Therefore, the following two phases should correspond to the central point of the conversion line $B-D$: NaF and $K_2WO_4 \cdot BaWO_4$. These compounds are stable products of exchange and complexation reactions.

The following equation is true for any other point of the conversion line $B-D$:

$$x(KF)_2 + (1-x)\,BaF_2 + Na_2WO_4 = (NaF)_2 + x\,K_2WO_4 + (1-x)\,BaWO_4. \quad (13)$$

Let us consider two cases: $x > 0.5$ and $x < 0.5$. Let $x = 0.6$. By summing the equations, we obtain

$$0.6(KF)_2 + 0.4BaF_2 + Na_2WO_4 = (NaF)_2 + 0.6K_2WO_4 + 0.4BaWO_4$$

$$0.4K_2WO_4 + 0.4BaWO_4 = 0.4(K_2WO_4 \cdot BaWO_4)$$

$$0.6(KF)_2 + 0.4BaF_2 + Na_2WO_4 = (NaF)_2 + 0.2K_2WO_4 + 0.4(K_2WO_4 \cdot BaWO_4).$$

Therefore, three phases, *viz*., NaF, K_2WO_4 and $K_2WO_4 \cdot BaWO_4$, should be observed at points on the conversion line $B-D$ with $B > 50\%$. This is consistent with the experimental data.

Let $x = 0.4$. Then

$$0.4(KF)_2 + 0.6BaF_2 + Na_2WO_4 = (NaF)_2 + 0.4K_2WO_4 + 0.6BaWO_4$$

$$0.4K_2WO_4 + 0.4BaWO_4 = 0.4(K_2WO_4 \cdot BaWO_4)$$

$$0.4(KF)_2 + 0.6BaF_2 + Na_2WO_4 = (NaF)_2 + 0.2BaWO_4 + 0.4(K_2WO_4 \cdot BaWO_4).$$

Hence, the NaF, $BaWO_4$ and $K_2WO_4 \cdot BaWO_4$ phases should be detected at the points on the conversion line $B-D$ with $B < 50\%$.

In addition to exchange reactions, the complexation reactions giving rise to the $KF \cdot K_2WO_4$ compound correspond to the conversion points B and F (see Fig. 20).

For the point B:

$$3\,(KF)_2 + 2\,Na_2WO_4 = 2\,(NaF)_2 + 2\,(KF \cdot K_2WO_4),$$

for the point F:

$$3\,(KF)_2 + 2\,BaWO_4 = 2\,BaF_2 + 2\,(KF \cdot K_2WO_4).$$

The following reaction corresponds to the central point of the conversion line $B-F$:

$$6\,(KF)_2 + 2\,BaWO_4 + 2\,Na_2WO_4 = \\ = 2\,(NaF)_2 + 2\,BaF_2 + 4\,(KF\cdot K_2WO_4)$$

or

$$3\,(KF)_2 + BaWO_4 + Na_2WO_4 = \\ = (NaF)_2 + BaF_2 + 2\,(KF\cdot K_2WO_4).$$

For any point on the $B-F$ line, the complex formation is described by the equation

$$3\,(KF)_2 + 2(1-x)\,BaWO_4 + 2x\,Na_2WO_4 = \\ = 2x\,(NaF)_2 + 2\,(KF\cdot K_2WO_4) + 2(1-x)\,BaF_2\,.$$

The reaction affords sodium fluoride, barium fluoride and $KF\cdot K_2WO_4$ for all x varying from 0 to 1.

However, the field of the $KF\cdot K_2WO_4$ compound is not observed in the plane of the diagonal triangle $(NaF)_2-BaF_2-K_2WO_4$ (Fig. 22), which is intersected by the conversion line $B-F$. From this it follows that a stable diagonal section with the $BaF_2-(NaF)_2$ edge and the third vertex $KF\cdot K_2WO_4$ should be present in the composition prism. This triangle was examined by the visual polythermal method.[46] The liquidus surface of this triangle consists of three crystallisation fields, *viz*., $(NaF)_2$, BaF_2 and $KF\cdot K_2\,WO_4$, intersecting at the point of crystallisation of three phases (a quasiternary eutectic point).

As can be seen from the phase diagrams of the conversion lines of the Na,K,Ba//F,WO_4 system, the central part of the composition prism includes the crystallisation volumes of stable components, which are products of exchange and complexation reactions: NaF, BaF_2, $BaWO_4$, K_2WO_4, $KF\cdot K_2WO_4$ and $K_2WO_4\cdot BaWO_4$.

The starting KF and Na_2WO_4 salts are absent in the phase diagrams, because they are metastable components and are consumed in the reaction.

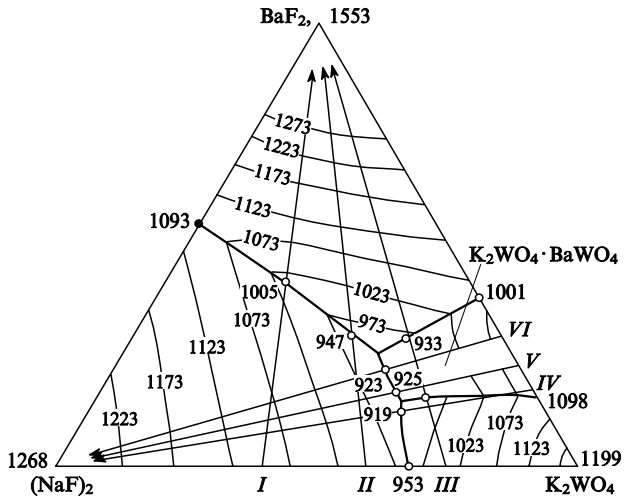

Figure 22. Phase diagram of the secant triangle $(NaF)_2-BaF_2-K_2WO_4$ of the Na,K,Ba//F,WO_4 system.

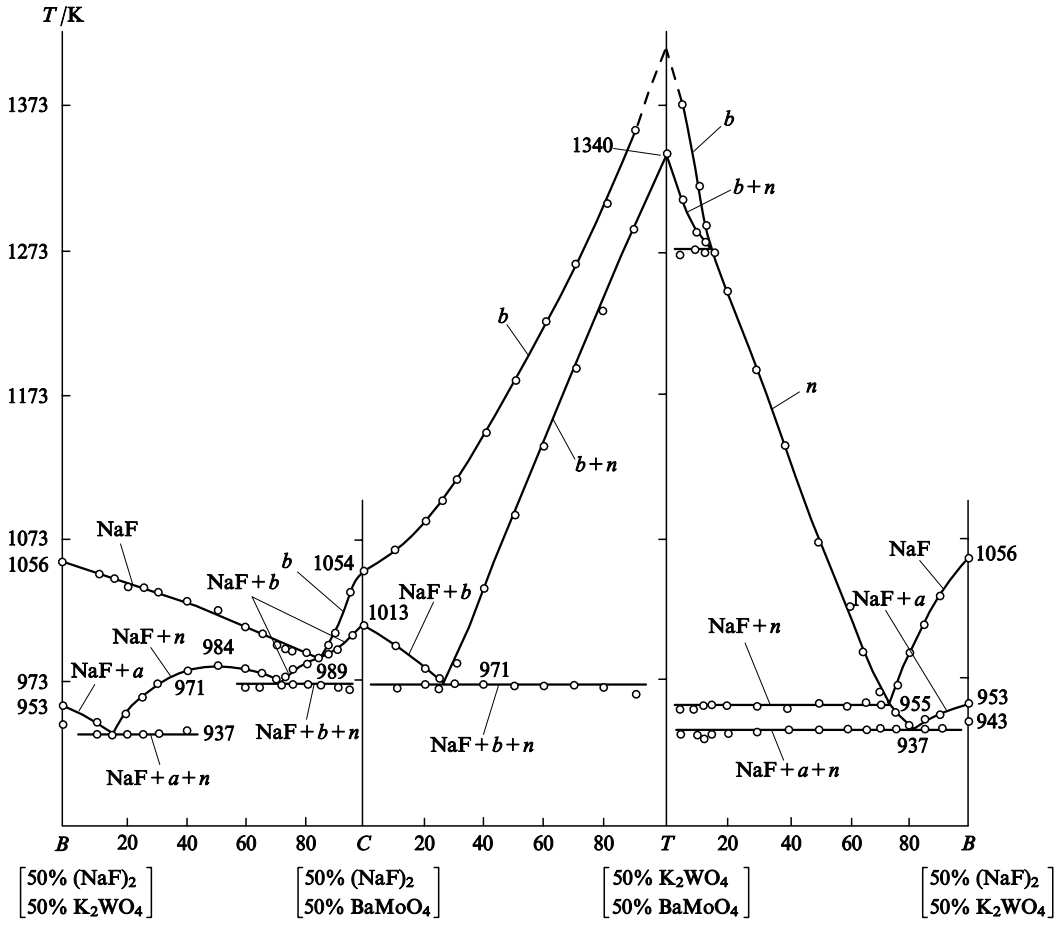

Figure 23. Temeprature–composition diagram for the quinary reciprocal system Na,K,Ba//F,MoO_4,WO_4.[11]
The composition axis represents the conversion lines $B-C$, $B-T$ and $C-T$ (see Fig. 10).

It should be noted that, in addition to two ternary invariant points, a quaternary eutectic point is present in the conversion lines.

The conversion figure of secant tetrahedra of quinary reciprocal systems consisting of nine salts represents a polythermal section and, consequently, the phase diagram of the system.

The conversion figure of the 9B ⇄ 9A-type quinary reciprocal system Na,K,Ba//F,MoO_4,WO_4 consisting of nine salts is shown in Fig. 10. The inner lines $C-T$, $B-T$ and $F-A$, $B-C$ of the conversion graph differ from other lines [46] in that the lines making up the conversion graph belong to none of the six prisms of the quaternary reciprocal systems, which bound the composition polytope of the quinary reciprocal system, and lie in the planes of the stable and non-equilibrium axial triangles.

The $B-C$, $B-T$ and $C-T$ lines intersect the stable axial triangle of the quinary reciprocal system Na,K,Ba//F,MoO_4,WO_4, and the $F-A$ line intersects the non-equilibrium triangle of this system.[46] Consequently, the crystallising phases involving all six ions correspond to these four lines. Hence, the lines were assigned to the quinary reciprocal system.

The $B-C$ line in Fig. 23 intersects the crystallisation volumes of NaF and the phase b (the $BaMoO_4-BaWO_4$ solid solution), as evidenced by two branches of primary crystallisation intersecting at the point with coordinates 989 K and 15.5% of B [the composition: 50% $(NaF)_2$, 43% $BaMoO_4$ and 7% K_2WO_4]. The curve of secondary crystallisation consists of the following three branches: NaF + a, NaF + b and NaF + n (a, the $K_2MoO_4-K_2WO_4$ solid solutions; b, the $BaMoO_4-BaWO_4$ solid solutions; n, the $K_2MoO_4\cdot BaMoO_4-K_2WO_4\cdot BaWO_4$ solid solutions). These branches intersect at the eutectic points of three phases: at 937 K and 28.5% B [33% $(NaF)_2$, 10% $BaMoO_4$ and 57% K_2WO_4], the solid phases NaF, a and n; at 971 K and 85% B [44% $(NaF)_2$, 39.5% $BaMoO_4$ and 16.5% K_2WO_4], the solid phases NaF, b and n.

The curve of secondary crystallisation has a maximum at 984 K and 50% B [44% $(NaF)_2$, 28% $BaMoO_4$ and 28% K_2WO_4], the solid phases NaF and n.[46] In Fig. 23, the conversion line $C-T$ intersects the crystallisation volume of the phase b, as evidenced by the curve of primary crystallisation (without extremes). Secondary crystallisation is represented by two branches, *viz.*, NaF – phase b and $n + b$, intersecting at the eutectic point of crystallisation of three phases, *viz.*, NaF, b and n (at 971 K and 27% T). The conversion line $B-T$ intersects the crystallisation volumes of NaF and the phases b and n. The branches of primary crystallisation intersect at two points with coordinates 1271 K and 15% B [7.5% $(NaF)_2$, 42.5% $BaMoO_4$ and 50% K_2WO_4], the solid phases b and n; and 955 K and 63% B [37% of $(NaF)_2$, 13% $BaMoO_4$ and 50% K_2WO_4], the solid phases NaF and n.

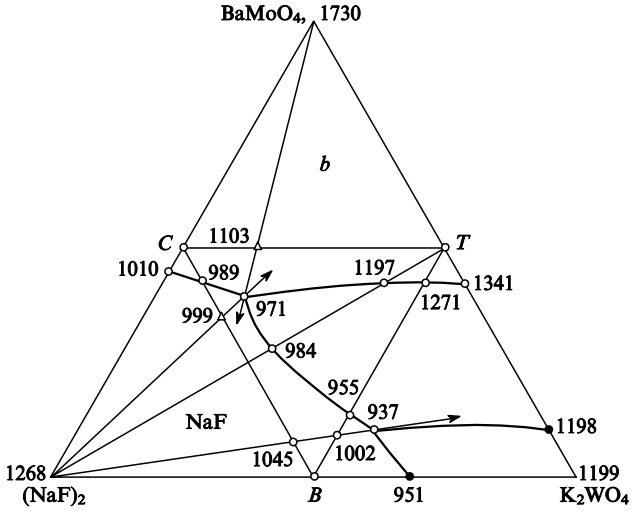

Figure 24. Phase diagram of the stable axial triangle $(NaF)_2-BaMoO_4-K_2WO_4$ of the Na,K,Ba//F,MoO_4,WO_4 system. Temperatures are given in Kelvin (K).

The phase diagram of the overall stable axial triangle can be constructed based on the data corresponding to the conversion lines $B-T$, $C-T$ and $B-C$ (Fig. 24).[11]

5. Stable tetrahedra of quinary reciprocal systems consisting of nine salts

The salt compositions of all tetrahedra of a singular star can be determined from a conversion figure of secant tetrahedra for quinary reciprocal systems of nine salts belonging to any topological type. Each point of the conversion figure of this system corresponds to an exchange reaction between stable and metastable salt pairs located at the vertices of the conversion graph.

The chemical interaction in the system under consideration can be described by reaction equations for the points lying in the planes of the conversion figure. Based on these equations, the crystallising phases in stable secant tetrahedra can be predicted.

The $A-B-C-D$ square of the conversion figure for the Na,K,Ba//F,MoO_4,WO_4 system is shown in Fig. 25. The equation for the central point of this square has the form

$$2(KF)_2 + 2Na_2MoO_4 + 2Na_2WO_4 + 2BaF_2 = 4(NaF)_2 + K_2MoO_4 + K_2WO_4 + BaMoO_4 + BaWO_4. \quad (14)$$

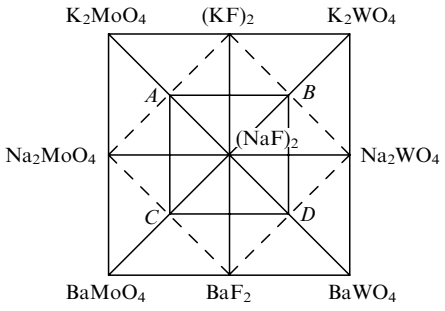

Figure 25. Conversion square $A-B-D-C$ (a fragment of the conversion figure) for the quinary reciprocal system Na,K,Ba//F,MoO_4,WO_4.

The right-hand side of this equation includes a metastable pair of salts, which react according to the equation

$$BaWO_4 + K_2MoO_4 = BaMoO_4 + K_2WO_4. \quad (15)$$

By summing Eqns (14) and (15), we obtain

$$2(KF)_2 + 2Na_2MoO_4 + 2Na_2WO_4 + 2BaF_2 = 4(NaF)_2 + 2BaMoO_4 + 2K_2WO_4. \quad (16)$$

Analysis of the data on the boundary elements demonstrated that crystallisation of $BaMoO_4$ and K_2WO_4 (taken in equivalent amounts) affords the phase n, *viz.*, the solid solutions of the $K_2MoO_4\cdot BaMoO_4-K_2WO_4\cdot BaWO_4$ compounds. Consequently, the latter reaction produces the phases NaF and n.

The central point of the conversion square $A-B-D-C$ coincides with the central point of the conversion line $B-C$ (see the diagrams of the conversion lines $B-T$, $C-T$ and $C-B$, Fig. 23). For this point, crystallisation of the phases NaF and n (the $K_2MoO_4-BaMoO_4$ and $K_2WO_4-BaWO_4$ solid solutions) was established experimentally. This fact is in complete agreement with the prediction of phases formed according to the above-given equation taking into account the data on the boundary elements.

The conversion square $A-B-D-C$ is divided by the $B-C$ line (the diagonal of the conversion square) into two triangles, $A-B-C$ and $B-D-C$. Each triangle is characterised by its own equation of the exchange reaction (Fig. 26).

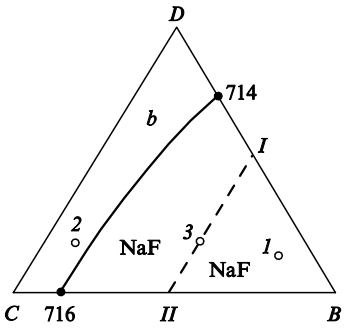

Figure 26. Phase diagram of a system represented by the conversion triangle $B-C-D$.

The composition of each point of the $B-C-D$ triangle can be expressed by the ratio between the B, C and D components, which reflect the transformation of a metastable salt pair into a stable pair. On the whole, the equation of exchange reactions for each point of the $B-C-D$ triangle can be written as follows:

$$x(Na_2MoO_4 + BaF_2) + y[(KF)_2 + Na_2WO_4] +$$
$$+ (1-x-y)(BaF_2 + Na_2WO_4) = x[BaMoO_4 + (NaF)_2] +$$
$$+ y[(NaF)_2 + K_2WO_4] + (1-x-y)[(NaF)_2 + BaWO_4].$$

After simple algebraic transformations, we obtain

$$x\,Na_2MoO_4 + (1-y)\,BaF_2 + y\,(KF)_2 + (1-x)Na_2WO_4 = \quad (17)$$
$$= (NaF)_2 + x\,BaMoO_4 + y\,K_2WO_4 + (1-x-y)\,BaWO_4.$$

Therefore, the exchange reactions afford stable salts located at the vertices of the secant tetrahedron, which is intersected by the conversion triangle $B-C-D$ (see Fig. 26). Let us analyse the possible reaction products for points on this triangle. Experimental studies demonstrated that the crystallisation surface of this triangle is represented by the fields of sodium fluoride and the phase b.

The triangle can be divided by the $I-II$ line, which connects the saddle points of the conversion lines $B-C$ and $B-D$, into two regions, $B-II-I$ and $I-II-C-D$. Particular stable phases correspond to both regions of the conversion triangle and the $I-II$ line. These phases are formed in the course of crystallisation of the products of the exchange reaction described by Eqn (17).

For each point of the $B-II-I$ region ($y > 0.5$, $x < 0.5$), the composition can be expressed as follows: y is the amount of the component B, x is the amount of the component C, the amount of the component D is $1-x-y$. Let us consider the arbitrarily chosen point 1, for which $x = 0.1$ and y = 0.7. The equation for this point has the form

$$0.1\,Na_2MoO_4 + 0.3\,BaF_2 + 0.7\,(KF)_2 + 0.9\,Na_2WO_4 = \quad (18)$$
$$= (NaF)_2 + 0.1\,BaMoO_4 + 0.2\,BaWO_4 + 0.7\,K_2WO_4.$$

If the $BaMoO_4 + BaWO_4$ and K_2WO_4 products are present in a ratio corresponding to the right-hand side of this equation, complete crystallisation affords the phases n (the $K_2MoO_4-BaMoO_4$ and $K_2WO_4-BaWO_4$ solid solutions) and a (the $K_2MoO_4-K_2WO_4$ solid solutions), as is obvious from the data on the boundary elements. Therefore, the following final reaction products correspond to the points in the $B-II-I$ region: NaF, the $K_2MoO_4-BaMoO_4$ and $K_2WO_4-BaWO_4$ solid solutions and the $K_2MoO_4-K_2WO_4$ solid solutions. For the point *2* in the $I-II-C-D$ region ($y < 0.5$) at $x = 0.7$ and $y = 0.1$, the equation has the form

$$0.7\,Na_2MoO_4 + 0.9\,BaF_2 + 0.1\,(KF)_2 + 0.3\,Na_2WO_4 = \quad (19)$$
$$= (NaF)_2 + 0.7\,BaMoO_4 + 0.2\,BaWO_4 + 0.1\,K_2WO_4.$$

At the above-mentioned ratio between the $BaMoO_4 + BaWO_4$ and K_2WO_4 products, crystallisation affords the phases NaF, b and n, as indicated by the data on the boundary elements. For the point *3* on the $I-II$ line ($y = 0.5$, $x = 0.5$) at $y = 0.5$, $x = 0.3$, the equation has the form

$$0.3\,Na_2MoO_4 + 0.5\,BaF_2 + 0.5\,(KF)_2 + 0.7\,Na_2WO_4 = \quad (20)$$
$$= (NaF)_2 + 0.3\,BaMoO_4 + BaWO_4 + 0.5\,K_2WO_4.$$

If $BaMoO_4 + BaWO_4$ and K_2WO_4 are present in equivalent amounts, crystallisation yields only the phase n. Consequently, the reaction affords NaF and n for all points on the $I-II$ line.

On the whole, the conversion triangle $B-C-D$ corresponds to products of the chemical reaction, *viz*., the phases NaF, b and n. This fact was confirmed experimentally.[46] Hence, the secant tetrahedron $(NaF)_2-BaMoO_4-BaWO_4-K_2WO_4$ corresponds to the crystallisation volumes of NaF, a, b and n (Fig. 27) intersecting along univariant curves. Quaternary invariant points are lacking.

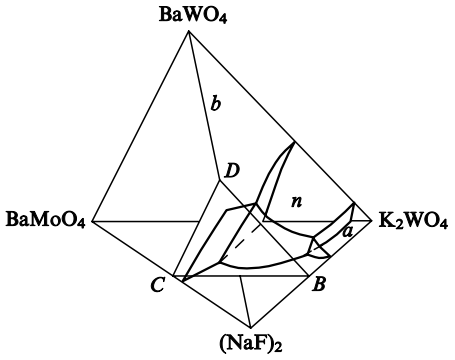

Figure 27. Crystallisation volumes of the $(NaF)_2-BaWO_4-K_2WO_4-BaMoO_4$ tetrahedron of the Na,K,Ba//F,MoO_4,WO_4 system.

The above-considered procedure can be used for determining the salt compositions and crystallisation volumes of all six secant tetrahedra of any quinary reciprocal system.[16,46]

V. Practical applications of multicomponent salt melts

The use of melts in various technological processes has attracted increasing attention in recent years. Considerable interest in molten salt systems as reaction media is associated with their specific properties, among which are their ability to dissolve many organic and inorganic compounds. Besides, these systems can intensify processes due to high heat- and mass-transfer coefficients, thermal conductivity and heat transfer; reacting compounds in these systems can occur in oxidation states, which are inaccessible in typical solutions; the density and viscosity of such reaction media are relatively low; the reaction products can easily be separated from the reaction mixtures; water as a solvent can completely be excluded from the technological scheme. (The growing problem of water deficiency needs urgent attention; hence, the above-mentioned possibilities are not only of scientific interest but are also sometimes technologically and economically advantageous.)

Electrochemistry, metallurgy and electrometallurgy are traditional areas of application of molten salt media. They also have promising applications in fuel cells and high-temperature information transformers, in single-crystal growth of optical materials and ferroelectric materials, in nuclear technology, as nuclear fuel, and as claddings for thermonuclear reactors. Inorganic synthesis in molten salts is yet another promising area of application of salt melts.[12] In many cases, reactions in molten salts proceed faster

and afford the target products in higher yields because of the highest possible concentrations of the reagents, one of which is the melt.[12]

The diversity of inorganic salts, all the more their mixtures, makes it possible to prepare a wide range of molten salt systems and, consequently, to carry out various syntheses in these media.[4,16–18,47] Actually, all main types of chemical reactions, *viz*., exchange, acid–base, redox and complexation reactions, have been performed in these media.

Systems containing eutectic composites, which are characterised by the constant melting points and compositions, are of great scientific interest. The melting points of the starting components of such systems decrease substantially already in binary systems.[48] In ternary systems, the melting points continue to decrease, the rate of decrease in the melting point being lower in quaternary systems. Nevertheless, even a slight decrease in the temperature of a eutectic composite (by 15–20 °C) may be of considerable practical importance for technological purposes.

Among salt melts, multicomponent reciprocal systems are of special interest. Reciprocal systems consisting of 4, 5, 6 or 7 components are the most difficult to study by methods of physicochemical analysis. These systems can be used for preparing materials possessing the desired combinations of properties, which is an important problem of applied chemistry. Hence, the rational choice of salt compositions is of considerable importance in improving conditions for the preparation of substances possessing the required characteristics.

1. Thermal chemical power sources

Ionic melts have found wide application in high-temperature power sources.[12]

Aqueous electrolytes are unsuitable for the construction of thermal chemical power sources, because certain electrode materials (alkali and alkaline-earth metals, halides) react with water. Salt melts serve as convenient electrolytes in high-temperature power sources.[13]

A molten electrolyte satisfying these requirements was designed on the basis of the quaternary reciprocal system Li,K,Ni//Cl,SO_4. The challenge was to find a low-melting electrolyte consisting of stable phases and exhibiting the required properties to use in chemical power sources.[13–15]

A procedure for revealing stable salt mixtures, which are modelled by tetrahedral simplexes in the composition diagram of a multicomponent system, and a procedure for the estimation of stability of such mixtures were described.[49]

A salt mixture is assumed to be stable, if the phase diagram obtained after heating the mixture above the melting point followed by crystallisation, includes crystallisation fields of salts produced by exchange reactions and crystallisation fields of double compounds formed by these salts, which are stable in the temperature range under consideration. A mixture is assumed to be metastable if the phase diagram has fields of the starting reactive salts involved in exchange reactions with each other and crystallisation fields of metastable double compounds, which decompose in the temperature range under consideration to yield reactive salts.

The procedure involves the following steps.

1. A composition figure of a multicomponent system is partitioned using one of the simplest procedures[11] with the aim of revealing tetrahedral simplexes, *i.e*., determining their salt compositions.

2. The possibilities of exchange reactions and complex formation for salts of each salt mixture are examined and estimated from the thermodynamical standpoint. It is most reasonable to study the regions of the conversion figure involved in this simplex.

3. If experimental data on the boundary subsystems are available, stability of the subsystems is estimated. Mixtures of three salts, which are modelled by triangles of ternary reciprocal systems, triangulating sections of quaternary reciprocal systems, *etc*., can serve as boundary subsystems of tetrahedra in reciprocal multicomponent systems consisting of six salts.

4. The stability of a salt mixture as a whole, which is modelled by a tetrahedron, is estimated from the data obtained in stages 2 and 3. If the mixture is estimated as metastable, further triangulation of the composition diagram is carried out and all of the procedure is repeated.

Let us apply this procedure to the quaternary reciprocal system Li,K,Ni//Cl,SO_4,[13] whose composition prism is divided into three tetrahedral simplexes by two triangular sections. The geometric partitioning is based on exchange reactions between the starting salts. The salt compositions of the tetrahedra can be determined from the matrix of reciprocal salt pairs with an inscribed conversion figure.[8] The composition prism of the quaternary reciprocal system Li,K,Ni//Cl,SO_4 along with the conversion figure $B-A-C$, the matrix of reciprocal salt pairs and the matrix of vertex indices is presented in Fig. 28. The stable tetrahedra of the singular star of the Li,K,Ni//Cl,SO_4 system are extracted from the matrix of reciprocal salt pairs:

$(LiCl)_2-(KCl)_2-NiCl_2-Li_2SO_4$,

$(KCl)_2-K_2SO_4-NiSO_4-Li_2SO_4$,

$NiCl_2-(KCl)_2-NiSO_4-Li_2SO_4$.

Figure 28. Models of the quaternary reciprocal system Li,Ni,K//Cl,SO_4. (*a*) The composition prism, (*b*) the matrix of reciprocal salt pairs with an inscribed conversion graph, (*c*) the matrix of vertex indices.

To predict stable phases crystallising from melts, the $(LiCl)_2-(KCl)_2-NiCl_2-Li_2SO_4$ tetrahedron with the conversion line $A-B$ was chosen (Fig. 29).[14]

The choice of the $(LiCl)_2-(KCl)_2-NiCl_2-Li_2SO_4$ tetrahedron was governed by the requirements imposed on chemical power sources. The stability of each boundary subsystem and the tetrahedron as a whole can be estimated from the morphological characteristics of the liquidus surface and the thermochemical relations in the quaternary reciprocal system Li,K,Ni//Cl,SO_4.

The $(KCl)_2-NiCl_2-Li_2SO_4$ face (Fig. 29). The conversion line $A-B$ intersecting the face reflects the exchange reactions in the Li,K,Ni//Cl,SO_4 system formed at the intersection of the stable triangle $(KCl)_2-NiCl_2-Li_2SO_4$ of a singular star with the corresponding metastable triangle $(LiCl)_2-NiSO_4-K_2SO_4$ of a non-equilibrium star.[14]

By summing the exchange reactions for the points of complete conversion A and B of the ternary reciprocal systems Li,K//Cl,SO_4 and Li,Ni//Cl,SO_4, we obtain

for the point A: $(LiCl)_2 + NiSO_4 = NiCl_2 + Li_2SO_4$

for the point B: $(LiCl)_2 + K_2SO_4 = (KCl)_2 + Li_2SO_4$

$$2\,(LiCl)_2 + NiSO_4 + K_2SO_4 = NiCl_2 + 2\,Li_2SO_4 + (KCl)_2\,. \quad (21)$$

This is the equation for the central point of the conversion line $A-B$. As can be seen from Eqn (21), the exchange equilibrium is shifted toward stable phases of the components of the face under consideration.

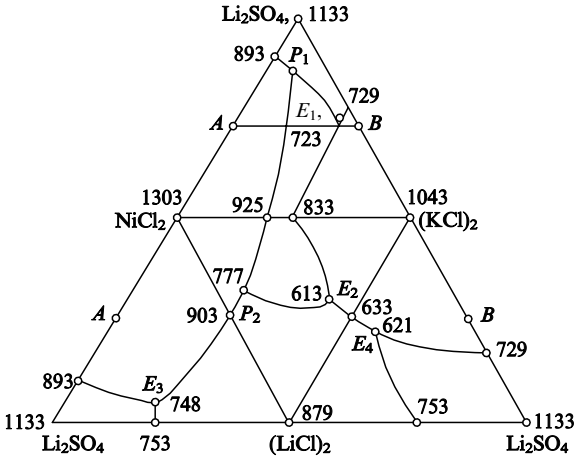

Figure 29. Development of the stable $(LiCl)_2-NiCl_2-Li_2SO_4-(KCl)_2$ tetrahedron of the quaternary reciprocal system Li,Ni,K//Cl,SO_4. The temperatures are given in Kelvin (K).

In addition to the exchange reaction, complex formation occurs in the Li,Ni//Cl,SO_4 system

$$(KCl)_2 + NiCl_2 = 2\,[KCl\cdot NiCl_2]. \quad (22)$$

By summing Eqns (21) and (22), we obtain

$$2\,(LiCl)_2 + NiSO_4 + K_2SO_4 + NiCl_2 = 2\,Li_2SO_4 + 2\,[KCl\cdot NiCl_2]. \quad (23)$$

The face of the $(KCl)_2-NiCl_2-Li_2SO_4$ tetrahedron is estimated as stable. Actually, the experiment gave the eutectic E_1 at 723 K and 51 mass% Li_2SO_4, 42 mass% KCl, 7 mass% $NiCl_2$ (see Fig. 29). The transition point P_1 has the following composition: 74 mass% Li_2SO_4, 13 mass% KCl and 13 mass% $NiCl_2$; the temperature is 833 K. The crystallisation surface of the $(KCl)_2-NiCl_2-Li_2SO_4$ system (the face of the tetrahedron) consists of the following four crystallisation fields: KCl, $NiCl_2$, Li_2SO_4 and $KCl\cdot NiCl_2$.[14]

The $(LiCl)_2-NiCl_2-Li_2SO_4$ face. As can be seen from Fig. 29, the point of complete conversion, which corresponds to the exchange reaction proceeding in the ternary reciprocal system Li,Ni//Cl,SO_4 [Eqns (21) and (23)], is located on the edge of the face. According to Eqn (21), $NiCl_2$ and Li_2SO_4 are stable phases. From the table of vertex indices, it follows that these salts are characterised by the highest indices. This prediction was confirmed experimentally. The crystallisation fields of the melting diagram converge at the eutectic point E_3 with coordinates 748 K, 45 mass% LiCl, 49.6 mass% Li_2SO_4 and 5.4 mass% $NiCl_2$. The LiCl, $NiCl_2$ and Li_2SO_4 compounds are solid phases.

The $(LiCl)_2-(KCl)_2-Li_2SO_4$ face. The exchange reaction giving rise to a stable pair of Li_2SO_4 and KCl salts [Eqn (21)], which are not involved in complex formation with the reactive K_2SO_4 and LiCl salts, occurs at the point of complete conversion B of the ternary reciprocal system Li,K//Cl,SO_4. The crystallisation surface of this system consists of crystallisation fields of the components; the eutectics occur at 621 K, 42 mass% LiCl, 50.5 mass% KCl and 7.5 mass% Li_2SO_4; LiCl, Li_2SO_4 and KCl are solid phases. Apparently, this section is stable (see Fig. 29).

The $(KCl)_2-NiCl_2-(LiCl)_2$ face. The melting diagram of the system was studied only partially because of decomposition of the mixtures containing large amounts of nickel chloride. The crystallisation surface of the $(KCl)_2-NiCl_2-(LiCl)_2$ system consists of four fields[14] belonging to the components and the incongruently melting $KCl\cdot NiCl_2$ compound (see Fig. 29).

Below are given the compositions, the equilibrium phases and the temperatures of invariant points of the $(KCl)_2-NiCl_2-(LiCl)_2$ system. This system is also stable.

Point	T/°C	Composition (mass%)			Equilibrium phases
		$NiCl_2$	LiCl	KCl	
E_2	340	3.5	42	54	LiCl, KCl, $KCl\cdot NiCl_2$
P_2	504	40	37.5	21.5	LiCl, $NiCl_2$, $KCl\cdot NiCl_2$

The $Li_2SO_4-(LiCl)_2-NiCl_2-(KCl)_2$ tetrahedron. Since the theoretical prediction of phases based on the boundary elements shows that all boundary systems of the tetrahedron are stable, the system, whose composition is represented by the $Li_2SO_4-(LiCl)_2-NiCl_2-(KCl)_2$ tetrahedron, should be stable. This assumption was confirmed experimentally.[15] The temperature and composition of the quaternary eutectic are 633 K, 39 mass% LiCl, 49.8 mass% KCl, 8 mass% Li_2SO_4, 3.2 mass% $NiCl_2$; the Li_2SO_4, LiCl, $NiCl_2$ and KCl solid phases.

2. High-temperature electrolytic aluminising of niobium

The quaternary reciprocal system Al,Ba,Na//F,Cl, *viz*., $BaCl_2$ (0.73%) – NaF (0.12%) – AlF_3 (0.15%), is used as a molten electrolyte for high-temperature electrolytic aluminising of niobium. The reaction of molten salts cannot be judged from the results of chemical analysis of a sample of the melt cooled and dissolved in water or acid. Chemical analysis provides only information on the concentrations of the ions dissolved in solution. Information on the true chemical reactions of molten salts in systems can be extracted from a phase complex, which is displayed in the melting diagram as crystallisation fields or volumes, lines of co-crystallisation and multiple points. This allows one to draw reliable conclusions about the reactions proceeding in systems at high temperatures. The quaternary reciprocal system Al,Ba,Na//F,Cl can be represented as a matrix of reciprocal salt pairs (Fig. 30 *a*), in which the conversion figure of secant triangles is inscribed. Using the conversion figure, the following secant triangles are extracted from the matrix: AlF_3-BaCl_2-NaCl and AlF_3-BaCl_2-NaF (elements of a singular star).

Data on the boundary elements are required to predict the crystallisation fields of these triangular sections. It is known that the NaF – AlF_3 subsystem contains two compounds, *viz*., Na_3AlF_6 and $5\,NaF\cdot 3\,AlF_3$, the $BaCl_2$ – NaF subsystem contains

a

6*b*	$AlCl_3$	$BaCl_2$	NaCl
AlF_3	0	1 *A*	1 *B*
BaF_2	0	0	0
NaF	0	1 *C*	0

b

	Cl^-	F^-	$\sum$
Al^{3+}	0	2	2
Ba^{2+}	2	0	2
Na^+	1 [a]	1 [b]	2
$\sum$	3	3	6

Figure 30. Models of the quaternary reciprocal system Al,Na,Ba//Cl,F. (*a*) The matrix of reciprocal salt pairs with an inscribed conversion graph, (*b*) the matrix of vertex indices.

the $BaCl_2 \cdot BaF_2$ compound, and the $AlF_3 - BaCl_2$ subsystem is characterised by a eutectic point (all data refer to the $AlF_3 - BaCl_2 - NaF$ system).

The required electrolyte can be chosen with the use of the phase diagrams of the triangular section of the Al,Ba,Na//F,Cl system. It was experimentally demonstrated that the liquidus surface of this stable triangular section consists of seven crystallisation fields: $BaCl_2$, NaF, AlF_3, BaF_2, Na_3AlF_6, $5\,NaF \cdot 3\,AlF_3$ and $BaCl_2 \cdot BaF_2$. Hence, the experimental results confirmed the predicted existence of three compounds in the $AlF_3 - BaCl_2 - NaF$ triangle of the singular star.

At the point of complete conversion *A*, the salt pairs undergo interchange according to the reaction

$$3\,BaF_2 + AlCl_3 = 2\,AlF_3 + 3\,BaCl_2.$$

The Na_3AlF_6 compound is formed at the point of complete conversion by the secondary reaction

$$2\,AlCl_3 + 12\,NaF = 2\,Na_3AlF_6 + 6\,NaCl.$$

At the point of complete conversion *C*, an exchange reaction and complex formation take place

$$BaF_2 + 2\,NaCl = 2\,NaF + BaCl_2,$$

$$4\,BaF_2 + 4\,NaCl = 2\,(BaF_2 \cdot BaCl_2) + 4\,NaF.$$

The conditions of the process are as follows: at a carbon anode, electrolysis is carried out at 900 °C; the thickness of an aluminium coating is 40 – 50 μm, the coating consists of Al, $NbAl_3$ and Nb_2Al.[12]

As can be seen from the matrix table of vertex indices (see Fig. 30 *b*), the $AlCl_3$ salt is most reactive and is completely consumed in the exchange reaction and the reaction giving rise to the compound, *i.e.*, this salt is absent in the melt (the index is 0). The system contains AlF_3 formed by the exchange reaction (the index of AlF_3 is 2). Barium chloride is consumed in the synthesis of the $BaF_2 \cdot BaCl_2$ compound and the exchange reaction yielding $BaCl_2$. The BaF_2 salt is most reactive (its index is 0). The $BaCl_2$ salt is stable and has the highest index (2). The latter salt is an exchange reaction product. The NaCl and NaF salts have the index 1. They are intermediate between the most reactive and stable salts.

From the above, it can be concluded that the composition of the electrolyte for high-temperature aluminising was chosen correctly.

3. Silver plating

Nitrate and halide – nitrate molten systems are used for electrolytic silver plating.[12] For example, the molten $AgI - NaNO_3 - KNO_3$ system is used for electrolytic silver plating. This system corresponds to a diagonal section of the composition prism of the quaternary reciprocal system Ag,K,Na//I,NO_3 consisting of six salts. The process occurs at 300 °C and at a current density of 50 A m^{-2}.

Electrolytic silver plating can be carried out with the use of a molten electrolyte developed on the basis of the quinary reciprocal system Ag,K,Na//Cl,Br,NO_3 consisting of nine salts, which belongs to the A ⇄ B thermochemical type.[21]

Let us construct the matrix table of vertex indices using the thermochemical relations for the salt pairs of the system. The stable axial triangle of a singular star with the highest indices in each row of the matrix can be determined from this matrix table.

9A	Br^-	Cl^-	NO_3^-	$\sum$
Ag^+	4	2	0	6
K^+	2	1	3	6
Na^+	0	3 [a]	3 [b]	6
$\sum$	6	6	6	18

This is the $AgBr - KNO_3 - NaCl$ triangle. The most stable salts formed by exchange (conversion) reactions are AgBr (the index is 4), KNO_3 (the index is 3) and NaCl (the index is 3 [a]). The $AgNO_3$ (the index is 0), NaBr (the index is 0) and KCl (the index is 1) salts are most reactive and are consumed in the interchange reaction

$$2\,AgNO_3 + 2\,KCl + 2\,NaBr = \\ = AgCl + KNO_3 + AgBr + NaNO_3 + KBr + NaCl.$$

The metastable salt pairs react further

$$AgCl + KBr = AgBr + KCl,$$

$$KCl + NaNO_3 = KNO_3 + NaCl.$$

Hence,

$$AgNO_3 + KCl + NaBr = AgBr + KNO_3 + NaCl.$$

As a result, stable salts forming a eutectic mixture should appear in the melt for electrolysis. It was experimentally demonstrated that a low-melting eutectic is formed in the $AgBr - KNO_3 - NaCl$ system at 513 K and 21.5% AgBr, 12% NaCl, 66.5% KNO_3.

A procedure for studying multicomponent reciprocal systems, which involves the experimental investigation of conversion elements, including elements of incomplete conversion, was also successfully used for solving some other problems, in particular, for preparing bronzes, rare-metal compounds, phase-transition materials, *etc.*[4, 50 – 53]

VI. Conclusion

Nowadays, the methodology of investigation of multicomponent systems involves the theoretical study of models of multicomponent systems followed by experimental examination of particular regions of phase diagrams and their construction as the necessary stages. This methodology can also serve as the basis for the development of important technological processes (construction of heat accumulators, heat carriers, galvanised coatings, *etc.*).

Modelling of multicomponent reciprocal salt systems provides a rational approach to solving numerous theoretical and practical problems. A conversion figure of secant elements plays a unique role, because it is common to non-equilibrium and equilibrium complexes and ensures spatial and physicochemical relationships between these complexes.

Conversion figures can be used in the analysis of the mechanisms of transformation from a non-equilibrium state of the system to equilibrium. These figures allow one to follow the sequence of transformations of the starting compounds into the final reaction products. In models, this is manifested as a spatial transformation from a non-equilibrium star through intermediate stars (containing partially non-equilibrium and partially equilibrium elements) to a singular (equilibrium) star. Conversion elements can be used for studying the structures of phase diagrams in more detail (determination of remarkable points and analysis of their metrics in various systems of coordinates, the polarity and symmetry in various multidimensional spaces).

The proximate analysis developed on the basis of the conversion method enables one to solve practical problems, such as the construction of a phase complex of a system with a minimum of experimental studies (investigation of a small number of compositions) as well as the construction of reciprocal systems with the desired direction of exchange reactions.

The practical value of the conversion method became evident after the development of media for electrolytic coatings and the preparation of low-melting composites, *viz.*, heat carriers and heat-accumulation composites, which are used to prolong the life of batteries with high energy characteristics. In particular, the composites, whose enthalpies of melting are almost twice as high as those of foreign standards, were constructed.

There are several directions of development of the conversion method for investigating reciprocal salt systems: construction and improvement of models; development of new methodological concepts; exploration of new areas of practical application of this methodology; integration of conversion models into scientific foundations of chemical disciplines.

The following theoretical problems are yet to be solved.

1. The thermodynamical description of conversion models taking into account the available data on the algebraic models of processes occurring in salt melts.[54, 55]

2. More detailed investigation of the energetics of exchange reactions using alternative models of multicomponent reciprocal salt systems, *viz*., energy diagrams and non-equilibrium, intermediate and singular stars.

3. Thermodynamical calculations of conversion processes at different temperatures.

4. The construction of models for the description of the behaviour of ionic liquids at different temperatures and the energy transfer performed by these liquids.

5. Study of the topology of the distribution of conversion elements over subspaces of the multidimensional space of the phase diagram of a multicomponent reciprocal system.

6. The development of models of conversion processes, involving complexation reactions.

The prospects of the development of the conversion method are tightly related to the worldwide scientific trends associated with investigations and applications of salt melts, which are reflected in papers presented at scientific conferences and symposia on molten salts.[56–62] Among these problems are investigations of the dynamic, structural, electrochemical and other properties of melts, thermodynamical modelling and calculations of phase diagrams, construction of models of ionic liquids and the energetics of melts, *etc*. The conversion method can be used for solving many of these problems.

Abstract. A new phenomenon, spin catalysis, *i.e.*, stimulation of chemical reactions by removing the prohibitions imposed for reasons of electron angular momentum (spin) of reactants is considered. The physical and chemical mechanisms of this phenomenon are discussed. The nature of spin catalysts, the quantitative measure of catalytic effects and the types of chemical reactions susceptible to spin catalysis are considered. The bibliography includes 37 references.

I. Spin catalysis as a new chemical phenomenon

Spin catalysis consists of stimulation of chemical reactions by changing the electron angular momenta (spins) of the reactants. This phenomenon originates from the fundamental law of spin conservation, *viz* ., only those reactions are allowed in which the total spin of the products is identical to the total spin of the reactants; all other reaction channels are strictly forbidden.

The physical sense and role of spin catalysis consist of eliminating the spin forbiddenness, changing the reactant spins and opening reaction channels closed for spin reasons. These functions are performed by a spin catalyst, *viz*., a species with its own electron spin (an atom, radical or ion). When interacting with the reaction system, the catalyst combines its own spin with those of reactants; in such a united spin system, the initially closed reaction channels are opened, *i.e*, spin-allowed.[1,2]

Like other kinds of catalysis, spin catalysis is a purely kinetic phenomenon: a catalyst modifies the reactivities of reactants thus increasing the reaction rate (often, by several orders of magnitude). Spin catalysis manifests itself at two levels: for barrierless reactions, the pre-exponential factor in the rate constant expression (the total cross-section of the reaction) increases, while for reactions with activation barriers the low-barrier channels can be opened and the activation energy can be lowered (together with the increase in the pre-exponential factor in the aforementioned equation).

Many examples of the effect of paramagnetics on the rate and direction of chemical reactions can be cited. The mechanism of these effects remained unclear and often even intriguing (*e.g*., the effect of local activation in paramagnetic polymers) for a long time.[3] It is since the discovery of the spin catalysis phenomenon in the last decade that these effects have been clearly understood.

II. Discovery of spin catalysis

The first reliable and unambiguous proof of the existence of spin catalysis[4] was obtained from studies on photolysis of optically active *d,l*-diphenylpentanone (DPP), the dissociation scheme of which was reliably established.

$$\mathrm{Ph(Me)CH\overset{\overset{\mathrm{O}}{\|}}{C}CH(Me)Ph} \overset{h\nu}{\rightleftharpoons}$$

$$\rightleftharpoons [\mathrm{Ph(Me)\dot{C}H\ \dot{C}OCH(Me)Ph}] \longrightarrow \text{products.}$$

Photodissociation of the ketone occurs in the triplet state, giving rise to a triplet radical pair of acyl and alkyl radicals, which can either recombine (following the triplet – singlet conversion) to yield the original ketone or dissociate to give free radicals which can undergo further transformation to the molecular products (predominantly through decarbonylation of the acyl radical). The inversion of the alkyl radical in the pair results in the loss of optical activity for the regenerated ketone. By separating the optical isomers into *d,l*- and *meso*-DPP and estimating their yields as a function of chemical conversion of the ketone, we can determine with a high accuracy the probability of recombination of the radical pair (P_r).

This method proposed for measuring the cage recombination[5] was used in determination of P_r for DPP decomposition in benzene at 20 °C. Under these conditions, the value of P_r turned out to be very small, *viz.,* only ~ 0.03 (3%). Hence, the spin prohibition for recombination of triplet pairs is strictly fulfilled. (For comparison, it may be mentioned that the probability of cage recombination of similar singlet pairs is 10 – 20 times greater.)

The following fact was quite unexpected: in the presence of such a strong scavenger of carbon-centred radicals as the stable iminoxyl radical TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl),

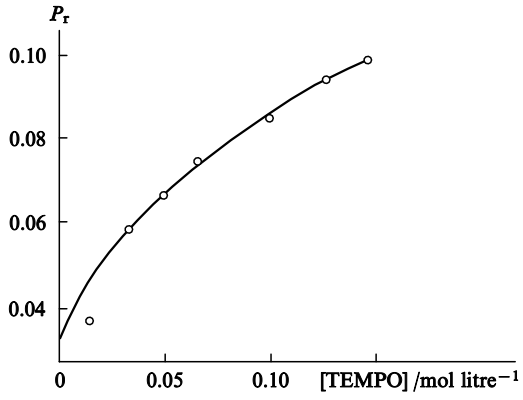

Figure 1. Probability of recombination of a triplet radical pair formed in the DPP photolysis as a function of concentration of TEMPO.[4] Points correspond to experiment, line corresponds to calculations.

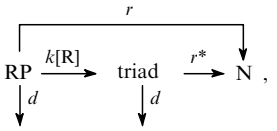
the probability of recombination P_r increased with the increase in its concentration (Fig. 1).[4] This result contradicted the fact that in the presence of different strong but diamagnetic scavengers (*e.g.,* dodecanethiol) the P_r value decreased with an increase in the scavenger concentration. It is evident that the paramagnetic nitroxide catalyses the recombination of radicals; moreover, its catalytic function prevails over the traditional function of a potent radical scavenger.

The increase in P_r with an increase in the TEMPO concentration (see Fig. 1) implies that two spin-conversion channels coexist for a radical pair, namely, a direct channel induced by magnetic interactions within the pair (this provides only 3% of recombination) and a catalytic one. The contributions of these channels can be assessed quantitatively by analysing the following kinetic scheme:



which takes into account both direct recombination of the pair to yield the product N (*meso*-DPP in the case of *d,l*-DPP) and catalytic recombination. The latter involves the integration of an iminoxyl radical R into the radical pair RP with the diffusion rate constant k, which is followed by spin conversion to give N. The meanings of constants r, r^* and d in the scheme are evident.

The following expression was derived[6] for such a scheme:

$$P_r = \frac{r}{r + d + k[R]} + \frac{r^*}{r^* + d}\,\frac{k[R]}{d + k[R]}. \qquad (1)$$

The terms in this equation define the contributions to the total probability of recombination made by the two channels, namely, a direct noncatalytic channel (for $[R] = 0$) and a catalytic channel *via* spin triads. The contributions are formed independently; the former channel defines the ratio $r/d = 3.4 \times 10^{-2}$, from which it follows that $r \ll d$. A numerical analysis of the catalytic contribution carried out by a trial-and-error procedure gives a stable solution at $d = 1.8 \times 10^8$ s^{-1}, $r = 6 \times 10^6$ s^{-1} and $r^* = 3.9 \times 10^7$ s^{-1}. For these parameters, the calculated P_r values coincide with those found experimentally (see Fig. 1) for all concentrations of the radical-catalyst.

The ratio for rate constants of catalytic and direct recombination r^*/r is 6.5, *i.e.,* the recombination rate constant for a given radical pair in the radical triad (in the presence of nitroxide as the third partner) is almost an order of magnitude higher than the recombination rate constant of the original (without nitroxide) radical pair. In other words, the third radical strongly catalyses the recombination of this pair, thus accelerating its conversion.

Such a remarkable conversion of a radical scavenger into a catalyst is the result of competition between the long-range potential responsible for spin exchange (and spin conversion) and the short-range potential of chemical bond formation. This effect is illustrated in Fig. 2: at an encounter between two radicals, namely, a catalyst and a partner of the pair, the exchange interaction of their unpaired electrons and spin conversion can begin even at great distances (l_{ex}), much larger than the distance required for the formation of a chemical bond (l_{ch}); the latter is formed at the Lennard-Jones contact of of rendezvous partners. In other words, sufficient overlap of wave functions, which induces the spin exchange, occurs long before the chemical contact of partners. Such a coordinate difference between two processes, namely, the spin exchange and the chemical reaction, is explained by their different energy scales: the exchange interaction frequency sufficient for spin conversion is of the order of magnitude of $10^8 - 10^{10}$ Hz, whereas chemical interaction is significant only at an exchange potential of no less than kT, *i.e.*, several orders of magnitude larger.

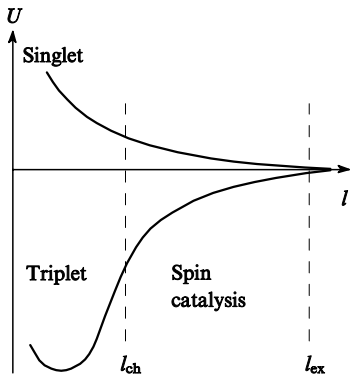


Figure 2. Potential energy (U) of triplet and singlet states of a radical pair as a function of the distance between unpaired electrons that form a chemical bond.

The relationship $l_{ex} > l_{ch}$ means that spin exchange is much more efficient than the reaction and its rate constant exceeds the cross-section of the chemical reaction. The efficiency of spin exchange (and spin catalysis) depends on details characterising the passage of the radical partners through the $l_{ex} - l_{ch}$ region (the time of their residence in this region, orientation dynamics, the extension of their orbitals and their spin delocalisation through solvent molecules).

Experiments on spin relaxation of muon-substituted radicals,[7] the transfer of spin polarisation between radicals[8–10] and other studies[11] directly confirmed the validity of the $l_{ex} > l_{ch}$ relationship. This problem is beyond the scope of this review and is not discussed below. Note that it is this relationship $l_{ex} > l_{ch}$ that is the key to the interpretation of spin catalysis as a chemical phenomenon; that is why organic paramagnetics are much more efficient spin catalysts than the chemical reactants.

III. Theory of spin catalysis

In fact, the theory of spin catalysis is a theory of spin states and spin transitions in multispin systems, namely, spin triads (where the third spin is that of the catalyst), four-spin systems (where the catalyst carries two spins, *e.g.,* an oxygen molecule or a Pr^{3+} ion), *etc.* The comprehensive theory of spin catalysis comprises two parts, namely, a static one, which studies new wave functions and spin states, and a dynamic one, which considers evolution of both the spin states and their population, and also time profiles. Both

parts are essential for the understanding of the physics of this phenomenon, purposeful selection of spin catalysts and prediction of the scope and limitations of catalysis.

1. Three-spin system

The three-spin system is a theoretical model of a radical triad (R^1,R^2,R^3), in which one of radicals (let it be R^3) is a spin catalyst, while the others, *i.e.*, R^1 and R^2, are the components of the reacting system, *e.g.*, a radical pair (note that these two spins can also pertain to any chemical bond which reacts in the presence of a spin catalyst, *e.g.*, to the π-bond of an alkene in its *cis–trans*-isomerisation or a carbene). Let the reacting spin pair (R^1 and R^2) be in the triplet state; the reaction product R^1R^2 is formed by recombination of the (R^1,R^2) pair in the singlet state. Hence, we have to find the probability of formation of R^1R^2 under the action of the spin of the third radical R^3. (Note that the problem is merely inversed if the original reacting spin pair is in the singlet state.)

If we neglect the Zeeman and hyperfine electron–nuclear interactions, the spin Hamiltonian of the triad can be presented as follows:[12]

$$H = -J_{12}(1/2 + S_1S_2) - J_{13}(1/2 + S_1S_3) - J_{23}(1/2 + S_2S_3). \quad (2)$$

This expression contains only exchange energies J_{ij} for pairs R^i and R^j ($i \neq j$; $i, j = 1, 2\ 3$); S_i and S_j are spin operators of spins i and j. Each spin in a triad has two spin states, so that the total number of states in the triad is eight (2^3). The exchange interaction (the spin-dependent part of the Coulomb interaction) splits these states into two groups: four quartet states Q with the total spin $S = 3/2$ and spin projections $S_z = \pm 3/2, \pm 1/2$ and four doublet states D and D' with the total spin of each state $S = 1/2$ and projections $S_z = \pm 1/2$. The spin functions of all four states are as follows:

$$|Q_{+3/2}\rangle = \alpha\alpha\alpha, \quad (3a)$$

$$|Q_{+1/2}\rangle = 3^{-1/2}(\alpha\alpha\beta + \alpha\beta\alpha + \beta\alpha\alpha), \quad (3b)$$

$$|Q_{-1/2}\rangle = 3^{-1/2}(\beta\beta\alpha + \beta\alpha\beta + \alpha\beta\beta), \quad (3c)$$

$$|Q_{-3/2}\rangle = \beta\beta\beta, \quad (3d)$$

$$|D_{+1/2}\rangle = 6^{-1/2}(\alpha\alpha\beta + \alpha\beta\alpha - 2\beta\alpha\alpha), \quad (4a)$$

$$|D_{-1/2}\rangle = 6^{-1/2}(\beta\beta\alpha + \beta\alpha\beta - \alpha\beta\beta), \quad (4b)$$

$$|D'_{+1/2}\rangle = 2^{-1/2}(\alpha\alpha\beta - \alpha\beta\alpha), \quad (4c)$$

$$|D'_{-1/2}\rangle = 2^{-1/2}(\beta\alpha\alpha - \beta\alpha\beta). \quad (4d)$$

These functions are eigenfunctions of energy and total spin; the energies of spin states are derived from the Schrödinger steady-state equation with the spin-Hamiltonian (2) and functions (3), (4)

$$E_Q = -(J_{12} + J_{13} + J_{23}), \quad (5)$$

$$E_D = 2^{-1/2}[(J_{12} - J_{13})^2 + (J_{12} - J_{23})^2 + (J_{13} - J_{23})^2]^{1/2}, \quad (6)$$

$$E_{D'} = -2^{1/2}[(J_{12} - J_{13})^2 + (J_{12} - J_{23})^2 + (J_{13} - J_{23})^2]^{1/2}. \quad (7)$$

Figure 3 illustrates the energy levels and spin transitions in a radical triad. In the quartet states, both the $R^1 + R^2$ recombination and scavenging reactions $R^1 + R^3$, $R^2 + R^3$ are spin-forbidden; these 'quartet' triads can only decompose due to diffusion or disappear due to some ' foreign' chemical reactions.

Of four doublet states in a triad, namely, $D_{\pm 1/2}$ and $D'_{\pm 1/2}$, only two ($D_{\pm 1/2}$) correspond to the singlet state of the reaction pair (R^1,R^2), *i.e.*, the $R^1 + R^2$ recombination occurs only in this state; the $D'_{\pm 1/2}$ state corresponds to the triplet state of the (R^1 , R^2) pair, for which recombination is forbidden. This is the point where spin catalysis is 'switched on', as a result of which the triads pass from non-reactive states D' to chemically active states D. This process is illustrated in Fig. 4. Let the exchange interaction be switched in the (R^1,R^2 ,R^3) triad between one of reacting pair partners, *e.g.*, R^2, and the spin catalyst R^3 . Then, the non-reactive state $D'_{+1/2}$ (corresponding to the triplet state of the reacting pair) is converted into a chemically active state $D_{+1/2}$ in which the (R^1,R^2) pair is a

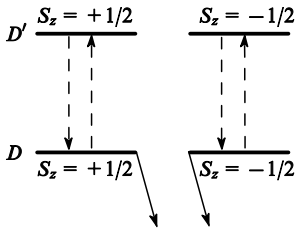

Figure 3. A scheme illustrating the doublet spin states of a radical triad. State D' corresponds to the triplet (chemically inert) state of the radical pair chosen (R^1 ,R^2); state D corresponds to the singlet (chemically active) state of the pair. Dashed lines indicate spin-catalytic $D' - D$ transitions.

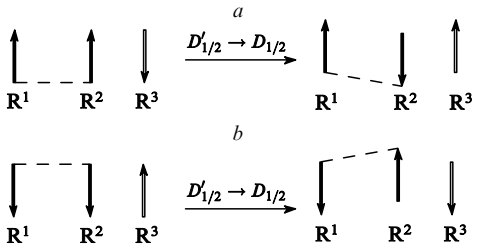

Figure 4. A scheme illustrating $D' - D$ transitions.
Triplet states of the radical pair (R^1,R^2) are transformed into the singlet state upon the interaction with a spin catalyst R^3; (*a*, *b*) are explained in the text.

singlet and hence can undergo recombination (see Fig. 4 *a*). This occurs due to the combining of S_2 and S_3 spins and their exchange (the mechanism of this process is shown below).

A spin catalyst converts $D'_{-1/2}$ into $D_{-1/2}$ by the same mechanism (see Fig. 4 *b*) and populates the chemically active singlet state of the (R^1,R^2) pair. Note that in these spin-catalytic processes neither the total spin S, nor its projection S_z, change. It is only the spin exchange within the triad that occurs in such a way that the chosen pair (R^1 ,R^2) undergoes a triplet–singlet conversion and becomes chemically active.

