF + H^+ \longrightarrow H_2OF^+ \quad (1)$$

‡ For G2 calculations, see Ref. 31.

and

$$HOF + H^+ \longrightarrow HOFH^+. \quad (2)$$

The former process was found to be preferred (Table 4).[30, 36–39] The O–F interatomic distance in the $HOFH^+$ and H_2OF^+ molecules is respectively longer and shorter than in the HOF molecule.[30, 36] According to G2 calculations, protonation of HOF at the oxygen atom is 18 kcal mol^{-1} more energetically favourable than protonation at the F atom.[34] (Protonation of other HOHal acids at the oxygen atom is also more energetically favourable.[30])

The possibility of using hypofluorous acid as the starting reagent in the synthesis of other compounds was studied by Appelman and co-workers.[2, 5, 6, 40–42] shortly after the synthesis of HOF. Hypofluorous acid appeared to be an excellent donor of oxygen atoms; however, the short lifetime of HOF at temperatures close to room temperature hampers the wide use of this compound.

[a] *Ab initio* density functional calculations with the Perdew–Wang functional (PW91).

Photolysis of HOF in low-temperature matrices is thought to proceed as concerted elimination of HF to produce O(^{1}D) or O(^{3}P).[21]

$$HOF \xrightarrow{h\nu} O + HF.$$

In the case of non-inert matrices, the oxygen atoms enter in the reaction with the matrix molecules or with the dopant. For instance, photolysis of HOF in argon matrices doped with PF_3, AsF_3 or H_2O produces OPF_3, $OAsF_3$ or H_2O_2, respectively.

The possibility of using hypofluorous acid as oxidant has been thoroughly studied by Rozen and co-workers.[43–58] It was found that bubbling gaseous fluorine diluted with N_2 through a vigorously stirring mixture of acetonitrile with distilled water (usually, 10 : 1 or 20 : 1 by volume) at 263 or 258 K results in an oxidising solution with the oxidant concentration exceeding 1 mol litre^{-1}. Shortly after, it was established that the active component is the complex MeCN · HOF. The half-life of this complex is longer than 10 h at 273 K or 3 to 4 h at room temperature. This indicates that acetonitrile stabilises hypofluorous acid formed in the reaction of fluorine with water (HOF retains its oxidising properties).

^{19}F NMR and IR spectroscopies confirmed that HOF and acetonitrile form a rather stable 1 : 1 complex.[59] An X-ray diffraction study[60] of the complex MeCN · HOF carried out at 143 K revealed that the HOF and MeCN molecules are linked *via* a linear hydrogen bridge, O–H...N, 2.81 Å long (interatomic distance H...N is 1.71 Å).

Reactions involving the complex MeCN · HOF proceed under mild conditions at temperatures between 273 K and room temperature. A feature of these processes is their high rates (the reactions are completed in a few seconds to several minutes). In many cases, the product yields are as high as 90% to 100%. Often, compounds obtained using this complex cannot be synthesised by other methods.[54] Hydrogen fluoride formed as a by-product can be readily neutralised with calcium hydroxide.[56]

Complex MeCN · HOF is used for fast and efficient epoxidation of various olefins.[43, 45, 47, 49] The time taken to convert cyclooctene into epoxycyclooctane by the reaction with the complex MeCN · HOF at 273 K is shorter than 1 min; this also holds for the epoxidation of *trans*-stilbene.[45] Epoxidation of $C_4F_9CH=CH_2$ proceeds at a lower rate while sterically hindered $C_4F_9CH=CHC_4F_9$ does not enter into reaction.[47] Since the oxygen atom of the oxirane ring is supplied by the HOF molecule, it is possible to obtain epoxides containing tracers (^{17}O or ^{18}O isotopes) when using labelled water to synthesise HOF. This method allows the oxygen isotopes to be introduced into other compounds.[44–46, 48]

Reactions of anthracene and phenanthrene with MeCN · HOF produce quinones,[50] while pyrene, 2-acetylphenanthrene and 9-acetylphenanthrene are converted into epoxides.[57] Complex MeCN · HOF is used for the oxidation of aromatic amines[46] and aliphatic amines[48] to corresponding nitro compounds and for the oxidation of amino acid esters into nitrate esters.[51] The oxidation of AlkOMe ethers involves elimination of methanol, the ethers

with Alk = n-C_nH_{2n+1} being oxidised to acids (*via* aldehydes) while those with Alk = *sec*-C_nH_{2n+1} are oxidised to ketones and lactones.[54]

MeCN·HOF readily oxidises both aliphatic and aromatic sulfides to sulfones.[56] The reactions proceed at 198 K and involve an intermediate formation of sulfoxides that can be isolated in high yields.[56] Under these conditions, thiophenes are converted into corresponding *S*-dioxides.[52]

Thus, the complex MeCN·HOF is an efficient oxygen transfer agent. The oxidation reactions with participation of this complex proceed under mild conditions and in some cases at very high rates. The complex offers yet another remarkable advantage as a reactant, namely, no isolation, purification or other specific operations are needed when using it.

III. Hypochlorous acid

Traditionally, hypochlorous acid is synthesised by the reaction of chlorine with an aqueous suspension of yellow (red) mercury oxide or with moist mercury oxide powder.

$$HgO + 2Cl_2 + H_2O \longrightarrow 2HOCl + HgCl_2.$$

Hydrochloric acid formed in the reaction of chlorine with water (for the kinetics of hydrolysis of chlorine, see Ref. 61) reacts with mercury oxide, thus shifting the equilibrium in the reaction (3) to the right and giving an aqueous hypochlorous acid solution.

$$Cl_2 + H_2O \rightleftharpoons HOCl + HCl, \qquad (3, -3)$$

$$HgO + 2HCl \longrightarrow HgCl_2 + H_2O.$$

The reaction of chlorine with mercury oxide in the absence of water is known as a method for the synthesis of dichlorine monoxide. An approximate reaction equation has the form

$$2Cl_2 + HgO \longrightarrow Cl_2O + HgCl_2.$$

Being an anhydride of hypochlorous acid, Cl_2O is readily soluble in water, thus producing HOCl.

$$Cl_2O + H_2O \rightleftharpoons 2HOCl. \qquad (4, -4)$$

At room temperature, the equilibrium mixture $H_2O-Cl_2O-HOCl$ is stable over a period of a few hours.[62, 63] The equilibrium constant for the gas-phase reaction (4, −4) of hydrolysis of Cl_2O at room temperature ($K = 0.25$) calculated [62] in a study of the UV spectrum of HOCl appeared to be overestimated as compared to the results obtained in more recent studies.[63–66]

T/K	K	Method	Ref.
298	0.25	UV	62
298	0.082	UV	63
295 ± 3	0.068	IR	64
298	0.092 ± 0.011	LPMS-DFS [a]	65
298	0.10 ± 0.01	UV	66

[a] LPMS-DFS stands for Low-Pressure Mass Spectrometry–Discharge Flow System.

Hypochlorous acid is also synthesised by the reaction of aqueous sodium hypochlorite solution with aqueous solutions of magnesium sulfate heptahydrate or anhydrous $MgSO_4$.[67–70]

The acid HOCl was obtained in the reaction of hydrogen chloride with calcium hypochlorite powder.[71] The interaction between hydrogen fluoride diluted with N_2 and calcium hypochlorite powder also results in hypochlorous acid.[72, 73]

$$2HF + Ca(OCl)_2 \longrightarrow 2HOCl + CaF_2.$$

Gaseous HOCl is obtained by bubbling gaseous chlorine diluted with helium through an aqueous suspension of $CaCO_3$ (see Ref. 65).

$$2Cl_2 + H_2O + CaCO_3 \longrightarrow 2HOCl + CO_2 + CaCl_2.$$

The acid thus formed is immediately converted to the gas phase to prevent its decomposition into Cl_2O and H_2O. Sodium hydrocarbonate can be used instead of calcium carbonate; in this case, the reaction proceeds at a higher rate.[74]

The reaction of chlorine with concentrated hydrogen peroxide solution in alkali medium produces excited dioxygen in 100% yield.[75–77]

$$Cl_2 + H_2O_2 + 2OH^- \longrightarrow O_2(^1\Delta) + 2H_2O + 2Cl^-.$$

The main goal of investigations on the properties of HOHal acids carried out in the last decades is to study the behaviour of these compounds in the Earth's atmosphere and to establish their role in the destruction of stratospheric ozone.

Formation and decomposition reactions of HOCl in the stratosphere have been the subject of scientific research since the 1980s. Most studies are concerned with the radical–radical reaction $ClO^{\bullet} + HO_2^{\bullet}$ and with hydrolysis of chlorine nitrate because both processes can produce HOCl.

Tentatively, a bimolecular reaction $ClO^{\bullet} + HO_2^{\bullet}$ results in the following products:[78, 79]

Reaction	Products	ΔH(298 K) /kcal mol^{-1}	Reaction channel
$ClO^{\bullet} + HO_2^{\bullet}$	$HOCl + O_2$	−46	(*a*)
	$HCl + O_3$	−15	(*b*)
	$ClOO^{\bullet} + OH^{\bullet}$	+2.9	(*c*)
	$OClO^{\bullet} + OH^{\bullet}$	+6.0	
	$HClO + O_2$	+17	

Hypochlorous acid is formed following route (*a*). At 210–300 K, the contribution of this channel to the overall reaction exceeds 95% while that of channel (*b*) is only 5 ± 2%.[79] Quantum-chemical calculations [80] also showed that route (*a*) is the most energetically favourable and that channel (*b*) is impracticable.§ The probability of a weakly endothermic reaction (*c*) is also low.

Hypochlorous acid is formed as a result of the reaction of radical $ClO^{\bullet}$ with the hydrogen atom of the radical $HO_2^{\bullet}$ and in a more complex way *via* decomposition of the cyclic intermediate OClOOH produced upon the attack of the Cl atom of the radical $ClO^{\bullet}$ on the terminal oxygen atom of the $HO_2^{\bullet}$ radical (see Refs 78, 79, 82–86). The former mechanism dominates at $T > 370$ K while the latter governs the reaction at temperatures below 270 K. The fast reaction $ClO^{\bullet} + HO_2^{\bullet} \longrightarrow HOCl + O_2$ is characterised by a rate constant of $(4.5-6.5) \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} at 298 K.[78] Yet another estimate of the rate constant for this reaction is $(7.1 \pm 1.8) \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} at 294 K.[81]

Chlorine nitrate is inert towards ozone; however, hydrolysis of $ClONO_2$ and its interaction with HCl which proceed on the surface of aerosol particles are followed by the formation of catalytically active molecules HOCl and Cl_2.[87, 88]

$$ClONO_2 + H_2O \longrightarrow HOCl + HNO_3,$$

$$ClONO_2 + HCl \longrightarrow Cl_2 + HNO_3.$$

The reaction of gaseous chlorine nitrate with water is very slow.[89] At the same time, hydrolysis of $ClONO_2$ adsorbed on the surface of aerosol particles proceeds at a much higher rate. This reaction was studied by many authors (see, *e.g.*, Refs 71, 89–112). The reaction rate is affected by several factors, namely, temperature, aerosol particle size, surface structure, $ClONO_2 : H_2O$ ratio, presence of unbound water. In type-I polar stratospheric clouds containing mainly nitric acid trihydrate, hydrolysis of chlorine nitrate proceeds at a lower rate compared to the process in type-II clouds (hexagonal ice Ih).[90] However, this reaction proceeds rapidly in water-enriched type-I clouds.[107] Solvation of $ClONO_2$

§ The contribution of channel (*b*) to the overall reaction $ClO^{\bullet} + HO_2^{\bullet}$ is at most 1%.[81]

causes a substantial decrease in the activation energy for the hydrolysis reaction.[105, 107, 109, 110]

Using a tracer technique, it was shown that hydrolysis of $ClONO_2$ on ice ($H_2{}^{18}O$) produces $H^{18}OCl$ rather than $H^{18}ONO_2$.[98] The presence of the ^{18}O isotope in the hypochlorous acid molecule indicates cleavage of the $Cl-ONO_2$ bond in the chlorine nitrate molecule upon hydrolysis. The positively charged chlorine atom (+0.08) in the $ClONO_2$ molecule appears to be more accessible to the attacking oxygen atom of the water molecule (−0.36) than the positively charged N atom (+1.34) shielded by oxygen atoms.[106]

One would assume that nucleophilic attack of the water molecule results in a reactive intermediate, H_2OCl^+, which can be rapidly hydrolysed in a sufficient amount of water.[89, 97, 106]

$$H_2O + ClONO_2 \longrightarrow H_2OCl^+ + ONO_2^-,$$

$$H_2O + H_2OCl^+ \longrightarrow H_3O^+ + HOCl.$$

However, another mechanism of hydrolysis was found to be preferred.

$$ClONO_2 + 3H_2O \longrightarrow HOCl\cdot NO_3^-\cdot H_3O^+\cdot H_2O.$$

This mechanism is 10 to 14 kcal mol^{-1} more energetically favourable.[107, 111] An IR spectroscopic study of the products of hydrolysis of $ClONO_2$ also gave no proofs of the formation of H_2OCl^+ ion (see Ref. 111). Hydrolysis of $ClONO_2$ on ice proceeds efficiently at 75–140 K.[105] At temperatures below 155 K, hypochlorous acid thus obtained is adsorbed on the surface of ice and then goes to the gas phase at 155–185 K.[104, 108] The measured enthalpy of adsorption of HOCl on ice is -8.5 ± 2 kcal mol^{-1}, which is close to the published experimental and calculated values (see Ref. 69). The HOCl molecule forms a hydrogen bond with the water molecule, thus acting as a proton donor.[103, 113]

Hypochlorous acid is also formed in the reaction of hydroxyl radicals with chlorine or dichlorine monoxide.

$$^{\bullet}OH + Cl_2 \xrightarrow{a} HOCl + Cl^{\bullet}$$
$$^{\bullet}OH + Cl_2 \xrightarrow{b} HCl + ClO^{\bullet}$$

$$^{\bullet}OH + Cl_2O \longrightarrow HOCl + ClO^{\bullet}. \quad (5)$$

The reaction with chlorine almost exclusively follows route *a*.[114] The rate constant for the reaction is 6.70×10^{-14} cm^3 $molecule^{-1}$ s^{-1} at 298 K (according to Ref. 114) and $(6.8 \pm 1.0) \times 10^{-14}$ cm^3 $molecule^{-1}$ s^{-1} at 293 K (according to Ref. 115).

The rate constant for reaction (5) in the temperature interval 236–383 K is inversely proportional to temperature:[116]

$$k_5 = (1.7 \pm 0.8) \times 10^{-12} \exp\left(\frac{420 \pm 170}{T}\right) \text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}.$$

At 298 K and a total pressure of 2 Torr, one has $k_5 = (7.4 \pm 0.6) \times 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1}. Probably, a long-lived cyclic compound HOClOCl is formed as an intermediate product of this reaction.[116]

The reaction of hydroxyl radicals with chlorine dioxide also produces hypochlorous acid.[117]

$$^{\bullet}OH + OClO^{\bullet} \longrightarrow HOCl + O_2.$$

The microwave and IR spectra of HOCl have been the subject of numerous experimental and theoretical studies.[110, 118–137] Table 5 lists the bond lengths and bond angles in the HOCl molecule reported by different authors.

The HOCl molecule is a nearly symmetrical prolate rotor characterised by the parameter $\kappa = -0.998$ (see Ref. 121) and rotational constants (for $HO^{35}Cl$) $A_e = 20.49760$, $B_e = 0.50735$ and $C_e = 0.49509$ cm^{-1} (see Ref. 133). CCSD(T)/TZ2P calculations[93] gave a value of 1.56 D for the dipole moment of the HOCl molecule.

Table 5. Experimental and calculated geometric parameters of the HOCl molecule.

Method	r(O–Cl) /Å	r(O–H) /Å	HOCl angle /deg	Ref.
Microwave spectroscopy	1.693	0.97	103	118
IR spectroscopy	1.6891	0.9643	102.96	126
IR spectroscopy	1.68897	0.96437	102.965	133
DFT/B3LYP/G-311G(3df)	1.700	0.965	103.4	138

Table 6 lists the main vibrational frequencies in the gas-phase high resolution IR spectra of hypochlorous acid.

Numerous studies (see, *e.g.*, Refs 26, 62, 63, 66, 74, 137, 139–146) concern the UV absorption spectrum and photolysis of gaseous HOCl. At room temperature, the absorption spectrum of the HOCl molecule in the region 200–380 nm exhibits two maxima at 242 and 304 nm [absorption cross sections, σ, are $(2.1 \pm 0.3) \times 10^{-19}$ and 0.61×10^{-19} cm^2, respectively].[66] A weak peak was also detected at 380 nm ($\sigma = 4 \times 10^{-21}$ cm^2); the long-wavelength absorption extends to 480 nm ($\sigma = 5.52 \times 10^{-23}$ cm^2).[146]

Table 6. Vibrational frequencies in the IR spectrum of the $HO^{35}Cl$ molecule.

Frequency	Numerical value /cm^{-1}	Assignment	Ref.
ν_1	3609.48013	O–H stretch	120
ν_2	1238.62460	bending vibration	125
ν_3	724.35807	Cl–O stretch	125

Photolysis of HOCl produces mainly $^{\bullet}OH$ and $^{\bullet}Cl$ radicals. Other decomposition channels ($O^{\bullet} + HCl$ or $H^{\bullet} + {}^{\bullet}OCl$) are of little importance or not involved.[140, 141, 144] Photodissociation of HOCl causes destruction of stratospheric ozone

$$HOCl + h\nu \longrightarrow {}^{\bullet}OH(^2\Pi) + Cl^{\bullet}(^2P)$$
$$^{\bullet}OH + O_3 \longrightarrow HO_2^{\bullet} + O_2$$
$$Cl^{\bullet} + O_3 \longrightarrow ClO^{\bullet} + O_2$$
$$HO_2^{\bullet} + ClO^{\bullet} \longrightarrow HOCl + O_2$$

$$2\,O_3 \longrightarrow 3\,O_2$$

The lifetime of hypochlorous acid in the stratosphere under photolysis conditions is at most 30 min.[140, 146] The lifetime of HOCl in the mid-stratosphere (no photolysis) could be as long as ~600 h.[65]

The EI mass spectrum of HOCl exhibits peaks of molecular ions at m/e 52 and 54 (two isotopes, ^{35}Cl and ^{37}Cl).[70] The adiabatic and vertical ionisation energies determined from the HeI photoelectron spectrum of hypochlorous acid are 11.12 ± 0.01 and 11.22 ± 0.01 eV, respectively.[147] A photoionisation mass spectrometric study[148] of HOCl gave an adiabatic ionisation energy of 11.12 ± 0.01 eV, which coincides with the published value.[147] Using this value, Thorn *et al.*[148] calculated the enthalpy of formation of $HOCl^+$ [$\Delta H^\circ_{298}(HOCl^+) = 238.2 \pm 0.9$ kcal mol^{-1}]

and the proton affinity energy of ClO [$PA_{298}(ClO) = 151.8 \pm 0.9$ kcal mol^{-1}].

The enthalpies of formation of HOCl reported in the studies carried out at different times differ only slightly from one another (the ΔH_0° are given in parentheses).

ΔH_{298}(HOCl) /kcal mol^{-1}	−17.9	−18.0	−18.0	−18.4	−19.0	(−16.7)	(−17.2)
Ref.	64	63	65	149	67	150	32

QCISD(T)/6-311 + + G(3df,3pd)//QCISD(T)/6-311G(2d,2p) calculations [151] led to $\Delta H_{298}^\circ(HOCl) = -19.9 \pm 2$ kcal mol^{-1}. The values obtained later on using other computational methods are −18.2 (G2 calculations for 298 K) [30] and −17.5 kcal mol^{-1} [MP4/6-311 + G(d,p)].[138]

An exactly measured bond dissociation energy, $D_0(^{35}Cl-OH)$, is 55.15 kcal mol^{-1} (19290.3 ± 0.6 cm^{-1}).[152, 153] *Ab initio* G2 calculations gave $D_0(HO-Cl) = 55.2$ (see Ref. 30) and 55.25 kcal mol^{-1} (see Ref. 138). The result of density functional calculations [138] [B3LYP/6-31G(d) approximation], 55.24 kcal mol^{-1}, is also close to the experimental data. The H−OCl bond is stronger than the HO−Cl bond; the dissociation energy $D_0(H-OCl)$ is 93.8 kcal mol^{-1} (see Ref. 33) or 92.9 kcal mol^{-1} (see Ref. 154).

According to calculations, the HOCl isomer is 51.6 ± 1.2 kcal mol^{-1} (0 K) more stable than the HClO isomer.[155] The electron affinity energy of the HOCl molecule is low, namely, 0.27 eV (6.23 kcal mol^{-1}).[70] Protonation of HOCl at the oxygen atom ($HOCl + H^+ \longrightarrow H_2OCl^+$) is energetically more favourable compared to protonation at the chlorine atom ($HOCl + H^+ \longrightarrow HOClH^+$). The G2 calculated proton affinity energy is 153.4 kcal mol^{-1} in the former and 139 kcal mol^{-1} in the latter case (298 K).[30] The corresponding values obtained from density functional (PW91) calculations are 157.7 (298 K) and 140.1 kcal mol^{-1} (0 K).[39] Yet another computational study [156] also revealed that protonation at the oxygen atom is 16.2 kcal mol^{-1} energetically more preferable. The geometric parameters of the H_2OCl^+ ion calculated [110] at the B3LYP/6-311 + + G(d,p) level are as follows: $r(O-Cl) = 1.772$ Å, $r(O-H) = 0.984$ Å, the H−O−H angle is 123.9° and the H−O−Cl angle is 111.0°. The O−Cl bond length was also estimated at 1.78 Å.[157]

The reaction of hypochlorous acid with hydrogen chloride proceeding on the surface of ice or in sulfate aerosols can be a source of active chlorine in the stratosphere.[68, 71–73, 94, 96, 108, 158]

$$HOCl + HCl \longrightarrow Cl_2 + H_2O.$$

It is assumed [73] that protonation of HOCl is followed by the reaction of H_2OCl^+ ion with Cl^- producing Cl_2 and H_2O. Besides, HOCl can participate in the formation of active bromine monochloride following the reaction

$$HOCl + HBr \longrightarrow BrCl + H_2O.$$

Table 7. Rate constants for reactions involving HOCl (298 K).

Reaction	k /cm^3 molecule^{-1} s^{-1}	Ref.
HOCl + NO → products	1.0×10^{-17} (see [a])	159
HOCl + O_3 → products	4.0×10^{-16} (see [a])	159
HOCl + OH → H_2O + ClO	$(1.7-9.5) \times 10^{-13}$	160
HOCl + H → products	$(5.0 \pm 1.4) \times 10^{-12}$	160
HOCl + H → products	$(3.5 \pm 0.7) \times 10^{-12}$	67
HOCl + H → HCl + OH	$(6.7 \pm 2.1) \times 10^{-13}$ (see [a])	67
HOCl + Cl → products	$(1.4 \pm 0.37) \times 10^{-12}$	67
HOCl + Cl → Cl_2 + OH	$(3.4 \pm 1.5) \times 10^{-13}$	67
HOCl + F → products	$(4.9 \pm 0.6) \times 10^{-11}$	67
HOCl + F → ClF + OH	$(1.2 \pm 0.4) \times 10^{-11}$	67

[a] Given is the upper bound.

However, this reaction is of little importance because the concentration of hydrogen bromide in the atmosphere is at most 2 ppt (1 ppt = 10^{-12}).[69]

Table 7 lists the rate constants for some reactions involving HOCl calculated using the microwave discharge technique and mass spectrometry.

IV. Hypobromous acid

The first syntheses of solutions of hypobromous acid date back to the 1860s (cited according to Refs 161 and 162). Aqueous HOBr solutions are prepared by slowly adding liquid bromine to an aqueous solution of silver nitrate at room temperature.[161, 162] Subsequent vacuum distillation gives solutions with HOBr concentrations of about 0.2 mol litre^{-1}. Hypobromous acid is also formed in the reaction of bromine with an aqueous suspension of yellow mercury oxide (for hydrolysis of bromine, see Ref. 163). The reaction is conducted by passing water vapour and bromine through a column filled with mercury oxide supported by glass beads.[164, 165] Yet another procedure for the synthesis of hypobromous acid involves prolonged stirring of bromine in excess of water in the presence of Ag_2O powder.[33] The reaction was reported to proceed better in the presence of Ag_2O rather than mercury oxide.[33] A solution of HOBr was also prepared by the reaction of bromine with a 0.5 N solution of sulfuric acid in the presence of silver sulfate.[166]

By analogy with HOCl, hypobromous acid can be synthesised in the reaction of Br_2O with water.

$$Br_2O + H_2O \rightleftharpoons 2\,HOBr. \qquad (6, -6)$$

However, unlike a rather stable (at room temperature) Cl_2O, dibromine monoxide is stable only at temperatures below 233 K. It is produced by the reaction

$$2\,Br_2 + HgO \longrightarrow Br_2O + HgBr_2,$$

the yield of Br_2O being at most 1%–2%.[167, 168]

The rate constant for the reaction (6, −6) at 298 K is 0.02 (see Ref. 167) or 0.037 ± 0.004 (see Ref. 168).

HOBr for spectroscopic studies is obtained by fast exothermic reaction of $^\bullet$OH radicals with molecular bromine.

$$^\bullet OH + Br_2 \longrightarrow HOBr + Br^\bullet, \qquad (7)$$

The rate constant for reaction (7) is $k_7 = (4.2 \pm 0.7) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} at 298 K (see Ref. 169). In the temperature range 262–303 K, reaction (7) proceeds barrierlessly or has a very low activation barrier (~1 kcal mol^{-1}).[115] A study of the UV absorption spectrum of gaseous HOBr revealed [170] that at room temperature more than 97% of the total amount of the $^\bullet$OH radicals generated by photolysis of H_2O_2 are consumed following route (7) and less than 3% of these radicals are consumed in the reaction

$$^\bullet OH + H_2O_2 \longrightarrow HO_2^\bullet + H_2O.$$

Similarly to the reaction $HO_2^\bullet + ClO^\bullet$, the radical–radical reaction $HO_2^\bullet + BrO^\bullet$ [reaction (8)] producing hypobromous acid should be taken into account in simulation of atmospheric processes resulting in the destruction of stratospheric ozone.

$$HO_2^\bullet + BrO^\bullet \longrightarrow HOBr + O_2 \qquad (8a)$$

$$HOBr + h\nu \longrightarrow Br^\bullet + {}^\bullet OH$$

$$Br^\bullet + O_3 \longrightarrow BrO^\bullet + O_2$$

$$^\bullet OH + O_3 \longrightarrow HO_2^\bullet + O_2$$

$$2\,O_3 \longrightarrow 3\,O_2$$

Reaction (8) mainly follows route (*a*), the contribution of reaction (8*b*)

$$HO_2^\bullet + BrO^\bullet \longrightarrow HBr + O_3 \qquad (8b)$$

is insignificant, namely, the rate constant ratio $k_{8b}:k_{8a}$ is at most 0.015 (at 233–298 K, according to Ref. 171) or 0.004 (at 298 K, according to Ref. 172). Different sources estimate the activation energy for reaction (8) at about -1 kcal mol^{-1}; however, the rate constants for this reaction obtained by different authors at 298 K are somewhat different, lying in the range $(1.4-3.4)\times10^{-11}$ cm^3 molecule^{-1} s^{-1} (see Ref. 173).

$k_8\times10^{11}$ /cm^3 molecule^{-1} s^{-1}	3.4 ± 1.0	3.3 ± 0.5	1.4 ± 0.3	2.0 ± 0.6	3.1 ± 0.8
Ref.	174	171	175	173	172

HOBr can be formed in the troposphere and in the lower stratosphere as a result of heterogeneous hydrolysis of bromine nitrate on sulfate aerosol particles and on polar stratospheric clouds.[176, 177]

$$BrONO_2 + H_2O \longrightarrow HOBr + HNO_3.$$

Hydrolysis of $BrONO_2$ in the dark causes accumulation of HOBr but in sunlight HOBr is rapidly photolysed; as a consequence, the lifetime of HOBr is $\sim$15 min in the lower stratosphere and a few seconds in the upper stratosphere.[177] Hydrolysis of $BrONO_2$ on ice produces Br_2O as the secondary product.[162, 178]

$$BrONO_2 + HOBr \longrightarrow Br_2O + HNO_3.$$

The HOBr molecule is a nearly symmetrical prolate rotor characterised by the parameter $\kappa = -0.99936$. The dipole moment of the HOBr molecule is 1.384 D.[179]

The geometric parameters extracted from the pure rotation spectrum of HOBr are as follows:[179] $r(O-Br) = 1.834$ Å, $r(O-H) = 0.961$ Å and the H–O–Br angle is 102.3°. The rotational constants (for HO^{79}Br) are as follows: $A = 613\,677.34$, $B = 10\,576.60290$ and $C = 10\,383.05728$ MHz.

The frequencies in the IR spectrum of the HOBr molecule are listed in Table 8.[180, 181]

Table 8. Vibrational frequencies in the IR spectrum of the HOBr molecule.

Frequency	Numerical value /cm^{-1}	Assignment	Ref.
ν_1	3614.903	O–H stretch	180
ν_2	1162.570	bending vibration	181
ν_3	620.18	O–Br stretch	181

The absorption spectrum of gaseous HOBr in the region 200–420 nm was first studied by Orlando and Burkholder[167] who reported two structureless bands with maxima at nearly 280 nm [absorption cross section, σ, is $(3.1\pm0.4)\times10^{-19}$ cm^2] and at nearly 350 nm [$\sigma = (6.1\pm1.0)\times10^{-20}$ cm^2]. Later on, the third band at about 440 nm ($\sigma\approx9\times10^{-21}$ cm^2) was detected.[164] *Ab initio* calculations[182] substantiated the possibility for HOBr to absorb in the visible region with a maximum at 477 nm. According to another study,[170] at 295 K the spectrum of HOBr exhibits three broad bands with maxima at 284, 351 and 457 nm and the corresponding absorption cross sections σ of $(25.0\pm1.2)\times10^{-20}$, $(12.4\pm0.6)\times10^{-20}$ and $(2.3\pm0.2)\times10^{-20}$ cm^2. The absorption of HOBr in the long-wavelength region must have a strong effect on the rate of photolysis of the acid.[183] Laser photolysis of HOBr at 363 nm produces Br($^2P_{3/2}$) atoms with a quantum yield greater than 0.95.[161] No HBr was found among the products of photolysis.

The adiabatic ionisation energy of HOBr is 10.62 ± 0.04 (according to Ref. 184), 10.638 ± 0.03 eV (photoionisation mass spectrometry data[33]) and 10.642 ± 0.005 eV (photoelectron spectroscopy data[185]). G2 calculations[186] gave nearly the same ionisation energy, *viz*., 10.65 eV.

Earlier, the enthalpy of formation of HOBr was estimated at -19 ± 2 kcal mol^{-1}. However, this value appeared to be strongly overestimated compared to the results obtained more recently. In particular, a new value of the enthalpy of formation of HOBr reported in an experimental study[184] is $\Delta H^\circ_{298} = -9$ kcal mol^{-1} while the results of study[33] are $\Delta H^\circ_0 \geqslant -10.93\pm0.42$ and $\Delta H^\circ_{298} \geqslant -13.43\pm0.42$ kcal mol^{-1}. The ΔH°_{298} values determined in spectroscopic investigations are -11 (see Ref. 167) and -14.3 ± 0.9 kcal mol^{-1} (see Ref. 187). G2 calculations gave $\Delta H^\circ_{300} = -14.2\pm1.6$ (see Ref. 188) and $\Delta H^\circ_{298} = -13.9$ kcal mol^{-1} (see Ref. 30). More recent density functional calculations[138] at the B3LYP/6-311G(3df,3pd) level led to $\Delta H^\circ_{298} = -14.8$ kcal mol^{-1}. Two recommended[154] values of the enthalpy of formation of HOBr are -11.9 ± 0.3 (0 K) and -14.5 ± 0.3 kcal mol^{-1} (298 K).

The HOBr isomer is more stable than the 'hypervalent' isomer HBrO (the enthalpy of HOBr → HBrO conversion calculated for 0 K is 56.3 kcal mol^{-1}).[189]

The bond dissociation energies in the hypobromous acid molecule are $D_0(HO-Br) = 48.45\pm0.42$ kcal mol^{-1} and $D_0(H-OBr) = 94.2$ kcal mol^{-1}.[33] G2 calculations gave the following results: $D_0(HO-Br) = 48.8$ (see Ref. 30) and 49.5 kcal mol^{-1} (see Ref. 154) and $D_0(H-OBr) = 95.5$ kcal mol^{-1} (see Ref. 154).

The proton affinity energy of HOBr in the case of protonation at the oxygen atom

$$HOBr + H^+ \longrightarrow H_2OBr^+$$

is estimated at 162.0 (298 K)[30] or 161.5 kcal mol^{-1} (see Ref. 190).

Decomposition channels of hypobromous acid in the atmosphere involve photolysis and the interaction with ground-state elemental oxygen O(^{3}P)[191]

$$HOBr + O \longrightarrow BrO^\bullet + {}^\bullet OH. \qquad (9)$$

Tracer (^{18}O isotope) experiments followed by mass spectrometric analysis of reaction products showed that elemental oxygen interacts with the bromine atom of the HOBr molecule (HOBr + ^{18}O ⟶ Br^{18}O$^\bullet$ + $^\bullet$OH).[161] At 298 K, the rate constant for reaction (9) is $(2.5\pm0.4)\times10^{-11}$ cm^3 molecule^{-1} s^{-1}, being nearly 200 times higher than the rate constant for analogous reaction involving HOCl.[191] In the temperature range 233–423 K the rate constant can be calculated by the equation[192]

$$k_9 = (1.4\pm0.5)\times10^{-10}\exp\left(-\frac{430\pm260}{T}\right)\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}.$$

Reactions of HOBr with F(^{2}P) and Cl(^{2}P) atoms proceed even more rapidly. At 298 K, the rate constants for these reactions are $k(F) = (2.0\pm0.7)\times10^{-10}$ and $k(Cl) = (1.1\pm0.7)\times10^{-10}$ cm^3 molecule^{-1} s^{-1} (see Ref. 191).

Gas-phase titration of HOBr with chlorine atoms revealed that the reaction exclusively follows one of the two possible channels, namely, route *a*.[161]

$$HOBr + Cl \xrightarrow{a} BrCl + {}^\bullet OH$$
$$HOBr + Cl \xrightarrow{b} BrO^\bullet + HCl$$

Heterogeneous reactions

$$HOBr + HBr \longrightarrow Br_2 + H_2O,$$
$$HOBr + HCl \longrightarrow BrCl + H_2O$$

can also proceed in the atmosphere on the surface of ice at $T < 228$ K. These reactions produce photochemically active Br_2 and BrCl.[166, 193] The interaction of HOBr with the surface of ice prepared by freezing aqueous NaBr solutions at 233 or 248 K results in the formation of Br_2; if ice contains NaCl, BrCl is formed. In the presence of both NaBr and NaCl, BrCl is the only gaseous product at 233 K but raising the temperature to 248 K causes the formation of Br_2 and BrCl.[194]

V. Hypoiodous acid

The main source of atmospheric iodine is methyl iodide liberated by algae and phytoplankton, but small amounts of ethyl iodide are also present in the atmosphere.[195] Photolysis of iodides produces elemental iodine, which then reacts with ozone

$$I^{\bullet} + O_3 \longrightarrow IO^{\bullet} + O_2.$$

Radical $IO^{\bullet}$ can react with radical $HO_2^{\bullet}$, thus resulting in hypoiodous acid

$$IO^{\bullet} + HO_2^{\bullet} \longrightarrow HOI + O_2. \quad (10)$$

Under photolysis conditions, HOI regenerates the iodine atoms or enters in the reaction with nitrogen oxide, which also leads to regeneration of elemental iodine [196]

$$IO^{\bullet} + NO \longrightarrow I^{\bullet} + NO_2.$$

Hypoiodous acid is the most abundant inorganic compound of iodine in the troposphere at heights below 8 km. It is of great importance for tropospheric chemistry, especially in marine areas.[197] However, the presence of HOI in the stratosphere and its active role in the catalytic cycle of ozone destruction cannot be ruled out.[198]

Unlike HOF, HOCl and HOBr which are produced in the reactions of corresponding halogens with water, large amounts of hypoiodous acid can hardly be obtained by the reaction of iodine with water. It is a common practice to perform *in situ* synthesis of HOI using some other reactions when carrying out spectroscopic studies of the acid.

It was proposed [199] to synthesise hypoiodous acid in the reaction of hydroxyl radicals with iodine (HONO can be used as a source of $^{\bullet}OH$ radicals). The rate constant for the reaction $^{\bullet}OH + I_2$ is $(2.1 \pm 1.0) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} (294 K).[199] A fast reaction

$$^{\bullet}OH + I_2 \begin{cases} \xrightarrow{a} HOI + I \\ \xrightarrow{b} IO + HI \end{cases}$$

was also proposed as a possible source of HOI.[200] The rate constant for this reaction is 1.6×10^{-10} cm^3 molecule^{-1} s^{-1} (298 K). It should be noted that channel (*b*) plays an insignificant role because $k_b : k_a < 0.01$.[200]

Hypoiodous acid is produced by photolysis (254 nm) of gaseous mixtures $I_2-H_2O_2$, $CH_3I-H_2O_2$ and $CH_2I_2-H_2O_2$.[197] The IR spectra of all these systems exhibit two absorption bands centred at 3620 and 1068 cm^{-1} and assigned to the stretching (O–H) and bending vibrations of the HOI molecule, respectively.[197] Photolysis of H_2O_2 followed by the reaction of $^{\bullet}OH$ radicals with iodine was also used to obtain HOI.[201, 202]

HOI can also be synthesised in the reactions of microwave discharge generated hydroxyl radicals with iodine or CF_3I and in the reactions of C_2H_5I with O(^{3}P).[198] Reactions of O(^{3}P) with two-carbon and longer alkyl iodides, *e.g.*,

$$C_2H_5I + O \longrightarrow HOI + C_2H_4,$$

$$C_3H_7I + O \longrightarrow HOI + C_3H_6,$$

produce excited (vibrationally hot) HOI molecules.[203] A study on the mechanisms of these reactions using ethyl iodide isotopomers CH_3CD_2I and CD_3CH_2I showed that attack of the O(^{3}P) atom on the I atom followed by hydrogen abstraction from the methyl group results in the formation of HOI.[204] The reaction with methyl iodide containing only one carbon atom yields no hypoiodous acid.

Similarly to HOCl and HOBr, hypoiodous acid can be synthesised in the radical–radical reaction (10). The first study on the kinetics of this reaction was reported in 1991.[205] The rate constant, k_{10}, for the reaction was estimated at $(6.4 \pm 0.7) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} at 298 K. Another k_{10} value available in the literature [206] is $(1.03 \pm 0.13) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} (298 K). The absence of ozone among the reaction products was demonstrated; this indicates an insignificant contribution of the channel

$$IO^{\bullet} + HO_2^{\bullet} \longrightarrow HI + O_3$$

to the overall reaction.

The temperature dependence of the rate constant for reaction (10) reported for the temperature range $T = 274-373$ K in a recent kinetic study [207] is described by the equation

$$k_{10} = 9.3 \times 10^{-12} \exp\left(\frac{680}{T}\right) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}.$$

At 298 K, the k_{10} value is $(9.7 \pm 2.9) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}. An inversely proportional temperature dependence ($T = 273-353$ K) of the rate constant for reaction (10) was also reported in another study [197]

$$k_{10} = (2.2 \pm 0.6) \times 10^{-11} \exp\left(\frac{400 \pm 80}{T}\right) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}.$$

The authors [197] concluded that the $IO^{\bullet}$ and $HO_2^{\bullet}$ radicals react exclusively to produce HOI and O_2.

The lack of simple methods for synthesis of HOI and the instability of the acid (its lifetime in an IR spectroscopic cell is only 1–2 min at room temperature [197]) strongly hamper studies on the structure and chemical properties of this acid.

The HOI molecule is a symmetrical prolate rotor characterised by the rotational constants $A_0 = 20.935$, $B_0 = 0.27894$ and $C_0 = 0.27507$ cm^{-1} and by the parameter $\kappa = -0.9996$.[203] The vibrational frequencies of HOI are $\nu_1 = 3625.84$, $\nu_2 = 1068$ and $\nu_3 = 575$ cm^{-1}.[203] The internuclear distance, r(O–I), is 1.991 Å, the distance r(O–H) is assumed to be 0.9643 Å (by analogy with the corresponding distances in the HOCl and HOBr molecules) and the angle H–O–I is 105.4°. Another set of geometric parameters of the HOI molecule is as follows: r(O–H) ≈ 0.96 Å, r(O–I) ≈ 1.959–1.995 Å and the angle H–O–I is 102.4°.[33] MultiConfiguration Self-Consistent Field (MCSCF) calculations [137] gave r(O–H) = 1.0078 Å, r(O–I) = 2.1044 Å and an H–O–I angle of 103.73°.

The absorption spectrum of gaseous HOI in the region 278–494 nm has been studied at 298 K.[201, 202] The spectrum exhibits two broad bands with absorption maxima at 340.4 and 406.4 nm [absorption cross sections, σ, are $(3.85 \pm 0.4) \times 10^{-19}$ and $(3.30 \pm 0.3) \times 10^{-19}$ cm^{-2}, respectively][201] or at 338.4 and 404.8 nm ($\sigma = 3.99 \times 10^{-19}$ and 2.85×10^{-19} cm^{-2}, see Ref. 202). Compared to HOCl and HOBr, the absorption bands of gaseous HOI are more intense and shifted towards the long-wavelength region.[202] The reaction $O + C_2H_5I$ used as a source of HOI provided evidence for the formation of oxide I_2O that can be a product of the reaction $2HOI \rightarrow I_2O + H_2O$.[202]

Photolysis of HOI (355 nm, 295 K) produces $^{\bullet}OH$ radicals with a quantum yield close to unity.[201] The lifetime of HOI in the troposphere in sunlight was estimated at a few minutes.[201, 202]

The adiabatic ionisation energy of HOI predicted [33] based on the analysis of trends in the changes in the properties of OHal and HOHal (Hal = F, Cl, Br) is the lowest among the HOHal compounds (9.71–9.80 eV). The experimental ionisation energy (9.81 ± 0.02 eV) [198] is close to the predicted [33] value. G2 calculations led to a value of 9.89 eV.[30]

According to an early estimation,[199] the enthalpy of formation of HOI lies in the range from −18.4 to −24.4 kcal mol^{-1} (more recently,[206] the average value, -21.4 ± 3.0 kcal mol^{-1}, was recommended). Revision [33] of these results led to a considerably different enthalpy of formation of HOI lying between −8 and −9 kcal mol^{-1} (*cf.* $\Delta H_0^{\circ} = -10.7$ and $\Delta H_{298}^{\circ} = -11.7$ kcal mol^{-1} obtained from G2 calculations [30]). Yet another pair of recommended enthalpy values is as follows: $\Delta H_0^{\circ} = -13.2$ and $\Delta H_{298}^{\circ} = -14.3$ kcal mol^{-1}.[154]

The calculated bond dissociation energies are D_0(HO–I) = 43–44 and D_0(H–OI) = 94.5–95.2 kcal mol^{-1}.[33] G2 calculations [30] gave a value of

45.3 kcal mol^{-1} for D_0(HO—I). The bond dissociation energies recommended in another study,[154] D_0(HO—I) = 48.2 and D_0(H—OI) = 93.7 kcal mol^{-1}, differ only slightly from those listed above.

* * *

The main goal of the studies on the properties of gaseous hypochlorous, hypobromous and hypoiodous acids is to establish their role in the destruction of stratospheric ozone. Hypofluorous acid, which also belongs to this group of oxy acids of halogens, is of little importance for atmospheric processes; however, this compound is of interest for preparative chemistry.

Abstract. The reagents used to transform epoxides, alkenes and α,β-unsaturated carbonyl compounds into allylic alcohols are considered. The bibliography includes 127 references.

I. Introduction

The presence of an allyl alcohol fragment in the molecules of organic compounds offers extensive opportunities for further modification for obtaining diverse natural and synthetic physiologically active compounds. Among the numerous existing methods for the synthesis of allyl alcohols, cleavage of α-epoxides, allylic hydroxylation and reduction of α,β-unsaturated carbonyl compounds are used most frequently. This review is devoted to these methods; the information is classified according to the type of reagent used for the transformations. Attention is concentrated on the studies published during the last 10 – 15 years.

II. Reagents for epoxide cleavage

Epoxides are important intermediates in the synthesis of various organic compounds. This is due not only to the ease of their preparation but also to the polarity and strain of the oxirane ring, which makes epoxides highly reactive towards electrophiles, nucleophiles, acids, bases, various reducing agents and some oxidants.

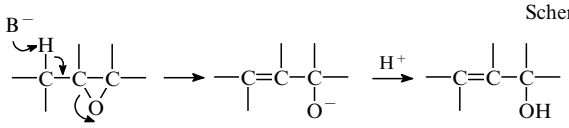
1. Isohypsic cleavage of epoxides to allylic alcohols

This Section covers the reactions of epoxide cleavage that are not accompanied by redox transformations (isohypsic reactions).

One of the most popular methods for the synthesis of allylic alcohols is treatment of epoxides with strong bases, for example, alkali metal amides. The role of the base is to eliminate the proton from the α-position with respect to the oxirane ring (Scheme 1).[1 – 3]

Unfortunately, these reagents are of little utility for the cleavage of epoxides containing additional labile functional groups. A number of reagents found in recent years have markedly extended the scope of application of this strategy.

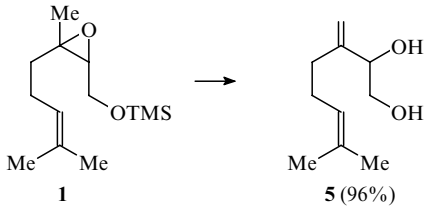
Scheme 1



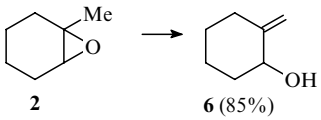
a. Methylmagnesium-*N*-cyclohexyl-*N*-isopropylamide

Falck and co-workers have shown[4] that methylmagnesium-*N*-cyclohexyl-*N*-isopropylamide [MeMgN(cyclo-C_6H_{11})Pr^i, NMA] induces efficient isomerisation of epoxides into allylic alcohols. This reagent is prepared by mixing toluene solutions of methylmagnesium bromide and lithium *N*-cyclohexyl-*N*-isopropylamide.

Examples of effective cleavage of epoxides **1** – **4** on treatment with MeMgN(cyclo-C_6H_{11})Pr^i to give allylic alcohols **5** – **8** are presented below.[4,5]



1 **5** (96%)



2 **6** (85%)

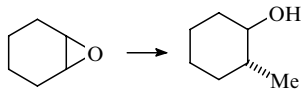
Uspekhi Khimii **73** (7) 675 – 691 (2004); translated by Z P Bobkova

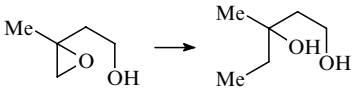
Presumably, the formation of allylic alcohols from epoxides follows a β-elimination mechanism.[1–3]

Ethylmagnesium- and isopropylmagnesium-*N*-cyclohexyl-*N*-isopropylamides behave in a similar way, whereas the use of phenylmagnesium-*N*-cyclohexyl-*N*-isopropylamide results in low yields of allylic alcohols.

On treatment with NMA, cyclohexene oxide (**9**) and 2-(2-hydroxyethyl)-2-methyloxirane (**10**) are converted into saturated alcohols **11** and **12**.[4] In this case, oxirane is attacked by the methyl anion formed from the reagent.



9 **11** (42%)

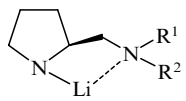


10 **12** (50%)

Smooth opening of the oxirane ring in labile epoxides of the oxylipin series containing carboxy and ester groups has also been effected using NMA.

b. Chiral lithium amides

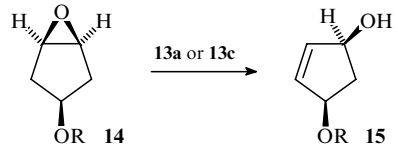
It has been shown [6,7] that oxides of cyclic and acyclic alkenes can be cleaved under the action of chiral lithium amides **13a**–**h** to give the corresponding optically active alcohols.



13a–**h**

R^1–R^2 = $(CH_2)_4$ (**a**), $(CH_2)_5$ (**b**), $(CH_2)_2O(CH_2)_2$ (**c**), $(CH_2)_2NMe(CH_2)_2$ (**d**), $R^1 = R^2$ = Et (**e**), Pr^i (**f**), R^1 = Et, $R^2 = Pr^i$ (**g**), R^1 = Bn, $R^2 = (CH_2)_2NBn_2$ (**h**).

For example, protected 3,4-epoxycyclopentanol (**14**) reacts with chiral lithium amides **13a** and **13c** to yield allylic alcohols **15** with a high enantiomeric excess (*ee* 89%–90%).[6]



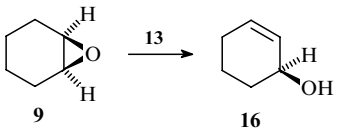
13a or **13c**

OR **14** OR **15**

R = THP (*ee* 90%) (THP is tetrahydropyran-2-yl), Bu^tMe_2Si (*ee* 89%).

Benzene, ether, toluene or THP can be used as solvents in this reaction (THF is the solvent of choice). This method has been used [8] in the synthesis of (−)-untenone A isolated from a sea sponge.

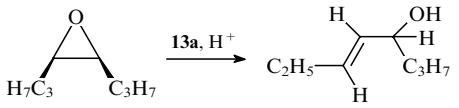
The transformation of epoxycyclohexane (**9**) on treatment with chiral lithium amides (**13a**,**b**,**d**–**h**) has been studied.[7,9] The enantiomeric excess of cyclohex-2-enol (**16**) varied from medium to high (40%–90%). The transformation of epoxycyclohexane was carried out in THF, ether, 1,2-dimethoxyethane (DME) and benzene; the best results were attained in THF.



9 **16**

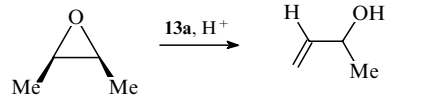
Amide **13**	Yield of **16** (%)	*ee* (%)
a	75–78	82–90
b	71	81
d	67	68
e	69	83
f	75	40
g	75	70
h	75	82

This reaction has also been carried out with symmetrical (*Z*)-4,5-epoxyoctane (**17**), which reacts with chiral lithium amide **13a** being converted into (*E*)-oct-5-en-4-ol (**18**) in 52% yield.[7] The yield of alcohol **18** can be increased to 60% by using additives, 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).

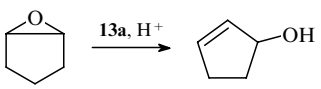


17 **18** (66%, *ee* 60%)

(*Z*)-2,3-Epoxybutane (**19**) and epoxycyclopentane (**20**) behave in a similar way being converted into compounds **21** and **22**.

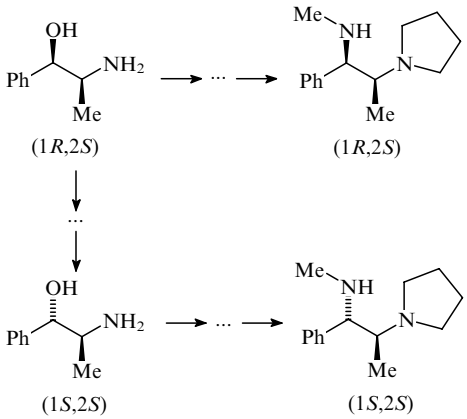


19 **21** (60%, *ee* 72%)



20 **22** (53%, *ee* 41%)

Colman *et al.*[10] used chiral diamines prepared on the basis of (1*R*,2*S*)- and (1*S*,2*S*)-norephedrine for opening of the oxirane ring.



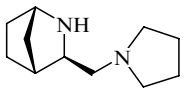
(1*R*,2*S*) (1*R*,2*S*)

(1*S*,2*S*) (1*S*,2*S*)

Opening of the oxirane ring in 4-amino-1,2-epoxycyclopentane under the action of chiral lithium amide obtained from (2*S*,3*aS*,7*aS*)-2-pyrrolidinomethyloctahydroindole has been reported.[11] A (1*S*,4*R*)-4-aminocyclopent-2-enol derivative has been synthesised with an enantiomeric excess of ~90%. O'Brien *et al.*[12] have used (*R*)-*N*-methyl-l-phenyl-2-pyrrolidinoethylamine to cleave the oxirane ring in the substituted epoxycyclopentane

(the enantiomeric excess of the alcohol was 60%). Several more examples of using chiral lithium amides for the synthesis of optically active compounds from prochiral epoxides have been reported.[13]

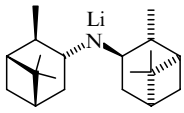
Using a large number of examples, Andersson and co-workers[14–16] have demonstrated efficient use of catalytic amounts of chiral diamines **23** and their derivatives for enantioselective transformation of *meso*-epoxides of cyclic and alicyclic olefins into optically active allylic alcohols.



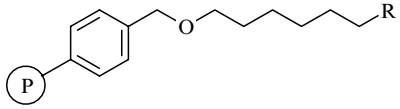
23

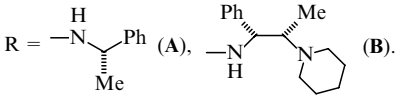
The reaction should be carried out in the presence of stoichiometric amounts of lithium diisopropylamide and up to 5 equiv. of DBU. Subsequently, it has been shown that this system of reagents is suitable for kinetic resolution of racemic epoxides (only one enantiomer reacts and, hence, the racemate is resolved).[17]

A recent study[18] describes the synthesis of chiral cyclohex-2-enol (**16**) from *meso*-epoxycyclohexane (**9**) with the use of chiral lithium amide.



Johansson *et al.*[19] performed cleavage of the oxirane ring in epoxycyclohexane on treatment with chiral lithium amides formed from amines attached to a polymeric support.





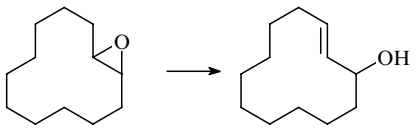
It was shown that immobilisation of ligand **A** on a support results in a markedly higher reaction enantioselectivity: the enantiomeric excess of (*S*)-**16** increases from 19% to 81%. Meanwhile, immobilisation of ligand **B** did not result in a desired increase in the enantioselectivity; conversely, the *ee* value decreased from 93% to 70%.

Thus, the above results demonstrate that chiral lithium amides are valuable reagents for the synthesis of chiral allylic alcohols from *meso*-epoxides of various structures.

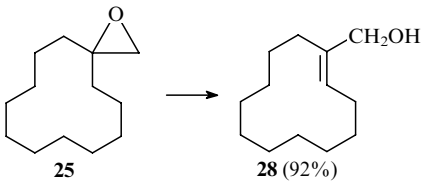
c. Organoaluminium amides

The behaviour of organoaluminium amides in the transformation of epoxides into allylic alcohols differs somewhat from the behaviour of lithium dialkylamides. Aluminium derivatives have a relatively low basicity and a higher Lewis acidity; therefore, they are mainly coordinated to the oxygen atom of the epoxide ring. The subsequent proton elimination from the α-position takes place within this complex.[20]

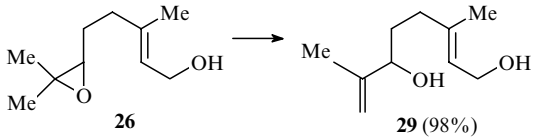
Diethylaluminium 2,2,6,6-tetramethylpiperidide (DATMP) is the most promising reagent. Using this compound, oxiranes **24**–**26** were converted into allylic alcohols **27**–**29** in very high yields.



24 **27** (99%)



25 **28** (92%)

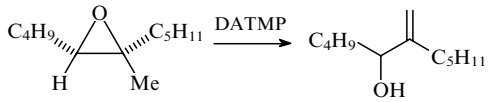


26 **29** (98%)

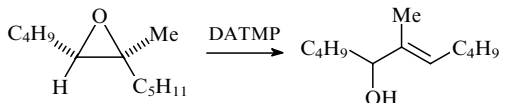
Benzene and hexane are the solvents of choice for the transformations of oxiranes into allylic alcohols on treatment with organoaluminium amides, because these solvents do not solvate aluminium amides. In ether, these reactions proceed in lower yields, while in THF, they barely take place. Other diethylaluminium amides Et_2AlNR_2 (R = Et, Pr^i, cyclo-C_6H_{11}) can also be used for converting oxiranes into allylic alcohols, but the reaction rates are markedly lower than that in the case of DATMP.

cis-Cyclododecene oxide reacts very slowly with DATMP, the corresponding allylic alcohol being formed in a low yield (~8%). Cycloalkene oxides with 5 to 8 carbon atoms in the ring do not react with DATMP.[20]

The structures of the allylic alcohols formed from oxiranes under the action of DATMP depend on the oxirane stereochemistry. For example, the transformation of *Z*-oxirane **30** gave methylene-type allylic alcohol **31** in 96% yield, while *E*-oxirane **32** was converted into allylic alcohol **33** with an internal double bond (yield 83%).[20]



30 **31** (96%)

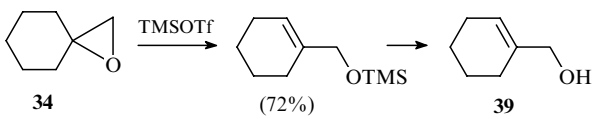


32 **33** (83%)

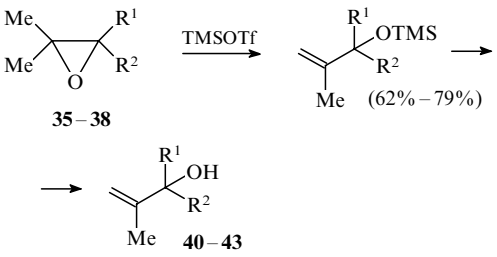
This reaction pattern is due to the fact that aluminium amides preferentially abstract the α-proton from the alkyl group that is located on the same side of the oxirane molecule as the hydrogen atom, because the aluminium-containing reagent attacks the substrate from the sterically less hindered side of the ring. This gives preferentially the allylic alcohol with the *E*-configured double bond.

d. Trimethylsilyl trifluoromethanesulfonate

Noyori and co-workers[21] have proposed the trimethylsilyl triflate (TMSOTf)–amine (DBU or lutidine) system for transformation of oxiranes into allylic alcohols. Trimethylsilyl triflate, which is a weak Lewis acid, activates the epoxide fragment; as a result, the amine basicity becomes sufficient for eliminating the hydrogen atom from the α-position relative to the oxirane ring. The reaction is carried out in benzene or toluene. The target allylic alcohols are formed initially as trimethylsilyl ethers. The trimethylsilyl group is removed by treatment with dilute hydrochloric acid or potassium fluoride in methanol. For example, oxiranes **34**–**38** were converted into allylic alcohols **39**–**43**.



34 (72%) **39**



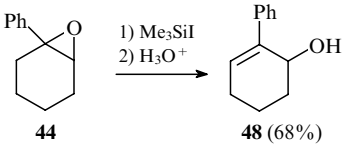
35 – 38 **40 – 43** (62% – 79%)

$R^1 = R^2 = H$ (**35**, **40**), Me (**36**, **41**); $R^1 = H$: $R^2 = CH(Me)CH_2C(O)Me$ (**37**, **42**), $(CH_2)_2CH(Me)CH_2CO_2Me$ (**38**, **43**).

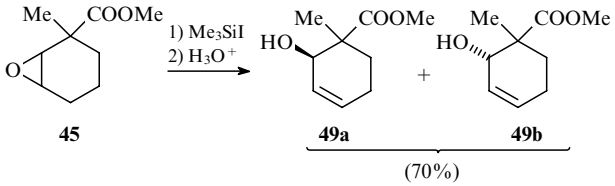
The method has some limitations, in particular, it is inapplicable to the synthesis of allylic alcohols from mono- and 2,3-dialkyl-substituted oxiranes.

e. Trialkylsilyl iodides

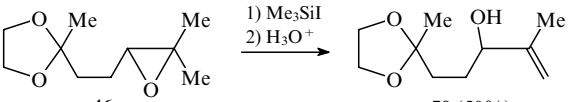
The transformation of epoxides **44** – **47** into allylic alcohols **48** – **51** under the action of iodotrimethylsilane and 1,5-diazabicyclo[4.3.0]non-5-ene has been reported.[22]



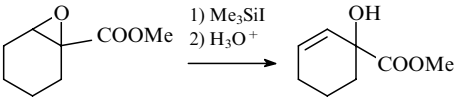
44 **48** (68%)



45 **49a** **49b** (70%)

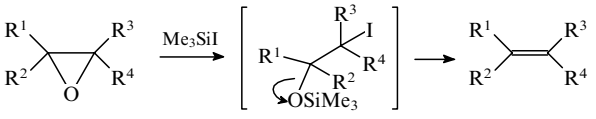


46 **50** (50%)

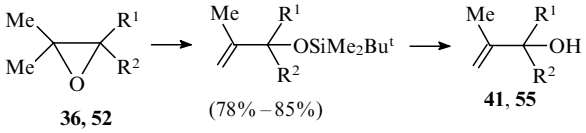


47 **51**

Allylic alcohols **48** – **50** were prepared in satisfactory yields (alcohol **51**, in a low yield). Triethylamine and diisopropylethylamine proved to be much less effective dehydrohalogenating agents than DBN. The reactions were carried out in acetonitrile. The initial ring opening in the epoxide rapidly occurs at room temperature, but dehydrohalogenation of the intermediate iodohydrin is completed only after heating the reaction mixture to the boiling point of the solvent. It is noteworthy that the ester and the ketal functional groups remain intact during the reaction, although they are known [23] to be reactive towards iodotrimethylsilane. In view of the mild reaction conditions, the ready accessibility of the reagents and the simple workup procedure for the reaction mixture, this method can make a good alternative to the Noyori method described above,[21] although the product yields are somewhat lower in this case, due to the formation of side deoxygenation products.

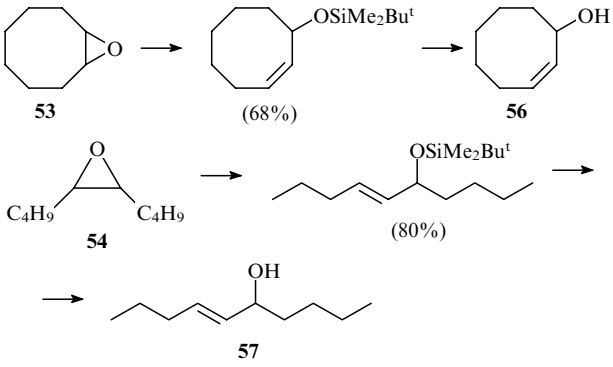


In the case of substituted oxiranes, the formation of deoxygenation products can be avoided by using Bu^tMe_2SiI in place of Me_3SiI;[24] however, this complicates somewhat the cleavage of the silyl ethers. This strategy was used to transform oxiranes **36** and **52** – **54** into the corresponding *tert*-butyl dimethylsilyl ethers in good yields. The protective group was removed by treatment of the ethers with tetraalkylammonium fluoride in moist DMSO or THF, or with potassium fluoride in the presence of catalytic amounts of 18-crown-6 ether; unsaturated alcohols **41** and **55** – **57** were thus liberated.



36, 52 (78% – 85%) **41**, **55**

$R^1 = R^2 = Me$ (**36**, **41**); $R^1 = H$, $R^2 = Et$ (**52**, **55**).



53 (68%) **56**

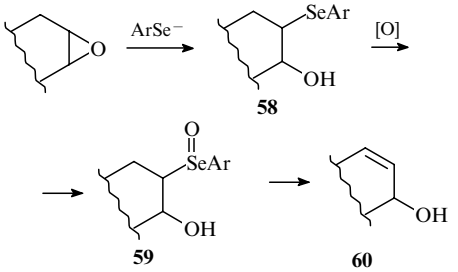
54 (80%)

57

The mechanism of the reaction of silyl iodides with oxiranes is not entirely clear.[25 – 27] The reaction furnishes a mixture of products of deoxygenation and ring opening (both silylated and non-silylated ones).

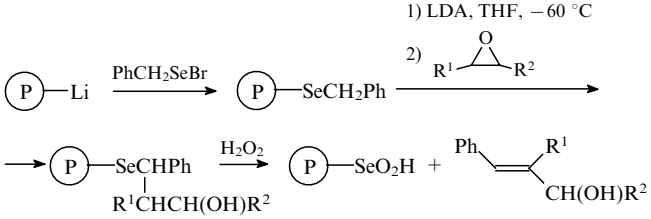
f. Selenols

The salts of selenols (usually, areneselenols) generated by various procedures easily cleave the epoxide ring giving rise to β-hydroxy selenides **58**.[28] Treatment of these products with mild oxidants gives selenium oxides **59**, which spontaneously split off ArSeOH with elimination of only the hydrogen atom located on the opposite side of the chain with respect to the oxygen function. This affords allylic alcohols **60**.[28] Most often, the products are formed in good yields.



58 **59** **60**

The use of polystyrene-immobilised selenides for opening of the oxirane ring has been documented.[29]

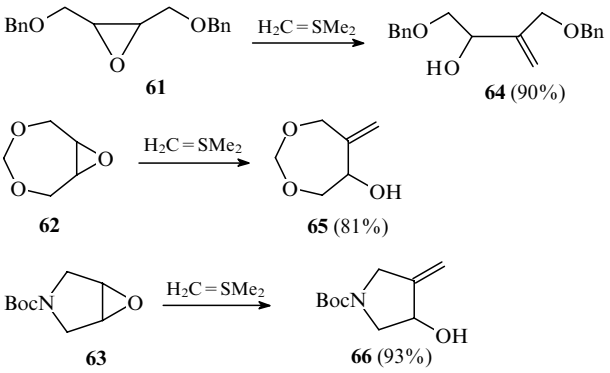


$R^1 = H$: $R^2 = Me$ (85%), Ph (86%), $PhOCH_2$ (84%);
$R^1 – R^2 = (CH_2)_4$ (77%).

g. Dimethylsulfonium methylide

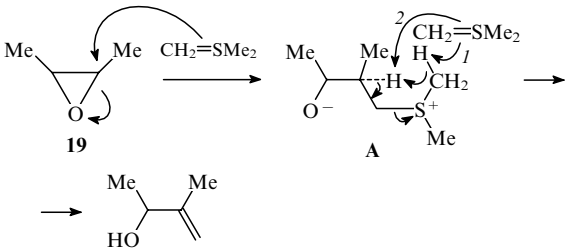
Dimethylsulfonium methylide (DMSM, Corey's reagent) represents a special case among the reagents considered in this Section. This compound reacts with epoxides C_n to give homological allylic alcohols C_{n+1}. Evidently, DMSM serves as the source of an additional carbon atom.[30,31] Since the oxidation state of the starting compound does not change upon the reaction, this reaction should be classified as isohypsic.

Treatment of *cis*-epoxides **61**–**63** with excess DMSM gave allylic alcohols **64**–**66** in very high yields.[32]



Noteworthy is the high chemoselectivity of this reaction: only the *cis*-isomers are cleaved, whereas the *trans*-isomers remain intact. Thus, the *cis*- and *trans*-isomers of the epoxides can be easily separated in this way. This method is widely used in the synthesis of natural products containing a fragment of 1,2-disubstituted allylic alcohol.

The reaction mechanism has been considered in relation to the cleavage of (*Z*)-2,3-epoxybutane (**19**). The nucleophilic addition of DMSM to epoxide **19** yields betaine intermediate **A**, which undergoes β-elimination of dimethyl sulfide. The elimination may follow either pathway *1* or pathway *2*. Both lead to the same allylic alcohol.



2. Reduction of epoxides, resulting in allylic alcohol

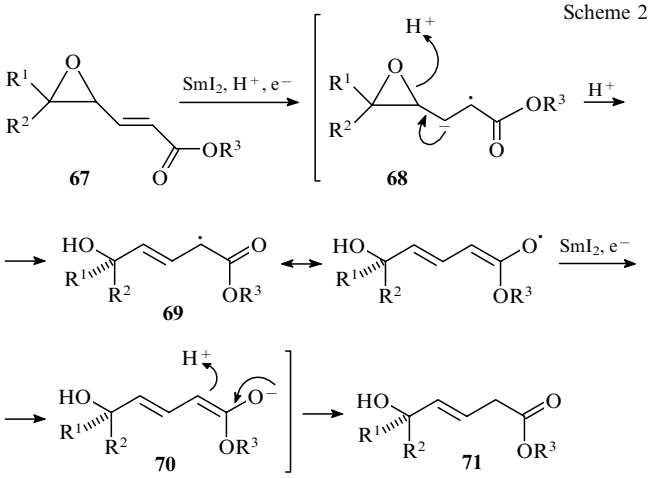
As noted above, oxiranes and allylic alcohols occur in the same oxidation state. Therefore, the reduction reactions considered in this Section are applied to epoxides that contain additional functional groups. The reducing reagents can be subdivided into two groups, *i.e.*, proper reductants and carbanionic synthons.

a. Samarium diiodide

It has been found[33] that treatment of functionalised vinyl-substituted oxiranes **67** with samarium diiodide in THF in the presence of a proton donor induces reductive opening of the oxirane ring, while functional groups such as keto, ester and nitrile groups remain intact. The reaction proceeds at a high rate at −90 °C and is complete, most often, over a period of five minutes.

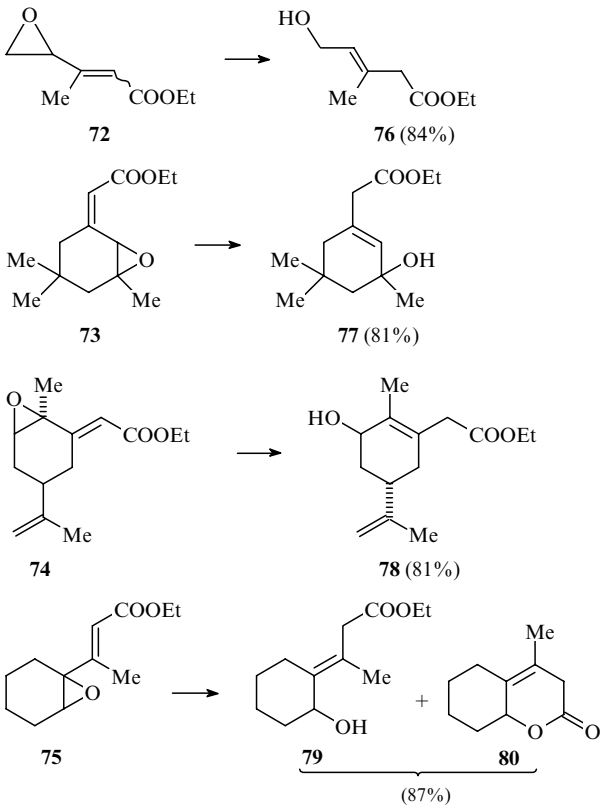
The reaction mechanism (Scheme 2) includes the formation of radical anion **68**, which adds a proton, being converted into radical **69** containing an ester group. This compound isomerises to a conjugated radical, which produces conjugated dienolate **70** upon the addition of an electron. Regioselective protonation of dienolate **70** furnishes β,γ-unsaturated carbonyl compound **71**.

Scheme 2

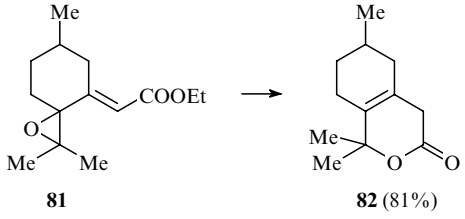


Since the reaction occurs in a nearly neutral medium, no shift of the equilibrium towards the conjugated isomer **70** is observed.

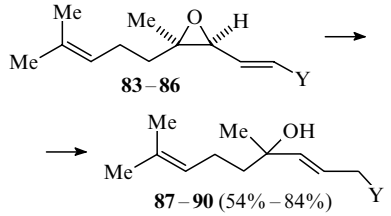
The reactions of epoxides **72**–**75** with samarium diiodide gave allylic alcohols **76**–**79** in very high yields.



In addition to allylic alcohol **79**, cleavage of epoxide **75** yields lactone **80** (the ratio **79** : **80** = 1 : 1). In the case of epoxide **81**, the formation of 'allylic' lactone **82** becomes the predominant reaction route.

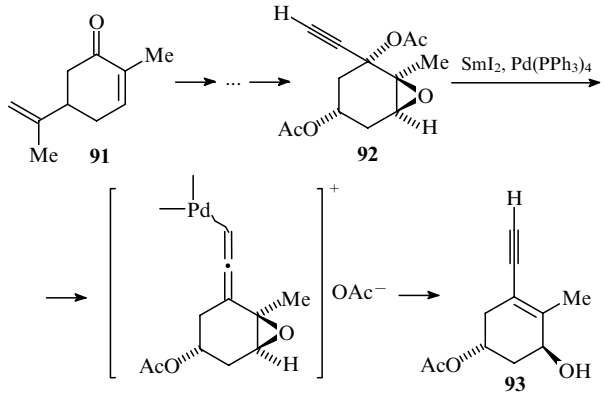


Apart from epoxides with ester groups, unsaturated epoxides with other electron-withdrawing groups can also participate in these reactions. Thus epoxides **83**–**86** were converted into allylic alcohols **87**–**90**.[33]



Y = COSEt (**83**, **87**), SO_2Ph (**84**, **88**), SPh (**85**, **89**), $PO(OEt)_2$ (**86**, **90**).

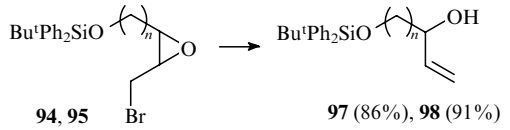
Okamura *et al.*[34] reported the synthesis of allylic alcohols from carvone (**91**) using samarium diiodide. Treatment of epoxy diacetate **92** with two equivalents of samarium diiodide and $Pd(PPh_3)_4$ in the absence of a proton donor yielded allylic alcohol **93**.



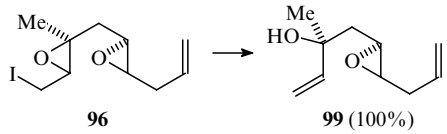
Thus, the reactions of samarium diiodide with epoxides constitute a promising method for the synthesis of diverse functionally substituted allylic alcohols. The use of chiral unsaturated epoxides in this reaction opens up the way to the synthesis of optically active compounds.

b. The reduction of α-haloepoxides catalysed by metal compounds

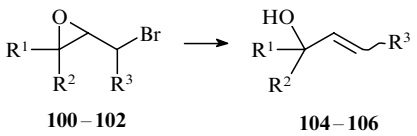
Epoxy halides **94**–**96** containing halogen atoms in the α-position to the oxirane ring react with sodium iodide and zinc dust in boiling methanol to give allylic alcohols **97**–**99** in high yields.[35] This strategy is used to prepare pure enantiomers by Sharpless asymmetric epoxidation of olefinic precursors.[36]



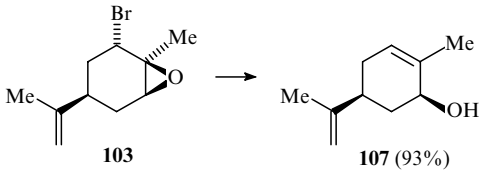
n = 1 (**94**, **97**), 2 (**95**, **98**)



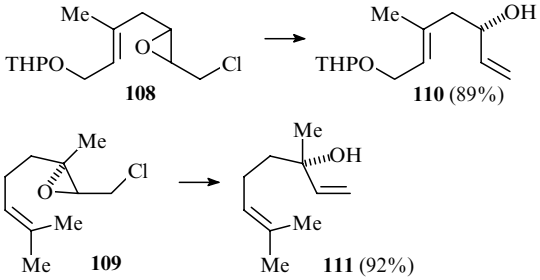
The same results were obtained upon the reduction of α-bromoepoxides **100**–**103** with a zinc/copper couple under sonochemical conditions.[37] The yields of allylic alcohols **104**–**107** were satisfactory. This method is applicable to oxirane ring opening not only in primary but also in secondary epoxy bromides.



Compound	R^1	R^2	R^3	Yield of alcohol (%)
100, **104**	Alk	Me	H	94
101, **105**	H	Ph	H	95
102, **106**	H	Ph	Me	93



n-Butyllithium can also be used for the reductive cleavage of the oxirane ring in α-haloepoxides. By treatment of α-haloepoxides **103**, **108** and **109** with this reagent, allylic alcohols **107**, **110** and **111**, respectively, have been prepared.[35]

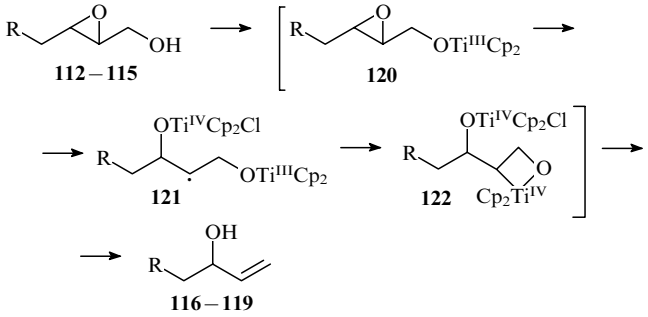


The reactions were carried out at −23 °C. In this case, the organolithium compound functions as a reducing agent rather than a C-nucleophile.

c. Bis(cyclopentadienyl)titanium chloride

It has been found[38] that α-hydroxyepoxides **112**–**115** react with Cp_2TiCl to give allylic alcohols **116**–**119** in good yields. Presumably, the reaction involves the intermediate formation of species **120**–**122** (Scheme 3).

Scheme 3



Compound	R	Yield of alcohol (%)
112, **116**	Bu	82
113, **117**	EtCH=CH	85
114, **118**	$CH_2=CH(CH_2)_2$	85
115, **119**	OBn	91

It is significant that the chirality of the starting epoxides at the 3-position is fully retained in allylic alcohols.

The starting optically active 2,3-epoxy alcohols are usually prepared by Sharpless asymmetric epoxidation[36] of isomeric allylic alcohols. Thus, the epoxidation–Cp_2TiCl reduction sequence represents a convenient protocol of an asymmetric

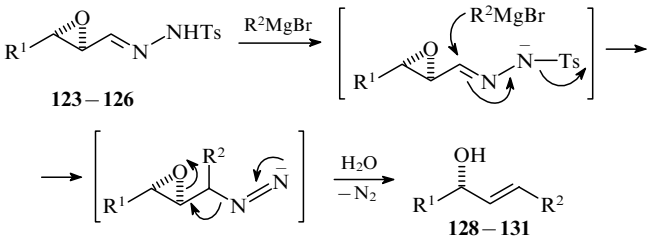
allylic rearrangement, which may yield multipurpose chiral synthons.[39]

The reagent Cp_2TiCl has also been used[40] to reduce vinylic epoxides to allylic alcohols.

d. Alkylmagnesium bromides

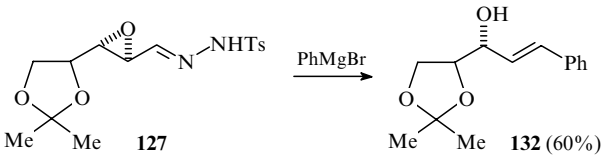
The Section deals with epoxide ring opening under the action of reagents serving as sources of additional carbon atoms.

As a further development of the research into alkylation of tosylhydrazones accompanied by elimination,[41] it has been shown[42] that α-epoxyaldehyde tosylhydrazones **123**–**127** can be converted into allylic alcohols **128**–**132** *via* the reaction with alkylmagnesium bromides.



123–**126** **128**–**131**

Epoxide	R^1	R^2	Alcohol	Yield (%)
123	n-C_7H_{15}	Et	**128a**	66
		Bu	**128b**	68
		Ph	**128c**	58
124	OBn	Et	**129a**	64
		Bu	**129b**	65
		Ph	**129c**	70
125	Ph	Et	**130a**	62
		Bu	**130b**	65
126	$CH_2=CH(CH_2)_8$	Et	**131a**	71

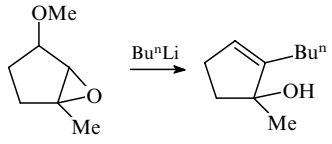


127 **132** (60%)

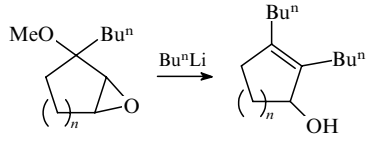
This reaction is also suitable for the preparation of optically active substances; for this purpose, the starting epoxy aldehydes are prepared by Sharpless asymmetric epoxidation.[43]

e. Organolithium compounds

Treatment of bicyclic α-methoxyepoxides **133**–**136** with various organolithium reagents leads to allylic alcohols **137**–**140**.[44]

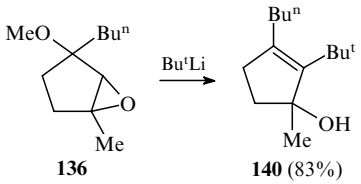


133 **137** (88%)



134, **135** **138** (85%), **139** (76%)

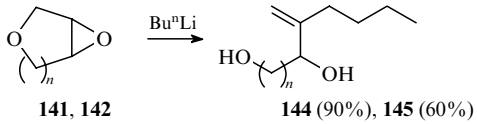
n = 1 (**134**, **138**), 2 (**135**, **139**).



136 **140** (83%)

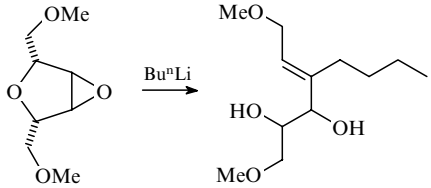
The reaction includes the formation of a carbene-like intermediate from the metallated oxirane followed by the insertion of alkyllithium and elimination of MeOLi.

Similar reactions involving 3,4-epoxydihydrofurans (**141**) and -pyrans (**142**) and derivative **143** result in diols **144**–**146**, containing an allylic alcohol fragment.[45]



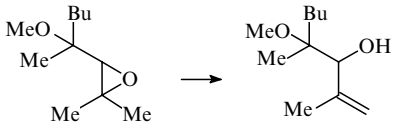
141, **142** **144** (90%), **145** (60%)

n = 1 (**141**, **144**), 2 (**142**, **145**).



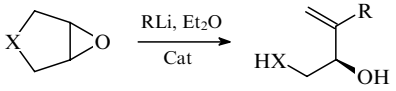
143 **146** (90%)

It is noteworthy that acyclic substrate **147** does not react to give the carbenoid, but is converted instead into the classical β-elimination product **148**.

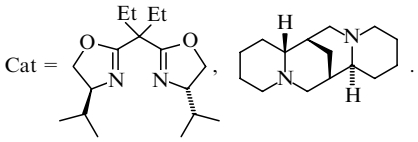


147 **148** (89%)

Hodgson *et al.*[46] reported the synthesis of unsaturated diols and amino alcohols containing an allylic alcohol fragment by cleavage of five- and three-membered heterocycles in the corresponding 3,4-epoxydihydrofurans and -pyrroles upon the reaction with alkyllithium in the presence of chiral diamines (Cat).

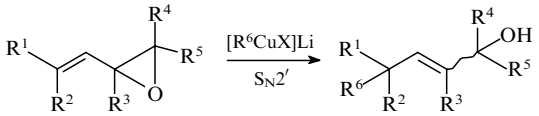


X = O, NSO_2Bu^t; R = Bu^n, Pr^i;

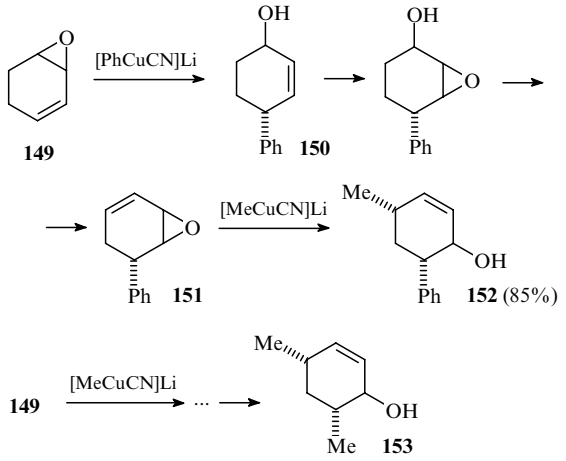


f. Lithium alkylcyanocuprates

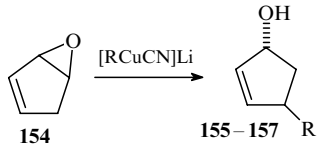
Yet another method for the preparation of allylic alcohols is based on the reaction of vinylic epoxides with lithium organocuprates. A review by Marshall[47] contains numerous examples of opening of the oxirane ring in vinyloxiranes by means of these reagents.



Thus the reaction of epoxycyclohexene **149** with lithium phenylcyanocuprate gives allylic alcohol **150** in a high yield. Alcohol **150** can be converted into the vinylic epoxide **151**, which is made to react with lithium methylcyanocuprate. This sequence of reactions can give allylic alcohol **152**.[48] If lithium methylcyanocuprate is used in the first step instead of phenylcyanocuprate, allylic alcohol **153** containing two methyl groups is formed.

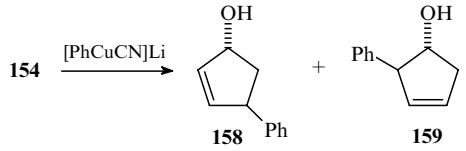


The readily available epoxycyclopentene **154** can also be involved in this reaction; allylic alcohols **155**–**157** were prepared by treatment of **154** with various alkylcyanocuprates.[49]



R = Bu^n (**155**, 95%), Bu^t (**156**, 88%), Me (**157**, 78%).

A similar reaction of lithium phenylcyanocuprate with epoxide **154** is non-regioselective and yields a mixture of isomeric phenylcyclopentenols **158** and **159** in 2 : 1 ratio and in an overall yield of 50%.

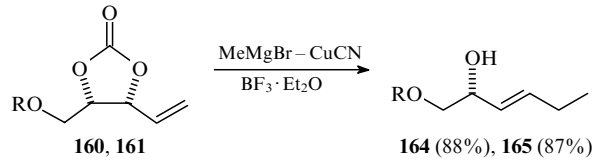


It was found that alkylcyanocuprates obtained from stabilised carbanions react with epoxycyclopentene **154** to give desired allylic alcohols in a low yield (17%). For example, with the use of cyanocuprate [Bu_3SnCH_2CuCN]Li, the yield of the alcohol does not exceed 5%.[48]

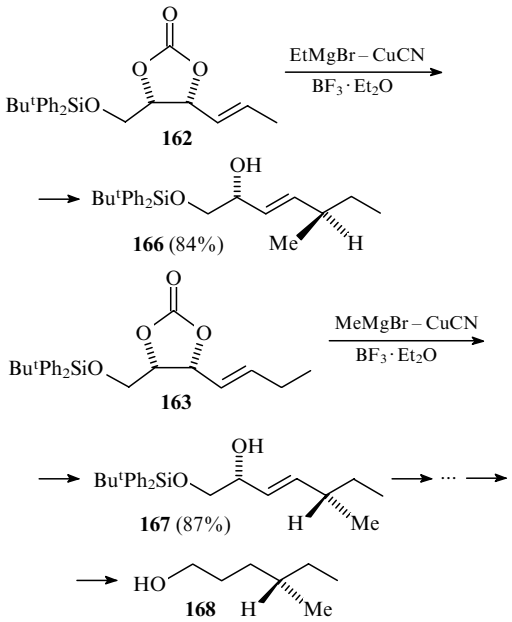
g. Synthesis of allylic alcohols from cyclic vinyl carbonates

This route is similar to the above-described method of synthesis of allylic alcohols from vinylic epoxides. Both reactions include a nucleophilic attack by the reagent on the double bond rather than on the centre bearing the leaving group (S_N2' mechanism).[50–52]

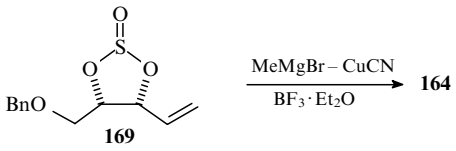
It was found[53] that many cyclic carbonates **160**–**163** react with organic cuprates [RCuCN]Li, [RCuCN]MgBr, RMgBr–CuI (Cat) (R = Me, Et, Bu^n) in the presence of $BF_3 \cdot Et_2O$ giving rise to alkylated (*E*)-allylic alcohols **164**–**167** with very high diastereoselectivities.



R = Bn (**160**, **164**), Bu^{t}Ph$_2$Si (**161**, **165**).



The configuration of the new stereocentre in molecule **167** was confirmed by transforming it into the known (*S*)-(+)-4-methylhexan-1-ol (**168**).[54] Cyclic sulfite **169** reacts with the MeMgBr–CuCN system in the presence of $BF_3 \cdot Et_2O$ in a similar way; the yield of the (*E*)-allylic alcohol **164** is 66%.



3. Miscellaneous methods for the synthesis of allylic alcohols from epoxides

To complete the Section, it is pertinent to mention some other methods used to prepare allylic alcohols from epoxides. Feringa and co-workers[55] have used the dialkylzinc–copper(II) triflate–chiral phosphoramidite system for oxirane ring opening in epoxides; this gave chiral alcohols. This procedure provided kinetic resolution of vinyloxirane isomers containing six- or seven-membered rings with *ee* values above 90%.[56] More detailed information on this topic is available from a review.[57] A recent publication[58] reports the reaction of phenylsulfonyl-substituted vinyl epoxides with various aromatic molecules (benzene, anisole, pyrrole, thiophene) in the presence of boron trifluoride etherate to give sulfonyl-containing allylic alcohols (Friedel–Crafts reaction).

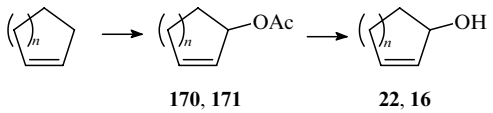
III. Reagents for allylic oxidation

α-Oxidation of alkenes represents yet another strategy for the preparation of allylic alcohols. Below we consider the reagents used for this purpose.

1. Manganese(III) acetate in acetic acid

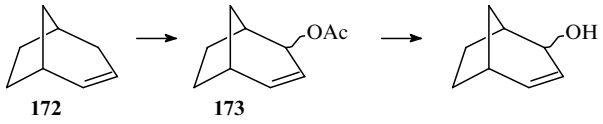
Alkenes are oxidised with manganese(III) acetate in acetic acid in the presence of metal halides to give allylic acetates,[59] which are readily transformed into allylic alcohols. For example, cyclopentene and cyclohexene can be converted into cyclopent- and cyclohex-2-enyl 3-acetates (**170**, **171**) in very good yields; hydrolysis of the acetates affords the corresponding alcohols **22** and **16**. Bicyclo[3.2.l]oct-2-ene (**172**) reacts with manganese acetate in a similar way to give acetate **173** in a good yield. Dihydronaphthalenes **174** and **175** were converted into acetates **176** and **177** but

the product yields were low.† Norbornene does not react with Mn(III) acetate. Manganese(III) acetate can be replaced by palladium,[60] thallium(III)[61] and lead[32] acetates.

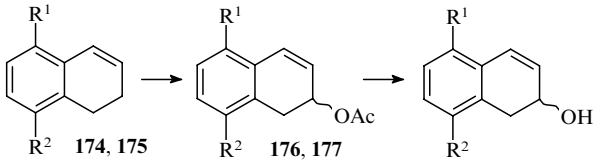


170, **171** **22**, **16**

n = 1 (**170**, **22**), 2 (**171**, **16**).



172 **173**



174, **175** **176**, **177**

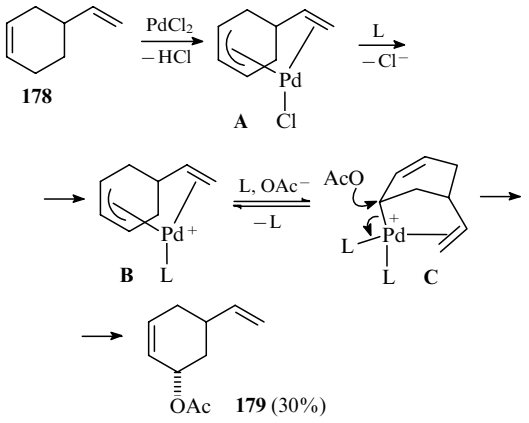
R^1 = R^2 = Me (**174**, **176**), R^1 = H, R^2 = OMe (**175**, **177**).

It has been suggested that alkene oxidation involves the initial abstraction of a hydrogen atom to give a radical, which is rapidly oxidised to give allylic acetate. It is worth noting that this reaction gives good product yields for simple alkenes, whereas in the case of bicyclic alkenes, the yields of allylic acetates are not satisfactory.

2. Acetoxylation of vinylcycloalkenes in the presence of $PdCl_2$

Wagell and co-workers[62] reported the transformation of 4-vinylcyclohexene (**178**) into allylic acetate **179** upon the reaction with $CuCl_2$ or the $CuCl_2$ – LiCl – O_2 system in the NaOAc – AcOH medium in the presence of palladium chloride as a catalyst and an excess of triphenylphosphine (or bisphosphine $Ph_2PCH_2.CH_2PPh_2$) (Scheme 4). Despite variation of the reaction conditions, the yield of allylic acetate was low.

Scheme 4



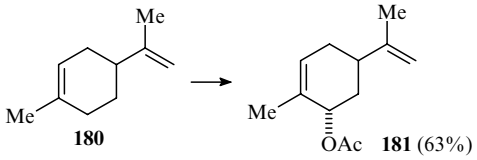
178 **A** **B** **C** **179** (30%)

The formation of compound **179** as the *trans*-isomer and high regioselectivity of the reaction can be explained in terms of the homogeneous catalysis mechanism. The reaction proceeds *via* intermediates **A** – **C**.

A model study has shown that the reaction route is determined by steric and stereoelectronic effects. The reasons for the formation of particularly the *trans*-isomer of compound **179** are related to the fact that triphenylphosphine (L), present in excess, blocks the metal atom in intermediate **C** and, hence, the weaker acetate ligand can approach the substrate only from the 'outside'.[63, 64]

In conformity with the proposed mechanism, the reaction stereochemistry is dictated by the vinyl group in compound **178**, and the phosphine ligand seems to be necessary for stabilisation of intermediate species **B** and **C**.

This reagent was also used to convert limonene (**180**) into allylic acetate **181**.[62]

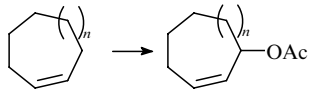


180 **181** (63%)

In this case, in view of the enhanced nucleophilicity of the vinyl group in limonene, acetoxylation can be carried out without a phosphine ligand.