The spin exchange mechanism between a spin catalyst and an (R^1,R^2) pair partners can be clearly demonstrated in terms of the vector model. Let there be a triad in the $D'_{+1/2}$ state (Fig. 5 *a*), in which the chosen pair (R^1, R^2) is in a non-reactive triplet state (both its spins are oriented upwards, while the catalyst spin is directed downwards). Now, let the exchange interaction J_{23} between the radicals R^2 and R^3 be switched (say, as a result of their approach to one another within the triad). This interaction induces the precession of spins S_2 and S_3 around the total spin vector $S_2 + S_3$ (Fig. 5 *b*). In time τ such that $J_{23\tau} = \pi$, reorientation of S_2 and S_3 spins occurs (Fig. 5 *c*). Now, the triad is in the $D_{+1/2}$ state, *i.e.,* the (R^1 , R^2) pair becomes a singlet and is ready to react: its spins S_1 and S_2 are oppositely oriented, while the catalyst

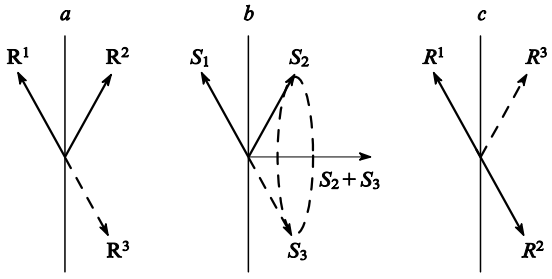

Figure 5. A vector model of spin conversion for a radical pair (R^1,R^2) from triplet to singlet state, induced by a spin catalyst R^3; (*a*, *b*) are explained in the text.

spin is oriented upwards. Moreover, both the triad total spin and spin projections are retained, whereas the chemical activity of the reacting system chosen changes dramatically.

2. Four-spin system

The spin dynamics in a four-spin triad (R^1,R^2,K) formed by a radical pair (R^1,R^2) and a third two-spin partner K, which may represent a biradical, a triplet molecule (*e.g*, O_2), a triplet carbene or a metal ion, resembles in principle the spin dynamics in the three-spin system.

Spin states of a four-spin system (the total number of states $2^4 = 16$) differ in energy, in total spin S and its projection S_z to the z axis and can be divided into three groups, *viz.,* five quintet states with the total momentum $S = 2$, nine states with the total momentum $S = 1$ (triplet states) and two four-spin singlet states ($S = 0$). Being induced by exchange interactions, the spin-catalytic triplet – singlet conversion of the (R^1,R^2) radical pair is only possible for the group of triplet states. The conservation laws for the total spin of the triad and the total spin of the catalyst prohibit the triplet – singlet conversion of the radical pair for triads in quintet and singlet states. The general theory of spin catalysis in the four-spin system was discussed in Ref. 13.

IV. Two mechanisms of spin catalysis

Two mechanisms were proposed for spin catalysis: the first was discussed in detail in the previous section and is realised due to the exchange (nonmagnetic) interaction of electron spins; the second mechanism is purely magnetic and realised due to interaction of spins as the magnetic dipoles.

When discussing the exchange mechanism in the previous section, we ignored the Zeeman and hyperfine interactions by assuming the absence of the magnetic field and magnetic nuclei in reactants. Including the Zeeman and hyperfine interactions does not affect the exchange mechanism. In this case, the energy levels of all eight states are modified only to a small extent, and additional channels of quartet – doublet spin conversion appear. Transitions $Q - D$ and $Q - D'$ forbidden in the absence of hyperfine coupling become partly allowed (like triplet – singlet transitions in isolated radical pairs). They create additional channels for populating the D and D' states of Q quartets. Populating these states increases the efficiency of spin catalysis; moreover, additional nuclear spin selectivity of spin-catalytic reactions and isotope fractionation are observed as side effects.[14] Spin transitions induced by hyperfine coupling can be reliably calculated in terms of spin chemistry (although it should be mentioned that these transitions are not directly related to spin catalysis).

Another mechanism of spin catalysis is purely magnetic and induced by the dipole – dipole interaction of electron spins. In contrast to the exchange mechanism, which stimulates only transitions between D and D' states, the dipole mechanism induces all transitions including $Q - D$ and $Q - D'$; moreover, the total spin and its projections are also changed (recall that both spin and its projections are retained for the case of exchange mechanism).

There is a clear criterion which allows distinguishing these two mechanisms: the exchange-induced spin catalysis is determined by the angular momentum (spin) of the catalyst, whereas the dipole-induced spin catalysis is unambiguously defined by the catalyst magnetic moment. The relative contributions of these mechanisms depend on the time of magnetic relaxation of the catalyst (T_1) and molecular dynamics, which modulates both spin and dipole interactions. Analysing the experimental results, we can see that the exchange mechanism contribution to spin catalysis prevails; the dipole effect is insignificant and operates only in exceptional cases.

V. Spin catalysis by radicals and high-spin molecules

The first clear example that opened up the spin catalysis as a new phenomenon in chemistry was discussed above (see Section III). Later, the spin-catalytic effect of the iminoxyl radical TEMPO in the recombination of a pair of isopropyl and acylisopropyl radicals was studied for photolysis of diisopropyl ketone by the method of chemically induced dynamic nuclear polarisation (CIDNP).[15]

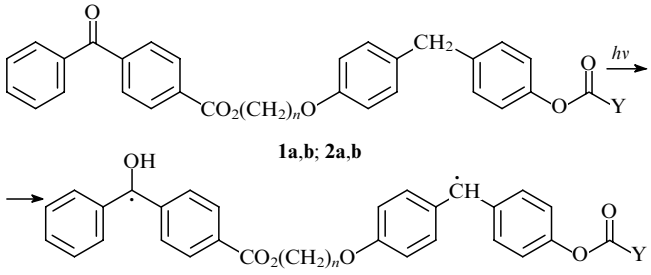
Spin catalysis is also performed by biradicals. Interaction of alkyl radicals R with nitroxide biradicals B proceeds in two steps

$$B + R \xrightarrow{2k_B} M,$$

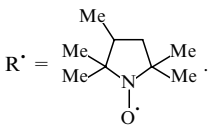
$$M + R \xrightarrow{k_M} MR.$$

The addition of R to any terminus of the biradical transforms it to a monoradical M, which in turn adds to another alkyl radical; the rate constants for these two reactions (k_B and k_M) should be strictly equal, because the radical fragments in the biradicals studied are absolutely identical. However, it turned out that the ratios k_B/k_M reliably measured for different biradicals and various radicals R always exceed unity [16] being equal to 1.1 – 1.5, *i.e*., the addition of the first radical occurs 1.1 – 1.5 times faster as compared with the second radical. It is evident that one of the radical fragments operates as the reactant, while the other operates as the spin catalyst accelerating the reaction of the former fragment. It is also clear that the catalysis proceeds for coiled conformations of flexible-chain biradicals — it is here that chains and nitroxide fragments are closer to one another and can form a spin triad with the reacting radical R. According to rough estimates, the fraction of coiled conformations is $\sim 10\%$; bearing in mind such a population of spin triads, we can assess the ratio of rate constants for catalytic and noncatalytic reactions, *viz*., $r^*/r \approx 2 - 5$ (this agrees with much more precise results shown in Section II).

The same result was obtained by Hayashi *et al*.;[17] with the only difference that all three triad partners were chemically bound within a single molecular system. In the photolysis of ketones, biradicals in the triplet state were generated by an intramolecular reaction of hydrogen abstraction (if Y = Me); for ketones where Y was a paramagnetic substituent (nitroxide fragment), this reaction generated triradicals.



Compound	*n*	Y
1a	8	Me
1b	8	R˙
2a	2	Me
2b	2	R˙



By studying the dynamics of intramolecular cyclisation of bi- and triradicals, it was discovered [17] that cyclisation rate constants in a triradical exceed similar constants for biradicals by an order of magnitude, although both cyclisation reactions are absolutely chemically identical. This is an example of spin catalysis where the third spin (on the nitroxyide fragment) induces the spin conversion of the triplet radical pair involved in cyclisation.

Similar examples of catalysis were observed for electron transfer reactions;[18] triplet radical pairs were found to be generated during photolysis. Their disproportionation (the reverse electron transfer) was dramatically accelerated in the presence of a spin label, *viz.*, a nitroxide fragment chemically attached to the radical-ion pair. In this case (as in the previous one), nitroxide was not involved in the reaction at all and served only as the spin catalyst inducing the triplet–singlet conversion of the reacting radical ion pair.

The function of the spin catalyst can be performed not only by bi- and polyradicals, but also by different high-spin molecules, *e.g.*, O_2. Thus catalytic effects of iminoxyl radicals and oxygen were observed in the reactions of 7-silanorbornadiene and dimethylsilane (carbene).[19—21]

VI. Paramagnetic ions as spin catalysts

Like iminoxyl radicals, paramagnetic ions can also catalyse barrierless reactions of radical recombination. An analysis of the spin-catalytic functions of ions was performed on the example of recombination of a triplet radical pair built of two benzyl radicals one of which is *para*-substituted in the phenyl ring; non-symmetrical dibenzyl represented the recombination product.[22] Figure 6 shows the dependence of its yield (the cage effect or recombination probability) on the lanthanide ion concentration in the micellar solution. This dependence is the same as for radicals (see Fig. 1); moreover, the spin-catalytic effect of ions is adequately described by Eqn (1). Figure 7 shows the rate constant ratio of catalytic and noncatalytic recombination r^*/r as a function of spin S_i; a clear correlation between the spin catalyst efficiency and its electron spin can be traced, which unambiguously suggests that the catalysis is governed by the exchange interaction between the radical pair and a paramagnetic ion. No correlation with the magnetic moments of ions was revealed, which additionally confirms the dominating role of the exchange mechanism in the catalysis.[23]

Figure 7 also shows the rate constant for cyclisation of a triplet biradical obtained by photodissociation of 2,10-diphenylcyclododecanone[24] as a function of the catalyst (lanthanide ion)

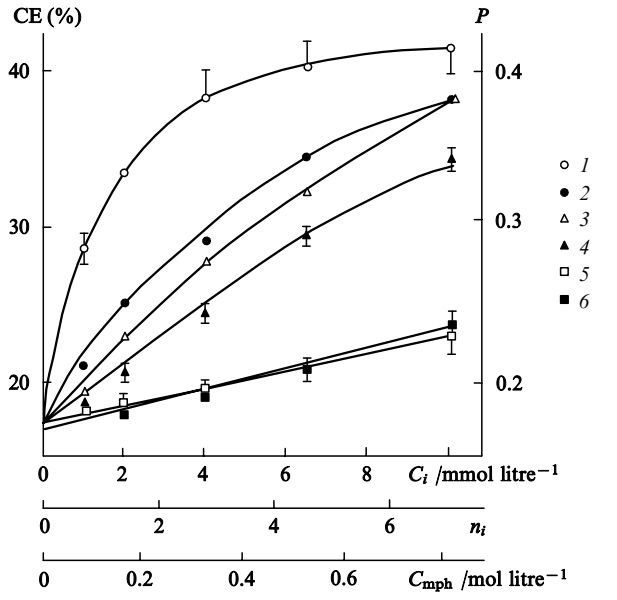


Figure 6. Dependences of the cage effect (CE) and the probability of recombination P for a triplet pair of benzyl radicals in micelles on the concentration of lanthanide ions. C_i is the concentration of ions in the micellar solution, C_{mph} is their concentration in the micellar phase; n_i is the average number of ions in each micelle; (*1*) $GdCl_2$, (*2*) $SmCl_3$, (*3*) $NdCl_3$, (*4*) $EuCl_3$, (*5*) $LaCl_3$, (*6*) $LuCl_3$.

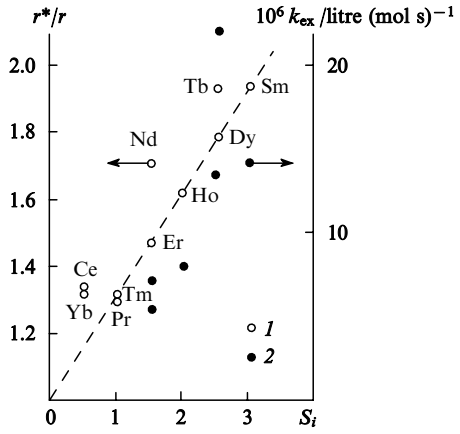

Figure 7. Dependences of (*1*) the rate constant ratio of catalytic and noncatalytic recombination of a radical pair ($PrCH_2$ CH_2Ph) and (*2*) the rate constant of catalytic recombination of the biradical on the catalyst electron spin (S_i).

spin. This dependence is also linear, which confirms the dominating contribution of the exchange mechanism of spin catalysis.

In addition to lanthanide ions, transition metal ions were also studied as spin catalysts of recombination of triplet pairs formed upon photolysis of naphthoquinones;[25] these ions proved to be potent catalysts, *viz.*, at the same level with Gd^{3+}, the best catalyst among lanthanides.

Table 1 shows the data on the efficiency of spin catalysts studied, which is represented as the ratio of rate constants for catalytic and noncatalytic recombination of radicals.

Table 1. Efficiency of spin catalysts.

Spin catalyst	r^*/r	Spin catalyst	r^*/r
Pr^{3+}	1.28	Tb^{3+}	1.93
Tm^{3+}	1.31	Gd^{2+}	4.4
Yb^{3+}	1.31	Co^{2+}	4.4
Ce^{3+}	1.34	Cu^{2+}	4.4
Er^{3+}	1.47	Fe^{2+}	5.3
Ho^{3+}	1.62	Mn^{2+}	5.7
Nd^{3+}	1.71	Ni^{2+}	5.7
Dy^{3+}	1.78	Cr^{3+}	6.2
Sm^{3+}	1.93	nitroxide	6.3

Diamagnetic ions (Sc^{3+}, La^{3+}, Zn^{2+}) or ions with zero angular momenta (Eu^{3+}) exhibit no catalytic effects. Lanthanide ions with unpaired electrons located in deep 4f electron shells and hence strongly shielded by upper electron layers are catalysts of low efficiency; the strongest catalyst is Gd^{3+} ($r^*/r = 4.4$). Note, by the way, that the latter ion drops out of the dependence shown in Fig. 7, its efficiency being higher than that predicted by the exchange mechanism. Probably, this is precisely that extraordinary case where the dipole-magnetic mechanism of spin catalysis operates together with the exchange mechanism.

Ions of transition metals with unpaired electrons in less shielded 3d electron shells display a catalytic activity substantially higher than that of lanthanide ions. Their activity increases systematically in the series from Co^{2+} to Cr^{3+} and approaches the highest value corresponding to the iminoxyl radical with an unpaired electron in the outer shell.

The quantitative hierarchy of spin catalysts with respect to their spin-catalytic activity agrees with a theory that predicts that the rate of spin conversion in a triad should be proportional to the exchange interaction energy of the catalyst with any partner of the

radical pair. Hence, it unambiguously follows that spin carriers with 'outer' unpaired electrons (radicals, oxygen) are much more potent spin catalysts than those spin carriers whose unpaired electrons are 'hidden' within the electron shell. However, being potent catalysts, the former function also as reactants (radical scavengers), whereas the latter are weak catalysts and as a rule chemically inactive, which is their practical advantage. In essence, the strategy of spin catalysis is to find a compromise between these two functions of spin catalysts, *viz*., to serve as a catalyst or a chemical reactant. This is not difficult to achieve by selecting suitable radicals or ions and varying their concentrations. Note that neither ionic radii nor the magnetic moments of ions are related to the catalytic activity. The absence of these dependences indicates that the exchange mechanism is the main driving force of spin catalysis.

VII. Spin catalysis in reactions with activation barriers

To this end, we analysed the spin catalysis in barrierless and low-barrier reactions such as recombination of radicals and disproportionation of radical ions. In reaction with activation barriers, spin catalysts not only increases the total reaction cross-section but also opens new earlier forbidden reaction channels.

A vivid example illustrating this idea is the spin catalysis of *cis*–*trans*-isomerisation of alkene derivatives. Rotation of one part of the molecule with respect to another by the angle π around the double bond occurs through a singlet channel but requires surmounting a high energy barrier ($\sim 50-60$ kcal mol^{-1}). The top of this barrier corresponds to the rotation angle $\pi/2$ where the parts of a molecule undergoing isomerisation are orthogonal to one another. However, there is another reaction trajectory along the reaction coordinate (the rotation angle φ) on the potential-energy surface of the triplet state of the molecule. At angles $\varphi = 0$, π, this surface lies well above the ground state energy; however, at $\varphi = \pi/2$ it has minima and lies well below the top of the singlet channel barrier. The overlap of singlet and triplet channels occurs at angles $\varphi \approx 40-50^\circ$ and $130-140^\circ$.

Kinetics of liquid-phase *cis*–*trans*-isomerisation of dimethyl maleate to dimethyl fumarate was studied.[26] Direct isomerisation proceeds slowly with a rate constant

$$k_d = 10^5 \exp\left(-\frac{27\,000}{RT}\right).$$

In the presence of stable iminoxyl radicals, isomerisation sharply accelerates, which is accompanied by neither their scavenging nor the formation of side products; moreover, the isomerisation rate is proportional to the concentration of iminoxyl radicals. For the unit concentration of iminoxyl (1 mol litre^{-1}), the rate constant of catalytic isomerisation is as follows:

$$k_c = 10^{12} \exp\left(-\frac{27\,000}{RT}\right).$$

A comparison of k_d and k_s constants provides grounds for the unambiguous explanation of these results. First, the identity of activation energies and their low values indicate that both the catalytic and noncatalytic reactions cross the coordinate $\varphi = \pi/2$ through the triplet channel; the spin-allowed singlet channel is too high to be surmounted for energy reasons.

Second, the small pre-exponential factor in the rate constant expression of the noncatalytic reaction suggests that the triplet channel of direct reaction is spin-forbidden. This prohibition is removed only partly due to the spin–orbit coupling along the reaction coordinate. Then, the spin changeover with the transition from the singlet channel to the triplet one at angles $\varphi\,40-50^\circ$ and $130-140^\circ$ is compensated for by the changes in the orbital angular momentum. However, in molecules containing carbon atoms, the spin–orbit coupling is very weak; hence, the triplet channel remains virtually closed.

In the catalytic reaction, a spin catalyst removes the spin-prohibition and opens the triplet channel of isomerisation; the latter becomes allowed so that for the unit concentration of the catalyst the pre-exponential factor in the expression for the catalytic reaction rate constant increases by seven orders of magnitude as compared with the similar factor for the non-catalytic reaction. The three-spin system susceptible to spin catalysis is formed by the catalyst spin and two electron spins of the double bond, which are weakly coupled in the coiled conformation and resemble the spin of a radical pair. The exchange interaction of the catalyst with this spin pair affords their triplet–singlet conversion by switching the reaction from the high-energy singlet channel to the low-energy triplet one.

Evidence for the spin catalyst interaction with the double bond by the exchange mechanism was obtained by analysing the paramagnetic shifts and paramagnetic broadening of NMR lines for dimethyl maleate in the presence of iminoxyl radicals.[27] It was reliably established that dimethyl maleate forms weakly bound complexes with nitroxide (the binding energy of $1-2$ kcal mol^{-1}), in which the spin density is transferred from the radical to the ligand (dimethyl maleate).[28,29] It is in this complex that the three-spin system is formed and the spin-catalytic event occurs.

Numerous examples of catalysing the *cis*–*trans*-isomerisation of alkenes by atoms and paramagnetic molecules (Br, I, NO, O_2, *etc*.) are known. McConnel referred to this phenomenon as 'paramagnetic catalysis',[30,31] although its physical sense had not yet been fully understood. Particularly, for Br and I atoms it had been assumed that the catalysis is realised due to spin–orbit coupling in their complexes with alkenes. The internal spin–orbit coupling in these atoms is substantial, whereas the intermolecular interaction should be weak and incapable of sustaining the efficient spin conversion of the alkene double bond, which always seemed puzzling. Now, however, it is clear that paramagnetic catalysis is, in fact, purely by spin catalysis in which the electron spin plays the key role.

Spin catalysis as a phenomenon may prove to be much more common than it seems at present. Charge separation and water oxidation during photolysis, C–H bond activation in CH_4 by metal complexes, ethylene activation by atoms and clusters, dissociative adsorption on metals, the performance of peroxidases, catalases and other metal enzymes — in many complex reactions involving spin carriers the role of spin catalysis in selecting the reaction pathways can turn out to be significant. This cannot be claimed for all cases, but the possibility of this should never be ignored.[6,32–36]

VIII. Coherent spin catalysis

The triad spin state D' corresponds to the non-reactive triplet state of a radical pair chosen (see Section III). The probability of spin conversion of D' to D in which this pair is in the chemically active singlet state is determined by the solution of a nonstationary Schrödinger equation. This solution is as follows:

$$\rho_{ss}(t) = \left(\frac{\Delta J}{\omega}\right)^2 \sin^2\left(\frac{\omega t}{2}\right). \tag{8}$$

Here, $c_{ss}(t)$ is the probability that the pair is in the singlet state, ΔJ is the difference in exchange energies of the spin catalyst and each partner of the radical pair

$$\Delta J = |J_{13} - J_{23}|; \tag{9}$$

ω is energy splitting of the doublet states D' and D, which is determined by equations (6) and (7)

$$\omega = 2[(J_{12}-J_{13})^2 + (J_{12}-J_{23})^2 + (J_{13}-J_{23})^2]^{1/2}. \tag{10}$$

It follows from equation (8) that both conjugated processes, *viz*., the doublet–doublet evolution of the triad and the triplet–

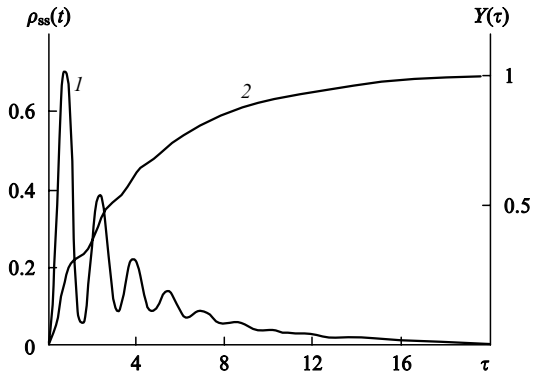

Figure 8. (*1*) Oscillating probability $\rho_{ss}(t)$ of the occurrence of (R^1,R^2) pair in the singlet state during its interaction with a spin catalyst R^3 and (*2*) the kinetics of accumulation of the recombination product.[37]

singlet conversion in the chosen pair of this triad, oscillate in time with a period $\mathbf{t} = \omega^{-1}$ (Fig. 8). In this case, both the total spin and its projection are retained.

The yield of reaction products (*e.g.*, as a result of recombination in ensembles of selected pairs) also oscillates in time with a frequency ω (Fig. 8). These oscillations (or quantum beats) can be observed in static triads with fixed distances between the partners, if the ensemble of these triads has been formed instantaneously and coherently, *i.e.*, in a fixed spin state and with the same phase. In such ensembles (or coherent wave packets), one can realise and observe the coherent spin catalysis with oscillating generation of the reaction product.[37]

A photosynthesis centre, *i.e.*, a molecular arrangement in which all the partners of a spin triad are rigidly organised, can serve as an example of a static triad. The photoinduced charge separation gives rise to a radical-ion pair, in which spin evolution is defined by the exchange interaction with Fe^{3+} ions as spin catalysts.

In non-rigid triads, the molecular motion induces random and incident changes in the distances between partners and modulates the exchange interaction, thus varying the frequencies of quantum beats. Ultimately, this motion modulates the phases and rates of spin evolution, upsetting coherency and suppressing quantum beats. The coherent spin catalysis has not yet been observed experimentally; however, it would be worthwhile to pursue its research in order to understand the structure and dynamics of spin triads.

* * *

Spin catalysis is the universal phenomenon typical of multispin molecular systems. This is observed in chemical reactions (both barrierless and with activation barriers), biological systems (primary light-accumulating reactions in photosynthesis centres, redox enzymes), in physical phenomena (the recombination of spin-oriented hydrogen atoms, which prevents their Bose-condensation, the spin conversion of positronium, the paramagnetic quenching of excited molecules). Scientists are often even unaware of its existence, although its abundance is much wider than seems at present. Any process of generation of radical or radical-ion pairs during catalytic or thermal decomposition or electron transfer can be accompanied by spin catalysis, so that such chemical catalysts as metal ions or metal complexes (especially, bi- and polynuclear) can also operate as spin catalysts. Such a coexistence of spin and chemical catalysis is also true for biocatalytic processes. Spin catalysis can also occur in heterogeneous processes such as hydrogenation, isomerisation, oxidation on zeolites, metals, oxides, *etc*.

The review was written with a financial support of the Russian Foundation of Basic Research (Project No. 02-03-32753), Program 'Integration', Federal Program 'Leading Scientific Schools of Russia' (Project NSh-1221.2003.03) and programs of the Division of Chemistry and Materials Science and the Presidium of the Russian Academy of Sciences.

V.	Oxoalkoxides as true precursors of oxide phases	1060

Abstract. The review surveys the pathways of formation of crystalline oligomeric oxoalkoxides $M_mO_n(OR)_p$, which are products of partially controlled (or uncontrolled) hydrolysis, oxidation, thermal decomposition of mono- and bimetallic alkoxides of the ortho series $M(OR)_n$ and $M_mM'_n(OR)_p$ or elimination of ethers from these compounds. The physicochemical properties of oxoalkoxides (solubility, the behaviour in solutions, volatility, *etc*.) differ considerably from the properties of the corresponding alkoxides. Hence, oxoalkoxides can be considered as immediate precursors of oxide materials produced by sol – gel technology. The $M_mO_n(OR)_p$ compounds are classified according to the sizes of associates. The crystal chemistry of alkoxides is discussed. The bibliography includes 249 references.

I. Introduction

Polymeric metal oxoalkoxides (OA) of the general formula $M_mO_n(OR)_p$, which are amorphous products of partial hydrolysis or thermolysis of alkoxides, have been used for years as heat-resistant insulating coatings, elastomers, resins for the production of plastics, lacquers, paints, enamels, *etc*. Andrianov,[1] who has made a considerable contribution to this area of chemistry, considered OA as 'polymers with inorganic main chains enclosed by OR groups',

$$-M(OR)_2-O-M(OR)_2-O-M(OR)_2-O-.$$

In the late 1950s, Bradley[2] studied hydrolysis of titanium alkoxides (and, in part, of zirconium alkoxides) primarily by ebullioscopy. He assigned structures to hydrolysis intermediates (which either occur in solution or exist in the amorphous state) based on his 'structural theory', according to which a metal atom has the maximum coordination number in the case of the lowest degree of association of $[MO_n(OR)_p]_x$. However, Bradley always emphasised that it is necessary to establish the structures by direct methods for solving this problem.

The present review is devoted to oligomeric crystalline oxoalkoxides belonging to a new class of oxo-bridged molecular compounds. These compounds have attracted considerable interest because they are immediate precursors in the 'sol – gel technology' of oxide materials, which is based on hydrolysis of alkoxides in organic solvents.[3]

$$M(OR)_n \xrightarrow{H_2O} MO_x(OR)_{n-2x} \xrightarrow{H_2O} M_2O_n\cdot y\,H_2O \xrightarrow[-H_2O]{} M_2O_n$$

The sol – gel method has assumed great importance, as evidenced by regular international conferences devoted to this problem. Beginning in 1981, information presented at these conferences was published in *J. Non-Cryst. Solids* and *J. Sol-Gel Sci. Technol*. The physicochemical fundamentals of various processes of sol – gel technology were discussed in the comprehensive monograph by Brinker and Scherer.[4] Applied aspects of this technology were covered in two collections of articles.[5, 6]

A substantial advantage of the alkoxide-based sol – gel technology is the possibility of deep purification of the starting compounds. Besides, mono- and bimetallic oxides are prepared as amorphous substances consisting of highly reactive nanosized particles. This allows one to perform ceramic sintering at lower temperatures compared to those used in alternative technologies. In the synthesis of complex oxides, the use of alkoxide solutions makes it possible to overcome the main difficulty of alternative methods, *viz*., the necessity of homogenising various metals at the molecular level. Subsequent hydrolysis and thermal treatment of such samples afford submicron particles. In particular, this method enables one to prepare particular composites inaccessible by direct reactions of oxides. Data on the compositions and structures of real particles involved in these processes are required to elucidate the mechanisms of formation of simple and complex oxide phases and to optimise the synthesis of materials based on these phases.

The class of oligomeric crystalline oxoalkoxides was discovered by the X-ray diffraction method. In the late 1960s, this method was used for establishing the structures of the partial hydrolysis products of titanium, niobium and zirconium alkoxides, *viz*., $Ti_7O_4(OEt)_{20}$,[7] $Nb_8O_{10}(OEt)_{20}$,[8] and $Zr_{13}O_8(OMe)_{36}$ (see Ref. 9) (Fig. 1 *a* – *c*). It was found that all oxo ligands in these molecules serve as bridges (even the Nb complex contains no terminal 'yl' oxygen atoms, which are typical of compounds with this metal). Oxo bridges were considered as units that formed upon condensation of two hydroxy groups resulting from the replacement of an OR group in the first step of hydrolysis.

X-Ray diffraction studies of OA revealed new molecules of various sizes and with different structures, which have greatly extended our knowledge of the crystal chemistry of metal alkoxo

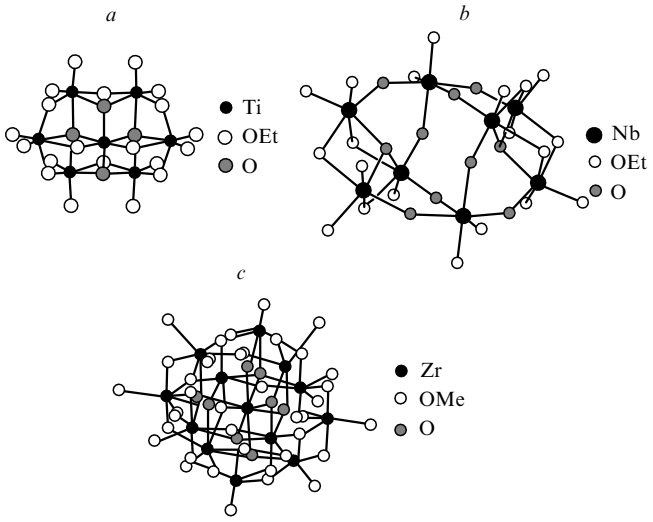

Figure 1. Metal–oxygen cores in the structures of $Ti_7O_4(OEt)_{20}$ (*a*),[7] $Nb_8O_{10}(OEt)_{20}$ (*b*)[8] and $Zr_{13}O_8(OMe)_{36}$ (*c*).[9]

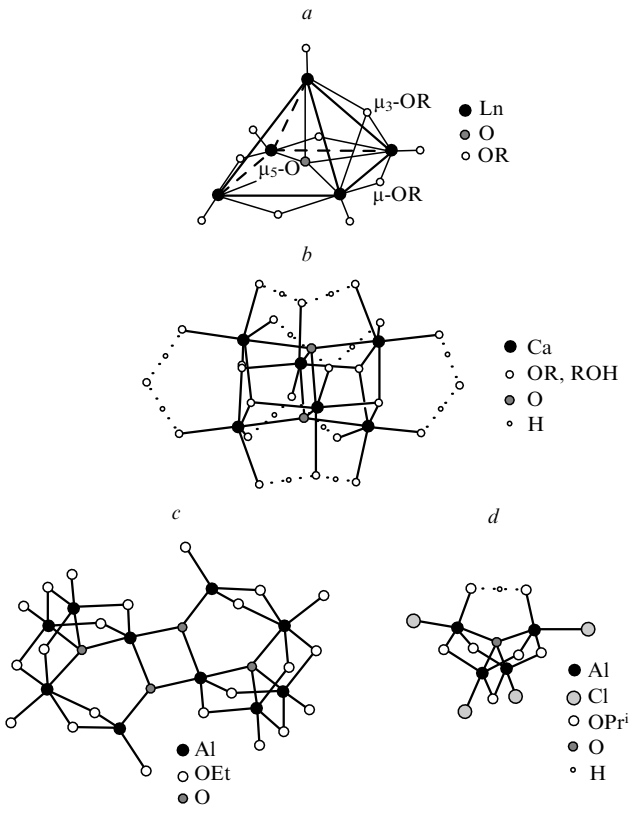

Figure 2. Metal–oxygen cores in the structures of $[M_5(\mu_5\text{-}O)(OR)_{13}]$ (M = Sc, Y, Ln, In, Al, Fe) (only one of four μ_3-OR groups is shown) (*a*),[10–15] $[Ca_6(\mu_4\text{-}O)_2(OEt)_8(EtOH)_{14}]$ (*b*),[16] $[Al_{10}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(OEt)_{22}]$ (*c*)[17] and $[Al_4(\mu_4\text{-}O)(OPr^i)_6(Pr^iOH)Cl_4]$ (*d*).[18]

complexes. It appeared that many crystalline compounds, which were initially considered as alkoxides of the ortho series $M(OR)_n$, contain, in reality, oxo ligands generally with high dentate numbers. Examples of such compounds are 'isopropoxides' of rare-earth elements[10–14] and In,[14] 'iron(III) ethoxide'[15] (these compounds, in reality, contain the pentadentate oxo group $[M_5(\mu_5\text{-}O)(OR)_{13}]$) (Fig. 2 *a*), 'calcium ethoxide disolvate' $[Ca_6(\mu_4\text{-}O)_2(OEt)_8(EtOH)_{14}]$ (Fig. 2 *b*),[16] and 'crystalline aluminium ethoxide' $[Al_{10}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(OEt)_{22}]$ (Fig. 2 *c*).[17] The '$AlCl(OPr^i)_2$' compound, which is a well-known catalyst and reducing agent used in organic chemistry, consists of the tetrahedral $[Al_4(\mu_4\text{-}O)(OPr^i)_6(Pr^iOH)Cl_4]$ molecules[18] (Fig. 2 *d*). Due to inclusions of organic solvents in the intercrystallite space and the formation of numerous solvates of OA with alcohols or hydrocarbons, the results of chemical analysis for OA are no different from those for $M(OR)_n$. For this reason, the present review deals only with compounds whose compositions were confirmed by the data on their structures. These compounds are listed in Tables 1–10 in order of increasing nuclearity. Unfortunately, space does not permit a discussion of abundant information on heteroleptic complexes, such as oxo alkoxo carboxides, oxo alkoxo β-diketonates, *etc*.

II. Pathways of formation of oxoalkoxides from alkoxides

There are several main pathways of formation of oxo ligands in alkoxide molecules. Among them are hydrolysis and oxidation, thermolysis, desolvation of solvates $M(OR)_n \cdot m\,L$ and decomposition accompanied by elimination of ethers. Only the first two above-mentioned processes can be controlled. Although some authors persist in considering OA only as products of uncontrolled hydrolysis (and often do not discuss the origin of oxo

groups at all), the conditions of formation of the latter indicate that various decomposition processes can occur. In most cases, the appearance of oxo groups is associated with uncontrolled decomposition of alkoxides *in situ* in attempting to synthesise these compounds according to conventional methods.

Apparently, the most stable forms of OA exist in each system. For instance, single crystals of $Nb_8O_{10}(OEt)_{20}$ and $Ti_7O_4(OEt)_{20}$ prepared according to two procedures, *viz*., by the reactions of water with ethoxides or upon spontaneous decomposition, were demonstrated to be identical. For example, the $Nb_8O_{10}(OEt)_{20}$ compound was formed upon prolonged storage of liquid samples of $NbO(OEt)_3$ in tubes (the process is accompanied by elimination of Et_2O),[151] whereas $Ti_7O_4(OEt)_{20}$ was prepared by heating solutions of $Ti(OEt)_4$ in an autoclave to 100 °C,[142] *i.e*., in the complete absence of moisture.

Of special note is the synthesis of OA by alcoholysis of metal oxides or the synthesis of oxo metallates by exchange reactions with compounds which already contain oxo groups. Examples are the synthesis of $(MoO)_2O[(CMe_2)_2O_2]_2[O(CMe_2)_2OH]_2$ from MoO_3 and pinacol,[28,29] the formation of $[R_4N]_2\cdot[(MoO_2)_4O_2(OMe)_6]$ by methanolysis of metamolybdate $[Bu_4N]_4Mo_8O_{26}$,[78] the preparation of $[Bu_4N]_3[Nb_2W_4O_{18}(OR)]$ (R = Me, Et, Pr^i, Bu^t, $SiAlk_3$) by alcoholysis of the $[HNb_2W_4O_{19}]^{3-}$ heteropolyanion [118] and the hydrothermal synthesis of numerous hexa- and decanuclear molecular and anionic V(IV,V) and Mo(V,VI) complexes by reactions of metal oxides with MeOH and polyatomic alcohols.[113,115–117,169,170,197]

1. Hydrolysis

Pioneering X-ray diffraction studies of the structures of partial hydrolysis products of alkoxides marked the beginning of systematic studies of this reaction (which was generally monitored by ^{17}O, ^{1}H and ^{13}C NMR spectroscopy). Condensed titanium OA molecules were investigated by Day and co-workers,[42,143,183,193] Mosset and co-workers [142,189] and Sanchez and co-workers.[184,185,191] These molecules contain from three to eighteen metal atoms linked *via* polydentate oxo and alkoxy groups. Hydrolysis of alcoholic solutions at a $[H_2O]:[Ti(OEt)_4]$ ratio varying from 0.5 : 1 to 0.7 : 1 (h = 0.5–0.7) afforded crystals of $[Ti_{16}O_{16}(OEt)_{32}]$ [142,189] along with the above-mentioned $Ti_7O_4(OEt)_{20}$ [7,142] (see Fig. 1 *a*). Oxoisopropoxide $Ti_3O(OPr^i)_{10}$ is formed in solutions at h = 0.05–0.2. However, only the heteroleptic complex $[Ti_3(\mu_3\text{-}O)(\mu_3\text{-}OMe)(OPr^i)_9]$ was isolated in the crystalline state.[42] The octanuclear $[Ti_8O_6(OEt)_{20}]$ molecules exist in an alcoholic solution, but only a derivative of benzyl alcohol with the $[Ti_8O_6]$ core, *viz*., the $[Ti_8O_6(OBn)_{20}]\cdot Et_2O$ complex, was prepared in the crystalline state.[143] The decanuclear $[Ti_{10}O_8(OEt)_{24}]\cdot PhMe$ complex was also prepared from toluene solutions of oxoethoxides. Hydrolysis of $Ti(OPr^i)_4$ in solutions at 100 °C (in an autoclave) afforded a mixture of two isomers with composition $[Ti_{12}O_{16}(OPr^i)_{16}]$. At 20 °C, the solution contains $[Ti_{11}O_{13}(OPr^i)_{18}]$, which crystallises in the presence of EtOH to form $[Ti_{11}O_{13}(OPr^i)_{13}(OEt)_5]$.[183] The largest molecule of this group, *viz*., $[Ti_{18}O_{28}(OBu^t)_{16}(Bu^tOH)]$, was prepared by hydrolysis of $Ti(OBu^t)_4$ (h = 1.14).[193] Condensation of $Ti(OPr^i)_4$ in the presence of acetic acid to form $[Ti_{12}O_{16}(OPr^i)_{16}]$ [183,184] results from the reaction with water (generated in the course of esterification of an excess acid) and alcohol eliminated upon the replacement of OR groups with OAc.

Hydrolysis also gave rise to $[Sn_3O(OBu^i)_{10}(Bu^iOH)_2]$,[40] $[U_3O(OBu^t)_{10}]$,[49] a series of bimetallic complexes, *viz*., $[BiTi_2O(OPr^i)_8]$,[41] $[LiTiO(OPr^i)_3]_4$,[158] $[K_4Zr_2O(OPr^i)_{10}]$,[107] $[Cu_4Zr_4O_3(OPr^i)_{18}]$,[156] $[MoTa_2O_4(OMe)_8]_2$,[133] *etc*. Among these compounds, the barium titanium oxo cellosolve molecule

$[Ba_4Ti_{13}O_{18}(OC_2H_4OMe)_{24}]$ (prepared at $h = 6$) [192] has the maximum size.

Recently, the following oxoalkoxides were synthesised by controlled hydrolysis in alcoholic solutions of aluminium and tantalum alkoxides:[33, 34, 53–55, 103, 152] the tetrahedral $[Al_4(\mu_4\text{-}O)(OR)_{10}(ROH)]$ complexes (R = Bu^i, $h = 0.25$; CF_3CH_2, $h = 0.5$), $Ta_5(\mu_3\text{-}O)_4(\mu\text{-}O)_3(OBu^t)_{11}$ ($h = 1.0$), $Ta_7(\mu_3\text{-}O)_3(\mu\text{-}O)_6(OPr^i)_{17}$ ($h = 0.55$) and $Ta_8(\mu_3\text{-}O)_2(\mu\text{-}O)_8.(OEt)_{20}$ ($h = 0.5-1.0$) with isopolyanion-type structures.

Controlled hydrolysis of aryloxoalkyl derivatives, in which water replaces alkoxy groups, while aryloxy groups remain intact, is also of interest.

$$M(OAr)_nR_m + H_2O \longrightarrow [M(OAr)_nO_{m/2}]_2 + ROH$$

Examples are the $[TiO(OC_6H_3Pr^i_2\text{-}2,6)_2(NC_5H_4\text{-}4\text{-}NC_4H_8)]_2$ (see Ref. 21) and $[NbO(OC_6H_3Pr^i_2\text{-}2,6)_3]_2$ complexes.[22]

2. Oxidation

Many oxo complexes were synthesised by controlled oxidation of alkoxides of metals in the lowest oxidation states. For example, oxoalkoxides $[M^{IV}_3O(OR)_{10}]$ (R = Pr^i, CH_2Bu^t), $[(Mo^VO)_4O_4(OPr^i)_4Py_4]$, $[Mo^{5.3+}_3O_5(OPr^i)_6]_2$, $[Mo^{VI}O_2(OBu^t)_2]$ and $W^{VI}_2O_3(OR)_6$ (R = Pr^i, Bu^t, CH_2Bu^t) were isolated from the reaction products of $M_2(OR)_6$ (M = Mo, W) with oxygen.[46, 47, 80, 199, 200] In the case of $W_2(OR)_6$, NO {in the synthesis of $[W^{IV}_2O(OBu^t)(OSiMe_2Bu^t)_5Py_2]$ [25]} or acetone {in the synthesis of $[W^{IV}_4O_2(OPr^i)_{12}]$ [88]} were used as oxidants.

Oxidation of bimetallic copper(I) alkoxides, *viz*., $Ba_2Cu_4(OR)_8$ and $Cu_2Zr_2(OR)_{10}$, with oxygen produced the oxo ligands $[Ba_4Cu^I_6O(OCEt_3)_{12}]$ and $[Cu^{II}_4Zr_4O_3(OPr^i)_{18}]$, respectively.[156, 161, 175] In the former compound, the oxidation state of copper remained unchanged.

The $MoO_2(OEt)_4$, $WO(OR)_4$ and $NbO(OR)_3$ compounds (R = Me, Et, Bu^n) were prepared by passing dry air through coloured alcoholic solutions of electrolytes, which are anodic oxidation products of molybdenum, tungsten or niobium (which were subjected to partial reduction on the cathode).[136, 201, 202]

Uncontrolled oxidation with oxygen traces present in the gaseous phase or solvents is typical of alkali or alkaline-earth metal alkoxides. The primary reaction products contain peroxide groups OOR or OOH.[203] Decomposition of the latter by a radical mechanism results in the appearance of water molecules, as well as oxo and carboxy groups, in the coordination environment of the metal atom. This process is accompanied by the appearance of a yellow-brown colour, whose intensity sharply increases upon storage of samples or refluxing of their alcoholic solutions. For example, refluxing (in particular, in the course of dehydration of EtOH) of yellow alcoholic solutions of $Ca(OEt)_2$ over a long period of time afforded crystals of the oxo complex $Ca_6O_2(OEt)_8 \cdot 14\,EtOH$ (see Fig. 2 *b*).[16] Apparently, this colour is attributable to the presence of radicals, which was confirmed by ESR spectroscopy of coloured $Ba(OR)_2$ samples. The IR spectra of such products show the following new bands (regardless of the nature of the starting radical): ν(OH) band of ethanol molecules coordinated to OA and ν(COO) and δ(OCO) bands of the formate group generated from peroxides upon their decomposition. The tendency of alkoxides to oxidation increases in the series Li ≪ Cs, Mg ≪ Ba and Et < Bu^n ≪ Pr^i ≪ C_2H_4OMe,[204] which corresponds to the rate of formation of radicals (the rate was determined by ESR spectroscopy, in particular, for LiOR).[205]

Samples of M^IOAlk or $M^{II}(OAlk)_2$, which were prepared by the reactions of metals with a stoichiometric amount of alcohol in a hydrocarbon medium, appeared to be much more resistant to oxidation compared to those synthesised in alcoholic solutions or prepared by desolvation of $M(OR)_n \cdot x\,ROH$. Oxidation of the alkoxides in their synthesis in a hydrocarbon medium is, apparently, hindered by precipitation of the unsolvated $M(OR)_n$ compounds and insolubility of O_2 in hydrocarbons (as opposed to alcohols). Uncontrolled microhydrolysis is favourable for oxidation due, apparently, to the appearance of free alcohol in samples.[3]

An interesting procedure for the synthesis of OA is based on the addition of ketones to certain molecules, in particular, to $Ti(OR)_4$ ('oxolation') giving rise to large cluster molecules.[185]

3. Decomposition (thermolysis and elimination of ethers)

At rather high temperatures, volatile thermolysis products of alkoxides can contain alcohols, ethers, aldehydes, saturated and unsaturated hydrocarbons, *etc*. The structures of crystalline products provide evidence for condensation attendant on this process. For instance, refluxing of $Al(OEt)_3$ under a benzene layer for several days leads to thermal destruction of the polymeric molecules to give products which go into solution, resulting in crystallisation of $[Al_{10}O_4(OEt)_{22}]$ in low yield.[17] The hydrocarbon-soluble 'α form of aluminium ethoxide' (which is, in reality, OA) was synthesised (according to the Meerwein method) by the reaction of the metal with a stoichiometric amount of alcohol in a xylene solution at 140 °C; in this case decomposition of $Al(OEt)_3$ occurs already *in situ*.[206]

The $[Al_8O_2(OH)_2(OBu^i)_{18}]$ [53] and $[Fe_9O_3(OEt)_{21}] \cdot EtOH$ [167] complexes crystallise from vacuum distillation products of the lower-nuclearity oxo complexes $Al_4O(OBu^i)_{10}$ and $Fe_5O(OEt)_{13}$. Copper oxosilane oxide $[Cu_{18}O_2(OSiMe_3)_{14}]$ was prepared by distillation of $CuOSiMe_3$ [the formation of $(Me_3Si)_2O$ was established].[194] Evidently, the process is accompanied by destruction followed by condensation of the resulting fragments. Decomposition of $W_4(OPr^i)_{10}$ to $[W^{III}_4O_2(OPr^i)_8]_2$ occurs with elimination of propane.[164] Thermolysis of bimetallic isopropoxide $KSb(OPr^i)_4$ afforded crystalline $[K_2Sb_2O(OPr^i)_6]_2$ and Pr^i_2O. Refluxing of toluene solutions of $KM^{III}(OBu^t)_4$ (M^{III} = Sb, Bi) over a long period of time resulted in elimination of isobutylene and afforded the oxo complexes $[K_4M^{III}_2O(OBu^t)_8]$. It should be noted that Na-containing compounds with the same composition are generated already in the step of the reaction of $NaOBu^t$ with $M^{III}(OBu^t)_3$.[109]

If decomposition of alkoxides occurs at rather low temperatures, the reaction gives ethers as the major products. For instance, thermolysis of methoxides $Al(OMe)_3$, $Pb(OMe)_2$ and $NaAl(OMe)_4$ (at ~120 °C) afforded dimethyl ether as the only gaseous product.[206–208] Heating of an alcoholic solution of $Ti(OEt)_4$ in an autoclave at 100 °C led to crystallisation of $Ti_{16}O_{16}(OEt)_{32}$ and elimination of Et_2O.[142, 190]

Condensation with elimination of ethers

$$M-OR + RO-M \longrightarrow M-O-M + R_2O$$

proved to be one of the main pathways of spontaneous decomposition of alkoxides. The formation of oxo bridges is, undoubtedly, thermodynamically favourable and, in the case under consideration, is analogous to ageing of oxide hydrates accompanied by condensation of two hydroxy groups with elimination of a water molecule. This type of reaction was first described by Bradley and co-workers,[209] who prepared oxo complexes by transesterification of niobium ethoxide with *tert*-butyl alcohol

$$Nb(OEt)_5 + Bu^tOH \longrightarrow$$
$$\longrightarrow NbO(OBu^t)_3 + Nb_2O(OBu^t)_8 + Bu^t_2O + EtOH.$$

The proposed mechanism involves the heterolytic cleavage of the O–R bond followed by the attack of the resulting carbocation on the M–O bond of another OR group. Ethers (like other volatile decomposition products, for example, unsaturated hydrocarbons) are not always detectable against the background of alcohols.[14]

Evidently, the size ratio of the metal atom and the substituent (as well as the degree of branching of the latter) is an essential factor responsible for the resistance of ortho derivatives to decomposition. As an example, let us consider iron(III) alkoxides. In the known structures of alkoxides {except for $[Fe(OMe)_3 \cdot MeOH]_\infty$ and unstable $[Fe(OEt)_3]_\infty$}, the coordina-

tion environment of Fe atoms always involves oxo groups.[15, 129, 149, 172] However, in the presence of the $CHBu^t_2$, C_6HMe_4-2,3,4,6, $SiMe_3$ (see Ref. 3) or CMe_2Ph [15] substituents, the reactions afford stable structures of alkoxides of the ortho series containing tetrahedrally coordinated metal atoms. Of aluminium derivatives (the atomic radius of aluminium is substantially smaller than that of iron), polymeric alkoxides $Al(OR)_3$ (R = Me, Et) with a layered structure consisting of $[AlO_6]$ octahedra [isostructural with the corresponding $Fe(OR)_3$] appear to be quite stable. The same is true for the crystalline $[Al(OPr^i)_3]_4$ compounds (Al has coordination numbers of 4 and 6) and $[Al(OBu^t)_3]_2$ (containing tetrahedrally coordinated metal atoms). Analogous iron homologues do not crystallise at all and, according to the IR spectroscopic data, contain oxo groups.[3]

Apparently, this type of decomposition is the main pathway in various synthesis reactions of alkoxides resulting in the 'unexplainable' formation of oxo complexes. This decomposition is particularly characteristic of derivatives containing large Ba, Ln, Zr, Mo, W and U atoms. It should be emphasised that their lighter analogues form alkoxides of the ortho series under comparable conditions.

For instance, barium compounds virtually always contain oxo groups even in the presence of large ligands. Examples are $[Ba_5(\mu_5\text{-}O)(OPh)_8(PhOH)(THF)_8]$ [89] and $[Ba_6(\mu_6\text{-}O)(OR)_{10}\cdot(ROH)_4]$ (R = C_2H_4OMe).[105] The Ba atoms in these molecules have coordination numbers from 7 to 9. Analogous Sr or Ca derivatives, *viz*., $[Sr_4(OPh)_8(PhOH)_2(THF)_6]$ [210] and $Ca_9(OR)_{18}\cdot 2\,ROH$,[211] belong to the ortho series. In the latter compounds, the metal atoms are octahedrally coordinated (only in the calcium cellosolve, the peripheral Ca atoms have a coordination number of 7). Even the reaction of barium metal with phenol in the presence of orthophenoxide $[Sr(OPh)_2]_3\cdot 5\,OP(NMe_2)_3$ affords the bimetallic oxo complex $[Ba_2Sr_6(\mu_5\text{-}O)_2(OPh)_{12}(PhOH)_2\cdot\{OP(NMe_2)_3\}_6]$.[162] An increase in the size of metal atoms in going from Sr to Ba leads to an increase in the coordination number. Evidently, stable polyhedra are formed only if one oxo group is involved in the coordination environment of the metal atoms along with large ligands.

The appearance of oxo groups in these compounds is not associated with uncontrolled hydrolysis or oxidation. This is evidenced by high yields of products and good reproducibility of experiments which were carried out by different research groups under various conditions. The corresponding ortho forms $Ba(OAr)_2$ can be prepared only upon their stabilisation by chelation with crown ethers or amino alcohols or after the introduction of one more substituent into the phenoxy group in the *para* position with respect to the OH group.[91, 212–214]

The formation of oxo groups upon coordination of 'small' ligands to the Ba atom can be exemplified by barium alkoxotitanates. The most stable complexes in the $Ba(OR)_2$–$Ti(OR)_4$–ROH systems have the composition $Ba[Ti_2(OR)_9]_2$ (R = Et, Pr^i, Bu^n). In these complexes, the central Ba atom has a coordination number of 8.[215, 216] However, the use of a system consisting of methoxides leads to the formation of the $[Ba_2Ti_4(\mu_3\text{-}O)(OMe)_{18}\cdot(MeOH)_7]\cdot MeOH$ complex,[131] in which the coordination number of Ba increases to 9 due to additional coordination of one oxo group (Fig. 3). Evidently, eight 'small' OMe groups are inadequate to provide a stable polyhedron of the Ba atom, but only an oxygen atom can be coordinated instead of the ninth alkoxy group for steric reasons, resulting in elimination of an ether molecule. It should be emphasised that in all the molecules under consideration, the coordination environment of the metal atom involves only one oxo group.

An analogous situation is observed in the structures of rare-earth metal alkoxides, which can be exemplified by methyl cellosolves (R = C_2H_4OMe). Cerium-group metals form seven- and eight-vertex polyhedra involving oxo atoms: $[Pr_4(\mu_4\text{-}O)_2\cdot(OR)_8(OPMe_3)]_2$ (see Ref. 150) and $[Gd_6(\mu_4\text{-}O)(OR)_{16}]$.[130] By contrast, derivatives of yttrium-group metals $[M(OR)_3]_{10}$ (M = Y, Dy) contain no oxo ligands and occur as planar decanuclear rings with seven-coordinate metal atoms.[217, 218]

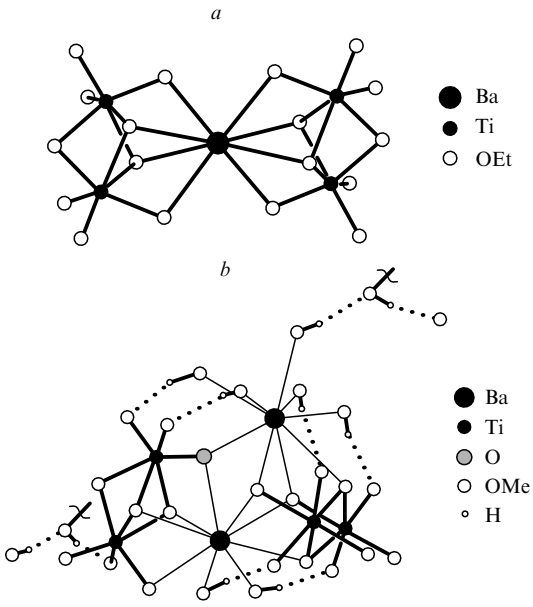

Figure 3. Metal–oxygen cores in the structures of $Ba[Ti_2(OR)_9]_2$ (*a*) [216] and $[Ba_2Ti_4(\mu_3\text{-}O)(OMe)_{18}(MeOH)_7]\cdot MeOH$ (*b*).[131]

Desolvation of the solvates $Ln(OR)_n\cdot m\,L$ (L = ROH, THF) is always attended by the formation of oxo groups. In certain cases, elimination of the corresponding ethers was observed.

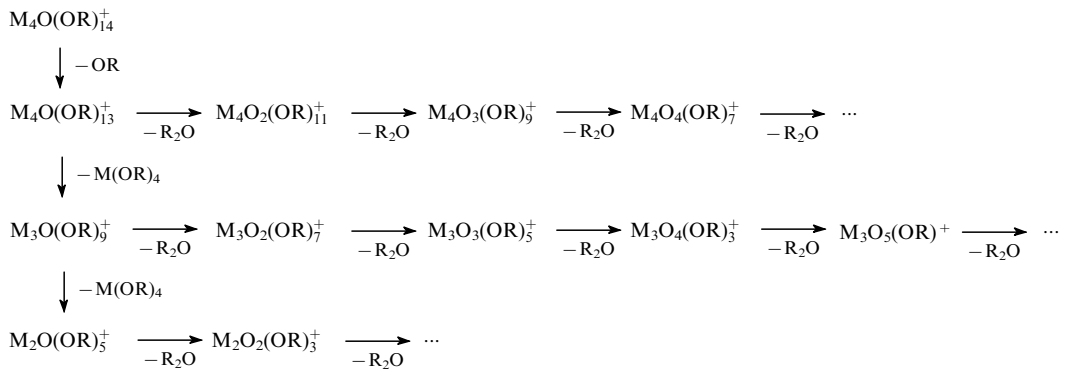
Solvate	Reaction conditions	Reaction product	Ref.
$[La_3(OBu^t)_9L_2]$, L = Bu^tOH, THF	PhMe, Δ	$La_5O(OBu^t)_{13}$	219
$[Nd(OPr^i)_3(Pr^iOH)]_4$	25 °C, vacuum	$Nd_6O_5(OR)_8$	220
$[Ce(OBu^t)_4(THF)_2]$	20 °C, 72 h	$Ce_3O(OBu^t)_{10}$	221
$[Ce(OPr^i)_4(Pr^iOH)]_2$	70 °C, 10^{-3} mm Hg	$Ce_4O(OPr^i)_{14}$	57

The extremely unstable praseodymium solvate $Pr_3(OPr^i)_9\cdot(Pr^iOH)_2$ decomposes to $Pr_5O(OPr^i)_{13}$ already at low temperatures (in the course of drying).[92] Taking into account that the ortho forms $Ln(OAlk)_n$ (n = 3, 4) exist only as solvates with alcohols, THF or Py, it can be hypothesised that the widely occurring form of oxoalkoxides $Ln_5O(OR)_{13}$ (R = Pr^i, Bu^t) is generated as a result of desolvation of unstable solvates. Transesterification of the solvate $[Ce(OPr^i)_4(Pr^iOH)]_2$ with pinacol giving rise to $Ce_2O[O(CMe_2)_2O]_2[O(CMe_2)_2OH]_2$ (see Ref. 75) can also be assigned to this type of reaction.

Decomposition with elimination of ethers (detected) is very typical of lead and bismuth alkoxides. For example, polymeric $Pb(OPr^i)_2$ readily undergoes oligomerisation to form $Pb_4O\cdot(OPr^i)_6$, $Pb_6O_4(OPr^i)_4$ and $Pb_7O_2(OPr^i)_{10}$.[127, 144, 222, 223] In this connection, the complex formation of these compounds with other alkoxides is generally accompanied by the formation of the oxo complexes $[Pb_2Ti_2O(OPr^i)_{10}]$,[60] $[Pb_3Zr(\mu\text{-}O)(OBu^t)_8]$ [62] and $[Pb_6Nb_4(\mu_4\text{-}O)_4(OEt)_{24}]$ [178] [for Sn(II) alkoxides, only oxomethoxide, which was prepared by hydrolysis, is known [123]].

In various synthesis reactions and subsequent transformations, bismuth alkoxides also give oxo complexes. The exchange reactions of $BiCl_3$ with alkali metal alkoxides produce $[NaBi_4O_2(OC_6F_5)_9(THF)_2]$, $[Na_2Bi_4O_2(OC_6F_5)_{10}(THF)_2]$, $[NaBi_3O(OC_6F_5)_8(THF)]$ and $[Bi_6O_3(OC_6F_5)_{12}(THF)_2]$.[64] The complex formation of bismuth and sodium alkoxides affords $[Na_4Bi_2O(OBu^t)_8]$ [109] and $[Na_4Bi_2O(OC_6F_5)_8(THF)_4]$.[111] Alco-

Scheme 1



M = Zr, Hf; R = Et, Pr^i, Bu^n, Bu^i, Bu^t.

holysis of $BiPh_3$ or $Bi[N(SiMe_2)_2]_3$ is accompanied by the formation of $[Bi_6O_3(OC_6H_3Cl_2\text{-}2,6)_{12}]$[132] and $[Bi_4O_2(OBu^t)_8]$.[73] Transsolvation of $[Bi(OC_6F_5)_3(C_6H_6)]_2$ with tetrahydrofuran gives $[Bi_9O_7(OC_6F_5)_{13}(THF)_2]$.[166] Even hydrolysis of $Bi(OEt)_3$ in benzene occurs with elimination of ether.[224] Due to the high sensitivity of bismuth derivatives to moisture traces, the results of the synthesis of particular compounds depend on the origin of the starting reagents. For example, the reaction of $BiCl_3$ with $NaOC_6F_5$ in phenol purchased from Aldrich affords $[NaBi_3O(OC_6F_5)_8(THF)]$, whereas the reaction with the use of phenol purchased from Strem gives rise to $[NaBi_4O_2(OC_6F_5)_9(THF)_2]$ and $[Na_2Bi_4O_2(OC_6F_5)_{10}]$, which are products of deeper decomposition.[64]

Unexpectedly, it was found that zirconium and hafnium 'isopropoxides' (commercial reagents) prepared by desolvation of $[M(OPr^i)_4 \cdot Pr^iOH]_2$ contain several types of oxo complexes [for example, $M_3O(OR)_{10}$ and $M_4O(OR)_{14}$]. These samples also contain impurities of the undecomposed starting solvates. Hence, their empirical composition corresponds to the formula '$M(OR)_4$'. The presence of oxo complexes was detected by ^1H NMR spectroscopy and mass spectrometry of the $M(OR)_4 \cdot ROH$ compounds, in which fragmentation of all oligomers is attended by elimination of ether (Scheme 1).[225]

Crystals of $Zr_3O(OBu^t)_{10}$ and $[Hf_3O(OEt)_{10}(EtOH)]_2$ were grown by allowing electrolytes, which were prepared by anodic dissolution of metals in the corresponding alcohols,[45] to stand for a long period of time (Fig. 4).

Recently, the crystalline ortho form $[Zr(OPr^n)_4]_4$ has been isolated from commercial reagents containing primarily $Zr_3O(OPr^n)_{10}$ by vacuum distillation with unprecedented protection against moisture[226] [it should be noted that alkoxides $Ti(OAlk)_4$, unlike Zr and Hf derivatives, are quite stable]. In the study,[226] it was hypothesised that the formation of numerous oxoalkoxides $Ln_5O(OPr^i)_{13}$ is also associated with extremely high hygroscopicity of the corresponding ortho forms.