3. Acetoxylation with palladium acetate-containing systems

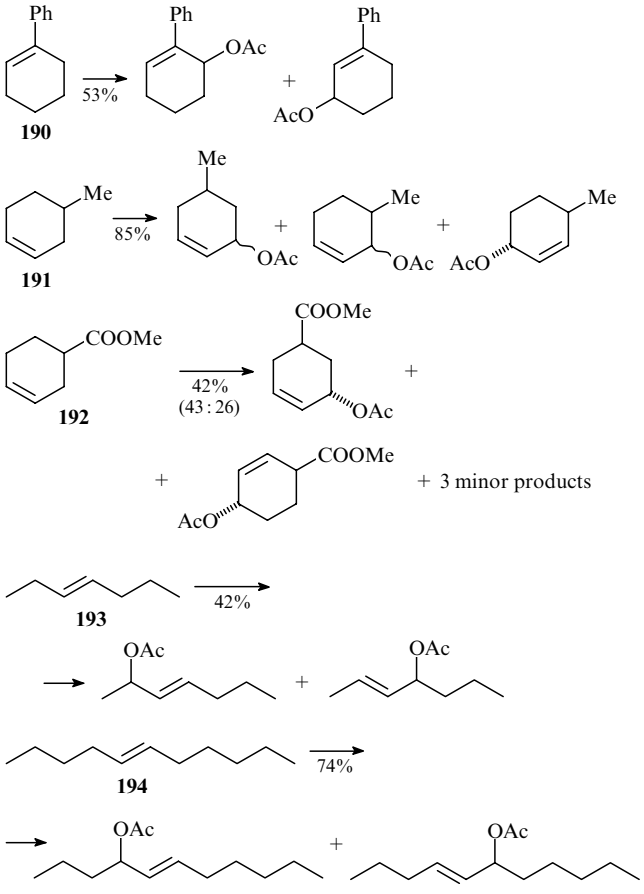
Allylic acetoxylation of alkenes and cycloalkenes by treatment with palladium acetate in the presence of magnesium dioxide (oxidant) and benzoquinone (co-oxidant) in acetic acid has been reported.[65] This procedure was used to transform cycloalkenes **182** – **185** into the corresponding acetates **186** – **189** (in the case of cyclooctene **183**, the yield of allylic acetate **187** is moderate).



182 – **185** **186** – **189**

n = 1 (**182, 186**, 73%), 2 (**183**, **187**, 35%), 4 (**184**, **188**, 78%), 6 (**185**, **189**, 72%).

Asymmetrical alkenes, for example **190** – **194**, are also converted into the corresponding allylic acetates; the total yields of products are quite high but they are formed as isomer mixtures.



190 **191** **192** **193** **194**

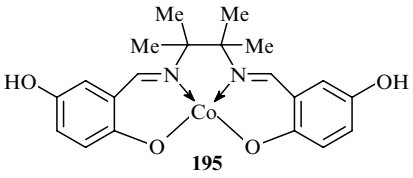
Study of the reaction mechanism has shown that allylic acetoxylation either follows the 1,2-acetoxypalladation mecha-

† A K Banerjee, W J Vera, J A Azocar, unpublished data.

nism with subsequent β-elimination of palladium hydride or involves the formation of an alkene-η^3-allylic complex, which is subjected to a nucleophilic attack by the acetate. The contributions of both mechanisms depend on the alkene structure. For simple alkenes, the η^3-allylic mechanism is relatively unlikely.

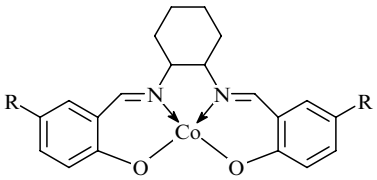
Bystroem *et al.*[66] has performed allylic acetoxylation of alkenes by a procedure similar to that described in another study,[65] but using oxygen instead of MnO_2 and hydroquinone instead of benzoquinone. The reaction was carried in the presence of copper(II) acetate. Copper acetate can be replaced by manganese(III) or cobalt(II) acetate, although these are less efficient. Palladium acetate is an obligatory component; otherwise, the target product is not formed. The reaction rate increases with an increase in the amount of hydroquinone and does not change upon the replacement of hydroquinone by benzoquinone (in the latter case, the induction period almost disappears).

Instead of the hydroquinone (or benzoquinone)–copper acetate system, the reaction can be carried out with complex **195**, which contains a hydroquinone fragment.



195

Acetoxylation of cyclohexene in the presence of complex **195** furnishes cyclohexenyl acetate **171** in 90% yield. The reaction occurs somewhat more slowly than with the copper acetate–hydroquinone system. The use of complexes **196** and **197** with similar structures affords acetate **171** in 68 and 19% yields, respectively. If the reaction is carried out in the presence of a mixture of compound **197** (5 mol %) and hydroquinone (10 mol %), the yield of product **171** increases to 80%.



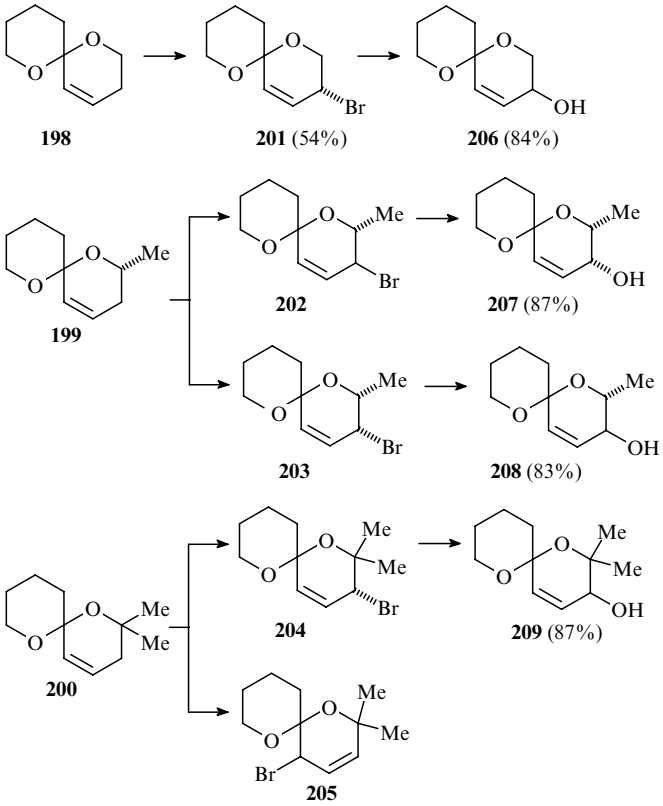
R = OH (**196**), H (**197**).

It is noteworthy that the acetoxylation of cycloalkenes we discuss has not been adequately studied (it has not been tested for all types of alkenes).

The acetoxylation of cyclohexene in the presence of system comprising 5 mol % of palladium acetate, 5 mol % of iron(III) nitrate and acetic acid under an oxygen atmosphere has been reported.[67] Cyclohexenyl acetate was obtained in a high yield (under an argon atmosphere, the acetate is formed in a low yield).[67] The addition of transition metal chlorides or acetates decreases the yield. The introduction of acetic anhydride results in a higher reaction rate. Non-symmetric 1-, 3 and 4-methylcyclohexenes are oxidised by palladium acetate or iron(III) nitrate giving rise to a mixture of isomeric products.

4. *N*-Bromosuccinimide

Brimple *et al.*[68] have developed an efficient method for the introduction of a hydroxyl group into the allylic position of unsaturated spiroketals using *N*-bromosuccinimide. Allylic bromination of unsaturated spiroketals with *N*-bromosuccinimide in tetrachloromethane furnishes bromo-derivatives containing an axial bromine atom. On treatment of these products with KO_2 and 18-crown-6 ether in a THF/DMSO mixture (10 : 1), the Br atom is replaced by an OH group by the S_N2 mechanism to give the alcohol with an equatorial hydroxyl group. This method was used to convert spiroketals **198**–**200** into bromo-derivatives **201**–**205**, which were then transformed into allylic alcohols **206**–**209**. It was found that allylic bromination of spiroketals **199** and **200** gives mixtures of isomeric products and bromide **205** does not enter into the substitution reaction to give the alcohol.



198 **201** (54%) **206** (84%)

199 **202** **207** (87%)

203 **208** (83%)

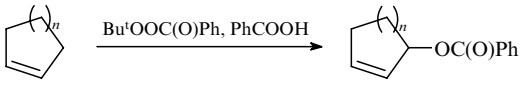
200 **204** **209** (87%)

205

Bernet *et al.*[69] have oxidised a bicyclic spiroketal at the allylic position by selenium dioxide.

5. *tert*-Butyl peroxybenzoate

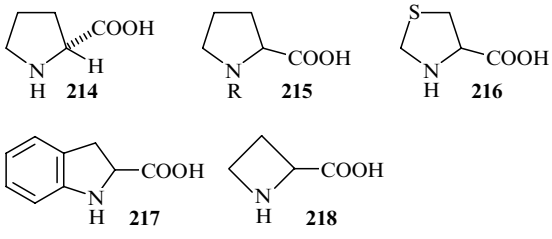
Acyloxylation of alkenes with $Bu^tOOC(O)Ph$ or Bu^tOOH and carboxylic acids RCOOH (R = CF_3, CCl_3, Me, Bu^t, *etc.*) in the presence of catalytic amounts of copper compounds and chiral promoters, (*S*)- and (*R*)-prolines, has been reported.[70] This reaction yields optically active esters. For instance, allylic benzoates **210** and **211** have been prepared from cyclopentene and cyclohexene. Cycloalkenes with larger rings have also been introduced in this reaction.



210–**213**

n = 1 (**210**, 39%, *ee* 56%), 2 (**211**, 59%, *ee* 37%), 3 (**212**, 27%, *ee* 23%), 4 (**213**, 32%, *ee* 4%).

Apart from proline (**214**) and its derivatives **215**, amino acids **216**–**218** were also used as chiral promoters, while acetonitrile or benzene were used as solvents.

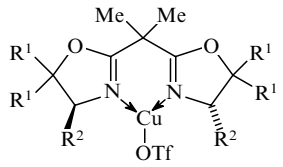


214 **215** **216**

217 **218**

The process enantioselectivity is dictated by the natures of the alkene and the auxiliary chiral reagent and depends little on the nature of the carboxylic acid.

Andrus *et al.*[71] have described allylic acyloxylation of alkenes with *tert*-butyl peroxybenzoate in the presence of catalytic amounts of copper compounds in boiling benzene. Thus cyclic alkenes and oct-1-ene react with $Bu^tOOC(O)Ph$ in the presence of chiral bisoxazoline complexes of copper(I) triflate **219**–**221**

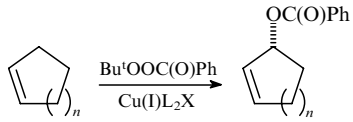


219: $R^1 = H$, $R^2 = Bu^t$;
220: $R^1 = Me$, $R^2 = Bu^t$;
221: $R^1 = Me$, $R^2 = Ph$.

219–**221**

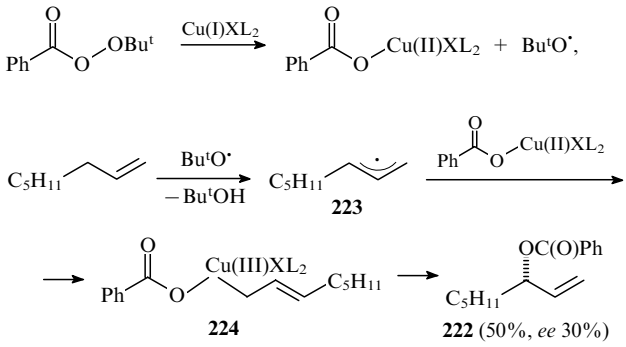
to yield non-racemic allylic benzoates **210**, **211**, **213** and **222**.

In most experiments, acetonitrile served as the solvent, but in some cases (for example, in the synthesis of compound **222**), benzene was used. The reaction mechanism was considered taking oxidation of oct-1-ene as an example.



210, **211**, **213**

Benzoate	*n*	Yield (%)	*ee* (%)
210	1	44	70
211	2	62	67
213	4	62	67



223

224

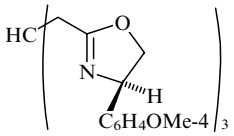
222 (50%, *ee* 30%)

X = OTf.

The reductive homolysis of the peroxide bond under the action of a copper(I) atom affords copper(II) benzoate and a *tert*-butoxyl radical. The latter splits off the allylic hydrogen atom from the olefin, which is converted into allylic radical **223**. This radical rapidly adds to copper(II) benzoate to give a copper(III) complex with the allylic ligand (**224**). The reaction ends in the rearrangement of complex **224** to give allylic ester **222** and to recover the copper(I)-containing catalyst.

Pfaltz *et al.*[72] have also utilised *tert*-butyl peroxybenzoate and copper(I) complexes obtained *in situ* from chiral bisoxazolines and Cu(I)OTf for the oxidation of cycloalkenes. They prepared cycloalk-2-enyl benzoates in satisfactory or good yields. For instance, the transformation products of cyclopentene and cycloheptene were isolated with an enantiomeric excess of 74% at 23 °C and 84% at a low temperature; in the case of cyclohexene, the enantioselectivity is somewhat lower (*ee* 64%–77%). Feringa and co-workers[73] have reported allylic oxidation of cyclohexene with a number of chiral Cu(II) complexes with amino acids.

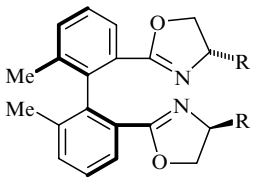
It was found[74] that the copper(II) triflate complex with the tridentate tris(oxazoline) ligand **225** is an efficient chiral catalyst for the asymmetric allylic oxidation of various cycloalkenes with *tert*-butyl peroxybenzoate (Kharash — Sosnovsky reaction).



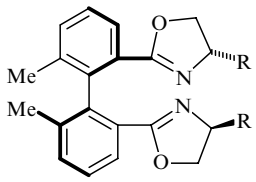
225

Cycloalkenyl benzoates are formed in this reaction in good yields and good enantioselectivities (*ee* > 81%). The reaction can be carried out in acetone, acetonitrile or 1,2-dichloroethane, the highest enantioselectivity being attained in the last-mentioned solvent.

The asymmetric allylic oxidation of cyclohexene and cyclopentene by treatment with *tert*-butyl 4-nitro-, 2-iodo- and 2,4,6-trichloro-substituted peroxybenzoates was also attempted for copper(I) hexafluorophosphate complexes with bis(*o*-tolyl)bisoxazolines **226a**–**d** and **227a**–**d**. This gave allyl benzoates with medium to high selectivities.[75]



(*S*,*S*,*S*)-**226a**–**d**

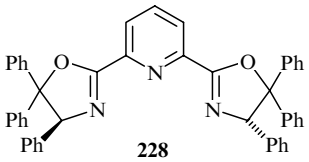


(*S*,*R*,*S*)-**227a**–**d**

R = Ph (**a**), Bu^t (**b**), Bn (**c**), Pr^i (**d**).

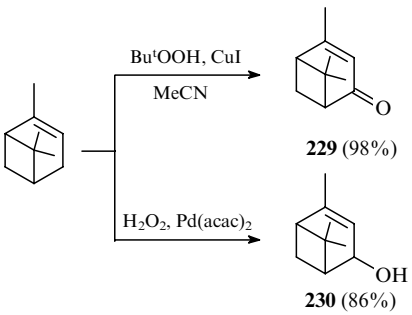
The highest selectivity was reached with 4-nitro-substituted *tert*-butyl peroxybenzoate and ligand **226a** (for cyclohexene, *ee* 73%) or **226c** (for cyclopentene, *ee* 72%).

Indian researchers[76] have used bisoxazoline ligand **228**. This allowed them to increase the enantioselectivity of allylic oxidation of cyclohexene to 86%.



228

Catalytic allylic oxidation of α-pinene with *tert*-butyl hydroperoxide and hydrogen peroxide in the presence of transition metal salts has been reported.[77] It was found that oxidation of α-pinene with the Bu^tOOH–CuI system gives verbenone (**229**) as the major product, while the oxidation with the H_2O_2–$Pd(acac)_2$ system gives predominantly verbenol (**230**).



229 (98%)

230 (86%)

Other terpene alkenes (limonene, 3-carene) have also been involved in this reaction.

Sartori and co-workers[78] reported the use of the Cu-Na-HSZ-320 zeolite as an efficient and reusable catalyst for allylic oxidation

of alkenes into allylic alcohols on treatment with *tert*-butyl peroxybenzoate.

Catalytic allylic oxidation of alkenes with the use of the asymmetric version of the Kharash – Sosnovsky reaction is the subject of a review.[79]

6. Miscellaneous reagents for alkene α-oxidation

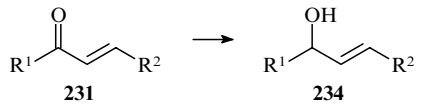
Oxidation of the methylene group in an allylic position with SeO_2 ‡ to give allylic alcohols has been reported.[79, 80]

The SeO_2-catalysed allylic oxidation with *tert*-butyl hydroperoxide as a stoichiometric reagent is more efficient.[28, 81] This reaction has been used for allylic hydroxylation of vinyl fluorides.[82] Photochemical synthesis of allylic alcohols from alkenes has also been described.[83] In this case, a benzene or pyridine solution of alkene or a conjugated diene is irradiated in the presence of oxygen and a sensitiser (methylene blue, some porphyrin derivatives); this gives a hydroperoxide, which is reduced to yield the allylic alcohol. By this method, one can convert alkenes into allylic alcohols with a shifted double bond.[84]

IV. Reagents for the reduction of α,β-unsaturated carbonyl compounds

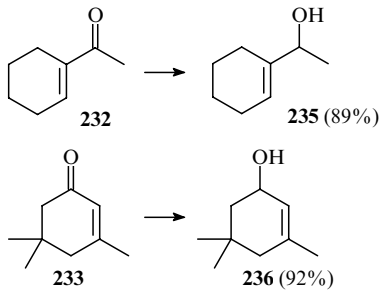
Reduction of α,β-unsaturated carbonyl compounds (aldehydes, ketones, and esters) is a key method for the synthesis of allylic alcohols. However, the use of the most readily available reducing agents such as $NaBH_4$ or $LiAlH_4$ results in the partial or even complete reduction of the double bond;[85] therefore, other hydride reducing agents have been proposed for this purpose.[86, 87]

For example, $Li[(CH_2)_4NBH_3]$ has been used for selective reduction of ketones **231** – **233** into allylic alcohols **234** – **236**.[88, 89]



231 **234**

R^1 = H, R^2 = Ph (99%); R^1 = Me: R^2 = Ph (99%), n-C_5H_{11} (96%).



232 **235** (89%)

233 **236** (92%)

The ratio of 1,2- to 1,4-reduction products was > 99 : 1 in all cases.

Lithium aminoborohydrides are not pyrophoric; therefore, they are used in large-scale reduction processes.

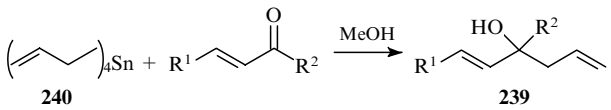
Later, it was shown[90] that α,β-unsaturated ketones **237** are reduced with the $Bu_2SnH_2 - Bu_2SnF_2$ system in combination with HMPA to give allylic alcohols **238**.

237 **238**

R = H (75%), Me (89%), Ph (56%).

If HMPA is replaced by LiI, the C = C bond is reduced, while the keto group remains intact.

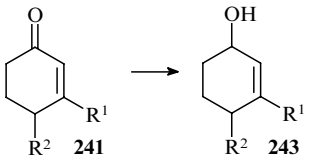
The synthesis of allyl vinyl alcohols **239** by treatment of α,β-unsaturated ketones with tetraallyltin (**240**) has been described.[91]



240 **239**

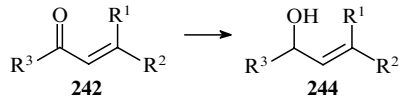
R^1 = H, R^2 = Et (73%); R^1 = Ph, R^2 = Me (91%),
$R^1 - R^2 = (CH_2)_3$ (65%).

Ranu and Das[92, 93] reported that the zinc borohydride – silica gel system is able to reduce conjugated ketones to allylic alcohols. For example, conjugated ketones **241**, **242** were converted into alcohols **243**, **244** in high yields.



241 **243**

R^1 = R^2 = H (15%); R^1 = Me: R^2 = H (80%), COOEt (82%), COOMe (85%).

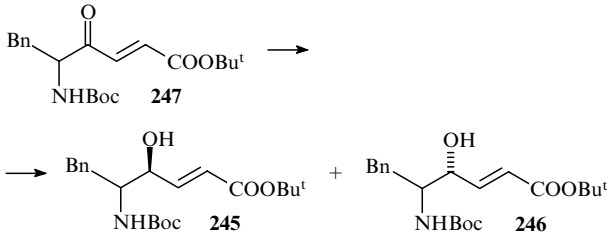


242 **244**

R^1 = H, R^2 = Me: R^3 = H (80%), Me (85%);
R^1 = H, R^2 = Ph: R^3 = H (82%), Me (85%);
R^1 = R^2 = R^3 = Me (79%).

The yield of the product of α-ionone reduction was 85%.

A recent publication[94] describes the formation of diastereomeric allylic alcohols **245** and **246** in 95 : 5 ratio (overall yield 80%) upon the diastereoselective reduction of *N*-Boc-protected δ-amino-α,β-unsaturated γ-ketoester **247** with $LiAlH(OBu^t)_3$ in EtOH at −78 °C under chelation control. The same reduction carried out with non-chelating NB-enantride in THF at −78 °C (so-called Felkin – Anh control) produces alcohols **245** and **246** in 5 : 95 ratio (overall yield 98%).



247

245 **246**

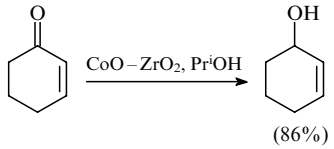
The reduction of ketoester **247** by standard reagents such as $NaBH_4 - CeCl_3$, $Zn(BH_4)_2$, Bu^i_2AlH (DIBAL-H) or a Bu^i_2AlH mixture with $ZnCl_2$ is non-selective.

Another study has also dealt with the reduction of enones to allylic alcohols.[95] It was shown that the reduction of amino-substituted enone obtained on the basis of L-serine with various reducing agents including L-selectride – THF, $LiAlH_4 - Et_2O$, $NaBH_4$ – MeOH, Red-Al – THF {Red-Al is $[(MeOCH_2.OCH_2)_2AlH_2]Na$} and so on results in a mixture of *syn*- and *anti*-isomers of aminoallylic alcohols in very high yields. The size of the hydride influences the diastereoselectivity of the reaction; the greater the hydride size, the higher the yield of the *syn*-isomer. The nature of the solvent also affects the isomer ratio.

Catalytic hydrogenation of the C = C – C = O fragment for the synthesis of allylic alcohols is normally difficult to arrange, especially under heterogeneous catalysis conditions. Nevertheless, a number of catalysts that increase the chemoselectivity and, in some cases, also the enantioselectivity of this reaction have been proposed in recent years.

‡ This reagent is also used in the synthesis of unsaturated carbonyl compounds.

The reduction of α,β-unsaturated ketones using isopropyl alcohol (as the source of hydrogen atoms) and a mixture of $CoO-ZrO_2$ oxides (as the catalyst) has been reported.[96]

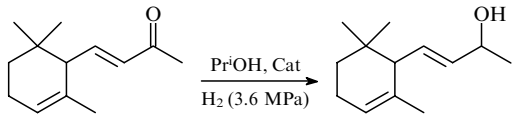


(86%)

$$R^1R^2C{=}CHCHO \xrightarrow{CoO-ZrO_2,\ Pr^iOH} R^1R^2C{=}CHCH_2OH$$

R^1 = H: R^2 = Pr^n (84%), Me (83%), Ph (80%);
R^1 = Me: R^2 = $(CH_2)_2CH{=}CMe_2$ (71%).

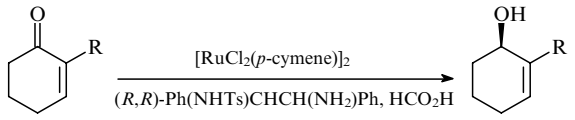
Iridium salts [for example, $Ir(acac)_3$] supported on various zeolites can be used as catalysts (Cat) instead of metal oxides. This method was used for chemoselective reduction of α- and β-ionones, testosterone, cholestenone, and so on.[97] For example,



(75%, *ee* 71%)

High catalytic efficiency in the Meerwein–Ponndorf–Verley reduction of unsaturated ketones to allylic alcohols was found for Zr and Hf catalysts supported on mesoporous materials of the MCM-41 and MCM-48 type.[98]

Wills and co-workers [99] reported the efficient use of asymmetric transfer hydrogenation for the reduction of enones. Numerous catalyst systems have been developed for this process. The system ruthenium(II) complex–chiral monotosylated diamine (or β-aminoalcohol)–formic acid is used most often.



R = Ph (47%, *ee* 72%), OBn (78%, *ee* 99%),
$NHCO_2Me$ (54%, *ee* > 99%).

Other examples of catalytic hydrogenation of enones can be found in the review by Noyori.[100]

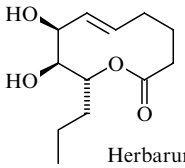
V. Miscellaneous methods

We have considered the most important reagents used to convert alkenes and their derivatives into allylic alcohols *via* cleavage of α-epoxides, allylic hydroxylation and reduction of α,β-unsaturated carbonyl compounds. This Section presents a brief discussion of other general methods for the synthesis of allylic alcohols.

1. Reactions of carbonyl compounds with alkenes and alkynes

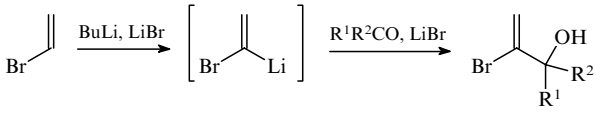
The reaction of alkenylmagnesium halides with aldehydes or ketones (Normann method) is a well-known method for the synthesis of allylic alcohols. The addition of divinylzinc to carbonyl compounds also deserves attention.[101] Subsequently, this strategy has been developed in the field of metal complex catalysis.

The use of nickel(II) chloride and palladium(II) acetate as catalysts of the cross-coupling of iodoalkenes with aldehydes, resulting in the formation of allylic alcohols, has been reported.[102] It is important that double bond configuration in the product is the same as that in iodoalkene. Diastereoselective synthesis of allylic alcohols from α-substituted aldehydes by the Nozaki–Hiyama–Kishi reaction has been reported.[103] This transformation was used in the synthesis of (+)-herbarumin I.



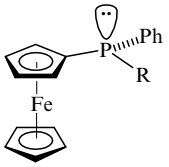
Herbarumin I

An efficient method for the synthesis of bromoallylic alcohols from 1-bromo-1-lithioethene and aldehydes or ketones has been reported.[104]



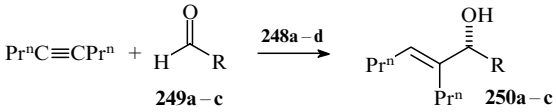
$R^1 = R^2$ = Me (77%); R^1 = Me, $R^2 = CH_2{=}CH$ (78%),
$CH_2{=}CH(CH_2)_2$ (84%), $CH_2{=}CHCMe_2CH_2CH_2$ (80%);
$R^1-R^2 = (CH_2)_5$ (85%); R^2 = H: R^1 = Et (46%), n-C_6H_{13} (50%),
Ph (81%), $CH_2{=}CH$ (74%).

Phosphines containing a ferrocene fragment proved to be efficient ligands for a number of catalytic reactions and a number of metal-catalysed asymmetric reactions.[105–107] It has been found [108] that P-chiral monodentate ferrocenylphosphines **248a–d** can be used as ligands in asymmetric catalytic reductive coupling of oct-4-yne with aldehydes **249a–c** to produce chiral allylic alcohols **250a–c** with high regio- and enantioselectivities.



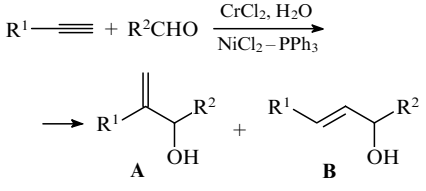
248a–d

R = Me (**a**), 4-$MeOC_6H_4$ (**b**), cyclo-C_6H_{11} (**c**), Bu^n (**d**);



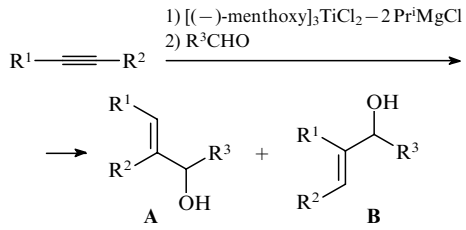
R = Ph (**a**), Pr^n (**b**), Pr^i (**c**).

Racemic allylic alcohols were also prepared *via* intramolecular [109, 110] and intermolecular [111] reductive coupling of alkynes and aldehydes. The reductive coupling of alkyne with aldehyde was also used to synthesise chiral allylic alcohols. Reductive coupling in the presence of stoichiometric amounts of transition metals has been studied by Takai and co-workers,[112] Negishi and co-workers,[113] Livinghouse and co-workers,[114] Takai and Utimoto and co-workers.[115, 116] For example,[112]



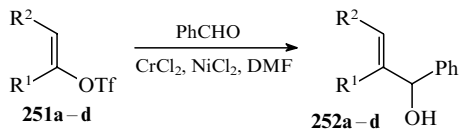
$R^1 = Ph(CH_2)_2$, R^2 = n-C_8H_{17} (82%, **A** : **B** = 95 : 5); R^1 = n-$C_{10}H_{21}$,
R^2 = Ph (99%, **A** : **B** = 94 : 6); R^1 = n-$C_{10}H_{21}$, R^2 = cyclo-C_6H_{11} (78%,
A : **B** = 90 : 10); $R^1 = HO(CH_2)_2$, $R^2 = Ph(CH_2)_2$ (83%, **A** : **B** = 99 : 1).

The use of a chiral titanium complex–alkyne system in the synthesis of chiral alcohols has been reported.[117]



$R^1 = R^2 = n\text{-}C_5H_{11}$: R^3 = Et, Pr^i, cyclo-C_6H_{11};
$R^1 = Me_3Si$, R^3 = cyclo-C_6H_{11}: $R^2 = n\text{-}C_6H_{13}$, Ph.

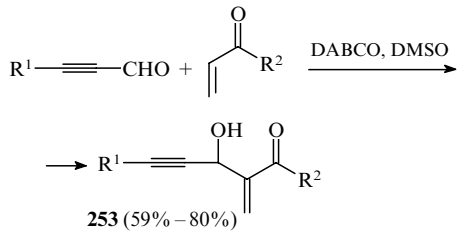
The reaction between alkenyl triflates and aldehydes[118] induced by $CrCl_2$ in the presence of catalytic amounts of $NiCl_2$ is similar in essence. For example, triflates **251a–c** react with benzaldehyde in the presence of $CrCl_2$ and catalytic amounts of $NiCl_2$ in DMF to give the corresponding allylic alcohols **252a–c** in high yields. In ether and THF, which sparingly dissolve $CrCl_2$, this reaction barely proceeds. Other aldehydes can also be introduced in this reaction, for example, $C_8H_{17}CHO$ or $Pr^iCH=CHCHO$. In the presence of other catalysts such as $MnCl_2$, $FeCl_3$, $CoCl_2$ and $PdCl_2$, the yield of the target product decreases. In addition, decomposition of triflates is possible. Steric factors associated with the presence of substituents at the double bond can have a pronounced influence on the reaction route.



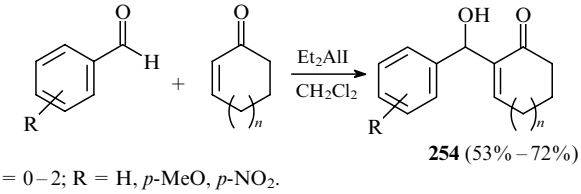
R^1 = Bu, R^2 = H (**a**); $R^1 = n\text{-}C_{10}H_{21}$, R^2 = H (**b**);
$R^1 - R^2 = (CH_2)_4$ (**c**); R^1 = Me, R^2 = Ph (**d**).

A mechanism including the reduction of nickel(II) chloride to nickel(0) with $CrCl_2$ has been proposed for this transformation. Nickel and triflates form organonickel compounds, which undergo transmetallation. The resulting organochromium compounds react with aldehydes.

For the synthesis of functionally substituted allylic alcohols, the Baylis–Hillman reaction is used. These alcohols are important intermediates in the synthesis of many natural compounds: alkaloids, pyrethroids, steroids, pheromones, and so on. In particular, allylpropargyl alcohols **253**[119] and 2-(α-hydroxybenzyl)cyclohex-2-enone (**254**)[120] have been synthesised in this way.



R^1 = Ph, $n\text{-}C_6H_{13}$; R^2 = Me, OEt; DABCO is diazabicyclooctane.

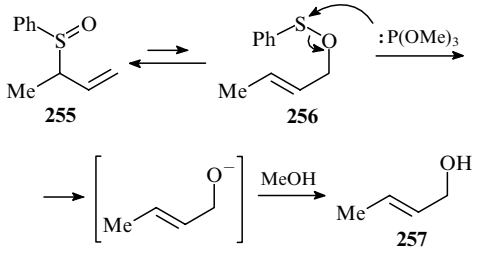


n = 0–2; R = H, *p*-MeO, *p*-NO_2.

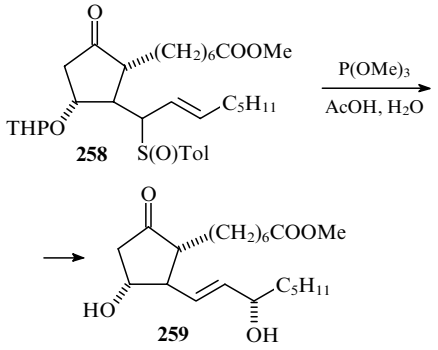
2. [2,3]-Sigmatropic rearrangements of chalcogen oxides

It has been noted above that oxidative elimination of a selenium group is a general method for the synthesis of alkenes.[28] However, during the oxidation of allyl selenides, the intermediate selenium oxide undergoes a [2,3]-sigmatropic rearrangement involving the double bond, resulting in the selenenic ester of the rearranged allylic alcohol and finally in the corresponding allylic alcohol.

In the case of analogous sulfur compounds, this reaction is less typical, although some examples are known (see the review[121]). Thus on heating in the presence of trimethyl phosphite, allyl sulfoxide **255** is partially rearranged into the allyl ester of sulfenic acid **256**.[121] As a rule, the equilibrium in this reaction is largely shifted toward the sulfoxide, but on treatment of the reaction mixture with a thiophilic reagent (for example, trimethyl phosphite and diethylamine), the sulfenate is irreversibly converted into allylic alcohol **257**.



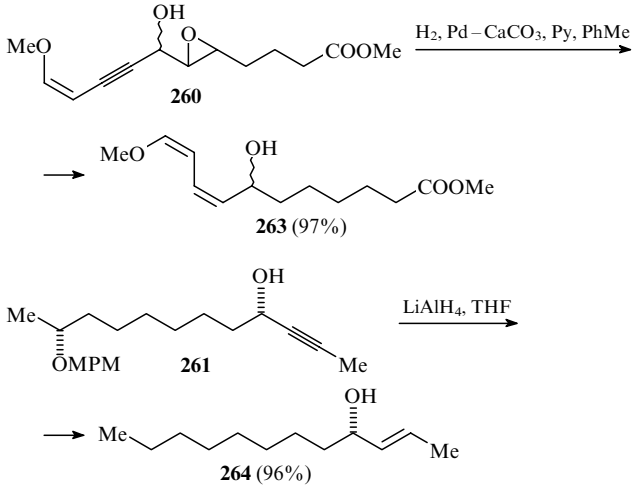
The transformation of sulfoxide **258** into allylic alcohol **259**, which is the racemic form of prostaglandin E (PGE_1), has been reported.[122]

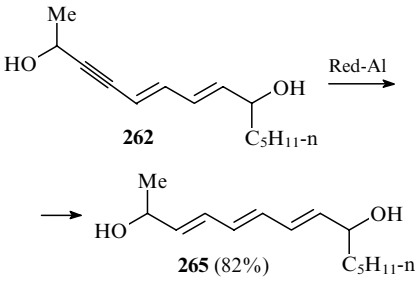


Other examples of rearrangement of sulfoxides and sulfones and the use of products of these rearrangements in total syntheses of natural compounds are given in the review by Prilezhaeva.[123]

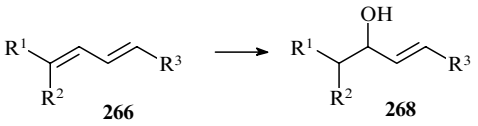
3. Other methods

In conclusion, we would like to note that allylic alcohols are formed upon partial hydrogenation of many acetylenic alcohols. The appropriate reducing agents include $LiAlH_4$, Red-Al, hydrogen with special catalysts, for example Pd–$CaCO_3$ (Lindlar catalyst) and so on. The reduction of acetylenes **260–262** has resulted in the preparation of allylic alcohols **263–265**.[124–126]





The reduction–oxygenation sequence induced by molecular oxygen and triethylsilane catalysed by cobalt(II) porphyrinate followed by treatment with trimethyl phosphite performs the transformation of compounds **266**, **267** into compounds **268**, **269**, containing an allyl alcohol fragment.[127]



$R^1 = R^2 = Me$, $R^3 = COOEt$ (81%); $R^1 = Bu^n$, $R^2 = H$, $R^3 = CHO$ (54%); $R^1 = n\text{-}C_6H_{13}$, $R^2 = H$, $R^3 = COOBu^t$ (73%); $R^1 = Pr^n$, $R^2 = H$, $R^3 = COOEt$ (82%).

IV.	Conclusion	660

Abstract. Data on the synthetic methods, reactivities, biological activities and other practically important properties of 1,8-naphthyridine derivatives published over the last 15 years are analysed. The bibliography includes 759 references.

I. Introduction

Of the six isomeric pyridopyridines, 1,8-naphthyridine derivatives have received the most study in the last 15 years. This class of compounds has attracted considerable attention primarily because the 1,8-naphthyridine skeleton is present in many compounds which have been isolated from natural substances and exhibit various biological activities. The number of publications (including patents) devoted to the chemical and biological properties of 1,8-naphthyridines which were issued over this period is substantially larger than the number of studies on all other types of isomeric pyridopyridines published in the last 90 years. In the last two years, more than 900 publications appeared, among which were about 200 patents. Most of these studies were devoted to specific aspects of biological activity assays of 1,8-naphthyridine derivatives.

The present article, which completes a series of reviews of the chemistry of pyridopyridines,[1,2] summarises and analyses data on the synthesis methods, reactivities, biological activities and other practically important properties of 1,8-naphthyridine derivatives. For convenience of representation, the data are classified according to the types of the starting substrates, reagents or the nature of the compounds synthesised. In the discussion of the synthetic methods and chemical transformations, the principal data on biological activities of the compounds synthesised are considered. In my opinion, it is reasonable to cite a virtually complete bibliography, including patents, on the synthesis and properties of 1,8-naphthyridine derivatives. However, since the literature on these problems is voluminous, only general and promising synthetic methods and most typical reactions are covered in detail in the present review.

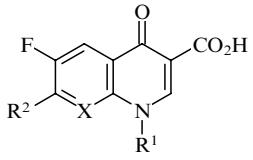
II. Synthetic methods and biological activities of 1,8-naphthyridine derivatives

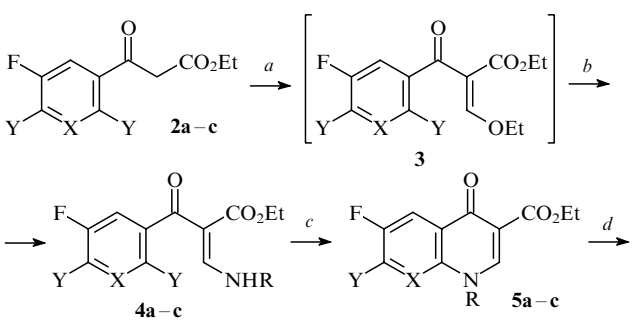
Among 1,8-naphthyridine derivatives, 6-fluoro-substituted 1,8-naphthyridin-4-ones, which are aza analogues of fluoroquinolones, have attracted most attention in the last 15 years. Fluoroquinolone- and fluoronaphthyridonecarboxylic acids provided the basis for the design of highly efficient antibacterial drugs, such as norfloxacin (**1a**),[3] pefloxacin (**1b**),[4] ciprofloxacin (**1c**),[5] enoxacin (**1d**),[6] trovafloxacin (**1e**),[7–10] *etc*.



1a – e

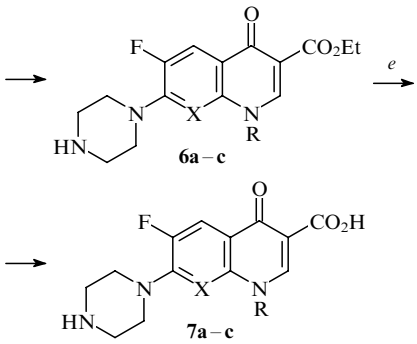
X = CH: R^1 = Et, R^2 = piperazin-1-yl (**a**), *N*-methylpiperazin-1-yl (**b**); R^1 = cyclo-C_3H_5, R^2 = piperazin-1-yl (**c**); X = N: R^1 = Et, R^2 = piperazin-1-yl (**d**); R^1 = 2,4-$F_2C_6H_3$, R^2 =  (**e**).

Fluoronaphthyridones are similar not only in biological activity but also in other properties to fluoroquinolones, whose chemistry has been studied in considerable detail.[11–15] The most commonly used method for the synthesis of fluoro-substituted 4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acids is based on approaches developed for preparing fluoroquinolone analogues [16–20] and can be represented by the following scheme:



2a – c **3** **4a – c** **5a – c**

† Dedicated to Academician Oleg Nikolaevich Chupakhin on the occasion of his 70th birthday.



X = N (**a**), CH (**b**), CF (**c**); Y = Cl, F;

R = Et, Pr^i, cyclo-C_3H_5, Bu^t, CH_2=CMe, 4-FC_6H_4;

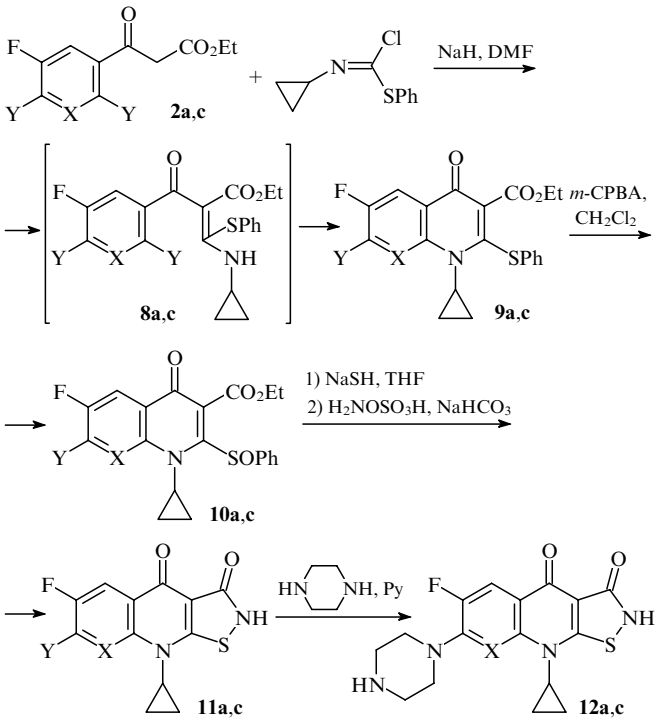
DBU is diazabicyclo[5.4.0]undec-7-ene;

(*a*) $HC(OEt)_3$, Ac_2O; (*b*) RNH_2, EtOH; (*c*) NaH, dioxane;

(*d*) $NH(CH_2CH_2)_2NH$, DBU, MeCN; (*e*) 1) NaOH, H_2O, Δ; 2) H^+.

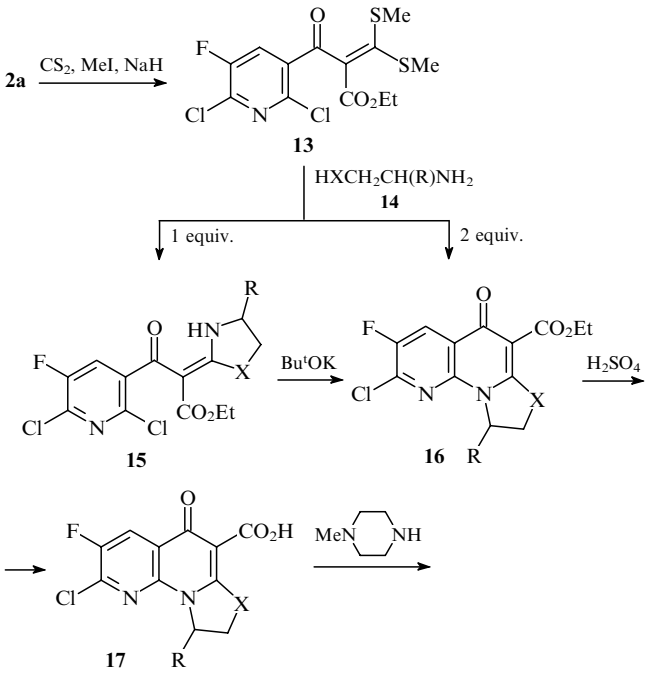
Condensation of ethyl (2,6-dichloro-5-fluoronicotinoyl)acetate **2a** and analogous benzoyl derivatives **2b**,**c** with ethyl orthoformate in acetic anhydride followed by the reaction of intermediates **3** with a small excess of amine (ethanol, 20 °C) yields the corresponding enamino ketoesters **4a**–**c**. Heating of enamines **4b** with sodium hydride in dioxane gives rise to ethyl 4-oxo-1,4-dihydroquinoline-3-carboxylates **5b**. Cyclisation of enamines **4a**, which can be carried out according to three procedures, *viz*., by reaction with sodium hydride in dioxane, with potassium carbonate in acetonitrile or with *tert*-butylammonium fluoride in THF, affords naphthyridones **5a** in good yields.[16–26] The replacement of the halogen atom at position 7 of compounds **5a** under the action of amine in acetonitrile (in some cases, in the presence of DBU as a base) gives rise to esters **6a**, which are hydrolysed to form acids. This procedure was used for the synthesis of naphthyridonecarboxylic acids **7a** (R = Et,[21] Pr^i,[16] isoprenyl,[24] Bu^t,[22] cyclopropyl,[25] 4-fluorophenyl [19]).

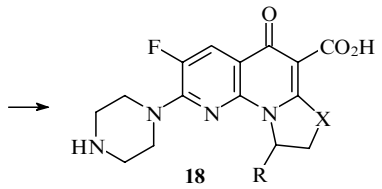
The high synthetic potential of esters **2** is also exemplified by their reactions with thioformates. For example, the reaction of ethyl 2,6-dichloro-5-fluoronicotinoylacetate (**2a**) with phenyl *N*-cyclopropyliminochlorothioformate in the presence of one equivalent of sodium hydride in xylene proceeds through intermediate **8a** to give ethyl 7-chloro-1-cyclopropyl-6-fluoro-4-oxo-2-phenylthio-1,4-dihydro-1,8-naphthyridine-3-carboxylate (**9a**) in 51% yield.[24] An analogous treatment of ethyl 2,3,4,5-tetrafluorobenzoylacetate (**2c**) produces ethyl 1-cyclopropyl-6,7,8-trifluoro-4-oxo-2-phenylthio-1,4-dihydroquinoline-3-carboxylate (**9c**) in 42% yield. Oxidation of 3-carboxylic esters **9a**,**c** with *m*-chloroperoxybenzoic acid (*m*-CPBA) (CH_2Cl_2, 20 °C) affords ethyl 7-chloro-1-cyclopropyl-6-fluoro-4-oxo-2-phenylsulfinyl-1,4-dihydro-1,8-naphthyridine-3-carboxylate (**10a**) (83% yield) or ethyl 1-cyclopropyl-6,7,8-trifluoro-4-oxo-2-phenylsulfinyl-1,4-dihydroquinoline-3-carboxylate (**10c**) (78% yield), respectively. The regiospecific replacement of the sulfinyl group of sulfoxide **10a** with freshly prepared sodium hydrosulfide in aqueous THF gives rise to a 2-mercapto derivative, whose treatment (without purification) with hydroxylamine-*O*-sulfonic acid in the presence of sodium bicarbonate affords the hydrosulfamino derivative. The latter undergoes cyclisation to form 7-chloro-9-cyclopropyl-6-fluoro-2,3,4,9-tetrahydroisothiazolo[5,4-*b*]quinoline-3,4-dione (**11a**) (67% yield). The reaction of naphthyridinedione **11a** with an excess of piperazine (pyridine, 60 °C) produces 9-cyclopropyl-6-fluoro-7-(piperazin-1-yl)-2,3,4,9-tetrahydroisothiazolo[5,4-*b*]-[1,8]naphthyridine-3,4-dione (**12a**) in 98% yield. An analogous sequence of transformations of quinolinedione **11c** gives rise to 9-cyclopropyl-6,8-difluoro-7-(piperazin-1-yl)-2,3,4,9-tetrahydroisothiazolo[5,4-*b*]quinoline-3,4-dione (**12c**) (74%). Naphthyridinedione **12a** and quinolinedione **12c** exhibit higher antibacterial activity compared to ciprofloxacin **1c**.[24]



X = N, Y = Cl (**a**); X = CF, Y = F (**c**).

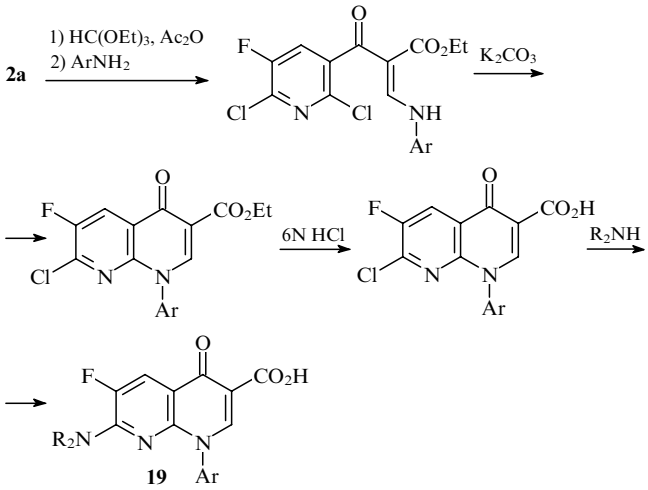
The reaction of ester **2a** with sodium hydride, carbon disulfide and methyl iodide in *N*,*N*-dimethylacetamide produces ketene dimethyl dithioacetal **13** (58% yield). The reactions of the latter with substituted amines **14** in toluene afford derivatives **15** in yields of up to 93%.[27] Their intramolecular cyclisation in the presence of potassium *tert*-butoxide gives rise to ethyl thiazolo-, oxazolo- and imidazolo[3,2-*a*][1,8]naphthyridine-4-carboxylates **16** (35%–92% yields). Condensation of ketene dithioacetal **13** with two equivalents of amines **14** allows one to prepare compounds **16** in one step. Acid hydrolysis of esters **16** gives the corresponding carboxylic acids **17** (55%–91% yields). The reactions of the latter with *N*-methylpiperazine are accompanied by the replacement of the chlorine atom at position 2 to form piperazine derivatives **18**, which exhibit *in vitro* antibacterial activity.





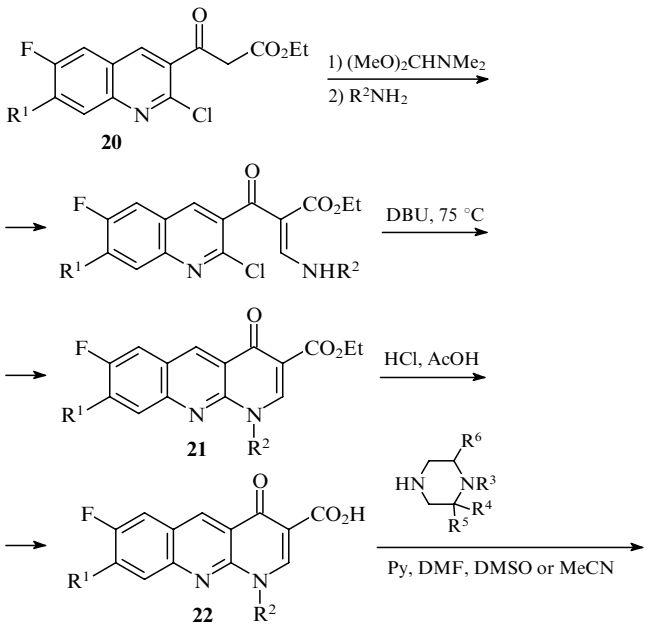
X = S,O, NMe; R = H, Me.

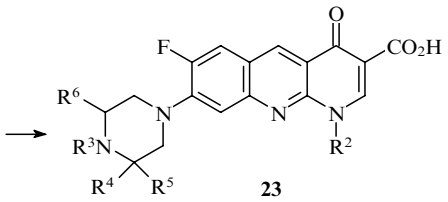
Ester **2a** was also used as the starting compound in the synthesis of previously unknown 7-substituted 6-fluoro-1-(1- or 2-naphthyl)-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acids **19**, which possess pronounced (comparable to that of the drug ataverdine) anti-HIV-RT activity.[28] The synthesis of acids **19** is illustrated by the following scheme:



Ar = 1-naphthyl, 2-naphthyl; R_2NH = piperazine, 2-methylpiperazine, *N*-methylpiperazine, (2*R*,6*S*)-2,6-dimethylpiperazine, (3*S*)-3-aminopyrrolidine.

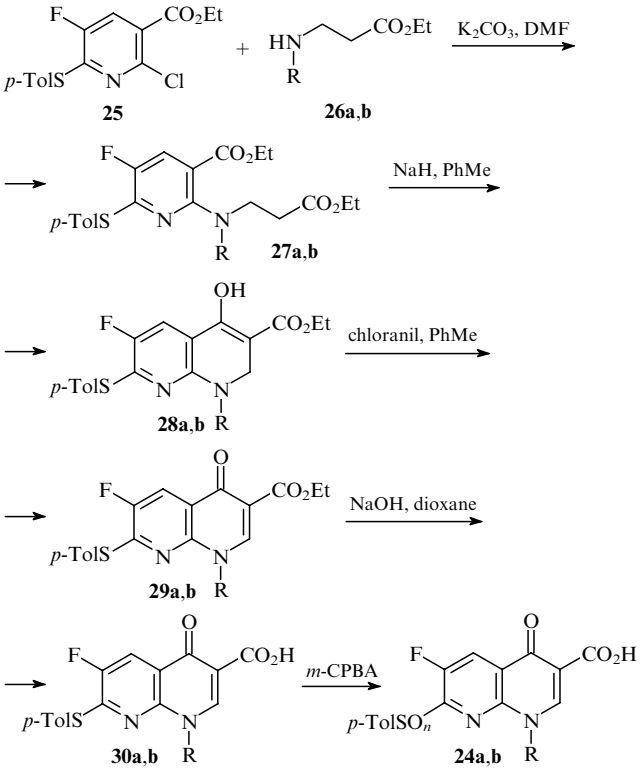
Ethyl (2-chloroquinolyl-3-carbonyl)acetates **20** served as the starting compounds for the preparation of benzo[*b*][1,8]naphthyridines **21**–**23**[29,30] possessing high antibacterial activity against Gram-positive bacteria. These compounds are used for the treatment of skin staphylococcus infections and water purification and also as preservatives and decontaminants.





R^1 = F, Cl; R^2 = Me, MeO, cyclo-C_3H_5; R^3, R^4, R^5, R^6 = H, Alk.

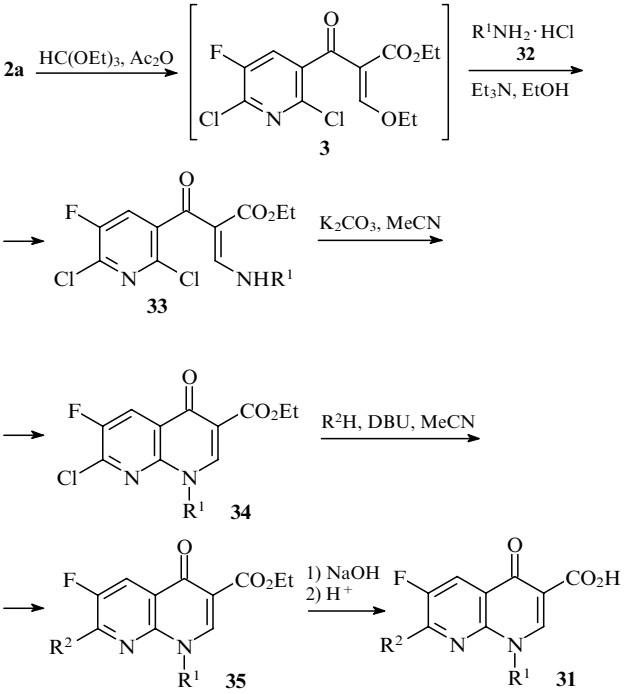
A procedure was developed for the synthesis of 1-ethyl-(or cyclopropyl)-6-fluoro-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid derivatives **24** containing the sulfinyl or sulfonyl group at position 7 of the naphthyridine system.[31,32] For example, heating (120–130 °C) of a mixture of ethyl 2-chloro-5-fluoronicotinate **25** and ethyl 3-(cyclopropylamino)propionate (**26a**) in DMF in the presence of Na_2CO_3 afforded diester **27a** (23%), the conversion of the starting nicotinate being 40%. Cyclisation of diester **27a** under the action of sodium hydride in toluene gave ethyl 1-cyclopropyl-6-fluoro-4-hydroxy-7-(*p*-tolyl)-1,2-dihydro-1,8-naphthyridine-3-carboxylate (**28a**), whose dehydrogenation with chloranil in toluene yielded 1,4-dihydro-4-oxo derivative **29a**. Alkaline hydrolysis of derivative **29a** gave 1-cyclopropyl-6-fluoro-4-oxo-7-(*p*-tolyl)-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid (**30a**). In the reaction of the latter with an equimolar amount of *m*-chloroperoxybenzoic acid, the sulfide group is readily oxidised to the sulfoxide group. In the presence of a twofold excess of the peroxy acid, the sulfide group is oxidised to the sulfonyl group to form naphthyridonecarboxylic acids **24a**. This approach was used for the synthesis of analogous compound **24b** (R = Et) and the antibacterial drug enoxacin (**1d**).



R = cyclo-C_3H_5 (**a**) Et (**b**); *n* = 1, 2; *p*-Tol is *p*-tolyl.

With the aim of studying the structure–antibacterial activity relationship, a series of new 7-substituted 6-fluoro-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acids **31** containing fluoro-substituted *tert*-butyl groups at the N(1) atom was synthesised.[22,23,33–35] For example, the reaction of intermediate **3** (X = N, Y = Cl) derived from ester **2a** with amines **32** in the presence of triethylamine in ethanol produces enamines **33**, whose

treatment with K_2CO_3 in acetonitrile results in their cyclisation to esters **34**. Condensation of the latter with amines upon refluxing in acetonitrile in the presence of DBU yields esters **35**, whose alkaline hydrolysis gives naphthyridonecarboxylic acids **31**. The latter exhibit high *in vitro* antibacterial activity against four types of Gram-positive bacteria and eight types of Gram-negative bacteria.[23] Examples of naphthyridonecarboxylic acids **31** are given in Table 1.



32: R^1 = Bu^t, FCH_2CMe_2, $(FCH_2)_2CMe$, $(FCH_2)_3C$.

6-Fluoro-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid derivatives possess a very broad spectrum of biological activities, in particular, antibacterial action. Many compounds of this class exhibit high activity against various Gram-positive bacteria (*Staphylococcus aureus* ATCC 6538P, CMX 686B, FDA 209P JC-1; *Staphylococcus epidermidis* 3519, IAM 1296; *Streptococcus faecium* ATCC 8043, *Streptococcus pyogenes* 930) and Gram-negative bacteria (*Escherichia coli* Juhl, KC-14, K-12 C600; *Enterobacter aerogenes* ATCC 130048; *Klebsiella pneumoniae* 8045, PCI-602; *Pseudomonas aeruginosa* EZ, 5070, K799/WT; *Acinetobacter* CMX 669, AC54).[19,27]

Table 1. Substituted 1,8-naphthyridinecarboxylic acids **31**.

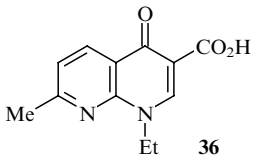
	$(FCH_2)_3C$	79	32
	FCH_2CMe_2	65	32
	$(FCH_2)_3C$	78	32

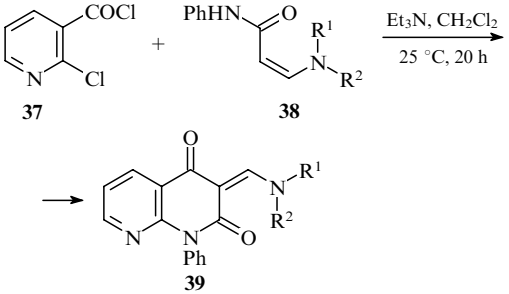
These properties stimulated researchers to modify the 1,8-naphthyridine system by introducing various substituents using standard synthetic approaches. Biological activities of the compounds synthesised were tested, most publications being devoted to problems of analysis of toxicity, synergism of action of these compounds in various mixtures, elucidation of fine details of physiological actions of these compounds, *etc*. These aspects are beyond the scope of the present review, where only a bibliography of recent studies on fluoro-substituted 1,8-naphthyridones is given. Among these publications, numerous papers and patents concerned with the antibacterial drugs enoxacin (**1d**)[36–67] and trovafloxacin (**1e**)[68–187] are noteworthy.

In the literature (particularly, patent), other derivatives of fluorine-containing 1,8-naphthyridines have been described. For example, the review[188] was devoted to the synthesis, pharmacology, pharmokinetics and metabolism of 6-fluoronaphthyridinecarboxylic acids. Antibacterial[189–198] and antimicrobial[199,200] activities of these compounds were studied. These problems were also covered by many recent patents.[201–262]

Voluminous literature on 1,8-naphthyridine derivatives containing no fluorine is available. Explosion of interest in this class of heterocyclic compounds dates back to 1962, when Lesher and co-workers[263,264] synthesised 1-ethyl-7-methyl-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid (**36**) (nalidixic acid) possessing strong antibacterial activity. The pharmacological properties of this compound are still being studied.[265–300]

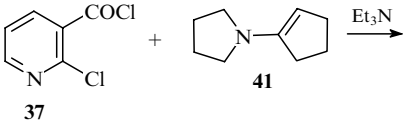


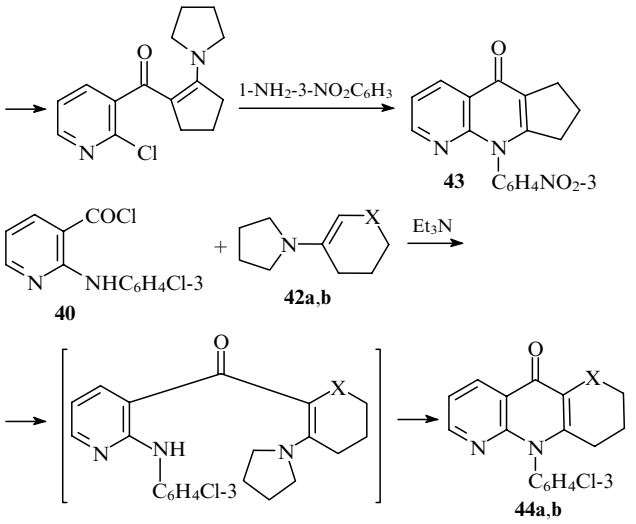
2-Chloronicotinoyl chloride (**37**) is widely used as the starting compound in the synthesis of various 1,8-naphthyridine derivatives. For example, its reactions with substituted 5-aminoacrylic acid anilides **38** produce aminomethylidene-1,8-naphthyridine-2,4-diones **39**.[301]



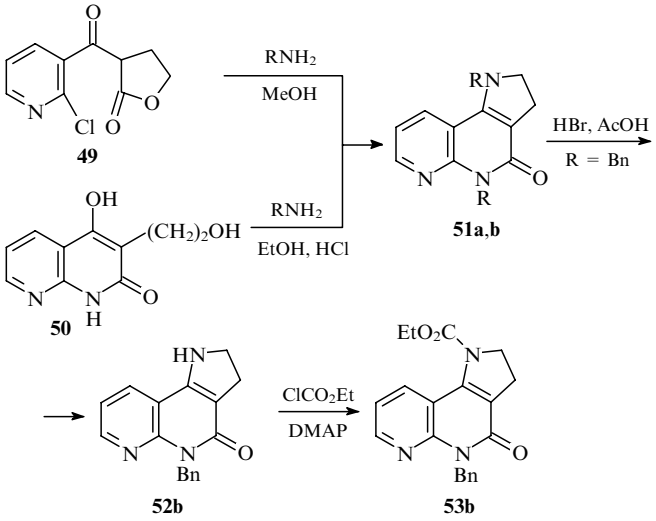
R^1 = H, Me; R^2 = Me, Et, Bn, 2-methyl-6-pyridyl.

The reactions of 2-chloronicotinoyl chloride (**37**) or 2-(3-chloroanilino)nicotinoyl chloride (**40**) with cyclic enamines (**41** and **42a**,**b**) in the presence of triethylamine afforded 1,8-naphthyridones **43** and **44a**,**b** possessing antiallergic, anti-inflammatory, antiulcerative and hypotensive actions.[302–306]





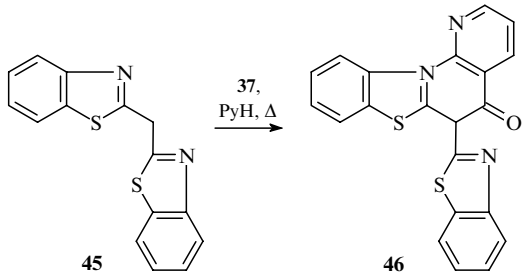
X = CH_2 (**a**), NAc (**b**).



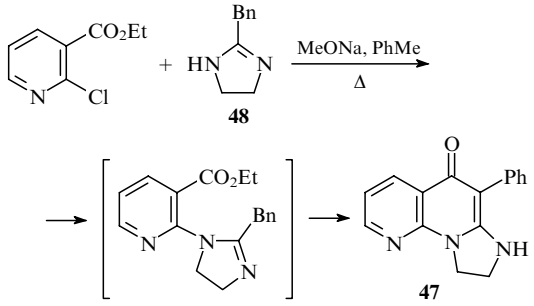
R = Ph (**a**), Bn (**b**); DMAP is 4-dimethylaminopyridine.

According to the ^{1}H NMR spectroscopic data, molecule **44a** is chiral. Naphthyridine **44a** exists as short-lived interconvertable atropoisomeric enantiomers, which form diastereomeric complexes with the shift-reagent [(*R*)-(−)-1-(9-anthryl)-2,2,2-trifluoroethanol]. The enantiomers were isolated in the individual form. The racemisation constant is 0.213 min^{-1} at 37 °C. The activation energy is E_a = 21.6 kcal mol^{-1}.[307]

The reaction of 2-chloronicotinoyl chloride **37** with di(benzothiazol-2-yl)methane (**45**) yielded fused naphthyridine system **46**.[308]

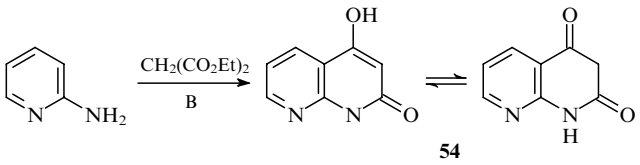


Imidazo[1,2-*a*][1,8]naphthyridine **47** was prepared by refluxing ethyl 2-chloronicotinate with 2-benzyl-4,5-dihydro-1*H*-imidazole (**48**) in toluene in the presence of sodium methoxide.[309]

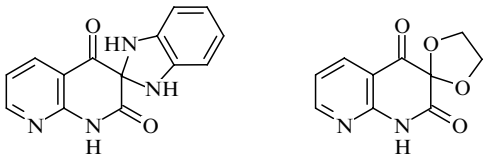


The reactions of 2-(2-chloronicotinoyl)butyrolactone (**49**) or 4-hydroxy-3-(2-hydroxyethyl)-1,8-naphthyridin-2-one (**50**) with amines (aniline or benzylamine) under an inert atmosphere afford pyrrolidinonaphthyridin-2-ones **51a**,**b**. Subsequent transformations of compound **51b** yield pyrrolidinonaphthyridones **52b** and **53b**. Derivatives **51a**,**b**, **52b** and **53b** possess anti-inflammatory and antihyperproliferative actions.[310, 311]

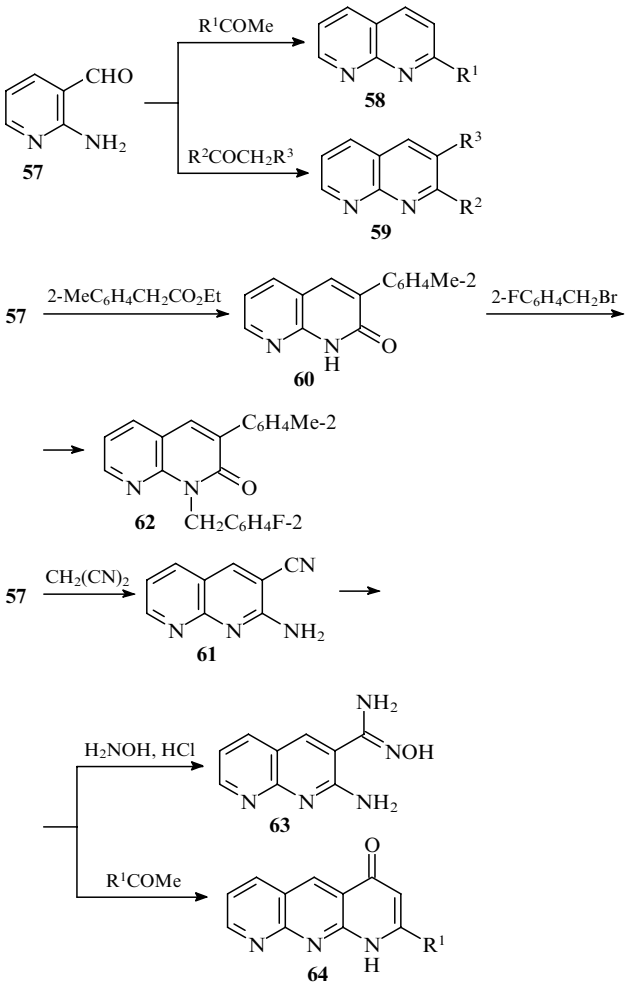
2-Aminopyridine and its derivatives are rather often used as the starting compounds in the synthesis of 1,8-naphthyridine derivatives.[312–353] For instance, the reaction of unsubstituted 2-aminopyridine with diethyl malonate in the presence of bases produces naphthyridinedione **54**, which exists as two tautomeric forms.[312, 313] Halogenation of compound **54** under various conditions (SO_2Cl_2, $POCl_3$, Br_2, I_2) gives rise to both 3-mono- and 3,3-dihalogen derivatives. The reactions of the latter with *o*-phenylenediamine and ethylene glycol form spiro-fused heterocycles **55** and **56**, respectively.[312]



B is a base.

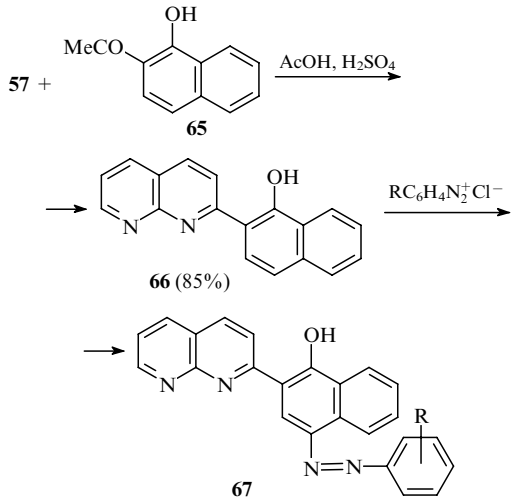


Substituted 2-aminopyridines, in particular, 2-amino-3-formylpyridine (**57**) and its derivatives, possess much higher synthetic potential.[316–319, 322–324, 326, 327, 331–333, 335, 336, 339, 353–356] For example, condensation of pyridine **57** in ethanol in the presence of piperidine as a base with compounds containing the active methylene group as well as with aldehydes, acyclic and cyclic ketones and diketones yielded 1,8-naphthyridines **58**–**61**, which were used as the starting compounds for the synthesis of derivatives **62**–**64**.[316, 318, 322–325, 349, 354] Naphthyridines **58** exhibit antibacterial and antihelmintic activities and are used in the synthesis of fungicides.[318, 323–325, 354] Compounds **59** are intermediates in the synthesis of some hypotensive drugs.[329] Naphthyridine **63** possesses herbicidal properties and is used for selective control of weeds in barley, wheat, maize, sorghum and rice crops.[349] 1,8-Naphthyridin-2-one derivative **62** is used for the treatment of memory disorders, in particular, Alzheimer's disease.[351]



R^1 = Ph, 1-naphthyl, 2-pyridyl, 2-furyl, 2-thienyl, 2-HOC_6H_4, CH=CHPh; R^2 = Me, Ph; R^3 = Ph, COPh, CONHPh, MeCO.

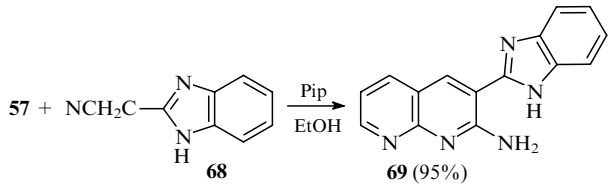
There are numerous examples of the use of 2-amino-3-formylpyridine (**57**) in the synthesis of substituted 1,8-naphthyridines and their fused analogues. For instance, condensation of compound **57** with 2-acetyl-1-naphthol (**65**) in the presence of glacial acetic acid containing catalytic amounts of concentrated



R = H, 2-Me, 4-Me, 3-MeO, 4-MeO, 3-OH, 3-NO_2, 3-Cl, 2-CO_2H, 3-CO_2H, 4-SO_3H, 4-SO_2NH_2.

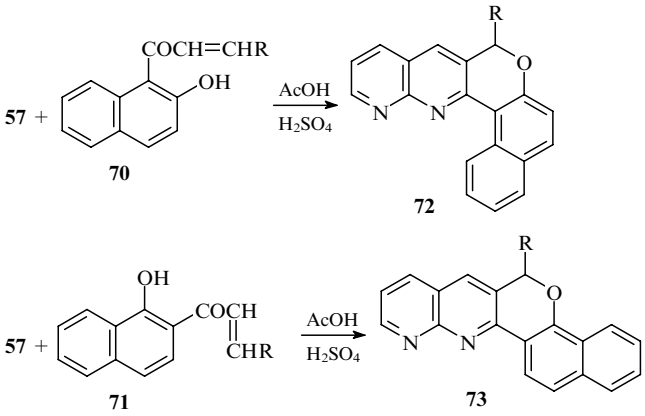
H_2SO_4 afforded 2-(1,8-naphthyridin-2-yl)-1-naphthol (**66**).[323] Treatment of the latter with aryldiazonium salts gave 4-arylazo-2-(1,8-naphthyridin-2-yl)-1-naphthols (**67**) (60%–84% yields) possessing noticeable antibacterial activity.

2-Amino-3-(2-benzimidazolyl)-1,8-naphthyridine (**69**) was synthesised by the reaction of 2-amino-3-formylpyridine (**57**) with 2-cyanomethylbenzimidazole (**68**) in ethanol in the presence of trace amounts of piperidine.[316]



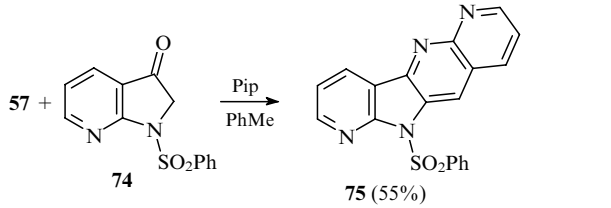
Pip is piperidine.

The reactions of aldehyde **57** with substituted 2-hydroxy-1-naphthyl styryl ketones **70**[318] or 1-hydroxy-2-naphthyl styryl ketones **71**[327] in glacial acetic acid in the presence of catalytic amounts of concentrated H_2SO_4 produce 8-aryl-8*H*-naphtho[1′,2′:5,6]pyrano[4,3-*b*][1,8]naphthyridines **72** or 6-aryl-6*H*-naphtho[2′,1′:5,6]pyrano[4,3-*b*][1,8]naphthyridines **73**, respectively. Compounds **72** and **73** showed no antibacterial activity.

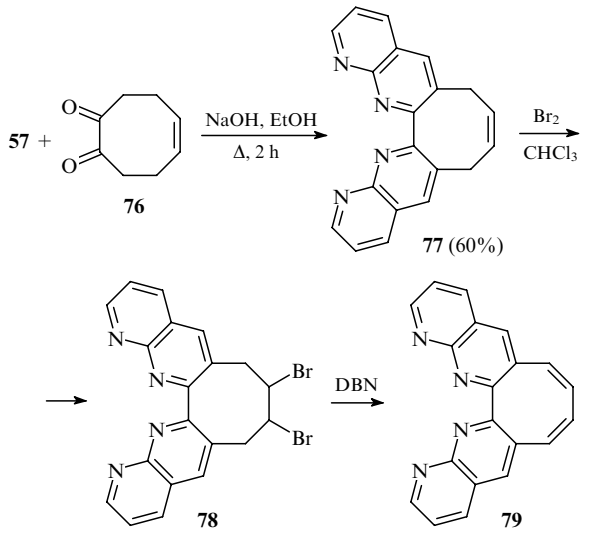


R = Ph, 4-$MeOC_6H_4$, 4-MeC_6H_4, 2-ClC_6H_4, 4-ClC_6H_4, 2-$NO_2C_6H_4$, 3-$NO_2C_6H_4$, 2-HOC_6H_4, 4-$Me_2NC_6H_4$, 1-naphthyl, 2-furyl, 2-thienyl.

Treatment of aminopyridinecarbaldehyde **57** with 7-azaindolinone **74** in toluene in the presence of piperidine affords pyrido[3′,2′:4,5]pyrrolo[3,2-*b*][1,8]naphthyridine (**75**).[334]

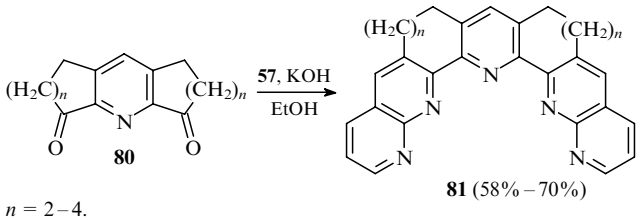


The same aminoaldehyde **57** was successfully used in the synthesis of polyannelated 1,8-naphthyridines. For example, 7,10-dihydrocycloocta[2,1-*b*:3,4-*b*′]di[1,8]naphthyridine (**77**) was prepared by the reaction of compound **57** with cyclooct-5-ene-1,2-dione (**76**) in ethanol in the presence of NaOH. The reaction of compound **77** with bromine in chloroform followed by debromination of adduct **78** with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) in toluene or DMSO produced cycloocta[2,1-*b*:3,4-*b*′]-di[1,8]naphthyridine (**79**), which is a new promising ligand system.[322, 333] The complex formation of ligand **79** with Cu(II) ions was studied.



DBN is 1,5-diazabicyclo[4.3.0]non-5-ene.

Friedländer condensation of aminoaldehyde **57** with cyclic diketones **80** (anhydrous ethanol, KOH, refluxing under N_2, 4 h) gives rise to heptaannelated heterocyclic systems **81**.[335]

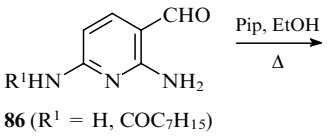


$n = 2-4$.

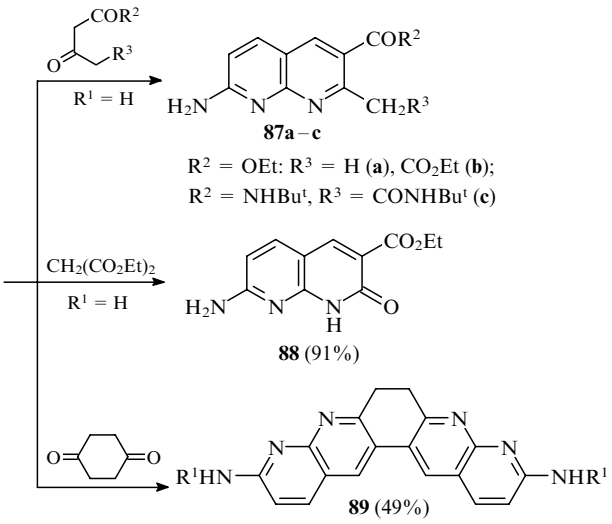
Analogous condensation with dione **82** in ethanol in the presence of piperidine as a base afforded a mixture of polyannelated bisnaphthyridines **83**–**85** in a total yield of 82% (Scheme 1).[336]

Under analogous conditions, α-aminopyridinealdehydes **86** react with activated and nonactivated ketones according to a cascade heterocyclisation scheme to form various 1,8-naphthyridine derivatives in satisfactory yields.

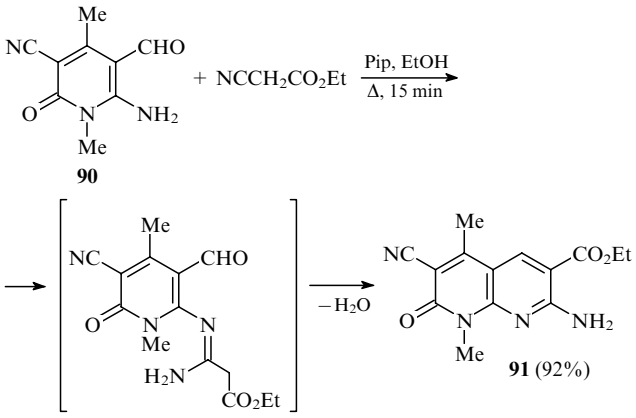
Treatment of compounds **86** with ethyl acetoacetate and piperidine in boiling ethanol affords aminonaphthyridine **87a** in 80% yield. Under the same conditions, the reactions with diethyl 3-oxoglutarate and *N*,*N*′-di-*tert*-butyl-3-oxoglutaramide produce naphthyridines **87b**,**c** in 35% and 40% yields, respectively. Condensation of aminoaldehyde **86** with diethyl malonate and 1,4-hexanedione affords naphthyridinone **88** and bis(aminonaphthyridine) **89**, respectively.[331]



86 (R^1 = H, COC_7H_{15})

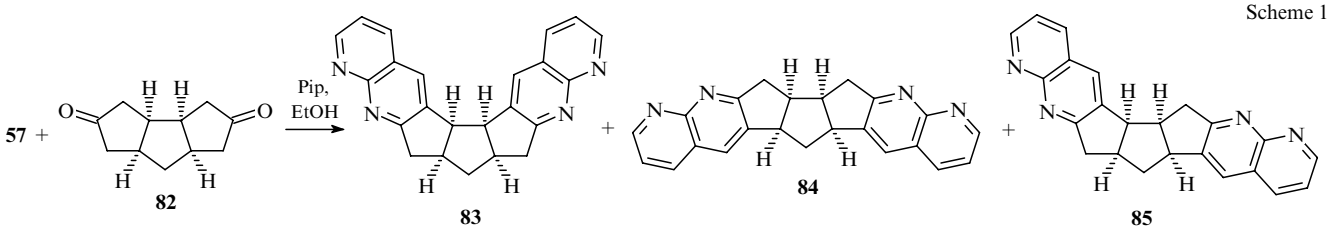


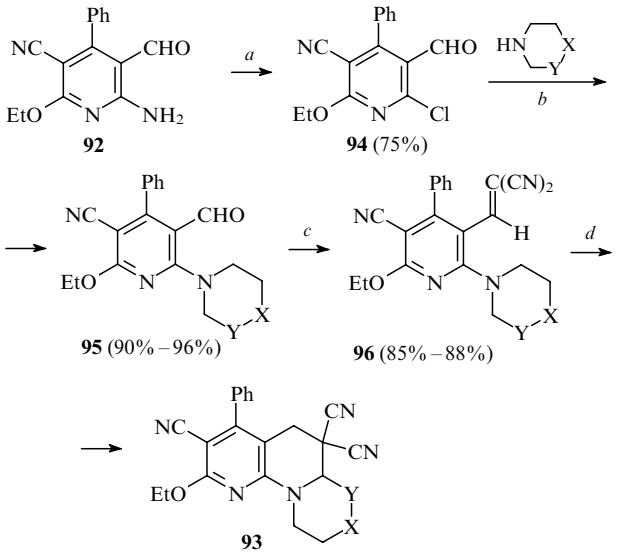
Analogous reactions with substituted 2-amino-3-formylpyridines as the starting substrates provide a promising approach to polyfunctional 1,8-naphthyridines, which are difficult to prepare. For example, refluxing of 6-amino-5-formyl-1,4-dimethyl-2-oxo-1,2-dihydropyridine-3-carbonitrile (**90**) and ethyl cyanoacetate in EtOH in the presence of piperidine produced the corresponding 1,8-naphthyridin-2-one (**91**).[353]



The use of 2-aminoaldehyde **92** in the synthesis of new polyfunctional heterocyclic systems **93** containing the 1,8-naphthyridine fragment serves as another example of this approach.[339] Deamination of amine **92** (*tert*-butyl nitrite, anhydrous $CuCl_2$, anhydrous MeCN) yields 2-chloro-3-formylpyridine **94**, whose treatment with secondary amine and triethylamine in THF gives rise to 2-dialkylamino-3-formylpyridines **95**. Knoevenagel condensation of compounds **95** with malononitrile in toluene (with the use of butylamine and ammonium acetate as catalysts) produces 2-dialkylamino-3-(2,2-dicyanovinyl)pyridine derivatives **96** in high yields. Thermolysis of the latter by boiling in a polar solvent (butanol or pentanol) or by heating in DMF or DMSO (140 °C) affords heterocyclic compounds **93** in yields from 10% to 100%.

Scheme 1





R = Pr^n, Bu^n; X = CH_2, $(CH_2)_2$, O, S; Y = CH_2, S.
(*a*) Bu^tONO, $CuCl_2$, MeCN, Δ, 15 min; (*b*) Et_3N, THF, Δ;
(*c*) 1) $CH_2(CN)_2$, Bu^nNH_2; 2) NH_4OAc, PhMe, Δ;
(*d*) RCH_2OH, Δ, 0.5 h – 7 days.

Substituted chloropyridine **94** was used as the starting compound in the synthesis of other derivatives of naphthyridine systems, such as isoindolo[2,1-*a*]-, isoquino[2,1-*a*]-, indolo[1,8,7-*a*,*b*]- and quino[1,9,8-*a*,*b*][1,8]naphthyridines.[340] The reactions of compound **94** with heterocyclic amines in the presence of triethylamine in THF or DMF produce the corresponding 2-dialkylamino-3-formylpyridine derivatives **97a**,**b** or 2-alkylarylamino-3-formylpyridine derivatives **98a**–**d** in 50%–95% yields. Knoevenagel condensation of the carbonyl groups of compounds **97a**,**b** or **98a**–**d** with malononitrile by refluxing in dichloromethane (2 h) in the presence of butylamine and ammonium acetate affords 2-dialkylamino- (**99a**,**b**) or 2-alkylarylamino-3-(2,2-dicyanovinyl)pyridine derivatives (**100a**–**d**, the yields of products **100a** and **100c** are 91%–95%), respectively. Heating of 2-dialkylamino derivatives **99a**,**b** and 2-alkylarylamino derivatives **100a**–**d** in polar solvents gives rise to tetracyclic compounds **101a**,**b** and **102a**–**d**, respectively.

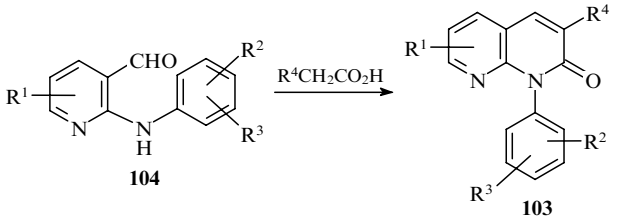
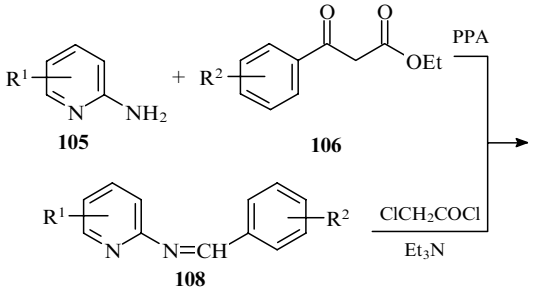
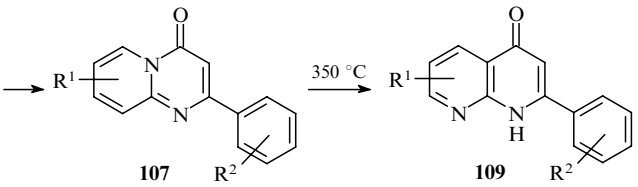
N-Aryl-1,8-naphthyridines **103** possessing antiulcerative action were synthesised by Stobbe, Claisen or Knoevenagel condensations of substituted arylaminopyridinecarbaldehydes **104** with substituted carboxylic acids and their derivatives (esters, anhydrides, sodium salts).[343–347]



R^1 = H, Alk, cyclo-Alk, Hal, MeO, CF_3, NO_2; R^2, R^3 = H, Alk, Hal, CF_3, NO_2, MeO, MeS, $(CH_2)_nCN$, $(CH_2)_nCONH_2$;
R^4 = H, Alk, Alkenyl, NH_2, CO_2H, $HO_2C(CH_2)_n$, Ar, Het; *n* = 0–5.

With the aim of designing new potential antitumour drugs, procedures were developed for the synthesis of substituted 2-aryl-1,8-naphthyridin-4(1*H*)-ones using substituted 2-aminopyridines **105** and ethyl benzoylacetates **106** as the starting compounds.[314, 315] Their condensation in the presence of polyphosphoric acid (PPA) affords the corresponding pyridopyrimidinones **107**. Compounds **107** were also prepared by cyclisation of Schiff bases **108** with monochloroacetyl chloride in the presence of triethylamine. The subsequent thermal rearrangement of pyridopyrimidinones **107** at 350 °C gives rise to 2-phenyl-1,8-naphthyridin-4(1*H*)-ones **109**. An analogous approach was also used for the preparation of the corresponding 2-naphthyl-substituted 1,8-naphthyridinones.[352]

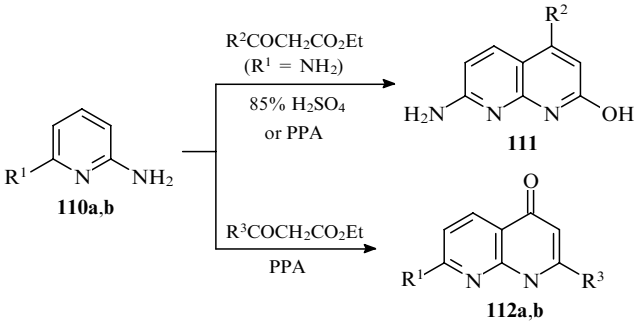




107 **109**

R^1 = H, Me, Cl, Br; R^2 = H, Me, F, Cl;
PPA is polyphosphoric acid.

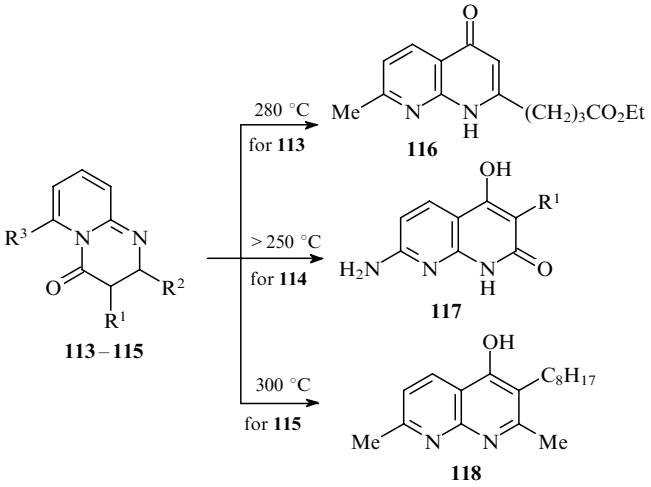
Condensation of 2-aminopyridines **110a**,**b** with β-ketoesters or dicarboxylic esters provides a promising approach to the synthesis of 1,8-naphthyridines. The reaction is carried out at high temperature in polyphosphoric acid or Dowtherm.[357–367] For example, this procedure was used for the synthesis of 7-amino-2-hydroxy-1,8-naphthyridines **111**[357] and naphthyridones **112**.[359, 367]



110a,**b** **111** **112a**,**b**

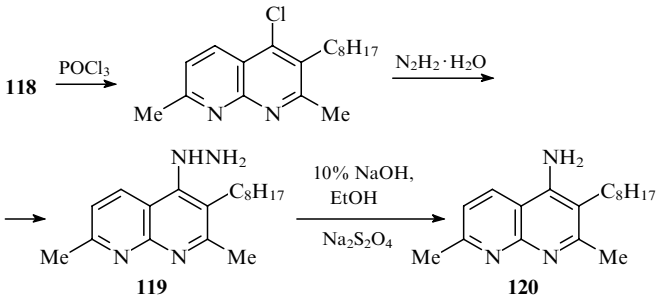
R^1 = Me (**a**), NH_2 (**b**); R^2 = Me, Pr, CF_3, $ClCH_2$, Ph;
R^3 = Me, Ph.

In some cases, pyrido[1,2-*a*]pyrimidines initially formed in analogous condensations (for example, compounds **113**–**115**) are isolated. Thermal isomerisation of these compounds affords oxo (**116**) or hydroxy derivatives (**117**, **118**) of 1,8-naphthyridines. Compounds **116**–**118** were subjected to subsequent transformations. For example, an additional ring was fused to naphthyridines **116** and **117**, and the successive reactions of naphthyridine **118** with $POCl_3$ and $N_2H_4 \cdot H_2O$ produced hydrazine **119**, which was transformed into amine **120**.[365]



113–**115** **116** **117** **118**

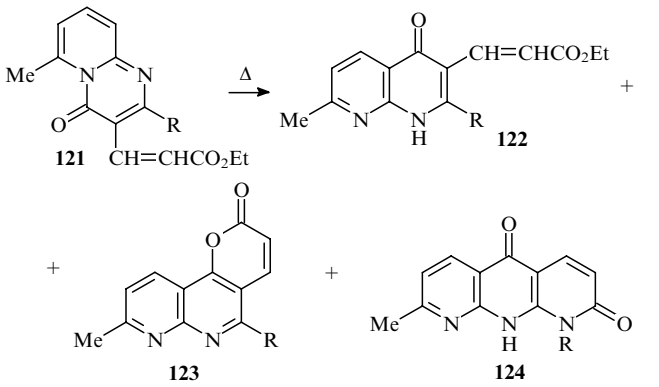
R^1 = H, R^2 = $(CH_2)_3CO_2Et$, R^3 = Me (**113**);
R^1 = H, Alk, Ph; R^2 = OH, R^3 = NH_2 (**114**);
R^1 = *n*-C_8H_{17}, R^2 = Me, R^3 = Me (**115**).