Condensation with elimination of ether is very typical also of rhenium,[227] molybdenum and, to a somewhat lesser extent, tungsten alkoxides. Of compounds belonging to the $Mo(OR)_6$ series, only highly unstable methoxide was isolated.[228–230] All oxoalkoxides $MoO(OR)_4$ are very prone to decomposition both in the free state and solutions to form polymeric compounds $MoO_2(OR)_2$ and ethers R_2O.[231] Numerous attempts to synthesise $W(OBu^t)_6$ led only to the formation of $WO(OBu^t)_4$, Bu^t_2O being detected among the reaction products.[232–234] Storage of the oily $MoO(OPr^i)_4$ compounds over a long period of time afforded crystalline $[Mo_3^{5,3+}O_5(OPr^i)_6]_2$ and Pr^i_2O (along with alcohol and acetone) as a result of a redox reaction.[141]

To summarise, it can be hypothesised that this type of decomposition is associated with the fact that metal atoms, which are coordinated only by alkoxy ligands and have no space for a new OR group, are coordinatively unsaturated. Hence, stable polyhedra are formed only in the presence of 'small' ligands, *viz*., an oxo group or solvate molecules (THF, ROH, MeCN, Py, *etc*.), in the coordination environment.

Decomposition of bimetallic alkoxides to oxo alkoxo metallates $M_mM'_nO_p(OR)_q$ containing heterometallic M–O–M′ bridges is of most importance among the reactions under consideration. Many complexes of this type are formed as a result of complexation of two alkoxides (*i.e*., decomposition occurs *in statu nascendi*). Attempts to isolate compounds devoid of oxo groups failed.

In most cases, alkali or alkaline-earth metal alkoxide is involved as one of the components. Examples are $[Li(MgTHF)_4O(\mu\text{-}OC_6H_4Me\text{-}2)_7]$,[98] $[LiTiO(OPr^i)_3]_4$,[158] $Sr(Pr^iOH)_2[Ti_2O(OPr^i)_7]_2$,[102] $[Sr_6Ti_4O_4(OPr^i)_{20}]$,[102] $[Na_2Zr_3O.(OEt)_{12}]_2$,[44] $[M_4Sb_2O(OBu^t)_8] \cdot n\,THF$[109] (M = Na, K; n = 0, 1, 4), $[Na_4Bi_2O(OBu^t)_8]$,[109] $[MgNbO(OMe)_5(MeOH)_2]_2$,[76] $[LiTa_9O_{10}(OEt)_{20}(EtOH)]$[173] and $Na_4[Mo_8O_{24}(OMe)_4] \cdot 8\,MeOH$.[153] However, processes are known where decomposition attends the complex formation of alkoxides of two transition metals, for instance, $[La_2(MoO)_4O_4(OPr^i)_{14}]$,[128] $[Zr_3Mo_8O_{24}.(OPr^i)_{12}(Pr^iOH)_4]$[182] (in these two cases, elimination of ether was observed), $[TaMo^V_2O_4(OPr^i)_7]_2$,[104] $[Er_2Ti_4O_2(OEt)_{18}.(EtOH)_2]$[140] and $[Cu_4Zr_4O(OPr^i)_{18}]$.[156]

The reactions of Ba and Nb (or Ta) ethoxides give rise to crystals of $[BaM^VO(OEt)_5(EtOH)_n]_4$ (M = Nb, Ta), although bimetallic complexes with composition $BaM^V_2(OEt)_{12}$ exist in freshly prepared solutions. By contrast, isopropoxides $[BaM^V_2(OPr^i)_{12}(Pr^iOH)_2]$ are not prone to decomposition and exist in the crystalline state.[85,160,235] The compound $[Ba_4Ti_4O_4(OPr^i)_{16}(Pr^iOH)_4]$ slowly crystallises from solutions of barium and titanium isopropoxides in isopropyl alcohol[159] [as mentioned above, the complexes in all solutions have the composition $BaTi_4(OR)_{18}$ (see Ref. 215)].

The influence of the nature of the substituent (steric factors) is observed, in particular, in the complexation of titanium and thallium(I) alkoxides. The reaction of two ethoxides and isopropoxides affords the octahedral $[Tl_4Ti_2O(OR)_{10}]$ molecules. However, even the partial introduction of OCH_2Bu^t groups gives rise to the ortho forms $TlTi_2(OR)_5(OCH_2Bu^t)_4$ (R = Et, Pr^i).[122]

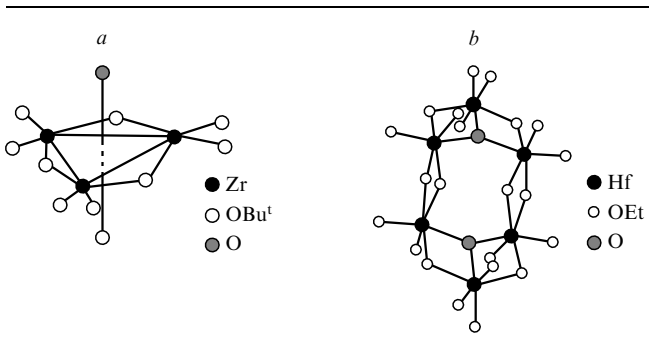


Figure 4. Metal–oxygen cores in the structures of $Zr_3O(OBu^t)_{10}$ (*a*) and $[Hf_3O(OEt)_{10}(EtOH)]_2$ (*b*).[45]

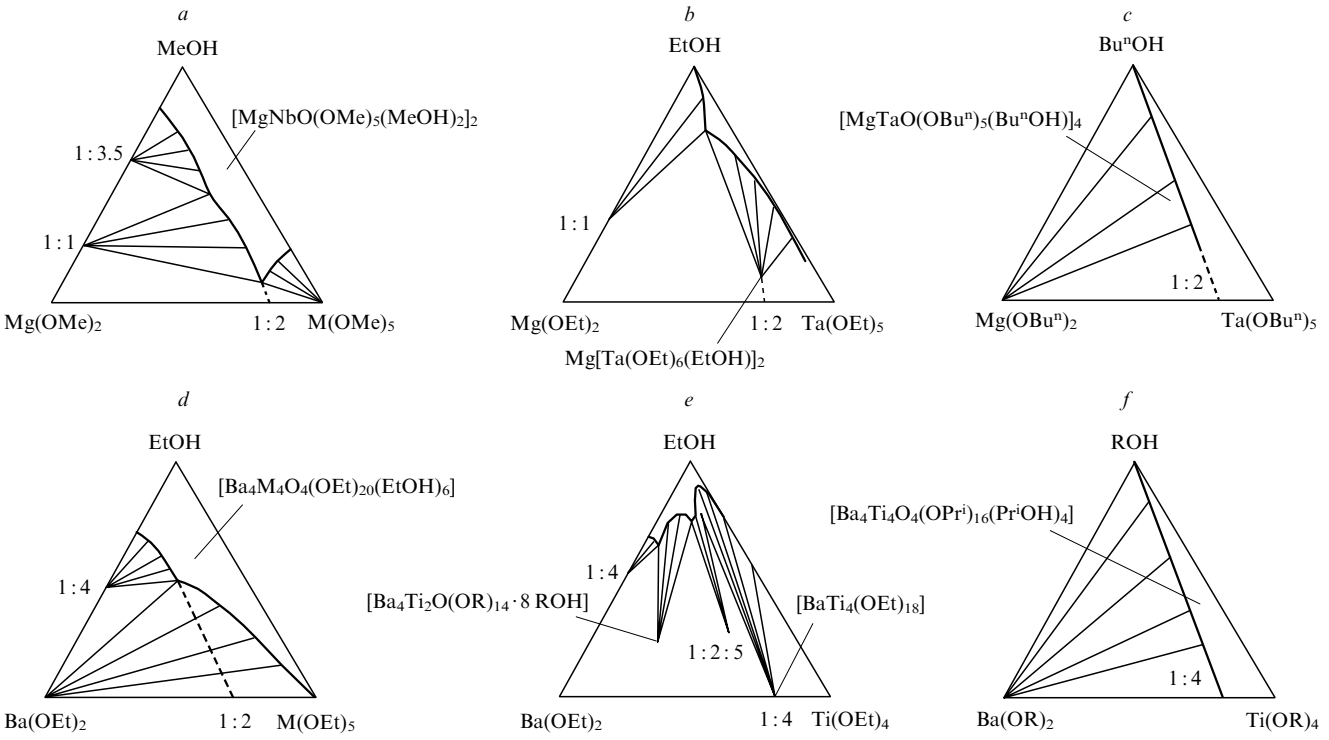

Figure 5. Solubility (20 °C) and the formation of bimetallic oxo complexes [76, 85, 159, 160] in the $Mg(OMe)_2-M(OMe)_5-MeOH$ (M = Nb, Ta) (*a*), $Mg(OEt)_2-Ta(OEt)_5-EtOH$ (*b*), $Mg(OBu^n)_2-Ta(OBu^n)_5-Bu^nOH$ (*c*), $Ba(OEt)_2-M(OEt)_5-EtOH$ (M = Nb, Ta) (*d*),[85, 235] $Ba(OEt)_2-Ti(OEt)_4-EtOH$ (*e*) and $Ba(OR)_2-Ti(OR)_4-ROH$ ($R = Pr^i$, Bu^n) (*f*)[215] systems.

Attempts to reveal a particular dependence of the decomposition pathway on the nature of metals and substituents failed. However, a comparison of the results of physicochemical analysis of the $M(OR)_m-M'(OR)_n-ROH$ systems (Fig. 5) with the results of structural studies of bimetallic oxo complexes demonstrated that crystallisation of OA occurs in systems (or concentration regions) where these compounds are least soluble. In these cases, $M_mM'_n(OR)_p$ are readily soluble or uncrystallisable products.

Molybdenum and tungsten derivatives are particularly prone to decomposition in the presence of alkali metal alkoxides. Judging from conductometric titration curves, the first step of the reactions of $MoO(OR)_4$ with NaOR in alcoholic solutions affords the addition products $NaMoO(OR)_5$ ($R = Et$, Pr^i). However, $[NaMo_2O_4(OR)_5(ROH)]_2$ [compounds of the $MoO_2(OR)_2$ series] crystallise from these solutions even if the reagents are present in a ratio $Na : Mo \leqslant 1 : 2$. In the presence of an excess of NaOR (compared to 1 : 2), the formation of Na_2MoO_4 is observed, and the crystallisation rate of this compound sharply increases with increasing concentration of NaOR. The process occurs with elimination of ether (which was detected chromatographically).[137, 138] Analogous results were obtained in the reactions of M^IOR with $WO(OR)_4$ or $WO_2(OR)_2$, but the rates of these reactions are substantially lower than that observed for $MoO(OR)_4$.[137]

The formation of oxo complexes [along with $M(OR)_n$ or instead of them] in the electrochemical synthesis of alkoxides is, apparently, attributable to decomposition of $M(OR)_n$ in the cathode compartment (presumably, due to local warming). Examples are the syntheses of $[M_5O(OPr^i)_{13}]$ (M = Sc, Y, La),[11, 93] $[Pb_6O_4(OPr^i)_4]$,[127] $[Hf_3O(OEt)_{10}(EtOH)]_2$,[45] $Ta_2O(OPr^i)_8 \cdot (Pr^iOH)$,[33, 34] $[LiTa_9O_{10}(OEt)_{20}(EtOH)]$,[173] a series of rhenium alkoxides $\{[Re_2^V(OMe)_8]_2O_2$,[71] $[Re_4^{VI}O_6(OMe)_{12}]$[72] and $[Re_4^{V,VI}O_6(OPr^i)_{10}]\}$[84] and numerous methyl cellosolves.[236]

Apparently, the above-described type of decomposition has a rather general character. For example, the synthesis of silane oxides $M(OSiMe_3)_2$ (M = Hg, Pb) by transesterification of $M(OR)_n$, alcoholysis of MCp_n or metathesis of $Pb[N(SiMe_3)_2]_2$ with Bu^tNCO is complicated by the formation of the oxo derivatives $Pb_4O(OSiPh_3)_6 \cdot PhH$,[59] $[Pb_7O_2(OSiMe_3)_{10}]$[145] and HgO[237] [with elimination of $(R_3Si)_2O$].

Heteroleptic complexes, in particular, alkoxo carboxylates, are even more prone to this type of decomposition[238, 239] than homoleptic alkoxides.

$$Sn(OR)_4 + Cd(OAc)_2 \longrightarrow$$
$$\longrightarrow Cd_4Sn_4O_2(OR)_{10}(OAc)_{10} + AcOR$$

$R = CH_2Bu^t$.

Since such complexes readily eliminate ester, they were proposed as precursors in the synthesis of complex oxides from the gaseous phase (CVD method):[240]

$$MM'_nO_x(OR)_y(R'COO)_z \longrightarrow MM'_nO_m + R'COOR.$$

Other examples of processes where the appearance of oxo groups cannot be related to the above-mentioned decomposition pathways of alkoxides, can be cited. In particular, transesterification of $Nb(OR)_5$ with pinacol affords $[Nb_3O_2\{O(CMe_2)_2O\}_5 \cdot \{O(CMe_2)_2OH\}]$ and $[Nb_4O_4\{\eta^2,\mu\text{-}O(CMe_2)_2O\}_2(OPr^i)_8]$.[52] By contrast, transesterification with ethylene glycol and methyl cellosolve gave rise to niobium compounds belonging to the ortho series.[241]

The formation of $[Al_4O(OBu^i)_{10}(Bu^iOH)]$,[53] $[Al_{10}O_6(OPr^i)_{18}NH_3]$[176] and $[K(18\text{-}C\text{-}6)_2]^+[Mo_4O(OCH_2 \cdot Bu^t)_{11}]^-$ (see Ref. 69) in the reactions with bases, such as DBU (1,8-diazabicyclo[5.4.0]undec-7-ene), NH_3 or KOH, may be associated with elimination of β-hydrogen atoms in radicals attended by elimination of alkenes.

Alcoholysis of chlorides, *viz.*, Lewis acids, can be accompanied by side reactions giving rise to HCl and water, which are responsible for the appearance of oxo groups {for example, in the $[Nb_2Cl_4(OEt)_2(THF)_2]_2O_2$ (see Ref. 70) and $[Th_4O \cdot \{(OC_2H_4)_4O\}_3Cl_8] \cdot 3MeCN$[63] molecules}. Presumably, the

same is also true for the formation of oxo complexes in numerous exchange reactions of chlorides in alcoholic solutions, where alcoholysis of MCl_n cannot be suppressed. Examples are the syntheses of $[IZnTa_2O_2(OPr^i)_7]_2$ [by the reaction of ZnI_2 with $KTa(OR)_6$],[134] $[Ti_3OCl(OCH_2Bu^t)_9]$ (from $TiCl_4$ and NaOR)[43] and $[Al_4O(OPr^i)_6Cl_4(Pr^iOH)]$ [from $AlCl_3$ and $Al(OR)_3$].[18]

Unfortunately, by-products of decomposition accompanied by the formation of OA have been thoroughly examined only in a few studies. The question about the relation between individual reactions is very complicated, particularly because oxidation and elimination of ethers are catalysed by water traces.

III. Properties of oxoalkoxides

Oxo complexes differ from alkoxides of the ortho series primarily in that the former compounds are not necessarily soluble in alcohols and hydrocarbons and they are much more prone to crystallisation. Numerous examples are known, where insoluble polymeric $M(OR)_n$ compounds undergo oligomerisation due to uncontrolled hydrolysis or oxidation. Solubility of these compounds sharply increases in alcohols and non-polar organic solvents. For instance, the replacement of OR groups in polymeric $Ba(OBu^n)_2$ up to the composition $BaO_{0.05}(OBu^n)_{1.9}$ leads to an increase in solubility in alcohols from 0% to ~40%.[204]

Crystalline oxo complexes go into an alcoholic solution only upon weak warming (or after mechanical grinding under an alcoholic layer). Cooling of such solutions generally leads to very slow crystallisation of $MO_m(OR)_n$ (even in the presence of a bottom phase), and crystals never precipitate in quantitative yields. Vacuum distillation of the mother liquor usually gives rise to a non-crystalline substance, which is compositionally different from crystals. In no case were the equilibrium values attained in the determination of the solubility of oxo complexes in alcohols. Polytherms measured on heating and cooling of solutions show a hysteresis.[151] The only exception is $Ta_2O(OPr^i)_8 \cdot Pr^iOH$, whose binuclear molecules apparently exist in an alcoholic solution.[33,34] These facts indicate that oxo complexes undergo solvolytic decomposition when going into solution to form fragments with different compositions and structures, and these fragments are involved in complex poly(oligo)merisation processes.

Certain information on the structures of fragments existing in the gaseous phase or alcoholic solutions can be obtained by their 'reconstruction' from the crystal structures of polynuclear complexes. For example, fragments of tetra-, penta- and hexanuclear oxo complexes can readily be distinguished in the $Al_{10}O_4(OEt)_{22}$ molecule (see Fig. 2 *c*).[17] These fragments were detected by mass spectrometry. The average degree of association [with respect to monomeric $Al(OR)_3$] is ~4.4. It should be noted that this value was obtained from the results of both mass spectrometry and cryoscopy in benzene, from which the decanuclear complex crystallises.[242] Analogously, the structures of molecules in amorphous $[NbO(OEt)_3]_n$ samples can be reconstructed from the data on the crystal structure of $Nb_8O_{10}(OEt)_{20}$ (see Fig. 1 *b*).[151]

The possibility of crystallisation of alkoxides of the ortho series from solutions containing oxo complexes is yet another consequence of the presence of particles with different compositions (including particles containing no oxo groups) in solutions of OA. For example, the starting solvate crystallises in low yield from an alcoholic solution of desolvation products of $[Zr(OPr^i)_4 \cdot Pr^iOH]_2$ containing, as mentioned above, $Zr_3O(OR)_{10}$ and $Zr_4O(OR)_{14}$.[225] Bimetallic alkoxides $ZrAl_2(OPr^i)_{10}$ and $LaNb_2(OPr^i)_{10}$ were prepared from solutions of the $Al(OPr^i)_3 - ZrO_n(OPr^i)_{4-2/n} - Pr^iOH$[243] or $Nb(OPr^i)_5 - La_5O(OPr^i)_{13} - Pr^iOH$ systems,[85] respectively, because they are apparently the least soluble of all the components and complexes present in these systems. In the presence of $Ti(OEt)_4$ or $Nb(OEt)_5$ (which add oxo groups), polymeric $Fe(OEt)_3$ precipitates from a solution containing iron oxoethoxide.[244]

Since oxoalkoxides undergo thermal destruction on heating, they are not, as a rule, transformed into the gaseous state. In some cases, mass spectra show low-intensity ions corresponding to fragmentation of the most stable molecules, for example, $[Ln_5O(OPr^i)_{13}]$[93,11,245] and $[Al_{10}O_4(OEt)_{22}]$.[17] The $[Na_4M_2O.(OBu^t)_8]$ complexes (M = Bi or Sb) sublime without decomposition at 180 and 120 °C (10^{-2} mm Hg), respectively.[109] In many cases, heating is accompanied by disproportionation of OA to form volatile $M(OR)_n$ and polymeric products containing a larger number of oxo groups per metal atom. This is the reason why $Ta(OPr^i)_5$ can be prepared by sublimation from the product of electrochemical synthesis $[Ta_2O(OPr^i)_8(Pr^iOH)]$[33] or by distillation of $Nb(OEt)_5$ from $[Nb_8O_{10}(OEt)_{20}]$.[151]

In conclusion, it should be noted that the reactivity increases substantially in going from alkoxides to oxo complexes. In many cases, high stability of one or both orthoalkoxides hinders their complexation. The replacement of inactive $M(OR)_n$ with the corresponding oxo complex substantially increases the reaction rate. For example, the reaction of $Ti(OPr^i)_4$ with partial hydrolysis products of polymeric $Pb(OPr^i)_2$ or $Bi(OPr^i)_3$ instead of these compounds as such proceeds rapidly at 20 °C to give $[Pb_2Ti_2O(OPr^i)_{10}]$[60] and $[BiTi_2O(OPr)_9]$, respectively.[41] Polymeric $Ba(OBu^n)_2$ reacts with alcoholic solutions of $Ta(OBu^n)_5$ only in the presence of traces of uncontrolled oxidation products to form highly soluble bimetallic oxo complexes. This allows one to prepare solutions of these two butoxides with different concentrations and any component ratio.[232] Under the same conditions, the reaction with $Ti(OBu^n)_4$ affords solutions with a ratio $Ba : Ti \gg 1 : 4$ (Fig. 5 *f*).[204] Zirconium, hafnium or tantalum isopropoxides react with $Al(OPr^i)_3$ only upon prolonged refluxing of alcoholic solutions, which is apparently accompanied by the appearance of OA particles.[243,246] Presumably, preliminary activation is not needed in reactions with M^IOR or $M^{II}(OR)_2$ due to the virtually unavoidable presence of microamounts of oxo groups in the samples.

IV. Structural types of oxoalkoxides

Since oxoalkoxides have various structures, it is convenient to consider these compounds in order of increasing nuclearity in their oligomeric molecules.

1. Binuclear OA

Binuclear oxoalkoxides (see Table 1) are represented by molecules consisting of two tetrahedra {$[(OsO)O(OCMe_2CH_2NHBu^t)]_2$,[19] $[Nd_2O(OCH_2Bu^t)_4]$[20]}, two five-vertex polyhedra, *viz*., trigonal bipyramids and tetragonal pyramids sharing a $(\mu\text{-O})_2$ edge {for example, $[Nb(\mu\text{-O})(OC_6H_3Pr^i_2\text{-}2,6)_3]_2$ (see Ref. 22)}, two octahedra sharing a μ-O vertex $[(MoO)_2O[O(CMe_2)_2O]_2.[O(CMe_2)_2OH]_2$[28]], sharing a $(\mu\text{-O})_2$ edge ($[(WO)O.(RO_2)(OROH)]_2$ (see Ref. 30), sharing a $[(\mu\text{-O})(\mu\text{-OR})]$ edge {$[Ta_2O(OPr^i)_8(Pr^iOH)]$[33,34]} or sharing a $[(\mu\text{-O})(\mu\text{-X})_2]$ face (X = OR, Cl) {for example, $[Ta_2OCl_3(OC_6H_3Pr^i_2\text{-}2,6)_5]$[35]}. The bonds between metals and oxo bridges are shorter than the M—(μ-OR) bonds and, in some cases, shorter than the terminal M—OR bonds. In the $[M_2(\mu\text{-OR})_2]$ rings of dimeric alkoxides, the M—(μ-OR)—M angles remain virtually constant (107–112°) and are independent of the nature of the metal atom, the substituent and the coordination polyhedron, whereas the M—(μ-O)—M angles in oxo complexes vary within a broad range {from 80.1° in the $[Mo^{III}_2O(OCH_2Bu^t)_4(PMe_3)_4]$ molecule[27] to 154–161° in the $[(WO)O(RO_2)(OROH)]_2$ molecule[30]}.

In the $[Ta_2O(OPr^i)_8(Pr^iOH)]$ complex,[33,34] the presence of one strong $Pr^iO\cdots HOPr^i$ hydrogen bond between the terminal ligands leads to a decrease in the distance between these ligands [O···O(H), 2.52 Å] and 'pushing off' of the OPr^i groups located on the opposite side of the equatorial plane (Fig. 6). Binuclear derivatives of metals in the lowest oxidation states, such as $[W^{IV}_2(\mu\text{-O})(\mu\text{-OBu}^t)(OSiMe_2Bu^t)_5Py_2]$,[25] $[Re^{VI}_2O_2(\mu\text{-O})(\mu\text{-OMe})_2.(OMe)_4]$[39] and $[(Mo^VO)(\mu\text{-O})(OC_6F_5)_2]^-_2$,[23] contain bridging groups along with M = M bonds (2.49–2.56 Å).

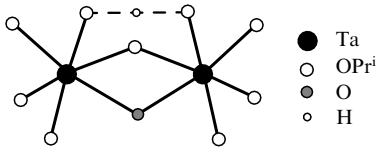

Figure 6. Metal–oxygen core in the structure of $[Ta_2O(OPr^i)_8.(Pr^iOH)]$.[33,34]

2. Trinuclear OA

Trinuclear oxoalkoxides (see Table 2) are represented by two types of triangles. In one type, the $[M_3]$ triangle is centred by a μ_3-O group on one side of the equatorial plane. In another (more widespread) type, there is not only a μ_3-O group but also a μ_3-X group located on the opposite side of the equatorial plane (X = OR, OH, Cl), resulting in the formation of the $[M_3(\mu_3\text{-}O).(\mu_3\text{-}X)(\mu\text{-}OR)_3]$ trigonal bipyramids (see Fig. 4 *a*) flattened along the threefold axis. In the $[Ti_3O(OMe)(OPr^i)_9]$ molecule,[42] the $(\mu_3\text{-}O)-Ti-(\mu_3\text{-}OMe)$ angles are 69°. In the $[W_3(\mu\text{-}O)_2(OBu^t)_8]$ molecules, the bonds in the triangle occur not only *via* the bidentate oxo groups but also *via* W–W single bonds and W=W double bonds (2.93 and 2.45 Å, respectively).[50]

In addition to triangular structures, there are also chain molecules, such as linear $[UO_2][U(\mu\text{-}O)(OBu^t)_5]_2$ (see Ref. 51) (as a result of the *trans* arrangement of two terminal groups in the central octahedron) and angular $[Nb_3O_2\{O(CMe_2)_2O\}_5.\{O(CMe_2)_2OH\}]$.[52]

3. Tetranuclear OA

Tetranuclear oxoalkoxides (see Table 3) are represented by two main groups, *viz*., tetrahedra and planar rhombuses consisting of four octahedra linked *via* two μ_3-ligands and four μ-ligands $[Ti_4(OMe)_{16}$ type [3]]. Apparently, a regular tetrahedron is present only in the $[Pb_4(\mu_4\text{-}O)(\mu\text{-}OSiPh_3)_6]$ molecule,[59] in which six μ-OR groups are located along its edges (Fig. 7 *a*). Taking into account the absence of one or several μ-OR groups in the $[Al_4.(\mu_4\text{-}O)(\mu\text{-}OR)_5X_5(ROH)]$ [X = OPr^i, Cl, OBu^i, OCH_2CF_3 (see Fig. 2 *d*)],[18,54,55] $[Pb_3Zr(\mu_4\text{-}O)(\mu_3\text{-}OBu^t)(\mu\text{-}OBu^t)_5(OBu^t)_2]$[62] and $[Ce_4^{3.75+}(\mu_4\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_4(Pr^iO)_7(Pr^iOH)]$[61] structures, these compounds can be assigned to 'butterfly-type' molecules, in which the wings are additionally linked *via* an oxo group. In solvates of these molecules with alcohols, the wings are linked not only *via* an oxo group but also *via* a very short hydrogen bond between the terminal OR and ROH groups. In the distorted $[W_4(\mu\text{-}O)(\mu\text{-}OPr^i)_2(OPr^i)_7Cl]$ tetrahedron, the central μ_4-O group is absent, and the tungsten atoms are linked to each other *via* μ-OR and μ-O bridges and W=W and W–W bonds (2.45 and 2.9 Å, respectively).[66]

In $Ti_4(OMe)_{16}$-type molecules, four sides of the $[M_4]$ rhombus are additionally linked *via* μ groups, and two $[M_3]$ triangular fragments are linked by μ_3 ligands located on the opposite sides of the plane of the rhombus. These molecules involve two types of metal atoms. Metal atoms of one type are coordinated by two μ_3 groups, whereas metal atoms of another type are coordinated by only one μ_3 group (in Fig. 7 *b*, these atoms are denoted M^1 and M^2, respectively). The oxo ligands are generally located in μ_3 positions. Examples are the $[Bi_4(\mu_3\text{-}O)_2(OBu^t)_8]$[73] and $[(MoO)_4(\mu_3\text{-}O)_2(OEt)_4Cl_4(EtOH)_2]$[81] molecules. However, the reverse situation is observed in the $[(VO)_4O_4(OMe)_4(bipy)_2]$ (bipy is 2,2′-bipyridyl)[74] and $[(MoO_2)_4O_2(OMe)_4(Me_2CNOH)]$[77] complexes and the $[(MoO_2)_2(MoO)_2O_4(OMe)_2(C_6H_4O_2\text{-}1,2)_2]^-$ anion,[78,79] in which the OMe groups are in μ_3 positions, whereas the oxo groups are bidentate.

In the $[LiNbO(OEt)_4(EtOH)]_2$ (see Ref. 85) and $[MgNbO(OMe)_5(MeOH)_2]_2$ molecules,[76] the oxo ligands are terminal and are involved in the 'niobyl' groups (these groups occupy the M^1 and M^2 positions in two molecules, respectively).

Compounds containing more than four metal atoms occur, as a rule, as conglomerates of smaller stable fragments described above. However, there are several more types of penta-, hexa- and octanuclear associates (often *closo*) with high symmetry.

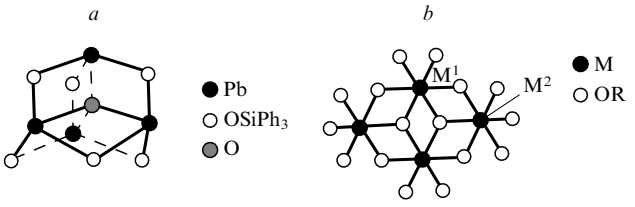

Figure 7. Metal–oxygen cores in the structures of $[Pb_4(\mu_4\text{-}O)(\mu\text{-}OSiPh_3)_6]$[59] (*a*) and $M_4(\mu_3\text{-}O)_2(\mu\text{-}OR)_4(OR)_n$ $[Ti_4(OMe)_{16}$ type] (*b*).

4. Pentanuclear complexes

Pentanuclear complexes (see Table 4) are represented by two main structural types, *viz*., clusters containing the $[M_5(\mu_5\text{-}O)]$ core and combinations of two $[M_2M']$ triangles.

In the molecules of isopropoxides $[Ln_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_4(\mu\text{-}OR)_4(OR)_5]$ (Ln = Sc, Y, Er, Yb, [Y_4Pr], In),[10–14,92,93] the $[M_5O]$ group can be described as a tetragonal pyramid, in which four μ_3-OR ligands are located above the centres of lateral faces, and four μ-OR groups are located along the edges of the base (see Fig. 2,*a*). The $[Al_5O(OBu^i)_{13}]$ and $[Fe_5O(OEt)_{13}]$ molecules have the structure of $[M_5(\mu_5\text{-}O)(\mu\text{-}OR)_8(OR)_5]$ and differ from the above-described molecules in that they contain no μ_3-OR groups. In these molecules, eight μ-OR groups are located along all edges of the pyramid.[15,53]

In the $[Ln_5O(OPr^i)_{13}]$ molecules with the group $[M_5]$ = $[Sm_4Ti]$, the $[(Tb_{0.9}Eu_{0.1})_4Ti]$ molecule and the $[Nd_5(\mu_5\text{-}O)(OPr^i)_{13}(Pr^iOH)_2]$ solvate, the 'cluster' has a trigonal-bipyramidal structure. In these molecules, two μ_3-OR groups are located above faces of two different pyramids, whereas six μ-OR groups serve as bridges between two axial metal atoms and three equatorial metal atoms.[10,13,99–101] In the tetragonal-pyramidal molecules $[Sr_5(\mu_4\text{-}O)(OCH_2Bu^t)_8(Bu^tCH_2OH)(THF)_4]$[95] and $[Eu^{III}Eu^{II}_4O_5(OAr)(ArOH)_5(MeCN)_8]$ (Ar = $C_6H_3Pr^i_2$-2,6),[96] the oxo group is located in the centre of the base and is coordinated in a tetradentate fashion. Aggregates of this type are very stable, exist in solutions and the gaseous phase and have low reactivity, in particular, in complex formation with other metal alkoxides.

A combination of two corner-sharing triangles is observed exclusively in bimetallic complexes, the more electropositive metal atom being common to two triangles. In the $[NaBi_4(\mu_3\text{-}O)_2(\mu\text{-}OC_6F_5)_7(OC_6F_5)_2]$ molecule, the $[NaBi_2]$ triangles are centred by μ_3-O groups.[64] The $[Mo^V_2Mo^{VI}Ta_2O_8(OPr^i)_{10}]$ complex is the first example of molecule in which all five metal atoms are involved in a non-planar ring containing a Mo=Mo bond (2.58 Å) along with μ-O and μ-OR groups.[104]

5. Hexanuclear OA

Many compounds belonging to this group of mono- and bimetallic complexes (see Table 5) contain μ_6-O-centred or non-centred $[M_6]$ octahedral 'clusters'. In the $[Ba_6(\mu_6\text{-}O)(OC_2H_4OMe)_{10}.(MeOC_2H_4OH)_4]$,[105] *trans*-$[Na_2Gd_4(\mu_6\text{-}O)(OBu^t)_{12}]$[106] and *trans*-$[K_4Zr_2(\mu_6\text{-}O)(OPr^i)_{10}]$ molecules,[107] the μ_3-OR ligands are located on eight faces of the octahedron. Structural analogues of the 'large octahedron' $[M_6O_{19}]^{n-}$ = $[M_6(\mu_6\text{-}O)(\mu\text{-}O)_{12}O_6]$ (M = Nb, Ta, Mo, W), in which twelve μ-O groups are located along the edges and six μ-O groups are terminal, are also well known. Among them are numerous oxo alkoxo vanadates,[113–117] $[V^{IV,V}_6(\mu_6\text{-}O)(\mu\text{-}OEt)_{12}O_6]$, which is a microhydrolysis product of $VO(OEt)_3$ (see Ref. 112) and the $[Fe_6(\mu_6\text{-}O)\{MeC(CH_2O)_3\}_6]^{2-}$ and $[Fe_6(\mu_6\text{-}O)(OMe)_{18}]^{2-}$ anions[120,121] (Fig. 8 *a*).

Among octahedral clusters containing no μ_6-O groups, the $[M_6(\mu_3\text{-}O)_4(\mu_3\text{-}OR)_4]$ compounds (M = Sn, Pb; R = Me, Pr^i) with

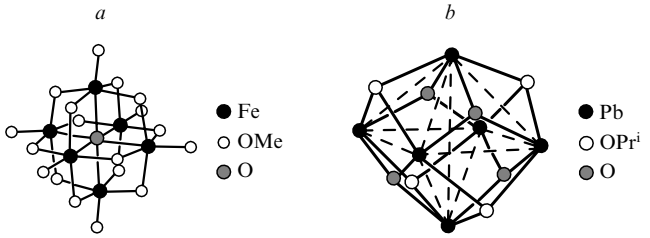

Figure 8. Metal–oxygen cores in the structures of $[Fe_6(\mu_6\text{-}O)(OMe)_{18}]^{2-}$ (*a*) [149] and $[Pb_6(\mu_3\text{-}O)_4(\mu_3\text{-}OPr^i)_4]$ (*b*).[127]

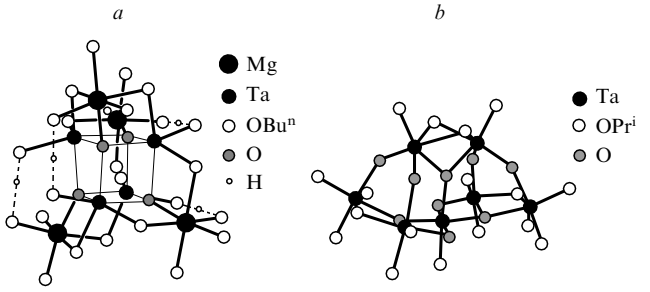

Figure 9. Metal–oxygen cores in the structures of $[Mg_4Ta_4O_4(OBu^n)_{20}(Bu^nOH)_4]$ (*a*) [160] and $[Ta_7O_9(OPr^i)_{17}]$ (*b*).[33, 103]

alternating oxo and OR ligands above the centres of the faces [124–127] [structural analogues of hydroxides of the same metals (see Fig. 8 *b*)] and the bimetallic $[La_2(MoO)_4(\mu_4\text{-}O)_4(\mu\text{-}OPr^i)_8(OPr^i)_6]$ complex,[128] in which four $[Mo_2La_2(\mu_4\text{-}O)]$ groups are located inside the octahedron, are of interest.

In yet another large group of hexanuclear complexes, two $[M_3(\mu_3\text{-}O)]$ triangles are linked to each other to form a ring *via* bidentate O or OR bridges. Examples are $[(MoO_2)Ta_2(\mu_3\text{-}O)(\mu\text{-}OMe)_3(\mu\text{-}O)(OMe)_5]_2$,[133] $[IZnTa_2(\mu_3\text{-}O)(\mu\text{-}OPr^i)_3(\mu\text{-}O)(OPr^i)_4]_2$ (see Ref. 134) and $[Hf_3(\mu_3\text{-}O)(\mu\text{-}OEt)_4(OEt)_6(EtOH)]_2$ (see Ref. 45, Fig. 4 *b*). In the $[Gd_3(OC_2H_4OMe)_8]_2(\mu_4\text{-}O)$ molecule, two triangles, which are perpendicular to each other, are linked *via* a tetradentate oxo group.[130]

In the bimetallic $[Er_2Ti_4O_2(OEt)_{18}(EtOH)_2]$ [140] and $[(NaTHF)_2Bi_4(\mu_3\text{-}O)_2(\mu\text{-}OC_6F_5)_{10}]$ [64] complexes, the $[Ti(\mu_3\text{-}OR)(\mu\text{-}OR)_2(OR)_2]$ and [NaTHF] groups, respectively, are additionally bound to two μ_3-O ligands of the core {$[Ti_4(OMe)_{16}]$ type}. Only the $[Ca_6(\mu_4\text{-}O)_2(\mu_3\text{-}OEt)_4(OEt)_4]\cdot 14\,EtOH$ molecule [16] contains two cuboidal tetramers sharing the $[Ca_2(\mu_4\text{-}O)_2]$ face (see Fig. 2 *b*). The $[Fe_6(\mu_4\text{-}O)_2(\mu\text{-}OMe)_8(OMe)_4.\{N(C_2H_4NH_2)_3\}_2]^{2+}$ cation [129] consists of two $[M_4]$ tetrahedra sharing the $[M_2]$ edge {the $[Fe_2(\mu_4\text{-}O)_2]$ group in the centre}. In the molecules $[(MoO)_3(\mu\text{-}O)_2(OPr^i)_6]_2$ (see Refs 46 and 141) and $[M^V(MoO)_2(\mu\text{-}O)_2(OPr^i)_7]_2$ (M^V = Nb, Ta),[104] the zigzag hexanuclear chains are linked *via* μ-O groups.

6. Oligomeric oxoalkoxides with nuclearity higher than six

The following structural types were found for oligomeric oxoalkoxides with nuclearity higher than six (see Tables 6–10): closed polyhedra, in which all atoms are bound to no more than two oxo groups; rings; condensed structures related to inorganic isopolyanions (metal atoms in the latter are coordinated by several oxo groups).

Among closed polyhedra, oxo complexes involving cuboidal cores (see Table 7) are of particular interest. The $[Li_4Ti_4(\mu_5\text{-}O)_2.(\mu_3\text{-}O)_2(OPr^i)_{12}]$ molecule consists of two cuboidal cores $[Li_2Ti_2O_3(OR)]$, which share the $[Ti_2(\mu_5\text{-}O)_2]$ face and are additionally linked *via* the 'external' trigonal bipyramids $[TiO(OR)_4]$.[158] A larger number of molecules contain one cube $[M^{II}_4(\mu_4\text{-}O)_4]$ in the centre. Examples are the $[Mg_4Ta_4O_4(OBu^n)_{20}(Bu^nOH)_4]$ (Fig. 9 *a*), $[Sr_4Ta_4O_4.(OMe)_{20}(MeOH)_{10}]$,[160] $[Ba_4M_4O_4(OEt)_{20}(EtOH)_6]$ (M = Nb, Ta) [85, 160] and $[Ba_4Ti_4O_4(OPr^i)_{16}(Pr^iOH)_{3.5}]$ [159] complexes.†

The M^{II} atoms are linked to the 'external' $[M'(OR)_m]$ groups (M' = Ti, Nb, Ta) *via* oxo ligands and two or more μ-OR groups. The coordination environment of the M^{II} atom also involves alcohol solvate molecules. In spite of the different nature (and even valence) of M' and R, these compounds are structurally very similar. The only difference is the orientation of the $[M'O(OR)_m]$ groups with respect to the cuboidal core. These groups can be located as continuations of edges (Mg–Ta), diagonals of faces (Ba–Nb) or body diagonals (Ba–Ti). It is reasonable to expect that the above-described structure would be observed also in other oxoalkoxides with a ratio $M^{II}:M^n = 1:1$. The complex $[Mg_4Ta_4O_4(OBu^n)_{20}(Bu^nOH)_4]$ is the first structurally characterised n-butoxide. Evidently, the cuboidal core (a matrix, on which an OA molecule is formed) prevents the hydrocarbon chain from knotting, which generally hinders crystallisation.

The same situation is observed in decanuclear molecules (see Table 9). In such molecules, the $[M_6]$ octahedral 'clusters' are located in the centre and the μ_3-OR and μ_4-O groups alternate on eight faces. The latter are involved in the $[(\mu_4\text{-}O)M'(OR)_5]$ octahedra. Examples are the $[Pb_6Nb_4O_4(OEt)_{24}]$,[178] $[Sr_6Ti_4O_4(OPr^i)_{20}]$ [102] and $[Ni_6Sb_4O_4(OEt)_{16}(EtOH)_4]$ [177] complexes. In all these complexes, the central octahedron is formed by more positive metals, *viz*., Pb, Sr and Ni, respectively. The $[Ba_4Cu_6(\mu_4\text{-}O)(\mu\text{-}OCEt_3)_{12}]$ molecule, in which the edges of the central $[(\mu_4\text{-}O)Ba_4]$ tetrahedron are linked *via* six linear $[Cu(\mu\text{-}OR)_2]$ groups,[175] can be considered as a tetrahedral analogue of the above-described structures. In the $[Fe_7O(OH)\{(OCH_2)_3CCH_2OH\}_4Cl_6(MeCN)_2]$ molecule,[146] the central $[Fe_6(\mu_6\text{-}O)]$ octahedron is linked to one $[Fe(OH)(MeCN)_2]$ group (see Table 6). In the $[Na_2Fe_6O(OMe)_{18}(MeOH)_6]$ complex [149] (with axial Fe atoms), the central octahedron is linked to two $[Na(ROH)_3]$ groups (see Table 7). In the structure of $[Bi_6(\mu_3\text{-}O)_7(\mu_3\text{-}OC_6F_5)[Bi(OC_6F_5)_4]_3(THF)_2]$,[166] the μ_3-O groups are located on seven faces of the $[Bi_6]$ octahedron {three of these groups are coordinated to $[Bi(OR)_4]$} and the eighth face is occupied by the μ_3-OR ligand (see Table 8).

Hepta-, octa-, deca- and octadecanuclear alkoxides (see Tables 6, 7, 9 and 10) form rings. The tetrahedral oxygen atom in the $[\{Cu_2Zr_2(OPr^i)_9\}_2(\mu_4\text{-}O)]$ molecule serves as a bridge between two eight-membered rings, each ring containing two linear $[CuO_2]$ groups and $[Zr(\mu\text{-}OR)_3Zr]$ octahedra.[156] One centrosymmetric ring, which consists of four $[Mo_2(\mu_3\text{-}O)]$ triangles linked to each other *via* μ-OH groups, is observed in the $[(MoO)_4O_2(OEt)_2(OH)_3Cl_3(EtOH)_2]_2$ molecule.[81, 157] The spherical $[Cu_{18}O_2(OSiMe_3)_{14}]$ molecule is formed by two intersecting μ_4-O-centred $[Cu_9O_8]$ rings.[194]

The pentanuclear $[M_5(\mu_4\text{-}O)(\mu_3\text{-}O)(\mu\text{-}OR)_6(OR)_4]$ rings, which differ only in the mode of binding to each other, were found in the structures of aluminium OA with nuclearity from 9 to 11. In the $[Al_{10}O_4(OEt)_{22}]$ molecule,[17] these rings are linked *via* the central $[Al_2(\mu_3\text{-}O)_2]$ group. In the $[Al_{11}O_6(OR)_{21}]$ complex (R = Pr^i, Pr^n), the rings are linked *via* the $[Al(\mu_3\text{-}O)_2(\mu\text{-}O)_2(OR)]$ group. In the $[Al_5Mg_4O_3(OH)_3(OPr^i)_8(acac)_6]$ molecule [180] (acac is acetylacetonate) and its structural analogue $[Fe_9O_3(OEt)_{21}]\cdot EtOH$,[167] the rings share the $[M(\mu_3\text{-}O)]$ edge and are additionally linked to each other *via* a μ-OH group. The $[Al_8O_2(OH)_2(OBu^i)_{18}]$ molecule [53] can be considered as a derivative of decanuclear oxoethoxide lacking one Al atom, which is not bound to the μ_4-O group, in each half of the molecule. Therefore, there is a homologous series of aluminium oxoalkoxides, including from octa- to undecanuclear molecules (Fig. 10).

† Taking into account the exceptionally short Ti–O bonds (1.71 and 1.79 Å), this structure can be considered as a combination of four ionic pairs $[Ba(ROH)]^{2+}_4[TiO(OR)_4]^{2-}_4$. In solution this complex, unlike molecular alkoxo titanates $Ba[Ti_2(OPr^i)_9]_2$, $[BaTi_2(OPr^i)_{10}]_2$ and $[BaTi_3.(OPr^i)_{14}]$,[247] can apparently exist as isolated ions or their associates.

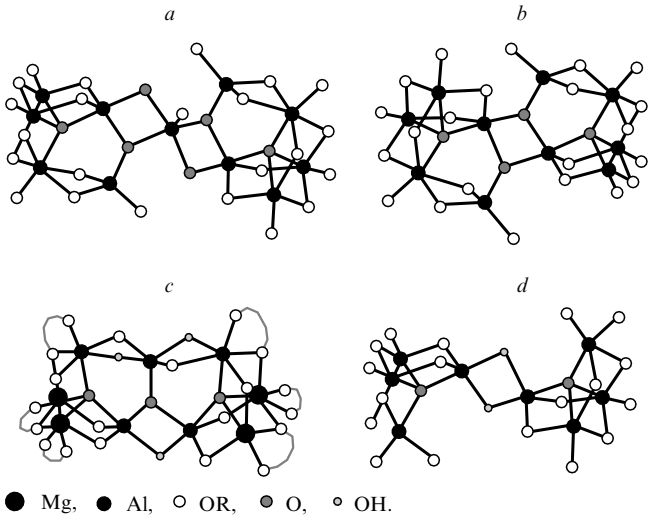

Figure 10. Comparison of the metal–oxygen skeletons in the molecules of undeca-, deca-, nona- and octanuclear aluminium oxoalkoxides — $[Al_{11}O_6(OPr^n)_{10}(OPr^i)_{10}(OR)(ROH)_2]$ (R = Pr^i, Pr^n) (*a*),[180] $[Al_{10}O_4(OEt)_{22}]$ (*b*),[17] $[Al_5Mg_4O_3(OH)_3(OPr^i)_8(acac)_6]$ (*c*)[180] and $[Al_8O_2(OH)_2(OBu^i)_{18}]$ (*d*).[53]

Many known oxo alkoxo complexes containing more than six metal atoms belong to condensed structures related to inorganic isopolyanions. All oxo groups in these compounds (except for 'yl' O atoms) serve as bridges (from bi- to hexadentate), and OR groups are either terminal ligands or bidentate bridges. Oxo alkoxo molybdates(VI) and (V,VI) and vanadates(IV), (V) and (IV,V), which are characterised by the closest packing of edge- and vertex-sharing octahedra, are worthy of notice. These compounds are analogous to metamolybdate $[Mo_8O_{26}]^{4-}$ (see Refs 154 and 155) and decavanadate $[V_{10}O_{28}]^{6-}$.[169, 170] Alkoxy groups of mono- or, more often, polyatomic alcohols $RC(CH_2O)_3$ are located on the surface of these compounds. Examples are the $[(MoO_2)_6(MoO)_2O_{10}(OMe)_4]^{4-}$ (see Ref. 153) and $[V^{IV}_{10}O_{13}\{EtC(CH_2O)_3\}_5]^-$ anions.[169] The $[Ta_7(\mu_3\text{-}O)_3(\mu\text{-}O)_6.(OPr^i)_{17}]$ molecule[33, 34, 103] consists of two vertex-sharing $[Ta_4]$ tetrahedra, which are additionally linked to each other *via* one μ_3-O group and two μ-OR groups (see Fig. 9 *b*). The structure of $[LiTa_9O_{13}(OEt)_{20}(EtOH)]$[173] contains Li atoms and two layers of rings consisting of the $[Ta_3O_7(OR)_6]$ and $[Ta_6O_6(OR)_{15}]$ octahedra, which are linked to each other *via* μ-O bridges. Apparently, the product of hydrothermal synthesis with composition $M_7[Na(H_2O)_3Mo^V_{36}Mo^{VI}_6H_{15}O_{109}\{(OCH_2)_3CCH_2OH\}_7]$[197] has the maximum size. The $[Na(H_2O)_3]$ group located in the centre of this molecule is surrounded by the $[Mo^V_6O_{24}]$ ring and the framework of the $[Mo^{V,VI}O]$ octahedra (see Table 10).

The spherical $[Zr_{13}O_8(OMe)_{36}]$[9] and $[Zr_3Mo_8O_{24}(OPr^i)_{12}.(Pr^iOH)_4]$[182] molecules also belong to the class of compounds under consideration. In these molecules, the $[ZrO_8]$ groups are located in the centre and OR groups are located on the surface (in the former complex, twelve OR groups serve as bridges). The $[Ba_4Ti_{13}O_{18}(OC_2H_4OMe)_{24}]$ molecule containing one central and twelve peripheral Ti octahedra {a structural analogue of the known $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ ion}[192] and the $[Mn_8Sb_4O_4(OEt)_{20}]$ molecule with the symmetry S_4 and two Mn octahedra in the centre belong to the same class of compounds (see Table 10).[186]

Unlike the structures with the closest packing of metal–oxygen polyhedra, the 'loose' $M_8O_{10}(OEt)_{20}$ molecules (M = Nb and Ta)[100, 148, 149] (see Fig. 1 *b* and Table 8) contain a cavity surrounded by pairs and triads of octahedra sharing a vertex and linked to each other *via* single octahedra.

Let us consider titanium oxoalkoxides, which have no analogues in inorganic chemistry, in more detail. The $Ti_7O_4(OEt)_{20}$ molecule, which is the first crystalline hydrolysis product of titanium ethoxide, can be considered as a condensation product of the $[Ti_4(OEt)_{16}]$ molecules and the $Ti(OEt)_2[(\mu\text{-}OEt)_2Ti(OEt)_3]_2$ trimer (the latter is present in solution).[248] This compound contains the linear $[Ti(\mu_4\text{-}O)(\mu\text{-}O)_2Ti]$ chain with the $[Ti(\mu_3\text{-}O).(\mu\text{-}O)Ti]$ groups located above and below this chain[7, 142] (see Fig. 1 *a* and Table 6). An analogous situation is observed in the structures of the large $[Ti_8O_6(OCH_2Ph)_{20}]\cdot Et_2O$, $[Ti_{10}O_8(OEt)_{24}]\cdot\cdot PhMe$,[143] $[Ti_{17}O_{24}(OPr^i)_{20}]$[191] and $[Ti_{18}O_{28}(OBu^t)_{16}(Bu^tOH)]$[193] molecules (first examples of Keggin-type structures containing Ti atoms). In these structures, chains composed of pairs or triads of edge-sharing octahedra are linked to each other *via* μ_4-O, μ_3-O and μ-OR bridges. The $[Ti_{16}O_{16}(OEt)_{32}]$ molecule[142, 189] contains two mutually perpendicular blocks consisting of eight octahedra. In each block, six octahedra form a NiAs-type layer, one octahedron is located above the layer, one octahedron is located below the layer, and a tetrahedral cavity is located in the centre of the molecule (see Table 10).

In summary, it can be concluded that most molecules belonging to the class of oxoalkoxides contain 4–10 metal atoms. A rather small number of dinuclear molecules have been described, and polymeric molecules are few in number, as opposed to alkoxides $M(OR)_n$, the majority of which belong to one of the latter two groups. Evidently, the reason is that OR bridges are, as a rule, bidentate (except for μ_3-OR groups on the surface of *closo*-aggregates $[M_n]$), whereas oxoalkoxide molecules contain oxo ligands with high dentate numbers (up to 8) responsible for coordination of metal atoms.

It should be noted that no cuboidal molecules of the $[M_4(\mu_3\text{-}X)_4]$ type were found in the class of tetranuclear oxo complexes {the only exception is $[(MoO)O(OSiMe_3)(Me_2NH)]_4$ (see Ref. 67)}, as opposed to orthoalkoxides, for which such molecules are very typical and these molecules are stable.

In many cases, the accumulated data allow one to predict the structures of unknown compounds of the ortho series with high probability.[3] At the same time, oxoalkoxides, on the whole, are characterised by high variability and unpredictability of molecular structures.

V. Oxoalkoxides as true precursors of oxide phases

It is quite apparent that oxo complexes (mono- and bimetallic) play a considerable role in the phase formation of simple and complex oxides and are true precursors. The M—O—M bridges in bimetallic oxo complexes provide homogeneity of the newly formed oxide phases at the molecular level.

The above-considered differences in the composition, stoichiometry, solubility and reactivity of ortho- and oxoalkoxides are widely used in the sol–gel synthesis of a series of very important composites. The synthesis of $BaTiO_3$ is the most prominent example. For the latter compound to be prepared, the starting solution must contain a precursor with a metal ratio of 1 : 1, which is attained only upon decomposition of $BaTi_4(OR)_{18}$ into oxoalkoxides $BaTiO_n(OR)_{6-2n}$. Otherwise the sol–gel synthesis affords a mixture of phases containing not only $BaTiO_3$ but also polytitanates and Ba_2TiO_4. The latter fact is attributable to the presence of free $Ba(OR)_2$ (along with a complex with 1 : 4 composition) in solutions containing Ba and Ti in a ratio of 1 : 1.[159, 215, 216] Therefore, for single-phase bimetallic oxides to be synthesised, it is necessary that the solution should contain not only components in a required ratio but also a complex with a specified stoichiometry.

Yet another aspect of the use of oxo complexes in the synthesis of crystalline oxide phases is associated with spontaneous decomposition of alkoxides at 20 °C accompanied by elimination of ethers (this method does not belong to the sol–gel technology). This procedure was employed for the preparation of Na_2MoO_4, Na_2WO_4, Li_2MoO_4, Li_2WO_4, γ-Bi_2MoO_6 and cubic solid solutions (δ* phase) of the Bi_2O_3–WO_3 system.[137, 224, 249] Alterna-

tively, the latter can be prepared by solid-phase synthesis. However, this method requires annealing at temperatures >700 °C over a long period of time. Crystallisation of oxide phases directly from solutions in organic solvents is unambiguously indicative of elimination of ether, whereas products prepared by the sol–gel method are amorphous and their crystallisation occurs only after dehydration by annealing.

Abstract. The published data on the synthesis, reactivities and applications of organic, coordination and organometallic compounds containing a $(Me_3Si)_3Si$ group are generalised and systematised. The bibliography includes 230 references.

I. Introduction

Among diverse organosilicon substituents of the type R_3Si, trialkylsilyl (Me_3Si, Et_3Si, Pr^i_3Si, Bu^t_3Si), triphenylsilyl (Ph_3Si) and tris(trimethylsilyl)silyl [$(Me_3Si)_3Si$] groups (hereinafter referred to as the TTS group)† attract the greatest attention of researchers. The choice of a particular group is usually determined not only by physicochemical characteristics of compounds that are essential for a specific goal, but also by commercial availability of their precursors. Until recently, compounds containing a TTS group were considered to be exotic. Significant progress has been achieved over the past decade in the development of methods for the synthesis and investigation of properties of TTS derivatives and their practical applications. Abundant experimental material accumulated thus far demands systematisation and generalisation. Yet another aim of this review is the discussion of specific characteristics of the TTS group, which differs markedly from other bulky substituents, such as [Bu^t_3Si (see Ref. 1), Pr^i_3Si (see Ref. 2) and Ph_3Si (see Ref. 3)], in its reactivity. This is due, first of all, to the high sensitivity of the highly polarisable Si – Si bond to nucleophilic and electrophilic reagents and to oxidation. In some cases, it can be activated by transition metals. In addition, molecules containing a system of Si – Si bonds can serve as precursors for silylenes when undergoing thermolysis or UV irradiation. Thus, the properties of the $(Me_3Si)_3Si$ group are rather specific and its functions are not confined solely to its use as a bulky substituent or a protecting group.

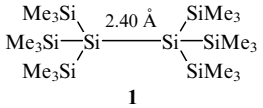
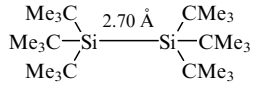
II. Steric and electronic effects of the $(Me_3Si)_3Si$ group

1. Steric effect

The tris(trimethylsilyl)silyl group possesses a pronounced steric effect which is nevertheless weaker than that of its closest analogue, *viz*., the tris(*tert*-butyl)silyl group. A comparison of the structures of $(Me_3Si)_6Si_2$ (**1**) and $(Bu^t_3Si)_2$ (**2**) molecules shows that the distance between the central silicon atoms in compound **1** (2.40 Å) does not differ substantially from the average normal value (2.35 Å), whereas that in molecule **2** is 2.70 Å. Nevertheless, the conclusion that molecule **1** is sterically overcrowded can be drawn from the fact that some distances between the carbon atoms belonging to different $(Me_3Si)_3Si$ groups are as small as 3.52 Å, which is 12% smaller than the sum of the van der Waals radii of two methyl groups, 2.00 Å each.[3, 4]



1



2

The steric effect of the TTS group was estimated using various methods including computation.[5] Thus the dynamic NMR method allowed determination of the barrier to rotation of the mesityl groups around the Mes – C bond in compounds $Mes_2C = C(OH)R$ [R = H, Me, Et, Pr^i, Bu^t, $(Me_3Si)_3Si$]. It was found that the steric effect of the TTS group on the coalescence of aromatic protons differs little from that of the *tert*-butyl group. Correlation and computational data suggest that the steric constant (E_s) of the TTS group varies from −1.46 to −1.6 (see Ref. 5), which is close to the E_s value for the Me_3C group (−1.54), but is significantly smaller than the corresponding value for the tris(trimethylsilyl)methyl group (−3.8) the van der Waals radius of which is close to that of the TTS group.[5] Such a pronounced difference in the steric constants is due to the greater distance between the TTS fragment and the reaction centre in comparison with the $(Me_3Si)_3C$ group owing to the difference in the lengths of the Si – Si and Si – C bonds.

† The term 'hypersilyl group' is generally accepted in the literature, this is also used in the present review.

2. Electronic effects of the $(Me_3Si)_3Si$ group

The tris(trimethylsilyl)silyl substituent can significantly stabilise the ground state of molecular ions. As can be seen from Table 1, the ionisation potentials of compounds containing a TTS group are much lower than those of their analogues due to significant delocalisation of the positive charge in the radical cations formed.

Table 1. The first ionisation potentials (I) of certain disilanes and benzene 1,4-derivatives.[6]

Compound	I /eV	Compound	I /eV
$F_3Si-SiF_3$	13.20	$H-C_6H_4-H$	9.24
$H_3Si-SiH_3$	10.53	$Me_3C-C_6H_4-CMe_3$	8.30
$Me_3Si-SiMe_3$	8.69	$(Me_3C)_3Si-C_6H_4-Si(CMe_3)_3$	7.45
$(Me_3Si)_4Si$	8.24	$(Me_3Si)_3Si-C_6H_4-Si(SiMe_3)_3$	7.37
$(Me_3Si)_3Si-Si(SiMe_3)_3$	7.79		

The changes in the ionisation potentials also agree with a decrease in the reduction half-wave potentials for Me_6Si_2 and $(Me_3Si)_4Si$ ($+1.400$ and $+1.320 \pm 0.005$ V, respectively),[7] which also suggests the somewhat greater proneness of tetrakis(trimethylsilyl)silane to oxidation.

A comparison of dissociation constants of carboxylic acids measured in 76% ethanol has shown[8] that tris(trimethylsilyl)silanecarboxylic acid [hypersilylcarboxylic acid, $(Me_3Si)_3SiCO_2H$] is weaker ($pK_a = 9.33$) than its closest analogues, *viz*., Me_3CCO_2H ($pK_a = 7.96$) and Ph_3SiCO_2H ($pK_a = 6.10$), which testifies to the σ-donor nature of the TTS group.

The tris(trimethylsilyl)silyl substituent can also stabilise the negative charge: more than half of the π-spin density in the 1,4-bis[tris(trimethylsilyl)silyl]benzene radical anion is localised on the $(Me_3Si)_3Si$ groups.[4] Studies on the phenyltris(trimethylsilyl)silane, $[(Me_3Si)_3SiPh]^{\bullet -}$ radical anion revealed that the TTS group behaves as a π-acceptor.[9]

Studies of electron affinities (EA) of a series of silyl radicals revealed that the radical $(Me_3Si)_3Si^{\bullet}$ has the highest value of EA (Table 2). The stability of silicenium anions increases significantly with an increase in the number of trimethylsilyl substituents at the central silicon atom.

Table 2. Electron affinities of silyl radicals.