118 **119** **120**

Naphthyridine **111** (R^2 = $ClCH_2$) was covered by a patent as an agent reducing the phytotoxicity of herbicides belonging to cyclohexenones or phenoxyacetic acids.[362] Naphthyridone **112** (R^3 = Me) was used as an intermediate in the synthesis of compounds possessing antimalarial activity against *Plasmodium vinckei vinckei*.[361] Compounds **119** and **120** in doses of 0.1–5 kg hectare^{-1} exhibit fungicidal activity against phytopathogenic fungi (particularly, *Phycomyceten*) and are efficient against *Phytophtora infestans* on tomatoes and potatoes as well as against *Pseudoperonspora cubensis* on cucumbers.[363]

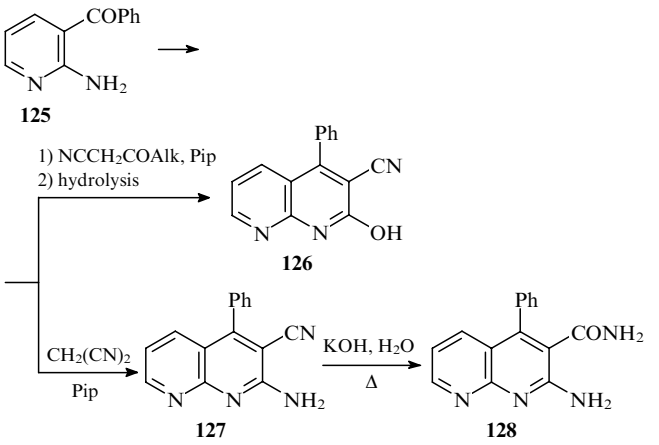
Other substituted pyridopyrimidines can also be used as starting compounds in the synthesis of 1,8-naphthyridine derivatives. For example, thermolysis of 4-oxo-4*H*-pyrido[1,2-*a*]pyrimidin-3-yl acrylates **121** afforded 2-substituted 1,8-naphthyridin-3-yl acrylates **122**, pyranonaphthyridines **123** or anthyridines **124** depending on the nature of the substituent at position 2 of the starting pyridopyrimidine.[365]



121 **122** **123** **124**

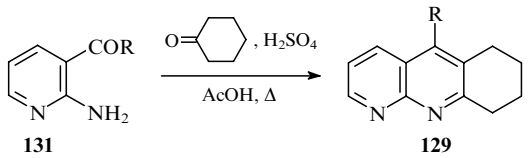
R = NHBu, Ph, Pip.

Other 2-aminopyridines were also successfully used in the synthesis of substituted 1,8-naphthyridines. For example, condensation of 2-amino-3-benzoylpyridine (**125**) with malonic acid derivatives in the presence of piperidine followed by hydrolysis of the reaction mixture affords 4-phenyl-1,8-naphthyridines **126** and **127**. Further hydrolysis of nitrile **127** gives amide **128**. Compounds **126** and **128** possess diuretic action.[330]

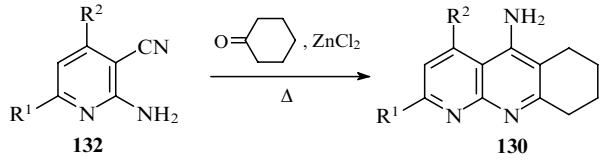


125 **126** **127** **128**

6,7,8,9-Tetrahydrobenzonaphthyridines **129** and **130** were prepared by condensation of 2-amino-3-acylpyridines **131**[366] or 2-amino-3-cyanopyridines **132**[367] with cyclohexanone.

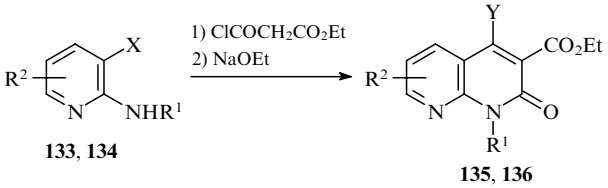


R = Me, Ph.



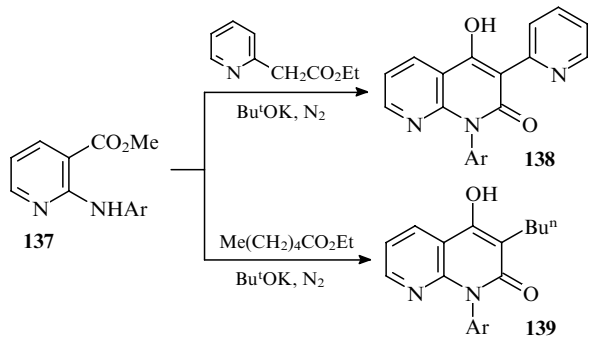
R^1, R^2 = Ph, 4-ClC_6H_4.

1,8-Naphthyridines can also be prepared by the reactions of substituted 2-alkylaminonicotinic acids with malonic acid derivatives. Cyclocondensation of nitriles **133** or esters **134** with $ClCOCH_2CO_2Et$ in anhydrous diethyl ether at 20 °C and then with EtONa in ethanol affords substituted 2-oxo-1,8-naphthyridine-3-carboxylic acids **135** and **136**, respectively. Compounds **135** were also synthesised by the reactions of nitriles **133** with a mixture of two equivalents of $(EtO_2C)_2CH_2$ and Na in anhydrous ethanol. Naphthyridinecarboxylic acids **135** and **136** were used in the synthesis of compounds which inhibit gastric secretion.[368]



X = CN (**133**), CO_2Me (**134**); Y = NH_2 (**135**), OH (**136**);
R^1 = H, Me, Et, All; R^2 = H, Me.

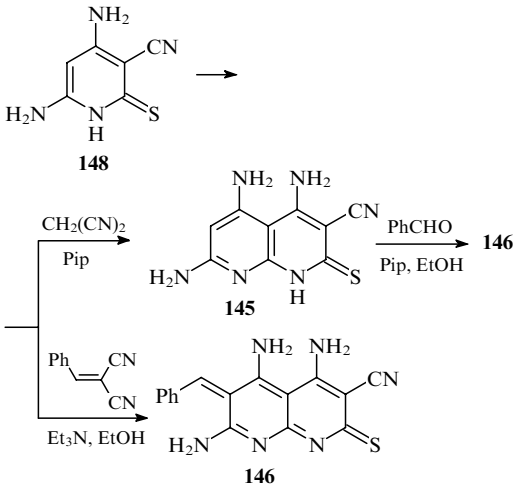
Procedures were developed for the synthesis of various 1,8-naphthyridin-2-one derivatives based on condensation of methyl 2-arylaminonicotinates **137** and carbonyl compounds containing an activated methylene group. This method was used, for example, for the preparation of naphthyridones **138** and **139** exhibiting antiallergic, anti-inflammatory and antiulcerative actions.[369–385]



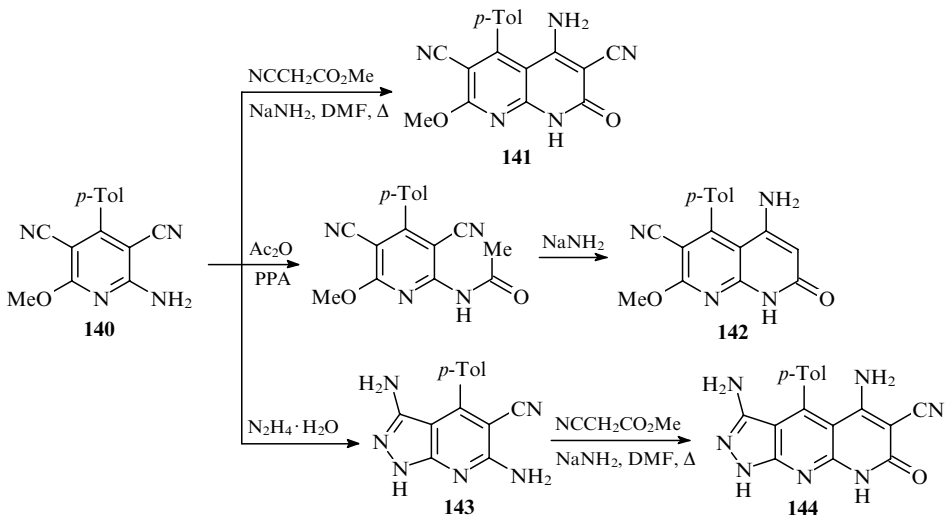
Ar = Ph, 4-$MeOC_6H_4$, 3,4-$(MeO)_2C_6H_3$, 4-FC_6H_4, 2,4-$F_2C_6H_3$, 2-Me-3-ClC_6H_3, 3-$MeSC_6H_4$.

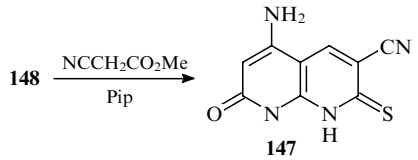
2-Amino-3,5-dicyano-6-methoxy-4-(*p*-tolyl)pyridine (**140**) was used in the synthesis of 4-amino-1,8-naphthyridin-2(1*H*)-ones **141** and **142**. Condensation of compound **140** with methyl cyanoacetate in the presence of sodium amide or acetic anhydride in polyphosphoric acid yields naphthyridones **141** and **142**. Compound **143**, which was prepared by the reaction of aminonitrile **140** with hydrazine hydrate, underwent condensation with methyl cyanoacetate to form naphthyridone **144** (Scheme 2).[385]

4,6-Diaminopyridine-2(1*H*)-thione **148** was used as the starting compound for the synthesis of amino derivatives of 1,8-naphthyridine-2(1*H*)-thiones **145**–**147**.[386, 387] The reactions of **148** with malonic acid derivatives proceed in DMF in the presence of piperidine or in ethanol in the presence of triethylamine.

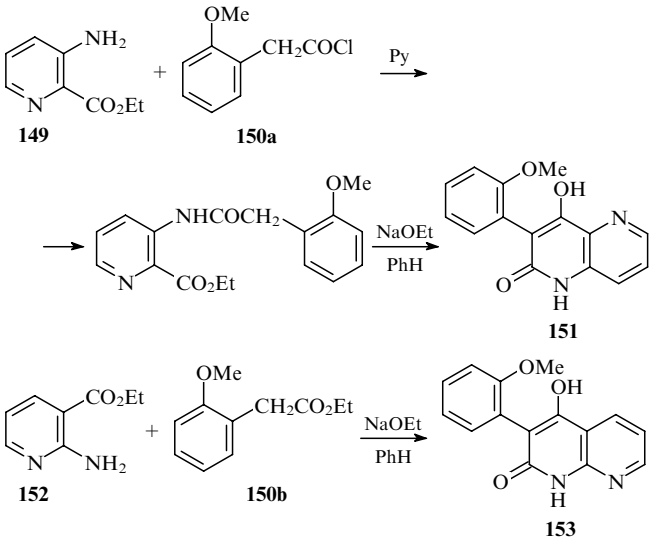


Scheme 2

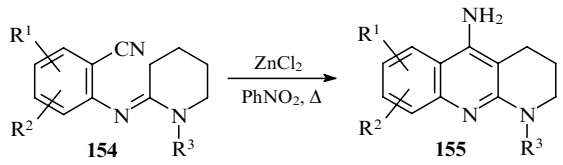




Ethyl 3-aminopyridine-2-carboxylate (**149**) reacts with 2-methoxyphenylacetyl chloride (**150a**) to form 1,5-naphthyridine (**151**). The analogous reaction of ethyl 2-aminopyridine-3-carboxylate (**152**) with ethyl 2-methoxyphenylacetate (**150b**) produces isomeric 1,8-naphthyridine (**153**).[388]



Cyclisation of substituted 2-(2-cyanophenylimino)piperidines **154** by refluxing in nitrobenzene in the presence of $ZnCl_2$ afforded 5-aminobenzonaphthyridines **155**, which were covered by a patent as drugs for the treatment of memory loss, aging and Alzheimer's disease.[389]



R^1 = H, 6-F, 6-Cl, 7-NO_2; R^2 = H, 8-Cl; R^3 = H, Ac, COPh.

A convenient regioselective procedure was developed for the synthesis of new heterocycles, *viz*., 5-phenyl-1*H*- (**156**) and 5-phenyl-3*H*-imidazo[4,5-*c*][1,8]naphthyridin-4(5*H*)-ones (**157**), starting from 2-phenylaminonicotinic acid (**158a**) or its methyl ester (**158b**).[390–394] Treatment of ester **158b** with trichloromethyl chloroformate in 1,2-dichloroethane at 80 °C affords *N*-phenyl-3-azaisatinic anhydride (**159**). The reaction of the latter with sodium hydride and ethyl nitroacetate in *N*,*N*-dimethylacetamide produces 4-hydroxy-3-nitro-1-phenyl-1,8-naphthyridin-2(1*H*)-one (**160**). Chlorination of naphthyridone **160** with phosphorus oxychloride gives rise to chloride **161**, which is transformed into the target naphthyridines by successive amination, reduction and cyclisation. Imidazonaphthyridones **156** and **157** are new non-steroid anti-inflammatory drugs possessing activity analogous to that of glucocorticoids (Scheme 3).

A new efficient procedure was proposed[368,395–398] for the synthesis of 3-substituted 1,8-naphthyridine-2,4-diones, which are of considerable pharmacological interest. The reactions of 2-methyl-4*H*-pyrido[2,3-*d*][3,1]oxazin-4-one (**162**) with compounds containing an active methylene group in the presence of potassium *tert*-butoxide in *tert*-butyl alcohol or in the presence of sodium hydride in anhydrous benzene produce 3-substituted 1-acetyl-1,2,3,4-tetrahydro-1,8-naphthyridine-2,4-diones **163** in yields of up to 87%.[399] Evidently, the reactions proceed through intermediates **164**.

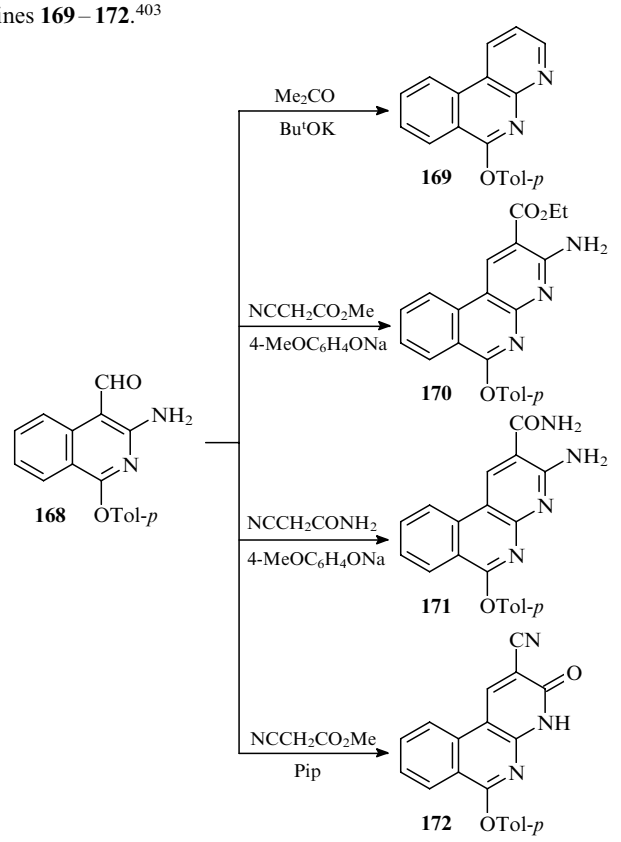
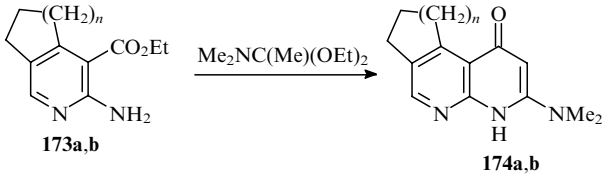
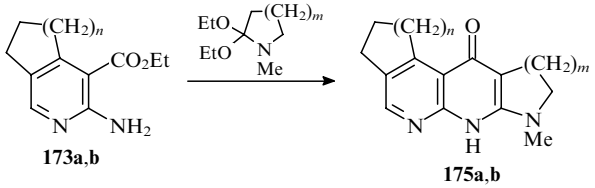
Cyclocondensation of 3-amino-1-(*p*-tolyloxy)isoquinoline-4-carbaldehyde **168** with acetone or cyanoacetic acid derivatives in the presence of bases yields substituted benzo[*c*][1,8]naphthyridines **169**–**172**.[403]



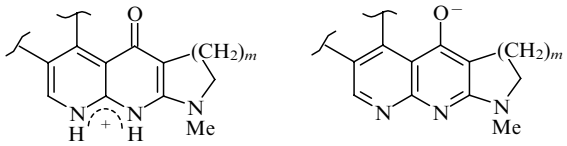
The reaction of ethyl 2-amino-5,6-dihydro-4*H*-cyclopenta[*c*]-nicotinate (**173a**, $n = 1$) with *N*,*N*-dimethylacetamide diethyl acetal produces 1,4-dihydro-4-oxo-1,8-naphthyridine derivative **174a**. Reactions with methylbutyro-, -valero- and -caprolactam diethyl acetals afford tetracyclic compounds **175a**. Similar reactions giving rise to naphthyridone **174b** ($n = 2$) and tetracyclic compounds **175b** were also performed using the cyclohexane analogue of compound **173**.[404]





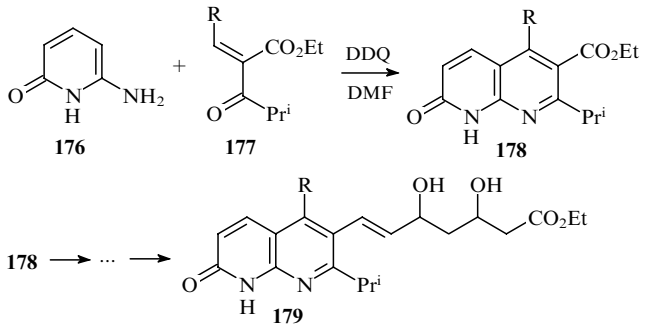
n = 1 (**a**), 2 (**b**); m = 1–3.

Protonation of naphthyridones **175a**,**b** was studied by UV and ^{1}H and ^{13}C NMR spectroscopy.[404] It was found that protonation occurs at the carbonyl group to give the cationic form **A**. In 70% DMF, the ionisation constants of naphthyridones **175a**,**b** depend on the size of the saturated cyclic fragments of the molecules, which is associated with steric factors, such as a change in steric accessibility of the polar groups of the cationic (**A**) and anionic (**B**) forms to solvation.[404]



m = 1–3.

1,8-Naphthyridinones were also synthesised starting from 6-aminopyridin-2-one (**176**).[405] Its condensation with enones **177** in the presence of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in DMF afforded ethyl 2-oxo-1,8-naphthyridine-6-carboxylate (**178**). This naphthyridine was transformed into compound **179** in five steps. This compound was covered by a patent as a drug for the treatment of hyperlipoproteinemia, atherosclerosis and lowering of blood cholesterol levels.[405]



R = Ar, Het.

5,5-Dimethyl-5,10-dihydrobenzo[*b*][1,8]naphthyridines **181** were prepared in yields of up to 87% by intramolecular cyclisation of 2-arylamino-3-(1-hydroxy-1-methylethyl)pyridines **180** in polyphosphoric acid. Alkylation of benzonaphthyridines **181** with dialkylaminoalkyl halides in the presence of KOH in toluene gives rise to 10-substituted benzonaphthyridines **182** (yields of up to 88%), which are analogues of the corresponding acridines possessing a broad spectrum of biological activities.[406]

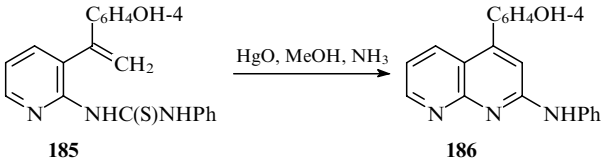
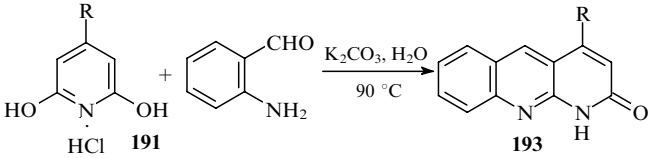
Cyclisation of substituted thiourea **185** occurs under the action of mercury oxide in methanol saturated with ammonia to give 1,8-naphthyridine derivative **186**.[408]



185 **186**

Photochemical cyclisation (DRL-400 mercury lamp, 60% *tert*-butyl alcohol, 20 °C, 10 h) of 8-chloro-1-(2-pyridylamino)naphthalene (**187**) was studied. The reaction proceeds non-selectively to form C–C and C–N bonds and produces new polyannelated heterocyclic systems, *viz*., 7*H*-7,8-diazabenzo[*de*]anthracene (**188**) containing the 1,8-naphthyridine fragment, dimer **189** and pyrido[1,2-*a*]perimidine (**190**). Compounds **188**–**190** were separated by chromatography on silica gel (Scheme 4).[409,410]

Hydroxy derivatives of the pyridine series were used as the starting compounds in the synthesis of annelated 1,8-naphthyridines. Benzo[*b*][1,8]naphthyridines **193** and **194** were synthesised



191 **193**

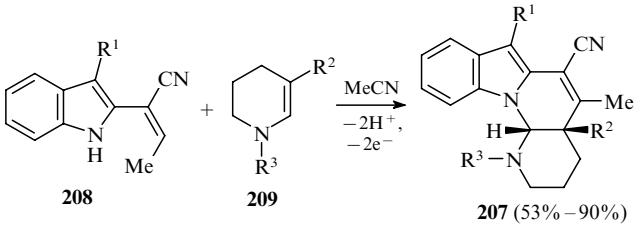
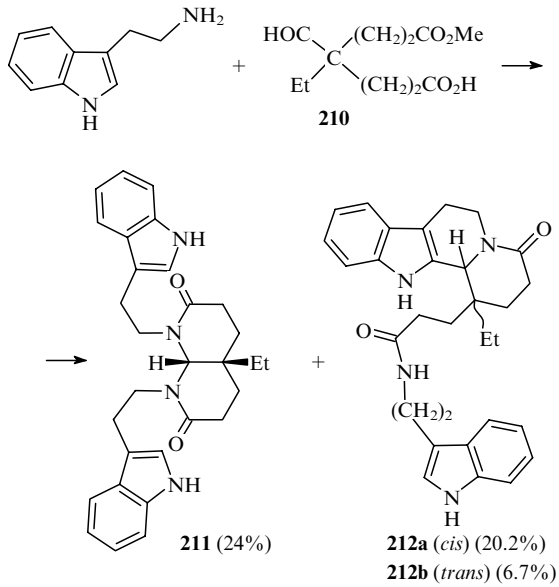
Hexahydroindolo[1,2-*a*]-1,8-naphthyridines **207** containing *cis*-fused rings were synthesised with high stereoselectivity by the electrochemical [4 + 2]-cycloaddition of 2-vinylindoles **208** and β-substituted enamines (**209**) of the tetrahydropyridine series in acetonitrile.[415]

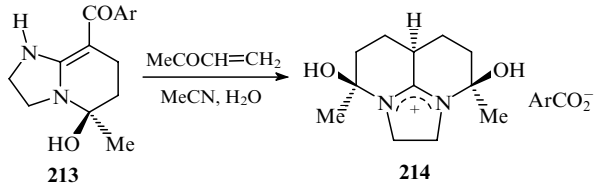


R^1 = Me, $(CH_2)_2OEt$; R^2 = CN, CO_2Me; R^3 = H, Me.

The Pictet–Spengler reaction of tryptamine with aldehyde **210** produces the bisindole derivative of decahydronaphthyridine-2,7-dione **211** along with two isomeric tryptamides **212a** (*cis*-1-Et) and **212b** (*trans*-1-Et).[416]

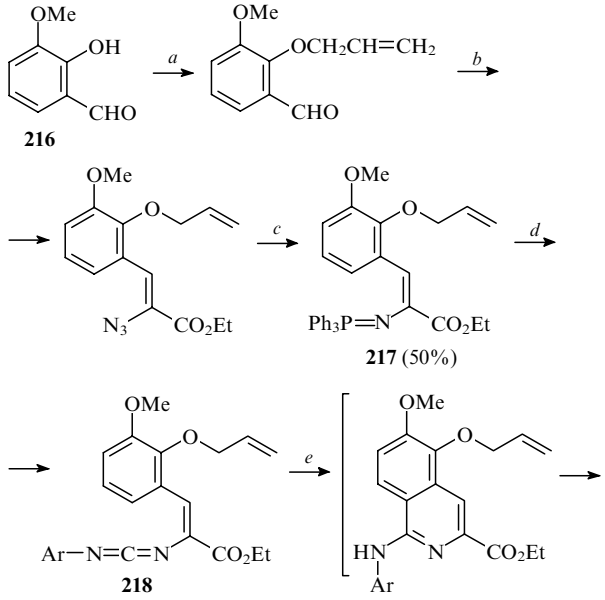


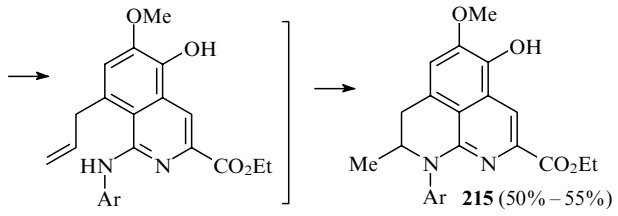
The reaction of imidazo[1,2-*a*]pyridine derivative **213** with a twofold excess of methyl vinyl ketone in acetonitrile proceeds with high stereoselectivity to form exclusively *cis*-dihydroxyimidazo[1,2,3-*ij*][1,8]naphthyridine **214**.[417]



Ar = Ph, 2-furyl, 2-thienyl.

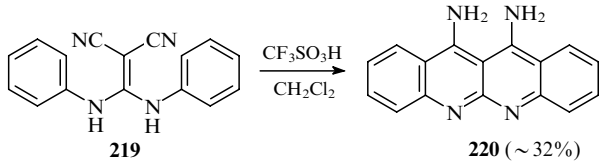
A one-step procedure was developed for the synthesis of the previously unknown dihydro-*1H*-1,9-diazaphenalene **215**, which also contains the 1,8-naphthyridine fragment.[418] The synthesis scheme involves O-allylation, condensation of the reaction product with ethyl azidoacetate and the Staudinger reaction with triphenylphosphine. This procedure was used for the preparation of iminophosphorane **217** from commercially available 2-hydroxy-3-methoxybenzaldehyde (**216**). The reactions of compound **217** with aromatic isocyanates produce carbodiimides **218**, whose thermolysis yields diazaphenalenes **215**.



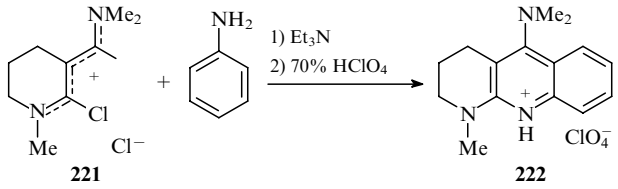


Ar = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4, 4-FC_6H_4;
(*a*) $BrCH_2CH=CH_2$, K_2CO_3, Me_2CO, Δ; (*b*) $N_3CH_2CO_2Et$, NaOEt, EtOH, −15 °C; (*c*) PPh_3, Et_2O, 20 °C; (*d*) ArNCO, PhMe, 20 °C, 1 h; (*e*) sealed tube, PhMe, 150–160 °C, 12 h.

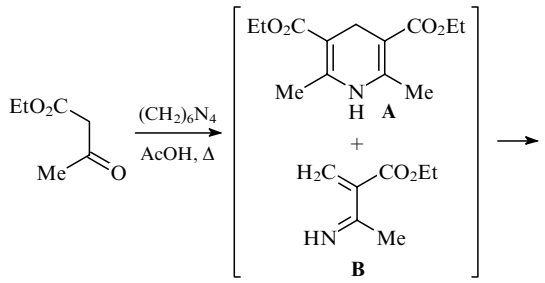
Cyclisation of 1,1-bisanilino-2,2-dicyanoethylene (**219**) under the action of trifluoromethanesulfonic acid in dichloromethane giving rise to 11,12-diaminodibenzo[*b*,*g*][1,8]naphthyridine (**220**) provides an example of the synthesis of annelated 1,8-naphthyridines.[419]

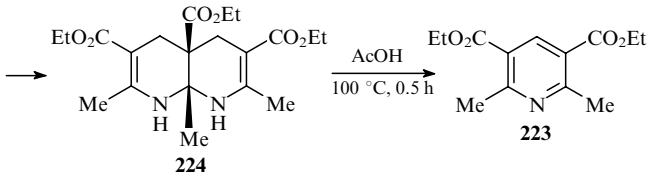


Condensation of iminium salt **221** with aniline in the presence of triethylamine occurs regioselectively. The subsequent replacement of the anion in the presence of 70% $HClO_4$ affords linearly annelated cycloadduct **222**.[420]

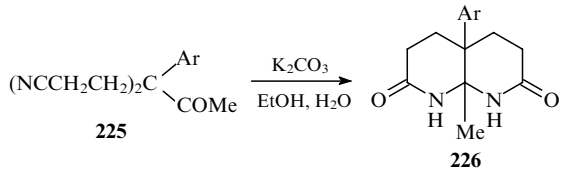


In the study,[421] diethyl 2,6-dimethylpyridine-3,5-dicarboxylate (**223**) was synthesised by the Hantzsch reaction of ethyl acetoacetate with hexamethylenetetramine (AcOH, 100 °C). In the course of the reaction, symmetrical bicyclic naphthyridine derivative **224** was detected. According to the X-ray diffraction data, the rings in compound **224** are *cis*-fused and adopt an envelope conformation. It was hypothesised that compound **224** is generated as a result of diene condensation of the intermediates, *viz*., 1,4-dihydropyridine **A** and heterodiene **B**, derived *in situ* from ethyl 2-methyleneacetoacetate and ammonia. The low yield of naphthyridine derivative **224** (2.3%) is attributable to its instability in AcOH. At 100 °C, the transformation of this derivative into pyridine **223** is completed in 0.5 h, although compound **224** is rather stable in EtOH, Pr^iOH and DMF.





Hydrogenated 1,8-naphthyridines were synthesised by the reaction of dinitriles **225** with K_2CO_3 in aqueous alcohol. Intramolecular cyclisation affords 4*a*-aryl-8*a*-methyl-2,7-dioxo-1,8-naphthyridines **226**.[422]



Ar = Ph, 3,4-$(MeO)_2C_6H_3$.

III. Physicochemical properties and reactivities of 1,8-naphthyridine derivatives

Data on the structures, physicochemical properties and reactivities of pyridopyridines, including 1,8-naphthyridine, published up to 1984 inclusive, have been analysed in sufficient detail in the reviews.[1,423–425]

1. Physicochemical properties

Studies on the physicochemical properties of 1,8-naphthyridines are being continued. 1,8-Naphthyridinium 1-tetraphenylborate,[426] 4-oxo-1,4-dihydro-1,8-naphthyridinium methanesulfonate[427] and some other derivatives[428–433] were studied by X-ray diffraction.

The behaviour of bromo-substituted isomeric naphthyridines, which include 2-amino-6-bromo-, 2-amino-3,6-dibromo- and 4-bromo-2-hydroxy-1,8-naphthyridines, was investigated by mass spectrometry.[434] It was demonstrated that fragmentation of aminobromonaphthyridines under electron impact follows three main pathways.

1. Elimination of the $Br^{\bullet}$ radicals followed by successive elimination of two HCN molecules (with high intensity) from the molecular ions.

2. Elimination of the HCN molecule followed by liberation of $Br^{\bullet}$ and HCN (with lower intensity).

3. Elimination of the HCN molecule can also be accompanied by competitive liberation of $Br^{\bullet}$ and HCN.

The fragmentation of bromohydroxynaphthyridines follows two main pathways: liberation of $Br^{\bullet}$ accompanied by elimination of CO and two HCN molecules or liberation of CO accompanied by competitive elimination of $Br^{\bullet}$, HCN and C_2H_2.

Mass spectra of aminonitro derivatives of naphthyridines were also studied.[435] Mass spectrometry was used for investigation of the structures and decomposition of the isomeric $[M-HCN]^{-\bullet}$ and $[M-2\,HCN]^{-\bullet}$ ions formed upon fragmentation of naphthyridines and benzoazines.[436] It was found that the $[M-2\,HCN]^{-\bullet}$ ions can exist as two isomeric forms, one of which is typical of naphthyridines, whereas the other is characteristic of benzoazines.

The absorption and transmission spectra of 1,8-naphthyridines were investigated in the region of 50 000–20 000 cm^{-1} in solutions and various mixed crystals at 4.2 and 300 K.[437] The $\pi^*-\pi$-band system of 1,8-naphthyridines is analogous to the corresponding bands in the spectra of the related naphthalene molecule taking into account perturbations caused by the replacement of the C atoms with N. The position of the long-wavelength

$\pi^* - \pi$ band at 27 000 cm^{-1} corresponds to that predicted based on calculations by the extended Hückel method. The bands at 31 600 – 31 900 cm^{-1} were tentatively assigned to the second $\pi^* - \pi$ transition.

With the aim of elucidating the influence of substituents on the absorption spectra, the UV spectra (in methanol) of 1,8-naphthyridines monosubstituted at positions 2 (Me, Cl, Br, OMe, OEt, SMe, NH_2, OH or SH as the substituent), 3 (Me, Cl, Br, NO_2 or NH_2 as the substituent) or 4 (Me, Cl, Br, OMe, OEt, OH or SH as the substituent) were examined.[438]

The electric dipole moment of 1,8-naphthyridine in benzene was determined (4.10 D).[439] The ESR spectrum of hexahydro-1,8-naphthyridinetetrazole was measured.[440]

Homonuclear 2D *J*-resolved ^1H NMR spectra of 2-(2-pyridyl)-1,8-naphthyridine were measured and a complete assignment of the resonances was made.[441]

The ^1H and ^{13}C NMR spectra of imidazo[1,2-*a*][1,8]naphthyridine were analysed based on the results of quantum-chemical calculations using the CNDO/2 method.[442]

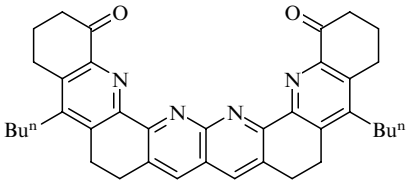
Complexes of the antitumour antibiotics naphthyridinomycins with DNA were investigated by molecular mechanics methods (molecular simulation).[443] It was found that the nature of the substituent at the C(11) atom as well as the stereoconfiguration of the C(7) centre are of importance for biological activity of naphthyridinomycins. The antibacterial activities of various substituted 1,8-naphthyridines,[444] including 2-phenyl-1,8-naphthyridin-4-one derivatives, were calculated using the QSAR method.[445]

The character of deuterium distribution in isotope exchange products of 1,8-naphthyridine and its methyl, hydroxy, amino and nitro derivatives indicates that the rate and pathway of this process depend on the pH of the medium as well as the nature and position of the substituent.[446] In neutral D_2O and a D_2O – DCl mixture, deuterium atoms are replaced with protons exclusively at positions 2 and 7. In D_2O solutions containing NaOD, deuterium atoms are replaced with protons in all positions of the naphthyridine system. In neutral D_2O, the replacement of the protons in monomethyl-substituted 1,8-naphthyridines occurs predominantly in the *ortho* positions with respect to the nitrogen atoms (positions 7 and 2, 7). The high reactivity of these positions is determined by the inductive effect of the substituent.

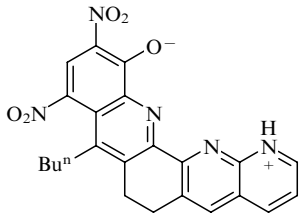
A spectrophotometric procedure [447] and a modified gas-chromatographic method [448] were devised for analysis of nalidixic acid **36**. Drug forms for intramuscular injection [449] and sublimed drugs for parenteral use [450] are available. These drug forms contain the gyrase inhibitor from 1,4-dihydro-4-oxo-1,8-naphthyridine-3-carboxylic acid derivatives as the active component.

The complexation properties of naphthyridines are widely used for analytical purposes, primarily, in medicine. A highly sensitive diagnostic was proposed [431] for bacterial infectious diseases based on scanning electron microscopy. Complexes of antibiotics of the 1,8-naphthyridin-4-one series or their salts with ^{99m}Tc, ^{67}Ga, ^{111}In, ^{113m}In and other radionuclides are used for revealing inflammatory focus. These compounds are involved in parenteral drug forms.[451]

Polycyclic compound **227**, which forms stable complexes with urea, guanidine, amidines and their derivatives, is covered by patents.[452, 453] These complexes were used in biological investigations. Receptor betaine molecule **228** was constructed for diagnostic tests for blood (serum) creatinine and renal insufficiency.

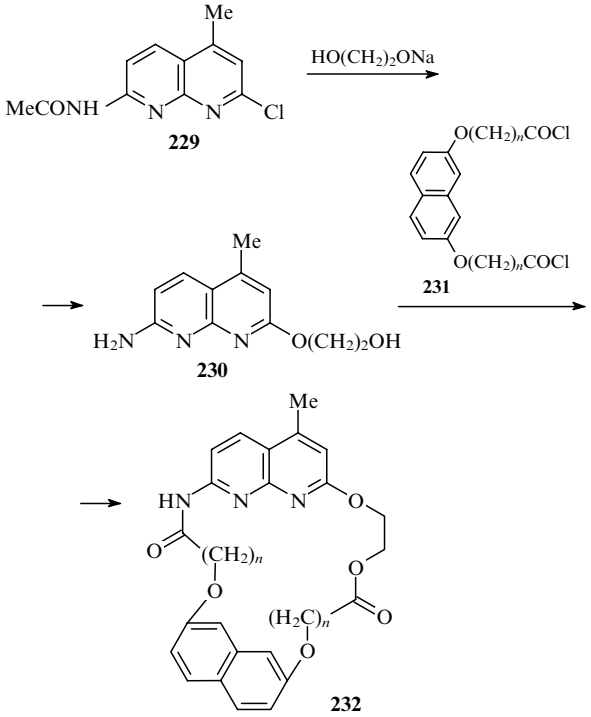


227



228

New guanine receptors were prepared based on 7-acetylamino-2-chloro-4-methyl-1,8-naphthyridine (**229**).[454] Amino alcohol **230** was prepared by the reaction of compound **229** with an excess of sodium 2-hydroxyethoxide. Compound **230** reacts with dicarboxylic acid chlorides **231** under high dilution conditions to form naphthyridine macrocycles **232**.



229

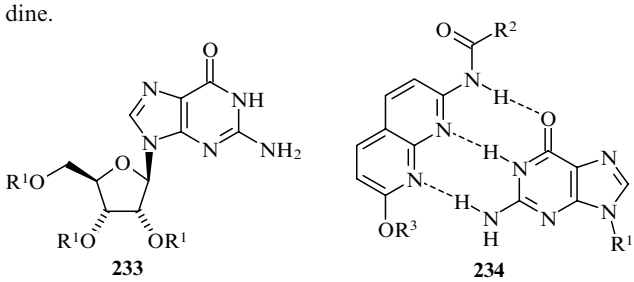
230

231

232

$n = 2, 3$.

It was demonstrated that the addition of 2′,3′,5′-tri-*O*-pentanoylguanosine (**233**) to a solution of macrocyclic compound **232** in $CDCl_3$ causes pronounced changes in the ^1H NMR spectra of both compounds: the resonances of the NH and NH_2 groups are shifted downfield, whereas all six resonances of the naphthalene system are shifted upfield. The assumed [454] structure of the complex consists of two molecules linked *via* three hydrogen bonds (analogous to the structure of complex **234**), and the naphthalene system forms a complex with guanine. The constant of association of compounds **232** and **233** is four times as high as that of the guanine complex with unsubstituted 1,8-naphthyridine.

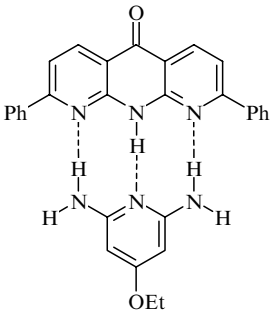


233 **234**

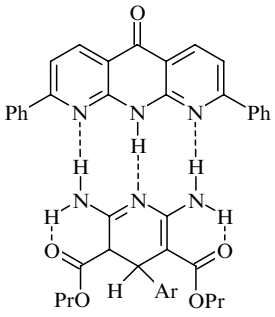
R^1 = C(O)Bu^n; R^2 = H, MeCO, Pr^nCO; R^3 = Cl, OEt, $O(CH_2)_2OH$.

The structures of other complexes based on 1,8-naphthyridine and pyrido[2,3-*b*][1,8]naphthyridine (1,9,10-anthyridine) derivatives containing three hydrogen bonds each were established.[331, 359, 362, 454–459]

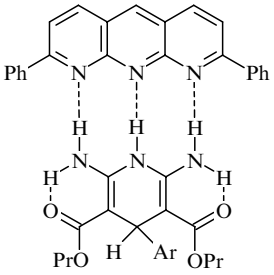
1,9,10-Anthyridine was used for the synthesis of analogous stable complexes **235**–**237**.[456]



235



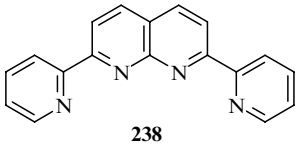
236



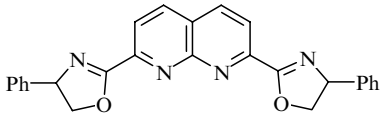
237

Ar = 2-$NO_2C_6H_4$ (**236**), 3-$NO_2C_6H_4$ (**237**).

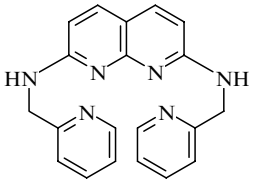
In recent years, 1,8-naphthyridine derivatives have attracted growing interest as promising ligand systems, which coordinate metal ions of different groups of the Periodic table, such as Cu,[460–462] Au,[463, 464] Zn,[465–467] Hg,[468] Mo,[469, 470] Fe,[471] Co,[472] Ni,[473] Ru,[474–477] Rh,[478, 479] Pd,[480] Pt,[480, 481] Eu and Tr.[482] The crystal structures of some complexes were studied by X-ray diffraction analysis.



238



239



240

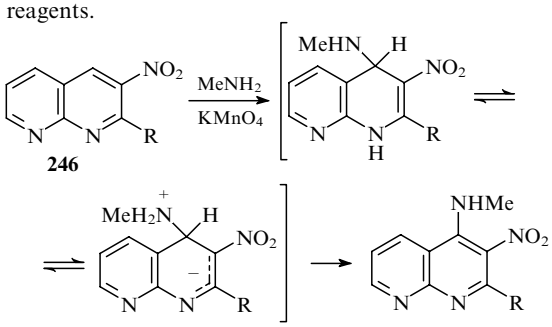
Various ligands based on 1,8-naphthyridines, including polydentate binuclear (compounds **238**,[460] **239**,[483] **240**[484]) and other compounds,[485, 486] were used for complexation with these metal ions.

2. Reactions of 1,8-naphthyridine derivatives

Among nitrogen-containing heterocyclic systems containing the 1,8-naphthyridine fragment, the above-mentioned 1,9,10-anthyridines, which are triaza analogues of anthracene, have attracted considerable attention. Earlier, these compounds have been synthesised according to multistep procedures starting from pyridine derivatives, such as 2,6-diaminopyridine,[487–491] 2,6-diamino-3,5-diformylpyridine,[492] *etc*.[493, 494] Later on, 1,8-naphthyridine derivatives became easily accessible,[316, 322, 358] which made it possible to simplify procedures.

Some transformations of 1,9,10-anthyridines were also described. 7-Nitroanthyridine-2,6-dione (**242**) or 3,7-dinitroanthyridine-2,6-dione (**243**) can be prepared by nitration of anthyridine-2,6-dione (**241**) with various amounts of a mixture of concentrated sulfuric and nitric acids (100 °C, 0.5–3 h). Treatment of nitro derivative **242** with sodium dithionite (in a 5% NaOH solution) gives rise to 7-aminoanthyridine-2,6-dione (**244**) in quantitative yield. The reaction with phosphorus pentasulfide in anhydrous pyridine produces 7-aminoanthyridine-2,6-dithione (**245**) (Scheme 6).[495]

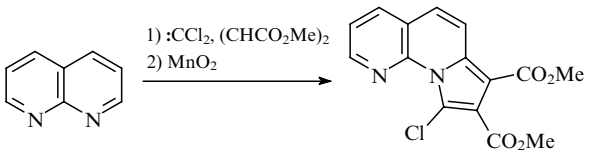
3-Nitro-1,8-naphthyridines (**246**) and their derivatives were subjected to amination at position 4 using liquid ammonia and potassium permanganate[496] or liquid methylamine and potassium permanganate[497–499] as aminating systems. Amination of naphthyridines **246** (−7 °C, 0.5 h) affords 4-methylamino-3-nitro-1,8-naphthyridines (**247**) in 50%–90% yields.[497, 498] Quantum-chemical calculations demonstrated that the reaction is controlled by interactions of frontal molecular orbitals of the reagents.



246 **247**

R = H, OH, OMe, Cl, NH_2, NHMe, NHPh.

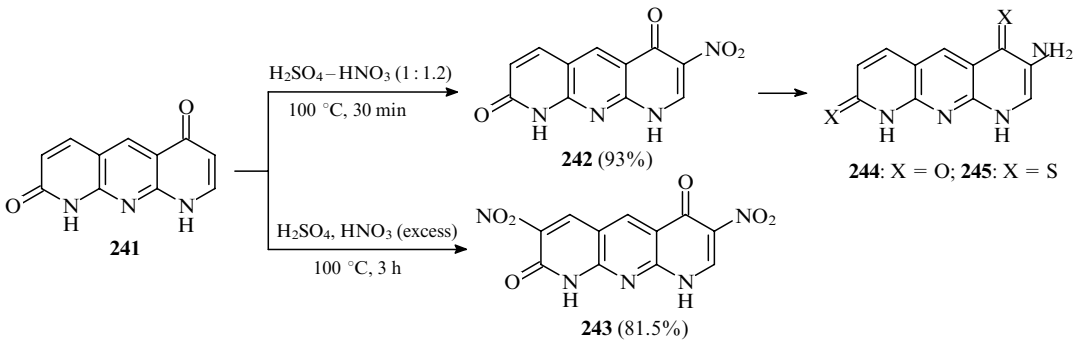
The reaction of 1,8-naphthyridine with dichlorocarbene and dimethyl maleate followed by oxidation of the reaction mixture containing the intermediate cycloadduct with manganese dioxide



248

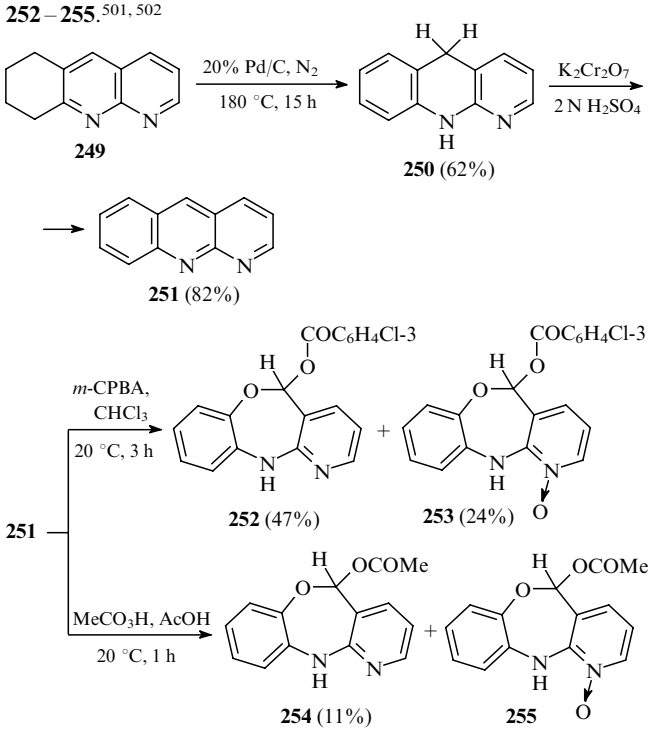
produced dimethyl 1-chloropyrrolo[1,2-*a*][1,8]naphthyridine-2,3-dicarboxylate (**248**) in 11% yield.[500]

Scheme 6

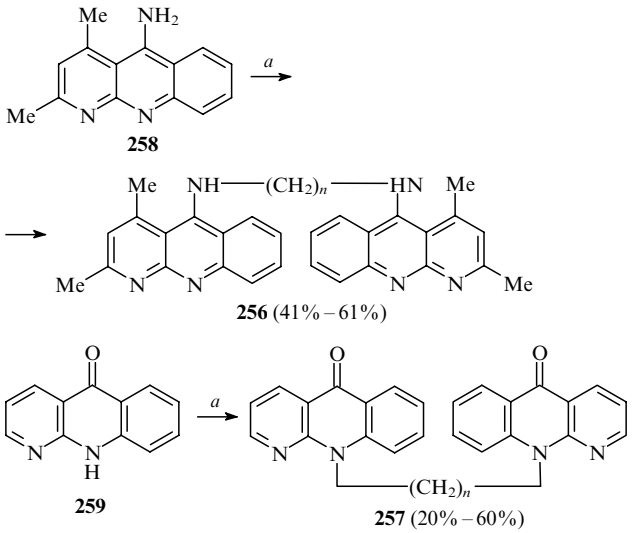


241 **242** (93%) **243** (81.5%) **244**: X = O; **245**: X = S

Dehydrogenation of 5,6,7,8-tetrahydro-1,9-diazaanthracene (**249**) over 20% Pd/C in diphenyl ether or *p*-cymene (250 °C, 3 h) affords 9,1-dihydro-1,9-diazaanthracene (**250**), whose oxidation with potassium dichromate in dilute H_2SO_4 (60 °C, 10 min) gives rise to benzo[*b*][1,8]naphthyridines (**251**). Oxidation of benzonaphthyridine **251** with peroxy acids yields 1,4-oxazepines **252** – **255**.[501, 502]

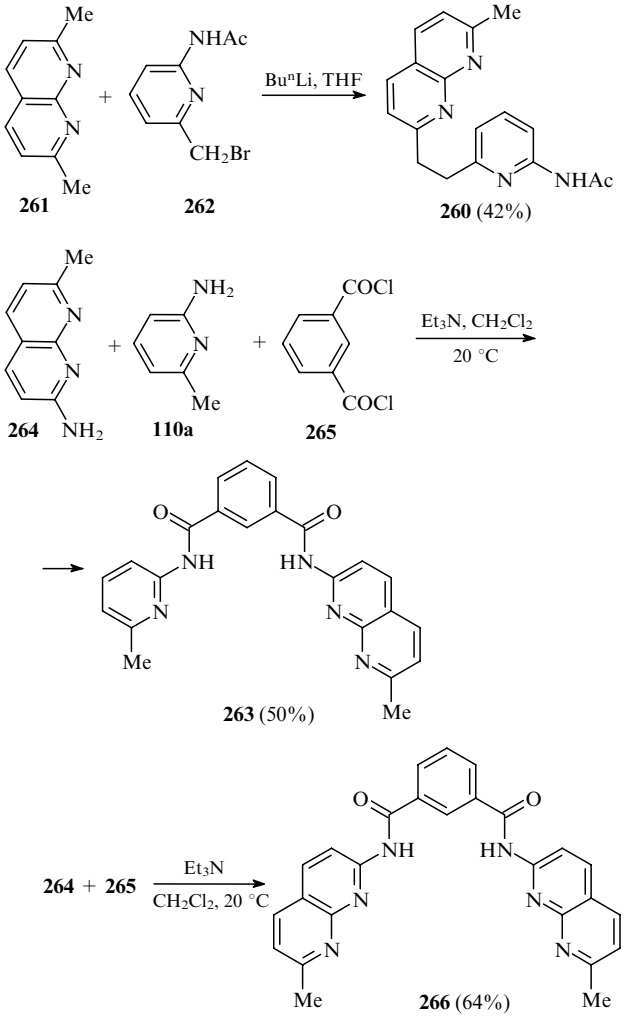


New bisnaphthyridines **256** and **257** containing the 5-amino-2,4-dimethylbenzo[*b*][1,8]naphthyridine or benzo[*b*][1,8]naphthyridone chromophores were synthesised in a phase-transfer system by the reaction of aminobenzonaphthyridine **258** or dihydrobenzonaphthyridone **259** with alkylene dibromides.[503] Such bisintercalates are of interest as potential antitumour drugs.

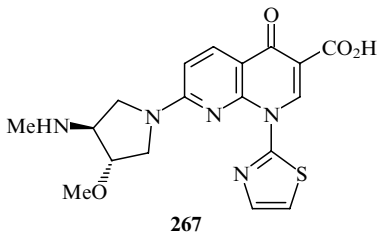


n = 3, 6, 8, 10; *a*) $Br(CH_2)_nBr$, TBAB, PhMe, 50% KOH, Δ; TBAB is tetrabutylammonium bromide.

Procedures were developed for the synthesis of new types of simple receptors based on substituted 1,8-naphthyridines. These receptors serve as carriers for transport of biologically important organic substrates (urea, amino acids, hydroxy acids) into cells. *N*-{6-[2-(7-Methyl[1,8]naphthyridin-2-yl)ethyl]pyridin-2-yl}acetamide (**260**) was prepared by the reaction of 2,7-dimethyl-1,8-naphthyridines **261** with n-butyllithium (2 equiv., THF, −78 °C) and 2-*N*-acetylamino-6-bromomethylpyridine (**262**). Another carrier, *viz*., *N*-(7-methyl[1,8]naphthyridin-2-yl)-*N*′-(6-methylpyridin-2-yl)isophthalamide (**263**), was synthesised from 2-amino-7-methyl-1,8-naphthyridine (**264**), 2-amino-6-methylpyridine (**110a**) and isophthaloyl chloride (**265**) in dry dichloromethane in the presence of triethylamine. *N*,*N*′-Bis(7-methyl[1,8]naphthyridin-2-yl)isophthalamide (**266**) was prepared from naphthyridines **264** and chloride **265** under analogous conditions. Isophthalamides **263** and **266** were used for the determination of L-(+)-tartartic acid as complexes (1 : 1) soluble in chloroform.[504, 505]

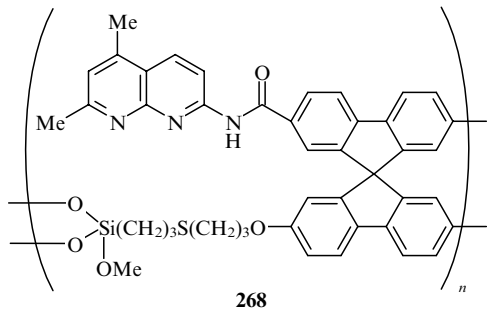


The new antitumour drug Ag-7352 (**267**) was designed based on 1,8-naphthyridin-4-one-3-carboxylic acid.[506, 507] An efficient stereospecific procedure was specially developed for the synthesis of (*S*,*S*)-3-methoxy-4-methylaminopyrrolidine, which is the key reagent in the synthesis of naphthyridine **267**.[508]



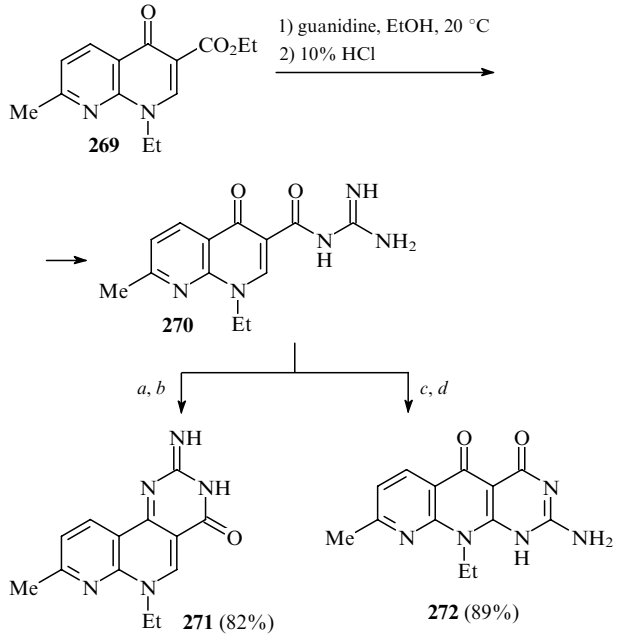
267

1,8-Naphthyridine derivatives were used for the preparation of polysiloxanes. New chiral stationary phase **268** was constructed on the basis of 2-*N*-(5,7-dimethyl-1,8-naphthyridin-2-yl)carboxamide.[509]



268

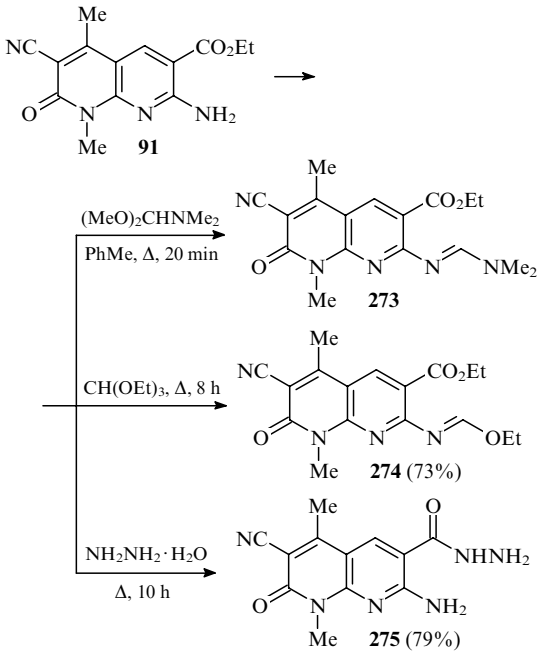
In studies of 1,8-naphthyridine derivatives possessing potential biological activities, a procedure was devised for the synthesis of a new tricyclic system containing the 1,8-naphthyridine fragment, *viz*., pyrimido-1,8-naphthyridines.[510, 511] The synthesis involves condensation of commercially available guanidine carbonate with ethyl nalidixate (**269**) to form *N*-[(1-ethyl-7-methyl-4-oxo-1,4-dihydro-1,8-naphthyridin-3-yl)carbonyl]guanidine hydrochloride (**270**). After pre-neutralisation with 10% NaOH, guanidine **270** readily undergoes cyclisation (EtOH, Δ, 1 h) to form the angularly annelated tricyclic system, *viz*., 6-ethyl-2-imino-8-methyl-2,3,4,6-tetrahydropyrimido[5,4-*c*][1,8]naphthyridin-4-one (**271**), which was isolated as the hydrochloride.[511] Treatment of guanidine **270** with an excess of sodium hydride in dry DMF at 20 °C afforded 2-amino-10-ethyl-8-methyl-1,4,5,10-tetrahydropyrimido[5,4-*b*][1,8]naphthyridine-4,5-dione (**272**), which was also isolated as the hydrochloride.



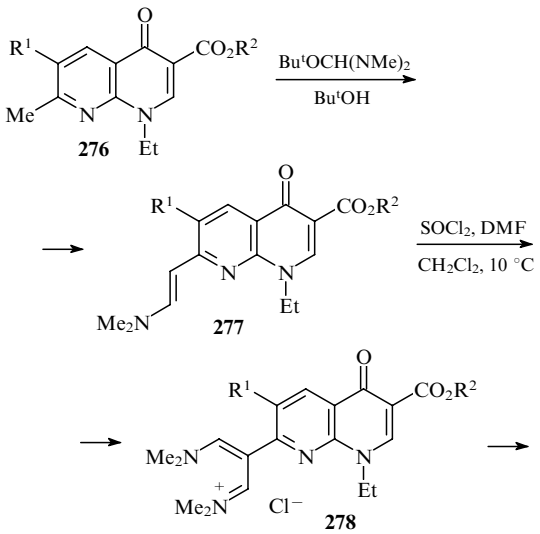
(*a*) EtOH, Δ, 1 h; (*b*) 10% HCl;

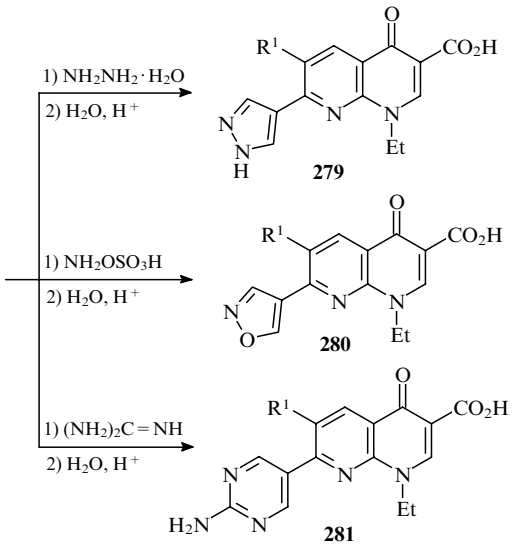
(*c*) NaH, DMF, 20 °C; (*d*) 10% HCl.

With the aim of searching for synthetic approaches to new 1,8-naphthyridin-2-one derivatives, transformations of ethyl 7-amino-1,4-dimethyl-2-oxo-1,2-dihydro-1,8-naphthyridine-6-carboxylate (**91**) were studied. Refluxing of this compound with *N*,*N*-dimethylformamide dimethyl acetal in dry toluene afforded 7-[(*N*,*N*-dimethylaminomethylene)amino]-1,8-naphthyridinone **273**. The reaction of naphthyridone **91** with triethyl orthoformate produced ethoxymethyleneamino derivative **274**. The reaction with hydrazine hydrate gave rise to 7-amino-3-cyano-1,4-dimethyl-2-oxo-1,2-dihydro-1,8-naphthyridine-6-carbohydrazide (**275**).[353]



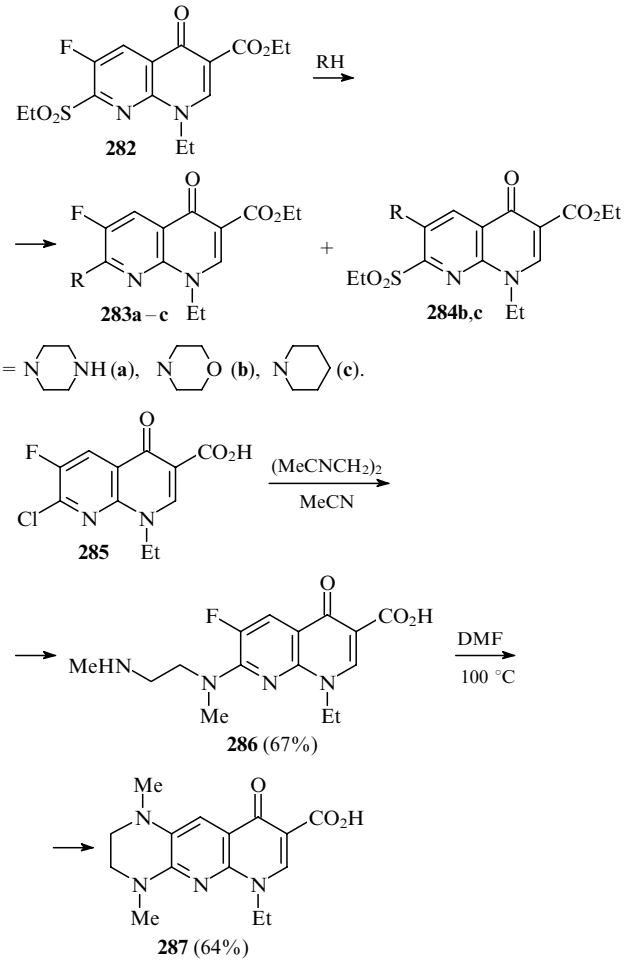
In the last 15 years, considerable attention has been given to variations of substituents in different positions of the molecule (predominantly at position 7), in particular, for the purpose of preparing new active fluoroquinolone and fluoronaphthyridone antibacterial drugs for peroral administration.[512–524] For example, esters of nalidixic acid (**276**) were used for this purpose.[523, 524] The reactions of these esters with *tert*-butoxybisdimethylaminomethane in Bu^{t}OH produce enamines **277**. The addition of the Vilsmeier reagent derived from DMF and thionyl chloride leads to the formation of enamines **278**. Treatment of the reaction mixture with hydrazine hydrate, hydroxylaminosulfonic acid or guanidine followed by hydrolysis of the reaction mixture gives rise to pyrazolyl- (**279**), isoxazolyl- (**280**) and pyrimidinyl-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid derivatives (**281**).[524]



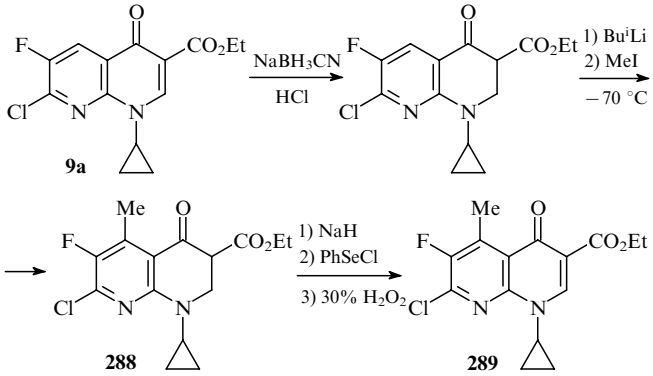


R^1 = H, F; R^2 = Me, Et.

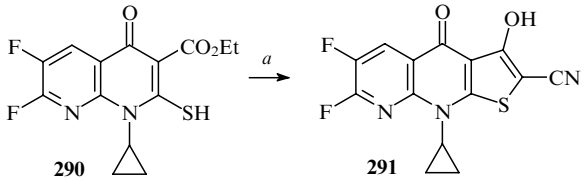
The reaction of ethyl 1-ethyl-7-ethylsulfonyl-6-fluoro-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylate (**282**) with piperazine is accompanied by the replacement of the ethylsulfonyl group at position 7 to form 7-piperazino derivative **283a** in good yield.[521] Treatment of the starting ester **282** with morpholine and piperidine leads to the replacement of the fluorine atom at position 6 or the ethylsulfonyl group at position 7 to form a mixture of 6- and 7-substituted derivatives **283b**,**c** and **284b**,**c**.[523] The reaction of 7-chloro-1-ethyl-6-fluoro-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid (**285**) with *N*,*N*′-dimethylethylenediamine in acetonitrile produces {*N*-methyl-*N*-[2-(methylamino)ethyl]}aminonaphthyridine **286**, which readily undergoes cyclisation upon heating in DMF to give 6-ethyl-1,4-dimethyl-9-oxo-1,2,3,4,6,9-hexahydropyrazino[2,3-*b*][1,8]naphthyridine-8-carboxylic acid (**287**).[523]



Selective reduction of the C(2)=C(3) bond in naphthyridone **9a** followed by treatment with Bu^iLi in THF and methylation affords compound **288**. Subsequent regeneration of the double bond occurs as a result of successive selenation, oxidation and *syn*-elimination to form naphthyridone **289**.[525] Earlier, an analogous scheme has been used for the synthesis of ethyl 7-chloro-1-ethyl-6-fluoro-2-methyl-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylate.[526]



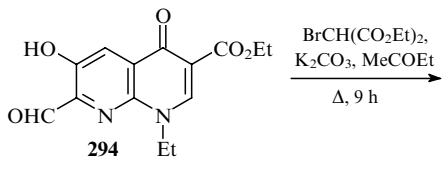
Thieno[2,3-*b*][1,8]naphthyridone **291** exhibiting antimicrobial and antitumour actions was synthesised starting from the 2-mercapto derivative of naphthyridone **290**.[527]

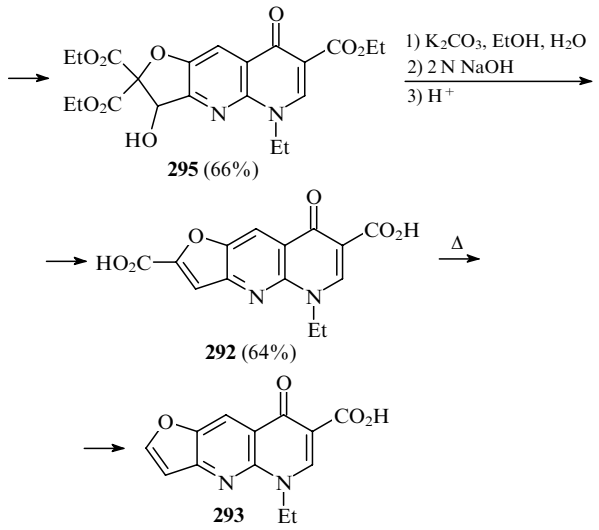


(*a*) 1) $BrCH_2CN$, THF, $NaHCO_3$; 2) $NaHSO_3$, THF, H_2O.

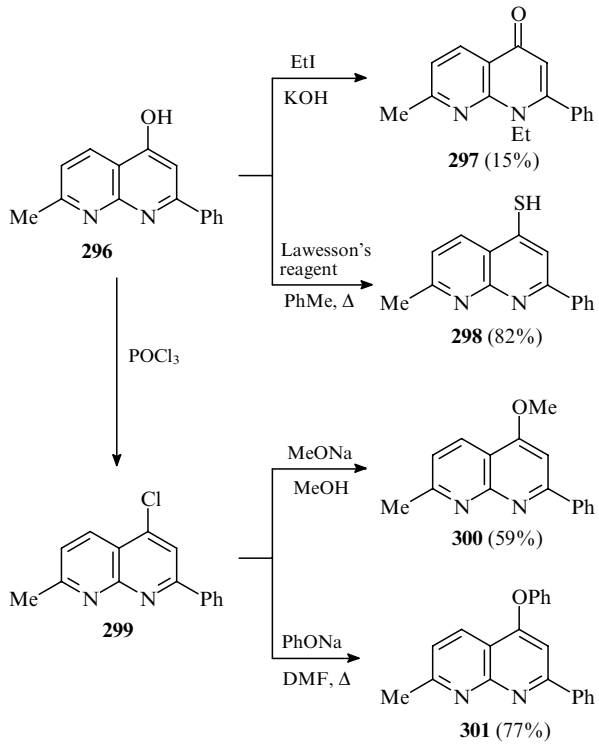
Procedures for the synthesis of compounds containing a five-membered heterocycle with a linearly fused 1,8-naphthyridine fragment (thiazolo[5,4-*b*]-,[528] imidazolo[4,5-*b*]-, triazolo[4,5-*b*]-,[529] oxazolo[5,4-*b*]-, thiadiazolo[5,4-*b*]-, isothiazolo[5,4-*b*]-, pyrazolo[3,4-*b*]-, thieno[2,3-*b*]-, furo[2,3-*b*]-1,8-naphthyridines[530]) were described and the antibacterial activity of these compounds was studied.

5-Ethyl-8-oxo-5,8-dihydrofuro[3,2-*b*][1,8]naphthyridine-2,7-dicarboxylic (**292**) and 5-ethyl-8-oxo-5,8-dihydrofuro[3,2-*b*][1,8]naphthyridine-7-carboxylic acids (**293**) were synthesised in the study.[531] Refluxing of a mixture of ethyl 1-ethyl-7-formyl-6-hydroxy-1,4-dihydro-4-oxo-1,8-naphthyridine-3-carboxylate (**294**), diethyl bromomalonate and K_2CO_3 in ethyl methyl ketone affords compound **295**. Successive treatment of the latter with K_2CO_3 in aqueous ethanol and 2 N NaOH gives dicarboxylic acid **292**. Selective decarboxylation of acid **292** on heating in dimethylformamide, dimethylacetamide or quinoline in the presence of copper compounds yields furonaphthyridinecarboxylic acid **293**.

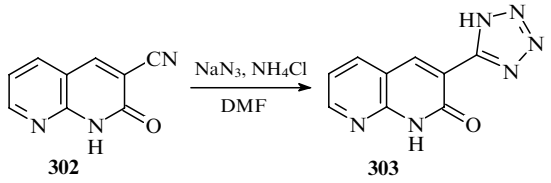




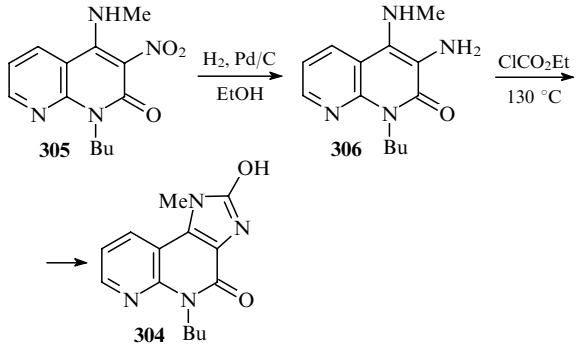
It was found [532] that 1,8-naphthyridine derivatives can react with adenosine receptors of subtypes A_1 and A_{2A}. This stimulated studies on the synthesis and investigation of the biological activities of various functionalised (particularly, at positions 1, 2, 4 and 7) naphthyridines. Alkylation and nucleophilic substitution of these compounds was studied. 7-Methyl-2-phenyl-1,8-naphthyridin-4-ol (**296**) is alkylated at position 1 with EtI and KOH in aqueous ethanol to form 1-ethyl-7-methyl-2-phenyl-1,8-naphthyridin-4(1*H*)-one (**297**).[533, 534] Refluxing of naphthyridone **296** with Lawesson's reagent in toluene affords 7-methyl-2-phenyl-4-thiol-1,8-naphthyridine (**298**). Treatment of 4-chloronaphthyridine **299** (which was prepared by the reaction of naphthyridone **296** with $POCl_3$) with sodium methoxide in methanol gave rise to 4-methoxy-7-methyl-2-phenyl-1,8-naphthyridine (**300**). Refluxing of compound **299** with PhONa in DMF produced 7-methyl-4-phenoxy-2-phenyl-1,8-naphthyridine (**301**). A series of other 1,8-naphthyridine derivatives was also prepared and their properties as A_1, A_{2A} and A_3 adenosine receptors were studied.[534]



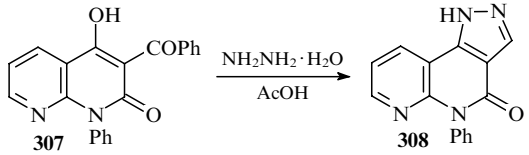
Along with substituted 1,8-naphthyridin-4-ones, derivatives containing the carbonyl group at position 2 were subjected to various transformations. For example, the reaction of 2-oxo-1,2-dihydro-1,8-naphthyridine-3-carbonitrile (**302**) with sodium azide and ammonium chloride in DMF produced tetrazolyl-1,8-naphthyridin-2-one **303**, which was covered by a patent as an anti-allergic drug.[535]



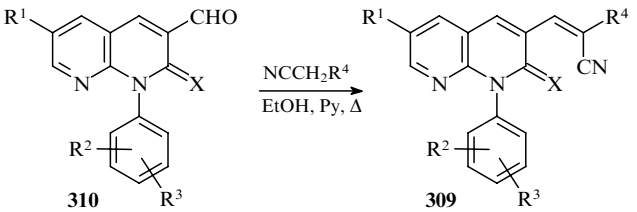
Imidazonaphthyridine **304** possessing anti-inflammatory action was synthesised by hydrogenation of 1-butyl-4-methylamino-3-nitro-1,8-naphthyridin-2(1*H*)-one (**305**) followed by cyclisation of diamino derivative **306** on heating with ethyl chloroformate.[536]



The reaction of 3-benzoyl-4-hydroxy-1-phenyl-1,8-naphthyridin-2(1*H*)-one (**307**) with hydrazine hydrate produces naphthyridone **308** possessing anti-inflammatory and broncholithic activities.[537]

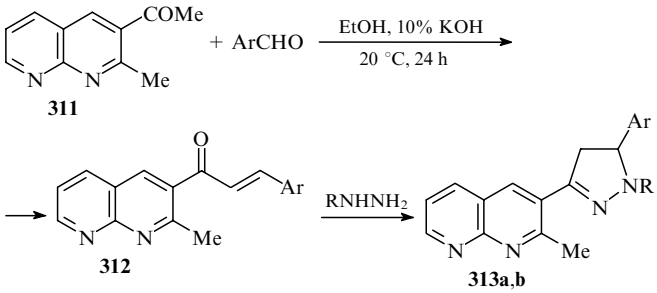


Numerous 3-(2-cyanovinyl)-substituted 1,8-naphthyridines **309** were prepared by refluxing 1,8-naphthyridine-3-carbaldehydes **310** with substituted acetonitriles in alcohol in the presence of catalytic amounts of pyridine. Compounds **309** were covered by a patent as promising starting compounds for the synthesis of new drugs for the treatment of cancer, psoriasis and atherosclerosis.[538]



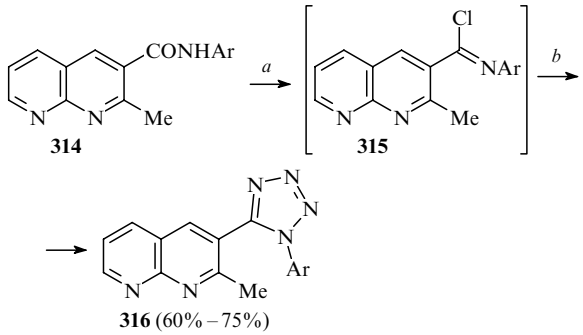
R^1 = H, AlkO, OH, Hal; R^2, R^3 = H, AlkO, AlkS, CF_3, HO, NO_2, CN, Hal; R^4 = Py, $CONH_2$, $CSNH_2$; X = NH, O, S.

Claisen–Schmidt condensation of 3-acetyl-2-methyl-1,8-naphthyridine (**311**) with aromatic aldehydes occurs in ethanol in the presence of KOH to give cinnamoyl-substituted 1,8-naphthyridines **312**. The latter undergo cyclisation under the action of hydrazine hydrate (AcOH, EtOH, Δ, 6 h) or phenylhydrazine (AcOH, Δ, 4 h) to form 3-(5-aryl-2-pyrazolin-3-yl)-1,8-naphthyridines (**313a**) (62%–84% yields) or 3-(5-aryl-1-phenyl-2-pyrazolin-3-yl)-2-methyl-1,8-naphthyridines (**313b**) (64%–86% yields), respectively, which exhibit pronounced antifungicidal activity.[539]



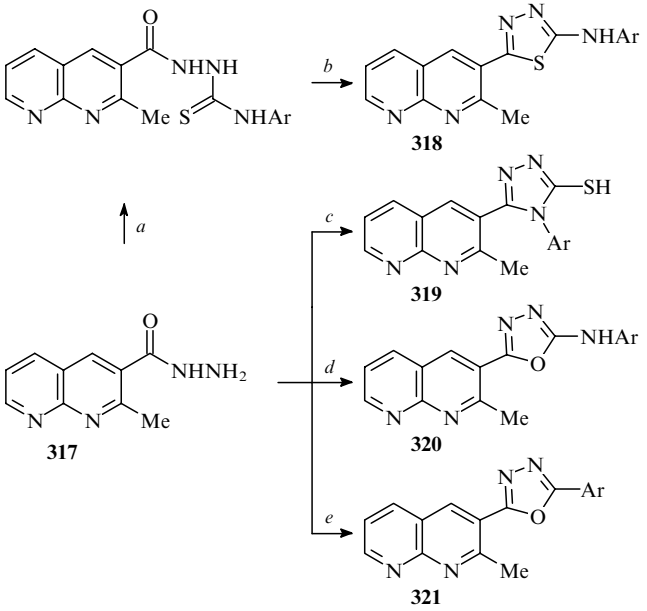
R = H (**a**), Ph (**b**); Ar = Ph, 3-MeC_6H_4, 4-MeC_6H_4, 2-$MeOC_6H_4$, 4-$MeOC_6H_4$, 4-HOC_6H_4, 2-ClC_6H_4, 4-ClC_6H_4, 3-$NO_2C_6H_4$, 4-$Me_2NC_6H_4$.

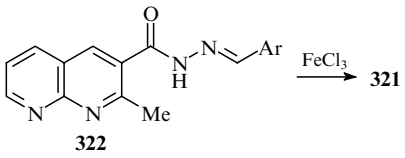
The reaction of *N*-aryl-2-methyl-1,8-naphthyridine-3-carboxamides **314** with $POCl_3$ (120 °C, 3 h) followed by the reaction of the imidoyl chloride **315** that formed with sodium azide afforded 3-(1-aryl-1*H*-tetrazol-5-yl)-1,8-naphthyridines **316**. However, assays of naphthyridines **316** demonstrated that these compounds do not exhibit the expected antibacterial activity.[540]



Ar = Ph, 2-MeC_6H_4, 3-MeC_6H_4, 4-MeC_6H_4, 2-$MeOC_6H_4$, 3-$MeOC_6H_4$, 4-$MeOC_6H_4$, 2-ClC_6H_4, 3-ClC_6H_4, 4-ClC_6H_4, 3-$NO_2C_6H_4$;
(*a*) $POCl_3$, 120 °C, 3 h; (*b*) NaN_3, AcONa, Me_2CO, H_2O, 20 °C, 24 h.

2-Methyl-1,8-naphthyridine-3-carboxylic acid hydrazide (**317**) served as the starting reagent for the synthesis of numerous 1,8-naphthyridine derivatives, such as 1,3,4-thiadiazol-2-yl- (**318**), 4*H*-1,2,4-triazol-3-yl- (**319**)[541] and 1,3,4-oxadiazol-2-ylnaphthyridines (**320**, **321**).[542] Compounds **321** can also be prepared by oxidative cyclisation of arylmethylidenehydrazides **322** with $FeCl_3$ in AcOH.[542]

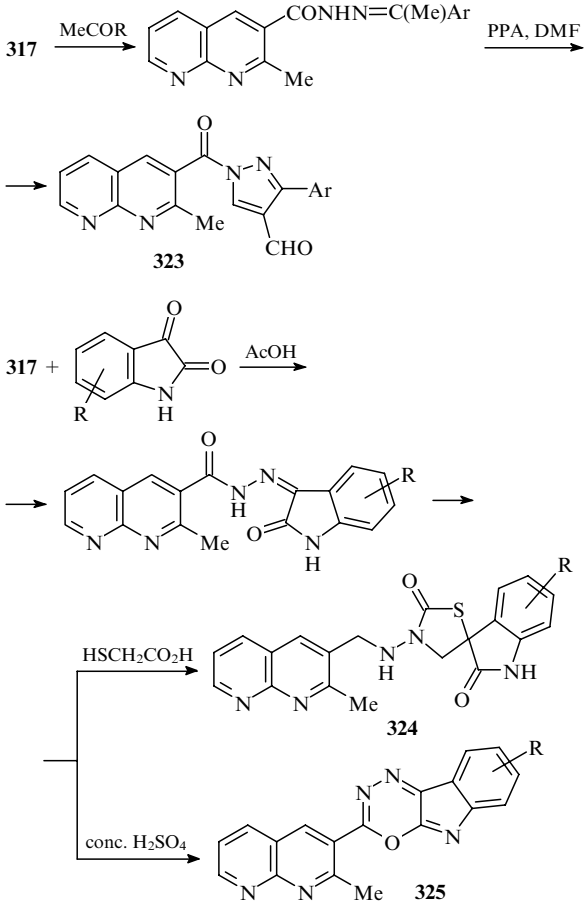




(*a*) ArNCS, EtOH; (*b*) concentrated H_2SO_4; (*c*) ArNCS, 2 N NaOH; (*d*) ArNCO, I_2, KI, 2 N NaOH; (*e*) $ArCO_2H$, 240 °C.

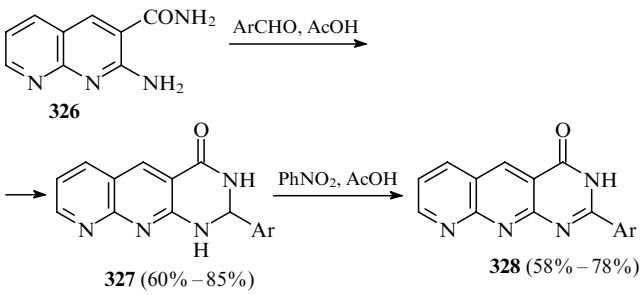
4-Formylpyrazole-1-substituted naphthyridines **323**[543] and compounds **324** and **325** containing complex heterocyclic substituents were synthesised starting from hydrazide **317**.[544]

Naphthyridines **318**–**321** and **323** exhibit bactericidal and fungicidal activities.[542, 543, 545]



R = H, Me, Cl, Br.

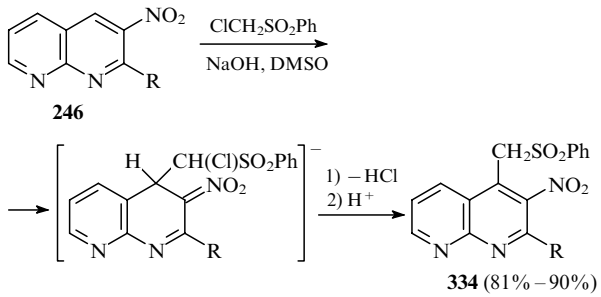
Condensation of 2-amino-1,8-naphthyridine-3-carboxamide (**326**) with aromatic aldehydes in glacial acetic acid affords 2-aryl-1,2,3,4-tetrahydropyrimido[4,5-*b*][1,8]naphthyridin-4-ones **327**, whose oxidation with nitrobenzene in glacial acetic acid gives rise to 2-arylpyrimido[4,5-*b*][1,8]naphthyridin-4(3*H*)-ones **328**. Compounds **328** were also synthesised without intermediate isolation of naphthyridones **327** (condensation of amide **326** with aromatic aldehydes by refluxing in a mixture of nitrobenzene and glacial acetic acid).[546]



Ar = Ph, 2-MeC_6H_4, 4-MeC_6H_4, 2-$MeOC_6H_4$, 4-$MeOC_6H_4$, 2-ClC_6H_4, 3-ClC_6H_4, 4-ClC_6H_4, 2-$NO_2C_6H_4$, 3-$NO_2C_6H_4$, 4-$Me_2NC_6H_4$.

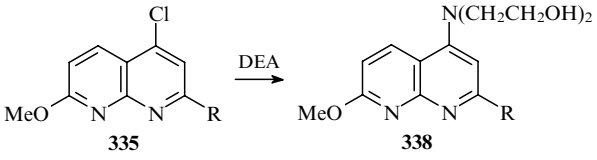
The reaction of 2-amino-5,7-dimethyl-1,8-naphthyridine (**329**) with 2-chlorophenyl sulfochloride produces sulfonamide **330**, which possesses herbicidal and growth-controlling properties.[547] Condensation of amine **329** with trichloroacetone affords a mixture of angular imidazo[1,2-*a*][1,8]naphthyridines **331** – **333** (Scheme 7).[548]

The reactions of substituted 3-nitro-1,8-naphthyridines **246** with chloromethyl phenyl sulfone (DMSO, 20 °C, 2 h) produce 3-nitro-4-(phenylsulfonylmethyl)-1,8-naphthyridines **334** in high yields. Quantum-chemical calculations by the MNDO method demonstrated that the pathway of this reaction, like that of amination (see above), is determined not by charge control but by the interaction between HOMO of the nucleophile and LUMO of the substrate.[549]

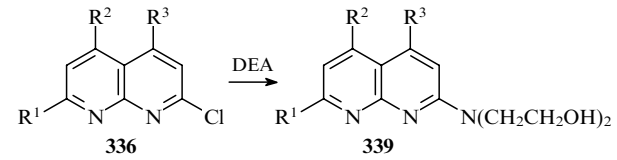


R = H, D, OH, OEt, Cl, NH_2.

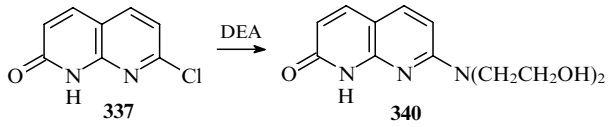
Treatment of chloronaphthyridines **335** – **337** with diethanolamine (DEA) (120 °C) afforded the corresponding bis(2-hydroxyethyl)amino derivatives **338** – **340**. However, the expected antitumour activity of these compounds was not revealed.[550]



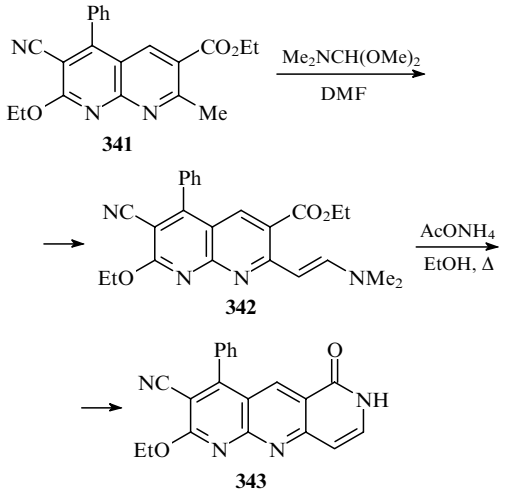
R = Me, Pr^n, Ph, CF_3, 4-$NO_2C_6H_4$.



R^1 = Me, NH_2, OH; R^2 = H, Me; R^3 = H, Ph.



The reaction of ethyl 3-cyano-2-ethoxy-7-methyl-4-phenyl-1,8-naphthyridine-6-carboxamide (**341**) with dimethylformamide dimethyl acetal produces enamine **342**. Subsequent refluxing of the latter with ammonium acetate in ethanol leads to cyclisation to form tricyclic naphthyridine system **343**.[551]



The study [552] was devoted to the transformations in a tetracyclic system containing the fused naphthyridines and benzimidazole ring. 5-Methoxybenzimidazo[1,2-*a*][1,8]naphthyridine-6-carbonitrile (**344**) was prepared by the reaction of 5-chlorobenzimidazo[1,2-*a*][1,8]naphthyridine-6-carbonitrile (**345**) with methanol in the presence of potassium carbonate. Upon heating to its melting point in DMF or in the absence of the solvent, compound **344** undergoes migration of the methyl group from the O atom to the N atom of the benzimidazole fragment to give 7-methyl-5-oxo-6-benzimidazo[1,2-*a*][1,8]naphthyridine-6-carbonitrile (**346**).

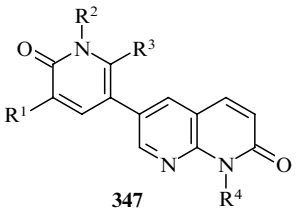
IV. Conclusion

The data surveyed in the present review convincingly demonstrate that the chemistry of pyridopyridines has attracted considerable interest. In the last decade, complex heterocyclic systems containing the 1,8-naphthyridine fragment have been synthesised and their reactions giving rise to functionalised naphthyridines have been investigated. The biological activities of 1,8-naphthyridine derivatives have received the most study. A detailed consideration of these studies is beyond the scope of the present review. For completeness of information, this review contains the bibliography, including patents [553–718] and papers,[719–752] published over the last 15 years, except for those in which 1,8-naphthyridine derivatives are used only in specific biochemical assays.

The activities exhibited by 1,8-naphthyridine derivatives are listed in Table 2. Several examples of the biological properties of this class of compounds are cited below.

With the aim of prolonging the action of nalidixic acid (**36**), which is used, in particular, for the treatment of infectious diseases, acid **36** was subjected to esterification with xanthine using dicyclohexylcarbodiimide in DMSO. The ester proved to be rather efficient against *Staphylococcus aureus* 209P.[753]

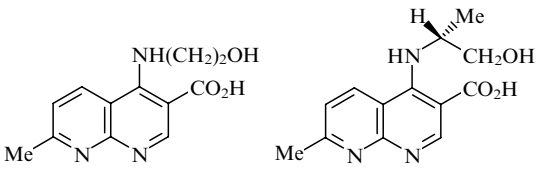
Naphthyridines **347** containing substituted pyridones at position 6 are used as components of cardiotonic drugs.[559]



347

R^1 = H, Alk, AlkO, CHO, CN, NO_2, NH_2; R^2, R^3, R^4 = Alk, Ar.

The inotropic activities of 4-(2-hydroxyethylamino)-7-methyl-1,8-naphthyridine-3-carboxylic acid **348** and its chiral methyl derivative **349** were compared with those of known drugs having an analogous action (isoproterenol, adrenaline, histamine, *etc.*) with the use of isolated samples of guinea-pig myocardium. Biological assays demonstrated that compounds **348** and **349** are similar to heart glycosides in many respects.[754, 755]



348 **349**

Table 2. Biological activities of 1,8-naphthyridine derivatives.

Activity	Ref.
Antibacterial	25, 137, 194, 195, 197, 215, 234, 236, 237, 241, 245, 247, 248, 253–256, 553, 568, 575, 614, 615, 617, 622, 623, 634, 635, 685, 689, 712, 718, 727, 732, 733, 735, 738–743

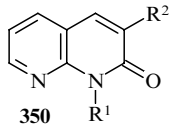
Immunostimulating	567, 570, 571, 650
Analgetic	343, 584
Various receptor antagonists	254, 260, 534, 575, 577, 579, 581, 582, 585, 587, 588, 592, 593, 596, 597, 686, 746
Fungicidal [a]	363

[a] This type of activity was found against phytopathogenic fungi *Phytophtora infestans* on tomatoes, *Phytophtora castonuma* on apples and *Pseudoperonospora cubensis* on cucumbers.

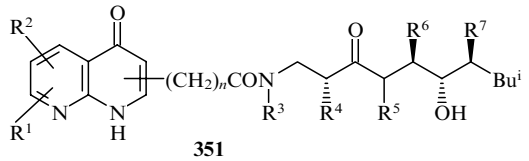
Substituted 1,8-naphthyridin-2(1*H*)-ones **350** were tested as selective phosphodiesterase inhibitors.[756]



350

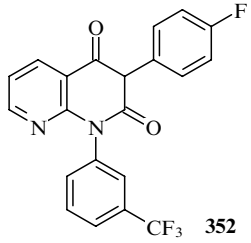
R^1 = Me, $(CH_2)_2Pr^i$, $(CH_2)_3OAc$, n-C_5H_{11}, Allyl, 2-$FC_6H_5CH_2$;
R^2 = H, Me, Ph, 2-Py, $(CH_2)_4OH$, $CH_2CH(OH)Me$.

Numerous substituted naphthyridines were studied and *N*-terminal aminohydroxy derivatives of β-amino acids **351** were demonstrated to inhibit renin.[566, 567] Naphthyridinedione **352** stimulates carotene biosynthesis;[757] (*E*)- and (*Z*)-*O*-(diethylamino)ethyl oximes of the naphthyridine series **353** are potential drugs for local anesthesia.[758] 1,8-Naphthyridine derivatives **354** exhibit high antihypertensive activity.[759]

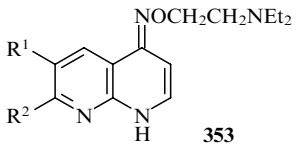


351

R^1, R^2 = H, Alk, OH, OAlk, Ar, CO_2H, NH_2; R^3, R^4 = H, Alk;
R^5 = H, Alk, cyclo-Alk, Bn; R^6 = Alk, cyclo-Alk, Ph;
R^7 = H, OH, OAlk, cyclo-Alk, NH_2.

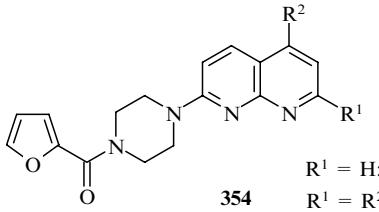


352



353

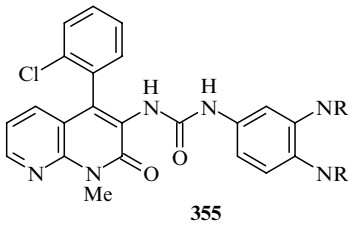
R^1 = H, Br;
R^2 = Me, OMe, OEt, Br.



354

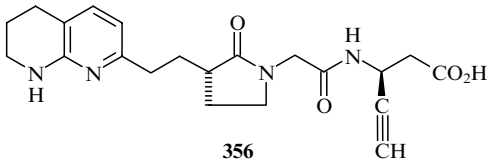
R^1 = H: R^2 = OH, OMe, NH_2;
R^1 = R^2 = Me, CF_3.