Radical	EA /kcal mol^{-1}	Ref.
$(Me_3Si)_3Si^{\bullet}$	46.8	10
$(Me_3Si)_2HSi^{\bullet}$	44.7	10
$Me_2HSiMe_2Si^{\bullet}$	32.3	10
$Me_2HSi^{\bullet}$	24.7	11
$Me_3Si^{\bullet}$	22.4	11

It is known that silyl radicals exist predominantly in the pyramidal form with high configurational stability.[12] The rates of subsequent reactions of these radicals exceed their inversion rates. However, the fact that silyl radicals containing a Si–Si group yield racemic products[13] is in accord with an increasing deviation from planarity in the series:[14] $(Me_3Si)_3Si^{\bullet} < (Me_3Si)_2MeSi^{\bullet} < Me_3SiMe_2Si^{\bullet} < Me_3Si^{\bullet}$. The constants of the hyperfine coupling a (^{29}Si) in the ESR spectra change in the same order (Table 3).

Presumably, the stabilities of silyl radicals increase in the following order: $Me_3Si^{\bullet} < Me_3SiMe_2Si^{\bullet} < (Me_3Si)_2MeSi^{\bullet} < (Me_3Si)_3Si^{\bullet}$, mainly due to hyperconjugation with the β-Si–C bond.[21]

^{29}Si NMR spectroscopy has proved to be the most efficient method for obtaining information about the nature of the fragment linked to the TTS group and, correspondingly, about the electronic state of the TTS group itself. The values of experimentally determined chemical shifts vary in the range of more than 300 ppm (Table 4).

Table 3. Some parameters of the ESR spectra of silyl radicals.

Radical	a (^{29}Si) /Gauss	g	Ref.
$(Me_3Si)_3Si^{\bullet}$	64	2.0053	15, 16, 17

$Me_3Si^{\bullet}$	181	2.0031	15, 16, 19, 20

Table 4. The chemical shifts (δ) in the ^{29}Si NMR spectra of central silicon atoms of some TTS derivatives.

Compound	δ (Si–$SiMe_3$)	Ref.
$(Me_3Si)_3SiK$	−195.8	22
$(Me_3Si)_3SiLi(THF)_3$	−185.4	23
$(Me_3Si)_3SiSnMe_3$	−136.6	24
$(Me_3Si)_3SiSiMe_3$	−135.6	22
$(Me_3Si)_3SiSi(SiMe_3)_3$	−129.5	22
$(Me_3Si)_3SiH$	−115.4	22
$(Me_3Si)_3SiEt$	−78.6	22
$(Me_3Si)_3SiHfCp^*Cl_2$ (see [a])	−49.77	25
Me_3SiK	−34.4	22, 26
$Me_3SiSiMe_3$	−20.5	22
$(Me_3Si)_3Si[B(C_6F_5)_4]$	+111.1	27
$[(Me_3Si)_3SiPh]^+$ (see [b])	+205.8	28
$(Me_3Si)_3Si^+$ (see [b])	+920.4	28

[a] Cp* is Me_5C_5; [b] calculated data.

The largest negative values of the chemical shifts (the high field) are characteristic of alkali metal hypersilanides where a considerable negative charge is localised on the central silicon atom. Contrariwise, the chemical shifts of the silicenium cations lie in the low field. The complex ion $[(Me_3Si)_3SiPh]^+$ formed upon dissolution of $(Me_3Si)_3Si[B(C_6F_5)_4]$ in benzene has the highest chemical shift for the TTS group hitherto known ($\delta = +111.1$). The calculated values of chemical shifts for the free ions $(Me_3Si)_3Si^+$ (in the gas phase) and $[(Me_3Si)_3SiPh]^+$, δ, are $+920.4$ and $+205.8$, respectively. It is suggested that the tris(trimethylsilyl)silicenium ion in benzene exists as a σ-complex $R_3Si-C_6H_6^+$ with a weak Si–C bond (13.6 kcal mol^{-1}).[28]

Quite naturally, the increasing applications of the Me_3Si group account for the progress in the chemistry of tris(trimethylsilyl)silane derivatives. By the time of the first synthesis of TTS derivatives, this group had widely been used in organic synthesis for protection of alcohols and enols.[29–32] Tetrakis(trimethylsilyl)silane and tris(trimethylsilyl)silane are the key compounds in the synthesis of numerous organometallic and organoelement compounds containing a TTS group; therefore, it seems expedient to begin with the consideration of methods for their synthesis and their reactivities.

III. Tetrakis(trimethylsilyl)silane and its reactions

The pioneering studies of the tris(trimethylsilyl)silyl group date back to 1964 when Gilman and Smith[33] synthesised tetrakis(trimethylsilyl)silane (**3**) by the reaction of chlorotrimethylsilane with $SiCl_4$ in the presence of metallic lithium in tetrahydrofuran.

$$4\ Me_3SiCl + SiCl_4 \xrightarrow[THF]{Li} (Me_3Si)_4Si$$

3 (70%)

In addition to compound **3**, this reaction yields an insoluble organosilicon polymer, which hampers the isolation of the target product.

It is known that tetrakis(trimethylsilyl)silane (**3**) is a side product in the preparation of tris(trimethylsilyl)silane (**4**);[34] however, it is often formed in substantial amounts due to exchange nucleophilic processes (see Section V.1.b).

$$Me_3SiCl\ (excess) + HSiCl_3 \xrightarrow[-10\ ^\circ C]{Li} \underset{\mathbf{4}\ (\sim 70\%)}{(Me_3Si)_3SiH} + \underset{\mathbf{3}\ (\sim 30\%)}{(Me_3Si)_4Si}$$

If this reaction is carried out at 20 °C, $(Me_3Si)_4Si$ is formed as the major product.

Compound **3** is stable in air and manifests high thermostability (m.p. 319–321 °C) (in a sealed capillary), sublimation temperature > 265 °C (at atmospheric pressure) and is easily sublimed *in vacuo*. The $(Me_3Si)_4Si$ molecule represents a virtually ideal sphere and has a rigid backbone with a tetrahedral symmetry.[35]

Tetrakis(trimethylsilyl)silane and other molecules containing a TTS fragment are easily obtained upon catalytic electrophilic rearrangements of linear polysilanes.[36]

$$Me(Me_2Si)_5Me \xrightarrow{AlCl_3,\ 1\%\ FeCl_3} \mathbf{3}\ (\sim 100\%)$$

Studies into the reactivity of $(Me_3Si)_4Si$ have shown that this is sensitive to both nucleophilic and electrophilic reagents. Treatment of compound **3** with methyllithium in THF results in elimination of the trimethylsilyl group in the form of tetramethylsilane and formation of a tris(trimethylsilyl)silyllithium–THF complex (**5**).[37]

$$\underset{\mathbf{3}}{(Me_3Si)_4Si} + MeLi \xrightarrow{THF-Et_2O} \underset{\mathbf{5}}{(Me_3Si)_3SiLi(THF)_3} + Me_4Si$$

The lithium derivative **5** is readily soluble in saturated and aromatic hydrocarbons, which is a prerequisite for subsequent syntheses.

Marschner[22] has prepared tris(trimethylsilyl)silylpotassium (**6**) in 80% yield by splitting the Si–Si bond with yet another strong nucleophile, *viz*., potassium *tert*-butoxide, in THF or dimethoxyethane (DME).[22]

$$\underset{\mathbf{3}}{(Me_3Si)_4Si} + Bu^tOK \longrightarrow \underset{\mathbf{6}}{(Me_3Si)_3SiK} + Bu^tOSiMe_3$$

Depending on the nature of the electrophile, treatment of silane **3** with strong electrophilic reagents results in cleavage of either Si–Si or Si–C bonds. Thus acetyl chloride reacts with compound **3** to eliminate four terminal methyl groups, which yields tetrakis(chlorodimethylsilyl)silane (**7**).[38]

$$\underset{\mathbf{3}}{(Me_3Si)_4Si} + 4\ MeC(O)Cl \xrightarrow{AlCl_3} \underset{\mathbf{7}}{(Me_2ClSi)_4Si} + 4\ Me_2CO$$

This reaction occurs in a stepwise manner in several steps, but the isolation and purification of the intermediate products present a considerable problem.

The reactions of halogens with silane **3** result in cleavage of the Si–Si bond.

$$\underset{\mathbf{3}}{(Me_3Si)_4Si} + 4\ Hal_2 \longrightarrow 4\ Me_3SiHal + SiHal_4$$

Hal = Cl, Br, I.

Compounds containing a $(Me_3Si)_3Si$ group and related compounds containing a $(Me_3Si)_3C$ group react with trifluoroacetic acid to yield different products.[39]

$$(Me_3Si)_3SiSiMe_2OMe + CF_3CO_2H \xrightarrow[-MeOH]{} (Me_3Si)_3SiSiMe_2O_2CCF_3,$$

$$(Me_3Si)_2C(SiMe_3)(SiMe_2OMe) \xrightarrow[-MeOH]{CF_3CO_2H} \underset{\mathbf{A}}{(Me_3Si)_2C^+(Me)(SiMe_2)_2\ CF_3CO_2^-} \xrightarrow[-CH_4]{CF_3CO_2H} (Me_3Si)_2C[SiMe_2OC(O)CF_3]_2.$$

Such a drastic difference is due to the formation, in the latter case, of intermediate cyclic silicenium cations **A** where elimination of methane occurs smoothly with simultaneous demethoxylation.[39]

IV. Tris(trimethylsilyl)silane and its reactions

Tris(trimethylsilyl)silane can be prepared by either direct synthesis from $HSiCl_3$ and Me_3SiCl or by acid hydrolysis of alkali metal silanides.[40]

$$(Me_3Si)_3SiLi + H_3O^+ \longrightarrow \underset{\mathbf{4}}{(Me_3Si)_3SiH} + Li^+ + H_2O$$

Despite its high cost, tris(trimethylsilyl)silane (TTSH, **4**) is becoming more and more popular as a versatile, mild and selective reducing agent for organic compounds.[41] Its efficiency exceeds those of other silicon hydrides. Presumably,[41] this can be attributed to the low dissociation energy of the Si–H bond in this compound in comparison with other organosilanes (Table 5).

Table 5. Dissociation energies (E_D) of the Si–H bond of some organosilanes.

$R-H \longrightarrow R^\bullet + H^\bullet$

Compound	E_D /kcal mol^{-1}	Ref.
$(Me_3Si)_3SiH$ (**4**)	79.0	10, 42
$Me_3SiSiMe_2H$	85.3	10, 42
Et_3SiH	90.1	10, 42
Me_3SiH	91.0	43, 44
F_3SiH	100.1	43, 44

1. Reduction of functional groups in organic compounds

Reduction with $(Me_3Si)_3SiH$ (**4**) is a radical-chain process. Di-*tert*-butyl peroxide and azobisisobutyronitrile (AIBN) are used as initiators. The mechanism of the Bu^tOOBu^t-induced reaction can be represented by the following scheme:

$$Bu^tOOBu^t \longrightarrow 2\ Bu^tO^\bullet,$$

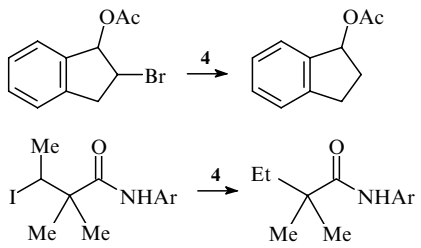
$$Bu^tO^\bullet + \underset{\mathbf{4}}{(Me_3Si)_3SiH} \longrightarrow Bu^tOH + (Me_3Si)_3Si^\bullet,$$

$$(Me_3Si)_3Si^\bullet + RX \longrightarrow (Me_3Si)_3SiX + R^\bullet,$$

$$(Me_3Si)_3SiH + R^\bullet \longrightarrow RH + (Me_3Si)_3Si^\bullet.$$

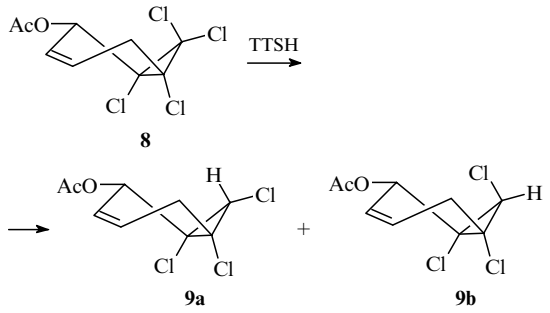
The rate ratios of individual steps make it possible to maintain the chain of radical reactions in an optimum regime for the majority of substrates. The use of other silicon hydrides (trialkyl, aryl and chlorosilanes) for the reduction of functional groups is limited due to the high dissociation energies of their Si–H bonds, which prevent the formation of extended radical chains.

The reduction of organic halides takes place upon heating equimolar amounts of $(Me_3Si)_3SiH$ and a substrate in a solvent in the presence of ~5%–10% of the initiator at the temperature of its decomposition. In these reactions, the product yields are usually high for the majority of RX substrates (R = Alk; X = Cl, Br, I).[45–47]



The selectivity of $(Me_3Si)_3SiH$ was found to be extremely high.

A detailed comparative study of the stereoselectivity of the reduction of organic *gem*-dichlorides with tris(trimethylsilyl)silane and tributylstannane has been carried out. It was found that despite numerous common features, these reagents manifest different stereoselectivities in certain cases. Thus the reduction of tetrachloride **8** with tributylstannane gives a mixture of isomers **9a** and **9b** in a ratio 1.3 : 1. At the same time, the reaction of compound **8** with tris(trimethylsilyl)silane gives a mixture of compounds **9a** and **9b** in a ratio 1.0 : 4.6.[48]



These observations are interpreted[48] as differences in the steric effects of substituents in the rigid-cage molecule $(Me_3Si)_3$. .SiH and in the molecule Bu_3SnH containing flexible mobile n-butyl groups. This hypothesis was confirmed by calculations of the geometry of the transition states.[48]

Despite the generally high reactivities of silyl radicals in halogen abstraction reactions from organic halides,[14] the radical $(Me_3Si)_3Si^{\bullet}$ manifests the lowest activity. The values of the absolute rate constants ($10^8 k$ litre mol^{-1} s^{-1}) in reactions with Me_3CBr decrease in the following order: $Et_3Si^{\bullet}$ (11.0) > $Ph_2Bu^tSi^{\bullet}$ (6.0) > $Me_3SiMe_2Si^{\bullet}$ (2.6) > $(Me_3Si)_3Si^{\bullet}$ (1.2).[14] The rate constants for each silyl radical decrease in the order: X = I > Br > Cl > F. Special mention should be made of the increasing role of electron-transfer reactions on going to polychloroalkanes; as a result, radical reactions occur spontaneously, *i.e.*, without any initiator. In the absence of exogenous radical initiators, $(Me_3Si)_3SiH$ reacts with carbon tetrachloride and bromoform. High yields of chlorotris(trimethylsilyl)silane are obtained on treatment of compound **4** with CCl_4 for 10 h at 20 °C. Trihalogenomethanes react in a similar way.[49]

$$(Me_3Si)_3SiH + CCl_4 \longrightarrow (Me_3Si)_3SiCl + CHCl_3,$$

$$(Me_3Si)_3SiH + CHX_3 \longrightarrow (Me_3Si)_3SiX + CH_2X_2$$

X = Cl, Br, I.

The spontaneous reaction of the hydride **4** with oxygen may result in its ignition in air. The mechanism of oxygen insertion into the Si–Si bond includes a series of intramolecular rearrangements.[41, 50]

$$(Me_3Si)_3Si^{\bullet} + O_2 \longrightarrow (Me_3Si)_3SiOO^{\bullet},$$

$$(Me_3Si)_3SiOO^{\bullet} \longrightarrow (Me_3Si)_2Si^{\bullet}OOSiMe_3,$$

$$(Me_3Si)_2Si^{\bullet}OOSiMe_3 \longrightarrow (Me_3Si)_2Si(O^{\bullet})OSiMe_3,$$

$$(Me_3Si)_2Si(O^{\bullet})OSiMe_3 \longrightarrow Me_3SiSi^{\bullet}(OSiMe_3)_2,$$

$$Me_3SiSi^{\bullet}(OSiMe_3)_2 + (Me_3Si)_3SiH \longrightarrow$$

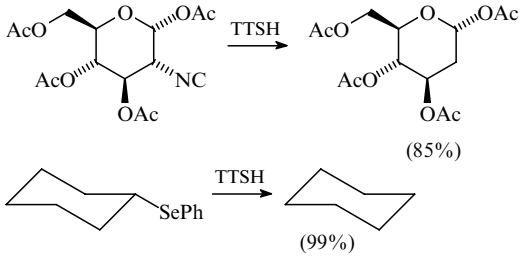
$$\longrightarrow Me_3SiSiH(OSiMe_3)_2 + (Me_3Si)_3Si^{\bullet}.$$

In the absence of other substrates and under conditions of radical initiation, recombination of the tris(trimethylsilyl)silyl radical occurs to give hexakis(trimethylsilyl)disilane in high yield.[51]

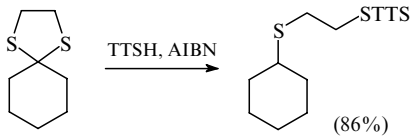
$$\underset{\mathbf{4}}{(Me_3Si)_3SiH} \xrightarrow[130\ ^{\circ}C]{(Bu^tO)_2} \underset{(92\%)}{(Me_3Si)_3SiSi(SiMe_3)_3}$$

It is noteworthy that under these conditions radical recombination products are formed in trace amounts from simpler organosilicon hydrides (Me_3SiH or Me_5Si_2H).

Tris(trimethylsilyl)silane reduces functional groups containing a heteroatom: NC, SR, SeR (R = Alk, Ar).[46, 52, 53] The yields in these reactions are rather high.



Upon treatment with 1 equiv. of $(Me_3Si)_3SiH$, 1,3-dithiolanes afford cleavage products of only one C–S bond.[54]



Under free-radical initiation conditions, carboxylic acid chlorides and phenyl selenoesters are reduced by tris(trimethylsilyl)silane to the corresponding aldehydes and alkanes.[55, 56]

$$RC(O)X + (Me_3Si)_3SiH \longrightarrow RC(O)H + RH + (Me_3Si)_3SiX$$

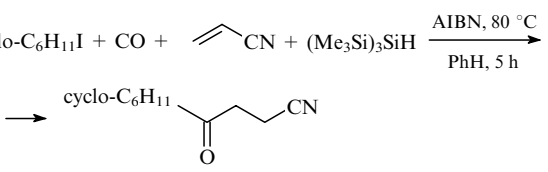
R = Alk, cyclo-Alk; X = Cl, SePh.

Tris(trimethylsilyl)silane is a convenient reagent for radical deoxygenation of alcohols following their conversion into *O*-phenoxythiocarbonyl derivatives.[57]

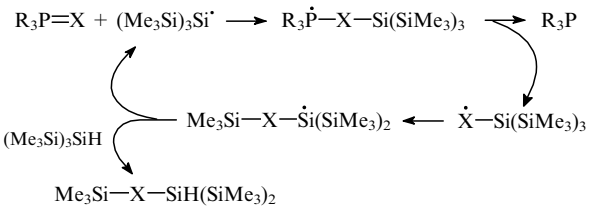
$$ROH + PhOC(S)Cl \xrightarrow[CH_2Cl_2]{Py} ROC(S)OPh \xrightarrow[AIBN]{\mathbf{4}} RH$$

The hydroxy group can also be reduced with $(Me_3Si)_3SiH$ *via* selenocarbonate derivatives.[58]

Successful application of tris(trimethylsilyl)silane as a promotor in multicomponent combination reactions of organic molecules is reported.[59, 60]



In the presence of AIBN, tris(trimethylsilyl)silane reacts with equimolar amounts of phosphine sulfides and phosphine selenides to give the corresponding phosphines in good yields.[7] Stereochemical studies with P-chiral phosphine sulfides have shown that this reduction occurs with retention of their configurations.[7]



R = Me, Bu^n, Ph; X = S, Se.

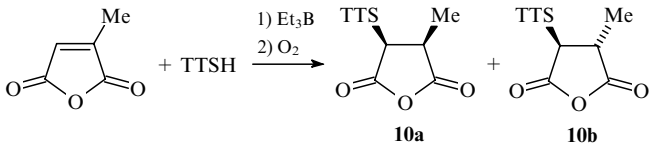
However, no reaction of tris(trimethylsilyl)silane with phosphine oxides occurs even on heating to 150 °C.

2. Hydrosilylation reactions

In the presence of radical initiators, tris(trimethylsilyl)silane easily reacts with alkenes; the addition to the double bonds occurs against the Markownikoff rule.[61, 62]

$$(MeSi)_3SiH + Bu^nOCH{=}CH_2 \longrightarrow Bu^nOCH_2CH_2Si(SiMe_3)_3 \quad (92\%)$$

The addition of $(Me_3Si)_3SiH$ to prochiral alkenes containing ester groups occurs stereoselectively. The selectivity increases with a decrease in temperature, *viz*., the **10a** : **10b** isomer ratio is 19 : 1 at 60 °C, while that at −15 °C is 99 : 1.[61]

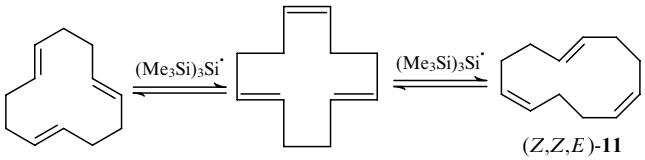


10a **10b**

The addition of $(Me_3Si)_3SiH$ to α-substituted chiral alkenes also occurs with high stereoselectivity.[63]

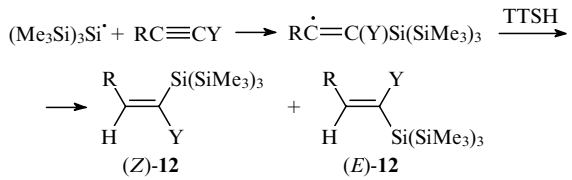
Generally, the activity of silyl radicals in addition reactions to the double bond of alkenes is high[46] (*e.g*., at 23 °C, $k = 10^6 - 10^8$ litre mol^{-1} s^{-1}), this decreases in the following order: $Et_3Si^{\bullet} > Me_3SiMe_2Si^{\bullet} > (Me_3Si)_3Si^{\bullet}$.

As a rule, the addition of trialkylsilyl radicals to alkenes is an irreversible exothermic reaction.[64] This general tendency notwithstanding, it was found that $(Me_3Si)_3Si^{\bullet}$ adds reversibly to many alkenes[65, 66] and catalyses their isomerisation. Thus treatment of each of the 1,5,9-cyclododecatriene isomers (**11**) with a $(Me_3Si)_3SiH - (Bu^tO)_2$ system at 143 °C affords a mixture of (*E*,*E*,*E*) : (*Z*,*E*,*E*) : (*Z*,*Z*,*E*) isomers in 80% yield and in a 78 : 22 : 2 ratio.



(*E*,*E*,*E*)-**11** (*Z*,*E*,*E*)-**11** (*Z*,*Z*,*E*)-**11**

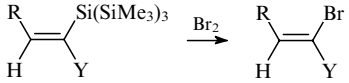
Alkynes also react with tris(trimethylsilyl)silane according to a radical-chain mechanism.[61] The stereoselectivity of this reaction strongly depends on the nature of the substituents at the triple bond. For R = Ph, Y = CO_2Et or R = Bu^t, Y = H, the *Z* : *E* isomer ratio is 1 : 99. For R = Ph and Y = Alk, CN or CHO the stereoselectivity is much lower.[61]



(*Z*)-**12** (*E*)-**12**

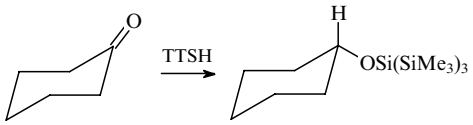
After termination of hydrosilylation reactions, the TTS group is removed using oxidative cleavage with 2,3-dimethylquinone and Bu_4NF or with bromine.[61]

X = Ph, CN, CO_2H.

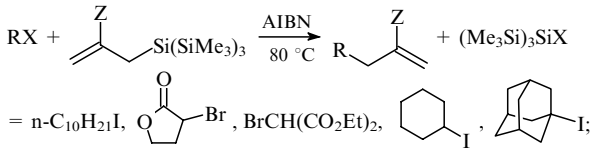


R = H, Bu^t, Ph; Y = CN, CO_2H.

The tris(trimethylsilyl)silyl radical adds easily to the carbonyl oxygen atom of aldehydes, dialkyl ketones and quinones,[67, 68] but the rate constants for these reactions were an order of magnitude lower than those of alkylsilyl radical reactions.



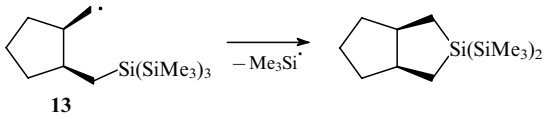
The tris(trimethylsilyl)silyl group is successfully employed in radical allylation reactions of the halogen-substituted organic compounds.[69]



Z = H, Me, Cl, CN, CO_2Et.

The use of $(Me_3Si)_3SiH$ in the synthesis of nucleosides, α-amino acids and prostaglandins[69] seems to be more preferable than that of Bu_3SnH due to high toxicity of the latter.

Some examples of radical substitution of the Me_3Si group at the silicon atom are known.[70–72] Thus the carbon-centred radical in the intermediate **13** formed from the corresponding bromide by a chain reaction displaces in an intramolecular manner the trimethylsilyl fragment of the TTS group.



13

3. Polymerisation involving $(Me_3Si)_3SiH$

Tris(trimethylsilyl)silane was found to be one of the most efficient chain transmitters in the radical polymerisation of vinylic monomers.[73] The chain transfer constants (c_s) are listed in Table 6.

Chain transmitters result in a much more narrow molecular-mass distribution, which is broadened in their absence due to the gel effect. This circumstance is of considerable practical importance because of the lack, until now, of ways to significantly

Table 6. Chain transfer constants (c_s) through silicon hydrides in the bulk polymerisation of styrene and methyl metacrylate at 60 °C.[73]

Compound	$10^3\,c_s$	
	styrene	methyl metacrylate
Et_3SiH	7.3	4.23
Me_5Si_2H	14	56
$(Me_3Si)_2SiMeH$	92	706
$(Me_3Si)_3SiH$	550	8300

decrease the polydispersity of polymers prepared by radical polymerisation.

4. Acidity of $(Me_3Si)_3SiH$

It is known that silyl anions cause metallation of weak CH-acids,[37, 74, 75] but their generation by direct deprotonation of silanes with carbanions or alkali metal amides could not be detected. Only metallation of Et_3SiH by potassium hydride in dimethoxyethane or hexamethylphosphorotriamide is known.[76] Attempts to abstract the proton from $(Me_3Si)_3SiH$ using Bu^nLi, MeLi or Ph_3CLi in THF were unsuccessful and resulted in the destruction of the substrate. Such a deprotonation could be effected only when less nucleophilic $Ph_3CLi(Et_2O)_2$ in diethyl ether was used.[77]

$$Ph_3CLi(Et_2O)_2 + (Me_3Si)_3SiH \xrightarrow{Et_2O} Ph_3CH + (Me_3Si)_3SiLi$$

The acidity of tris(trimethylsilyl)silane in solution was established in reactions of the complex $(Me_3Si)_3SiLi(THF)_3$ (**5**) with various CH-acids.[78] Thus $(Me_3Si)_3SiH$ and 9-phenylxanthyllithium ($pK = 28.7$) form an equilibrium mixture in diethyl ether with a silane : silyl anion molar ratio of 12 : 7, which corresponds to $pK = 29.4$ for $(Me_3Si)_3SiH$.

The energy of deprotonation of $(Me_3Si)_3SiH$ in the gas phase was estimated to be equal to 350.8 kcal mol^{-1}, which is by $\sim$22 kcal mol^{-1} smaller than that of SiH_4 (372.8 kcal mol^{-1}) and significantly smaller than that of methane (416.6 kcal mol^{-1}).

The use of tris(trimethylsilyl)silane as a starting reagent in the synthesis of organoelement and organometallic compounds will be considered in subsequent chapters devoted to individual groups of elements.

V. Tris(trimethylsilyl)silyl derivatives of elements of the main subgroups

1. Elements of Groups IA – IIA

a. Preparation

The synthesis of $(Me_3Si)_3SiLi$ (**5**), first developed by Gilman and Smith,[37] was modified further.[23] The reaction rate depends on the procedure used for the preparation of methyllithium. The reaction with MeLi prepared from methyl iodide or bromide proceeds at a sufficiently high rate and is significantly slower, if methyl chloride has been used. Tris(trimethylsilyl)silyllithium was isolated and characterised as a colourless crystalline adduct with THF.[23, 35] This can be stored in an atmosphere of argon for several months. It is noteworthy that if the reaction is incomplete, a crystalline compound containing one tetrakis(trimethylsilyl)silane molecule per two lithium silanide molecules, $[(Me_3Si)_4Si][(Me_3Si)_3Si.Li(THF)_3]_2$, can be isoated from the reaction mixture.[35]

Tris(trimethylsilyl)silylpotassium (**6**) is yet another popular reagent. This is highly stable, can be stored at 20 °C for a long time and is highly reactive and its synthesis from tetrakis(trimethylsilyl)silane (**3**) is rather simple and convenient.[22]

Potassium, rubidium and caesium tris(trimethylsilyl)silanides can be prepared by treatment of $(Me_3Si)_3SiLi$ with *tert*-butoxides of the corresponding alkali metals.[79]

$$(Me_3Si)_3SiLi(THF)_3 + Bu^tOM \longrightarrow (Me_3Si)_3SiM + Bu^tOLi$$

M = K, Rb, Cs.

The solid reaction products can be separated by addition of crown ethers, which also determine the formation of contact or separated ion pairs. The following ionic compounds, *e.g.*, $K(18\text{-C-}6)Si(SiMe_3)_3$, $[K(12\text{-C-}4)_2][Si(SiMe_3)_3]$, $[Rb(15\text{-C-}5)_2].[Si(SiMe_3)_3]$, $[Cs(18\text{-C-}6)_2][Si(SiMe_3)_3]$ and $[Rb(18\text{-C-}6)_2].[Si(SiMe_3)_3][Rb(18\text{-C-}6)Si(SiMe_3)_3]_2$ were prepared in this way and their structures were established.[79]

Non-solvated $(Me_3Si)_3SiLi$ was prepared by substitution of lithium for mercury in a reaction of bis[tris(trimethylsilyl)-silyl]mercury with metallic lithium in toluene.[80]

$$[(Me_3Si)_3Si]_2Hg \xrightarrow{Li,\ PhMe} 2\,(Me_3Si)_3SiLi + Hg$$

Using ^7Li NMR spectroscopy, it was found that in hydrocarbon solvents the central silicon atom in $(Me_3Si)_3SiLi$ carrying a negative charge is associated with two lithium atoms, whereas the silicon atom in Me_3SiLi is associated with three lithium atoms.[80]

Non-solvated tris(trimethylsilyl)silanides of other alkali metals were prepared using transmetallation reactions of zinc tris(trimethylsilyl)silanide with an alkali metal in saturated hydrocarbons.[81]

$$[(Me_3Si)_3Si]_2Zn \xrightarrow{M} 2\,(Me_3Si)_3SiM + Zn$$

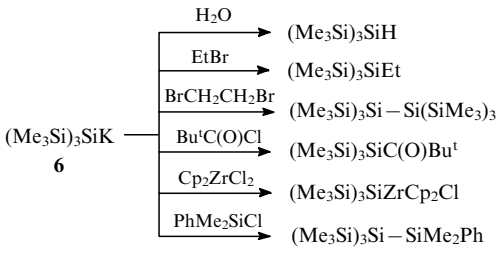
M = Na, K, Rb, Cs.

Tris(trimethylsilyl)silanides of alkali metals exist in a crystalline state as dimers with a nearly planar M_2Si_2 ring. The dimeric molecules are associated into a coordination polymer by abnormally short bonds between the alkali metal atom of one molecule and the methyl group of another molecule.[81]

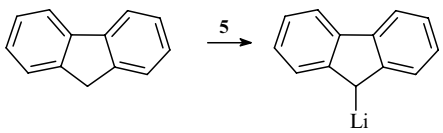
b. Reactivities of tris(trimethylsilyl)silanides

Alkali metal silanides manifest extremely high reactivities. Many of them easily react even with the solvent. Potassium triethylsilanide, for example, deprotonates weak acids such as benzene or toluene. These reactions yield potassium hydride and triethylphenylsilane or benzyltriethylsilane, respectively.[82] The main advantage of alkali metal tris(trimethylsilyl)silanides is that they maintain high reactivities with respect to electrophilic sites without affecting the molecules of aromatic solvents (*e.g.*, benzene, toluene) and ethers. This can partly be due to the steric shielding of the nucleophilic centre and the simultaneous intramolecular stabilisation of the complex by $M\cdots CH_3$ interactions.[81]

Reactions of tris(trimethylsilyl)silylpotassium (**6**) with various electrophilic reagents proceed in high yields.[22]



Tris(trimethylsilyl)silyllithium (**5**) lithiates hydrocarbons containing an active hydrogen atom.[37]



However, this reaction cannot be used for preparative purposes, since it is concomitant with side metathesis.

$$(Me_3Si)_3SiLi + (Me_3Si)_3SiH \longrightarrow (Me_3Si)_4Si + (Me_3Si)_2Si(H)Li$$

Treatment of magnesium bromide with 1 or 2 equiv. of lithium or potassium tris(trimethylsilyl)silanides in THF yielded the corresponding mono- $[(Me_3Si)_3SiMgBr(THF)_2]$ and disubstituted $\{[(Me_3Si)_3Si]_2Mg(THF)_2\}$ derivatives.[83] The crystalline complex $[(Me_3Si)_3Si]_2Mg(THF)_2$ is thermally highly stable and does not melt at temperatures up to 200 °C. However, in solution it slowly

(within 7 days) decomposes to give hexakis(trimethylsilyl)disilane and metallic magnesium.

$$[(Me_3Si)_3Si]_2Mg(THF)_2 \xrightarrow{C_6D_6} (Me_3Si)_3Si-Si(SiMe_3)_3 + Mg \quad (40\%)$$

Tris(trimethylsilyl)silylmagnesium bromide yields symmetrisation products upon addition of dioxane:

$$(Me_3Si)_3SiMgBr(THF)_2 + C_4H_8O_2 \longrightarrow [(Me_3Si)_3Si]_2Mg(THF)_2 + MgBr_2(C_4H_8O_2)$$

Since alkali metal tris(trimethylsilyl)silanides are used in the synthesis of diverse organoelement and organometallic compounds, their reactions will be considered in the appropriate sections.

2. Group IIIA elements

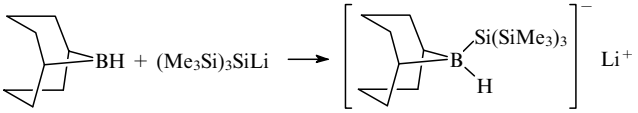
a. Boron

Silyl boranes constitute a small class of compounds due to instability of the Si–B bond. The tris(trimethylsilyl)silyl group has good potential for steric and electronic stabilisation of the electron-deficient boron atom. The reaction of lithium tris(trimethylsilyl)silanide with boron halides and alkylamides yields highly stable derivatives.[84]

$$n\,(Me_3Si)_3SiLi(THF)_3 + R_{3-n}BX_n \longrightarrow R_{3-n}B[Si(SiMe_3)_3]_n + n\,LiX$$

R = Me, Bu^t, bicyclo[3.3.1]nonane, Me_2N; X = Br, Cl.

Boron hydrides react with TTS-Li to give lithium salts:



Upon methanolysis in acidic media, boroakylamides yield methoxyboranes with retention of the Si–B bond.[84]

$$[(Me_3Si)_3Si]_2BNMe_2 + HCl + MeOH \longrightarrow [(Me_3Si)_3Si]_2BOMe + [Me_2NH_2]Cl$$

Tris(trimethylsilyl)silyllithium reacts with aminodifluoroboranes to give substitution products.[85]

$$(Me_3Si)_3SiLi + F_2BN(R)SiMe_3 \longrightarrow (Me_3Si)_3SiB(F)N(R)SiMe_3 + LiF$$
14

R = Me, Et, Pr^i, Bu^t, $SiMe_3$.

The thermolysis of hypersilylaminofluoroboranes **14** results in stable iminoboranes **15**, which proved to be highly reactive compounds. They easily add water, methanol and even sterically hindered aromatic amines.[85]

$$(Me_3Si)_3SiB(F)N(R)SiMe_3 \xrightarrow{400-500\ ^\circ C} (Me_3Si)_3SiB{\equiv}N-R\ ,$$
14 **15**

$$(Me_3Si)_3SiB{\equiv}N-R + ArNH_2 \longrightarrow (Me_3Si)_3SiB(NHR)NHAr$$
15

R = $SiMe_3$, Bu^t; Ar = 2,4,6-$Me_3C_6H_2$.

b. Aluminium

Reactions of aluminium chloride, alkyl- and arylaluminium chlorides with TTS-Li give the corresponding hypersilyl derivatives.[86]

$$(Me_3Si)_3SiLi(THF)_3 + R_{3-n}AlCl_n \longrightarrow (Me_3Si)_3SiAlR_{3-n}AlCl_{n-1}(THF)$$

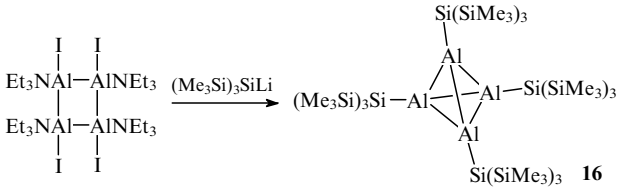
R = Me: n = 1 (81%); 3 (60%); R = Et: n = 1 (78%); 2 (83%).

It was shown that at low temperatures aluminium chloride forms a lithium adduct $[Li(THF)_4][(TTS)AlCl_3]$,[87] which decomposes at −15 °C. Trialkylaluminium gives a complex salt with TTS-Li.

$$(Me_3Si)_3SiLi(THF)_3 + R_3Al \xrightarrow{THF} [(Me_3Si)_3SiAlR_3]Li(THF)_n$$

R = Me, Et.

The reaction of lithium hypersilanide with tetrameric aluminium(I) bromide or iodide was used for the preparation of a tetranuclear complex of monovalent aluminium **16**.[88]



16

The interatomic distance Al–Al in compound **16** is equal to 2.602 Å, *i.e.*, is only slightly greater than the sum of the covalent radii (2.48 Å).

c. Gallium

In the past decade, the chemistry of silicon–gallium compounds has been developing especially intensely due to considerable interest in these compounds as precursors of materials for microelectronics.[89] In this context, much attention is being given to hypersilyl derivatives containing Si–Si and Si–Ga bonds initially.

The structurally characterised compounds with $(Me_3Si)_3SiGa$ fragments can be classified into three groups, *viz.*: (1) mononuclear gallium complexes containing a single Si–Ga bond of the type $(Me_3Si)_3Si-GaR_2$; (2) digallanes; (3) nuclear clusters containing gallium atoms surrounded by silyl substituents.

Compounds with Si–Ga bonds are prepared by reactions of the corresponding chlorides R_2GaCl with TTS-Li.

$$R_2GaCl + (Me_3Si)_3SiLi(THF)_3 \longrightarrow R_2Ga-Si(SiMe_3)_3 + LiCl$$
17

R = Me, Ph, 2,2,6,6-tetramethylpiperidine (tmpp).

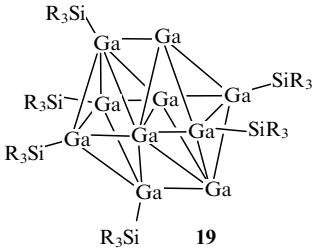
The 2,2,6,6-tetramethylpiperidine derivative, $(tmpp)_2Ga$-TTS (**17**), is easily split at the Ga–N bond by treatment with water, EtOH, PhOH or HCl to give the corresponding derivatives, *viz.*, $[(Me_3Si)_3SiGa(OH)_2]_3$, $[(Me_3Si)_3SiGa(OEt)_2]_2$, $\{[(Me_3Si)_3Si.Ga(OPh)_3]^-[(tmpp)H_2^+]\}$ or $\{[(Me_3Si)_3SiGaCl_3]^-[(tmpp)H_2^+]\}$ where the coordination number of gallium is usually equal to 4.[90]

By virtue of their high proneness to form coordination compounds, gallium halides yield products with various compositions depending on the stoichiometric ratios of the components.[90,91] Two compounds with tentative compositions $Li[(Me_3Si)_3Si-GaCl_3](THF)_4$ and $(Me_3Si)_3Si-GaCl_2(THF)$[91] are formed at the $GaCl_3:(Me_3Si)_3SiLi$ ratio of 1 : 1 that could not be isolated in the pure state. The same reaction with two moles of $(Me_3Si)_3SiLi$ gives a structurally characterised ate-complex with lithium chloride **18**.[92] The TTS-$GaCl_2(THF)$ complex was prepared in the presence of an excess $GaCl_3$.[90]

$$(Me_3Si)_3SiLi + GaCl_3 \xrightarrow{THF} [(Me_3Si)_3Si]_2Ga(\mu\text{-}Cl)_2Li(THF)_2$$
18

Gallium(I, III) chloride, $Ga[GaCl_4]$, reacts with lithium tris(trimethylsilyl)silanide and, depending on the ratio of reagents, reaction temperature and the solvent type, yields a tetranuclear

cluster $[(Me_3Si)_3SiGaCl]_4$,[93] a homoleptic gallium(I) silanide, $[(Me_3Si)_3SiGa]_4$,[94] or gallium bis(hypersilyl)chloride, $[(Me_3Si)_3Si]_2GaCl$.[95] Larger clusters have been isolated, *e.g.*, the complex $Ga_{10}[Si(SiMe_3)_3]_6$ (**19**),[96] which represents two edge-shared octahedra one of which contains four TTS substituents, while the other one contains only two substituents.



R = $SiMe_3$.

19

The reaction of Ga(I)Br with TTS-Li gives the cluster $Ga_{22}[(Me_3Si)_3Si]_8$ (**20**) which contains 22 gallium atoms;[97] the central gallium atom in this complex is surrounded by 13 different gallium atoms carrying eight $GaSi(SiMe_3)_3$ fragments on the outer side.

$$GaBr + (Me_3Si)_3SiLi(THF)_3 \longrightarrow$$
$$\longrightarrow [(Me_3Si)_3Si]_2GaBr_2 \cdot Li(THF)_2 + [(Me_3Si)_3SiGaBr]_4 +$$
$$+ Ga_{22}[(Me_3Si)_3Si]_8$$

20

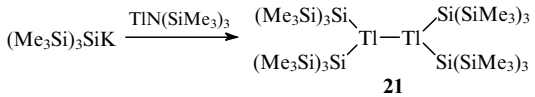
The reactions of the cluster $[(Me_3Si)_3SiGaCl]_4$ with iron carbonylates, *e.g.*, $Na_2Fe(CO)_4$, $Na_2Fe_2(CO)_8$ and $Na_2Fe_3(CO)_{11}$, have been studied.[95] The reaction products, *viz.*, $(CO)_3Fe[Ga(TTS)]_3Fe(CO)_3$ and $(CO)_3Fe[Ga(TTS)]_2(\mu\text{-}CO).Fe(CO)_3$, represent $Fe_2(CO)_9$ derivatives where the bridging CO groups are partly or completely replaced by the $GaSi(SiMe_3)_3$ fragment.

d. Indium, thallium

Indium hypersilyl derivatives are not numerous. One of them is the ate-complex of indium bis(hypersilyl)chloride with LiCl , *viz.*, $[(Me_3Si)_3Si]_2In(\mu^2\text{-}Cl)_2Li$.[92] All attempts to obtain monovalent indium derivatives by reaction of indium(I) chloride with TTS-Li gave the same product, presumably, as a result of disproportionation of indium(I) chloride by the reaction:

$$3\,InCl \longrightarrow 2\,In + InCl_3.$$

The reaction of indium trichloride with TTS-Li at −60 °C yields $[(Me_3Si)_3Si]_2$ and metallic indium; however, at lower (−100 °C) temperatures, it is the bimetallic derivative $(TTS)_2In-In(TTS)_2$ that is formed.[98] A similar thallium derivative, *viz.*, compound **21**, was isolated by treatment of the monovalent thallium silylamide with potassium hypersilanide.[99]



21

3. Group IVA elements

a. Carbon

Numerous compounds in which the hypersilyl group is bound to carbon are referred to in different sections of the present review. Let us give some additional examples.

The reaction of fullerene C_{60} with $(Me_3Si)_3SiLi$ in toluene at −78 °C and subsequent treatment of the reaction products with ethanol resulted in 1,16-bis[tris(trimethylsilyl)silyl]-C_{60}-fullerene in 69% yield. Its structure (in the form of a solvate with CS_2) was confirmed by X-ray diffraction analysis.[100]

The sterically overcrowded TTS derivatives present certain interest. Thus bis(hypersilyl)methoxymethane **22** is formed in the reaction of $(Me_3Si)_3SiLi$ with dichloromethoxymethane.[101, 102]

$$(Me_3Si)_3SiLi + Cl_2CHOMe \longrightarrow [(Me_3Si)_3Si]_2CHOMe$$

22 (35%)

The methoxy group in compound **22** is so strongly shielded that it is resistant to acid hydrolysis under drastic conditions;[101] the Si−C−Si angle is equal to 132.7°, which suggests steric overcrowding of this molecule. The reaction of TTS-Li with methyl formate afforded sterically overcrowded bis(hypersilyl)-methanol, $[(TTS)_2CHOH]$.

Treatment of hypersilyllithium with carbon dioxide and subsequent hydrolysis yielded thermally stable ($T_{decomp.}$ = 225 °C) hypersilylcarboxylic acid $(Me_3Si)_3SiCO_2H$.[8] Stable acylsilanes are formed in reactions of TTS-Li with acyl halides.[103]

$$(Me_3Si)_3SiLi + RC(O)Cl \longrightarrow (Me_3Si)_3SiC(O)R + LiCl$$

R = Bu^t, CEt_3, 1-adamantyl.

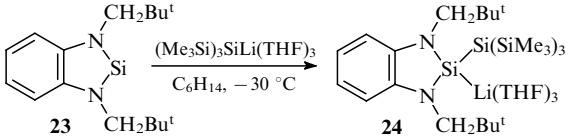
The properties of acylsilanes are considered in Section VIII. The tris(trimethylsilyl)silyl group confers stability also to the aldehyde $(Me_3Si)_3SiC(O)H$; however, this can be prepared exclusively using organometallic reagents (see Section VI.4).

b. Silicon

Treatment of $(Me_3Si)_3SiLi$ with various organosilicon halides was used for the preparation of derivatives of the type $(Me_3Si)_3SiSiR_2X$ (R = Cl, Me, Pr^i, Bu^t, Ph, X = Cl; R = $Bu^t(Me_3Si)N$, X = F)[104] as well as compounds of the type $(Me_3Si)_3SiR$, where R = $SiCl_3$, $SiMe_2H$, $SiPh_2Cl$.[39] Halogen or hydrogen atoms in the latter are fairly mobile and can easily be substituted by other functional groups, *e.g.*, OMe, I, OH, OAc, O_2CCF_3.[39]

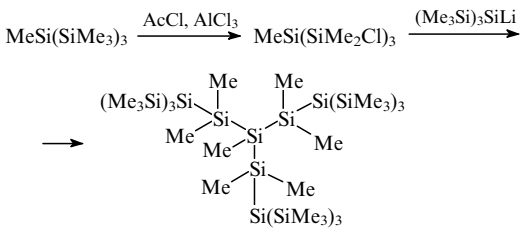
Careful hydrolysis of disilane $(Me_3Si)_3SiSiCl_3$ allowed isolation of the thermally stable (m.p. = 210–213 °C) silanetriol $(Me_3Si)_3SiSi(OH)_3$, which exists as a hexamer in the crystalline state. The core of this spherical molecule consists of six associated silanetriol groups.[105]

Under mild conditions, lithium tris(trimethylsilyl)silanide reacts with stable silylene **23** to give the addition product **24**.[106]



23 **24**

The tris(trimethylsilyl)silyl group plays a key role in the synthesis of branched polysilanes, since it allows one to elongate the chain by substitution of SiLi or SiCl for the terminal fragments SiMe.[107–109]

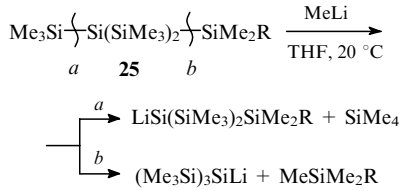


The synthesis of branched polysilanes has a number of specific features related to the steric factors and the ability of the Si−Si bond to be cleaved by nucleophilic reagents. Although some examples of Si−Si bond cleavage in disilanes[110, 111] resulting in Me_3SiM (M is an alkali metal) are known, this process never takes place in branched polysilanes. The formation of a silyl anion with a 'tertiary' silicon atom ($\equiv Si)_3Si^-$ is thermodynamically the most favourable process.

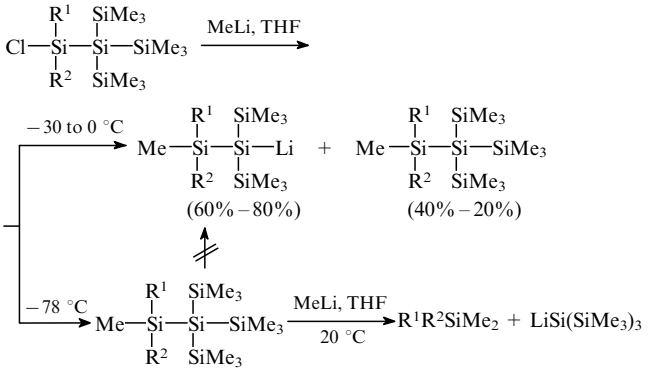
Splitting of branched polysilanes **25** under the action of methyllithium is mainly controlled by steric factors; MeLi largely attacks the least sterically hindered silicon atom (Table 7).[112]

Table 7. Relative yields (%) of the lithiation products of branched polysilanes $(Me_3Si)_3SiR$ **25**.[112, 113]

R	Route *a*	Route *b*
$SiMe_2H$	< 2	> 98
$SiMe_2Bu^t$	> 99	< 1
Si_2Me_5	70	30
$SiMe_2SiMe_2Bu^t$	98	2
$SiMe(SiMe_3)_2$	40	60
$Si(SiMe_3)_3$	< 2	> 98
$SiMeHSi(SiMe_3)_3$	< 2	> 98
$SiMe_2Si(SiMe_3)_3$	< 2	> 98



In branched chloropolysilanes, chlorine is relatively inactive; however, being an electronegative substituent, it stabilises 'tertiary' silyl anions. Therefore, at 0 – 30 °C (60% – 80%) the initial elimination of the trimethylsilyl group prevails.



R^1, R^2 = Me, $SiMe_3$, $Si(SiMe_3)_3$.

The formation of disilenes as intermediates in this reaction is not excluded.[112] With a decrease in temperature down to −78 °C, the mobility of the TTS-group seems to decrease considerably and substitution of the methyl group for the chlorine atom becomes predominant.

The use of bulkier silyllithium reagents, such as Ph_3SiLi and TTS-Li as well as of Bu^tOK,[22] results in the cleavage of one or two peripheral Si – Si bonds.[113]

$$(Me_3Si)_3SiSi(SiMe_3)_3 \xrightarrow{RLi} (Me_3Si)_3SiSi(SiMe_3)_2Li + Li(Me_3Si)_2SiSi(SiMe_3)_2Li + RSiMe_3$$

R = Ph_3Si, $(Me_3Si)_3Si$.

$$(Me_3Si)_3SiSi(SiMe_3)_3 \xrightarrow{Bu^tOK} (Me_3Si)_3SiSi(SiMe_3)_2K + Bu^tOSiMe_3$$

The reaction of the resulting silyllithium derivatives with silicon halides constitutes the second step in the synthesis of branched polysilanes.

In one of the methods for the synthesis of bis(hypersilyl) derivatives, silyl triflate $(CF_3SO_3)_2SiH_2$ formed *in situ* from Ph_2SiH_2 and CF_3SO_3H is treated with tris(trimethylsilyl)silyllithium.[114]

$$2\,LiSi(SiMe_3)_3 + (CF_3SO_3)_2SiH_2 \longrightarrow (Me_3Si)_3Si-SiH_2-Si(SiMe_3)_3 \quad (19\%)$$

c. Germanium, tin, lead

A series of organotin TTS derivatives have been obtained in satisfactory yields by the reaction of $(Me_3Si)_3SiLi(THF)_3$ with alkyltin(IV) halides.[24]

$$R_{4-n}SnCl_n + n\,(Me_3Si)_3SiLi(THF)_3 \longrightarrow [(Me_3Si)_3Si]_nSnR_{4-n} + n\,LiCl$$

R = Me, Bu^n; n = 1, 2.

The reaction of lithium tris(trimethylsilyl)silanide with silicon, germanium and tin tetrachlorides provides an illustrative example of the steric effect of the TTS group on nucleophilic substitution. Silicon tetrachloride reacts with only 1 equiv. of $(Me_3Si)_3SiLi$ to yield $(Me_3Si)_3SiSiCl_3$;[104] $GeCl_4$ gives a dimer with a Ge – Ge bond, $[Cl_2GeSi(SiMe_3)_3]_2$,[115] while the substitution of two chlorine atoms in $SnCl_4$ affords $Cl_2Sn[Si(SiMe_3)_3]_2$.[24]

The reactions of trichlorosilane and germanium(II) silylamide with TTS-Li are more complicated and give cyclic compounds **26** and **27**, which formally represent the rearrangement products of tris(trimethylsilyl)silyl derivatives of bivalent silicon and germanium.[81]

$$2\,(Me_3Si)_3SiLi \xrightarrow[C_5H_{12},\ -30\ ^\circ C]{HSiCl_3} (Me_3Si)_2Si\langle Si(SiMe_3)_2 \rangle Si(SiMe_3)_2$$

26

$$2\,(Me_3Si)_3SiLi \xrightarrow[C_5H_{12},\ -30\ ^\circ C]{Ge[N(SiMe_3)_2]_2} (Me_3Si)_2Ge\langle Si(SiMe_3)_2 \rangle Si(SiMe_3)_2$$

27

Treatment of bivalent tin chloride with TTS-Li gives the ate-complex $[(Me_3Si)_3Si]_2Sn(\mu\text{-}Cl)Li(THF)_3$.[116]

The reaction of tris(trimethylsilyl)silyllithium with $PbCl_2$ occurs as a redox process resulting in metallic lead and hexakis(trimethylsilyl)disilane.[117]

$$PbCl_2 + 2\,(Me_3Si)_3SiLi(THF)_3 \longrightarrow (Me_3Si)_3SiSi(SiMe_3)_3 + 2\,LiCl + Pb$$

Chlorotriphenylplumbane reacts with TTS-Li to give a colourless crystalline thermostable product **28** in 81% yield.[118]

$$Ph_3PbCl + (Me_3Si)_3SiLi(THF)_3 \longrightarrow Ph_3PbSi(SiMe_3)_3 + LiCl$$

28

An attempt to obtain a bis(hypersilyl) derivative $Ph_2Pb[Si(SiMe_3)_3]_2$ resulted in diplumbane **29**.[118]

$$Ph_2PbCl_2 + 2\,(Me_3Si)_3SiLi(THF)_3 \longrightarrow (Me_3Si)_3Si-Pb(Ph_2)-Pb(Ph_2)-Si(SiMe_3)_3 + Si_2(SiMe_3)_6$$

29

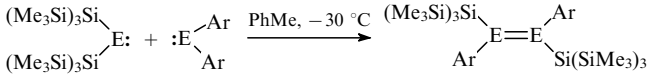
Homoleptic hypersilanides of bivalent tin and lead were prepared by reactions of the corresponding silylamides with tris(trimethylsilyl)silyl derivatives of alkali metals.[119, 120]

$$[(Me_3Si)_2N]_2E + 2\,MSi(SiMe_3)_3 \longrightarrow [(Me_3Si)_3Si]_2E + 2\,(Me_3Si)_2NM$$

E = Sn, Pb; M = Na, K, Rb, Cs.

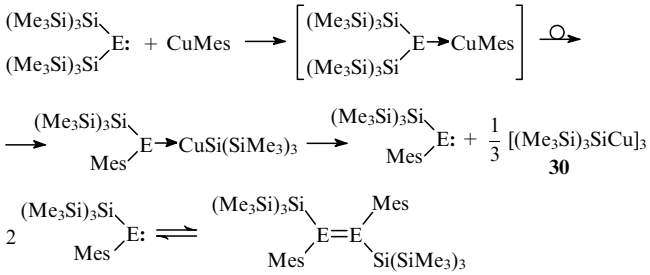
Di(hypersilyl)stannylene and -plumbene manifest amphoteric properties and behave as Lewis acids or bases. Quantum-chemical calculations of model compounds have demonstrated that the Lewis acidity of the carbenoids $(H_3Si)_2E$ (E = Sn, Pb) significantly exceeds that of the related diorganyl derivatives Me_2E, which increases their ability to form adducts (Lewis acid – base)

and dimers. The equilibrium between the monomeric and dimeric forms is more typical of di(hypersilyl)stannylene in solution, whereas in the crystalline state this compound is a dimer with an interatomic Sn–Sn distance of 2.825 Å. Di(hypersilyl)plumbene exists as a monomer both in solution and in the crystalline state, but forms adducts with other, less sterically overcrowded plumbenes. Such an interaction is also typical of di(hypersilyl)stannylene; it is of note that the formation of an adduct is accompanied by the migration of substituents.[119]



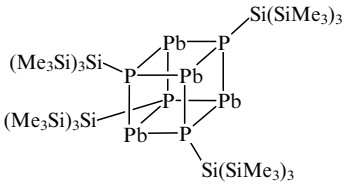
E = Sn, Pb; Ar = 2,4,6-$Me_3C_6H_2$; 2,6-$Me_2C_6H_3$.

Di(hypersilyl)stannylene and -plumbene react as Lewis bases with mesitylcopper. Hypersilylcopper **30** and mesityl(hypersilyl)-stannylene or -plumbene are the final reaction products.[121]

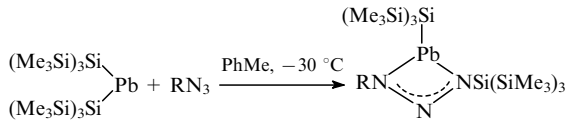


E = Sn, Pb.

In contrast to diarylstannylenes and -plumbenes, the dihypersilyl derivatives react faster with white phosphorus in toluene even at low temperatures (−30 °C).[119] Compounds containing Si–P bonds, $[(Me_3Si)_3SiP]_4Pb_4$ and $(Me_3Si)_3Si-P=P-Si(SiMe_3)_3$, are formed in the reaction of $Pb(TTS)_2$ in addition to the simple adduct $P_4[Pb(TTS)_2]_4$. $[(Me_3Si)_3SiP]_4Pb_4]$ has a cubane-like structure ($\delta\ ^{31}P = -506$).[119]

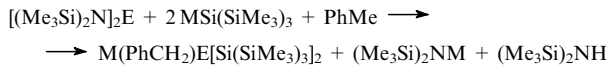


Organic azides form 1,3-addition products with di(hypersilyl)plumbene with simultaneous migration of the TTS group to the terminal nitrogen atom:[119]



R = 1-adamantyl, Me_3Si.

Numerous reactions of di(hypersilyl)stannylenes and -plumbenes with various bases, including organic and silyl derivatives of alkali metals, have been studied.[119] However, only some of them yielded stable products. Thus di(hypersilyl)stannylene reacts with $(Me_3Si)_3SiNa$ in toluene to give $[(Me_3Si)_3Si]_3SnNa(PhMe)$ in a quantitative yield. At temperatures above −30 °C, tris(trimethylsilyl)silyl derivatives of alkali metals react with tin and lead silylamides in toluene to give toluene metallation products.

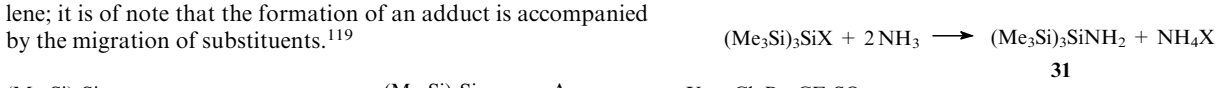


E = Sn, Pb; M = K, Rb, Cs.

4. Group VA elements

a. Nitrogen

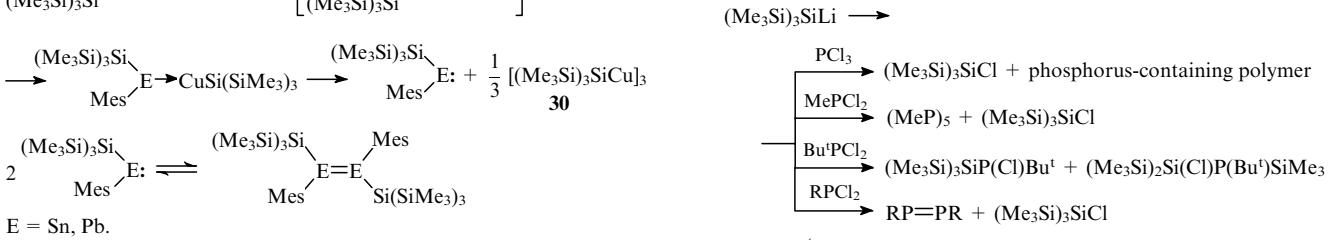
Tris(trimethylsilyl)silyl derivatives of amines can be easily prepared by treatment of TTS halides with amines. Of particular interest in this respect is aminotris(trimethylsilyl)silane **31**, a highly stable compound which does not yield self-condensation products on heating.[122]



X = Cl, Br, CF_3SO_3.

b. Phosphorus

The Si–P bond is rather unstable. This has a certain effect on the chemistry of silicon–phosphorus compounds at large, on the chemistry of hypersilyl derivatives, in particular. The majority of reactions of lithium hypersilanide with phosphorus chlorides are accompanied by the formation of $(Me_3Si)_3SiCl$ (which is thermodynamically a very favourable product), and poly- or oligophosphines.[123–126]



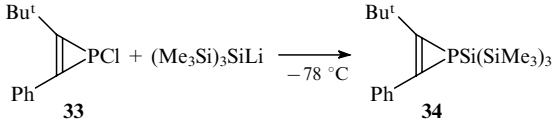
R = 2,4,6-$Bu^t_3C_6H_2$ (see [124]), $(Me_3Si)_3C$ (see [123]).