Of numerous compounds of the naphthyridine series covered by patents as various receptor inhibitors, cholesterol acyl transferase inhibitors **355**,[574, 580] integrin receptor antagonists **356** and **357**,[579, 581, 587, 588, 592, 593, 595, 596] vitronectin receptor antagonist **358**,[585] *etc*. are worthy of notice.

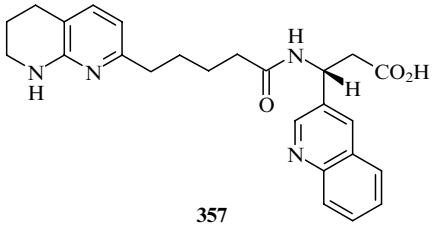


355

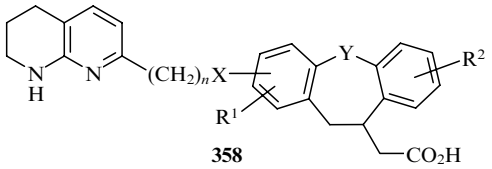
R = H, Alk, cyclo-Alk, Alkenyl.



356



357



358

R^1 = H, Hal, C_1–C_6-Alk; R^2 = H, C_1–C_6-Alk;
X = Y = O, CH_2; n = 2, 3.

The present review, devoted to the chemistry and biological activities of 1,8-naphthyridine derivatives, will hopefully be of interest for organic chemists and biologists. Due to the presence of two geminal endocyclic nitrogen atoms, the 1,8-naphthyridine molecule is more promising for interactions with various biological receptors, coordination to metal ions and other intermolecular contacts compared to other isomeric pyridopyridines and the majority of known nitrogen heterocycles. In the immediate future it is hoped that new regio- and stereoselective procedures will be developed for the introduction of pharmacophoric groups at different positions of the naphthyridine molecule with the use of cascade heterocyclisation and combinatorial chemistry for the design of more efficient medical drugs possessing prolonged action or improved pharmokinetic characteristics. In particular, the design of the so-called dual action antibiotics, *viz*., systems consisting of β-lactam antibiotics of the penicillin and cefalosporin series and fluoroquinolonecarboxylic or fluoronaphthyridonecarboxylic acid derivatives, holds promise.

I thank Doctor S V Roman for help in collecting patent data.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-32063).

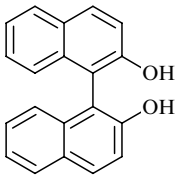
Abstract. The data published during the last five years on the application of chiral derivatives of phosphorous acid in coordination chemistry and enantioselective catalysis are summarised and discussed. The effect of the nature of these ligands on the structure of metal complexes and on the efficiency of catalytic organic syntheses is shown. Hydroformylation, hydrogenation, allylic substitution and conjugate addition catalysed by transition metal complexes with optically active phosphites and hydrophosphoranes are considered. The prospects for the development of this field of research are demonstrated. The bibliography includes 215 references.

I. Introduction

Organic reactions catalysed by chiral transition metal complexes are the basis of modern asymmetric synthesis. This statement was substantiated by the fact that three leading researchers working in this field of chemistry were awarded the Nobel Prize in 2001. The key to obtaining high catalytic results is targeted synthesis of optically active ligands. Among them, of prime importance are phosphorus-containing compounds which are crucial to the progress of such avenues of organic synthesis as asymmetric reduction, isomerisation and formation of carbon – carbon and carbon – heteroatom bonds.[1] These ligands also play an important role in the development of concepts of the geometry and structure of complexes, mutual influence of intra-sphere ligands and the nature of coordination bond.[2] Initially, emphasis was placed on systems with P – C bonds, especially tertiary phosphines. We cannot but agree with Ansell and Wills[3] that this situation is unjust. Indeed, compounds with three P – O and (or) P – N bonds offer a number of considerable advantages.[3–5] First, they are synthetically accessible, because most of them can be synthesised rather simply and in high yield from a variety of optically active precursors. This makes possible a direct one-step phosphorylation of chiral compounds, whereas the synthesis of corresponding phosphine derivatives requires preliminary modification. Second, these compounds exhibit higher oxidative stability because of the absence of the P – C bond in the corresponding structures. This is of great importance in those cases where the oxidation of a phosphorus-containing ligand faces considerable difficulties, *e.g.*, in the synthesis of some types of coordination compounds and catalysis of hydroformylation. Third, these compounds possess a pronounced π-acceptor ability, which allows the coordinated phosphites to stabilise low oxidation states of metals used as complexing agents, thus enhancing their electrophilicity. By and large, replacement of carbon atoms by heteroatoms [oxygen and (or) nitrogen] in the first coordination sphere of phosphorus atom appeared to be a much more efficient tool for control of the chemical stability of ligands and their donor – acceptor properties and steric features compared to traditional introduction of various substituents into benzene rings of the PAr_2 fragment typical of most phosphine systems.

The aforesaid is responsible for an increase, in the last decade, in the number of communications concerned with applications of chiral derivatives of phosphorous acid in the synthesis of coordination compounds and in catalysis. Studies in the field reported before 1998 were summarised in two reviews.[6,7] Most of the P-monodentate ligands considered in these reviews were carbohydrate derivatives but some chiral amino alcohols and diols were also presented. No systematic investigations on their complexation were carried out at that time. The optical yields of catalytic reactions (hydrogenation, hydrosilylation, hydrocyanation) involving these compounds were at most 20% – 30%.[6] However, the first phosphorus-containing derivatives of BINOL (**1**) were synthetically available at that time.



1 (BINOL)

Later on, these BINOL-based compounds were top-ranked among the P-monodentate phosphites (type **A**). The group of P,N-bidentate ligands (type **B**) comprised a few compounds containing sp^3-hybridised peripheral nitrogen atoms, *i.e.*, phosphites and phosphoramidites containing an amino group in the

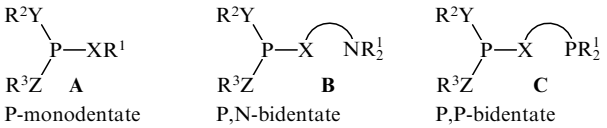
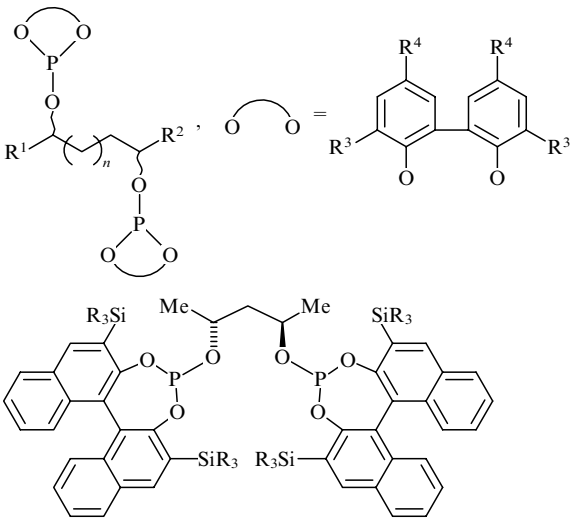
substituent; for simplicity, hereafter we will call them 'aminophosphites' and 'aminophosphoramidites.' No interesting results were obtained when catalytic reactions were performed involving these species.[6] This also holds for the phosphite derivatives of alkaloids.[8] On the contrary, P,P-bidentate ligands (type **C**) have been the subject of numerous studies, which were carried out to gain a better insight into their coordination chemistry and revealed high catalytic efficiency of these compounds.



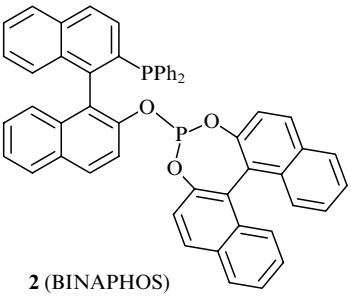
A **B** **C**

X, Y, Z = O or N.

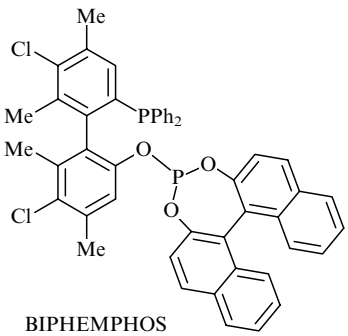
The advances made before 1998 and fully considered in Ref. 7 are as follows: design of two groups of structures providing an enantioselectivity of up to 87% in Rh-catalysed hydroformylation of styrene



by van Leeuwen's group and a series of studies by Takaya *et al.* who first synthesised dissymmetric phosphine-phosphites BINAPHOS (**2**) and BIPHEMPHOS and their simplest derivatives.



2 (BINAPHOS)



BIPHEMPHOS

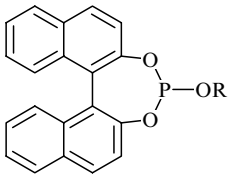
The use of these compounds in Rh-catalysed hydroformylation of a broad spectrum of substrates (vinyl acetate, styrene and its homologues, *N*-vinylphthalimide, cyclic and fluorinated alkenes, 4-vinyl-β-lactam) allowed an *ee* of 87% – 98% to be achieved. They also demonstrated a high enantioselectivity in Pd-catalysed copolymerisation of alkenes and dienes with CO.

Based on analysis of the role played and niche occupied by chiral phosphites in the coordination chemistry and catalytic studies (see above), some predictions were made concerning further use of these compounds.[7] In particular, dissymmetric P,P-bidentate compounds based on amino alcohols, active use of P,N-bidentate systems in asymmetric catalysis and the development of new fields of application of phosphite ligands (hydrosilylation and hydroboronation of C=C bonds) were predicted. These predictions were fully substantiated by further progress in the field, which appeared to be so rapid that recently reported studies[6,7] are now in essence out of date. A large body of new experimental material requires systematisation and discussion. The aim of this review is to consider the data published during the last five years. The data are classified based on the structure (first of all, denticity) of chiral phosphite ligands. This approach seems to be quite logical because it allows the advances of asymmetric catalysis and coordination chemistry to be analysed from a unified standpoint based on the nature of the phosphorus-containing ligand. In addition, in discussing the material we tried to group the studies reported by researchers from the leading scientific schools together and to highlight the most important results concerned with catalytic processes.

II. P-Monodentate phosphites

1. Phosphite derivatives of BINOL

This group of ligands comprises axially chiral compounds (**3a**–**q**) and compounds containing additional C*-stereocentres in the exocyclic substituent (**3r**–**w**).



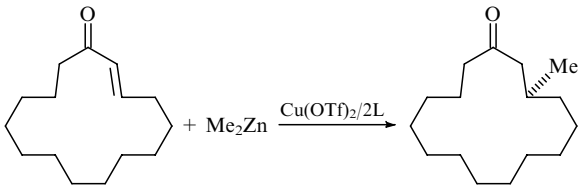
3a–**w** [(S_{ax}) and/or (R_{ax})]

Compound **3**	R	Compound **3**	R
a	Me	**n**	2-BrC_6H_4
b	Pr^i	**o**	2,6-$Me_2C_6H_3$
c	cyclo-C_5H_9	**p**	2,6-$Ph_2C_6H_3$
d	Bu^i	**q**	2-naphthyl
e	CH_2CHEt_2	**r**	(*S*)- or (*R*)-Bu^s
f	neopentyl	**s**	(*S*)- or (*R*)-CH(Ph)Me
g	Bn	**t**	(1*S*,2*R*)- or (1*R*,2*S*)-Ph(cyclo-C_6H_{11})
h	CH_2CH_2OMe	**u**	(1*S*,2*R*)- or (1*R*,2*S*)-(2-naphthyl)cyclohexyl
i	CH_2CH_2Cl	**v**	*O*-methyldianhydro-D-mannityl
j	CH_2CCl_3	**w**	menthyl
k	Ph		
l	4-$MeOC_6H_4$		
m	4-$CF_3C_6H_4$		

They are used in enantioselective processes resulting in the formation of C–C bonds and in hydrogenation of unsaturated esters. For instance, phosphites (S_{ax})-**3k**–**m** provided an *ee* of 32% – 96% in the Ir-catalysed allylic alkylation of esters of cinnamyl alcohol by dimethyl malonate. The highest enantioselectivity at a regioselectivity of 93 : 7 (branched : linear product) was demonstrated by ligand **3k** {$[IrCl(cod)]_2$ was used as precatalyst; cod = cyclooctadiene}.[9]

Asymmetric Cu-catalysed addition of Et_2Zn to acyclic enones $R^1-CH=CH-C(O)-R^2$ (R^1 and/or R^2 = Me, Pr^i, C_5H_{11}, Ph)

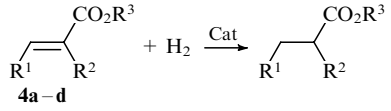
involving phosphites **3t**,**u** was studied.[10,11] It was found that enantioselectivity is governed by the axial chirality, namely, the enantiomeric excess was 56% to 87% for (R_{ax})-**3t**,**u** and at most 33% for (S_{ax})-**3t**,**u**. An odorant (*R*)-(−)-muscone was synthesised following reaction (1) using (R_{ax})-**3t** with a chemical yield of 53% and an optical yield of 79%.



(1)

Tf = CF_3SO_2.

No less important were the results obtained in hydrogenation of prochiral esters **4a**,**b** [reaction (2)].

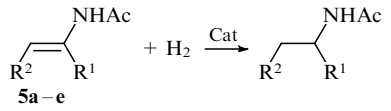


4a–**d** (2)

Compound **4**	R^1	R^2	R^3
a	H	CH_2CO_2Me	Me
b	H	NHAc	Me
c	4-AcO-3-$MeOC_6H_3$	NHAc	H
d	Ph	NHAc	Me

The optical yields of reactions involving (S_{ax})-**3a**,**b**,**k**,**n** were 89%–98% for compound **4a** and 70%–95% for compound **4b** {with $[Rh(cod)_2]^+BF_4^-$ as precatalyst}.[11] Noteworthy is that systems (S_{ax})-**3o**,**p** containing *ortho*-substituted exocyclic phenoxy groups appeared to be of low efficiency, namely, the optical yields in reaction (2) involving substrate **4a** were at most 39%. At the same time ligands bearing additional C*-stereocentres appeared to be excellent stereoselectors: hydrogenation of ester **4a** in the presence of (S_{ax})-**3v** and (R_{ax})-**3v** gave an *ee* of 95% to 98%; the optical yields in hydrogenation of esters **4a**,**b** using phosphites (S_{ax}, S_C)-**3s** and (S_{ax}, R_C)-**3s** were 93% to 99%.[12,13] Similarly, hydrogenation of substrate **4a** and in the presence of epimers (S_{ax})-**3w** and (R_{ax})-**3w** led to an *ee* of 91% to 95%.[14]

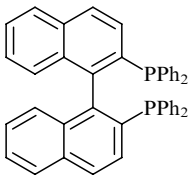
Phosphites **3a**–**j**,**r**,**s** also exhibited a high enantioselectivity (*ee* 75%–97%) in hydrogenation of enamides **5a**–**e** {also with $[Rh(cod)_2]^+BF_4^-$ as precatalyst, reaction (3)}.[15]



5a–**e** (3)

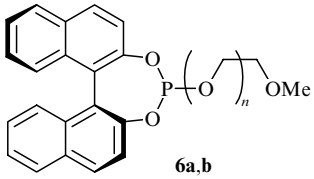
Compound **5**	R^1	R^2	Compound **5**	R^1	R^2
a	Ph	H	**d**	Ph	Me(*Z*)
b	4-ClC_6H_4	H	**e**	Ph	Me(*E*)
c	2-naphthyl	H			

Except for the reaction with ligand **3j** containing a CCl_3 group, which strongly withdraws the electron density and thus increases the π-acceptor ability of the P-centre, a 99%–100% conversion was obtained (*cf.* less than 5% for compound **3j**). Taking into account the above and the low cost of phosphite derivatives of BINOL (about 2% of the cost of the known P,P-bidentate phosphine ligand BINAP),[15] the conclusion about great prospects for industrial applications of these systems seems to be quite substantiated.



BINAP

Probably, this was the reason for the synthesis of phosphites **6a**,**b** with long-chain exocyclic substituents.[16]



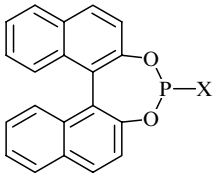
6a,**b**

n = 16 (**a**), 17 (**b**).

Being used with $[Rh(cod)_2]^+BF_4^-$, ligands **6a**,**b** accelerate hydroformylation of styrene under conditions of phase transfer catalysis. This example demonstrates the possibility of re-use of the catalytic system without loss of efficiency in spite of the low optical yield (17%).

2. Phosphoramidite derivatives of BINOL

Similarly to the phosphite systems, both axially chiral compounds (**7a**–**k**) and compounds containing additional C*-stereocentres (**7l**–**u**) were studied.



7a–**u** [(S_{ax}) and/or (R_{ax})]

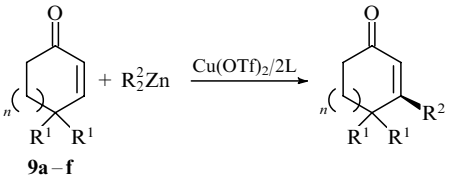
b	Pr^i	Me	**e**	Me	Ph
c	$(CH_2CH_2)_2O$	Me			

Undoubtedly, the scientific school headed by Feringa is a leader in the field of synthesis and catalytic applications of ligands **7**. As early as 1994, Feringa reported the synthesis of the first compound in this class, **7a** (MonoPhos).[17] The main field of application of these phosphoramidites is processes involving formation of C–C bonds (first of all, by Cu-catalysed addition of organozinc reactants). For instance, reactions with participation of cyclic α,β-unsaturated ketones **9** [reaction (4)] were studied.



(4)

9a–f

Compound **9**	R^1	*n*	Compound **9**	R^1	*n*
a	H	1	**d**	H	3
b	H	0	**e**	Me	1
c	H	2	**f**	Ph	1

The results of these studies for Et_2Zn are summarised in Table 1. As can be seen, ligand (S_{ax},R_C)-**7n** provides the highest enantioselectivity.[18–20] Its homologue, (S_{ax})-**7o**, bearing bulkier naphthyl substituents is somewhat less efficient, but stereomer (S_{ax},S_C)-**7n** is much less efficient (*ee* 75%).[19] Systems containing no additional C*-stereocentres **7a–j** appeared to be the worst stereoselectors (the maximum optical yield in the reaction with substrate **9a** was 60%, see Table 1).[19]

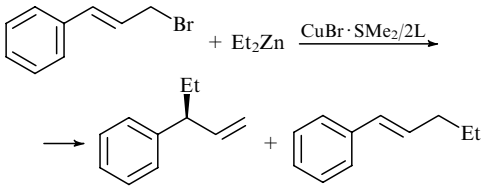
Table 1. Comparative enantioselectivity of a number of P-monodentate chiral phosphoramidites in the Cu-catalysed asymmetric addition of Et_2Zn to cyclic enones [reaction (4)].

Substrate	*ee* (%)	
	ligand (S_{ax})-**7c**	ligand (S_{ax},R_C)-**7n**
9a [a]	60	98
9b	–	10
9c	55	98
9d	–	97
9e	81	98
9f	–	98

[a] The enantioselectivity provided by other ligands involved in the reaction with this substrate was also studied; the results obtained are as follows: 25% for S_{ax}-**7a**, 72% for S_{ax}-**7m** and 94% for S_{ax}-**7o**.

Reactions of other R_2Zn derivatives [R = Me, Pr^i , Bn, C_7H_{15}, $(CH_2)_5OAc$ and $Me_2CH(OEt)_2$] in the presence of compounds **9a** and (S_{ax},R_C)-**7n** were also characterised by high enantioselectivity (*ee* 94%–98%).[20,21] Therefore, it is quite logical that the most efficient ligand, (S_{ax},R_C)-**7n**, also provided excellent results in other related reactions of R_2Zn addition to cyclic aliphatic vinyloxiranes (*ee* up to 96%);[22] α,β-unsaturated nitroacetals (*ee* up to 92%);[23] 4,4-disubstituted cyclohexadienones (*ee* up to 99%);[24] cyclic unsaturated ketones (followed by aldol condensation to give bicyclic enones with an optical yields of up to 98%);[25] and to 4,4,5-trisubstituted cyclohexanones (*ee* up to 97%).[26] Systems R_2Zn/Cu(OTf)$_2$/2L [L = (S_{ax})-**7c**, (S_{ax})-**7l–o**] were employed to achieve enantioselective kinetic resolution of racemic cyclohex-2-enones.[27] Again, ligand (S_{ax},R_C)-**7n** was the best stereoselector and provided a greater than 99% optical purity of the product [*cf*. an *ee* of only 22% for (S_{ax})-**7c**]. A related kinetic resolution of racemic vinyloxiranes with phosphoramidite (S_{ax},R_C)-**7n** was also characterised by *ee* up to 99%.[28] Very high enantioselectivity achieved in the key stage of R_2Zn addition to cyclic enones under the action of Cu(OTf)$_2$/2L [L = (S_{ax},R_C)-**7n**] permitted the development of efficient procedures for the synthesis of optically pure bicyclic alcohols[29] and methyl ester of (–)-prostaglandin E_1.[30]

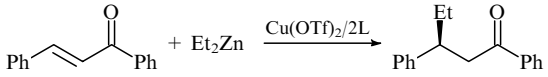
Phosphoramidite (S_{ax},R_C)-**7n** is also used in a promising reaction of synthesis of chiral alkenes. Namely, the optically active product was obtained at 85 : 15 regioselectivity (branched : linear products) and an *ee* of 77% [ligands (S_{ax})-**7c**, (S_{ax})-**7m**, (S_{ax})-**7o** provide an *ee* of at most 31%].[31]



It should be noted that in some cases the best results were obtained using the (R_{ax},S_C)-**7n** enantiomer. A case in point is the addition of Et_2Zn to cyclic enones (*ee* up to 92%)[10] and a variety of nitroolefins (*ee* up to 94%).[32,33]

Recently synthesised[34] ligand (R_{ax})-**7q** can also be considered rather promising. Indeed, the addition of Et_2Zn to enone **9a** catalysed by Cu(OTf)$_2$/2L [reaction (4)] was performed with an optical yield of 93%. Besides, the catalytic synthesis of (*R*)-(–)-muscone involving ligand (R_{ax})-**7q** [reaction (1), see above] is characterised by much higher enantioselectivity (*ee* 95%)[34] compared to the reaction with phosphite (R_{ax})-**3t**.

By and large, phosphoramidites bearing additional C*-stereocentres are much better stereoinductors in reactions of Cu-catalysed addition of organozinc compounds. However, there are also a few exceptions. In particular, the reaction with chalcone showed an *ee* of 90% with ligand (S_{ax})-**7c** and only 75% with (S_{ax},R_C)-**7n**.[18,19]

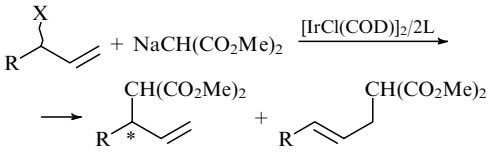


Efforts to obtain *ortho*-disubstituted phosphoramidites **8a–e** lacked support because the enantioselectivity showed by these compounds was no higher than that provided by their unsubstituted analogues **7a–u**.[18,19]

Note that, in spite of quite impressive catalytic results achieved using phosphoramidites **7a–q**, the coordination chem-

istry of these ligands is still poorly studied. Though a general scheme for the catalytic cycle of addition of organozinc reactants to cyclic enones has been reported,[19,20] no data confirming the structure of intermediates are available. The structure of catalytically active complexes is also unknown. Only Feringa and coworkers[18] earlier reported the synthesis and X-ray diffraction study of compound $CuI(L)_3$ [L = (S_{ax})-**7a**], while the course of complexation in the system $Cu(OTf)_2/2L$ is still to be clarified. We believe that one should expect publication of studies aimed at developing polymer-immobilised catalysts for asymmetric conjugate addition reactions. The first step along this line of investigation was reported recently.[35] Cu-Catalysed reaction of Et_2Zn with substrate **9a** [reaction (4)] using various modifications of the (R_{ax})-**7k** ligand covalently bound to hydroxymethylpolystyrene showed optical yields of up to 67%.

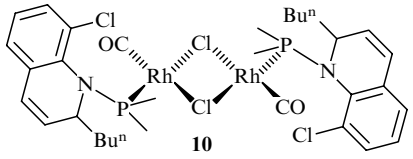
Phosphoramidite derivatives of BINOL (**1**) have also found applications in other reactions of C–C bond formation, in particular, Ir-catalysed allylic substitution.



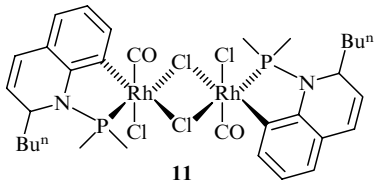
R = Me, CH_2CH_2Ph, Pr^i; X = OAc, Cl, OCO_2Et, $PO(OEt)_2$.

For instance, ligand (R_{ax})-**7a** usually provides a nearly 100% regioselectivity and an optical yield of up to 86% (R = CH_2CH_2Ph and X = OAc).[36,37] Very high chemical yields and regioselectivities are also observed in the presence of ligand (R_{ax},R_C)-**7n** in a related allylic amination reaction of a broad spectrum of substrates R–CH=CH–CH_2OCO_2Me by various amines (with enantioselectivities of 76%–97%).[38]

An interesting group of ligands **7s**,**t** was reported by Faraone *et al.*[39] The first communication was concerned with the synthesis and complexation of epimers **7s**. ^{31}P NMR and IR spectroscopy studies of the system $[RhCl(CO)_2]_2$/L [L = (S_{ax},R_C)-**7s**] revealed the formation of not only a conventional binuclear complex **10** but also its structural isomer **11** with a coordiation number of the Rh atom of 6.



10

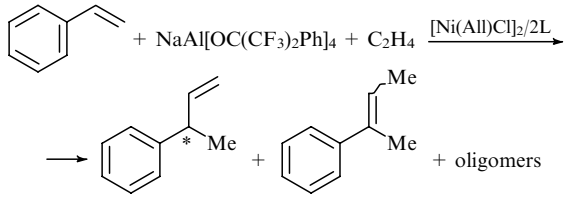


11

The formation of complex **11** involves oxidative addition of the ligand C–Cl bond to rhodium. In the case of epimer (S_{ax},S_C)-**7s** the process is sterically hindered and therefore only complex **10** is formed. The reactions of phosphoramidite (S_{ax},R_C)-**7s** with $[PdCl_2(PhCN)_2]$ or $[PtI_2(cod)]$ (at L : M = 2 mole ratio) resulted in corresponding complexes *cis*-$[MHal_2L_2]$. They were studied by ^{31}P and ^1H NMR, long-wavelength IR spectroscopy and X-ray analysis (complexes $[PtI_2L_2]$).[39]

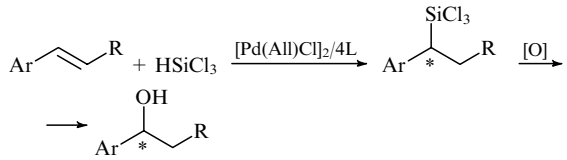
The use of both epimers **7s** in Cu-catalysed addition of Et_2Zn to substrate **9a** [reaction (4)] led to different results. Namely, the optical yield obtained with the ligand (S_{ax},S_C)-**7s** is close to zero, but was 70% for (S_{ax},R_C)-**7s**.[40] This was ascribed to the different orientation of the chloroquinoline fragments in the intermediate copper complexes.

A similar situation was also observed for Ni-catalysed hydrovinylation of styrene.[41,42]



The reaction involving ligand (R_{ax},S_C)-**7s** results nearly exclusively in oligomeric side products, whereas epimer (R_{ax},R_C)-**7s** provides the synthesis of optically active product with nearly 100% regioselectivity and an *ee* of 87%. Related reactions using ligand (R_{ax},R_C)-**7t** and its epimer (R_{ax},S_C)-**7t** showed optical yields of only 8% and 56%, respectively. Nevertheless, the known ligand (R_{ax},S_C)-**7n** is more efficient than phosphites **7s**,**t** in this reaction, because it provides an optical yield of 95%.[41]

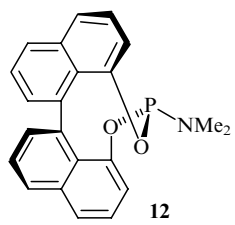
Recently, it was shown that phosphoramidite derivatives of BINOL (**1**) are excellent stereoselectors in not only C–C bond formation reactions but also other catalytic processes. For instance, the best results for hydrosilylation–oxidation of styrene (Ar = Ph, R = H), namely, an *ee* of 99%, were achieved using ligand (S_{ax},R_C)-**7n**.[43]



The optical yields of reactions with other aryl-substituted alkenes are also high (89%–98%). Systems without additional C*-stereocentres demonstrate much lower selectivities, *e.g.*, *ee*'s of 55% and 20% for the ligands (R_{ax})-**7a** and (R_{ax})-**7c**, respectively (with styrene as substrate).

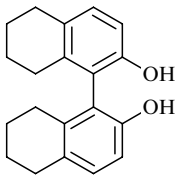
At the same time the structurally simplest phosphoramidites (S_{ax})-**7a**,**b** appeared to be highly efficient ligands in asymmetric reduction. For instance, acetophenone is transformed in α-phenylethanol under the action of complex $BH_3 \cdot THF$ in the presence of catalytic amounts of ligand (S_{ax})-**7b** with an optical yield of up to 99%.[44] Catalytic hydrogenation of prochiral esters **4a** and **4b** following reaction (2) using the catalytic system $[Rh(cod)_2]^+BF_4^-$/2L [L = (S_{ax})-**7a**] is characterised by enantiomeric excesses of 94% and greater than 99%, respectively.[45] Hydrogenation of a large number of enamides [reaction (3)] using the same catalytic system showed optical yields of up to 96% (in particular, 95%, 93% and 89% for substrates **5a**, **5b** and **5d**, respectively).[46,47] The enantioselectivity obtained with derivatives of β-dehydroamino acids is as high as 99% [L = (S_{ax})-**7a**, (S_{ax})-**7e** and (S_{ax},R_C)-**7u**].[48]

Phosphoramidite derivatives of other chiral binaphthyldiols deserve separate consideration. Ligand **12**

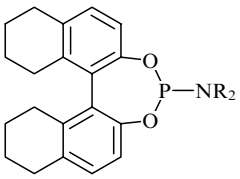


12

was successfully used in the reduction of acetophenone by complex $BH_3 \cdot THF$ (*ee* 96%) and in Cu-catalysed addition of Et_2Zn to enone **9a** [reaction (4), *ee* 83%].[49] For the latter reaction similar results were also shown by phosphoramidite (S_{ax})-**14b** based on H_8-BINOL (**13**), namely, the *ee* was 85% for substrate **9a** and 88% for substrate **9e**.[50]



13 (H_8-BINOL)

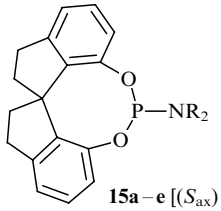


14a, **b** [(S_{ax}) and/or (R_{ax})]

R = Me (**a**), Pr^i (**b**).

The advantage of compound (R_{ax})-**14a** over its analogue **7a** is better solubility in organic solvents and a larger dihedral angle between the tetrahydronaphthalene fragments. It is quite logical that hydrogenation of α-dehydroamino acid esters [reaction (2) with $[Rh(cod)_2]^+BF_4^-$ as precatalyst] in the presence of (R_{ax})-**14a** is more efficient than the process involving ligand **7a**. For all substrates under study, the optical yields exceeded 90% (for compounds **4b**–**d**, it was 99% at nearly 100% conversion).[51,52] It should be noted that ester **4c** is a precursor of the known drug L-DOPA.

Recently,[53] a direct phosphorylation of (*S*)- or (*R*)-1,1′-spiroindan-7,7′-diol to give ligand **15a** was reported. Hydrogenation of substrate **4a** [reaction (2), *ee* 94%] and a number of methyl esters of α-dehydroamino acids in the presence of enantiomer (*S*)-**15a** with $[Rh(cod)_2]^+BF_4^-$ as precatalyst showed *ee* values of up to 99%.[53]



15a–**e** [(S_{ax}) and/or (R_{ax})]

R = Me (**a**), Et (**b**), Pr^i (**c**), cyclo-C_6H_{11} (**d**), CHMePh (**e**).

Ligand (*S*)-**15a** also possesses very high stereoinduction in $[Rh(cod)_2]^+BF_4^-$-catalysed hydrogenation of a series of prochiral enamides [reaction (3)]: the *ee* values obtained were between 91 and greater than 99%.[54] The dependence of enantioselectivity on the ligand structure can be illustrated by the following data:

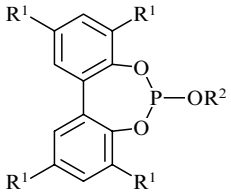
Ligand	(S_{ax})-**7a**	(S_{ax})-**14a**	(S_{ax})-**15a**	(R_{ax})-**15a**	(S_{ax})-**15b**	(S_{ax})-**15c**
ee (%)	95	96	99	96	57	38

Thus, the optical yield dramatically decreases as the substituents at the nitrogen atom (compounds **15a**–**c**) become bulkier. Since the dihedral angle between the aromatic fragments in (S_{ax})-**15a** is larger than in (S_{ax})-**14a**, the enantiomeric excess provided by the former ligand was somewhat higher. Cu-Catalysed addition of Et_2Zn to enone **9a** [reaction (4)] involving ligands **15a**–**e** is also characterised by an *ee* of 98% [the NR_2 fragment of ligand **15e** has the (*R*,*R*)-configuration].[55]

Summarising the material presented in Sections II.1 and II.2, it should be noted that P-monodentate derivatives of BINOL and related binaphthyldiols are highly efficient in various asymmetric catalytic reactions. This first of all concerns Cu-catalysed addition of R_2Zn to unsaturated substrates and Rh-catalysed hydrogenation of C=C bonds. To date, the best results were obtained using phosphoramidite ligands. As applied to the processes mentioned above, phosphoramidite ligands are at least competitive with (and often better than) phosphites in the number of substrates and in stereoinduction achieved, being also active in Ni-catalysed hydrovinylation, Pd-catalysed hydrosilylation–oxidation and reduction of ketones by $BH_3 \cdot THF$ complex. All these reactions are characterised by high and very high optical yields.

3. Phosphites and phosphoramidites based on biphenyldiols

Interest in these systems is based on an attractive idea of replacing axially chiral derivatives of binaphthyldiols by much more accessible and inexpensive biphenyldiols. Though the corresponding ligands (*e.g.*, **16**) undergo atropoisomerisation, bonding to a metal stabilises the configuration of the biphenyl frame.[56]



16a–**j**

Compound **16**	R^1	OR^2	Compound **16**	R^1	OR^2
a	H		**g**	H	b	Bu^t		**h**	Bu^t	
c	H		**i**	H	d	Bu^t		**j**	Bu^t	
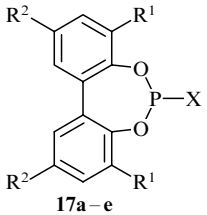
e	H				
f	Bu^t				

Complexation and catalysis using the $[Rh(cod)_2]^+BF_4^-$ system involving compounds **16a**–**j** have been studied.[57] ^{31}P NMR studies revealed a nearly 5:1 ratio of atropoisomers in the complexes $[Rh(cod)(L)_2]^+BF_4^-$ (*cf.* an equimolar mixture of unbound ligand atropoisomers). Unsubstituted structures (R^1 = H) provided higher enantioselectivity of hydrogenation of dimethyl itaconate (**4a**) following reaction (2); the enantiomeric excesses were 29% to 75% (the latter value was obtained with ligand **16i**) while at most 19% with $R^1 = Bu^t$.

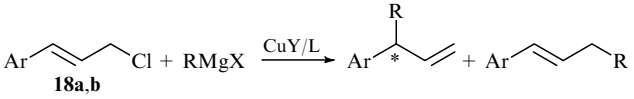
Phosphoramidites **17a**–**d** were studied in Cu-catalysed addition of Et_2Zn to cyclic α,β-unsaturated ketones [reaction (4)] and nitroolefins.[58–60] Not only were a variety of substrates tested but also the reaction conditions varied [in particular, Cu(I) and Cu(II) salts used in the reactions].



17a–**e**

Compound **17**	R^1	R^2	X
a	H	H	(*S*)- or (*R*)-N(1-PhEt)$_2$
	Me	Me	
c	H	H	(*S*)- or (*R*)-N(1-PhPr)$_2$
	Me	Me	
e	Bu^t	OMe	(*S*)- or (*R*)- 
For instance, substrate **9a** provided an *ee* of 96% to 99% (93%–95% for substrate **9c**), which is comparable with the enantioselectivity of phosphoramidite (S_{ax},R_C)-**7n** (see Table 1). The asymmetric induction achieved with other substrates was strongly affected by the nature of the ligand. In particular, for Ph–CH=CH–NO_2 the ligand (*S*)-**17b** provides an *ee* of 82% [*cf.* only 48% obtained with (R_{ax}, S_C)-**7n**].[60] Unlike derivatives **16a**–**j**, there is no correlation between the stereoinduction achieved and the presence of substituents in the phenyl rings of compounds **17a**–**e**, though by and large systems with $R^1 = R^2 = Me$ appeared to be more efficient.

The asymmetrising potential of ligands **17a**–**d** has found applications in the synthesis of silyl ethers of cyclic enols[61] and in reactions of Grignard reagents with allyl chlorides,[62] which involve conjugate addition of R_2Zn to cyclohexenones.



18a,**b**

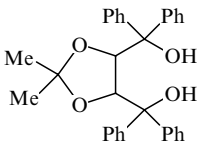
Ar = Ph (**a**), 3-$MeOC_6H_4$ (**b**).

The reaction of EtMgBr with substrate **18a** shows an *ee* of up to 79% involving ligand (*S*)-**17a** and 54% with substituted ligand (*S*)-**17b** [*cf.* at most 49% provided by two BINOL derivatives, (S_{ax})-**7a** and (S_{ax}, S_C)-**7n**]. The best results, that is, an *ee* of 86% at 91 : 9 regioselectivity (branched : linear products) was obtained using ligand (*S*)-**17a** [substrate **18b**, Pr^iMgBr, CuTC (TC is thiophene-2-carboxylate)]. $[IrCl(cod)]_2$/2L-Catalysed allylic amination of Ph–CH=CH–CH_2OCO_2Me by benzylamine was characterised by an optical yield of 87%.[38]

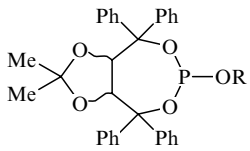
Thus, biphenyldiol-based phosphoramidites **17a**–**d** successfully compete with analogous derivatives of BINOL (**1**). In contrast to ligand **7s**, the reaction of ligand **17e** with $[RhCl(CO)_2]_2$ proceeds selectively and results in a binuclear Rh(III) complex, which is similar to compound **11** and was studied by IR and ^{31}P NMR spectroscopies and by X-ray analysis.[39] The synthesis of compound *cis*-$[PdCl_2(L)_2]$ (L = ligand **17e**) was also reported in that study.[39]

4. TADDOL-based phosphites and phosphoramidites

This group comprises the ligands obtained by phosphorylation of (+)- or (−)-α,α,α′,α′-tetraaryl-1,3-dioxolane-4,5-dimethanol (TADDOL, **19**).



19 (TADDOL)



20a–**m** [(*S*) and/or (*R*)]

Compound **20**	OR	Compound **20**	OR
a	OMe	**i**	b	OBu^t		
c	O-cyclo-C_6H_{11}		
d	OPh	**j**	e	OH		
f	$OCH_2C{\equiv}C-SiMe_3$		
		k	g			
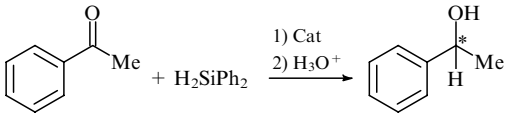
		l	 (see [a])
h			
		m	 (see [a])

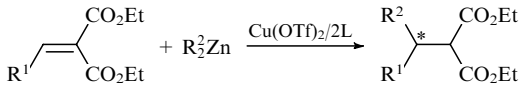
[a] $C_{10}H_7$ is naphthyl.

Initially, phosphites **20a**,**d** were employed in hydrosilylation of acetophenone followed by hydrolysis [reaction (5)].

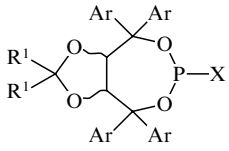


(5)

However, the optical yield appeared to be low {less than 25% with $[RhCl(cod)]_2$ as precatalyst}.[63] The enantioselectivity in Cu-catalysed addition of Et_2Zn to enone **9a** [reaction (4)] involving ligands **20a**–**f** was also low (*ee* less than 18%). Among phosphites with fragments of chiral alcohols, the best results in this reaction were provided by compounds (*S*)-**20m** (*ee* 86%) and (*S*)-**20k** (*ee* 96%).[64,65] Thus, in some cases the use of TADDOL-based phosphites leads to worse results compared to the use of, *e.g.*, phosphorus-containing BINOL derivatives. However, the stereoinduction achieved in conjugate addition to alkylidene malonates with L = (*S*)-**20m** can be as high as 73% and only 26% with ligand **7n**.[66]



In a model reaction of Et_2Zn with enone **9a** [reaction (4), $Cu(OTf)_2$/2L], ligands **21a**–**h** provide an *ee* of 71%.[65,67]



21a–**h** [(*S*) and/or (*R*)]

Compound **21**	R^1	Ar	X	Compound **21**	R^1	Ar	X
a	Me	Ph	NHMe	**g**	Me	2-MeC_6H_4	NMe_2
b	Me	Ph	NMe_2				c	Me	Ph	NPr^i_2				
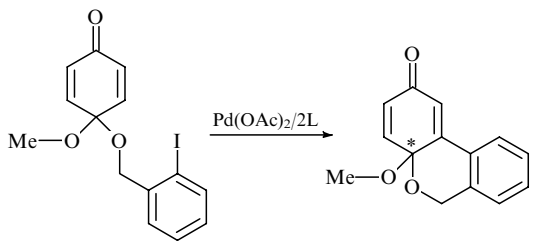
d	Me	Ph	NBn_2	**h**	Me	Ph	
e	Me	Ph	$N(CH_2)_5$				
f	$(CH_2)_4$	Ph	NMe_2				

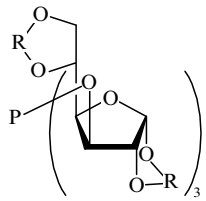
In contrast to the situation for BINOL-based phosphoramidites, in this case the asymmetric induction increases as the substituents at the nitrogen atom become less bulkier. Because of this, the best results are provided by ligand **21b**.[67] It is of considerable importance that the reaction with substrate **9b** (also involving **21b**) shows[67] an *ee* of up to 62% [*cf.* 10% with (S_{ax},R_C)-**7n**, see Table 1]. The enantioselectivities of phosphites (*R*)-**21c** and (S_{ax},S_C)-**7n** in conjugate addition of R_2Zn to alkynylepoxides are comparable (*ee* 36% and 38%, respectively).[68] Recently,[69] ligand (*R*)-**21b** was successfully used in an intramolecular Heck reaction [reaction (6)]; the enantiomeric excess was 96% at 100% conversion.



(6)

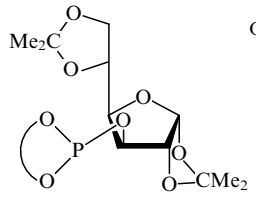
5. Phosphites and phosphoramidites based on carbohydrates and their derivatives

As mentioned above, the pioneering studies in this field were considered earlier.[6] Some examples were also presented in a review [70] concerned with complexes of platinum subgroup metals with carbohydrates. In spite of the fact that phosphorus-containing sugar derivatives are among the long-studied groups of chiral phosphite ligands, they still attract the attention of researchers. For instance, the reaction was reported [71] of compound **22a** with $[CuCl(CO)]_x$ to give a tetranuclear copper(I) complex $[\{CuCl(L)\}_4]$, which was studied by X-ray analysis. The structure of compound **22a** is characterised by a large Tolman cone angle ($\sim 180^\circ$). Because of this, the complex in CD_2Cl_2 solution is in equilibrium with $[\{CuCl(L)_2\}_2]$ dimer (^{31}P NMR data).

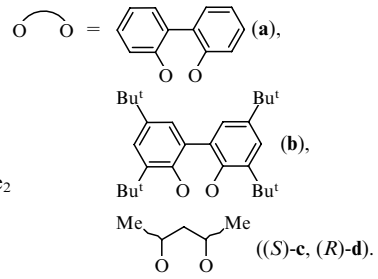


22a,**b**

Ligands **22a**,**b** and **23a**–**d** are used in the synthesis of rhodium(I) complexes and in Rh-catalysed hydrosilylation of acetophenone by diphenylsilane [reaction (5), *ee* less than 58%].[72]

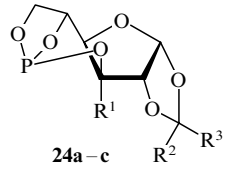


23a–**d**

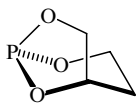


The reactions of compounds **22a**,**b** and **23b** with $[RhCl(cod)]_2$ result in mononuclear complexes [RhCl(cod)(L)]. Further increase in the L : Rh mole ratio (L = **22a**) is not accompanied by the formation of the desired product, $RhCl(L)_3$. Attempts at obtaining $RhCl(L)_3$ starting from $[RhCl(C_2H_4)_2]_2$ also failed. This is also associated with the large cone angle in ligand **22a**. Nevertheless, these two ligands can be in a *cis*-position relative to each other in the coordination sphere of rhodium, which was confirmed by the synthesis of complex $[Rh(acac)L_2]$. It was found that $[RhCl(cod)]_2$ is inefficient as a precatalyst in the hydrosilylation of acetophenone (*ee* at most 11%). The best result, *ee* 58% (see above), was obtained using the $[RhCl(C_2H_4)_2]_2$/6L system (L = compound **22b**).

Bicyclophosphites **24a**–**c** and **25** were proposed as efficient ligands for synthesis of coordination compounds. Complexes $[\{CuBr(L)\}_4]$, $[M(CO)_5(L)]$ (M = Cr, Mo) and *cis*-$[PtCl_2(L)_2]$ were synthesised using phosphites **24a**–**c**; and studied by IR spectroscopy, ^{31}P and ^{13}C NMR and by X-ray analysis.[73]



24a–**c**

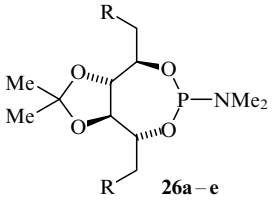


25

Compound **24**	R^1	R^2	R^3
a	H	Me	Me
b	H	H	CCl_3
c		Me	Me

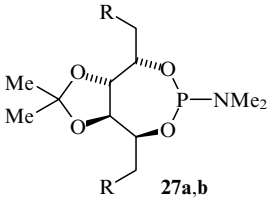
Phosphite **25** derived from (*S*)-1,2,4-butanetriol was employed in the synthesis of complexes with an open and a half-open titanocene.[74]

A novel group of phosphoramidites **26** and **27** [75,76] should be pointed out.



26a–**e**

R = H (**a**), Me (**b**), Et (**c**), Bu^i (**d**), Ph (**e**).



27a,**b**

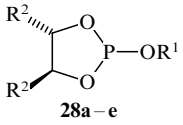
R = H (**a**), Ph (**b**).

They were used to obtain cationic complexes of rhodium(I), $[Rh(cod)(L)_2]^+OTf^-$, and neutral complexes of palladium(II), *cis*-$[PdCl_2(L)_2]$. Two Pd complexes with L = **26a** and **27a** were studied by X-ray analysis. These coordination compounds were also studied by ^1H and ^{31}P NMR spectroscopy and by FAB mass spectrometry. It is unclear why the set of ^{31}P NMR spectral parameters does not include the $^1J(P,Rh)$ spin-spin coupling constants, which are useful for assessing the electron-donor ability of phosphorus-containing ligands.

Complexes $[Rh(cod)L_2]^+OTf^-$ (L = **26**, **27**) were studied as catalysts for the hydrogenation of unsaturated acids, namely, α-(*N*-acetylamino)cinnamic (*ee* up to 89%) and itaconic acid (*ee* up to 94%).[76] In both cases the best results were obtained using phosphoramidite **27b**, whereas its diastereomer **26e** is much less efficient and provides enantiomeric excesses of 36% and 61%, respectively.

6. Other P-monodentate chiral phosphites

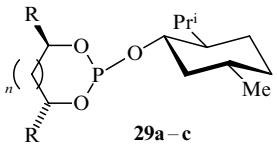
Cyclic phosphites **28a**–**e** based on tartaric acid derivatives are also of interest.



28a–**e**

Compound **28**	R^1	R^2	Compound **28**	R^1	R^2
a	(L)-menthyl	CO_2Et	**d**	(L)-menthyl	CO_2Pr^i
b	(D)-menthyl	CO_2Et	**e**	(L)-menthyl	$CONMe_2$
c	bornyl	CO_2Et			

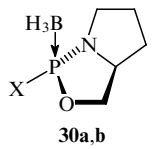
They provided an *ee* of up to 40% in conjugate addition for Et_2Zn to enone **9a** [reaction (4)] and up to 65% in the reaction with benzylidenacetone [with the $Cu(OTf)_2$/2L catalytic system].[77] Though these optical yields cannot be considered high, ligands **28a**–**e** are much better stereoselectors than related phosphites **29a**–**c** whose efficiency in these reactions was characterised by an *ee* of at most 11%.[77]



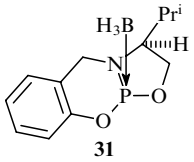
29a–**c**

R = Me: *n* = 1 (**a**), 0 (**b**); R = Ph, *n* = 0 (**c**).

Complexes **30a**,**b** and **31** were used as catalysts of acetophenone reduction by the $BH_3 \cdot THF$ adduct; however, the optical yield was at most 37%.[78]



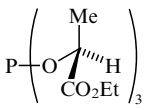
30a,**b**



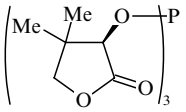
31

X = OPh (**a**), NMe_2 (**b**).

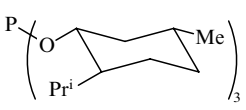
Mention also may be made of phosphites **32**–**34**.



32



33



34

Ligands **32** and **33** were used in complexation with [Fe(chd)$(CO)_3$] (chd = 1,3-cyclohexadiene)[79] and [Ni$(cod)_2$] (see Ref. 80), respectively. Trialkyl phosphite **34** was involved in Cu-catalysed addition of Et_2Zn to enone **9a** [reaction (4), *ee* 36%].[77]

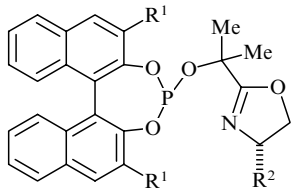
Thus, at present the catalytic potential of compounds **22**–**34** seems to be quite modest as compared to the potential of ligands based on BINOL (**1**) and TADDOL (**19**). However, we believe that it is not completely explored and considerable progress is possible in this field. A good example is provided by the successful use of phosphite **27b** in Rh-catalysed hydrogenation (see above).

III. P,N-Bidentate compounds of phosphite nature

The first synthesis of ligands belonging to this class and their complexation with rhodium(I) was reported in 1993.[81] Since then, methods of synthesis and the coordination chemistry of these compounds have been the subject of some studies;[5,6,8] however, they have been efficiently used in asymmetric catalysis only during the last five years. The introduction of the N-donor centre into the chiral ester or phosphorous acid amidoester molecule makes it possible to extend the field of application of P,N-bidentate compounds of phosphite nature. Therefore, the material presented in this Section is classified with emphasis on the nature of the nitrogen donor centre.

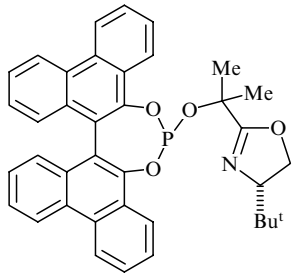
1. Phosphites and phosphoramidites containing an oxazoline fragment

The major contribution to the design of these systems was made by Pfaltz *et al.*[82,83] who proposed a broad spectrum of ligands **35**–**38** based on BINOL (**1**) and related structures.

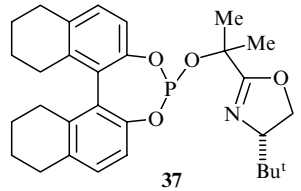


35a–**h** [(S_{ax}) and/or (R_{ax})]

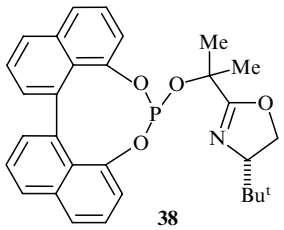
Compound **35**	R^1	R^2	Compound **35**	R^1	R^2
a	H	Pr^i	**e**	Ph	Bu^t
b	H	Ph	**f**	4-PhC_6H_4	Bu^t
c	H	Bu^t	**g**	2,4,6-$Me_3C_6H_2$	Bu^t
d	Me	Bu^t	**h**	3,5-$Bu^t_2C_6H_3$	Bu^t



36 [(S_{ax}) and/or (R_{ax})]

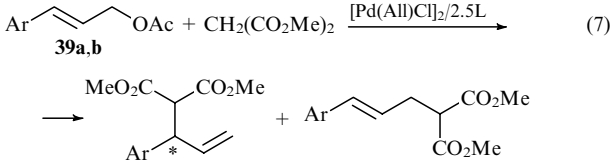


37



38

Pd-Catalysed allylic substitutions involving ligands **35a**–**d** and substrate **39a** [reaction (7)] showed the enantiomeric excesses lying between 7% and 92% and the yields of the branched products in the range 46%–76%.[82,83] The highest enantioselectivity was provided by ligand (S_{ax})-**35d**.[83]



(7)

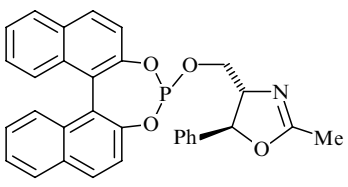
39a,**b**

Ar = Ph (**a**), naphthyl (**b**).

The asymmetric induction depends first of all on the configuration of the oxazoline fragment. Namely, the enantiomeric excess provided by the ligands is 79% for (R_{ax})-**35c** and 90% for (S_{ax})-**35c**, the product configurations in both cases being the same.[83] Substrate **39b** is characterised by greater steric requirements and makes it possible to achieve an *ee* of up to 96% at high regioselectivity and chemical yield [L = (S_{ax})-**35c**].[84] The structure of catalytically active complex {Pd(All)[(S_{ax})-**35c**]}$^+PF_6^-$ was confirmed by X-ray analysis.[82]

Oxazolinophosphites **35c**–**h** and **36**–**38** were studied in the Cu-catalysed addition of Et_2Zn to cyclic enones **9a**–**c** [reaction (4)].[85–87] The enantiomeric excesses obtained for different substrates are as follows: up to 90% for **9a** [L = (R_{ax})-**35d**], up to 94% for **7b** [L = (R_{ax})-**35f**] and up to 94% for **9c** [L = (S_{ax})-**36**]. The high enantioselectivity of the reaction involving enone **9b** should be pointed out, which could not be provided by other phosphites (*cf.* the data listed in Table 1). A study on the dependence of enantioselectivity on the ligand structure revealed no direct correlation between the optical yields and the size of substituents in the *ortho*-positions of the naphthyl rings. However, the presence of these substituents is a necessary condition for high stereoinduction.[85,87]

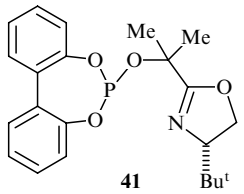
Both epimers of ligand **40** were also described.[88]



40 [(S_{ax}) and (R_{ax})]

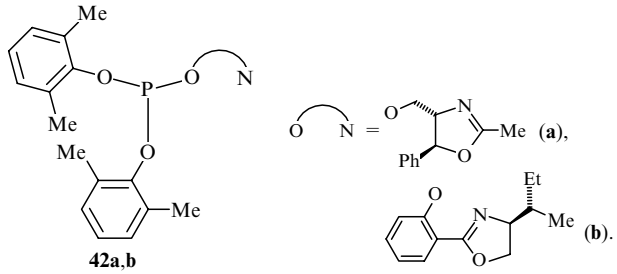
^{31}P NMR spectroscopy, IR spectroscopy and electrospray mass spectrometry data showed that ligand **40** unexpectedly forms dimeric rather than chelate complexes of rhodium(I) with a 'head-to-tail' bridging bonding of the P,N-bidentate ligand and that the structures of the complexes depend on the absolute configuration of BINOL. This remarkable fact should be taken into account in analysis of applications of P,N-bidentate ligands as catalysts, the more so as the stereoinduction involving epimers **40** is also significantly different. Namely, ligands (R_{ax})-**40** and (S_{ax})-**40** provide an *ee* of up to 58% and at most 4%, respectively, in Rh-catalysed hydrosilylation of acetophenone [reaction (5)] .

As mentioned above, the enantioselectivity of oxazolinophosphites **35a**–**d** in Pd-catalysed allylic alkylation is to a great extent governed by the oxazoline fragment. This makes it possible to rule out the axially chiral template BINOL for ligand design purposes. In particular, compound **41** provides an *ee* of 83% in the reaction involving substrate **39a** [reaction (7)].[82]



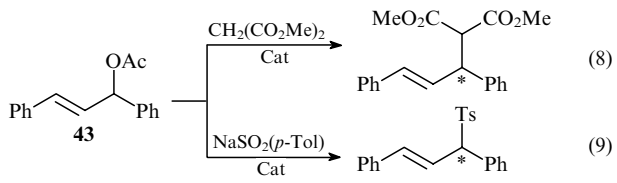
41

Moreover, acyclic ligands **42a**,**b** also appeared to be efficient.



42a,**b**

Pd-Catalysed allylic substitutions of substrate **43** for dimethyl malonate [reaction (8)] and $NaSO_2$(*p*-Tol) [reaction (9)] respectively showed an *ee* of 85% {for $[Pd(All)Cl]_2$/2.5L, L = **42a**}[89] and an *ee* of 92% {for $[Pd(All)(\mathbf{42b})]^+BF_4^-$}.[90]



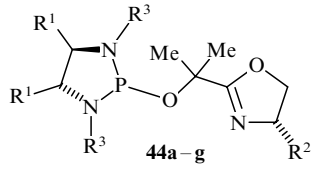
43

(8)

(9)

Chelate mononuclear complexes [RhCl(CO)(L)] with L = **42a**,**b** were synthesised. The complex with phosphite **42a** was studied by X-ray analysis.[89]

Systems based on chiral 1,2-diamines and TADDOL (**19**) and containing oxazoline fragments and phosphite cyclic groups were also synthesised. Oxazolinophosphoramidites **44a**–**g** were found to be highly efficient.



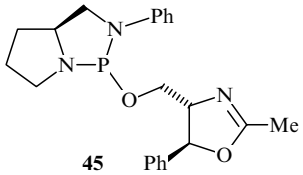
44a–**g**

Compound **44**	R^1	R^2	R^3
a	Ph	Bu^t	Ts
b	$(CH_2)_2$ (see [a])	Bu^t	Ts
c	Ph	Ph	Ts
d	Ph	Bu^t	(1-naphthyl)methyl
e	Ph	Bu^t	4-$MeOC_6H_4$
f	$(CH_2)_2$ (see [a])	Bu^t	4-$MeOC_6H_4$
g	Ph	Bu^t	4-biphenylyl

[a] Here, R^1-R^1.

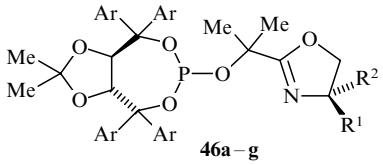
They showed high enantioselectivities in Pd-catalysed substitution of substrates **39a** (*ee* up to 95%), **37b** (*ee* greater than 99%) [reaction (7)] and **43** (*ee* up to 88%) [reaction (8)] for dimethyl malonate. Additionally, Ir-catalysed hydrogenation of various vinylarenes showed an *ee* of greater than 99%.[91,92]

The catalytic system $[Pd_2(dba)_3\cdot CHCl_3]$/2L (L = **45**, dba = dibenzylideneacetone) provides an optical yield of 92% in the reaction of substrate **43** with $NaSO_2$(*p*-Tol) [reaction (9)].[93]



45

Note that in addition to three C*-stereocentres compound **45** also contains a P*-stereocentre in the (*R*)-configuration. In contrast to oxazolinophosphite **42b**, ligand **45** provides a lower stereoinduction in the cationic complex $[Pd(All)(\mathbf{45})]^+BF_4^-$ (*ee* 77%).



46a–**g**

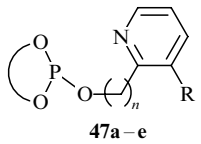
Compound **46**	Ar	R^1	R^2	Compound **46**	Ar	R^1	R^2
a	Ph	H	Ph	**e**	2-naphthyl	Pr^i	H
b	Ph	Ph	H	**f**	Ph	H	Bu^t
c	Ph	H	Pr^i	**g**	2-naphthyl	H	Bu^t
d	Ph	Pr^i	H				

Ligands **46a**–**e** were used[94] in the synthesis of cationic complexes of rhodium(I) $[Rh(cod)(L)]^+BF_4^-$ (complex with L = **46b** was studied by X-ray analysis) and in hydrosilylation of a number of aliphatic and aromatic ketones {with $[RhCl(cod)]_2$ as precatalyst}. The best results were obtained with ligand **46d**, which provided the optical yields of 88% and 95% for the reduction of acetophenone and *tert*-butyl methyl ketone, respectively. Phosphite **46f** provides high optical yields in the Pd-catalysed substitution of substrate **39b** [reaction (7), *ee* 94%] while phosphites **46f**,**g** also behave analogously in Ir-catalysed hydrogenation of 4-$MeOC_6H_4C(Me)=CHMe$ (*ee* 95%).[91,92]

The use of ligand **46c** in Cu-catalysed addition of Et_2Zn to enone **9a** [reaction (4)] and to alkylidene malonates has also been reported; however, the enantioselectivities achieved were low (*ee* at most 22%).[65,66]

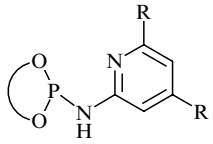
2. Phosphites and phosphoramidites containing pyridine fragments

As in the ligand group considered above, BINOL-based systems **47**–**49** are also known in this group. Phosphites **47a**–**e** and **48a**,**b** were found to be inefficient in the reaction of Pd-catalysed alkylation of substrate **43** by dimethyl malonate [reaction (8)]. They provided optical yields of at most 37%[95] while the use of ligands **47a**,**b** resulted in racemic product.[95,96] Multinuclear NMR studies (including 2D NOESY experiments) showed that this is due to the presence of different configurational isomers of the intermediate palladium complexes.[95,96]



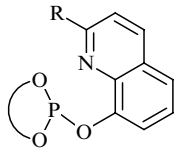
47a–e

n = 0, R = H (**a**);
n = 1: R = H (**b**), Me (**c**), Ph (**d**), Br (**e**).



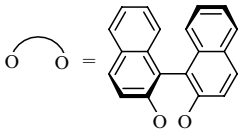
48a,b

R = H (**a**), Me (**b**).



49a,b

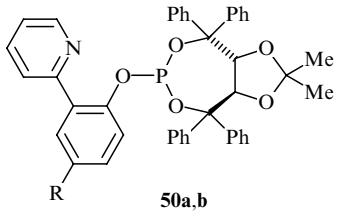
R = H (**a**), Me (**b**).



= S_{ax}-BNaph(O)$_2$.

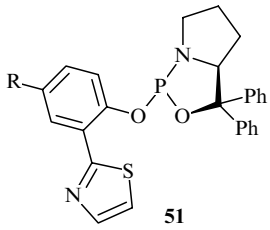
Cu-Catalysed addition of Et_2Zn to enone **9a** [reaction (4)] in the presence of ligands **49a**,**b** also showed a moderate enantioselectivity (*ee* up to 51%).[40] Note that phosphite **49a** is used as a chelate-forming ligand in the synthesis of half-sandwich complexes of ruthenium(II) and rhodium(III), *e.g.*, [RhCl(η^5-C_5Me_5)(S_{ax}-**49a**)]$^+PF_6^-$ (see Ref. 97), which was studied by X-ray analysis. Yet another enantiomer, (R_{ax})-**49a**, was used in the substitution reaction involving substrate **43** and dimethyl malonate {reaction (8), with [Pd(All)Cl]$_2$ as precatalyst, *ee* 31%}.[98]

Quite interesting compounds **50a**,**b** [99, 100]



50a,b

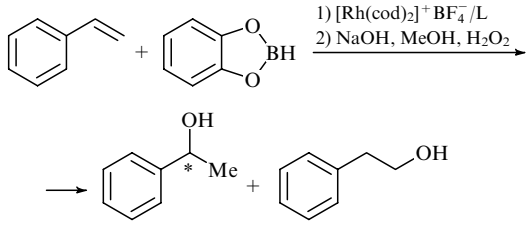
R = H (**a**), OSiBu^{t}Me$_2$ (**b**).



51

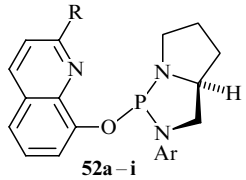
R = OSiBu^{t}Me$_2$.

were studied in the Rh-catalysed hydroboronation–oxidation of styrene.



The optical yield was 59% at chemical yields in the range 52%–56% and regioselectivities (branched : linear product ratios) from 77 : 23 to 80 : 20.[100] Similar results were also obtained for compound **51** containing no pyridine fragment.[99, 100]

Shortening of the distance between the chiral fragment and the donor atoms of the ligand is known to favour a significant enhancement of stereoinduction. It is particularly appropriate if these atoms are stereocentres. A number of ligands **52**, **53** containing asymmetric phosphorus atoms were proposed by Buono *et al.*[101–103]



52a–i

Compound **52**	R	Ar	Compound **52**	R	Ar
a	H	Ph	**g**		Ph
b	Me	Ph

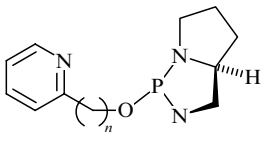
d	Ph	Ph			
e	CN	Ph	**i**	H	1-naphthyl
f		Ph			



53a,b

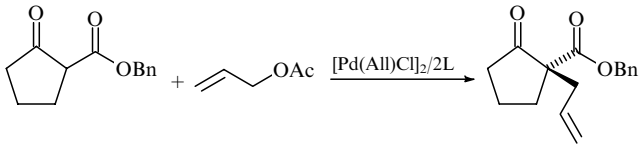
n = 0 (**a**), 1 (**b**).

^{13}C NMR and X-ray diffraction studies of complex [Pd(All)(**52a**)]$^+ClO_4^-$ revealed the (*R*)-configuration of the P*-stereocentre.[101]

The classical allylic substitution in the reaction of substrate **43** with dimethyl malonate {reaction (8), catalytic system [Pd(All)Cl]$_2$/4L, L = **52a–h** or **53a**,**b**} is characterised by an optical yield of up to 87% and by nearly 100% conversion.[98, 102] The highest enantioselectivity was obtained with ligand **52a**, whereas the *ee* provided by its derivatives **52b–h** was at most 55%.[98] A related process, allylic amination of substrate **43** involving benzyl- and veratrylamines as nucleophiles (L = **52a–i** and **53a**,**b**) showed an *ee* of up to 94%.[103] Here, phosphite **52a** was also the most efficient (compound **52b–h** provided the enantiomeric excesses in the range 38%–78%).[98]

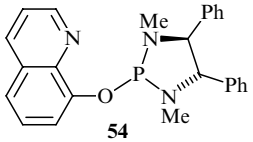
Phosphoramidite **52a** is also used in Pd-catalysed allylic amination of prochiral bicyclic diacetates (*ee* up to 89%),[104] Cu-catalysed Diels–Alder reactions (*ee* greater than 99% at 99% conversion)[105] and conjugate addition of Et_2Zn to cyclohexenone **9a** [reaction (4), *ee* up to 61%].[106]

Yet another example of the potential of ligand **52a** is provided by an elegant reaction to give quaternary C*-stereocentres by allylation of β-ketoesters.[107]

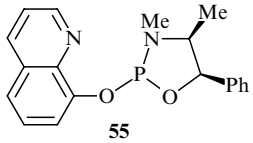


It is characterised by an *ee* of 95%; however, one should keep in mind that the enantioselectivity is quite 'sensitive' to the nature of the substrate and allylating agent. For instance, the optical yield in the reaction involving a homologous keto ester containing a six-membered ring was at most 17%.

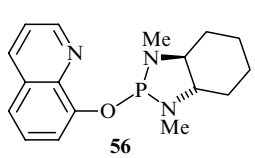
The efficiency of ligand **52a** as stereoselector is most pronounced when comparing it with phosphoramidites **54–57**.



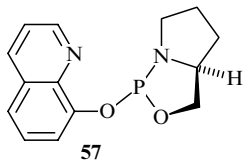
54



55



56



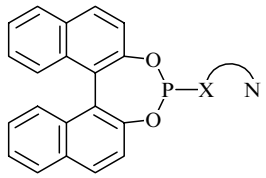
57

Studies of compounds **54**–**57** and (R_{ax})-**49a** in the catalytic processes mentioned above revealed low asymmetrising activities of these species. Namely, the optical yield of Pd-catalysed allylic substitution of substrate **43** for dimethyl malonate [reaction (8)] was at most 31% and 35% in the case of benzylamine; the enantiomeric excess in Cu-catalysed addition of Et_2Zn to enone **9a** [reaction (4)] was only 27%.[98]

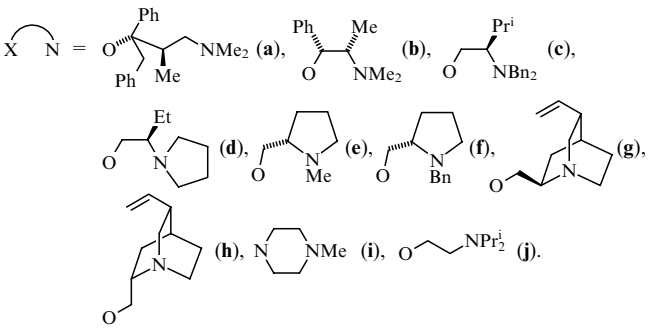
Thus, most ligands containing a pyridine fragment possess low or moderate enantioselectivities. The exceptions are phosphoramidites **52a** and **53**; however, their efficiency may be due to the unique structure of the bicyclic phosphite centre rather than the nitrogen-containing fragment.

3. Aminophosphites and aminophosphoramidites

We begin our discussion of this group of ligands (type **B**) with phosphite derivatives of BINOL **58a**–**j**.

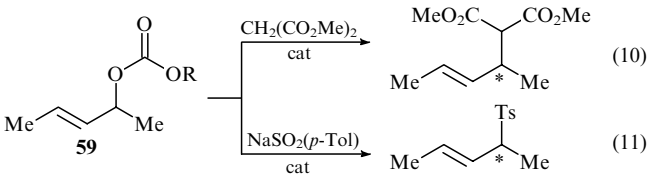


58a–**j** [(S_{ax}) and/or (R_{ax})]



Reactions of compounds **58a**–**g** with $[RhCl(CO)_2]_2$ result in chelate mononuclear complexes [RhCl(CO)(L)]. It was shown that coordination of ligand **58c** proceeds non-selectively due to significant steric hindrances to chelation produced by benzyl substituents at the nitrogen atom. As a result, a *trans*-$[RhCl(CO)(L)_2]$ complex is formed in addition to the metal-containing chelate.[88]

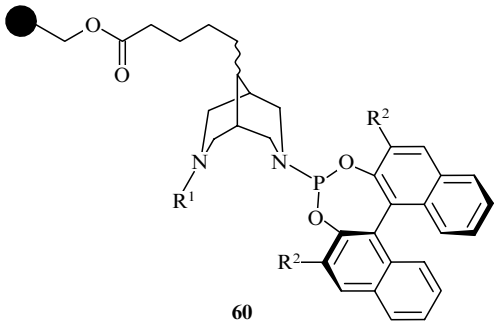
Compounds **58a**,**b** were studied in Pd-catalysed alkylation of substrates **59** by dimethyl malonate {reaction (10), catalytic system $[Pd(All)Cl]_2/2L$}. The optical yield was at most 34%.[88]



(10)

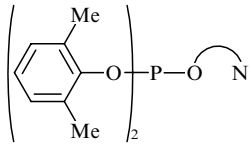
(11)

Similarly to this, phosphite **58h** showed a low enantioselectivity (*ee* 16%) in Rh-catalysed hydroformylation of styrene.[108] Cu-Catalysed addition of Et_2Zn to cyclic enone **9a** in the presence of ligand **58i** [reaction (4)] and Rh-catalysed hydrogenation of enamide **5a** in the presence of ligand **58j** [reaction (3)] result in racemates.[15,19] In this case, the attainment of an *ee* of 67% in the last-mentioned reaction involving a large group of polystyrene-immobilised systems [109] of general structural type **60** seems to be encouraging.

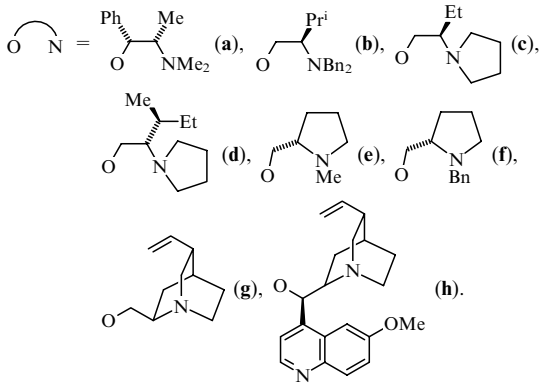


60

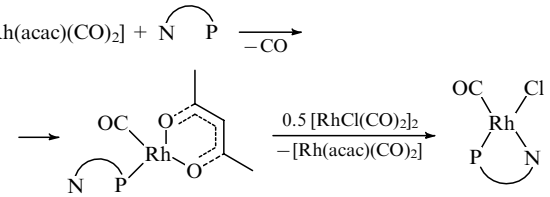
Acyclic aryl phosphites **61** are related to compounds **58**.



61a–**h**

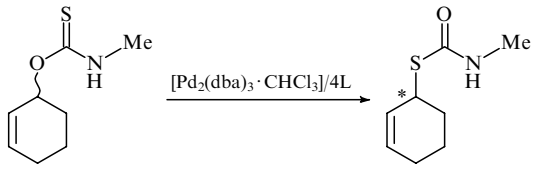


They were used to synthesise chelate complexes [RhCl(CO)(L)]. Similarly to the case of compound **58c**, complexes *trans*-$[RhCl(CO)(L)_2]$ are formed as side reaction products.[110] It is possible to overcome this difficulty and obtain individual metal-containing chelates using an original exchange reaction, which is considered below taking ligand **61b** as an example.



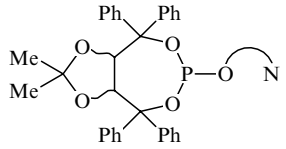
Unfortunately, aryl phosphites **61** are inefficient in Pd-catalysed allylic substitution of substrates **43** [reaction (8)] and **59** [reaction (10)] by dimethyl malonate,[110,111] in sulfonylation of substrate **59** under the action of $NaSO_2$(*p*-Tol) [reaction (11)] and in Rh-catalysed hydrosilylation of acetophenone [reaction (5)].[110] The enantiomeric excess in these reactions was at most 28%.

A quinine-based aryl phosphite **61h** was used in Pd-catalysed enantioselective rearrangement of allyl thiocarbamate, which proceeds at a 100% conversion and an *ee* of 47%.[112]

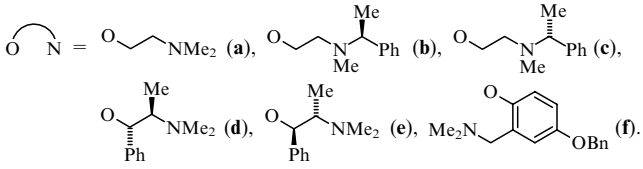


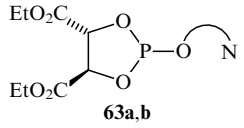
Noteworthy is that ligand **61g** is inefficient in this reaction (*ee* 2%). This is likely due to the large cone angle in structure **61h** ($\Theta = 190^\circ$) and to the presence of additional quinoline donor N atom.

Cu-Catalysed addition of Et_2Zn to cyclic enone **9a** [reaction (4)] in the presence of TADDOL-based phosphites **62** and phosphites **63** based on tartaric acid was also studied. The optical yields were rather low (*ee*s less than 38% for compounds **62a**–**e**[65] and less than 30% for compounds **63a**,**b**). In the latter case, the configuration of the product is controlled by the (*R*,*R*)-diethyl tartrate fragment.[77]

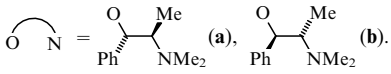


62a–**f** [(*S*) and/or (*R*)]



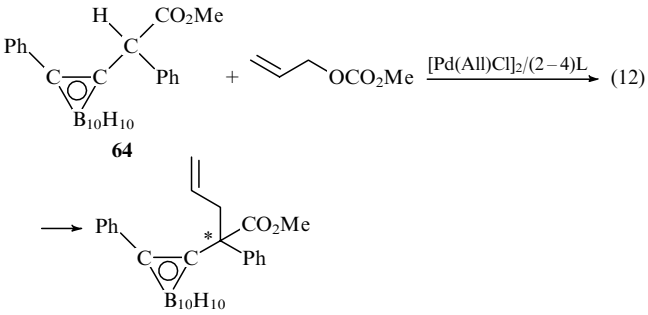


63a,**b**



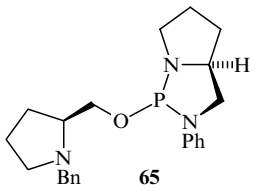
Low optical yield (20%) was also obtained in the methoxycarbonylation of $[Cr(o\text{-}Cl_2C_6H_4)(CO)_3]$ in the presence of complex $[PdCl_2(\mathbf{62f})]$.[113]

Nevertheless, the use of some aminophosphites permitted enhancement of the enantioselectivity. In particular, the first direct Pd-catalysed asymmetric synthesis of carboranes was reported[114] and a number of ligands were studied. The highest optical yield was 48% [reaction (12)].



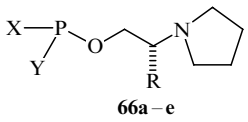
64

^{31}P NMR spectroscopy, IR spectroscopy and mass spectrometry studies of the catalytic system $[Pd(All)Cl]_2$/**65** revealed that phosphoramidite **65** behaves as a P-monodentate ligand, namely, a large amount of complex $[Pd(All)(L)_2]^+Cl^-$ is formed even at an L : Pd = 1 mole ratio (see Ref. 114).



65

Palladium-catalysed allylic substitution reactions involving dimethyl malonate in the presence of phosphite derivatives of (2*R*)-2-pyrrolidin-1-ylbutan-1-ol (**66a**–**e**) were studied.[111]

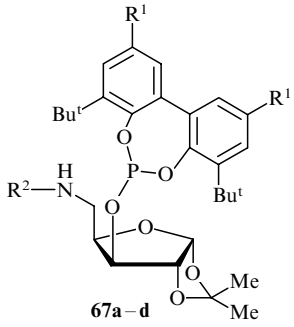


66a–**e**

Compound **66**	X—P / Y	R	Compound **66**	X—P / Y	R
a		Et	**d**		Et
b	$(Pr^iO)_2P$	Et			
c		Et	**e**	$(Pr^iO)_2P$	Pr^i

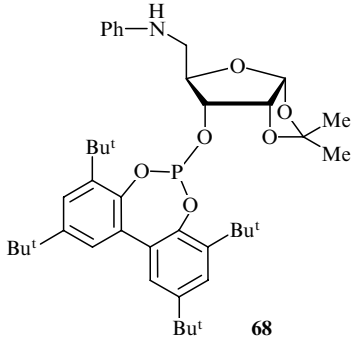
In the case of substrate **43** [reaction (8)] the optical yield was at most 14%, being 61% for allyl acetate **39a** [reaction (7)] {with $[Pd(All)Cl]_2$ as precatalyst, the most efficient ligand was **66b**}.

Cu-Catalysed conjugate addition of Et_2Zn to cyclohexenone **9a** [reaction (4)] in the presence of aminophosphites **67** and **68** based on D-xylose and D-ribose, respectively, is characterised by similar enantioselectivity (*ee* up to 63%).[115]



67a–**d**

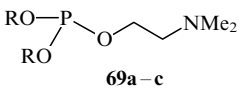
Compound **67**	R^1	R^2
a	Bu^t	Bu^t
b	OMe	Bu^t
c	Bu^t	Pr^i
d	Bu^t	Ph



68

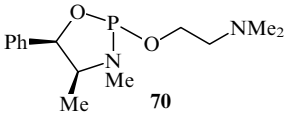
The best stereoselector was found to be ligand **67d**.

A number of chiral aminophosphites, which are used at present only in coordination chemistry of platinum metals, should be pointed out.

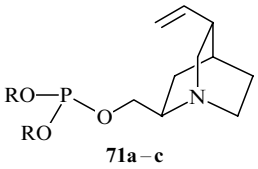


69a–c

R is bornyl (**a**), menthyl (**b**), cholesteryl (**c**).

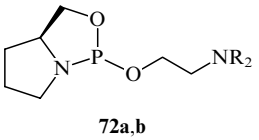


70



71a–c

R–R = $(CH_2)_2$ (**a**);
R = Pr^i (**b**), bornyl (**c**).



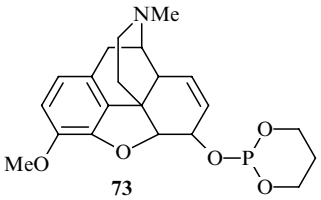
72a,b

NR_2 = NMe_2 (**a**), (**b**).

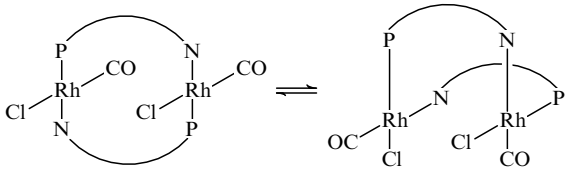
For instance, reactions of compounds **69a–c** with $[PdCl_2(cod)]$ afforded mononuclear chelate complexes $[PdCl_2(L)_2]$, whch were studied by multinuclear NMR spectroscopy, IR spectroscopy, sedimentation analysis and X-ray analysis (for ligand **69a**).[116,117] Aminophosphoramidite **70** also forms an analogous metal-containing chelate in the reaction with $[PdCl_2(cod)]$, whereas the reaction with $[PtCl_2(cod)]$ results in an exclusive product, a compound with P-monodentate bonding of the *cis*-$[PtCl_2(L)_2]$ ligand (according to ^{31}P, ^{13}C and ^{195}Pt NMR spectroscopy and IR spectroscopy).[118]

Similarly to compounds **66a–e** (see above), aminophosphites **71a–c** act as typical chelate-forming agents towards $[RhCl(CO)_2]_2$.[111,119] Ligands **71b,c** behave analogously in the reaction with $[PdCl_2(cod)]$. However, the reaction with phosphite **71a** results not only in chelate $[PdCl_2(L)]$ but also in products of composition $[PdCl_2(L)_2]$, which may be due to the insufficient strength of the metallacycle in the presence of a *spiro*-fragment in the chelate complex.[119]

The reaction of compound **72a** with $[RhCl(CO)_2]_2$ results in a metal-containing chelate [RhCl(CO)L], while ligand **72b** containing a piperidine nitrogen centre also forms a large amount of dimer $[RhCl(CO)L]_2$,[120,121] which has a 'head-to-tail' structure and a *trans*-orientation of the phosphorus and nitrogen atoms at the Rh atom.[121] A codeine-based aminophosphite **73** also forms a structurally similar dimer; in this case, the *trans*-dimer is in equilibrium with *cis*-$[RhCl(CO)(L)]_2$.[122]



73

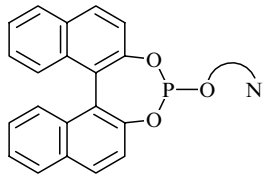


The equilibrium position is governed by the solvent, *viz*., in DMF the complex exists as a *trans*-isomer while a nearly equimolar mixture of the *cis*- and *trans*-isomers is observed in DMSO.

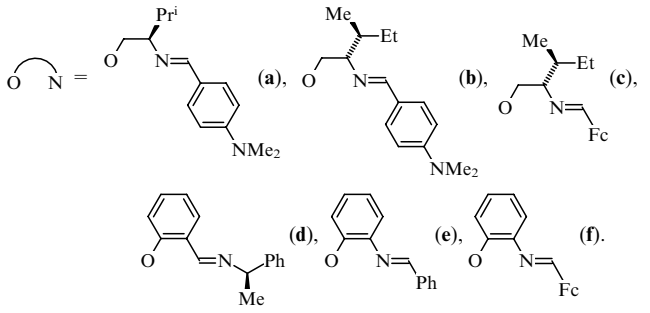
Thus, the coordination behaviour of ligands containing peripheral amino groups is ambiguous. *A priori*, they seem to be typical chelate-forming compounds; however, P-monodentate bonding is often observed. The choice of a particular type of bonding is controlled by the nature of the ligand, the starting metal complex and the solvent. Chelation-preventing factors first of all include the involvement of donor atoms in the five- and six-membered rings (see also Ref. 123) and the presence of bulky substituents at the nitrogen atom. Undoubtedly, these features should be taken into account when predicting and analysing the use of aminophosphites in catalysis. The enantioselectivities obtained to date cannot meet the requirements imposed by modern asymmetric catalysis. Therefore, further investigations and search for new, more efficient ligands are required.

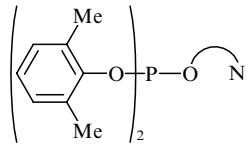
4. Phosphite derivatives of Schiff bases

This is the 'youngest' group of P,N-bidentate derivatives of phosphorous acid, which has been little studied. First of all, aryl phosphite ligands **74** and **75** should be pointed out.

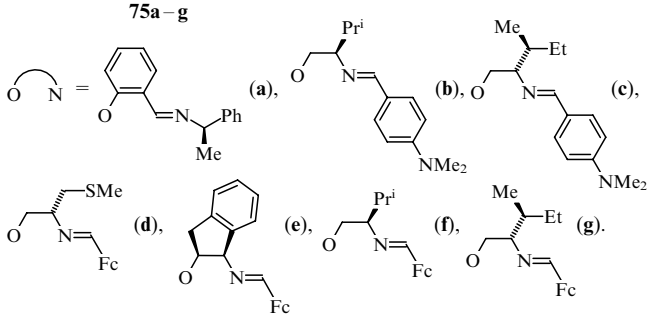


74a–f [(S_{ax}) and/or (R_{ax})]

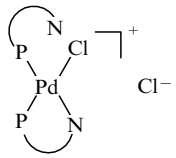




75a–g



Ligands **74a–f** act as typical chelate-forming compounds towards $[RhCl(CO)_2]_2$ and the corresponding reactions result in complexes [RhCl(CO)L].[88] At the same time, particular reaction routes in complexation with Pd(II) are governed by the nature of the starting organometallic compound. For instance, the use of $[PdCl_2(MeCN)_2]$ or $[Pd(All)Cl]_2$ permits high yields of the corresponding metal-containing chelates, *e.g*., $[Pd(All)(L)]^+X^-$ [L = (R_{ax})-**74a**, (R_{ax})-**74c**, (S_{ax})-**74e**; X = Cl, BF_4]. On the contrary, the reaction with $[PdCl_2(cod)]$ proceeds non-selectively [this was shown taking ligands (R_{ax})-**74a** and (R_{ax})-**74f** as examples], resulting in chelates $[PdCl_2(L)]$ and large amounts of side products:



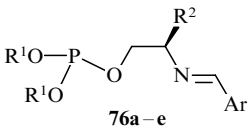
These results must be taken into account when choosing a starting metal complex for Pd-catalysed reactions involving aryl phosphites **74a**–**f**.

Ligands **75a**–**g** containing no cyclic phosphite fragments react with $[RhCl(CO)_2]_2$, $[PdCl_2(cod)]$ or $[Pd(All)Cl]_2$ to give exclusively mononuclear metal-containing chelates, which was also proved by X-ray analysis.[110]

Allylic alkylation of substrate **59** by dimethyl malonate {reaction (10) with $[Pd(All)Cl]_2$ as precatalyst} in the presence of compounds **74a**–**f** proceeds with an optical yield of up to 81% [the most efficient ligand is (R_{ax})-**74c**].[88] However, the presence of the BINOL fragment is not necessary for stereoinduction. Indeed, an *ee* of 82% was also achieved using acyclic aryl phosphite **75g**.[110] Moreover, additional axial chirality even decreases the enantioselectivity in Rh-catalysed hydrosilylation of acetophenone [reaction (5)], namely, ligand **75g** provides an *ee* up to 50%, whereas the epimers (S_{ax})-**74c** and (R_{ax})-**74c** can show at most 20%. Pd-Catalysed reaction of substrate **59** with $NaSO_2(p\text{-Tol})$ [reaction (11)] in the presence of ligand **75g** is also characterised by high enantioselectivity (*ee* 80%).[110]

It should be noted that, according to Ito,[124] substrate **59** is 'uncontrollable' and therefore the optical yields achieved (80%–82%) are in fact very high, thus indicating a great stereodiscriminating potential of phosphites containing Schiff bases. Unfortunately, attempts at realising this potential in other Pd-catalysed allylations have failed as yet. Namely, the enantioselectivity of asymmetric synthesis involving a carborane derivative **64** [reaction (12)] and ligands **74a**,**b** and **75b**,**c**,**f**,**g** was at most 32%.[125]

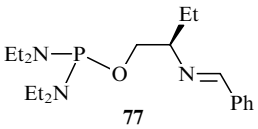
Systems with another structure at the phosphorus centre are also available.



76a–**e**

Compound **76**	R^1	R^2	Ar
a	Pr^i	Et	Ph
b	Pr^i	Pr^i	4-$Me_2NC_6H_4$
c	bornyl	Et	Ph
d	cholesteryl	Pr^i	Ph
e	 (see [a])	Pr^i	4-$Me_2NC_6H_4$

[a] Here, R^1-R^1; menthyl is $Me(CHMe_2)C_6H_9$.



77

Similarly to phosphites **75a**–**g**, compounds **76a**–**e** and **77** behave in reactions with $[RhCl(CO)_2]_2$ and $[PdCl_2(cod)]$ as good chelate-forming compounds[89,126,127] {complexes [RhCl(CO)L] with L = **76a**,**c** were studied by X-ray analysis[126]}. The exception is ligand **76d** containing bulky cholesteryl fragments, which forms a side product $[PdCl_2(L)_2]$ in the reaction with $[PdCl_2(cod)]$.[89] Alkylation of substrate **43** by dimethyl malonate [reaction (8)] in the presence of compounds **76a**–**e** and $[Pd(All)Cl]_2$ is characterised by an *ee* of up to 76%, the best ligand being **76e**.[89,126]

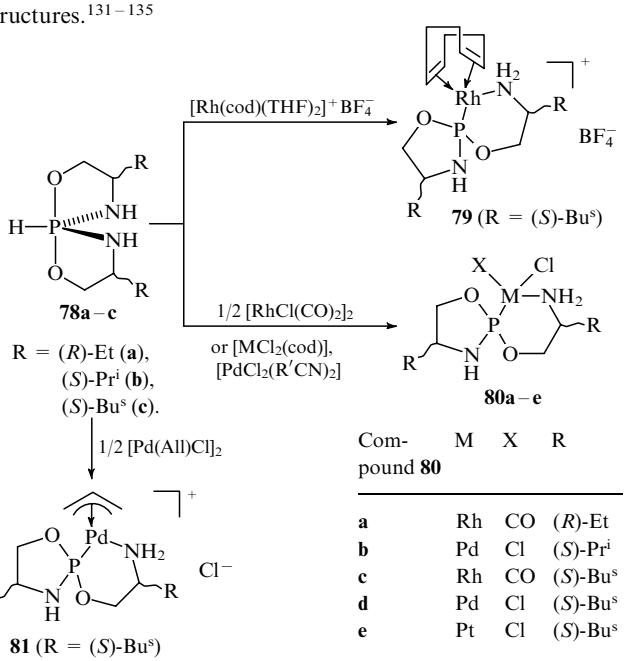
By and large, a small (at the moment) group of phosphites containing Schiff bases appears to be more efficient in asymmetric catalysis than the best aminophosphites known so far. There are grounds for believing that in the future these new compounds will successfully compete with ligands containing oxazoline structural fragments.

It should be emphasised that all P,N-bidentate phosphites possess enhanced π-acceptor abilities (even as compared to the most electron-accepting phosphines containing an amino group in the substituent).[5] This affects the spectral characteristics of chlorocarbonyl rhodium complexes with these ligands. For instance, the spin–spin coupling constants ^1J(P,Rh) of such complexes are, on average, increased by 80–100 Hz and the ν(CO) frequencies are nearly 20–25 cm^{-1} higher. Direct correlations between the optical yields of hydrosilylation of ketones, allylation, hydroboronation–oxidation and the π-acceptor ability of the P,N-bidentate ligand should be pointed out (see Refs 5 and 128 and references cited therein). In some cases one should also take into account the σ-donor ability of nitrogen-containing fragments. In this connection a convenient spectral characteristic was suggested, which permits fast evaluation of the electronic effect of any P,N-bidentate ligand. This is the parameter ν_{Rh}, or the ν(CO) vibrational frequency of [RhCl(CO)L] complexes.[128] The steric characteristics are determined by another parameter, the cone angle at the phosphorus atom, which can be obtained with ease from the semiemirical AM1 calculations.[129]

5. Hydrophosphorane ligands

Hydrophosphoranes (HPs) form a rare and original group of phosphorus-containing ligands. At first glance, their structures contain no potential donor centres because phosphorus atoms have no lone electron pairs while the lone electron pairs of nitrogen or oxygen atoms must be involved in $p_\pi-d_\pi$-conjugation with d orbitals of the phosphorus atom. However, it is these compounds that show a variety of types of bonding to metal ions, namely, the P-, N-, P,N-, P,O- and N,N-coordination. Coordination chemistry of HPs has been analysed in detail in a separate review;[130] however, since then new information on complexation and catalysis involving chiral HPs has been reported. This first of all concerns hydrospirophosphoranes (HSPs) **78** and tricyclic hydrophosphoranes (TCHPs).

Hydrospirophosphoranes are typical chelate-forming compounds, which form metal-containing derivatives of their 'open' structures.[131–135]



Compound **80**	M	X	R
a	Rh	CO	(*R*)-Et
b	Pd	Cl	(*S*)-Pr^i
c	Rh	CO	(*S*)-Bu^s
d	Pd	Cl	(*S*)-Bu^s
e	Pt	Cl	(*S*)-Bu^s

Complexes **79**–**81** are stable compounds. They were thoroughly studied by various methods of physicochemical analysis.[131,133–135] Unfortunately, they usually exist as equimolar mixtures of epimers with respect to the P*-stereocentre, which significantly reduces the scope of their application in asymmetric catalysis.

TCHPs (**82**) provide a source of richer coordination chemistry owing to a larger number of possible complexation routes. However, usually one route (sometimes, two routes) can be realised for a particular ligand; therefore, the corresponding

complexes retain, as a rule, their stereochemical individuality.[133–139]