The complex of lithium tris(trimethylsilyl)silanide with THF (**5**) reacts with aminodifluorophosphines to give thermally stable derivatives **32a–d**.[127]

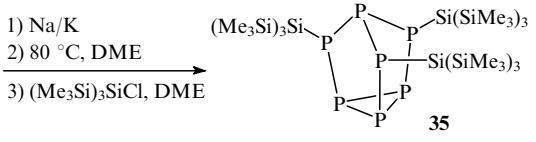
R = Bu^t (**a**), 2,4,6-$Me_3C_6H_2$ (**b**), $SiMe_3$ (**c**), 2-adamantyl (**d**).

Heating or distillation of compounds **32a–d** does not result in the elimination of Me_3SiF, whereas related tris(trimethylsilyl)-methyl derivatives are unstable and are readily converted into ylides $(Me_3Si)_2C=PN(R)SiMe_3$ (R = Bu^t, 2-adamantyl) upon elimination of fluorotrimethylsilane.[127]

The reaction of TTS-Li with 1-chloro-1*H*-phosphyrene **33** yielded the TTS-derivative **34**, which is relatively stable at 20 °C, but decomposes in light.[128]



Sodium-potassium phosphide prepared from white or red phosphorus and a Na/K alloy reacts with chloro tris(trimethylsilyl)silane to give $[(Me_3Si)_3Si]_3P_7$ (**35**), a colourless crystalline compound in which the nortricyclane cell P_7 contains three TTS substituents.[129]



The phosphanortricyclanic cell is a relatively stable structure. Compounds of an analogous structure with other silyl substituents ($SiMe_3$, $SiPh_3$, $SiBu^t_3$) can be prepared as well.[129]

5. Group VIA elements

a. Oxygen

Tris(trimethylsilyl)silanol. Tris(trimethylsilyl)silanol, $(Me_3Si)_3Si.OH$, can be prepared by hydrolysis of TTS halides.

It is known that hydrolysis of halogenosilanes usually gives disiloxanes. The bulky TTS group prevents both the hydrolysis and subsequent condensation of silanols. Of the TTS halogen derivatives, only iodo- and bromosilanes are hydrolysed at satisfactory rates. Chlorotris(trimethylsilyl)silane does not react with water in neutral media. Its hydrolysis demands long-term (7 days) stirring of a TTS chloride solution in THF with 20% KOH. During this time, the greater part of the product is lost as a result of cleavage of the Si–Si bonds in the alkaline medium. An alternative method consists of long-term intense stirring of $(Me_3Si)_3SiCl$ with aqueous triethylamine in hexane.[130] In aqueous THF, bromotris(trimethylsilyl)silane is in an equilibrium with silanol and HBr; the latter is easily titrated with 5% NaOH. The equilibrium is shifted as a result of removal of HBr and the yield of $(Me_3Si)_3SiOH$ exceeds 90%.[131] Tris(trimethylsilyl)silanol is moderately sensitive to oxygen. Upon 1-month exposure to air, its content decreases by 30% with formation of a complex mixture of oxidation products.

Tris(trimethylsilyl)silanol differs from ordinary compounds of this class in thermal stability, this does not undergo condensation to disiloxane. In acidic media, substitution reactions take place instead of self-condensation, but in the case of ordinary silanols they proceed in the opposite direction.[131]

$$(Me_3Si)_3SiOH + HCl\,(aq.) \longrightarrow (Me_3Si)_3SiCl + H_2O,$$

$$(Me_3Si)_3SiOH + Me_3SiCl \longrightarrow (Me_3Si)_3SiCl + Me_3SiOH$$

Substitution reactions with carboxylic acids and primary alcohols (MeOH, EtOH) also take place.[132]

$$(Me_3Si)_3SiOH + MeC(O)OH \longrightarrow (Me_3Si)_3SiOC(O)Me + H_2O,$$

$$(Me_3Si)_3SiOH + EtOH \longrightarrow (Me_3Si)_3SiOEt + H_2O$$

However, in the case of isopropyl alcohol no reaction occurs, presumably due to steric hindrance. The esterification of tris(trimethylsilyl)silanol by carboxylic acids easily occurs even in an aqueous medium, since the reverse reaction (hydrolysis) is impossible in neutral or weakly acidic media.[132]

The IR spectrum of $(Me_3Si)_3SiOH$ contains intense absorption bands: a narrow band at 3660 cm^{-1} and a broad band around 3240–3600 cm^{-1}, which can be associated with the free and bound hydroxy groups, respectively.[130] The bands at 3443, 1080 and 1049 cm^{-1}, which relate to the protonated OH and SiO groups, are not detected in the Raman spectra. Such a difference is explained by changes in the symmetry due to dimer formation.[130]

Hypersilanolates $[(Me_3Si)_3SiO]_nML_m$. Alkali metal triorganylsilanolates are usually synthesised by treatment of triorganylsilanols with alkali metals or their hydrides.[133] However, alkali metal tris(trimethylsilyl)silanolates cannot be prepared by this method, since they either do not react with silanol or cause its destruction under more drastic conditions.[131,134] Lithium and sodium derivatives were prepared by treatment of tris(trimethylsilyl)silanol in hexane with butyllithium or sodium isopropoxide.[131]

$$(Me_3Si)_3SiOH + Bu^nLi \longrightarrow (Me_3Si)_3SiOLi + Bu^nH,$$

$$(Me_3Si)_3SiOH + Pr^iONa \longrightarrow (Me_3Si)_3SiONa + Pr^iOH$$

The thermal stabilities and reactivities of compounds containing $R_3Si-SiR_2OM$ groups depend on several factors, *viz*., the redox potential of a metal, its oxidation state, electron-donor properties of the polysilyl substituent, the degree of ionicity of the M–O bond and enthalpy of the rearrangement:

$$Si-Si-O-M \longrightarrow Si-O-Si-M.$$

Lanthanide derivatives with high affinities for oxygen and a moderately negative value of the standard redox potential appear to be the most stable compounds.

Thus the reaction of lanthanide silylamides with tris(trimethylsilyl)silanol gives gadolinium and lanthanum hypersilanolates **36a–f**.[135]

$$[(Me_3Si)_3N]_3Ln + 3\,(Me_3Si)_3SiOH + m\,L \longrightarrow [(Me_3Si)_3SiO]_3Ln(L_m) + 3\,(Me_3Si)_2NH$$

36a–f

Ln = Gd: L_m = $(THF)_2$ (**a**), $(MeCN)_2$ (**b**), 1,4-diazobicyclo[2.2.2]octane (**c**), (4,4′-bipiridyl)$_2$ (**d**), (4,4′-bipiridyl) (**e**);
Ln = La, L_m = $(THF)_4$ (**f**).

Homoleptic hypersilanolates, which contain no coordinating molecules, cannot be prepared because of their mobile equilibra and incomplete substitution. The bidentate ligand, 4,4′-bipyridyl, yields the coordination polymer **36e** upon coordination with the fragment $[(Me_3Si)_3SiO]_3Gd$, whereas 1,4-diazabicyclo[2.2.2]octane forms only a mononuclear complex **36c** at any ratio of the reagents due to steric hindrance. Gadolinium hypersilanolate **36a** absorbs only one mole of CO_2 to give $[(Me_3Si)_3SiO]_2Gd[OCOSi.(SiMe_3)_3](THF)_2$, whereas the analogous lanthanum complex **36f** yields the percarboxylate derivative $[(Me_3Si)_3SiOCO]_3La(THF)_2$.

Gadolinium and lanthanum hypersilanolates are stable at temperatures up to 200 °C. $(Me_3Si)_3SiOH$ and polylanthanosiloxane are the only decomposition products of compound **36a** at higher temperatures. It is noteworthy that thermolysis of more ionic lithium hypersilanolate, $(Me_3Si)_3SiOLi$, affords H_2, $(Me_3Si)_3SiH$ (55%), $Me_3SiOSi(SiMe_3)_3$ (10%) and $(Me_3Si)_3SiOH$ (13%).[131]

An increase in the redox potential on going from manganese to nickel and a simultaneous increase in the energy of the metal–silicon bond in the hypersilanolates of bivalent metals of Groups VII and VIII (Mn, Fe, Co, Ni) cause a significant decrease in their stability and increase their ability for intramolecular rearrangements eventually resulting in formation of the silicon–metal bond.

Cobalt(II) and iron(II) silanolates of the general formula **37a–k** were prepared by the reaction of tris(trimethylsilyl)silanol with the corresponding silylamides.[136] The reaction of $FeBr_2$ with $(Me_3Si)_3SiONa$ in dimethoxyethane was also used for the preparation of the ate-complex $(Me_3Si)_3SiOFe[\mu\text{-}OSi(SiMe_3)_3]_2.Na(DME)$ (**38**).[137]

$$[(Me_3Si)_2N]_2M + 2\,(Me_3Si)_3SiOH + L_n \longrightarrow [(Me_3Si)_3SiO]_2M(L_n) + 2\,(Me_3Si)_2NH$$

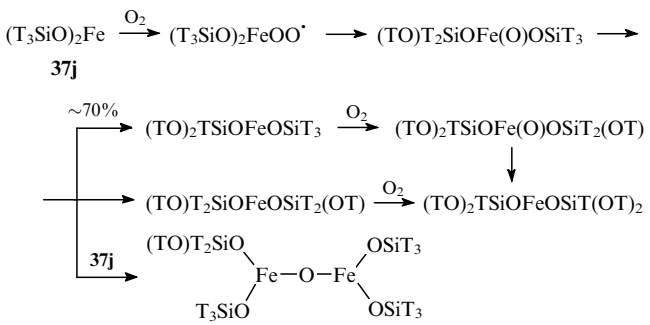
37a–l

M = Co: L_n is absent (**a**), L_n = THF (**b**), $(THF)_2$ (**c**), DME (**d**), $(MeCN)_2$ (**e**), $(PhCN)_2$ (**f**), 2,2′-bipyridyl (**g**), 4,4′-bipyridyl (**h**), $(Ph_3P)_2$ (**i**); M = Fe: L_n absent (**j**), L_n = 2,2′-bipyridyl (**k**), 4,4′-bipyridyl (**l**).

According to X-ray diffraction analysis, the homoleptic silanolates **37a**, **j** represent dimers in the crystalline state, but are monomers in solution (data from cryoscopic measurements in benzene). In contrast to other complexes, compound **37a** reversibly binds two THF molecules, which are easily removed *in vacuo* and upon dissolution in nonpolar solvents. 4,4′-Bipyridyl interacts with silanolates **37a**,**j** to give insoluble coordination compounds **37h**,**l**.[136]

It is of note that iron tris(trimethylsilyl)silanolates **37j**, **38** are pyrophoric in air, although they are in fact oxides. The oxidation of the Si–Si bonds proceeds at a high rate due to activation of the O_2 molecule on the coordinatively unsaturated iron atom. A detailed study of this oxidation in the example of compound **37j** revealed that oxygen is consumed in two routes, *viz*., in the

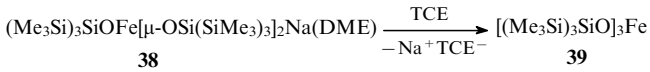
oxidation of the ligand (which is predominant) and in the oxidation of Fe(II) to Fe(III).[136]



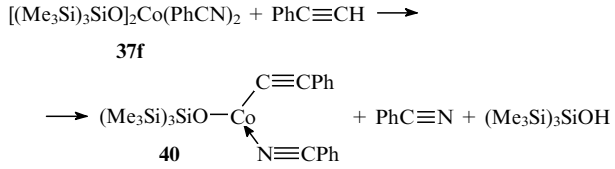
T = Me_3Si.

In the case of cobalt complexes, all of the oxygen is consumed for oxidation of the ligand.

The ate-complex of bivalent iron **38** reacts smoothly with tetracyanoethylene (TCE) to give Fe(III) hypersilanolate (**39**). Compound **39** does not react with oxygen.[137]



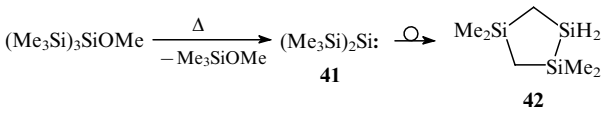
Under ordinary conditions, homoleptic cobalt silanolate **37a** adsorbs CO to give a complex with a tentative structure $(Me_3Si)_2(Me_3SiO)SiCo_x(CO)_y$. Compounds **37** are active as catalysts in the oligomerisaton of phenylacetylene. The reaction of equimolar amounts of silanolate **37f** and PhC≡CH results in the substitution of one silanolate group. Subsequent addition of PhC≡CH to the complex **40** yields 1,3,5-triphenylbenzene and polyphenylacetylene.



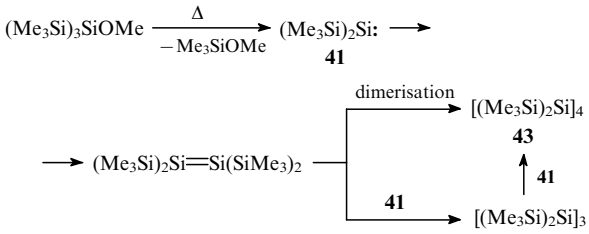
Thermal transformations of hypersilanolates have been studied. The decomposition of cobalt silanolate **37a** in solution begins at 40 °C. Acid hydrolysis of the solid thermolysis product gave Me_3SiH and $(Me_3Si)_3SiOSiH(SiMe_3)(OSiMe_3)$, which suggests a rearrangement occurs:

Thermolysis of $[(Me_3Si)_3SiO]_2Fe$ (**37j**) at 180–250 °C yields $(Me_3Si)_3SiOH$, $(Me_3Si)_3SiOSiMe_3$ and solid polyferro(Fe^{II})siloxane, whereas the ate-complex $(Me_3Si)_3SiOFe[\mu\text{-}OSi(SiMe_3)_3]_2.Na(DME)$ (**38**) gives silanes $[(Me_3Si)_3SiSi(SiMe_3)_3]$, $(Me_3Si)_4Si]$ and solid polyferri(Fe^{III})siloxane.[137] The reason for such a substantial difference is the presence, in the ate-complex, of sodium silanolate fragment possessing basic properties, which favours their disproportionation. Nickel hypersilanolates $LNi[OSi(SiMe_3)_3]_n$ cannot be synthesised because of smooth rearrangements leading to the formation of compounds with a Ni–Si bond.

For comparison, thermolysis of methoxytris(trimethylsilyl)silane, $(Me_3Si)_3SiOMe$, is accompanied by the formation of bis(trimethylsilyl)silylene (**41**).[138] Its further conversions depend on the reaction conditions. In the gas phase, compound **41** undergoes rearrangement into trisilylcyclopentane **42**.[139]

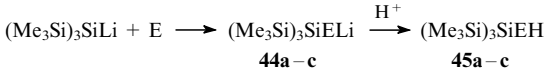


Thermolysis in the liquid phase yielded a totally different product, *viz*., octakis(trimethylsilyl)cyclotetrasilane (**43**).



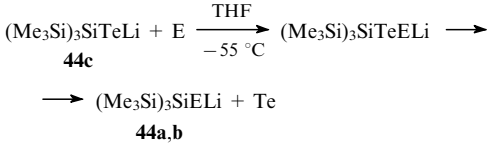
b. Chalcogens

Tris(*trimethylsilyl*)*silylchalcogenols* $(Me_3Si)_3Si-EH$ (E = S, Se, Te) *and their metal derivatives*. Chalcogens are easily inserted into the Si–Li bond of lithium hypersilanide to give the lithium derivatives **44a–c**.[140]



E = S (**a**), Se (**b**), Te (**c**).

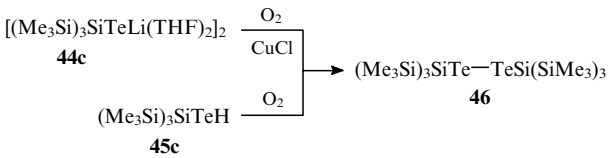
Subsitution of lighter chalcogens for tellurium is a convenient approach to the synthesis of sulfur and selenium derivatives.[140]



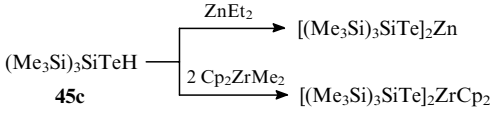
E = S, Se.

Acid hydrolysis of the lithium salts **44a–c** gives the corresponding chalcogenols **45a–c** in quantitative yields.[140,141] The acidic properties of hypersilylchalcogenols are increased, as expected, on going from sulfur to tellurium. The experimental values of pK_a for $(Me_3Si)_3SiEH$ are equal to 10.7 (**45a**, E = S), 8.3 (**45b**, E = Se) and 7.3 (**45c**, E = Te). The stretching vibration frequencies of the E–H bonds decrease significanly from sulfur to tellurium in the following order: 2557, 2294, 2017 cm^{-1}, respectively.[140]

Oxidation of the dimeric lithium hypersilyltellurolate–THF complex **44c**, like tellurol itself **45c**, gives hypersilyl ditelluride **46**.[142]



Tellurol **45c**, which possesses pronounced acidic properties, easily reacts with alkylmetal derivatives.[141]



Hypersilylselenolates and -tellurolates of bivalent lanthanides (Yb, Eu, Sm) were prepared using reactions of the corresponding silylamides with hypersilylselenol or -tellurol and characterised as complexes with donor molecules.[143]

$$(THF)_2Ln[N(SiMe_3)_2]_2 + 2\,(Me_3Si)_3SiEH + n\,L \longrightarrow$$
$$\longrightarrow [(Me_3Si)_3SiE]_2Ln(L_n) + 2\,HN(SiMe_3)_2$$

E = Se, Te; Ln = Yb, Eu, Sm;
L = TMEDA, $n = 2$; L = $(Me_2PCH_2)_2$, $n = 1.5$;
TMEDA is *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

The thermally induced decomposition of ytterbium(II) hypersilylselenolate and -tellurolate results in their conversion into polycrystalline metal chalcogenides with elimination of bis(hypersilyl)chalcogen at 150–200 °C.

$$[(Me_3Si)_3SiE]_2Yb(TMEDA)_2 \longrightarrow [YbE] + E[Si(SiMe_3)_3]_2 + 2\,TMEDA$$

E = Se, Te.

Hypersilylselenolates $[(Me_3Si)_3SiSe]_3Ln(THF)_2$ (Ln = La, Sm, Yb) and -tellurolates $[(Me_3Si)_3SiTe]_3Ln(dmpe)_2$ [Ln = La, Ce, Y; dmpe is 1,2-bis(dimethylphosphino)ethane] of trivalent lanthanides with coordinating ligands were prepared in a similar way.[144] The homoleptic derivatives appeared to be significantly less stable. On storage, hypersilylselenides of Sm, Eu and Yb decompose, predominantly into the bivalent complexes $[(Me_3Si)_3SiSe]_2Ln$ and bis(hypersilyl)diselenide. An attempt to isolate homoleptic hypersilyltellurides of trivalent lanthanides yielded cluster compounds, $Ce_5Te_3[TeSi(SiMe_3)_3]_9$ in particular.[144]

First attempts at the synthesis of homoleptic tellurolate derivatives of transition metals of the first row were unsuccessful. Treatment of bivalent Cr, Mn, Fe, Co and Ni halides with 2 equiv. of $(Me_3Si)_3SiTeLi(THF)_2$ yielded ditelluride $[TeSi(SiMe_3)_3]_2$ and a pyrophoric residue of an unknown nature.[145] Reactions of metal silylamides $M[N(SiMe_3)_2]_2$ with $(Me_3Si)_3SiTeH$ gave oily products, no pure compounds could be isolated. It was the use of coordinating phosphine ligands that allowed the isolation and characterisation of individual complexes.[145]

$$M[N(SiMe_3)_2]_2 + 2\,(Me_3Si)_3SiTeH + n\,dmpe \longrightarrow$$
$$\longrightarrow [(Me_3Si)_3SiTe]_2M(dmpe)_n + 2\,HN(SiMe_3)_2$$

M = Mn, $n = 1$; M = Fe, $n = 2$.

Halides of Cr, Mn and Fe afford analogous compounds in reactions with lithium hypersilyltelluride in the presence of coordinating molecules. The redox reaction of the cobalt(II) bromide diphosphine complex with TTS-TeLi is an exception.

$$CoBr_2(PMe_3)_3 + 2\,(Me_3Si)_3SiTeLi(THF)_2 \longrightarrow$$
$$\longrightarrow \underset{\mathbf{47}}{Co[TeSi(SiMe_3)_3](PMe_3)_3} + 1/2\,[(Me_3Si)_3SiTe]_2$$

The Co(I) complex (**47**) actively absorbs 2 equiv. of CO at atmospheric pressure.[145]

$$\mathbf{47} + 2\,CO \longrightarrow (CO)_2Co[TeSi(SiMe_3)_3](PMe_3) + 2\,PMe_3$$

It should be noted that the electronegative silyltellurolate ligand in compound $[(Me_3Si)_3SiTe]_2Fe(dmpe)_2$ is highly labile and can be displaced into the outer coordination sphere with acetonitrile to give the salt $[Fe\{TeSi(SiMe_3)_3\}(dmpe)_2(MeCN)].[TeSi(SiMe_3)_3]$.

Vanadium hypersilylselenides[146] and -tellurides[147] were prepared starting from vanadium(III) amidobromide **48**.

$$[(Me_3Si)_2N]_2VBr + (Me_3Si)_3SiELi(THF)_2 \longrightarrow$$
$$\underset{\mathbf{48}}{\longrightarrow} [(Me_3Si)_2N]_2VESi(SiMe_3)_3$$

E = Se, Te.

Further substitution of the hypersilylselenol group for the silylamide groups gives the disproportionation products **49** and **50**.[148]

$$[(Me_3Si)_2N]_2VSeR + 2RSeH \longrightarrow \underset{\mathbf{51}}{[V(SeR)_3]} \longrightarrow \underset{\mathbf{49}}{\tfrac{1}{2}V(SeR)_2} + \underset{\mathbf{50}}{\tfrac{1}{2}V(SeR)_4}$$

R = $Si(SiMe_3)_3$.

The trivalent vanadium derivative **51,** which is formed first, can be isolated as adducts $[(Me_3Si)_3SiSe]_3V(L)$, where L is the donor molecule (pyridine, 2,6-dimethylisocyanobenzene, pyrazine).

An attempt to substitute the hypersilyltelluride groups for the silylamide groups in $[(Me_3Si)_2N]_2V-TeR$ by treatment with hypersilyltellurol gave only the tetrasubstituted product $V[TeSi.(SiMe_3)_3]_4$ (**52**) in 20% yield.[147] A similar derivative of tetravalent molybdenum $Mo[TeSi(SiMe_3)_3]_4$ (**53**) is formed upon treatment of tetrakis(*o*-tolyl)molybdenum with hypersilyltellurol.[147] Under the action of 1,2-bis(dimethylphosphino)ethane, compounds **52** and **53** easily undergo reductive elimination to give $[TeSi(SiMe_3)_3]_2$.

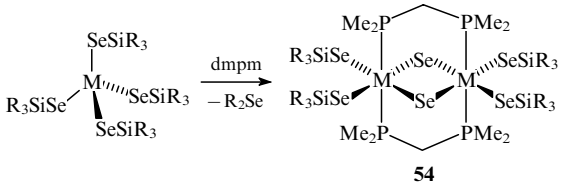
$$\underset{\mathbf{52,\ 53}}{M[TeSi(SiMe_3)_3]_4} \xrightarrow{dmpe} [TeSi(SiMe_3)_3]_2 + (dmpe)_2M[TeSi(SiMe_3)_3]_2$$

M = V (**52**), Mo (**53**).

In the presence of CO (1 atm), compound **53** readily eliminates two ditelluride molecules to give hexacarbonylmolybdenum.[147]

$$\underset{\mathbf{53}}{Mo[TeSi(SiMe_3)_3]_4} + 6\,CO \longrightarrow Mo(CO)_6 + 2\,[TeSi(SiMe_3)_3]_2$$

Homoleptic hypersilylchalcogenolates of Group IVB metals, *viz*., $M[ESi(SiMe_3)_3]_4$ (M = Ti, Zr, Hf), were prepared by treatment of the corresponding metal chlorides with TTS-ELi (E = S, Se, Te).[149] They represent thermally stable (m.p. > 220 °C) intensely coloured compounds. Treatment of zirconium and hafnium hypersilylselenides with the Lewis base bis(dimethylphosphino)methane (dmpm), yields binuclear complexes **54** the metal atoms in which are linked through selenide and phosphine bridges.[149]



54

R = $SiMe_3$; M = Zr, Hf.

With dmpm, hypersilyltellorolates $[(Me_3Si)_3SiTe]_4M$ (M = Zr, Hf) form the mononuclear complexes $(dmpm)_2.[(Me_3Si)_3SiTe]_2M$ = Te, whereas ordinary octahedral complexes $[(Me_3Si)_3SiTe]_4M(2,6\text{-}Me_2C_6H_3NC)_2$ are formed under the action of 2,6-dimethylisocyanobenzene.

6. Group VIIA elements (TTS halides)

Chloro, bromo and iodo derivatives $(Me_3Si)_3SiX$ can be prepared by the reaction of tris(trimethylsilyl)silane with polyhalohydrocarbons (see Section IV.1).[49] They cannot be prepared by selective halogenation of $(Me_3Si)_4Si$ (**3**), since the reaction rates of intermediate compounds with halogens significantly exceed those of the starting silane. Tetrahalosilane and halotrimethylsilane are formed in these reactions. However, selective substitution of bromine for lithium atoms in lithium tris(trimethylsilyl)silanide can be effected at low temperatures.[150]

$$(Me_3Si)_3SiLi \xrightarrow[-78\ °C]{Br_2} (Me_3Si)_3SiBr + LiBr$$

Fluorotris(trimethylsilyl)silane was prepared by an exchange reaction of TTS bromide with antimony trifluoride.[151]

$$(Me_3Si)_3SiBr + 1/3\,SbF_3 \longrightarrow (Me_3Si)_3SiF + 1/3\,SbBr_3$$

Careful chlorination of chlorotris(trimethylsilyl)silane has led to dichlorobis(trimethylsilyl)silane in satisfactory yields.[151]

$$(Me_3Si)_3SiCl + Cl_2 \xrightarrow[-23\ ^\circ C]{C_5H_{12},\ N_2} (Me_3Si)_2SiCl_2 + Me_3SiCl \quad (94\%)$$

Tris(trimethylsilyl)silyl halides are highly thermally stable. The decomposition of $(Me_3Si)_3SiCl$ begins at 300 °C and formally yields insertion products of silylene $(Me_3Si)_2Si$ into the Si–Cl bond. $(Me_3Si)_3SiH$ behaves in a similar way.[138]

$$(Me_3Si)_3SiX \xrightarrow{\sim 300\ ^\circ C} (Me_3Si)_3Si-Si(SiMe_3)_2X$$

X = H (1 h, 67%), Cl (4 h, 30%).

The reactivities of halides $(Me_3Si)_3SiX$ with respect to nucleophilic reagents depend substantially on the halogen and decrease in the following order: X = I > Br > Cl > F. Hydrolysis of hypersilyl halides in the presence of bases gives stable silanol $(Me_3Si)_3SiOH$ (see Section V.5.a). Bromide $(Me_3Si)_3SiBr$ is the most convenient substrate for substitution reactions. Reactions involving this compound proceed at sufficiently high rates and in good yields.[150]

$$CpH \xrightarrow{Bu^nLi} CpLi \xrightarrow[-78\ ^\circ C]{TTS\text{-}Br} CpSi(SiMe_3)_3 \quad (98\%)$$

Hypersilyl chloride is highly inert and its reactions occur under more drastic conditions and require longer times. The reaction of $(Me_3Si)_3SiCl$ with the Grignard reagent gives a TTS derivative in low yield.[4]

$$p\text{-}BrC_6H_4Br \xrightarrow[2)\ TTS\text{-}Cl]{1)\ Mg,\ THF} p\text{-}(Me_3Si)_3SiC_6H_4Si(SiMe_3)_3 \quad (5\%)$$

Other reactions of TTS halides used as starting reagents in the synthesis of organometallic and organoelement compounds are considered in the sections that follow.

VI. Tris(trimethylsilyl)silanides of d- and f-elements

The $(Me_3Si)_3Si$ group is a convenient ligand and is used in the chemistry of transition metals. It provides sufficient steric protection of the metal centre, and the products formed possess good solubilities in organic solvents. Unique electron properties of the TTS group and its electronic 'amphoteric' character allow the preparation of various types of stable transition metal complexes. It should be remembered, however, that the TTS group itself (especially in the form of a TTS anion) is a very strong reducing agent. Therefore, its interactions with transition metal ions possessing a high redox potential are complicated by redox reactions. The use of metal complexes with stabilising ligands as the starting compounds and the correct choice of reaction conditions opens up the way to the synthesis of numerous TTS derivatives of d- and f-elements endowed with unique physical and chemical characteristics.

1. Group IB elements

a Copper

Upon reaction with copper(I) chloride, TTS-Li forms a complex $Li(THF)_4[Cu_5Cl_4(TTS)_2]$, which is stable at temperatures below −30 °C.[87] This compound may conventionally be regarded as an adduct of $[Li(THF)_4][Cu(TTS)_2]$ with four CuCl molecules. The central silicon atom in its TTS groups are coordinated simultaneously by two copper atoms. Other products of this redox reaction are Cu, $CuCl_2$ and LiCl.

Reactions of alkali metal tris(trimethylsilyl)silanides with copper *tert*-butoxide yield mixtures of complex silanides.[152]

$$MSi(SiMe_3)_3 \xrightarrow{Bu^tOCu} M[(Me_3Si)_3SiCuOBu^t] + (Me_3Si)_3SiCu + M[(Me_3Si)_3SiCuSi(SiMe_3)_3]$$

M = Li, Na, K, Cs.

The best results [the yield of $(Me_3Si)_3SiCu$ is > 60%] are obtained by metathesis of lead silanide with mesitylcopper (see Section V.3.c).[121] In the crystalline state, hypersilylcopper represents a planar cyclic trimer with a short Cu–Cu distance (2.384–2.415 Å).[121] The central silicon atoms in the hypersilyl groups act as bridging groups, each being linked with two copper atoms.

b. Silver

Tris(trimethylsilyl)silyl silver derivatives, $TTS\text{-}Ag(R_3P)_n$ (n = 1, R = Ph; n = 2: $R_3P = Ph_2PMe$, $Ph_2PTol\text{-}p$), were prepared by treatment of appropriate silver phosphine halides with TTS-Li.[153] The stabilities of these compounds increase with an increase in the number of phosphine substituents.

c. Gold

Of the TTS gold derivatives, the phosphine complexes $Ph_2MeP.AuTTS$ [154] and $TTSAuPh_2PCH_2CH_2PPh_2AuTTS$ (see Ref. 155) prepared by treatment of appropriate gold chlorides with TTS-Li in THF are especially well-characterised. The Au–Si bond is easily destroyed upon treatment with halogens, but withstands hydrolysis and methanolysis.[154] Presumably, the steric requirements for the two-coordinated gold atom are not very strict (in comparison with metals with greater coordination numbers); therefore, the length of the Au–Si bond in the TTS derivatives does not differ from that of other, less sterically hindered gold silanides.[154, 155]

2. Group IIB elements (Zn, Cd, Hg)

Compounds $(TTS)_2M$ (M = Zn, Cd, Hg) were prepared by treatment of bivalent metal halides with lithium tris(trimethylsilyl)silanide in ether.[156] In contrast to their trimethylsilyl analogues, TTS derivatives are thermally stable in the absence of air over a sufficiently long period of time. These compounds were found to be rather inert and did not react with metal halides such as $TaCl_5$, $TiCl_4$, $ZrCl_4$ and VCl_3. Hydrolysis of $(TTS)_2Zn$ is complete within several hours. Cadmium iodide forms an anionic complex $[Li(THF)_4][(Me_3Si)_3SiCd(I_3)CdSi(SiMe_3)_3]$ in a reaction with TTS-Li at 20 °C.[157]

$(TTS)_2Hg$ was synthesised using the Vyazankin method.[158]

$$2\,(Me_3Si)_3SiH + Bu^t_2Hg \longrightarrow [(Me_3Si)_3Si]_2Hg + 2\,Bu^tH$$

4

It is of note that a similar reaction of Bu^t_2Hg with tris(pentamethyldisilanyl)silane (**55**) yields a binuclear complex **56** where the organosilicon ligand has an umbrella shape 'covering' the mercury atoms.[159]

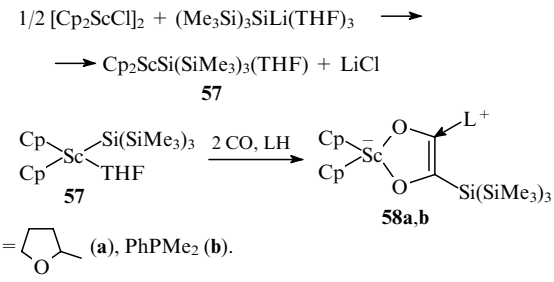
$$2\,(Me_5Si_2)_3SiH + Bu^t_2Hg \longrightarrow (Me_5Si_2)_3SiHg-HgSi(Si_2Me_5)_3 + 2\,Bu^tH$$

55 **56**

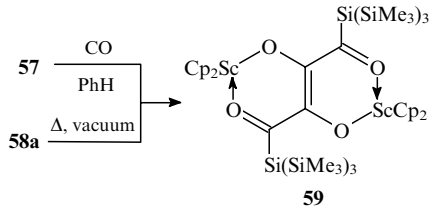
Upon heating to 180 °C, compound **56** eliminates one mercury atom to give $[(Me_5Si_2)_3Si]_2Hg$, whereas upon irradiation (λ > 330 nm) it generates a silyl radical $(Me_5Si_2)_3Si^\bullet$ stable at 20 °C.

3. Group IIIB elements, lanthanides, actinides

Tris(trimethylsilyl)silyl derivatives of Group IIIB elements, lanthanides and actinides are not numerous, only cyclopentadienyl complexes are known.[160] For example, the complex **57** containing a Sc–Si bond is extremely sensitive to oxygen and atmospheric moisture and easily absorbs two equivalents of CO to give the scandoxyketene derivatives **58** stabilised by donor molecules.[160]

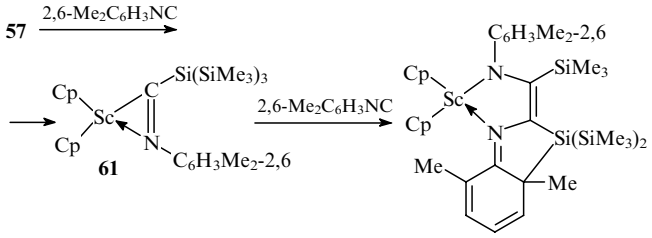


Heating of the complex **58a** *in vacuo* or carbonylation of compound **57** in a nonpolar medium gives the endione-diolate derivative **59**.

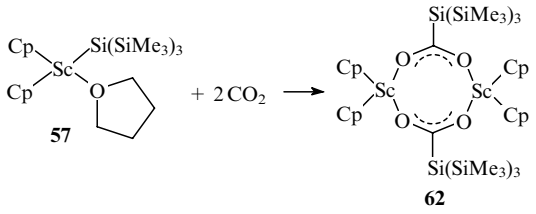


The addition of phenylacetylene to a solution of complex **57** in benzene results in the quantitative yield of $(Me_3Si)_3SiH$ and acetylenide **60**.[160]

Isocyanides are inserted into the Sc–Si bond; the primary product **61** undergoes attack by a second isocyanide molecule resulting in migration of the Me_3Si group.[160, 161]

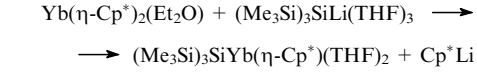


Carbon dioxide is easily incorporated into the Sc–Si bond of compound **57** to give the dimeric carboxylate **62**.[162]

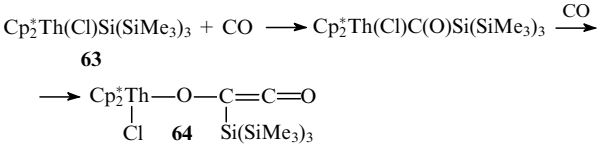


Compound **62** is unstable in solution and decomposes to the polymeric silanolate complex $[Cp_2ScOSi(SiMe_3)_3]_n$ with evolution of CO.[162]

The reaction of bis(pentamethylcyclopentadienyl)ytterbium with $(Me_3Si)_3SiLi$ in toluene results in substitution of the TTS group for one cyclopentadienyl ring.[163]



For as yet unknown reasons, silyl complexes of actinides are very difficult to isolate. The reaction of $Cp^*_2ThCl_2$ with TTS-Li yields the complex $Cp^*_2Th(TTS)Cl$ (**63**);[164] an attempt at its isolation results in its decomposition into $Cp^*_2ThCl_2$, $(Me_3Si)_3SiH$ and other products. Notwithstanding, carbonylation of compound **63** in solution with sequential insertion of two CO molecules and formation of the metalloxyketene derivative **64** takes place.[164]



4. Group IVB elements (Ti, Zr, Hf)

Numerous TTS derivatives of Group IVB elements also containing cyclopentadienyl, alkyl, alkylamide or alkoxide substituents are known. The methods for the preparation of some of them are listed in Table 8.

Attempts to synthesise TTS titanium derivatives starting from $TiCl_4$ and TTS-Li gave predominantly a complex mixture of redox reaction products among which trimethylsilane and hexamethyldisilane were isolated.[165] Mixed titanium halogenoamides were used in the synthesis of the triamide complexes TTS-Ti$(NMe_2)_3$ and TTS-Ti$(NEt_2)_3$ (see Table 8). The resulting compounds are

Table 8. Conditions of the synthesis of TTS complexes of Group IVB transition metals.

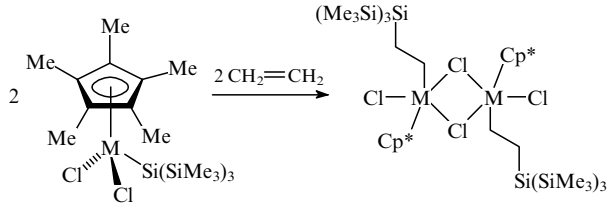
Starting compound	Reaction product	Yield (%)	Reaction conditions	Ref.
$ClTi(NMe_2)_3$, TTS-Li	TTS-Ti$(NMe_2)_3$	40	C_6H_{14}, 20 °C, 0.5 h	165
$ClTi(NEt_2)_3$, TTS-Li	TTS-Ti$(NEt_2)_3$	–	C_6H_{14}, 20 °C, 0.5 h	166
$ClTi(CH_2SiMe_3)_3$, TTS-Li	TTS-Ti$(CH_2SiMe_3)_3$	–	C_6H_{14}	167
$ClZr(NMe_2)_3$, TTS-Li	TTS-Zr$(NMe_2)_3$	–	Et_2O	168
$(Bu^tO)_3ZrCl$, TTS-Li	TTS-Zr$(OBu^t)_3$	70	Et_2O, 0 °C, 12 h	169
$(Bu^tO)_3HfCl$, TTS-Li	TTS-Hf$(OBu^t)_3$	70	Et_2O, 0 °C, 12 h	169
Cp*$ZrCl_3$, TTS-Li	TTS-ZrCp*Cl_2	–	Et_2O, −78 °C	25
Cp*CpZrCl_2, TTS-Li	TTS-ZrCp*CpCl	62	PhH, 20 °C, 12 h	170
Cp*CpHfCl_2, TTS-Li	TTS-Hf(Cl)Cp*Cp	–	Et_2O, 20 °C	171
Cp_2ZrCl_2, TTS-Li	TTS-ZrCp_2Cl	70	Et_2O, 20 °C, 2 days	172
Cp*$ZrCl_3$, TTS-Li	TTS-ZrCpCl_2	–	Et_2O	25
(TTS)ZrCp_2Cl, MeMgBr	TTS-ZrCp_2Me	71	Et_2O, −78 to 20 °C	172
(TTS)ZrCp*CpCl, MeMgBr	TTS-ZrCp*CpMe	82	Et_2O, −78 to 20 °C	170
Cp_2ZrCl_2, TTS-K	$(TTS)_2ZrCp_2$	85	C_5H_{12}, 0–20 °C, 12 h	173
$(Bu^tCH_2)_3ZrCl$, TTS-Li	TTS-Zr$(CH_2Bu^t)_3$	–	C_6H_{14}	174, 175
Cp*$HfCl_3$, TTS-Li	TTS-HfCpCl_2	–	Et_2O	25
Cp_2HfCl_2, TTS-K	$(TTS)_2HfCp_2$	81	C_5H_{12}, 0–20 °C, 12 h	173

thermally stable and chemically inert.[166, 176] The triamide and trialkoxide complexes of zirconium and hafnium possess low reactivities and are inactive as catalysts of alkene polymerisation.[168, 169]

TTS zirconium and hafnium derivatives of the type TTS-MCp_nCl_{3-n} (n = 1, 2) present special interest by reason of their high reactivities and catalytic activities.

The complexes Cp*M(TTS)Cl_2 in which M = Zr (**65**) and Hf (**66**) are stable in argon, but are rapidly decomposed in humid air. Compounds **65** and **66** in C_6D_6 are thermally rather stable as follows from the NMR spectra recorded after storage at 95 °C for 1 day in tubes protected from light. However, these compounds rapidly decompose in light.

Tris(trimethylsilyl)silylzirconium and -hafnium derivatives **65** and **66** as well as CpCp*Zr(TTS)Cl (**67**) react with ethylene with insertion into the Si–M bond.[177]

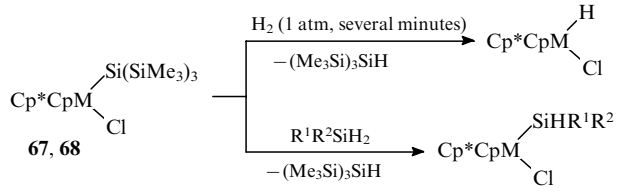


65, **66**

M = Zr, Hf.

At the same time, substituted alkenes (styrene, propene, trimethylsilylethylene) as well as diphenylacetylene do not react. The complex Cp_2Zr(TTS)Cl with non-substituted Cp ligands was found to be inert with respect to ethylene.

Compounds Cp*CpM(TTS)Cl **67** and **68** react with hydrogen and organosilanes with elimination of tris(trimethylsilyl)silane.[178]

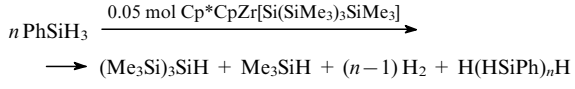


67, **68**

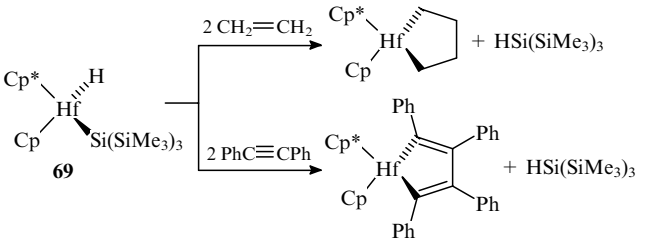
M = Zr (**67**), Hf (**68**); R^1 = H, Alk, Ar; R^2 = Alk, Ar.

The tris(trimethylsilyl)silyl group is the best leaving group for the metathesis in comparison with other R_3Si derivatives; therefore, compounds **67** and **68** are the most convenient reagents for the synthesis of novel d^0-hydridosilyl complexes in reactions with dihydrides.[171]

Dehydropolymerisation of primary silanes $RSiH_3$ in the presence of the TTS derivatives Cp*CpM(TTS)X (M = Zr, Hf; X = Me, Cl, $SiMe_3$) proceeds at a much faster rate than that with other analogous complexes.[178]

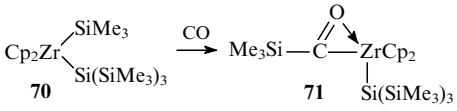


The hydride hafnocene complex **69** adds to molecules of unsaturated compounds with displacement of $(Me_3Si)_3SiH$.[179]



69

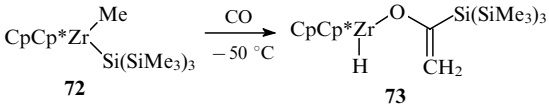
Compound **70** contains both trimethylsilyl and TTS groups, but one equivalent of CO is inserted exclusively into the Zr–$SiMe_3$ bond.[172]



70 **71**

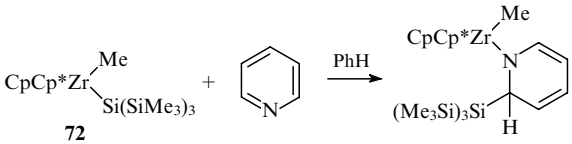
This fact is difficult to explain with account of the fact that, in the general case, CO is easily inserted into the $(Me_3Si)_3Si$–M bond, where M is a Group IVB metal. The reactivity of compound **71** is also unusual. Its treatment with HCl results in the quantitative evolution of $(Me_3Si)_3SiH$, but the use of benzoic acid causes elimination of the trimethylsilylcarbonyl group and formation of Cp_2Zr(TTS)(O_2CPh).[172] Carbon monoxide readily reacts across the Zr–Si bond of the spatially hindered CpCp*Zr(TTS)Cl molecule to give CpCp*Zr[C(O)TTS)]Cl,[170] but is not inserted into the Zr–Si bond within the Cp_2Zr(TTS)Cl complex.[172] This is attributed to the fact that the steric strains in the CpCp*Zr(TTS)Cl molecule exceed those in Cp_2Zr(TTS)Cl.[170]

The methyl derivative CpCp*Zr(TTS)Me (**72**) reacts with CO in a more complicated manner. The primary insertion product undergoes two sequential rearrangements eventually resulting in hydride-enolate **73**.[170]



72 **73**

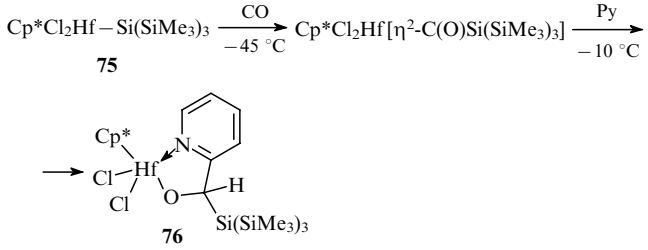
The complex **72** reacts with nitriles RCN to give the azomethine derivatives CpCp*ZrN = C(R)(TTS) (R = Me, CH = CH_2, Ph). Compound **72** reacts with pyridine to give the addition product **74**.[180]



72 **74**

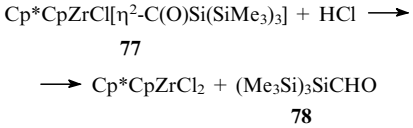
The analogous TTS zirconium complexes Cp_2Zr(TTS)Me and CpCp*Zr(TTS)Cl are significantly less reactive in reactions with nitriles and pyridine.

It was found that the insertion of CO into the Hf–Si bond of compound **75** results in an η^2-silylacyl derivative, which in turn gives rise to an insertion product **76** into the α-CH-bond of pyridine.[181]



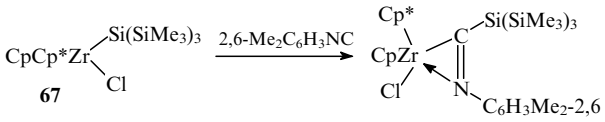
75 **76**

Protonation of the η^2-hypersilacyl zirconium complex **77** yields the organosilicon aldehyde **78**, which could not be prepared by any alternative methods.[182]



77 **78**

The insertion of isonitriles into the Zr–Si [182] bond is similar to that of carbon monoxide into the complex **70**.[175]



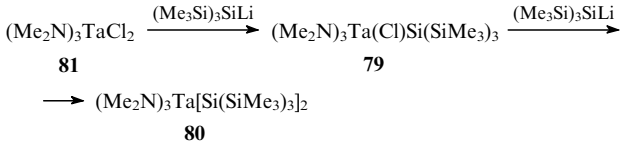
The tris(trimethylsilyl)silyl group was employed in the synthesis of 14-electron cationic complexes $[Zr(\eta\text{-}C_5H_4TTS)_2R]^+$ (R = Cl, Me), which proved to be efficient catalysts in ethylene polymerisation.[150] In the presence of a complex containing a tris(trimethylsilyl)silyl group in the cyclopentadienyl ring as a substituent, the polymerisation proceeds at a satisfactory rate. The molecular mass of the polymer (M_w = 126 000) was maximised in comparison with polymers prepared in the presence of catalysts of this series in which other substituents, *e.g.*, CH_2Ph and $CHPh_2$, were used instead of the TTS group.

Tris(trimethylsilyl)silylzirconium and -hafnium derivatives containing *tert*-butoxy groups instead of cyclopentadienyl ligands were found to be inactive with respect to CO, ethylene and $PhSiH_3$. However, both zirconium and hafnium complexes react with isocyanides to give the insertion products $[(Bu^tO)_3M(\eta^2\text{-}CNC_6H_3Me_2\text{-}2,6)(TTS)]$ (M = Zr, Hf).[169]

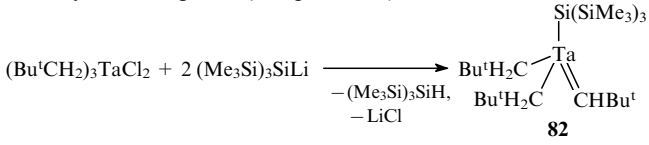
5. Elements of Groups VB – VIIIB

a. Tantalum

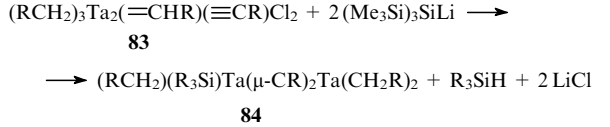
Group VB compounds are represented by tantalum complexes. The amidosilyl complexes **79** and **80** prepared from dichloride **81** are unstable and decompose even at 20 °C, which prevents their isolation.[183]



Stabilisation of neopentyl tantalum TTS complexes occurs owing to elimination of tris(trimethylsilyl)silane and formation of the alkylidene fragment (compound **82**).[175]

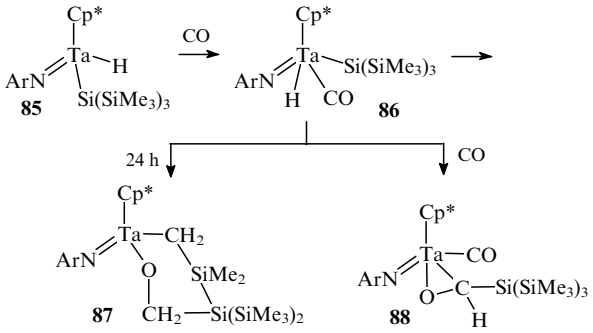


The reaction of the binuclear alkylidene – alkylidyne tantalum complex **83** with TTS-Li is also accompanied by elimination of tris(trimethylsilyl)silane. In this case, the bisalkylidyne complex **84** is formed.[184]



R = $SiMe_3$.

The reaction of 1 equiv. of CO with the tris(trimethylsilyl)silyl tantalum hydride complex **85** yields the addition product **86**, which isomerises within the next 24 h into the cyclic derivative **87**. This process involves the hydride, the carbonyl and the silyl groups.[185] The adduct **88** is formed in the presence of an excess of CO; its hydrolysis affords the organosilicon alcohol $(Me_3Si)_3SiCH_2OH$ in 90% yield.



Ar = 2,6-$Pr^i_2C_6H_3$.

b. Chromium, manganese, iron

The reactions of lithium tris(trimethylsilyl)silanide with chromium(II), manganese(II) and iron(II) halides in a coordinating solvent yield the bishypersilyl complexes **89a – c** of the anionic type.[186]

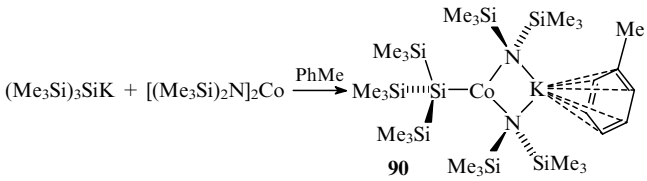
M = Cr (L = THF, *n* = 3) (**a**), Mn (L = DME, *n* = 2) (**b**), Fe (L = DME, *n* = 2) (**c**).

The iron and manganese complexes **89b,c** are rather thermally stable ($T_{decomp.}$ > 140 °C). The chromium complex **89a** was isolated and characterised only at temperatures below −20 °C.

All the low-coordination complexes obtained have high magnetic moments, which correspond to the high-spin configuration of metal atoms, but is uncommon to silyl transition-metal complexes.

c. Cobalt

Attempts to synthesise TTS cobalt derivatives by treatment of $CoCl_2$ with potassium tris(trimethylsilyl)silanide resulted in cobalt(II) cobalt(0) reduction products. However, $(Me_3Si)_3SiK$ reacts smoothly with cobalt silylamide to give the adduct **90**.[187]



Compound **90** is stable in the crystalline state, but is rapidly decomposed in solution. The length of the Co–Si bond (2.513 Å) is the highest known value due to steric overcrowding of the complex **90**.

d. Carbonyl derivatives of Mn, Fe and Re

It is known that the reaction of metal carbonyls with silicon hydrides is one of the main approaches to the synthesis of compounds containing a silicon–metal bond [188] (see, *e.g.*, Refs 189 and 190).

However, this method is not generally employed in the synthesis of polysilyl carbonyl derivatives because of the low yields of the target products, since the side reaction (*viz.*, the cleavage of the Si–Si bond) yields siloxanes and carbonylhydride metal clusters.[188, 191] An alternative approach consists of the reaction of anionic metal carbonyl complexes with TTS halides [191] or the reaction of carbonyl halides with tris(trimethylsilyl)silyllithium.[189, 191, 192]

$$BrMn(CO)_4PPh_3 + (Me_3Si)_3SiLi \longrightarrow (Me_3Si)_3SiMn(CO)_4PPh_3, \quad (8\%)$$

$$BrM(CO)_nL + (Me_3Si)_3SiLi \longrightarrow (Me_3Si)_3SiM(CO)_nL$$

M = Mn, $(CO)_nL = (CO)_4PPh_3$; M = Re, $(CO)_nL = (CO)_5$.

d. Molybdenum, tungsten, rubidium

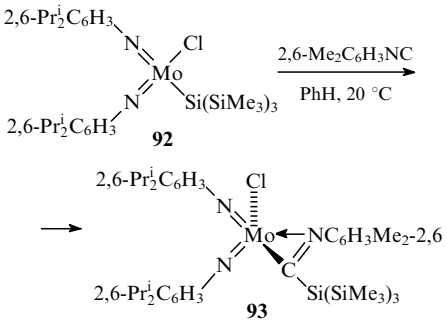
Treatment of molybdenum amidochloride, $(Me_2N)_4Mo_2Cl_2$, with TTS-Li yields the expected complex $(Me_2N)_4Mo_2(TTS)_2$, which contains a Mo≡Mo bond.[193]

Molybdenum bis(2,6-diisopropylphenylamido)dichloride (**91**) reacts with 1 equiv. of tris(trimethylsilyl)silyllithium to give the TTS derivative **92**.[194]

$$(2,6\text{-}Pr^iC_6H_3N{=})_2MoCl_2 + (Me_3Si)_3SiLi \longrightarrow$$
91

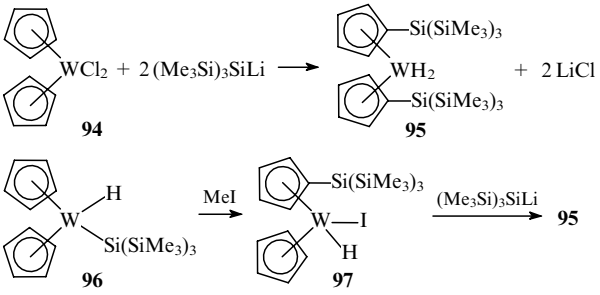
$$\longrightarrow (2,6\text{-}Pr^iC_6H_3N{=})_2Mo(Cl)Si(SiMe_3)_3 + LiCl$$
92

The complex **92** appeared to be non-reactive with respect to H_2, CO and C_2H_4, but reacted actively with 2,6-dimethylisocyanobenzene to give compound **93**, which is the isocyanide insertion product into the Mo–Si bond.[194]



The alkylidyne tungsten complex $(Bu^tCH_2)_3W(\equiv CBu^t)(TTS)$ is prepared from the corresponding chloride, $(Bu^tCH_2)_3W(\equiv CBu^t)Cl$, by treating the latter with lithium tris(trimethylsilyl)silanides.[175]

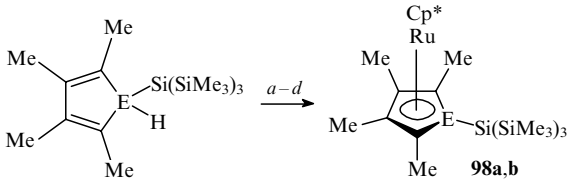
In the reaction of TTS-Li with bis(cyclopentadienyl)tungsten dichloride (**94**), substitution of the TTS group for a hydrogen atom in the cyclopentadienyl ring occurs rather than formation of the expected complex containing a W–Si bond resulting in tungsten dihydride **95**.[195,196]



The silyl complex **96** prepared from $Cp_2W(H)Cl$ and $(Me_3Si)_3SiLi$ also reacts with methyl iodide to give the substitution product of the cyclopentadienyl ring **97**. Apparently, the molecular rearrangement of the tungsten complex does not require deprotonation of the Cp ring by a base; otherwise, $(Me_3Si)_3SiH$ would be formed as a side product.

It is of note that TTS-substituted cyclopentadiene, which can also be prepared by conventional methods from CpLi and $(Me_3Si)_3SiBr$, is used in the synthesis of metal complexes, *e.g.*, $[Cp\text{-}TTS)_2Zr]$.[150]

Stable η^5-sila- and η^5-germacyclopentadienylruthenium derivatives **98a,b** were synthesised using the TTS group in the ring as a stabilising substituent.[197,198]



E = Si (**a**), Ge (**b**);
(*a*) $Cp^*Ru(OMe)_2$, (*b*) $Me_3SiOSO_2CF_3$ (2 equiv.), (*c*) 3 $NaBF_4$ (3 equiv.), (*d*) $LiSi(SiMe_3)_3$.

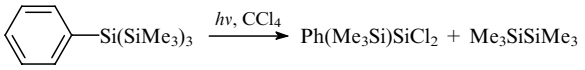
Synthesis of certain TTS derivatives of elements of Groups V–VIII is accompanied by rearrangements where the $(Me_3Si)_3Si$ fragment is destroyed, especially if the formation of metal silylene complexes is more preferable (see Section VIII).

VII. Photochemical reactions of hypersilyl derivatives

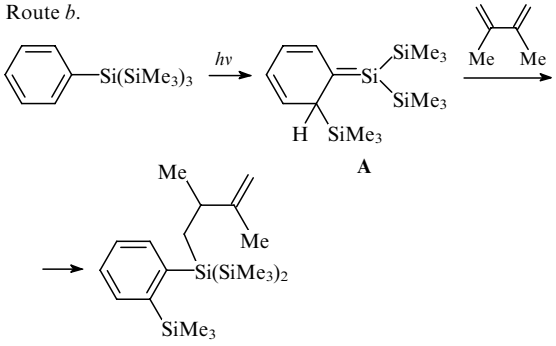
In comparison with linear derivatives, branched organooligosilanes, particularly $(Me_3Si)_4Si$, are little sensitive to UV light. However, if the TTS group is linked to a chromophore or an auxochromic group, the photoreactions involving the $(Me_3Si)_3Si$ fragment occur at noticeable rates.

Photolysis of aromatic TTS-containing compounds occurs through at least two pathways, *viz.*, with elimination of trimethylsilylphenylsilylene (route *a*) and with migration of the trimethylsilyl group into the aromatic ring (route *b*). The unstable intermediate **A** was identified following its reaction with 2,3-dimethylbuta-1,3-diene.[199,200]

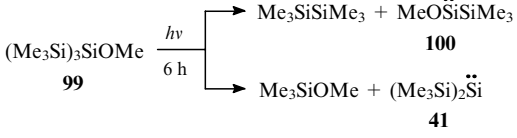
Route *a*.



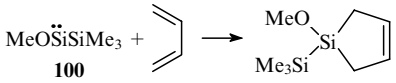
Route *b*.

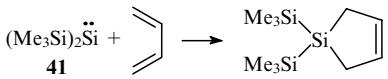


Photolysis (λ = 254 nm) of methoxytris(trimethylsilyl)silane **99** also proceeds non-selectively to yield methoxy(trimethylsilyl)silylene **100** and bis(trimethylsilyl)silylene **41** in a ~2 : 1 ratio.[201]



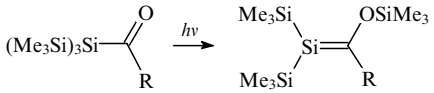
The silylenes formed were scavenged with traps, *e.g.*, buta-1,3-diene.





41

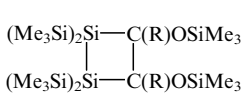
Photolysis of acyltris(trimethylsilyl)silanes is accompanied by migration of the trimethylsilyl group to the oxygen atom and the formation of silenes **101**, which undergo further conversions depending on the nature of the substituent in the acyl group and the reaction conditions.[202]



101

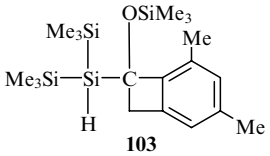
R = Me, Bu^t, 1-Ad (1-adamantyl), Ph, 2,4,6-$Me_3C_6H_2$.

The dimer **102a** of the 'head-to-head' type is formed in inert solvents for R = Ph.[203]

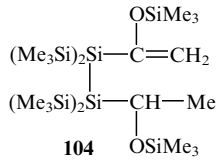


102a,**b**

R = Ph (**a**), Bu^t (**b**)



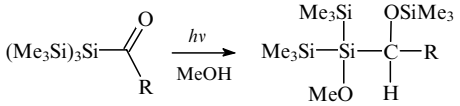
103



104

The bulkier *tert*-butyl group favours the formation of an equilibrium mixture of the dimer **102b** and the monomer **101** (R = Bu^t) in a 4 : 1 ratio.[203] The adamantyl substituent (R = 1-Ad) prevents dimerisation and a stable silene **101** is formed (R = 1-Ad).[103] However, in the case of yet another bulky substituent, *viz*., mesitylene, the sylene photochemical insertion product into the C–H-bond of one of the methyl groups (compound **103**) is formed.[202] If compound **101** contains α-protons in the substituent R (*e.g*., R = Me), the dimer undergoes disproportionation to give compound **104**.[203]

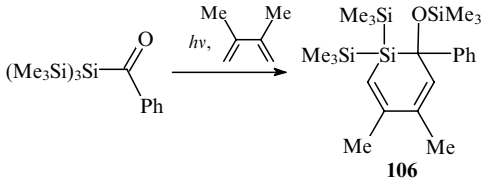
Photolysis of acylpolysilanes in the presence of methanol gives compounds **105** as the addition products to the double bond Si=C.[203]



105

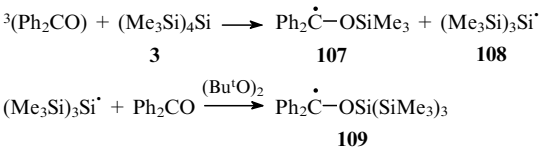
R = Me, Bu^t, Ph.

Unsaturated compounds (2,3-dimethylbutadiene, methylphenylacetylene) yield cyclic derivatives (*e.g*., compound **106**) as the addition products to the double bond Si=C of the photochemically generated silene **101**.[203]



106

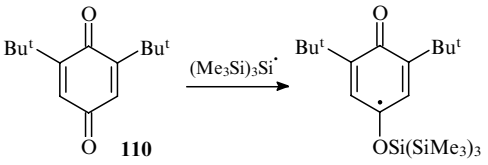
The photochemical reaction of benzophenone in a triplet state with tetrakis(trimethylsilyl)silane (**3**) affords two radical products, **107** and **108** (data from ESR spectroscopy).[203]



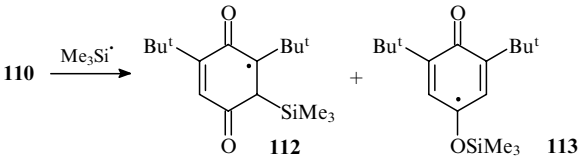
109

Photolysis of a benzophenone – tris(trimethylsilyl)silane mixture in the presence of di-*tert*-butyl peroxide yields exclusively the radical **109**. It should be noted that in contrast to $(Me_3Si)_3SiH$, $(Me_3Si)_4Si$ reacts with Bu^{t}O$^\cdot$ radicals generated upon photolysis of di-*tert*-butyl peroxide exclusively with abstraction of the hydrogen atom from the methyl groups to give the silylmethyl radicals $(Me_3Si)_3SiSiMe_2CH_2^\cdot$.

The photochemical reaction of 2,6-di-*tert*-butyl-1,4-benzoquinone **110** with tetrakis(trimethylsilyl)silane generates the radicals $(Me_3Si)_3Si^\cdot$ and $Me_3Si^\cdot$. The former adds exclusively to the oxygen atom of the quinone to give compound **111**, whereas the latter yields predominantly addition products at the carbon atom **112**. The addition product $Me_3Si^\cdot$ at the oxygen atom **113** is a minor component.[204]

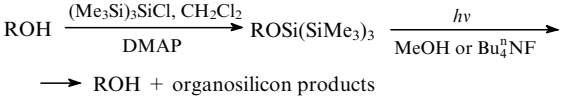


110 **111**

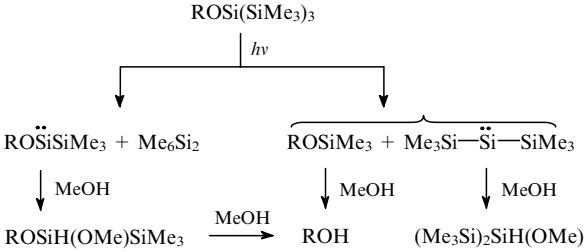


112 **113**

The tris(trimethylsilyl)silyl group can be used as a photolabile protecting group for the alcoholic function. The possibility of the use of the TTS group for this purpose was studied by Brook *et al*.[205, 206] Tris(trimethylsilyl)silyl ethers of primary and secondary alcohols were prepared in 70% to 97% yields by the reaction of tris(trimethylsilyl)silyl chloride with the corresponding alcohols in the presence of 4-dimethylaminopyridine (DMAP). The best yields are achieved in the case of more acidic alcohols. Tertiary alcohols do not react due to steric hindrance. Extremely high stability of the ethers formed with respect to aqueous bases, Grignard and Wittig reagents, butyllithium and caesium fluoride is their salient feature. Removal of the silyl protection was achieved by irradiation with UV light (254 nm; 30 min) in the presence of methanol or tetrabutylammonium fluoride



An obvious disadvantage of this silyl protection is the formation of heavy organosilicon products upon photolysis.



The use of chromatographic methods has made it possible to obtain desilylated alcohols in 80% – 90% yields.[205, 206]

VIII. Rearrangements involving the tris(trimethylsilyl)silyl fragment

The tris(trimethylsilyl)silyl group is 'milder', more mobile and more reactive in various rearrangements induced by acids, bases, light, heat and treatment with transition metals than other commonly used bulky groups (Bu^t_3C, Bu^t_3Si, Pr^i_3Si). It is of note that depending on the active site (charge) and modes of its stabilisation this group (or, to be more precise, its Si_3Si fragment) can be either destroyed or formed in different rearrrangements.

1. Migrations of silyl groups

In the presence of $AlCl_3$, permethylated polysilanes, $Me(Me_2Si)_nMe$ ($n = 4-10$) undergo skeletal rearrangements to give thermodynamically more stable branched isomers in nearly quantitative yields.[36]

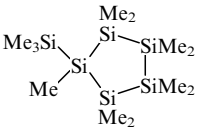
$$Me(Me_2Si)_4Me \xrightarrow{AlCl_3} (Me_3Si)_3SiMe$$

$$Me(Me_2Si)_5Me \xrightarrow{AlCl_3} (Me_3Si)_4Si$$

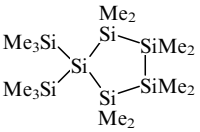
Permethylated cyclopolysilanes also yield isomeric branched cyclosilanes under the action of $AlCl_3$ containing 1% $FeCl_3$.[207]

$$(Me_2Si)_5 \xrightarrow{AlCl_3} \not\rightarrow$$

$$(Me_2Si)_6 \xrightarrow{AlCl_3}$$



$$(Me_2Si)_7 \xrightarrow{AlCl_3}$$



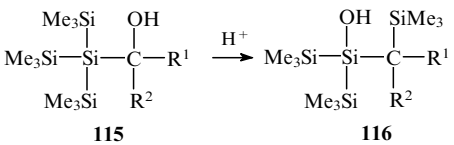
The photolytic rearrangement of the oligosilyl iron complex **114** produces the TTS fragment.[208]

$$(\eta^5\text{-Cp})Fe(CO)_2(SiMe_2)_4Me \xrightarrow{h\nu} (\eta^5\text{-Cp})Fe(CO)_2Si(SiMe_3)_3$$

114

This reaction occurs *via* the formation of silyl-silylene complexes $(\eta^5\text{-Cp})Fe(CO)(=SiMe_2)(Si_nMe_{2n+1})$ with subsequent migration of the silyl and methyl groups. The photochemical isomerisation of nonamethyltetrasilane, $H(SiMe_2)_4Me$, in the presence of catalytic amounts of $(\eta^5\text{-Cp})Fe(CO)_2SiMe_3$ or carbonyls $Fe(CO)_5$, $W(CO)_6$ initially results in $(Me_3Si)_3SiH$, which is further converted into the dimethylsilylene insertion product with insertion into the Si–H bond, $(Me_3Si)_3SiSiMe_2H$.[209] Thermal isomerisation in the presence of catalytic amounts of $(\eta^5\text{-Cp})Fe.(CO)(Ph_3P)SiMe_3$ gives exclusively tris(trimethylsilyl)silane.

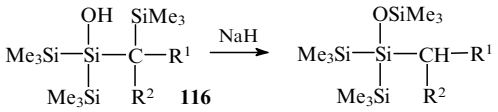
Under the action of strong acids, such as HCl or H_2SO_4, 1-hydroxyalkyltris(trimethylsilyl)silanes **115** undergo isomerisation through a 1,2-Me_3Si–OH exchange to give trimethylsilylmethylsilanols **116**.[210,211]



115 **116**

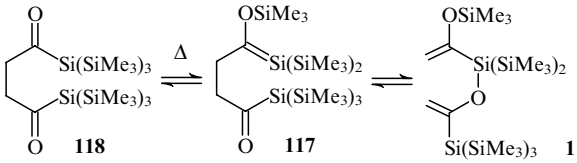
R^1 = H: R^2 = 4-MeC_6H_4, 4-$Pr^iC_6H_4$, Mes, 2-$Me_2NC_6H_4$, 2,4,6-$(MeO)_3C_6H_2$; $R^1 = R^2$ = Me.

Deprotonation of compounds **116** with sodium hydride results in migration of the trimethylsilyl group from the carbon atom to the oxygen atom.



116

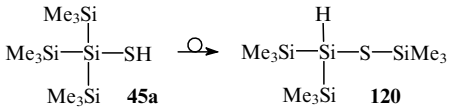
Silene **117** formed as a result of thermolysis of bis[tris(trimethylsilyl)silylcarbonyl]ethane **118** undergoes skeletal rearrangements to give the isomeric unsaturated compound **119**.[212]



118 **117** **119**

2. Rearrangements of organoelement derivatives

Tris(trimethylsilyl)silanethiol **45a** undergoes smooth radical-induced skeletal rearrangement through a 1,2-shift of the Me_3Si group from the silicon atom to the sulfur atom eventually resulting in thiohydride **120**.[213]



45a **120**

The migration of the Me_3Si group to the oxygen atom is energetically a very favourable process, this takes place in the autooxidation of tris(trimethylsilyl)silane (see Section IV.1)[50] as well as in its oxidation by alkyl nitrates.[214] The rearrangement of TTS-silanolate complexes into siloxysilyl complexes takes place in the thermolysis of transition metal hypersilylsilanolates.[136,137]

The reaction of $(Me_3Si)_3SiLi$ with *tert*-butyldichlorophosphine yields the expected product, *viz*., hypersilylphosphine **121**; however, its distillation (110–115 °C at 0.01 Torr) gives the rearrangement product **122**.[123]

$$(Me_3Si)_3SiLi + Bu^tPCl_2 \xrightarrow[-20\ ^\circ C]{THF} (Me_3Si)_3SiP(Cl)Bu^t \longrightarrow$$

121

$$\longrightarrow (Me_3Si)_2Si(Cl)P(SiMe_3)Bu^t$$

122

Alkyldichlorophosphines containing less bulky substituents, *e.g*., dichloromethylphosphine **123**, react with TTS-Li with elimination of tris(trimethylsilyl)chlorosilane.

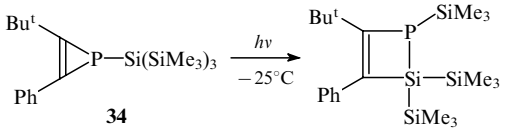
$$(Me_3Si)_3SiLi + MePCl_2 \longrightarrow [(Me_3Si)_3SiP(Cl)Me] \longrightarrow$$

123

$$\longrightarrow (Me_3Si)_3SiCl + 1/5\,(MeP)_5$$

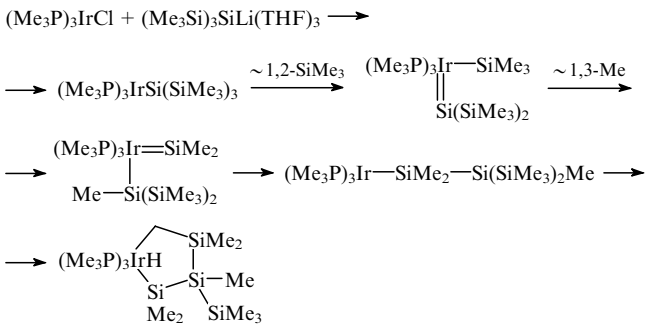
No formation of free phosphinydene took place in the presence of buta-1,3-diene in control experiments,[123] which is in favour of a bimolecular mechanism of splitting of tris(trimethylsilyl)chlorosilane.

Photochemical (λ = 280 nm) expansion of the three-membered phosphorus-containing ring **34** involving the tris(trimethylsilyl)silyl group is known.[128]

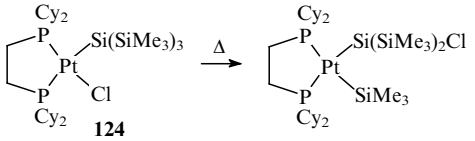


34

Low-valent transition metal complexes containing a TTS group are usually unstable; their stabilisation occurs at the expense of the migration of the silyl group.[215]

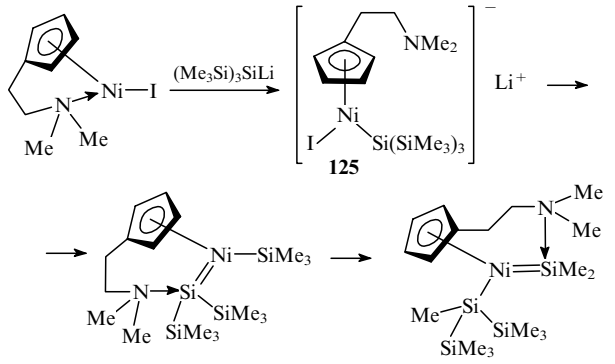


Similar migration is observed in the case of the TTS platinum complex **124**.[216, 217]



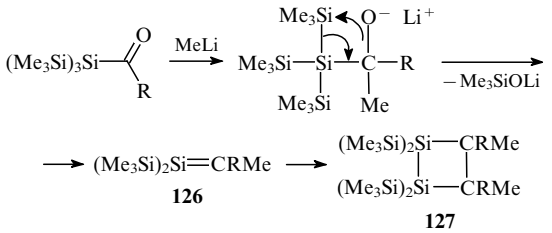
Cy is cyclohexyl.

Complex rearrangements of the TTS fragment, which first include migration of the trimethylsilyl and then of the methyl group, take place in the coordination sphere of the cyclopentadienylnickel derivative **125**.[218]



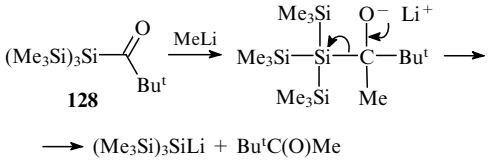
3. Migration of the trimethylsilyl group (the Peterson migration) and related processes in the series of hypersilyl derivatives

The formation of the O-nucleophilic centre in the β-position relative to the TTS group usually results in elimination of the trimethylsilanolate anion and formation of silaethenes **126**, which are further condensed to form disilacyclobutanes **127**.[219]



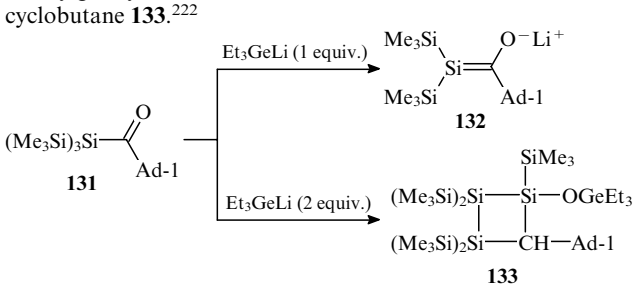
R = Me, Ph.

However, this reaction is extremely sensitive to steric factors. Under the action of methyllithium, compound **128** easily decomposes into *tert*-butyl methyl ketone and tris(trimethylsilyl)silyllithium.[219]

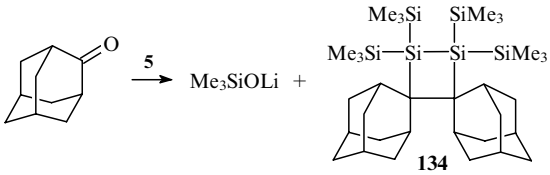


The introduction of a donor amino group that stabilises the intermediate silaethene **129** changes the direction of the dimerisation. In this case, the 'head-to-tail' dimer **130** is formed (Scheme 1).[220]

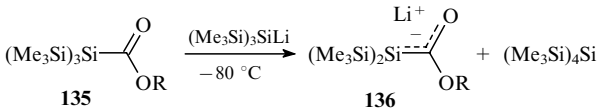
Apparently, triethylgermyllithium cannot add to the carbonyl group of 2-adamantyl tris(trimethylsilyl)silyl ketone **131** due to considerable steric hindrance. With the stoichiometric ratio of the reagents, the reaction product is silaenolate **132**; the half-conversion time is 12 h.[221, 222] In the presence of a twofold excess of triethylgermyllithium, silaenolate **132** is converted into trisilacyclobutane **133**.[222]



The Peterson elimination also occurs in the reaction of $(Me_3Si)_3SiLi(THF)_3$ with adamantanone in hexane and gives an unstable silene, which undergoes spontaneous dimerisation of the 'head-to-head' type to give disilacyclobutane **134**.[223]

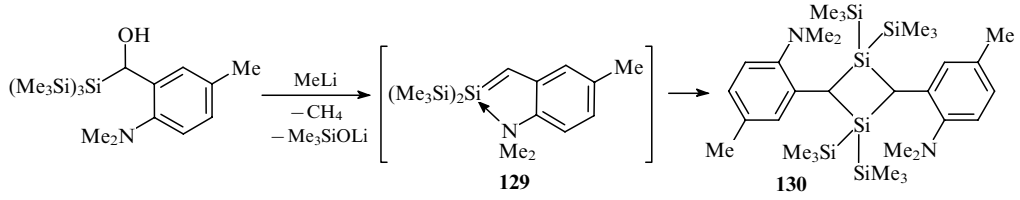


The reactions of tris(trimethylsilyl)silylcarboxylates $(Me_3Si)_3SiC(O)OR$ with lithium reagents have been studied in great detail.[224, 225] Depending on the nature of R and the reagent used, this reaction occurs through several main pathways, *viz.*: (1) formation of lithium tris(trimethylsilyl)silylcarboxylate; (2) elimination of the TTS group by a lithium reagent; (3) addition of a lithium reagent to the carbonyl group of carboxylates. In particular, the reaction of alkyl tris(trimethylsilyl)silacarboxylates **135** with $(Me_3Si)_3SiLi$ is accompanied by elimination of the Me_3Si group and formation of new silyllithium derivatives **136**.[225]

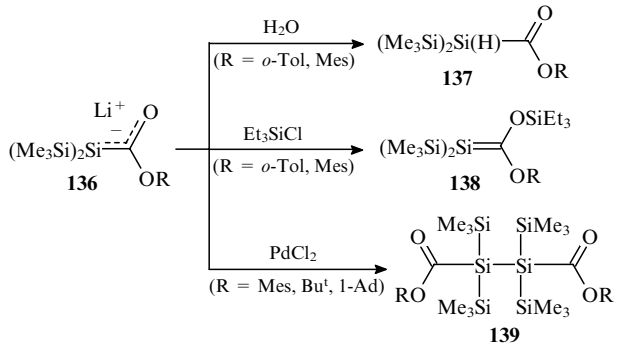


R = Cy, 1-Ad, Bn, *o*-Tol, Mes.

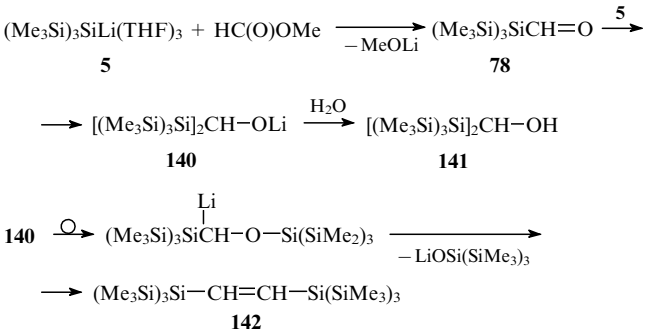
Scheme 1



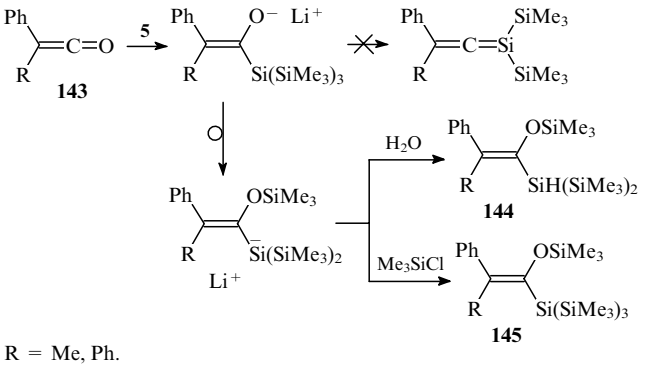
Hydrolysis, silylation and oxidation of silanoenolate **136** afford compounds **137**–**139**.



The reaction of tris(trimethylsilyl)silyllithium (**5**) with methyl formate[226] occurs *via* formylsilane **78** which adds the second molecule of $(Me_3Si)_3SiLi$. The intermediate lithium bis(trimethylsilyl)silylmethoxide **140** can be detected after hydrolysis as the corresponding bis(TTS)methanol **141**. Under the reaction conditions, compound **140** is further converted into the final product, *viz*., 1,2-bis[tris(trimethylsilyl)silyl]ethylene **142** in 60% yield.

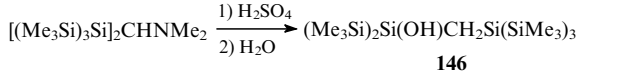


The reaction of ketenes **143** with tris(trimethylsilyl)silyllithium occurs with the migration of the anionic centre from the oxygen atom to the silicon atom, which eventually results in unexpected products **144** and **145**.[227]



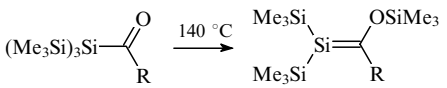
R = Me, Ph.

The synthesis of silanol **146** proceeds formally through elimination of (dimethylamino)trimethylsilane in accordance with the acid-induced Peterson reaction to give the intermediate silene $(Me_3Si)_2Si{=}CHSi(SiMe_3)_3$.[228]



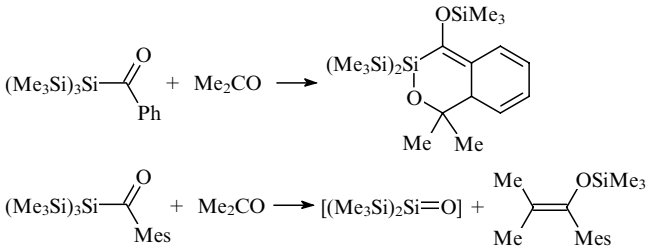
4. Thermal reactions of acylpolysilanes

Similar to photolysis, the thermolysis of acyltris(trimethylsilyl)silanes yields silaethenes.[229]



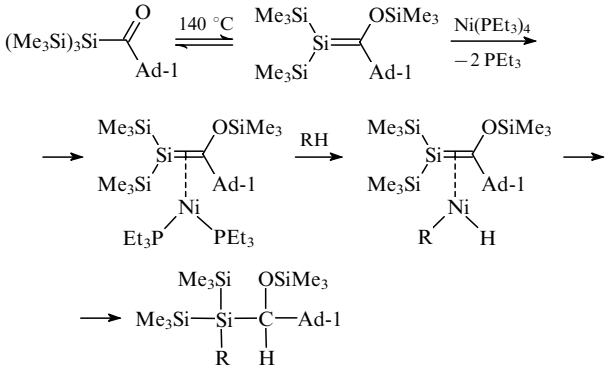
R = Me, But, 1-Ad, Ph, Mes.

Heating of acylsilanes in the presence of ketones affords products the composition of which is determined by the nature of the acyl substituent. This reaction consists of several consecutive insertion and rearrangement steps, which hinder significantly the prediction of the final products.[229]



Acetyltris(trimethylsilyl)silane, $MeC(O)Si(SiMe_3)_3$, gives no adducts when heated with ketones, presumably due to rapid dimerisation of the silaethene formed.

An unusual system $(Me_3Si)_3SiC(O)(1\text{-Ad})-Ni(PEt_3)_4$ is reported,[230] which allows activation of the C−H bonds of aromatic compounds and of the Si−H bonds of silanes. Catalytic amounts of tetrakis(triethylphosphine)nickel catalyse the addition of RH (R = Ph, $PhMe_2Si$) to the silaethenes formed upon heating 1-adamantoyltris(trimethylsilyl)silane.



R = Ph, $PhMe_2Si$.

* * *

The data on the synthesis, reactivities and applications of tris(trimethylsilyl)silyl derivatives demonstrate the high potential of the $(Me_3Si)_3Si$ ligand in organic and organometallic chemistry and testify to the uniqueness of the TTS group. The present review is an attempt to draw a 'portrait' of the TTS group from different standpoints, which may facilitate the correct choice of this ligand for concrete experimental tasks. Currently, wide application of the TTS ligand is limited due to the high cost of the starting reagents, *viz*., $(Me_3Si)_3SiH$ and $(Me_3Si)_4Si$. It remains to be hoped that the rapid development of the chemistry of TTS derivatives in the next few years will make it possible to reduce the cost and to expand the range of the reagents based on them.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-07041-ano).

XI.	Conclusion	1116

Abstract. Kinetic data on intramolecular abstraction of hydrogen atoms in alkyl, alkoxyl and peroxyl radicals are generalised and analysed. It is shown that the activation energies of these reactions are affected by ring strain. The kinetic parameters of mono- and bimolecular elimination reactions are compared. The difference between the activation energies of these reactions is interpreted using the model of intersecting parabolas. The same model is used to discuss the results of analysis of cyclisation of alkyl radicals; the ring strain energy is shown to play an important role in the activation of these reactions. It is noted that the difference between the electron affinities of the C, N and O atoms is clearly manifested in the cyclisation of aminyl and ω-formylalkyl radicals. The kinetic parameters of cyclisation and bimolecular radical addition reactions are compared. The experimental data on the transfer of the vinyl and aryl groups in alkyl radicals are analysed. The bibliography includes 146 references.

I. Introduction

The possible mechanisms of isomerisation of free radicals were discussed by N N Semenov back in 1958;[1] however, no quantitative kinetic data for these reactions were available at that time. The kinetics of these reactions has been studied rather intensively since the late 1970s.[2–4] Radical isomerisation reactions can be classified into (i) hydrogen atom migrations from one position to another; (ii) cyclisation reactions in radicals; (iii) ring opening reactions; (iv) cleavage of a peroxide bridge and epoxide formation; (v) migrations of aryl and vinyl groups in alkyl radicals.[2]

The isomerisation of alkyl radicals, for example

$$R^1C^{\bullet}H(CH_2)_nCH_2R^2 \longrightarrow R^1CH_2(CH_2)_nC^{\bullet}HR^2,$$

accompanied by migration of a hydrogen atom from one carbon to another is involved in chain processes of hydrocarbon cracking, photolysis and radiolysis,[5] radical polymerisation and oligomerisation of monomers,[6] and thermal and thermooxidative destruction of polymers.[7] These reactions affect appreciably both the overall process rates and the composition of products. The isomerisation of peroxyl radicals

$$R^1CH(OO^{\bullet})(CH_2)_nCH_2R^2 \longrightarrow R^1CH(OOH)(CH_2)_nC^{\bullet}HR^2$$

takes place during oxidation of hydrocarbons and yields bifunctional products (dihydroperoxides, dihydric alcohols, and so on) even at early oxidation steps.[8–10] These reactions play an important role in the oxidation of carbochain polymers.[7,11] Decomposition of peroxoalkyl radicals takes place during the oxidation of monomers[8,12] and is accompanied by cyclisation to give epoxides.

Alkyl radicals containing double bonds rapidly undergo intraradical cyclisation,[3] giving rise to cyclic radicals. The rings thus formed contain $n + 2$ or $n + 3$ carbon atoms.

$$C^{\bullet}H_2(CH_2)_nCH{=}CHR \longrightarrow \begin{cases} \text{cyclo-}[(CH_2)_{n+1}CH(C^{\bullet}HR)] \\ \text{cyclo-}[(CH_2)_{n+1}C^{\bullet}HCHR] \end{cases}$$

These reactions have been studied intensively during the last two decades. They are used in physical chemistry, for example, as a clock reaction in the method of competing reactions. For synthetic purposes, such reactions are employed to prepare diverse cyclic and spirocyclic compounds.[13–15]

Recently, we have analysed a number of classes of radical isomerisation reactions using the method of intersecting parabolas (MIP)[16–19] and have revealed some new features. Note that analysis of radical isomerisation reactions in terms of the MIP allows one to compare them with one another and with analogous bimolecular reactions involving radicals. This review presents the experimental kinetic parameters for radical isomerisation processes and the results of their analysis and comparison with reactions of other classes.

II. Parabolic model of radical reactions

The isomerisation reactions of free radicals

$$R^1C^{\bullet}H(CH_2)_nCH_2R^2 \longrightarrow R^1CH_2(CH_2)_nC^{\bullet}HR^2,$$

$$R^1CH(O^{\bullet})(CH_2)_nCH_2R^2 \longrightarrow R^1CH(OH)(CH_2)_nC^{\bullet}HR^2,$$

$$R^1CH(OO^{\bullet})(CH_2)_nCH_2R^2 \longrightarrow R^1CH(OOH)(CH_2)_nC^{\bullet}HR^2$$

are represented, within the framework of the MIP, as an intersection of the potential energy curves of the stretching vibrations of the reacting bonds, *i.e.*, the bond being cleaved and the bond being formed.[16, 20–23] The *y*-coordinate of the intersection point of these curves in the 'bond vibration amplitude–potential energy' coordinate system corresponds to the activation energy. The stretching vibration of the bond is taken to be harmonic.

The cyclisation reaction

$$Y^{\bullet}(CH_2)_nCH{=}CHR \longrightarrow \text{cyclo-}[(CH_2)_nYCH(C^{\bullet}HR)]$$

is represented, within the framework of the MIP, as an intersection of the potential energy curves of the stretching vibrations of the reacting bonds, *i.e.*, the C=C double bond to which the addition takes place and the C–Y bond that forms upon the addition of the Y atom having a free valence to a double-bond C atom.

The isomerisation reaction is described in terms of the MIP by the following parameters: the enthalpy (ΔH_e), the activation energy (E_e), the coefficients b and b_f ($2b^2$ is the force constant of the bond being cleaved, $2b_f^2$ is that of the bond being formed) and the overall elongation (r_e) of the bonds in the transition state. The reaction enthalpy (ΔH_e) includes the difference between the zero-point vibration energies of the reacting bonds

$$\Delta H_e = D_i - D_f + 0.5\,hN_A(v_i - v_f), \tag{1}$$

where D_i and D_f are the dissociation energies of the bond being cleaved (i) and the bond being formed (f), v_i and v_f are the stretching vibration frequencies of these bonds, respectively, h is the Planck constant, and N_A is Avogadro's number. The activation energy (E_e) also involves the zero-point vibration energy of the bond being cleaved and is related to the Arrhenius activation energy (E_a) as follows:

$$E_e = E_a + 0.5\,(hN_Av_i - RT). \tag{2}$$

Radical reactions of one class are described by equal pre-exponential factors A_{C-H} per C–H bond being attacked (n_i is the number of these bonds).[20] Therefore, from a known experimental rate constant of the reaction, one can calculate the activation energy

$$E_a = -RT\ln\left(\frac{k}{n_iA_{C-H}}\right). \tag{3}$$

Each class of radical reactions is described according to the MIP by the parameters $\alpha = b/b_f$ and br_e. The br_e parameter is related to the reaction enthalpy (ΔH_e) and the activation energy (E_e) by the equation

$$br_e = \alpha\sqrt{E_e - \Delta H_e} + \sqrt{E_e}. \tag{4}$$

This equation has been used to calculate the br_e parameter from experimental data. In addition to the α and br_e parameters, each class of radical reactions is characterised in terms of the MIP by a classical potential barrier (the activation energy which includes the zero-point vibration energy of the bond being attacked) to the thermally neutral reaction (E_{e0}) and the position ($r_0^{\neq}$) of the hydrogen atom in the transition state (TS) in the r_e segment at $E_e = E_{e0}$:

$$\sqrt{E_{e0}} = \frac{br_e}{1+\alpha}, \tag{5}$$

$$r_0^{\neq} = r_e(1+\alpha)^{-1}. \tag{6}$$

The values of α and b [measured in (kJ mol^{-1})$^{1/2}$ m^{-1}], $0.5\,hN_Av_i$ and $0.5\,hN_A(v_i - v_f)$ (both in kJ mol^{-1}) for different classes of radical isomerisation reactions accompanied by hydrogen migration are given below.

Reaction	α	$10^{-10}\,b$	$0.5\,hN_Av_i$	$0.5\,hN_A(v_i-v_f)$
$R^{\bullet}+H-C$	1.000	37.43	17.4	0.0
$RO^{\bullet}+H-C$	0.796	37.43	17.4	−4.3
$ROO^{\bullet}+H-C$	0.814	37.43	17.4	−3.8

The α and E_{e0} parameters can be used to calculate the activation energies of reactions of one class from their enthalpies. When α is close to 1 and the inequality $\Delta H_e(1-\alpha^2) \ll (br_e)^2$ holds, the dependence of the activation energy E_e on the enthalpy ΔH_e assumes the form

$$\sqrt{E_e} = \sqrt{E_{e0}} + \frac{\alpha\Delta H_e}{2(1+\alpha)\sqrt{E_{e0}}}. \tag{7}$$

For hydrogen transfer in alkyl radicals, the force constants of the outgoing and incoming bonds are equal; therefore, $\alpha = 1$. Thus, Eqn (7) assumes the form

$$\sqrt{E_e} = \sqrt{E_{e0}} + \frac{\Delta H_e}{4\sqrt{E_{e0}}}. \tag{8}$$

The contribution ΔE_H of the enthalpy to the activation energy of an individual reaction can be readily estimated from the formula

$$\Delta E_H = E_e - E_{e0}. \tag{9}$$

An important advantage of the MIP is the possibility to compare reactions of different classes through comparison of their characteristics such as the activation energy of the thermally neutral reaction (E_{e0}) and bond elongation (r_e) in the TS.

III. Migration of a hydrogen atom in alkyl radicals

The kinetic and thermodynamic parameters of hydrogen migration in alkyl radicals are summarised in Table 1.

The enthalpies of such reactions vary from −65 to +26 kJ mol^{-1} and the activation energies, from 12 to 40 kJ mol^{-1}. The transition states of these reactions are cyclic. The configuration of atoms in the TS of 1–4- and 1–5-migrations of a hydrogen atom calculated by the density functional theory (B3LYP)[17] is shown in Fig. 1.

Activation entropy of hydrogen migration. The formation of a cyclic TS eliminates the free rotation of alkyl fragments around the C–C bond. This results in a negative activation entropy ($\Delta S^{\neq}$). Comparison of the experimental pre-exponential factors A with the theoretical value [32] calculated from the formula

$$A = \frac{RT}{N_Ah}\exp\left(\frac{\Delta S^{\neq}}{R}\right), \tag{10}$$

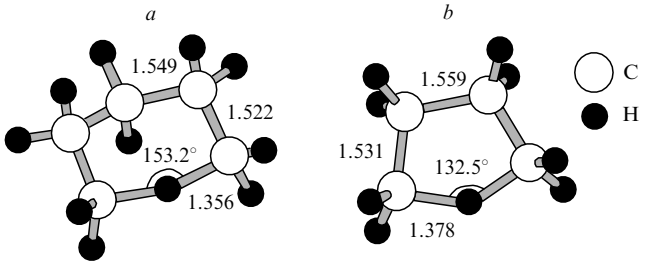

Figure 1. Geometric structure of the TS for hydrogen migration in the pentyl (*a*) and butyl (*b*) radicals based on quantum-chemical calculations (B3LYP).[17]
The bond lengths are in Å.

Table 1. Thermodynamic (D_i, D_f, ΔH) and kinetic (E_a) parameters of hydrogen migration in alkyl radicals.

Radical [a]	D_i (see [b])	D_f (see [b])	ΔH (see [b])	E_a (see [b])	Ref.

$C^{\bullet}Cl_2(CH_2)_3(C-H)HMe$	413.0	388.7	24.3	39.9	24
$C^{\bullet}Cl_2(CH_2)_3(C-H)HEt$	414.5	388.7	25.8	39.0	24
$C^{\bullet}Cl_2(CH_2)_2SiEt_2(C-H)HMe$	413.0	388.7	24.3	44.8	25, 26
$C^{\bullet}H_2(CH_2)_3(C-H)HC(O)OMe$	398.8	422.0	−23.2	25.1	27
$(C-H)(O)CH_2CHBu^tCH_2C^{\bullet}H_2$	385.6	422.0	−36.4	12.5	28
$CH(O)(C-H)HCH_2CHBu^tCH_2C^{\bullet}H_2$	397.8	422.0	−24.2	17.1	28
Five-membered ring					
$C^{\bullet}H_2(CH_2)_2(C-H)HC(O)OMe$	398.8	422.0	−23.2	32.4	27
2-$[Me_2C(C-H)H_2]$-4,6-$Bu^t_2C_6H^{\bullet}_2$	422.0	474.0	−52.0	19.0	29–31
2,4,6-$Ad_3C_6H^{\bullet}_2$ (see [c])	408.8	474.0	−65.2	18.0	29, 31

[a] Here and in Tables 2, 3, 6, 7 and 8, the bond being attacked is designated by C—H; [b] in kJ mol^{-1}; [c] AdH is adamantane.

has shown that the $\Delta S^{\neq}$ value is exactly equal to the difference between the entropies of the linear and cyclic hydrocarbons:[18]

$$\Delta S^{\neq} = S(\text{cyclo-}C_nH_{2n}) - S(C_nH_{2n+2}).$$

The logarithms of the pre-exponential factors calculated from relation (10) are listed in Table 2.

Effect of the size of the ring formed in the transition state on the activation energy. The activation energy of hydrogen migration in an alkyl radical obviously depends on the reaction enthalpy.[20] What other factors influence the rate of migration of the hydrogen atom? This issue has been addressed in a study [16] where the br_e, r_e and E_{e0} parameters were calculated by the method of intersecting parabolas on the basis of experimental data. The activation energy for hydrogen migration in an alkyl radical was found to depend on the size of the ring formed in the TS. The reactions whose TS contain rings with equal numbers of carbon atoms are characterised by the same set of parameters ($\alpha = 1$, br_e, r_e and E_{e0}) and differ only in their activation enthalpies and energies. These parameters for the reactions

$$R^1C^{\bullet}H(CH_2)_nCH_2R^2 \longrightarrow R^1CH_2(CH_2)_nC^{\bullet}HR^2$$

are shown in Table 2. Below the classical potential barriers (E_{e0}) for such reactions are juxtaposed with the ring strain energies (E_{rsc}) in cycloalkanes (n is the number of carbon atoms in the TS ring).[33]

n	5	6	7
E_{e0} /kJ mol^{-1}	72.5 ± 0.9	52.0 ± 1.7	72.2
E_{rsc} /kJ mol^{-1}	26.7	0.7	26.8
$10^{10}\, r_e$ /m	0.455	0.385	0.454

It can be seen that the classical potential barriers to the reactions whose TS contain five- (72.5 kJ mol^{-1}) or seven-membered rings (72.2 kJ mol^{-1}) are markely higher than those for TS with six-membered rings (52.0 kJ mol^{-1}). Obviously, this is due to the difference between the ring strain: the higher the strain, the higher the activation energy. An empirical dependence between the E_{e0} and E_{rsc} values (expressed in kJ mol^{-1}) is as follows:

$$E_{e0} = 51.5 + 0.788\, E_{rsc}. \quad (11)$$

Thus, the dependence of the activation energy E_e on the ΔH and E_{rsc} values has the form [18]

$$\sqrt{E_e} = \sqrt{51.5 + 0.788E_{rsc}} + \frac{\Delta H}{4\sqrt{51.5 + 0.788E_{rsc}}}. \quad (12)$$

Table 2. MIP parameters for hydrogen migration in alkyl radicals.[16]

$RC^{\bullet}H(CH_2)_4(C-H)HY$	16.99	72.2	0.454	8.20	74.8
$RC^{\bullet}H(CH_2)_4(C-H)HPh$	17.42	75.9	0.465	7.20	79.2
$RC^{\bullet}H(CH_2)_4(C-H)HCH=CH_2$	18.14	82.3	0.485	7.20	86.5

[a] E_{e0}(m) and E_{e0}(b) are the classical potential barriers for the monomolecular cyclisation and bimolecular hydrogen abstraction, respectively.

Quantum-chemical calculations have shown[17] that in the TS for isomerisation of the butyl radical, the angle between the C, H and C atoms of the ring is about 21° smaller than the corresponding angle in the TS for pentyl radical isomerisation (see Fig. 1). Hence, the activation energy (determined by quantum-chemical calculations) for isomerisation of the butyl radical is higher than that for the pentyl radical by 31 kJ mol^{-1}. The results of quantum-chemical calculations for the ω-isomerisation of the butyl and pentyl radicals are presented below (the activation energies are expressed in kJ mol^{-1}; φ is the C···H···C angle).[17]

Reaction	E_a	$10^{10}\,r$(C···H) /m	φ /deg
$C^{\bullet}H_2(CH_2)_2Me \rightarrow Me(CH_2)_2C^{\bullet}H_2$	96.8	1.378	132.5
$C^{\bullet}H_2(CH_2)_3Me \rightarrow Me(CH_2)_3C^{\bullet}H_2$	65.8	1.356	153.2

Thus, the calculated parameters are in good agreement with experimental data.

Effect of the α-π-bond on the activation energy. Analysis of the experimental data on bimolecular reactions

$$(R^1)^{\bullet} + R^2H \longrightarrow R^1H + (R^2)^{\bullet}$$

indicates that a double bond or an aromatic ring present in the α-position relative to the bond being attacked results in a higher E_{e0} value (see Ref. 20). This effect is illustrated in Table 2, which presents the MIP parameters characterising hydrogen migration reactions in radicals with different structures.[16] Table 3 summarises the results of calculations, using this method, of the rate constants for the migration of hydrogen atoms from the β-, γ-, δ- and ε-positions with respect to the carbon atom with a free valence in different radicals.

Comparison of mono- and bimolecular hydrogen abstraction. Bimolecular reactions of hydrogen abstraction from hydrocarbon molecules by alkyl radicals have been analysed.[20] This allowed one to compare the classical potential barriers to monomolecular and bimolecular hydrogen abstraction reactions. The difference between the structures of these TS is obvious. In the bimolecular reaction, the C···H···C atoms of the reaction centre are arranged in one straight line. In an intramolecular hydrogen migration to the δ-position, which is accompanied by the lowest ring strain, the C···H···C atoms form an angle of 153° (quantum-chemical calculations, see Fig. 1).[16] According to the absolute reaction rate theory, the minimum repulsion between the atoms in the TS is attained in the reaction centre with a linear atom configuration;[1,32] it can therefore be expected that $E_{e0}(m) > E_{e0}(b)$. However, analysis of the experimental data using the MIP provides the opposite result: $E_{e0}(m) = 52$ kJ mol^{-1}, $E_{e0}(b) = 74.8$ kJ mol^{-1}, *i.e.*, $E_{e0}(m) < E_{e0}(b)$.[16] As shown by quantum-chemical calculations of the activation energy of the reactions

$$C_2H_5^{\bullet} + C_2H_6 \longrightarrow C_2H_6 + C_2H_5^{\bullet}$$

and

$$C^{\bullet}H_2(CH_2)_3Me \longrightarrow Me(CH_2)_3C^{\bullet}H_2,$$

the bimolecular reaction of the ethyl radical with ethane is characterised by $E_{e0} = 62.5$ kJ mol^{-1}, and the monomolecular migration of the H atom in the pentyl radical has $E_{e0} = 65.8$ kJ mol^{-1}, *i.e.*, the calculated activation energies of these two thermally neutral reactions are approximately equal.[17]

What is the reason for the fact that $E_{e0}(b) \geqslant E_{e0}(m)$? The answer can be derived from MIP considerations. In attaining the TS of mono- and bimolecular hydrogen abstraction, the following factors are important. In a bimolecular reaction whose TS has a linear reaction centre, C···H···C, the crucial role in the activation is played by the stretching vibration of the C–H bond being attacked. In this case, the activation energy depends on the force constant of the stretching vibration of the C–H bond being cleaved [$b = 37.43 \times 10^{10}$ (kJ mol^{-1})$^{1/2}$ m^{-1}]. In the case of intraradical migration of hydrogen, the situation is more complicated. The angular configuration of the C···H···C fragment needed for TS formation is attained through excitation of both the stretching vibration of the C–H bond being cleaved and the angular bending vibrations of the C–C–C and C–C–H bonds, which form a cyclic TS. There are five such bonds in a pentyl radical. The frequencies and the force constants of bending vibrations of the C–C–C bonds are much smaller than these parameters for the C–H bond. Owing to these 'soft' vibrations, this TS is attained more easily (as regards the energy expenditure), despite its seemingly less favourable angular configuration. In this case, the br_e parameter is the sum of $b_j r_{ej}$, where every partial parameter present in the $\Sigma b_j r_{ej}$ sum reflects the shifts of atoms in the TS induced by activation of vibrations of the corresponding bonds. Since the force constants of bending vibrations are lower than those of stretching vibrations, $\Sigma b_j r_{ej} < br_e$(b).

Polar effect. The polar interaction in the TS of bimolecular reactions is manifested in the reactions of halide-containing radicals with haloalkanes. The introduction of a halogen atom into a molecule or a radical not only changes the reaction enthalpy but also decreases the activation energy of the thermally neutral reaction.[20] The role of polar effect in the activation energy can be judged from the difference between the E_{e0} values of the reactions of radicals with a haloalkane and the corresponding hydrocarbon

$$\Delta E_{\mu} = E_{e0}(RX) - E_{e0}(RH). \qquad (13)$$

The data illustrating this effect for reactions of trichloromethyl radicals with a number of chloroalkanes are presented below.[19]

Compound	ΔE_{μ} /kJ mol^{-1}
CH_2Cl_2	−8.0
$CH_2ClCH_2CCl_3$	−18.8
$EtCCl_3$	−17.9
Pr^nCCl_3	−16.0

The polar interaction also shows itself in hydrogen migration (see Table 1). The E_{e0} and ΔE_{μ} values (in kJ mol^{-1}) calculated from experimental data for the hydrogen migration processes that involve the formation of a six-membered transition state are presened below.[19]

Table 3. Enthalpies, activation energies, and rate constants (k) for hydrogen migration in alkyl radicals calculated using the MIP relations.[16]

$C^{\bullet}Cl_2(CH_2)_5Me \rightarrow CHCl_2(CH_2)_3C^{\bullet}HEt$	41.3	−10.7
$C^{\bullet}Cl_2(CH_2)_2SiEt_2CH_2Me \rightarrow CHCl_2(CH_2)_2SiEt_2C^{\bullet}HMe$	36.1	−15.9

Similar results were obtained by quantum-chemical calculations carried out by the B3LYP technique (the activation energies are expressed in kJ mol^{-1}; φ is the C···H···C angle).[19]

Reaction	E_a	$10^{10}\,r$(C···H) /m	φ /deg
$C^{\bullet}H_2(CH_2)_3Me \rightarrow Me(CH_2)_3C^{\bullet}H_2$	65.8	1.356	153.2
$C^{\bullet}Cl_2(CH_2)_3Me \rightarrow CHCl_2(CH_2)_3C^{\bullet}H_2$	50.8	1.350	101.5
$C^{\bullet}Cl_2(CH_2)_3CCl_2H \rightarrow CHCl_2(CH_2)_3C^{\bullet}Cl_2$	28.7	1.342	152.5

It can be seen that the polar effect markedly decreases the activation energy for hydrogen migration in chloroalkanes.

IV. Isomerisation of alkoxyl radicals

Alkoxyl radicals are highly active and rapidly enter into bimolecular hydrogen abstraction.[2,8]

$$R^1O^{\bullet} + R^2H \longrightarrow R^1OH + (R^2)^{\bullet}$$

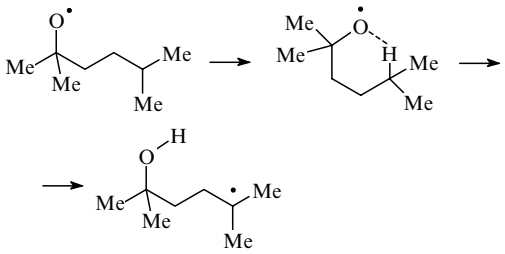
In addition, alkoxyl radicals with rather long hydrocarbon chains ($>C_4$) also undergo intraradical hydrogen migration. Table 4 presents the rate constants for these reactions calculated from the ratio of the rate constants for RO$^{\bullet}$ isomerisation and RO$^{\bullet}$ destruction.[2]

Each of the reactions implies elimination of the hydrogen atom located in the γ-position, *i.e.*, the transition state contains a six-membered ring.

Table 4. Experimental rate constants and activation energies for hydrogen migration in alkoxyl radicals.

Reaction	E_a (see [a])	log$A$ (s^{-1})	$k_{350\,K}$ (see [b])	Ref.
	30.1	9.78	1.93×10^5	2
	29.8	9.78	2.14×10^5	2
	23.4	9.60	1.29×10^5	2
	22.8	9.60	1.57×10^6	34
	25.4	9.30	3.23×10^5	34
	9.8	8.78	2.08×10^7	35

[a] Expressed in kJ mol^{-1}; [b] in s^{-1}.



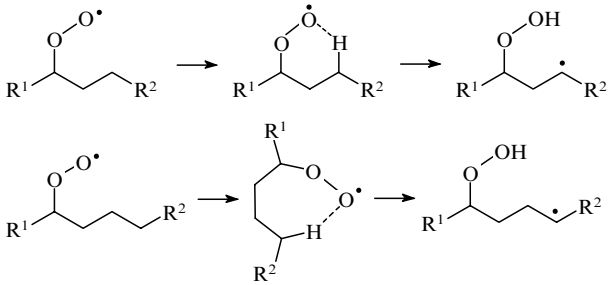
The kinetic parameters (br_e, E_{e0}, r_e and A_{C-H}) which describe this reaction in terms of the MIP are summarised in Table 5.

The hydrogen abstraction from the C−H bond located in the vicinity of the phenyl or vinyl group has a higher classical potential barrier (E_{e0}) due to stronger triplet repulsion.[20] However, the pre-exponential factor is smaller in this case due to entropy loss caused by the elimination of the free rotation of these groups in the TS. The activation energy of the thermally neutral isomerisation of alkoxyl radicals coincides with that of the bimolecular abstraction reaction:[16] E_{e0}(RO$^{\bullet}$ isomer.) = 53.4 kJ mol^{-1}, E_{e0}(RO$^{\bullet}$ + R^1H) = 53.2 kJ mol^{-1}. Thus, for the isomerisation with a non-linear TS, the relationship E(m) > E(b) expected theoretically does not hold either. The reason is apparently the same as in the case of hydrogen migration in alkyl radicals (see above).

Using MIP parameters, the activation energies and the rate constants for isomerisation of diverse alkoxyl radicals have been calculated.[16] The results of these calculations are summarised in Table 6.

V. Isomerisation of peroxyl radicals

The intraradical hydrogen migration also takes place in peroxyl radicals.[10,12,23] Hydrogen migrates from either β- or γ-position, *i.e.*, a TS with either six- or seven-membered ring is formed.



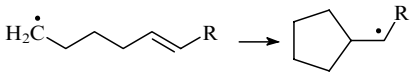
Experimental data on isomerisation of the alkyl and alkylaryl peroxyl radicals are listed in Table 7.

The MIP parameters for $RO_2^{\bullet}$ isomerisation calculated on the basis of these data are presented in Table 5. As in the case of isomerisation of alkoxyl radicals, in this case, too, the classical potential barriers (E_{e0}) are close to the E_{e0} values for the bimolecular reaction $RO_2^{\bullet}$ + RH (see Table 5). The activation energies E_{e0} of the reactions whose TS contain six- and seven-membered rings do not differ much. The activation energies and the rate constants for isomerisation of diverse peroxyl radicals calculated in terms of the MIP are summarised in Table 8.[16]

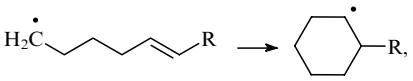
For these reactions, the E_a(m) values are close to E_a(b). The reason is apparently the same as in the case of isomerisation of the R$^{\bullet}$ and RO$^{\bullet}$ radicals.

VI. Cyclisation and ring opening in alkyl radicals

Alkyl radicals containing a multiple bond rapidly undergo intraradical cyclisation



or



resulting in the formation of cyclic five- or six-membered radicals. These reactions have been intensively studied for the last 20 years. The experimental rate constants and the activation energies for the cyclisation of alkyl radicals are summarised in Table 9.

Recently, the experimental data have been analysed by means of the MIP protocol.[18] The ΔH_e, E_e and br_e values were calculated [see Eqns (1)–(4)] using the parameters presented below [b are expressed in (kJ mol^{-1})$^{1/2}$ m^{-1}, hN_Av_i and $hN_A(v_i-v_f)$ are in kJ mol^{-1}].

Attacked bond	α	$b\times10^{-10}$	$0.5hN_Av_i$,	$0.5hN_A(v_i-v_f)$
C=C	1.202	53.89	9.9	1.7
C≡C	1.542	69.12	12.7	4.5

The br_e, E_{e0} and r_e parameters and the experimental pre-exponential factors A are listed in Table 10.

The activation energy of cyclisation is undoubtedly affected by the reaction enthalpy. This is equal to the sum of the energy of formation of the new C–C bond and the strain energy of the newly formed ring (E_{rsc}) minus the energy of rupture of the C–C π-bond. Comparison of the br_e parameters for cyclisation reac-

[a] Expressed in kJ mol^{-1}; [b] ΔE_μ is the contribution of the polar interaction to the activation energy.

tions of various alkyl radicals (see Table 10) leads to the following conclusions.

1. The br_e parameter depends on the size of the ring formed.

2. This parameter does not depend (or slightly depends) on the number and the positions of substituents in the radical which undergoes cyclisation.

3. The br_e parameters of cyclisation are equal for radicals containing rings of the same size and chains, both composed of C atoms alone and incorporating also O and Si atoms.

4. For cyclisation reactions of perfluorinated radicals, the br_e parameters are higher.

5. Cyclisation that takes place through intramolecular attack of the radical on the triple bond is described by higher br_e parameters.

Effect of the ring strain energy on the activation energy. It follows from the data listed in Table 10 that, depending on the ring size, the activation energy of the thermally neutral cyclisation passes through a maximum, E_{e0} = 85.7 kJ mol^{-1}, which is attained upon the formation of a six-membered ring. The minimum value E_{e0} = 36.4 kJ mol^{-1} is observed for the formation of a three-membered ring. For radical cyclisation reactions resulting in three- to six-carbon rings, the following linear correlation is observed:

$$E_{e0} = 85.5 - 16.4\,(6 - n), \qquad (14)$$

where E_{e0} is expressed in kJ mol^{-1}, n is the number of C atoms in the ring.

6	20.39 ± 0.64	85.7	0.7	0.378	9.90
7	19.45 ± 0.66	78.0	26.8	0.361	9.10
5 (see [d])	21.38	94.3	26.7	0.397	10.20
5 (see [e])	22.98	81.7	26.7	0.332	10.20

[a] The number of atoms in the ring; [b] in (kJ mol^{-1})$^{1/2}$; [c] in kJ mol^{-1}; [d] for C_nF_{2n}; [e] for RC≡CR.

When a linear hydrocarbon is transformed into a cyclic one, a ring strain energy appears. This is due to the fact that the C–C–C angle best suited for sp^3-hybridisation (109°) decreases upon cyclisation, for example, to 60° in the case of cyclopropane, and this enhances the energy of the cyclic molecule. This strain in the formed ring may affect the E_{e0} value. The published [33] strain energies (E_{rsc}) for some rings are presented in Table 10; Fig. 2 juxtaposes the E_{e0} and E_{rsc} values.

The E_{e0} and E_{rsc} values (expressed in kJ mol^{-1}) obey the following linear correlation:

$$E_{e0} = (85.5 \pm 2.8) - (0.43 \pm 0.05)E_{rsc}\,. \qquad (15)$$

Thus, the higher the strain energy in the ring, the lower the classical potential barrier to the thermally neutral reaction. In addition, the higher the E_{rsc}, the higher the reaction enthalpy and, hence, the higher the activation energy of cyclisation, which depends on ΔH. Substitution of expression (14) into Eqn (4) followed by transformations gives an expression for calculating the activation energy E_e:

$$\sqrt{E_e} = 3.28\sqrt{194.4 - E_{rsc}}\left(1.202\sqrt{1 + \frac{0.208\Delta H_e}{194.4 - E_{rsc}}} - 1\right), \qquad (16)$$

which allows one to calculate the Arrhenius activation energy (E_a) of cyclisation from the reaction enthalpy ΔH ($\Delta H_e = \Delta H + 1.7$) and the strain E_{rsc} of the ring formed. Presented below are the results of calculation of the E_a values for the reactions

$$CH_2{=}CH(CH_2)_{n-2}C^{\bullet}HR \longrightarrow \text{cyclo-}[CHR(CH_2)_{n-2}CH(C^{\bullet}H_2)],$$

where $n = 3-10$ is the number of C atoms in the ring; the enthalpies and the activation energies are expressed in kJ mol^{-1}, $T = 350$ K.

n	ΔH_e	E_{rsc}	E_{e0}	E_a(calc)	E_a(exp)
3	21.7	115.1	36.4	38.9	44.9
4	16.7	110.1	54.1	38.1	34.8
5	–62.7	26.7	69.7	34.5	32.1
6	–90.8	0.7	85.7	33.5	34.3
7	–36.9	26.3	78.0	46.4	–
8	–19.8	40.6	–	48.7	–
10	–8.4	52.0	–	49.6	–

It can be seen that the lowest calculated E_a(calc) value corresponds to the formation of a six-membered ring, and starting from $n = 7$, the activation energy depends only slightly on the ring size. The influence of ΔH_e and E_{rsc} on the activation energy is largely compensated.

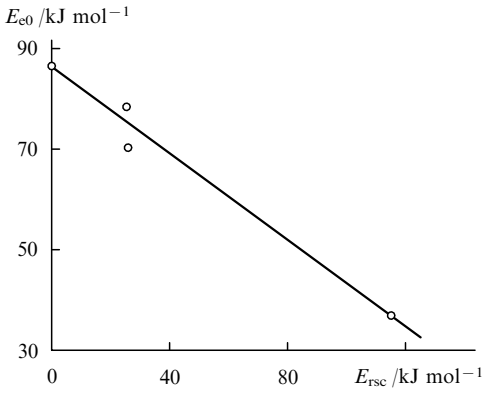

Figure 2. Activation energy of thermally neutral reaction (E_{e0}) *vs.* ring strain energy (E_{rsc}) for cyclisation of alkyl radicals.

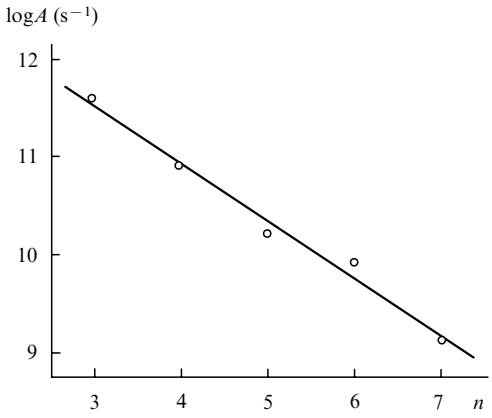

Figure 3. Dependence of log$A$ on the number (n) of carbon atoms in the ring for cyclisation of alkyl radicals.

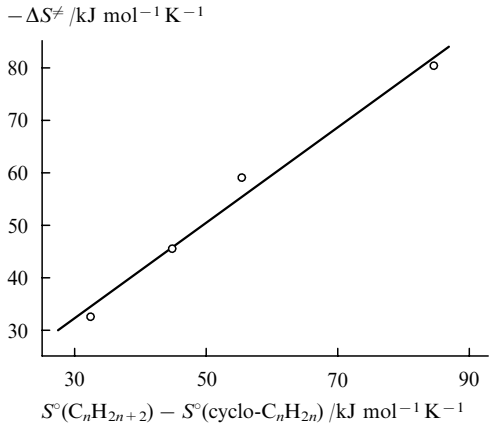

Figure 4. Correlation between the activation entropy ($\Delta S^{\neq}$) for cyclisation of alkyl radicals and the difference between the formation entropies (S°) of the corresponding linear and cycic hydrocarbons.

Effect of the ring size on the pre-exponential factor for cyclisation. As noted above (see Table 10), the pre-exponential factor for the radical cyclisation reaction depends on the size of the ring formed. Figure 3 shows the dependence of log$A$ on the number of atoms (n) in the ring of the resulting molecule.

For $n \geqslant 3$, this linear dependence is described by the relation

$$\log A\ (s^{-1}) = (13.34 \pm 0.21) - (0.60 \pm 0.04)\, n. \qquad (17)$$

This type of dependence of the pre-exponential factor on the ring size is due to the decrease in the activation entropy caused by the formation of a ring. The formation of a cyclic TS from a linear radical, for example, $CH_2{=}CH(CH_2)_{n-2}C^{\bullet}H_2$, eliminates free rotation of radical fragments around the corresponding C–C bonds. This results in a lower TS entropy compared to the starting radicals. The magnitide of this entropy change can be evaluated by comparing the S° values of the linear and the corresponding cyclic hydrocarbon molecules. The termination of rotation of one CH_2 group around a C–C bond decreases the entropy of a species by about 40 J mol^{-1} K^{-1}; therefore, the variation of log$A$ *vs.* n is linear. The entropies (S°) of the linear (C_nH_{2n+2}) and cyclic (cyclo-C_nH_{2n}) molecules, the difference between them (ΔS°) and the activation entropy ($\Delta S^{\neq}$) (J mol^{-1} K^{-1}) are presented below.

n	log$A$ (s^{-1})	$-\Delta S^{\neq}$	S°(cyclo-C_nH_{2n})	$S^{\circ}(C_nH_{2n+2})$	ΔS°
3	11.60	32.5	237.4	270.0	32.6
4	10.90	48.4	265.2	310.0	44.8
5	10.20	59.3	293.1	348.9	55.8
6	9.90	65.2	298.6	388.1	89.5
7	9.10	80.5	342.6	427.9	85.3

It can be seen that the difference $\Delta S^{\circ} = S^{\circ}$(cyclo-$C_nH_{2n}$) $- S^{\circ}(C_nH_{2n+2})$ increases with an increase in the ring size (for $n = 3-7$). This trend is caused by the following: the greater the number of C–C bonds in the ring around which the rotation takes place, the more pronounced the entropy loss that accompanies the cyclisation of a molecule or a radical. The cyclohexane ring provides an exception [$\Delta S^{\circ}(n = 6) > \Delta S^{\circ}(n = 7)$], probably, due to the presence of two conformations (a chair and a boat) where transition from one conformation to the other increases the entropy of the six-membered ring. It can be seen from Fig. 4 that the activation entropy ($-\Delta S^{\neq}$) depends linearly on the ΔS° value for $n = 3, 4, 5$ and 7; the reaction giving a cyclohexane ring ($n = 6$) is an exception. The variation of $\Delta S^{\neq}$ *vs.* ΔS° (both are in J mol^{-1} K^{-1}) is linear having a slope ratio close to unity (see Fig. 4):

$$-\Delta S^{\neq} = (5.36 \pm 0.08) + \\ + (0.90 \pm 0.08)\,[S^{\circ}(C_nH_{2n+2}) - S^{\circ}(\text{cyclo-}C_nH_{2n})]. \qquad (18)$$

This attests to a purely entropy influence of the ring size on the pre-exponential factor.

Role of the force constant in cyclisation reactions. The activation energy of the bimolecular elimination–addition reaction depends on the force constants on the reacting bonds.[20] The classical potential barrier to the thermally neutral reaction (E_{e0}) is determined, according to the MIP, by three parameters, namely, the total elongation of the reacting bonds (r_e) and the force constants of the bond being cleaved (b) and the bond being formed (b_f) [see Eqns (4), (5)]. The force constant of the triple C≡C bond is greater than that of the double C=C bond; therefore, it should be expected that the classical potential barrier (E_{e0}) to cyclisation involving a triple bond should be higher than that for cyclisation at a double bond. The data on cyclisation of the $CH_2{=}CH(CH_2)_3C^{\bullet}H_2$ and $HC{\equiv}CH(CH_2)_3C^{\bullet}H_2$ radicals confirm this assumption (see Table 10). This can also be seen from comparison of the MIP parameters [br_e in (kJ mol^{-1})$^{1/2}$, E_{e0} in kJ mol^{-1}, b in (kJ mol^{-1})$^{1/2}$ m^{-1}, r_e in m] for the cyclisation of radicals yielding a five-membered ring.

Bond	br_e	E_{e0}	$10^{-10}\,b$	$10^{10}\,r_e$
C=C	18.39	69.7	53.89	0.341
C≡C	22.98	81.7	69.12	0.332

Notably, the r_e parameters for reactions of these two classes are similar. Therefore, the difference between the activation energies of these reactions is due only to different force constants of the double and triple bonds.

Polar interaction. Cyclisation of perfluorinated radicals has a higher classical potential barrier than the cyclisation of hydrocarbon radicals (see Table 10): for $n = 5$, the E_{e0} values are 94.3 and 69.7 kJ mol^{-1}, respectively. The difference between the activation energies, $\Delta E_{e0} = 24.6$ kJ mol^{-1}, is rather high and characterises the contribution of the polar interaction of the C–F bonds to the TS energy.

Comparison of cyclisation with other reactions. Previously, bimolecular radical addition reactions have been analysed in terms of the MIP.[90] It appears pertinent to compare the kinetic parameters of these, rather similar reactions. Since the transition state of the bimolecular reaction is acyclic, these reactions should be compared most legitimately with the cyclisation resulting in a six-membered ring, devoid of bond strain, as the cyclic transition state. The parameters for these two types of reaction are listed below.

Parameter	Cyclisation ($n = 6$)	Bimolecular reaction
br_e /(kJ mol^{-1})$^{1/2}$	20.39 ± 0.64	20.01 ± 0.41
E_{e0} /kJ mol^{-1}	85.6 ± 2.7	82.6 ± 1.7
$10^{10}\, r_e$ /m	0.378 ± 0.012	0.371 ± 0.008
A	8.0×10^9 s^{-1}	5.0×10^8 litre mol^{-1} s^{-1}

It can be seen that the MIP parameters virtually coincide to within the error of determination. Thus, the activation energies of the bimolecular addition and the cyclisation giving rise to a six-membered ring do not differ much for the same enthalpy of the addition. Their rates are expected to be similar when the monomer concentration (c_m) is 16 mol litre^{-1}, where

$$A(\text{cycl}) = A(\text{b})\, c_m.$$

Section III outlines an analysis of intraradical hydrogen abstraction reactions

$$RCH(CH_2)_nC^{\bullet}H_2 \longrightarrow RC^{\bullet}(CH_2)_nMe.$$

It is of interest to compare isomerisations of radicals with hydrogen migration and with addition of the free valence to a double bond. The kinetic parameters [br_e in (kJ mol^{-1})$^{1/2}$, E_{e0} in kJ mol^{-1}, r_e in m], which describe the reactions of these two types giving rise to five-, six- and seven-membered rings in the TS are presented below.[90]

Type of reaction	n	br_e	E_{e0}	$10^{10}\, r_e$

Abstraction of H	6	14.42	52.0	0.385
Addition	7	19.45	78.0	0.361
Abstraction of H	7	14.40	51.8	0.385

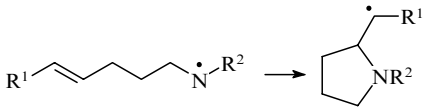
From comparison of the activation energies of thermally neutral reactions, it can be seen that hydrogen abstraction is characterised by lower E_{e0} values than addition for rings with $n \geqslant 6$, while in the case of the five-membered ring, the E_{e0} values are similar (69.7 and 72.5 kJ mol^{-1}, respectively). The dependences of E_{e0} on the ring size are antiparallel: for addition reactions, the $E_{e0}(n = 6)$ value is the highest, whereas for abstraction, $E_{e0}(n = 6)$ is the lowest. Hence, ring strain has different effects on the height of the classical potential barrier E_{e0} of the intramolecular addition and hydrogen abstraction in alkyl radicals. The difference between the E_{e0} values is probably due to the following circumstance. In the addition reaction, the cyclic TS structure coincides with the cyclic structure of the product and differs from the initial linear structure of the reactant. In the intramolecular abstraction, only the TS has a cyclic structure, while both the reactant and the product are linear.

Thus, the activation energies and the rate constants for cyclisation of alkyl radicals are determined by the following three factors: the reaction enthalpy, the size of the ring formed and the force constants of the reacting bonds. The ring size influences both the reaction enthalpy and the classical potential barrier to the thermally neutral reaction. The activation entropy also depends on the number of atoms in the ring, being directly proportional to the loss of entropy upon transition from linear to ring hydrocarbon structure [see Eqn (18)].

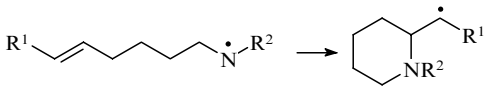
Ring opening in the cyclic alkyl radicals is the reverse reaction with respect to cyclisation. Experimental data on these reactions are summarised in Table 11.

VII. Cyclisation and ring opening in aminyl radicals

Aminyl radicals containing a double bond in the alkyl substituent undergo cyclisation, like alkyl radicals, giving rise to heterocyclic alkyl radicals. This may give either five- or six-membered rings.

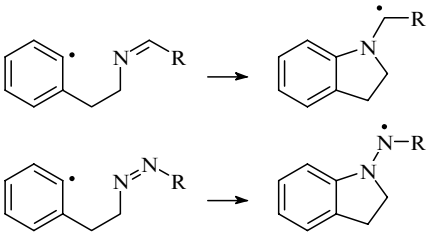


(A)



(B)

The aryl radicals with an imino group and a diazo group in the side chain also undergo cyclisation.



The experimental data on this type of isomerisation are summarised in Table 12. Cyclisation processes involving aminyl,

Table 11. Experimental activation energies, rate constants and pre-exponential factors for ring opening in alkyl radicals.

iminoalkyl and diazoalkyl radicals and resulting in five-membered rings are described, in terms of the MIP, by the parameters presented below [r_e in m, hN_Av and $hN_A(v_i - v_f)$ in kJ mol^{-1}].

Radical (n = 3, 4)	α	$10^{10}\,r_e$	$0.5\,hN_Av$	$0.5\,hN_A(v_i - v_f)$
$R^1CH=CH_2(CH_2)_nN^{\bullet}R^2$	1.410	0.539	9.9	3.1
$R^1N=CH_2(CH_2)_nC^{\bullet}HR^2$	1.478	0.565	10.0	3.2
$R^1N=N(CH_2)_nC^{\bullet}HR^2$	1.593	0.609	10.8	4.0

The br_e, E_{e0}, and r_e parameters calculated from the data of Table 12 are presented in Table 13.

Unlike alkyl radicals, cyclisation of aminyl radicals to give a six-membered ring is characterised by lower activation energies E_{e0} than the cyclisation to give a five-membered ring. Obviously, this is due to the strain energy in the ring being formed, as follows from comparison of the E_{e0} and E_{rsc} values (in kJ mol^{-1}).

Table 12. Experimental enthalpies, activation energies and rate constants for cyclisation of aminyl radicals.

Reaction	E_{e0}	E_{rsc}	E_{e0}(b)
(A)	75.2	26.7	61.0
(B)	61.5	3.1	61.0

The same trend is observed for cyclisations occurring through addition to an N=N bond [$E_{e0}(n=5)$ = 66.7 kJ mol^{-1}, $E_{e0}(n=6)$ = 62.4 kJ mol^{-1}]. It is noteworthy that classical potential barriers to intraradical and bimolecular addition of alkyl radicals to a C=C bond are equal, $E_{e0}(m) = E_{e0}(b)$ (see above).

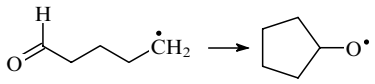
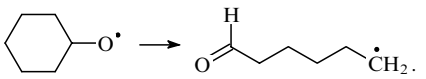
[a] Expressed in (kJ mol^{-1})$^{1/2}$; [b] in kJ mol^{-1}; [c] in m.

VIII. Cyclisation and ring opening in oxygen-containing radicals

As examples, one can consider the cyclisation of oxoalkyl radicals



and the reverse ring opening reaction in cycloalkoxyl radicals



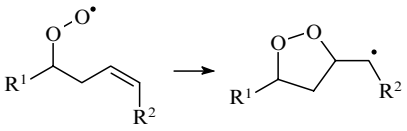
The MIP parameters for cyclisation and ring opening in oxygen-containing radicals are summarised in Table 14. Experimental data for these reactions are given in Table 15. The kinetic parameters found using the MIP relations for various classes of cyclisation and ring opening reactions for these radicals are presented in Table 16.

It can be seen that the E_{e0} values for the forward and reverse reactions coincide to within the error of measurements (±2 kJ mol^{-1}). For a five-membered ring, the activation energy (E_{e0} = 38 kJ mol^{-1}) is higher than that for a six-membered ring (E_{e0} = 32 kJ mol^{-1}). The bimolecular reaction

$$(R^1)^{\bullet} + O=CR^2R^3 \longrightarrow R^1R^2R^3CO^{\bullet}$$

has a higher activation energy (73 kJ mol^{-1}).

Peroxyl radicals undergo cyclisation to give a five-membered ring.[139]

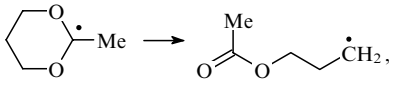


The thermally neutral cyclisation of peroxyl radicals has the activation energy $E_{e0} = 67.4$ kJ mol^{-1} (see Table 16), which is much higher than the E_{e0} value for cyclisation of the oxoalkyl radicals considered above. The bimolecular analogue of these reactions, namely, the addition of $R^1O_2^{\bullet}$ to the double bond of olefins

$$R^1O_2^{\bullet} + CH_2{=}CHR^2 \longrightarrow R^1OOCH_2C^{\bullet}HR^2,$$

is characterised by a much higher potential barrier, $E_{e0} = 90.5$ kJ mol^{-1}.

Ring opening in 1,3-dioxa-2-cycloalkyl radicals, for example,



proceeds rather fast and is accompanied by heat evolution (see Table 15). It can be seen from Table 16 that for these reactions, too, $E_{e0}(n = 6) < E_{e0}(n = 5)$; the difference between these values is 47 kJ mol^{-1}. Thus, for all cyclisation and ring opening reactions in oxygen-containing radicals studied, the inequality $E_{e0}(n = 6) < E_{e0}(n = 5)$ also holds.

IX. Decomposition and ring opening in peroxoalkyl radicals to give epoxides

The oxidation of monomers follows a chain mechanism and includes the following chain propagation steps:[11, 12, 23]

$$R^1O_2^{\bullet} + CH_2{=}CHR^2 \longrightarrow R^1OOCH_2C^{\bullet}HR^2,$$

$$R^1OOCH_2C^{\bullet}HR^2 + O_2 \longrightarrow R^1OOCH_2CH(OO^{\bullet})R^2.$$

The last reaction is accompanied by parallel cyclisation of the peroxoalkyl radical, resulting in the epoxide.

The kinetic data for decomposition of peroxoalkyl radicals with different structures are presented in Table 17.

Decomposition of cyclic peroxoalkyl radicals results in the formation of one (rather than two) alkoxyl radical with an epoxide ring.

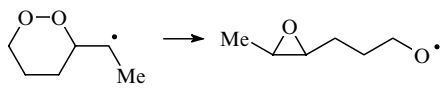

Table 17. Kinetic parameters for decomposition of alkylperoxyl radicals to give epoxides.[10, 31]

$ROOCH_2C^{\bullet}MePh$	28.1	323	6.8×10^4	47.2	14.57
	35.0	368	6.6×10^4	53.8	15.60
	30.4	368	4.7×10^4	54.9	15.53
	35.5	368	7.6×10^4	53.4	15.58
	68.5	323	4.5×10^6	36.0	14.97
	64.5	333	2.9×10^7	32.0	14.32

[a] Expressed in (kJ mol^{-1})$^{1/2}$; [b] in kJ mol^{-1}.

During this reaction, the weak O–O bond is cleaved (D_{O-O} = 162 kJ mol^{-1}) to give a stronger C–O bond. Therefore, such reactions are exothermic. Their enthalpies vary in the range from −28 to −102 kJ mol^{-1} (see Table 17). The br_e parameters calculated for these reactions are very similar (see Table 16). For decomposition of cyclic peroxoalkyl radicals, the br_e and E_{e0} values depend on the ring size, as follows from the data given below.

Radical	$R^1OOCH_2C^{\bullet}HR^2$		br_e/(kJ mol^{-1})$^{1/2}$	15.13	18.25	14.09
E_{e0}/kJ mol^{-1}	68.7	99.9	59.5
E_{rsc}/kJ mol^{-1}	0	29	10

It can be seen that for this reaction $E_{e0}(n = 5) > E_{e0}(n = 6)$ again. This is consistent with the E_{rsc} value: the higher the ring strain, the higher the activation energy of the thermally neutral reaction.

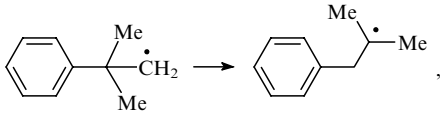
The bimolecular reaction of the alkyl radical with the peroxide

$$(R^1)^{\bullet} + R^2OOR^2 \longrightarrow R^1OR^2 + R^2O^{\bullet}$$

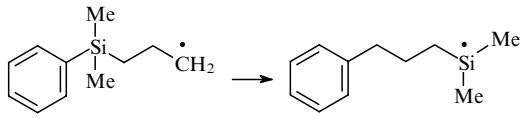
is characterised by a much higher E_{e0} value (122.7 kJ mol^{-1}).[140] For these reactions, the intraradical attack by the alkyl radical on the peroxy bridge proceeds more easily (with less potential energy required).

X. Migrations of aryl and vinyl groups in alkyl radicals

Alkylaromatic radicals undergo isomerisation accompanied by 1,2-transfer of the aromatic ring,[2] for example,



or by 1,4-transfer of the aromatic ring,[2] for example,



Reactions of this type have also been reported for alkyl radicals with naphthyl, pyridine, vinyl and acetylene fragments in the β-position relative to the carbon atom bearing a free valence. The enthalpies and the rate constants for these reactions are summarised in Table 18.

Table 18. Enthalpies and rate constants for the migration of aryl, vinyl and methylidine groups in alkyl radicals.

Reaction	$-\Delta H$ /kJ mol^{-1}	T /K	k /s^{-1}	Ref.
Migration of the aryl group				
	22.0	283–307	$50\times10^{11}\exp(-56/RT)$	141
	30.8	298–375	$6.3\times10^{11}\exp(-61.5/RT)$	142
	22.0	235–291	$6.3\times10^{11}\exp(-48/RT)$	141
	29.7	343	5×10^{3}	143
	44.0	413	7.3×10^{3}	144
	44.0	413	6.1×10^{3}	144
	44.0	413	1.9×10^{4}	144
	44.0	413	8.3×10^{3}	144
	22.0	235–291	$5.0\times10^{11}\exp(-50.1/RT)$	141
	22.0	237–256	$5.6\times10^{11}\exp(-46.0/RT)$	141
	22.0	283–307	$5.0\times10^{11}\exp(-56.4/RT)$	141
	73.2	298–318	$6.3\times10^{11}\exp(-35.6/RT)$	117
	73.2	373	5.0×10^{7}	145
Migration of the vinyl group				
	0	298	$1.1\times10^{11}\exp(-38.0/RT)$	51
	38.0	338	2.5×10^{4}	117
Migration of the methylidine group				
	22.0	318–361	$2.5\times10^{12}\exp(-61.1/RT)$	146

The isomerisation reactions presented in Table 18 are exothermic, some of them proceeding very rapidly, for example the fairly exothermic isomerisation of the 2,2,2-triphenylethyl radical. The average pre-exponential factor A for the 1,2-migration is 5.6×10^{11} s^{-1} ($\log A = 11.75 \pm 0.05$). The Ar–C bonds cleaved and formed during this migration are of the same type; therefore $\alpha = 1$ (MIP, see above). Analysis of the experimental data given in Table 18 within the framework of the MIP provided the following parameters for isomerisation reactions accompanied by transfer of a group bearing an unpaired π-electron.

Radical	br_e /(kJ mol^{-1})$^{1/2}$	E_{e0} /kJ mol^{-1}	$10^{10}\, r_e$ /m
	17.00	72.2	0.379
	17.21	74.0	0.384
	17.04 ± 0.33	72.6 ± 1.4	0.380
	16.36 ± 0.13	66.9 ± 0.5	0.365
	17.46 ± 0.17	76.2 ± 0.7	0.389

It can be seen that the 1,2-migrations of the vinyl, acetylene and phenyl groups are characterised by the same E_{e0} value (72.9 ± 0.8 kJ mol^{-1}). The activation energy for the 1,4-migration of the phenyl group is not much different (E_{e0} = 76.2 kJ mol^{-1}). The potential barrier to the 1,2-migration of pyridine is somewhat lower (66.9 kJ mol^{-1}). Upon comparison of the 1,2-migration of the vinyl group with the cyclisation of radicals containing a vinyl group (see above), one can note that the E_{e0} values for 1,2-migration (72.2 kJ mol^{-1}) and for cyclisation giving a five-membered ring (69.7 kJ mol^{-1}) are similar. Meanwhile the 1,2-migration of groups with π-bonds proceeds much more readily than the addition of the R$^{\bullet}$ radical to a double bond (E_{e0} = 82.6 kJ mol^{-1}).[122]

XI. Conclusion

The material considered in this review provides conclusions concerning the influence of various factors on the kinetic parameters of radical reactions of diverse classes.

The size of the ring formed. This factor is very important for both hydrogen migration and cyclisation or ring opening. First, this affects the reaction enthalpy, as the strain energy of the resulting ring (E_{rsc}) is included with a plus sign in the cyclisation enthalpy and, correspondingly, with a minus sign in the ring opening enthalpy. For three- and four-membered rings, the E_{rsc} value exceeds 100 kJ mol^{-1} (see Section III). Second, as follows from comparison of the activation energies of thermally neutral cyclisation and ring opening reactions, the ring strain influences also the classical potential barrier to the thermally neutral reaction (E_{e0}). For the cyclisation of alkyl radicals, this dependence obeys Eqn (15) (see Section VI): the higher E_{rsc}, the lower E_{e0}. The type of influence involved in the cyclisation of aminyl, iminoalkyl and ω-formyl radicals is different. This can be seen from comparison of the $E_{e0}(n = 6)$ and $E_{e0}(n = 5)$ values presented below (in kJ mol^{-1}) for the above-mentioned radicals.

Radical	$E_{e0}(n = 6)$	$E_{e0}(n = 5)$	$E_{rsc}(n = 5) - E_{rsc}(n = 6)$
$CH_2{=}CH(CH_2)_n\dot{N}R$	68.4	75.1	24
$\dot{C}H_2(CH_2)_nCH{=}CHR$	77.8	66.7	24
$\dot{C}H_2(CH_2)_nCHO$	31.7	38.0	26

A similar regularity is also found for the activation energy (in kJ mol^{-1}) of ring opening in the radicals formed from 1,2- and 1,3-dioxacyclanes (see Section V):

Reaction	$E_{e0}(n = 6)$	$E_{e0}(n = 5)$
	–	99.9
	59.5	–
	–	54.3
	101.6	–

Thus, a different pattern of dependence can be followed for cyclisation of N- and O-containing radicals, namely, the higher the ring strain, the higher the classical potential barrier to the thermally neutral reaction. This also holds for hydrogen migration.

Third, the size of the resulting ring influences the activation entropy and, hence, the pre-exponential factor [see Eqn (17)].

Electronegativity of atoms involved in the ring formation. In radical abstraction reactions

$$X^{\bullet} + HY \longrightarrow XH + Y^{\bullet}$$

the electronegativity (EA) of the atoms X and Y plays an important role by affecting the activation energy E_{e0}.[18] The greater the electronegativity difference (ΔEA) between the atoms X and Y, the lower the E_{e0} value. Does this factor influence also the activation energy of cyclisation? In the cyclisation reactions considered in this review, we were dealing with the the C···C···Y type reaction centres in the TS, where Y = C, N, O. To find out whether or not the electronegativity difference between the C and Y atoms (ΔEA) influences the E_{e0} value for cyclisation, let us juxtapose the kinetic parameters with the ΔEA values for the C···C…C, C…C···N and C···C…O reaction centres. Since the E_{e0} value for addition reactions depends also on the force constants of the reacting bonds,[20] which are different for the C=C, C=N, C=O, C–C, C–O and C–N bonds, we will juxtapose the electronegativity difference ΔEA with the r_e parameter, which does not depend on the force constants of the reacting bonds (underlined) but determines the E_{e0} value [see Eqn (5)].

Radical	Reaction centre	$10^{10}\, r_e$ /m	ΔEA /kJ mol^{-1}
$R^{\bullet}CH(CH_2)_3CH{=}CH_2$	C···C…C	0.378	0
$RCH{=}CH(CH_2)_4\dot{N}R$	C…C···N	0.333	29.5
$CH(O)(CH_2)_4\dot{C}H_2$	C···C…O	0.225	78.5

It can be seen that the r_e value decreases with an increase in the electronegativity difference for the C and Y atoms (Y = N, O). For the three classes of reactions considered, the r_e (in m) and ΔEA (in kJ mol^{-1}) values are correlated satisfactorily through the following relation (Fig. 5):

$$r_e \times 10^{11} = 3.81 \pm 0.06 - (1.91 \pm 0.23) \times 10^{-2}\, \Delta EA. \qquad (19)$$

Thus, the electronegativity of atoms in the reaction centre does really influence the activation energy of cyclisation. The

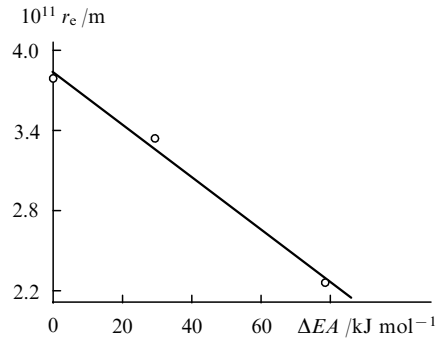


Figure 5. Parameter r_e describing the elongation of the reacting bonds upon cyclisation *vs.* electronegativity of atoms in the reaction centre (ΔEA).

higher the electronegativity difference between the C and Y atoms, the smaller the r_e parameter, and, correspondingly, E_{e0} [see Eqn (5)].

Role of the bending vibrations in the attaining of the activation barrier. According to the transition state theory, bimolecular radical abstraction reactions usually involve a linear configuration of atoms in the reaction centre, *i.e.*, the X···H···Y atoms occur in one straight line. This is confirmed by *ab initio* quantum-chemical calculations.[17] As a rule, the C···H···Y angle in these reactions equals 180° or is close to this value. In the intramolecular migration of the hydrogen atom in the alkyl radical, the corresponding angle in the TS inevitably differs from 180°. Therefore, as noted above, one should expect that $E_{e0}(b) \geqslant E_{e0}(m, n = 6)$ for abstraction reactions. However, it was shown in Section III that this is not really the case.

Reaction	$(R^1)^{\bullet} + R^2H$	$R^1O^{\bullet} + R^2H$	$R^1O_2^{\bullet} + R^2H$
$E_{e0}(m, n = 6)$ /kJ mol^{-1}	46.6	53.4	53.2
$E_{e0}(b)$ /kJ mol^{-1}	74.8	53.2	56.3

It can be seen that for the six-membered ring in the TS, $E_{e0}(m) \leqslant E_{e0}(b)$. This is due to an additional involvement of 'soft' bending vibrations in the radical activation towards isomerisation. A similar situation is observed for the cyclisation reactions resulting in a six-membered ring, namely, $E_{e0}(b) \geqslant E_{e0}(m)$ to within the error of measurements (± 2 kJ mol^{-1}).

Reaction	$E_{e0}(m)$ /kJ mol^{-1}	$E_{e0}(b)$ /kJ mol^{-1}
$R^{\bullet} + C{=}C$	85.7	82.6
$(R^1)^{\bullet} + O{=}CR_2^2$	32	72.9
$RO_2^{\bullet} + C{=}C$	67.4	90.5
$(R^1)^{\bullet} + R^2OOR^2$	59.5	122.7

Obviously, the 'soft' bending vibrations of the C–C bonds in the resulting ring play an important role in the formation of the transition state for cyclisation and for the reverse ring opening reaction and this is responsible for the lower activation energy compared to that for the bimolecular reaction.

Thus, the activation energy of radical isomerisation is determined by, at least, the following four factors: first, the enthalpy; second, the strain energy in the ring in the transition state; third, the electronegativity difference between the atoms forming the reaction centre; and fourth, the involvement of the bending vibrations of bonds in the radical activation.

III.	Polymer networks as binders for solid propellants	1129
IV.	Mathematical modelling of decomposition of energetic materials	1133
V.	Stability prediction of energetic materials	1136
VI.	Conclusion	1137

Abstract. The review is concerned with analysis of the results obtained in the kinetic and mechanistic studies on decomposition of energetic materials (explosives, powders and solid propellants). It is shown that the state-of-the art in this field is inadequate to the potential of modern chemical kinetics and chemical physics. Unsolved problems are outlined and ways of their solution are proposed. The bibliography includes 235 references.

I. Introduction

The kinetic and mechanistic studies of decomposition of energetic materials (explosives, solid propellants and powders; hereafter, EMs) are first of all necessary for solving practical problems. Design of novel EMs, establishment of safe conditions for their synthesis, storage life calculations and control of the stability, combustion and detonation of EMs require knowledge of the mechanism of thermal decomposition and quantitative data for the description of the process over a wide temperature interval and for different states of aggregation. Studies on the kinetics and mechanism of thermal decomposition are necessary to solve not only technical problems but also some fundamental problems of chemical physics, *e.g.*, establishment of interrelations between the structure and reactivity of EMs, development of theoretical concepts of solid-phase reactions, understanding of the mechanism of combustion and detonation of EMs, *etc*.

Intensive research on the kinetics and mechanism of decomposition of explosives and powders began in the 1950s. Investigations on thermal decomposition of particular classes of explosives and model compounds, *viz*., aliphatic nitro compounds,[1] secondary nitramines,[2–4] nitro esters,[3,5] ammonium perchlorate,[6,7] *etc*., have been well documented. The results of thermal decomposition studies of the explosives mentioned above and some other compounds (organic difluoroamino compounds, furazans, furoxans, tetrazoles, ammonium nitrate and metal nitrates, hydrazinium and hydroxyammonium salts, metal perchlorates, nitric acid and perchloric acid) were summarised in a monograph.[8]

High demand for preparation of solid propellants and other polymeric materials including polymeric composite materials (PCMs) for civil purposes gave an impetus to studies on the physical chemistry of polymers. Considerable advances in this field were made by researchers belonging to the scientific schools headed by V A Kargin, N M Emanuel and N S Enikolopov; the most important results were reported earlier.[9–15]

In regard to design of solid propellants, studies on decomposition of explosives and powders were followed by investigations of destruction of polymer networks that are also widely used in national economy. The authors of monographs[9,15] also analysed the results of kinetic and mechanistic studies of molecular destruction of various classes of unfilled polymers (mostly linear carbochain polymers) exposed to heat treatment, various kinds of radiation, mechannical load and corrosive media and formulated the physical and chemical principles of stabilisaiton of these compounds. Studies of destruction processes showed that distinctions between linear polymers and polymer networks cause marked differences in character of molecular destruction of these compounds.[16–31]

In writing this review the author tried to present a critical analysis of the results obtained in the kinetic and mechanistic studies of decomposition of EMs in order to reveal unsolved problems and to compare the state-of-the-art in this field and the potential of modern chemical kinetics and chemical physics. Such a critical assessment for EMs has not been reported as yet, though it would be useful for outlining prospects for the development of this branch of chemical physics and for formulating and planning further research of decomposition of EMs.

II. Kinetics and mechanism of decomposition of explosives and oxidisers

1. Explosives and model compounds

A chemical reaction can be characterised both qualitatively by dividing into elementary stages (mechanism) and quantitatively by determining the corresponding rate constants; therefore, interrelations between the kinetics and mechanism are of great importance. At present, the mechanism of a complex chemical reaction is usually established using experimental data on the composition of the reaction system obtained from thermochemical measurements, while the rate constants for elementary stages of the process are determined from the results of measurements of changes in the concentrations of the starting compounds, inter-

mediates and end products in the course of reaction. Usually, the reaction kinetics and mechanisms are studied in relation to the reactant concentrations and state of aggregation, temperature and other external factors. A combination of this approach and modern physicochemical methods (EPR, IR and NMR spectroscopy, gas-phase electron diffraction, gas-phase neutron diffraction, positron annihilation, *etc.*) has been successfully employed in, *e.g.*, studies on thermal destruction and oxidation of linear carbochain polymers.[9,15]

To date, hundreds of explosives and model compounds belonging to various chemical classes have been studied. Usually, the mechanisms of their decomposition are multistage. A characteristic example is provided by the decomposition of 1,1,1-trinitroethane vapours, which involves the following elementary stages:[1,8]

$$CH_3C(NO_2)_3 \longrightarrow CH_3\dot{C}(NO_2)_2 + NO_2, \quad (1)$$

$$CH_3\dot{C}(NO_2)_2 \longrightarrow CH_3\dot{C}O + NO + NO_2, \quad (2)$$

$$CH_3\dot{C}(NO_2)_2 + NO_2 \longrightarrow CH_3\dot{C}O + NO + 2NO_2, \quad (3)$$

$$CH_3\dot{C}(NO_2)_2 + NO \longrightarrow CH_3C(NO)(NO_2)_2, \quad (4)$$

$$CH_3C(NO)(NO_2)_2 \longrightarrow CH_3CN + NO_2 + NO_3, \quad (5)$$

$$CH_3\dot{C}O \longrightarrow \dot{C}H_3 + CO, \quad (6)$$

$$CH_3\dot{C}O + NO_2 \longrightarrow CH_3CO\dot{O} + NO, \quad (7)$$

$$CH_3CO\dot{O} \longrightarrow \dot{C}H_3 + CO_2, \quad (8)$$

$$CH_3CO\dot{O} + RH \longrightarrow \mathbf{CH_3COOH} + \dot{R}, \quad (9)$$

$$CH_3CO\dot{O} + \dot{C}H_3 \longrightarrow \mathbf{CH_3COOCH_3}, \quad (10)$$

$$\dot{C}H_3 + NO_2 \longrightarrow \mathbf{CH_3NO_2}, \quad (11)$$

$$\dot{C}H_3 + NO_2 \longrightarrow CH_3\dot{O} + NO, \quad (12)$$

$$\dot{C}H_3 + NO \longrightarrow CH_3NO, \quad (13)$$

$$CH_3NO \longrightarrow \mathbf{HCN} + H_2O, \quad (14)$$

$$CH_3NO + 2NO \longrightarrow \dot{C}H_3 + N_2 + NO_3, \quad (15)$$

$$CH_3NO + NO_2 \longrightarrow \mathbf{CH_3NO_2} + NO, \quad (16)$$

$$CH_3\dot{O} + RH \longrightarrow \mathbf{CH_3OH} + \dot{R}, \quad (17)$$

$$CH_3\dot{O} + NO_2 \longrightarrow \mathbf{CH_3ONO_2}, \quad (18)$$

$$CH_3\dot{O} + NO_2 \longrightarrow CH_2O + HNO_2, \quad (19)$$

$$CH_3\dot{O} + NO \longrightarrow \mathbf{CH_3ONO}, \quad (20)$$

$$CH_3\dot{O} + NO \longrightarrow CH_2O + HNO, \quad (21)$$

$$2HNO \longrightarrow H_2O + N_2O, \quad (22)$$

$$CH_2O + NO_2 \longrightarrow H_2O + NO + CO_2. \quad (23)$$

However, the actual decomposition mechanism of 1,1,1-trinitroethane vapours is more complex than that described by Eqns (1)–(23). For instance, Eqn (23) is unbalanced and seemingly describes several stages simultaneously. A number of compounds treated as end reaction products in Eqns (1)–(23) (they are given in bold) differ only slightly in stability from the starting compound (similarly to NO_3 and HNO_2) and react with other components of the reaction system (*e.g.*, CH_3OH reacts with NO_3 and HNO_2). According to Refs 1 and 8, at least twenty-six reactions are needed to schematically describe the decomposition of CH_3NO_2 up to ignition, the primary stage being a homolysis of the C–N bond. However, there is no consensus of opinion concerning the decomposition mechanism of even such a simple compound as nitromethane.[32] It was established that at temperatures below 700 °C the initial stage of the reaction involves cleavage of the C–N bond accompanied by rearrangement of CH_3NO_2 to give methyl nitrite and by decomposition of the last-mentioned compound.[33–35]

Decomposition of explosives is usually a complex process that involves at least several tens of elementary stages. Therefore, determination of the true rate constants for all these stages is a complicated task. The compositions of explosives, oxidisers of solid propellants and powders also contain carbon, hydrogen, oxygen and nitrogen and chlorine or fluorine (more rarely; the oxidation states of nitrogen and chlorine can vary over a wide range). The decomposition mechanisms of these compounds are hardly simpler than the destruction and oxidation mechanisms of carbochain polymers. Because of this, studies on decomposition of explosives, oxidisers of solid propellants and powders should be *a priori* carried out using modern methods. Up to date, almost all studies on thermal decomposition of explosives (with few exceptions) are carried out by sufficiently sensitive and simple methods of formal kinetics.[8] Abroad, research in recent ten to fifteen years has been carried out using improved methods of isotope mixing, pulsed laser irradiation, mass spectrometry with modulation of gas beam, fast IR spectroscopy and other dynamical methods of detection of products, which allows the temporal evolution of chemical compounds in the gas phase to be followed.[4]

Studies on the kinetics of thermal decomposition of explosives and model compounds using gas manometric technique involve determination of the pressure of gaseous compounds in the course of a reaction performed in a closed volume. The degree of decomposition of explosives (η) is calculated as the ratio of the current pressure of gases $p(t)$ to the pressure corresponding to complete cessation of the increase in the pressure in the course of decomposition (p_∞),

$$\eta = \frac{p(t)}{p_\infty}.$$

The decomposition of 1,1,1-trinitroethane [see Eqns (1)–(23)] is characterised by a $\sim 35 : \sim 25 : \sim 40$ ratio (in per cent with respect to the total number of stages) between the reaction stages accompanied by an increase in, a decrease in and constancy of the number of moles of gases. This ratio remains nearly the same for other explosives.[1–8] Therefore, the major drawback of the manometric technique is that it introduces an element of uncertainty and provides incomplete kinetic data. This method cannot in principle provide information on the stages proceeding without changing the number of moles of gases. Generally, it can be used to obtain generalised information on the stages accompanied by changes in the number of moles of gases because usually the kinetic curves of decomposition of explosives are described by relatively simple reaction equations (first-order reaction or first-order autocatalysis equations) containing one or two empirical rate constants. Often, a certain equation can describe only a portion of rather than the whole kinetic curve. The temperature interval for kinetic studies of thermal decomposition of explosives is usually no wider than 40–50 °C. The complete gas evolution, ΔV_∞, is related to the pressure p_∞ and is expressed in units of reduced volume (volume of gaseous products evolved under normal conditions per 1 gramme of explosive under study). Usually, the parameter ΔV_∞ is only determined at elevated temperatures in spite of the fact that the ΔV_∞ value considerably increases with temperature. The dependence of ΔV_∞ on temperature and changes in the composition of gaseous products in the course of reaction introduce errors in the determination of the rate constants, activation energy, E_a, and pre-exponent, k_0, in the Arrhenius equation. By and large, the method is characterised by low accuracy so that determination of the activation energy with an error of at most 4 kJ mol^{-1} in a temperature interval of 40 °C requires a series of 10–12 runs.[36]

Solving some practical problems at least requires knowledge of the true rate constant for the initial stage of a complex reaction (k_{in}). Usually, it is believed that k_{in} can be determined using methods of formal kinetics provided that the rate of the overall reaction is limited by the first step[36] or that the k_{in} value much exceeds the rate constants for the subsequent stages. Thus, to determine k_{in}, one should know all the rate constants for the subsequent stages. If the manometric technique is employed, it is also necessary that the initial stage of the reaction be accompanied

by a change in the number of moles of gases and irreversible. Yet another necessary condition is the absence of competing concurrent reactions. However, these conditions are far from being met.[8, 37, 38] For instance, the primary stages of the decomposition of 1,5- and 2,5-disubstituted tetrazoles proceed without evolution of gas.[37, 38] Decomposition of some nitro derivatives of cyclic compounds containing strained bonds also involves no formation of gaseous products in the first step. A conventional assumption that the experimental rate constant (k_{exp}) equals the rate constant for the primary (limiting) step of a successive reaction is qualitative in character. To assess feasibility of this assumption, information on the kinetics and mechanisms of further steps is required, because the accuracy depends on the number of stages and on the corresponding rate constants. However, relations between k_{exp} and the rate constants for elementary stages were established only for relatively simple reactions.[37, 39] An example is provided by the decomposition of 1,5-disubstituted tetrazoles, which involves a reversible formation and decomposition of azidoazomethines:[37]

$$k_{exp} = k_1 k_2 (k_{-1} + k_2)^{-1},$$

where k_1, k_{-1} and k_2 are the rate constants for the direct and reverse formation of azidoazomethine from tetrazole and for the decomposition of azidoazomethine with evolution of N_2, respectively. The rate constants for a concurrent decomposition channel involving no intermediate formation can also contribute to k_{exp}.[37] The rate constant, k_{exp}, for the radical-chain decomposition of 2,4,6-trinitrotoluene can be expressed as the sum:[39]

$$k_{exp} = a_1 k_1 + a_2 k_1 k_2 k_5^{-1} + a_3 k_1 k_3 (k_2 k_5)^{-1},$$

where k_1, k_2, k_3 and k_5 are the rate constants for the chain initiation, propagation, transfer and termination steps, respectively, and a_1, a_2 and a_3 are constants.

The primary step of decomposition of explosives can be directly studied in the gas phase by suppressing secondary reactions. Detection of gaseous products of primary decomposition in the condensed phase is a much more complicated task compared to gas-phase studies, because diffusion even through thin layers of explosives takes a finite time, which is responsible for a finite degree of conversion with respect to secondary reactions.[4] It is believed [8] that the possibility of changing gas-phase reaction conditions over a wide range allows the first monomolecular stage of a complex decomposition reaction to be distinguished and its kinetic characteristics to be determined by the manometric technique. This approach was employed in studies of gas-phase decomposition of nitroaromatic compounds. However, the radical-chain mechanism of these reactions was not proved, the amounts of inhibitors (I_2, NO_2, NO) introduced were comparable with the amounts of compounds under study and the kinetic chain length was not determined. Clearly, the assumption mentioned above is inapplicable to those explosives for which the primary step of decomposition is due to competition between a number of reactions proceeding by a radical or molecular mechanism.

Often, the molecules of energetic compounds contain a number of (different-type) active reaction centres. These atomic groups interact with one another and compete in the initial stages of thermal decomposition reactions. In this connection the most reactive centre must be determined. The interaction of atomic groups causes the electron density to be redistributed between them as a result of the donor–acceptor interaction, which manifests itself in specific properties of complex energetic compounds (structural elasticity and conformational mobility of atomic groups), electron density redistribution in the transition state of a chemical reaction, *etc.*[40, 41] Extensive literature on manifestation of the mutual influence of atomic groups in various complex organic molecules is available. Combining a number of experimental methods (IR and Raman spectroscopy, X-ray diffraction and neutron diffraction, measurements of dipole moments, *etc.*) allows reliable information on the structural features of complex molecules and intramolecular dynamics to be obtained. Unfortunately, interrelations between different characteristics are still poorly studied. Because of this, many correlations can only be applied to structurally similar compounds.[42]

At present, a number of stubborn problems related to the presence of and donor-acceptor interaction between several reaction centres in the molecules of explosives can be solved only experimentally.[36, 43] For instance, the decomposition of compounds $RN(NO_2)CH_2C(NO_2)_2X$ begins with homolysis of the $C-NO_2$ bond ($X = NO_2$) and the $N-NO_2$ bond ($X = F$).[36] The inductive effect of substituents causes a decrease in the bond dissociation energies by 4–8 kJ mol^{-1}. Experiments showed that at least in those cases where the molecules of explosives contain unstable functional groups some rate constants for the subsequent stages of decomposition are comparable with k_{in} in magnitude. This can lead to the formation of rather stable products which can still undergo further decomposition.[43] This phenomenon called a stepwise (two-stage) decomposition has long been known;[44–46] recently, it again attracted considerable attention.[36, 43, 47]

A few studies concerned with comparison of the kinetic parameters of decomposition obtained by methods of formal kinetics and by direct analytical techniques have been reported. For instance, liquid chromatography and UV spectroscopic studies of decomposition of trinitrophenylmethylnitramine (**1**) showed [46] that the concentration of this compound decreases down to zero before the evolution of gaseous products ceases (Table 1). The composition of gaseous products changes in the course of the process, *viz.*, the NO_2 content passes through a maximum and decreases down to zero nearly simultaneously with full consumption of compound **1**, which decomposes into three condensed compounds, *N*-methyltrinitroaniline (**2**), trinitroanizole (**3**) and picric acid (**4**). It seems likely that the primary step of decomposition is characterised by three rate constants, the ratios between them being varied with temperature because the fraction of compound **2** in the condensed phase increases as temperature increases. Products **2** and **3** undergo a slow decomposition to give compound **4**, so the exact rate constants for the primary step of decomposition of compound **1** can be determined by studying not only the kinetics of comsumption of **1** but also the kinetics of accumulation of the condensed products **2**–**4**. Thus, the true rate constant, k_{in}, for the initial stage of decomposition of explosives cannot be determined using methods of formal kinetics.[46] Changes in the ratios between the rates of particular stages of 1,1,1-trinitroethane decomposition are also indicated by the dependence of the composition of decomposition products on the degree of decomposition η (Fig. 1).

Table 1. Composition of reaction system (in moles of product per mole of starting compound) for thermal decomposition of trinitrophenylmethylnitramine at 433 K.[46]

Usually, calorimetric or gravimetric methods of studies on the kinetics of complex chemical reactions are also inappropriate for the determination of true rate constants. Indeed, the decomposition of explosives involves both exothermic and endothermic stages that can strongly differ from one another in thermal effects. Generally, different elementary stages of a complex reaction are accompanied by different changes in the mass of the condensed phase. Despite the fact that methods of formal kinetics do not allow the true rate constants for thermal decomposition to be determined, they can be useful for comparing the stability of functional groups with strongly different reactivities.[48]

However, often the activation parameters (E_a and k_0) determined using methods of formal kinetics differ even for the same compound.[4,8,49] Scatter of data can be explained by inadequacy of procedures employed that makes it impossible to distinguish between the initial steps and catalytic stages and between different phase states of a compound under study and by the influence of side effects on the decomposition. Large scatter of data can be a reason for incorrect conclusions concerning the influence of the structure on the stability of explosives. For instance, the nitramine N–N bonds are only slightly influenced by the inductive effect of substituents; in this case, the geometry of the nitramine group is of great importance, namely, the N–N bond dissociation energy, D(N–N), is 169.5 kJ mol^{-1} for planar nitramine groups and 157.5 kJ mol^{-1} for pyramidal ones. Different degree of structural distortion of pyramidal nitramine group caused by steric strain results in different degree of conjugation between nitrogen atoms in this group, which in turn influences the N–N bond length and, hence, strength. Since it is this bond whose cleavage is the primary step of the decomposition of nitramines, a change in the N–N bond length affects the activation energy, E_a, for the initial stage of the reaction. It was found that the E_a value increases rather than decreases as the N–N bond elongates.[49,50] Thus, it does not always happen that the results obtained by methods of formal kinetics permit estimation of the thermal stability ratios of related compounds.

Usually, it is appropriate to generalise the results of kinetic studies of various classes of explosives and to reveal relations between the reactivity, structure and physical characteristics of explosives using the Hammett–Taft equations that relate different rate constants to one another.[51–53] Correlations between the activation energy, E_a, for decomposition of nitro compounds and their structural characteristics were established using home-made codes.[54,55] These correlations are to some extent useful for systematisation of experimental data on the rate constants; however, detailed analysis of the reactivity problem can be performed only for groups of related reactions. Moreover, interpretation of the physical meaning of the correlation coefficients is arbitrary. In addition, because we don't know with certainty whether the experimental rate constant for decomposition, k_{exp}, is the true rate constant for the primary elementary step, the scientific value of the relations between the structure of explosives and their reactivities characterised by methods of formal kinetics seems to be doubtful.

In solving a number of practically important problems one should know the rate constants for not only initial stages of decomposition. Determination of all the rate constants for multistage reactions is a complicated task. The situation is simplified if the case in point is a study on in-service explosives because decomposition of related explosives involves a number of identical stages. Knowledge of the rate constants for many elementary stages of decomposition of explosives is also necessary to solve other problems.[56,57] Obtaining detailed kinetic information requires the use of modern methods that allow one to monitor changes in the reactant concentrations directly in the reaction system, to establish position of the reaction centre, to obtain information on transient structures, *etc.*[58–62]

However, these techniques are scarcely employed in the decomposition studies of explosives. Because of this, neither the mechanisms of nor rate constants for elementary stages are known even for in-service explosives. In this case, the decomposition of cyclic nitramines near the melting temperature was studied in most detail.[63] Generally, thermal decomposition of 1,3,5-trinitro-1,3,5-triazacyclohexane in the liquid phase can follow four reaction paths in the primary stage. These are HNO_2 release (30%), N–N bond cleavage (10%), formation of a mononitroso compound in the reaction of the explosive with NO (35%) and, finally, autocatalysis of the decomposition of the explosive (or the mononitroso compound) with the end product containing amide groups (25%). A similar composition of products was observed for the decomposition of molten 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane, but the decomposition mechanism of this compound was not established because of the lack of quantitative data.[4] In addition to the reactions considered above there is a number of examples that suggest unreliability of at least particular stages of the decomposition mechanism of explosives and model compounds.[3,4] This can likely be explained by the fact that the mechanism of a complex decomposition reaction of an explosive is usually studied in isolation from the studies on the kinetics of elementary stages of the reaction. For instance, compounds **2** and **3** were not included[8,64] in the scheme of decomposition of compound **1**, though they were experimentally detected among the decomposition products.[46]

Reliability of a reaction mechanism can be established by performing a complex study on the kinetics of elementary stages and by comparing the experimental and calculated kinetic curves plotted for intermediates and end reaction products. In this case, computer simulation can offer considerable advantages (Fig. 2).

Data on the elementary stages and corresponding rate constants for decomposition of explosives in the condensed phase are scarce and less reliable compared to similar data for the gas phase.[3,4,8] For instance, no well-substantiated chemical schemes of liquid-phase decomposition of some classes of explosives are available and there is no consensus of opinion of the reasons for the fact that some nitro compounds decompose in the liquid phase faster than in the gas phase.[39,65] It should be kept in mind that passage from the gas phase to the liquid phase can be accompanied by a change in the reaction mechanism.[3,4] Here, even if the elementary reactions remain unchanged, physics of reactions in the condensed phase is significantly different from physics of gas-phase reactions. Namely, the ratios between the rates of competing processes, the limiting stages and the physical meaning of the kinetic constants are often changed. Studies on the decomposition kinetics in the condensed phase are complicated by the appearance of the gas phase. Differences between the mechanisms of decomposition in different phases and ignoring the distribution of

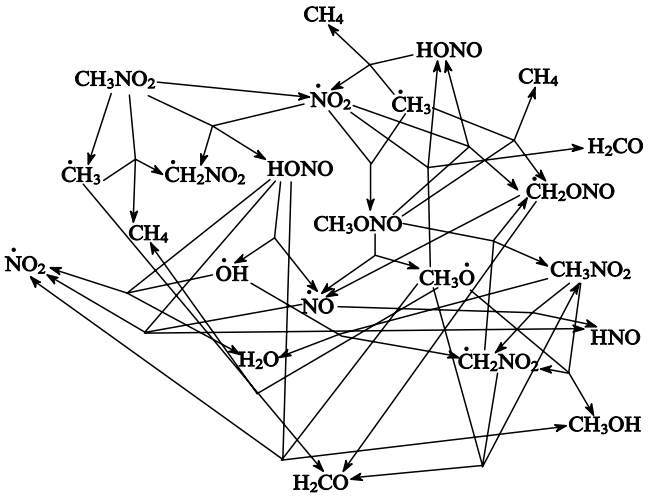

Figure 2. Nitromethane decomposition graph obtained by computer simulation.[32]

reaction products and sometimes reactants between phases cause the reaction kinetics to be dependent on the ratio of the mass, m, of the sample to the volume, V, of the reaction vessel. The influence of experimental conditions on the results of studies carried out using methods of formal kinetics has been the subject of a wide but unsuccessful speculation.

Many explosives are polar compounds. A reason for a possible change in the decomposition mechanism of explosives on going from the gas phase to the liquid phase is intermolecular interaction. Recently, supramolecular chemistry has been intensively developed. The subject of this branch of science is physical chemistry of systems that are (i) more complex than single molecules and (ii) connected to one another through intermolecular (non-covalent) interactions.[66] Supramolecular systems can be characterised by the spatial arrangement and architecture (supramolecular structure) of their components and by types of the intermolecular interactions responsible for interconnection of the components. Liquids whose molecules contain centres of intermolecular interactions can form hydrogen, dipole–dipole and other strong bonds with energies ranging between 10 and 60 kJ mol^{-1}. Association of liquid molecules is a consequence of the formation of labile intermolecular bonds, the equilibrium concentration of which increases as temperature decreases. Association of molecules can influence their reactivities [67] due to (i) a change in the structure of valence electron shells, (ii) such a mutual arrangement of the molecules, which favours (or precludes) a chemical reaction and (iii) a decrease in the molecular mobility. The higher the concentration of intermolecular bonds, the greater the decrease in the molecular mobility in the system on the time scale comparable with the lifetimes of the labile bonds.

Molten trinitrotoluene contains both free molecules and trimolecular associates.[68] Intramolecular oxidation of a CH_3 group proceeds *via* transformation of a transient cyclic complex, resulting in 4,6-dinitroanthranyl. In the associate a CH_3 group of one trinitrotoluene molecule is oxidised owing to NO_2 groups of other molecules in the associate, which are reduced to give azoxy and azo compounds. On going from vapour-phase decomposition to liquid-phase decomposition a number of high-melting thermally stable explosives (nitropyrroles, nitro derivatives of pyridine, pyrazole and triazole, furazans, benzofuroxans and pyridofuroxans) exhibit a dramatic decrease in E_a (by up to 125 kJ mol^{-1}) and in thermal stability (by 50–140 °C). This can be explained by the formation of associates, which allows the radical mechanism of decomposition to be replaced by the molecular mechanism.[69] IR spectroscopic studies revealed self-association in dimethylnitramine [70] and nitroglycerine.[71] At room temperature, nitroglycerine monomers, dimers, trimers and tetramers are in 1 : 1 : 4 : 5.5 ratio.

Despite the fact that association of molecules can affect their reactivities (and, hence, should be taken into account in the kinetic and mechanistic studies of decomposition of explosives), the role of molecular association in the course of decomposition of explosives is still to be clarified. Based on indirect data (feasibility of Trouton's rule), it was assumed[8] that association has no effect on thermal decomposition of explosives, because no association possibly takes place at corresponding elevated temperatures. However, this assumption does not simplify the situation because data obtained at elevated temperatures cannot be used for stability prediction of explosives under the working and storage conditions if uncorrected for molecular association. Self-association of the molecules of explosives both at low and at elevated temperatures has not been studied in detail as yet, though this phenomenon and formation of clusters of associates can be directly quantitatively studied by IR and NMR spectroscopy. If inhomogeneity of a system is due to the presence of associates, an exchange between the associated and non-associated states must affect the transverse magnetisation decay. NMR spectroscopy allows the rate of magnetisation exchange between nuclear spin subsystems with different mobilities and/or different resonance frequencies to be evaluated.[72] This technique can be used in the kinetic studies of complex chemical processes involving transitions from high-populated ground states to less populated but kinetically more active states.[73] To follow structural changes in molecular and supramolecular systems on the picosecond and shorter time scales, a number of multidimensional nonlinear coherent NMR, IR, Raman and EPR spectroscopic techniques were developed.[60–62, 74, 75]

According to modern concepts,[76] multistaginess of the mechanism of a chemical reaction, which involves reversible, concurrent and successive stages and catalysis by gaseous or condensed products, causes the appearance of spatial and temporal dissipative structures (DS). In the former case the distribution of reactants and, hence, the rates of elementary stages and of the overall process is nonuniform in space, the nonuniformity being microheterogeneous in character. In this case, traditional methods of kinetic studies providing volume-averaged values of measured parameters are inapplicable and local methods should be developed. A rather high spatial resolution (a few nanometres) can be obtained in spin diffusion studies.[72, 77]

In the case of temporal DS the concentration of intermediates and the corresponding rates of formation are characterised by oscillations, which can be either regular of chaotic in character. The discovery of oscillations of the heat release rate in studies [78] of thermal decomposition of moist nitrocellulose (Fig. 3) was followed by observations of this phenomenon in the course of decomposition of explosives in the presence of water and in the decomposition of aqueous HNO_3 solutions.[79, 80]

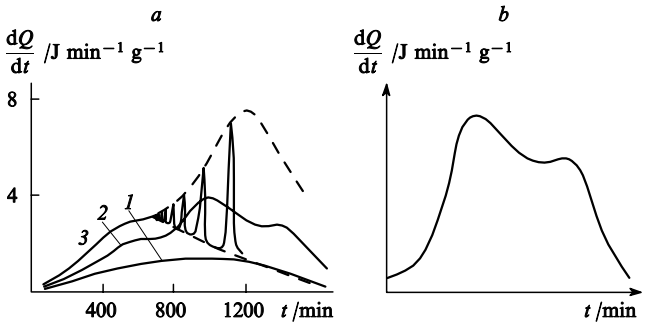

Figure 3. Heat release rate, dQ/dt, plotted *vs.* time for decomposition of nitrocellulose at 423 K (*a*) and total oscillation profile (*b*);[79] open system (*1*); $mV^{-1} = 0.5 \times 10^{-3}$ g cm^{-3}, humidity 1% (*2*); $mV^{-1} = 0.5 \times 10^{-3}$ g cm^{-3}, humidity 23% (*3*).

Detailed studies on the stability of a reaction system require methods that permit the determination of the concentrations of intermediates in the course of reaction and provide a reasonably high temporal (for monitoring) or spatial resolution. A calorimetric technique [78–80] allows the sum of the rates of the changes in the enthalpies due to the occurrence of chemical and physical processes rather than the reactant concentrations to be measured, so oscillations of the total rate of heat release (absorption) can be significantly different from oscillations of the concentrations of intermediates. When using manometric technique, the pressure of gaseous products of decomposition of explosives is usually measured manually in relatively long time intervals (as a rule, tens and hundreds of minutes). Therefore, small pressure oscillations remain undetected in the course of decomposition, though the method permits detection of dramatic changes in pressure in the case of low-frequency, large-amplitude oscillations.

Stability studies of reaction systems are of importance for both elucidation of reaction mechanism and determination of true rate constants for elementary stages of decomposition. If an attempt to describe a self-oscillation reaction using a kinetic model based on a hypothetical mechanism fails, either the reaction mechanism involves no appropriate stages or some constants for the stages under study are incorrect. In this connection theoretical methods [81–83] seems to be promising. For instance, oscillations in the course of decomposition of aqueous HNO_3 solutions cannot be explained in the framework of the mechanism proposed in Ref. 8. Reversibility of HNO_3 decomposition has not been experimentally proved as yet. Probably, the following reactions proceed at rather high temperatures

$$HNO_3 + NO \longrightarrow HNO + NO_3,$$

$$2\,HNO \longrightarrow H_2O + N_2O,$$

therefore, the overall decomposition of HNO_3 is irreversible. The rate constants calculated [8] from the data of calorimetric experiments do not correspond to elementary stages because the calculation procedure ignores the presence of HNO_3 monohydrates and trihydrates in aqueous HNO_3 solutions and the enthalpy changes upon the formation of hydrates.[84] The need of determination of the rate constants for elementary stages of decomposition of HNO_3 and nitrogen oxides is also due to the fact that these compounds are intermediates of decomposition of many explosives.

Experiments showed that solid-phase thermal decomposition of explosives is a spatially inhomogeneous process.[8,85] Corresponding studies of liquid-phase thermal decomposition have not been reported so far. NMR spectroscopy is an efficient method of DS studies in the condensed phase, which allows the appearance of microheterogeneous species to be detected and their size and concentration to be determined.[77,86,87]

Information on the mechanisms of solid-phase decomposition of explosives and oxidisers of solid propellants and corresponding rate constants for elementary stages is scarce. It was repeatedly pointed out that the determination of low degrees of conversion (a few tenths of a per cent) in studies of solid-phase decomposition is precluded by the fact that some products remain solid and cannot thus be determined gravimetrically and manometrically. For instance, it was established [88] that the pressure of gaseous decomposition products in microcavities of ammonium perchlorate crystals reaches 2–3 MPa. It is assumed [89] that accumulation of gaseous products in a crystal having cavities filled with gas leads to the formation of two zones differing in reactivity, namely, a near-surface zone (here, the compound is under tension) and an internal zone where the compound is under uniform compression.

It was proposed to characterise the effect of the lattice of molecular crystals on the reactivity of explosives by the ratio of the apparent rate constants for gas-phase [90] (or liquid-phase [91]) and solid-phase [$k_{exp,(s)}$] decomposition, or the so-called retardation effect of the crystal lattice.[90,91] This effect ignores both the concentration and type of defects. Studies [90,91] were carried out without evaluation of crystal defectivenesses; the $k_{exp,(s)}$ values obtained were low (up to nearly 10^{-12} s^{-1}) and not corrected for dissolution of gases in the explosives under consideration and for the absence of quasi-stationary concentrations of intermediates (this is of importance at low degrees of decomposition), so the parameters $k_{exp,(s)}$ seem to be determined with a low accuracy. In addition, no proofs were presented that the reaction mechanism remains unchanged on going from the gas-phase to the solid-phase reaction, though such a change is possible.[3,68,69] In particular, mention may be made that the energy barrier to interconversion of 1,3,5-trinitro-1,3,5-triazacyclohexane conformers in the gas phase is low (6 to 20 kJ mol^{-1}) and the results of kinetic measurements of gas-phase decomposition of this compound correspond to the dynamically averaged structure.[92] Based on comparison of similar experimental data with the conclusions drawn using an approximate theory that ignores many essential factors, it was concluded [8] that the decomposition of all plastic crystals and compounds with the melting temperatures below 100 °C proceeds as a homogeneous bulk reaction.[8] This conclusion seems to be not proved and the criteria for reaction homogeneity (plasticity of crystals and $T_m < 100$ °C) lack substantiation.

2. Decomposition of explosives under fast initiation

Recently, considerable progress has been made in studies of pre-explosion phenomena under fast initiation of explosives [93–97] due to the use of equipment with submicrosecond and nanosecond time resolutions. The results obtained using fast pulse radiolysis and flash photolysis techniques allowed conclusions about the mechanism of an elementary act of explosive decomposition of metal azides and a chain nature of the process to be drawn.[94] The decomposition of metal azides involves the following stages: hole localisation on a cationic vacany, reconstruction of a reactive site *via* a chemical reaction resulting in the formation of a quasi-local hole state in the valence band, hole delocalisation from the reconstructed reactive site, generation of charge carriers by impact ionisation by 'hot' holes and recovery of the local state in the forbidden band, which provides conditions for repetition of this sequence of stages. Propagation velocity measurements for explosive decomposition of a silver azide whisker were reported.[95] The results obtained ($\sim$1500 m s^{-1}) were associated with the propagation velocity of the diffusion front of holes generated in the course of decomposition.

Pre-explosive phenomena in secondary explosives studied taking 1,3,5-trinitro-1,3,5-triazacyclohexane as an example are characterised by a larger number of stages compared to similar phenomena in metal azides.[96] Initiation of an explosive involves a destruction stage, which is necessary for subsequent efficient supply of energy and is local in character. Energy dissipation occurs in the so-called hot spots. Dislocations or associations of dislocations play an important role in the hot spot nucleation stage. A key feature of this stage are electronic excitations. Local narrowing of the forbidden band near dislocations on compression of explosives dramatically increases the probability of electronic excitation and cleavage of the $N-NO_2$ bond.[4,93]

The decomposition kinetics of explosives under fast initiation was studied by direct detection of gaseous decomposition products on the millisecond time scale using time-resolved mass spectrometers with a performance of up to a hundred of scans per second.[96] More than ten neutral and ionised particles (NO_2, NO, HCN, CN, *etc.*) were detected near the surface of the sample 40 μs after application of a 20 ns pulse of an excimer (KrF) laser with a fluence of 5 J cm^{-2} to a 1,3,5-trinitro-1,3,5-triazacyclohexane single crystal.[96] Photon emission in the near UV and visible regions, delayed by 200 ns to 1.2 μs relative to the laser pulse was also detected. An increase in the laser fluence was accompanied by the appearance of long-lived excited neutral species identified as NO.

In discussing the results of studies on laser-initiated decomposition of explosives it was hypothesised that optical breakdown can compete with chemical decomposition of explosives. Mani-

festation of a particular mechanism is governed by the porosity, dispersion and reactivity of explosives. The problem of extraction of kinetic information from the data obtained under fast initiation of decomposition is still to be solved. In this connection time-resolved magnetic resonance spectroscopy based on detection of the nuclear polarisation of diamagnetic reaction products offers great prospects for research on the spin dynamics and chemical kinetics of short-lived radical species in photochemical reactions.[98]

3. Ammonium perchlorate

Among oxidisers of solid propellants, ammonium perchlorate (AP) has undoubtedly been studied in most detail. Nearly a thousand of publications concerned with the properties of this compound have been reported (see, *e.g.*, Ref. 7 and references cited therein). The results of studies carried out in the 1960s and 1970s changed our concepts of the mechanism of AP decomposition, though researchers still have contradictory opinions of some important issues.[88,99–101] In particular, it was established that the primary act of solid-phase decomposition of AP involves transfer of a proton followed by the formation of ammonia and perchloric acid.

The topographical features of thermal decomposition of AP were studied by optical microscopy.[88] Note that optical microscopy has a limited spatial resolution, which prevents structural elements smaller than 0.2 μm from being observed. The decomposition was accompanied by the appearance of spherical mobile 'nuclei' at depths greater than 5 μm (below dislocation outcrops), which grew until a size of nearly 1 μm. As time passed, the nuclei formed an ellipsoidal decomposition centre elongated along the ⟨010⟩ crystallographic direction. The number of decomposition centres in the crystal can vary over a wide range (from one or two to several tens), being (probably) dependent on uncontrollable factors influencing the sample in the course of preparation; the defectiveness of AP crystals on the nanolevel was not assessed prior to the experiments.

Based on the results of studies on the topographical features of AP decomposition,[88] a dislocation-chain mechanism (DCM) of reaction was proposed.[8] According to this mechanism, dislocations can be generated in the course of reaction under the action of mechanical stress produced on accumulation of gaseous decomposition products in the bulk of the crystal and the motion of dislocations favours the decomposition reaction owing to rearrangement of the AP lattice. This is a phenomenological concept, because experimental data[88] provide no unambiguous proof of the effect of dislocations on the decomposition of AP crystals. For instance, a substantial increase in the starting dislocation density (from 10^2 to 10^6 cm^{-2}) affects only slightly the induction period in the curves of relative mass change in the course of thermal destruction, which becomes nearly three times shorter; however, the change in the dislocation density has no effect on the acceleration stage (Fig. 4).

Preliminary deformation of a crystal to saturate it with dislocations is accompanied by a nearly 105 kJ mol^{-1} increase rather than a decrease in the activation energy for the formation of a decomposition centre. As a result, the induction period of the formation of decomposition centres increases by a factor of nearly 25 even at 230 °C. The increase in the activation energy can be explained by the fact that the formation of a potential nucleation centre in the crystal lattice involves polygonisation and interaction between the newly formed dislocations and is followed by vacancy diffusion from the deformation zone towards the dislocations.[88] Thus, contrary to the basic principles of the DCM concept, the newly formed dislocations are inactive. It is believed that ellipsoidal shape of reaction centres is an argument in favour of the mechanism proposed.[88] [This shape is associated with the fact that the motion and generation of dislocations along the ⟨010⟩ direction occur much easier than in perpendicular directions due to anisotropy of mechanical properties of AP crystals.] For instance,

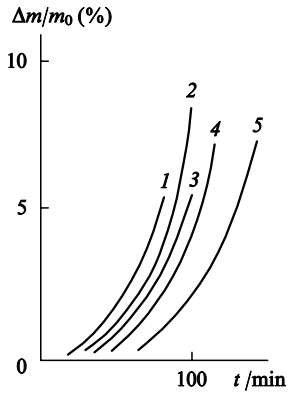

Figure 4. Relative mass change, $\Delta m/m_0$, of ammonium perchlorate crystal in the primary stage of decomposition at 503 K plotted *vs.* time at different dislocation densities.[88]
Initial dislocation density: 10^6 (*1*), 10^5 (*2*), 10^4 (*3*), 10^3 (*4*), 10^2 cm^{-2} (*5*).

it was found that the mechanical characteristics of an AP crystal under tensile stress along the ⟨100⟩ and ⟨001⟩ axes are better than the those of the same AP crystal under tensile stress along the ⟨010⟩ axis. However, it is known that the action of both external forces and the pressure of gases filling microcracks[102] cause the microcracks to grow along the direction perpendicular to the force direction. In other words, growth of the reaction centre along the ⟨010⟩ direction is caused by the forces acting along the ⟨100⟩ and ⟨001⟩ axes. We can agree with the authors of Ref. 100 who said that the available data are insufficient to establish the growth mechanism of an AP decomposition centre. It seems likely that the DCM concept underestimates the role of point defects and overestimates the role of dislocations in the AP decomposition. It should be noted that the starting AP crystals had pores up to 100 nm in diameter, but their prehistory was unknown and the pore size distribution and its evolution in the course of AP decomposition were not characterised.

To gain a better insight into the role of defects in the decomposition of AP and other solid explosives and oxidisers, the formation of vacancy pores of size 1–10 nm and the evolution of the pore size distribution should be studied using, *e.g.*, ^{1}H, ^{15}N or ^{129}Xe NMR spectroscopy (see Refs 103–105). For instance, ^{14}N NMR spectroscopy can be lifted to a level of high usefulness in chemistry and materials science.[105]

The results of studies on AP decomposition indicate an important role played by the kinetic and diffusion factors, exchange with the environment and peculiarities of the crystal structure of AP in localisation of thermal decomposition reaction. A study on topokinetic regularities of low-temperature decomposition of AP crystals as functions of the concentration of additives and temperature suggested that the nucleation rate of decomposition centres is governed by the content of ClO^{3-} impurity ions and by the concentration of free protons, while the growth rate of decomposition centres is nearly independent of the presence of additives.[100] A mechanism of the formation and growth of the AP decomposition centres was proposed.[99] It is assumed that the appearance of spatial and spatial-temporal DS is promoted by the phenomena caused by the pressure of gaseous reaction products. The equation for the reaction front velocity (μm min^{-1}) obtained using a simplest model with allowance for diffusion of perchloric acid has the form

$$u \approx 10^{12.4}\exp\left(-\frac{128\,000}{RT}\right).$$

The results of calculations were found to be similar to the observed 'slow' rates.

4. Hezanitrohexaazaisowurtzitane

Recently, hezanitrohexaazaisowurtzitane (HNIW) first obtained in the USA in 1987 has been the subject of intensive research. This energetic compound belongs to cage-type polynitramines and is of practical interest as a high explosive and a component of solid propellants.[106] The cage structure of HNIW is responsible for high density and enthalpy of formation (ΔH_f = 416 kJ mol^{-1}) and for structural strain. X-Ray diffraction, spectroscopic and quantum-chemical studies revealed [107] violation of the close packing principle in the nitramine crystals. A feature of the polynitramine molecules is the possibility of orbital interaction between the lone electron pairs of amine nitrogens. The variety of interactions of the lone electron pairs in the molecules of conformers is in excellent agreement with the diversity of polymorphs of cyclic and cage-type nitramines. Crystals of the ε-phase are characterised by the highest density (d = 2.062 g cm^{-3}).

The mechanism of thermal decomposition of HNIW has not been established as yet. Data on the kinetics and composition of gaseous decomposition products are contradictory.[108–112] The kinetic parameters of HNIW decomposition exhibit a large scatter (Fig. 5). Solid-phase thermal decomposition of α-, β-, γ- and ε-polymorphs and liquid-phase thermal decomposition of ε-modification were studied in detail by thermogravimetry, manometric technique, IR spectroscopy and optical microscopy.[108, 109] It was shown that decomposition of crystalline HNIW is a pure solid-phase process characterised by self-acceleration due to nucleation and growth of reaction centres. Decomposition follows the phase transitions α → γ, β → γ and ε → γ. The ε → γ transition occurs in the temperature range 180–220 °C and is endothermic in character.[106] The thermal stability of HNIW depends on the initial polymorph state and changes as follows: α < β < γ < ε. The kinetic parameters of decomposition of particular samples are governed by the size, size distribution and crystal morphology. The molecule of a solid product of ε-HNIW decomposition at temperatures below 210 °C contains one of the six nitro groups. The solid product is comprised of transparent microporous particles whose sizes correspond to the sizes of the initial crystals. Heating of the solid product to 600 °C results in a solid residue with a network structure composed mainly of carbon and nitrogen atoms.

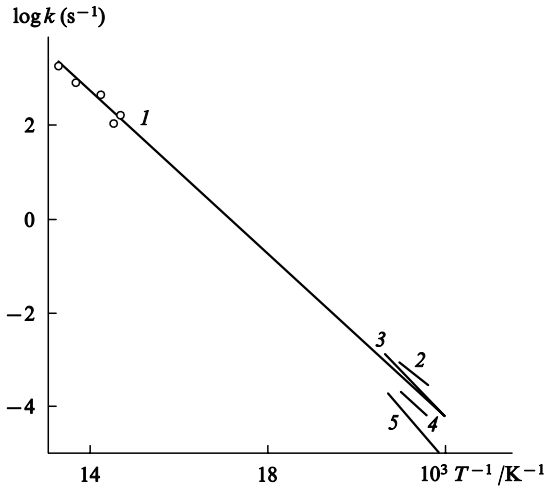

Figure 5. Temperature dependences of the rate constants for decomposition of HNIW.
Rate constants for the leading stage of combustion (open circles) calculated using the Zel'dovich combustion model for a first-order reaction [106] (*1*); rate constants determined from changes in the νNO_2 vibrational intensity in the IR spectrum [110] (*2*) and rate constants for mass change [108, 110] (*3*)–(*5*).

5. Nitrocellulose

Nitrocellulose has a rather complex structure. This is a polymer characterised by some distribution trinitrate, dinitrate and mononitrate units along the polymer chain. Nitro groups can be bonded to both primary and secondary carbon atoms of the monomer unit. A method of assessing structural inhomogeneities in nitrocellulose was developed.[113]

Decomposition of nitrocellulose involves a number of concerted and successive reactions, namely, initial cleavage of the O–NO$_2$ bond, redox interaction between nitrogen oxide (nitrogen dioxide) and macroradicals that are formed in the decomposition of nitrocellulose, hydrolysis of nitrate and glycoside groups, *etc*. However, the mechanism of decomposition has not been completely established as yet. In the early studies carried out in the 1950s and 1960s, the decomposition of nitrocellulose was studied by methods of formal kinetics, *viz*., using the complete gas evolution, loss of the sample mass and formation of the so-called 'condensing' and 'hardly condensing' gases.[114–117] The composition of gaseous products in the initial stage of nitrocellulose decomposition was assessed indirectly;[116, 117] it is inconsistent with the results of more recent mass spectrometric studies.[118] It should be noted that the authors of Refs 116 and 117 pointed that their conclusions about the mechanism of nitrocellulose decomposition are tentative and that the numerical data (E_a and k_0 values) cannot be used in calculating the kinetic parameters of particular stages. The results of IR spectroscopic study of nitrocellulose decomposition are available;[119] however, the reactivity ratios of the primary and secondary ONO$_2$ groups in the dinitrate and trinitrate units was not reported.

The mechanism of decomposition was detailed and the rate constant for the primary step determined in Refs 120–122. Thermal decomposition of nitrocellulose with a nitration degree of 2.7 was studied [120] by UV and IR spectroscopy, gravimetric and photometric methods, gas chromatography and gel permeation chromatography (GPC). It was shown that the reaction begins with cleavage of the O–NO$_2$ bond at a secondary carbon atom in the trinitrate unit. The temperature dependence of the rate constant for loss of secondary nitrate groups in the trinitrate unit (according to IR spectroscopy data) in a system with running medium and the temperature dependence of the rate constant for NO and NO$_2$ formation (according to UV spectroscopy data) in a closed system (at $mV^{-1} \leqslant 5 \times 10^{-4}$ g cm^{-3}) are described by an Arrhenius equation with the same parameters (E_a = 149 kJ mol^{-1} and k_0 = 13.9 s^{-1}). The kinetics and mechanism of subsequent transformations of nitrocellulose are to a great extent determined by conditions for removal of gaseous products. An EPR study of thermal decomposition of nitrocellulose in inert runnimg medium [121] revealed accumulation of free iminoxyl radicals in the primary step. This indicates that the decomposition mechanism involves a stage of formation of a nitroso compound, which subsequently isomerises into an oxime, which then readily decomposes to give an iminoxyl radical.

The average number of breaks of the nitrocellulose polymer chain in the course of decomposition was determined [123] assuming a constant molecular mass. Changes in the molecular mass distribution (MMD) in the course of nitrocellulose decomposition were determined more recently.[120, 122] The conditions for removal of gaseous products from the reaction volume affect the character of the changes in the MMD in the course of thermal decomposition of nitrocellulose. In the system with running medium the MMD becomes narrower due to breakdown of chains with large molecular masses. Terminal macroradicals thus produced undergo partial recombination within the same cage. However, by and large the molecular mass of nitrocellulose decreases due to evolution of gaseous products. In a closed system, the MMD is broadened (Fig. 6) because of production of middle-type macroradicals that recombine to give macromolecules with the molecular masses exceeding that of the starting nitrocellulose.

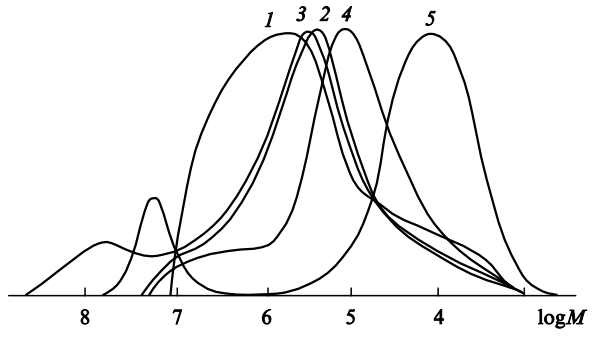

Figure 6. Changes in the MMD of macromolecules in the course of thermal decomposition of nitrocellulose in closed system at $mV^{-1} = 0.02$ g cm^{-3} and $T = 373$ K.[122]
Duration of decomposition /h: 0 (*1*), 48 (*2*), 104 (*3*), 612 (*4*), 1096 (*5*); *M* is the molecular mass of nitrocellulose.

III. Polymer networks as binders for solid propellants

A solid propellant can be treated as a composite material composed of a polymeric binder (10 mass % – 20 mass %), which is usually based on a sparse polymer network containing distributed oxidiser and metal particles of preset dispersion. The compositions of solid propellants depend on the requirements imposed on the specific momentum, stress – strain behaviour, burning rate and the dependence on pressure. A promising way is to prepare binders possessing improved adhesive properties (see Ref. 124).†

1. Structure of polymer networks

A polymer network can be considered as a system comprised of two subsystems, *i.e.*, molecules and the free volume. Each subsystem has a complex multilevel structure.[14] The chemical level of the structure of polymer networks is governed by the structure of the monomer unit. Abstracting of the chemical composition of polymer networks, the topological level of their structure characterises the connectivity of the network structure. The topological structure of a polymer network is characterised by the MMDs of its elements, *viz.*, chain fragments between cross-link points, dangled chains attached to the network through one end, loops formed through end attachment to the initial point of the same chain and free chains. In addition to stable chemical branchings, polymer networks contain labile physical nodes ('entanglements'). The nature of the nodes of physical network and its role in the macromolecular dynamics has been comprehensively reviewed.[126, 127]

The properties of a material are strongly affected by self-organisation on the supramolecular level.[128] This level of structural organisation of polymer networks is characterised by the presence of both highly cross-linked and sparser domains of size of a few nanometres and more. The formation of microheterogeneous domains in polymer networks can be due to various reasons including diffusion and kinetic factors.

The most important operating characteristics of polymer networks including stability and stress – strain characteristics depend not only on the chemical, topological and supramolecular levels of the molecular subsystem but also on the structure of the free volume subsystem. The pore distribution in polymer networks and in other materials with pore sizes from a few tenths of nanometre to a few nanometres can be characterised using positron annihilation method or NMR spectroscopy with hyperpolarised ^{129}Xe or water as probes.[129 – 131]

Some characteristics of the topological structure, *viz.*, the density of cross-links and the average molecular mass of the chain fragments between cross-link points are related to the elastic modulus of a network polymer by a known relation. Direct methods of studies of the supramolecular design of polymers including polymer networks are unavailable as yet. Attempts to construct supramolecular models of linear polymers were reported.[9] Inequality of traditional concepts of the non-crystalline phase of linear polymers as a high-molecular-mass homogeneous liquid disturbed by fluctuations to the task of relevant description of the phase has been exemplified[132] and a framework-micelle model of structural organisation of this phase proposed. QSPR studies of glassy polymers are carried out using principles of synergetics of nonequilibrium systems and fractal analysis.[133] The model of the polymer structure includes a sparse matrix with cross-links represented by entanglements comprised of close-packed segments (the entanglements form a cluster network).

The effect of fillers on polymers manifests itself in variations of the physicomechanical, structural, thermodynamic and chemical properties of binders.[13, 134, 135] Adsorption bonds are formed between the polymeric binder and disperse filler. These bonds are intermediate between the intermolecular and chemical bonds in strength. Filler particles act as polyfuntional nodes; the amount of the 'bound' binder can exceed 40% of the total mass of the binder. A decrease in the molecular mobility of elastomers upon introduction of fillers can be detected by NMR spectroscopy.[135, 136] An NMR-based method of determination of the network structure of filled elastomers135 allows the total concentrations of physical nodes and chemical cross-link points, the fraction of polymer in nearly immobile adsorbed layer at the filler – polymer interface and the fraction of topological nodes that are formed by the polymer chains present between filler particles (Fig. 7) to be determined.

The molecular mass distribution is an important structural characteristic of polymer networks. Methods of determination of the MMDs of linear polymers are based on analysis of the

† In contrast to solid propellants, binders for PCMs are usually linear polymers containing 30 mass % – 40 mass % of reinforcing fibres (or mineral filler), antipyrene and other additives.[13] The main operating characteristics of PCMs are improved strength, rigidity, impact strength and incombustibilty. The properties of PCMs depend on particular field of applications.[12, 13] For instance, aviation PCMs must have a heat resistance of 300 – 400 °C and be stable at 500 – 520 °C.[125] For fundamentals of preparation of PCMs with preset properties, see a monograph.[13]

properties of dilute polymer solutions. The MMDs of many insoluble polymers cannot be evaluated using these techniques. Methods based on the degradation of those polymers [137] appeared to be impracticable because they are time-consuming and destructive in character. In this connection recently attempts have been undertaken at using the relaxation properties of polymers for MMD evaluation because the relaxation time spectrum is related to MMD.[16–19, 138–141]

Investigations of the kinetics and mechanism of decomposition of polymer networks and solid propellants based on them are necessary to solve two problems, namely, service life assessment and control of items made of these materials and mathematical modelling of corresponding combustion processes. The service life of the items mentioned above usually depends on the stress–strain properties of polymer networks and solid propellants. Its determination requires knowledge of kinetic data and information on the mechanism responsible for changes in the topological and supramolecular structures of polymer networks and on adhesive properties of solid propellants. Mathematical modelling of combustion of solid propellants requires information on the kinetics and mechanism of thermal decomposition of these compounds.

2. Molecular degradation of polymer networks

Polymer degradation is governed by the chemical and physical transformations of these materials under action of temperature, mechanical stress, aggressive media (water, acids, alkali, oxygen, ozone, *etc.*), various kinds of radiation (photoemission, radioactivity, laser radiation, cosmic rays).[9, 142] In practice, polymeric materials are subject to a number of factors simultaneously. Complexity of studies on the chemical degradation processes is due to diversity of the mechanisms and reactive particles (radicals, ions, unstable molecules) responsible for the development of these processes. The key role in the degradation of linear polymers is played by the radical and radical-chain mechanisms. Ionic mechanisms are of importance for the degradation in acid-base media and in the presence of strong oxidisers; molecular mechanisms are less-common.[9]

Thermal degradation mechanism of polymer networks is to a great extent similar to the degradation mechanism of corresponding linear polymers. For instance, a radical-chain degradation mechanism of polymer networks and the degradation mechanism of linear polymers involve the same elementary stages, *viz.*, chain initiation, propagation, transfer and termination. The molecular mechanism of degradation of polymer networks usually involves a relatively small number of elementary stages. Therefore, studies on the degradation kinetics and the determination of true rate constants for the elementary stages can be performed using methods of formal kinetics. Mathematical formalism developed to analyse the kinetic curves in the case of radical-chain mechanism of degradation of linear polymers [143] can with some variations be applied to polymer networks. When analysing kinetic data for molecular mechanism of degradation, one should take into account that every act of evolution of volatile products (change in the mass of the sample) requires two acts of degradation of chain fragments between cross-link points.

Usually, thermal degradation of polymer networks is studied by simpler methods, namely, thermogravimetry and differential thermal analysis in the dynamic heating regime [144, 145] rather than methods of formal kinetics. Often, assuming a simple one-step degradation mechanism, the thermal stability is characterised by the empirical parameters determined from the experimental data, *viz.*, the degradation onset temperature, maximum mass loss rate temperature and integrated decomposition temperature rather than the activation energy E_a.

The results obtained in studies of the temporal dependence of the charactetistics of the topological structure (*e.g.*, density of cross-links, MMD of chain fragments between cross-link points) can be used for the determination of true rate constants for degradation. In this case, account must be taken of the fact that the chain scission and cross-linking can occur simultaneously.

Mechanical stress is an important factor affecting the rates of chemical reactions of polymers.[15, 142] Often, it is responsible for changes in the reactivities of strained macromolecules, that is, stress influences the kinetics of those reactions that involve structural rearrangements in the reaction centre.[15] If these changes are similar in character to spontaneous structural changes occurring in the course of reaction, the process is accelerated. Otherwise, retardation occurs. Tensile stress causes activation of C–H bonds in the reactions accompanied by proton abstraction.[15] If the hybridisation of a main-chain atom changes, the rate constant, k_σ, for an elementary stage under stress and the rate constant, k, for the same elementary stage in the absence of stress are related as follows

$$k_\sigma = k \exp[\gamma\sigma(RT)^{-1}],$$

where the coefficient γ, or the reaction sensitivity to stress, can be considered as the product of two independent coefficients, $\gamma = \gamma_a\beta$. The coefficient γ_a depends on the energy capacity of the strained structural fragment and on the extent of structural changes in this fragment in the transition state; the sign of the coefficient γ_a depends on the type of stress (tensile or compressive) and on the type of the hybridisation change ($sp^3 \rightarrow sp^2$ or $sp^2 \rightarrow sp^3$). The coefficient β depends on the nonuniformity of stress distribution over the system of bonds. Under tensile stress, chemical reactions accompanied by the $sp^2 \rightarrow sp^3$ rehybridisation of two neighbouring carbon atoms (*e.g.*, addition to the main-chain double bond) are characterised by acceleration of the addition of all reactants to the *trans*-C=C-bond; in the case of addition to the *cis*-isomer, this is only valid for those reagents that have the reaction coordinate $\delta^{\neq} > 0.68$. At $\delta^{\neq} < 0.68$, tensile stress has a retardation effect on the reaction. Compressive stress causes the opposite effect.

The reaction rate sensitivity to mechanical stress can be used to study the reaction mechanism and to determine the constants for elementary reactions.[142] The influence of stress on the reaction kinetics is detected not only in the case of external mechanical stress but also in the presence of internal structural strain in, *e.g.*, polymeric composites, swelled polymer networks, *etc.*

3. Kinetic regularities of decomposition of cross-linked polymers

Kinetic regularities of decomposition of cross-linked polymers have been studied in most detail taking polyurethanes (PUs) as examples.[16–24, 26, 27] Sparse PUs have, on the one hand, a number of valuable service properties typical of elastomers and, on the other hand, a significant drawback, because they are readily degradable at elevated temperatures.

Thermal decomposition of linear PU and model low-molecular-mass urethanes has been the subject of extensive literature. In studies of the degradation of linear PUs the emphasis was placed on analysis of reaction products. Only a few publications concern the degradation kinetics. It was established that the most unstable structural unit of linear PU is the urethane group, which can dissociate into initial alcohol and isocyanate or decompose *via* formation and subsequent decomposition of an intermediate cyclic complex following a molecular or quasi-ionic mechanism.[146–148] Degradation of linear PUs and low-molecular-mass urethanes results in the same products,[149–151] but the data on the degradation kinetics of linear PU are nonsystematic, namely, the Arrhenius equation parameters were usually determined from the rate constants measured at three or four temperatures while the effect of the chemical structure on the thermal stability was characterised using the results obtained only at one temperature.

Calorimetric and gravimetric studies of the degradation kinetics of sparse PUs showed that the parameters, E_a and k_0, of the process depend on the sample synthesis conditions (temperature, presence of catalyst, solvent).[20, 21, 26, 27, 152] This can be explained as follows. Polyurethanes are synthetised in the presence of a catalyst at relatively low temperatures. The process is accompanied by association of reactants, which results in the

formation of nonequilibrium network structures containing systems of strained bonds. Studies on the evolution of structural characteristics of PU networks in the course of PU degradation became possible owing to the use of modern methods of determination of the sol fraction MMD,[21,27] the MMD of chain fragments between cross-link points [16–20] and the microheterogeneity of the sparse polymer networks.[22]

The MMD evolution of the sol fraction in the course of thermal degradation of sparse PU networks was studied by GPC.[21,27] The sol fraction has a trimodal molecular mass distribution with two peaks at $M \approx 300$ and 600 corresponding to the low-molecular-mass fraction and a peak with a maximum at $M \approx 10^4$ corresponding to the 'polymeric' fraction (Fig. 8). It was shown that the urethane groups near cross-link points are the most probable chain scission sites and that the MMD of the 'polymeric peak' of the sol fraction characterises the MMD of the chain fragments between cross-link points in the PU network. The results of computer simulation [27,153] showed that the reactivity of the most stable (urethane) functional group depends on its position in the polymer chain. The formation of a cross-link point of a network based on 1,1,1-trimethylolpropane causes a strong deformation of the neighbouring urethane groups. Steric hindrances to arrangement of three bulky diisocyanate units in the cross-link point lead to the formation of urethane groups with less stable strained bonds compared to the urethane groups in the linear chain fragments. Thus, the primary step of degradation of cross-linked PUs mainly involves breakdown of the urethane groups near the cross-link points.

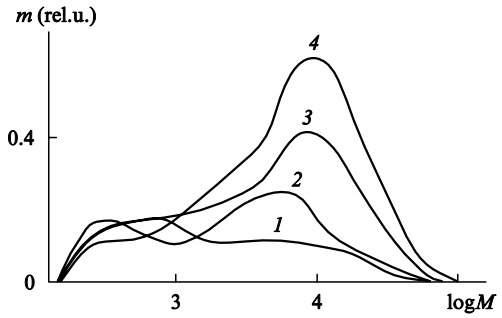

Figure 8. Molecular mass distribution of sol fraction for *in vacuo* thermal destruction of cross-linked polyurethane at 393 K.[21,27]
The amount of the sol fraction in the initial sample was 2.89 mass % and the initial density of cross-links was 2.13×10^4 cm^{-3}. Duration of destruction, days: 0 (*1*), 8 (*2*), 15 (*3*), 35 (*4*); *M* is the molecular mass of the sol fraction.

A theory was developed, which relates the molecular mobility of the chain fragments between cross-link points in sparse polymer networks to the MMD of these chains.[18,24] The MMD evolution of the chain fragments between cross-link points of cross-linked PUs in the course of thermal degradation of these compounds was studied by NMR spectroscopy.[17–20,24] The results obtained are illustrated in Fig. 9. As can be seen, in the initial stage of the process the unimodal MMD is transformed into a broader bimodal MMD and not only longer but also short chain fragments between cross-link points appear; *i.e.*, breakdown of cross-links and cross-linking occur simultaneously. The longest chain fragments between cross-link points are also the most unstable, which is seemingly due to microheterogeneous character of the supramolecular structure of sparse PU networks.[22]

Studies on the MMD evolution of the chain fragments between cross-link points of sparse PU networks under permanent tensile stress or strain showed [17,19] that in this case the network structure changes long before the macroscopic degradation of the sample, the structural changes being similar to those observed in the course of thermal degradation (Fig. 10). Distinctions between

the character of changes in the MMDs of the chain fragments connecting cross-link points under permanent stress and strain were revealed. The results obtained allowed the degradation mechanism of strained elastomers to be clarified because opposite views of this mechanism were reported.[9,142,154,155]

This nondestructive method of studying the MMD evolution of the chain fragments between cross-link points in the course of thermal degradation of elastomers under stress and strain is of importance for estimation of accumulated defects. However, the technique has not been employed in studies of solid propellants as yet.

The kinetic regularities of the degradation of three highly cross-linked polymers, *viz.*, dimethacrylate triethylene glycol (DMATG), cross-linked and 'hyper-cross-linked' polystyrene (HPS) and poly(epoxyamine) (PEA) have been studied in sufficient detail.[23–26,29,30]

DMATG has a microheterogeneous supramolecular structure formed by highly cross-linked 'granules' distributed in a highly defect matrix. Degradation of DMATG was studies by NMR and gravimetry.[23–26] The kinetic regularities of the degradation depend on the initial degree of conversion (Γ_0) of the sample and dramatically change at $\Gamma_0 = \Gamma_m$ (Γ_m is the degree of conversion at which highly cross-linked granules contact one another and the polymer becomes monolithic). Degradation of the samples with $\Gamma_0 < \Gamma_m$ is characterised by cleavage of the weak, strained matrix bonds and a decrease in the total mass of granules; the density of cross-links remains unchanged. The process proceeds by a radical-chain mechanism and involves partial formation of new cross-links. At $\Gamma_0 > \Gamma_m$, degradation follows the molecular mechanism *via* decomposition of the ester groups of DMATG and formation of polymethacrylic anhydride.

The character of PEA and HPS degradation depends on the density of cross-links.[29,30] The process proceeds by the mechanism of radical-chain depolymerisation at relatively low values of this parameter and by the molecular mechanism in the case of more cross-linked samples. The degradation of the HPS samples with the density of cross-links greater than 40% obeys a more complex pattern and proceeds much lower than in the case of the samples characterised by lower densities of cross-links (Fig. 11). The presence of strained network fragments in HPS affects the shape of the initial portions of the dependences of the specific degradation rate on the degree of degradation. An increase in the thermal stability of the networks with higher density of cross-links can be explained by a decrease in the chain initiation probability and by an increase in the kinetic chain termination probability for radical-chain depolymerisation of the short, and therefore, nearly immobile chain fragments connecting cross-link points. The fact that fullerenes inhibit the degradation of these samples confirms the radical-chain degradation mechanism of the cross-linked polymer networks with a density of cross-links less than 40%.

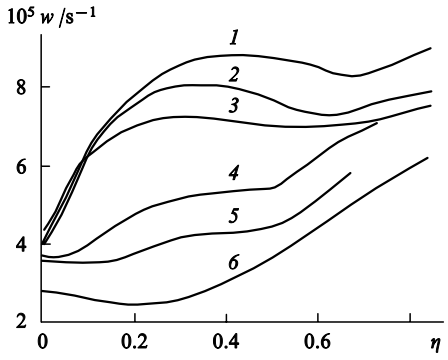

Figure 11. Specific rate of change in mass (w) plotted *vs.* degree of decomposition η for *in vacuo* destruction of cross-linked polystyrene samples at 613 K.[30]
Initial density of cross-links (%): 11 (*1*), 17 (*2*), 25 (*3*), 43 (*4*), 66 (*5*), 100 (*6*).

The formation of polymer networks is usually accompanied by noticeable reaction shrinkage. Sometimes this results in the polymer networks with a large nonequilibrium excess free volume and sometimes causes defect formation (micropores appear and cracking occurs). The kinetic regularities of the PEA degradation are affected by the value of the excess free volume and, in partiular, by the excess free volume distributions over the *n*-defects, clusters and microcavities and across the width of the sample.[31,156]

Degradation of polymeric composite materials based on linear polymers is usually studied by thermogravimetry and differential thermal analysis in the dynamic heating regime. Statistical treatment of experimental data is often carried out assuming a simple one-step kinetics. Because of this, the results obtained and conclusions drawn are, as a rule, qualitative in character. Clearly, the reasons for contradictory results of many studies on thermal and oxidative degradation of PCMs are differences between the experimental methods and procedures employed.[157]

There are a few studies on the degradation of filled polymers based on polymer networks. The decomposition kinetics of these compounds is significantly different from the decomposition kinetics of binders and depends on the type of the filler used (Fig. 12).[28,31] An increase in the decomposition rate in the presence of chemically inert fillers cannot be explained by the chemical interaction between the binder and filler. An increase in the binder decomposition rate can be attributed to the action of internal stress that depends on the type of filler, adhesion strength of the filler and binder, and the difference between the thermal expansion coefficients of the filler and binder. Residual shrinkage stress should also be taken into account because the formation of polymer networks is usually accompanied by noticeable shrinkage. A procedure based on pulsed NQR technique was developed for the determination of internal stress in polymers and polymeric composites.[158]

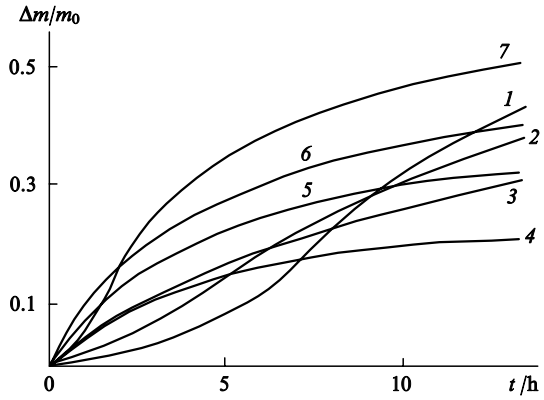

Figure 12. Relative mass change, $\Delta m/m_0$, of PEA samples for *in vacuo* destruction at 543 K.[28,31]
Unfilled samples (*1–3*), filled samples (*4–7*); particles of size 1–2 mm (*1*), film 0.2 mm thick (*2*), particles of size 0.09–0.16 mm (*3*); filler: boron fibre (*4*), organic fibre (*5*), glass fibre (*6*), carbon fibre (*7*).

Highly cross-linked polymers can be considered as best model systems suitable for establishment of the effect of microheterogeneity, restricted molecular mobility of binder with an increase in the density of cross-links, the excess free volume and its distribution over the structural elements and the stressed state of the binder (due to the difference between the thermal expansion coefficients of the binder and filler) on the thermal stability of polymer networks.

4. Effect of decomposition products of solid propellant oxidisers on the degradation of polymeric binder

Often, oxidisers or some other components of solid propellants decompose faster than binders. The decomposition products of a given component can interact with the binder. The kinetics and mechanism of this interaction depend on the nature of the oxidiser decomposition products and on the type of the polymeric binder. Oxidative degradation of linear polymers has been studied in most detail.[9,15] A monograph [15] is concerned with peculiarities of this process, supramolecular and conformational effects in the oxidation kinetics of oriented polyolefins, changes in the structure and properties of polymers under stress and analysis of the degradation regularities of polymers exposed to aggressive media under mechanical stress. Among numerous studies on the ozone ageing of strained cross-linked rubbers based on natural rubber, polyisoprene, polybutadiene, butadiene–styrene or butadiene–acrylonitrile copolymers, *etc.*, most are applied in character and

mainly concern cracking assessment and the time to rupture measurements (see monograph [15] and references cited therein). The critical strain observed during the ozone degradation of elastomers (maximum crack growth rate and minimum sample durability under nearly 20% tensile strain) can be explained [15] by a change in the reactivity of the strained C=C bond.

The kinetics and mechanism of oxidative degradation of the elastomers used as binders for solid propellants have almost not been studied. For instance, studies on the oxidative degradation of a PU elastomer based on polybutadiene containing terminal hydroxyl groups and diisocyanate were aimed at solving practical problems, *viz*., elucidation of the reasons for embrittlement of elastomers and deviation of the experimental data on thermal ageing from the Arrhenius equation.[159–163] The temperature dependences of the oxidation products of the elastomer samples containing and containing no antioxidant was studied by IR and NMR spectroscopy, GPC and oxygen uptake measurements.[162] Dynamic and chemical heterogeneity of size nearly 20 nm was found in the aged samples. The major oxygen-containing products are alcohols (~60%). Ester and acid groups were found but no ketones were detected. It was shown that chain scission is cross-linking of macromolecules occur simultaneously during degradation. The gel content increases from 60% to 90% during the oxidation, the density of cross-links in the gel substantially increases and the sol molecular mass decreases. Nevertheless, the reason for cross-linking was not established. Probably, this is due to radical-chain polymerisation of the polybutadiene fragment at the double bonds.[152]

Undoubtedly, the decomposition products of solid propellant oxidisers that intensely interact with polymeric binder are nitrogen oxides and chlorine oxides, perchloric acid and nitric acid. The interaction of nitrogen oxides and nitric acid with low-molecular-mass organic compounds and polymers was mainly investigated in relation with the kinetic and mechanistic studies of nitration of organic compounds.[164–168] It was shown that nitration of aromatic compounds is an ionic process and that nitration of paraffinic hydrocarbons is a free-radical process initiated by nitrogen dioxide. Nitration of cellulose only proceeds under the action of a nitric acid pseudoform ($HONO_2$) present at HNO_3 concentrations greater than 70%.[168] At concentrations below 60%, HNO_3 is present in the form of a trihydrate which causes oxidative degradation of cellulose. Liquid-phase oxidation of decane by nitrogen dioxide proceeds by the mechanism of degenerate branched-chain reaction.[169] Gas-phase oxidation of glyoxal by nitrogen dioxide follows a radical-chain mechanism.[170]

The effect of nitrogen oxides on polymers was mainly studied in relation with the problem of maintenance of the operating characteristics of polymeric materials exposed to aggressive media (see a review [171] and references cited therein). Degradation of various classes of polymers in NO, NO_2 and $(NO_2)_2$ atmospheres was usually studied phenomenologically without determining the rate constants and parameters of the Arrhenius equation. It was shown that at temperatures similar to room temperature NO_2 is capable of abstracting mobile hydrogen atoms from polymers to produce side nitro and nitrite groups. These processes are accompanied by scission of the main polymer chain. Nitrogen dioxide can also add to the double bonds of carbochain polymers to generate macroradicals and thus initiate free-radical ageing of the polymers. Exposure to nitrogen dioxide causes not only degradation but also cross-linking of polyisoprene and polybutadiene macromolecules. At elevated temperatures ($T \geqslant 373$ K), NO_2 also reacts with less responsive methylene C–H bonds. Interacting with alkyl, alkoxy and peroxy macroradicals, NO_2 can inhibit free-radical transformatins of polymers to give macromolecular products of different thermal stability.

Nitrogen monoxide is much less reactive compared to nitrogen dioxide. It is incapable of abstracting mobile hydrogen atoms from organic molecules and cannot add to isolated double bonds to produce free radicals at temperatures similar to room temperature. Being an efficient acceptor of free radicals, nitrogen monoxide inhibits free-radical processes.

A few phenomenological studies on the oxidation of polymers with the decomposition products of ammonium perchlorate are available.[172–174] It was shown that at high temperatures oxidative pyrolysis of polymers [poly(methyl methacrylate), polystyrene, butyl rubber, polyethylene, SKDN rubber, *etc*.] in perchloric acid vapours and in mixtures with AP becomes the predominant process proceeding with an effective activation energy of 200–240 kJ mol^{-1} (*cf*. 140 kJ mol^{-1} for the decomposition of pure AP). The kinetic and mechanistic aspects of the interaction between the oxidiser decomposition products and the binder on the topological and supramolecular levels, the effect of stress on the kinetics and mechanism of this interaction and the adhesive properties of the binder towards the filler have almost not been studied so far, though this is of great importance for well-warranted stability control of solid propellants. In this context the use of NMR, IR and EPR spectroscopies can play a significant role.[62, 74, 75] For instance, two-dimensional IR Fourier spectroscopy allowed one to study fine details of the oxidative degradation mechanism of polymer networks that cannot be established using one-dimensional spectroscopy in the frequency domain.[62] It is also possible to study the evolution of the structural characteristics of filled polymer networks in the course of binder degradation to reveal the most unstable block in the composite structure. In particular, nanolayer spectroscopy seems to be promising for studies of degradation of filled polymer networks. This method permits measurements of temporal intervals corresponding to the appearance of different types of radicals in nanolayers of a compound and establishment of the sequence of elementary acts of a chemical reaction up to the formation of molecular products.[175] However, these techniques have not been employed in studies of filled polymer networks including solid propellants as yet.

IV. Mathematical modelling of decomposition of energetic materials

1. Modelling of structure – reactivity relations

The strategy of development of weapon systems involves design of new and improvement of the existing EMs. At present, the problem of development of a cheap, efficient and fast method for testing newly designed EMs is topical in connection with enhanced requirements for the service properties of EMs.[176] An improved screening methodology is required to avoid expensive tests of inappropriate materials. This can be realised using methods of mathematical modelling that are divided into two main classes: (1) classical Monte Carlo (MC) simulation and molecular dynamics (MD) modelling and (2) quantum-chemical calculations. Quantum-chemical calculations are based on fundamental principles of quantum chemistry; solving quantum chemistry equations provides a complete and exact description of an atomic system. MD modelling using realistic models allows the reaction dynamics of large atomic systems to be described correctly.

A basic problem of theoretical chemistry is establishment of relations between the electronic structure and reactivities of reactants (rate constant for an elementary reaction can be considered as a measure of reactivity). The methodology and computational procedures employed for calculating the potential energy surfaces, dynamics and rate constants for gas-phase reactions were developed in the 1970s.

At present, quantum-chemical calculations can be carried out only for the simplest explosives and their models.[177–182] The molecular geometries in the equilibrium and transition states, Mulliken atomic charge distributions and electric dipole moments were calculated for, *e.g*., the simplest nitramines.[177, 178] These characteristics, as well as their changes caused by intramolecular motions are of importance in discussing the chemical properties of compounds. Quantum-chemical calculations of the force field,

analysis of vibrational spectra of several nitro compounds and the force constants of stretching vibrations, internuclear distances and spectral characteristics of the simplest nitramines were reported.[179]

Ab initio (including multiconfigurational) quantum-chemical methods were employed to calculate the potential energy surfaces of nitroso compounds in the ground state and in the lowest excited electronic state and to determine the equilibrium geometric parameters, vibrational frequencies and the potential functions of internal rotation of molecules.[180] The structures of nitroso compounds were calculated and the Y—NO (Y = C, N, O, S) bond dissociation energies determined.[57] The bond lengths and bond angles in ammonium dinitramide $NH_4N(NO_2)_2$ in the gas phase were obtained from *ab initio* MO calculations.[181,182]

No substantiated assumptions of the molecular geometries of 1,5- and 2,5-substituted tetrazoles, furazans and furoxans in the transition states of thermal decomposition of these compounds are available; therefore, the principle of least motion cannot be used.[183] For instance, the ground-state parameters characterising those bonds in the heterocycle that are involved in thermal decomposition were used[184] as reactivity indices. The relations established are consistent with the assumptions[37,38] of the mechanism of thermal decomposition of tetrazoles.

Quantum-chemical methods offer great computational potentials and are employed in calculations of the properties of particular molecules. Much less attention has been paid to the interpretation of results obtained in terms of the chemical bonding, molecular structure and mutual influence of molecular fragments. A quantum-chemical procedure for analysis of the electronic structure and physicochemical properties of complex molecules in terms of the interactions between the fragment orbitals was reported.[185] This approach has long been known[186] but was not systematically employed in the analysis of intramolecular interactions in order to distinguish between the key mechanisms of the mutual influence of structural fragments in complex organic molecules (inductive effect, conjugation, *etc.*) and in studies of their relations to the physicochemical properties of compounds.

Using quantum-chemical methods, it is possible to calculate the rate constant for a certain individual reaction;[187] however, generalisaiton of kinetic data for different classes of chemical reactions and the problem of establishing relations between the reactivity and structure (and physical characteristics) of reactants remain unsolved. Two empirical models (a model of intersecting parabolas and a model of intersecting Morse curves) for hydrogen abstraction reactions have been reported.[188] It was shown that the activation energy of such a reaction depends on ten parameters. These models allows the transition-state geometry (interatomic distances in the reaction centre and bond angles) to be calculated from experimental data.[189]

Recently, considerable attention has been paid to studies on the reactions dynamics in the condensed phase. Detailed consideration of the main methods of theory of liquid-phase reactions, *viz.*, numerical simulation by the Monte Carlo and molecular dynamics methods, numerical and analytical studies of the Langevin stochastic equations, Focker–Planck equation and Bohm–Gross kinetic equation has been given.[190–192] The potentials and limitations of moderm methods were exemplified by calculations of the rate constants for particular isomerisation, substitution, addition and electron transfer reactions.

Attempts at calculating the activation energy, E_a, for a dissociation reaction from the IR spectra using a relation between the anharmonicity constant and the dissociation energies of those diatomic molecules in which the interatomic interaction is described by a Morse function were undertaken.[193,194] The dissociation energies of the C—N bond in CH_3NO_2 and of the N—N bond in solid *N*-nitrodimethylamine and in CCl_4 and CH_3NO_2 solutions were calculated.

Studies[195,196] concerned more rigorous mathematical modelling of the primary steps of thermal decomposition of explosives. Density functional calculations of the initial stages of decomposition of 5-nitro-2,4-dihydro-3*H*-1,2,4-triazol-3-one dimer were reported.[195] The reaction is characterised by an activation energy of 369 kJ mol^{-1}; its elementary stages involve the formation of four intermediates and five transition states and result in CO_2 evolution.

The initial decomposition process of urea nitrate were studied by the Hartree–Fock, density functional and second-order Müller–Plesset perturbation theories.[196] Calculations revealed the sequence of elementary stages of urea nitrate decomposition which involves one intermediate and two transition states (TS1 and TS2) with successive formation of NH_3, HNCO and HNO_3. A potential energy profile for the urea nitrate decomposition is shown in Fig. 13 *a*. The decomposition begins with intramolecular proton transfer from one NH_2 group to another to produce NH_3. The optimised geometry of TS1 corresponding to the beginning of intramolecular proton transfer is shown in Fig. 13 *b* (arrows

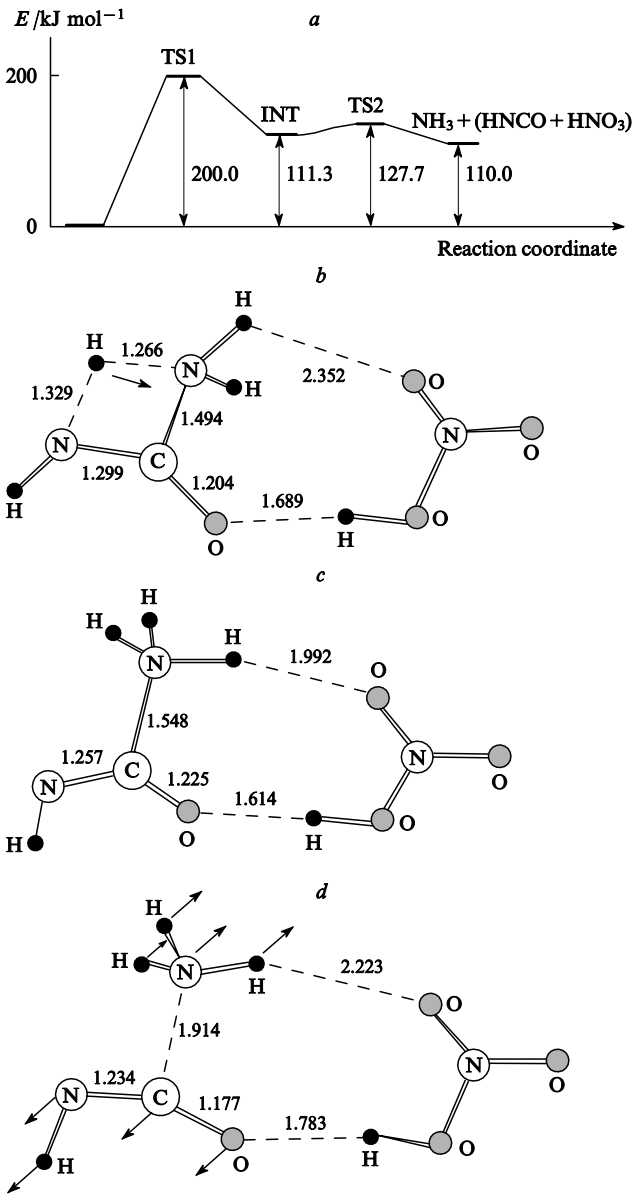

Figure 13. Results of mathematical modelling of primary stages of thermal decomposition of urea nitrate.[196]
Changes in potential energy (*a*), optimised geometry of TS1 and displacement vectors of the normal mode at 1762.7 cm^{-1} (*b*); optimised geometry of (*c*), optimised geometry of TS2 and displacement vectors of the normal mode at 319.2 cm^{-1} (*d*). Bond lengths are given in Å.

denote the displacement vectors). Transition state 1 is a four-membered ring. The intermediate formed after proton transfer goes to TS2. The directions of the displacement vectors in TS2 correspond to the decomposition with production of NH_3, HNCO and HNO_3. Transition state 1 is formed only based on the optimised structure of urea nitrate. In the case of $(NH_2)_2COH^+$, which is the ground state of the crystal structure of urea nitrate, no formation of the four-membered ring N–H–N–C occurs. Therefore, it is assumed that the two-dimensional network of strong hydrogen bonds in the crystal needs to be destroyed by external stimuli (*e.g.*, heat or impact) to begin the decomposition reaction of urea nitrate.

To design new low-sensitive EMs with improved service properties, the effect of mechanical stress on the kinetics and mechanism of their decomposition should be studied.[197] Detailed mathematical modelling of stress action on the reactivity of EMs has been carried out only for polymers.[15]

2. Modelling of solid-phase decomposition

Solid-phase decomposition of EMs can produce some products that form individual phases. Mathematical description of the formation of a new phase has attracted considerable attention.[198, 199] In particular, kinetic concepts of the nucleation and growth of vacancy pores in crystals are based on the kinetic equation of formation of a new phase.[200] According to these concepts, vacancy pores are associations of vacancies that form clusters in the form of vacancy voids (negative crystal), the cluster size varying from tens to hundreds of lattice constants. In the vicinity of each pore there is a nonuniform vacancy distribution, which depends on the vacancy size and can be treated as a vacancy-gas cloud. Diffusive motion of vacancies to a pore and settling on it cause pore motion and growth. The higher the curvature of the pore surface area, the higher the concentration of vacancies above this area.

A closed kinetic equation for the description of radiation-induced evolution of vacancy pores in the coordinate space was derived.[199] The stability regions of the vacancy pore lattice with respect to pore growth and pore displacements from the lattice sites were established. The main processes responsible for changes in the pore distribution in supersaturated vacancy gas are condensation, evaporation and surface diffusion of vacancies and coagulation of pores.

Detailed mathematical modelling of the primary step of solid-phase thermal decomposition of explosives is unavailable as yet. Mathematical treatment of decomposition of a model solid compound involving formation of solid and gaseous products was reported [8, 201] assuming deep stages of conversion where the overall steady-state process is governed by production of the solid product isolated in individual phase. Expressions for the interface propagation velocity, characteristic thickness of the reaction zone and concentration distribution were derived for the simplest idealised case of reversible first-order reaction with allowance for diffusion of the solid product ignoring the stress and strain effects on the reaction rate.

A steady-state mathematical model [8, 202] for reaction front propagation in AP crystal was constructed assuming a dislocation-chain mechanism of AP decomposition ignoring diffusion of reaction products. According to the DCM model, AP decomposes on dislocations, multiplication of dislocations being stress induced. However, the kinetic description of dislocations in this model is phenomenological. The dependences of the dislocation multiplication rate on stress applied and on the concentration of dislocations have no substantiation. The model also ignores such important stages of plastic deformation of the crystalline material as dislocation annihilation, mutual entrapment of dislocations in the intersecting slip planes, dislocation absorption at grain boundaries and dislocation multiplication by double cross sliding.[203, 204] In addition, stress distribution was preset arbitrarily and relations between the stress–strain state and fracture micromechanics of the crystal and the pressure of gaseous products were ignored. Linear dependence of the AP decomposition rate on the dislocation concentration postulated in the model is inconsistent with the experimental data. It should also be noted that evaluation of the model is impossible due to the lack of methods suitable for the determination of the constants appeared in the model equations.

N S Enikolopov and co-workers (see a review [205] and references cited therein) showed that shear deformation causes a substantial (by 3–8 orders of magnitude) increase in the rate of solid-phase reactions compared to the rate of liquid-phase reactions. It was assumed that reactions in the detonation regime proceed isothermally at low temperatures due to immediate conversion of chemical energy into mechanical energy.

Theoretical studies of pre-explosive phenomena under shock-wave initiation showed that the key step of the solid-phase stage of the process are electronic excitations. Narrowing of the forbidden band upon compression of explosives at the reaction wave front was considered.[206] Calculations of the electronic structure of 1,3,5-trinitro-1,3,5-triazacyclohexane revealed [207] a local narrowing of the forbidden band near dislocations and additional narrowing of the forbidden band upon compression in the shock front, which leads to considerable increase in the electronic excitation probability (formation of an exciton) and cleavage of the $N-NO_2$ bond. A molecular dynamics study [176] revealed that metallisation (loss of covalency) upon compression of explosives must be taken into account as the primary step of a sequence of reactions leading to detonation. On the molecular level, a shock-initiated chemical reaction is described [208, 209] as a nonequilibrium non-thermal process whose rate is determined by the average vibrational rate of radical pairs produced *via* molecular decomposition on the 10^{-14}–10^{-12} s time scale. This model is consistent with the results of MD calculatios.[210]

Almost all EMs are heterogeneous in nature, being often composed of a polycrystalline material and a binder. The presence of internal interfaces differs the behaviour of EMs from that of pure materials. Compaction (consolidation), strain and a chemical reaction in a porous explosive was studied using three-dimensional modelling of shock action on an 'array of discrete crystals'.[211] It was shown that fast deformation at contact points induces large-amplitude fluctuations of the strain state characterised by a wavelength of the order of a few particle diameters. Energy localisation causes the appearance of 'hot' spots. Chemical reaction produces multiple wave structures depending on the particle size distribution.

Modelling of thermal decomposition of solid propellants on the mesolevel (oxidiser particle — binder layer) was not performed.

3. Modelling of combustion of energetic materials

Combustion of EMs is a complex physicochemical process, which involves decomposition reactions, heat and mass transfer and strain and decomposition. The complexity of the process makes experimental studies and the development of rigorous quantitative theories of EM combustion difficult. It is believed that elaboration and analysis of simplified combustion models with allowance for particular factors only in order makes possible clarification of the physical picture of combustion and a relatively simple mathematical description. The problem of mathematical modelling of EM combustion goes beyond the scope of this review and should be considered separately due to extensive literature on the problem. However, we will dwell on those aspects of mathematical modelling of the process that are immediately related to the influence of the kinetics and mechanism of EM decomposition on the regularities of their combustion.

A number of simple models of linear combustion with allowance for dispersion, foaming, evaporation and sublimation of the solid compound have been analysed.[212–219] Usually, one-step or two-step reactions are considered ignoring differences between the kinetic regularities of heat release and gas evolution in the course of decomposition. For instance, combustion of highly volatile compounds is analysed using a reaction kinetics scheme

involving two concurrent or two successive steps.[215, 216] Combustion studies of individual explosives were carried out assuming a one-step kinetics with allowance for the difference between the activation parameters for the condensed phase and the gas phase.[217, 218] Combustion of mixed systems was analysed in the homogeneous condensed zone approximation taking into account (i) thermal decomposition and sublimation of oxidiser and (ii) binder degradation and oxidation by the oxidiser decomposition products; however, the corresponding reaction kinetics were described by zero-order reaction equations.[219]

As shown above, the decomposition of EMs proceeds by a complex multistage mechanism. The results of the combustion rate calculations obtained in the analysis of simple combustion models are in good agreement with the experimental data of combustion studies of several oxidisers (NH_4ClO_4, $NH_3OH.ClO_4$, NH_4NO_3, $CH_3NH_3ClO_4$) with complex decomposition mechanisms.[8, 220] Because of this, it may appear that complexity of the EM decomposition kinetics and mechanism is insignificant for mathematical modelling and there is no longer need of detailed studies on the EM decomposition. However, this conclusion is incorrect, because mathematical modelling of combustion of EMs often involves an arbitrary closure of the system of equations by introducing one or two arbitrary parameters, *e.g.*, an additional heat flow from the gas phase to the condensed phase and the degree of dispersion (sublimation). These models ignore the mechanical problem; therefore, a relation between the dispersion and combustion conditions is established based on the simplest estimates.[8] Following this way, the interrelation between the stress–strain state of EMs and the regularities of combustion is reduced to the dependence of the burning rate on pressure.

Note that an increase in pressure has almost no effect on thermal decomposition of binder in the case of radical-chain mechanism. The molecular mechanism is characterised by a decrease in the rate of evaporation of high-molecular-mass degradation products.[221] Consideration of the mechanical problem in combustion modelling is also necessary because combustion of charges with actual geometry requires allowance for not only hydrostatic pressure but also the deviator components of the stress tensor. As shown above, these components can strongly influence the decomposition of solid propellants.

Finally, note that in the early 1960s studies on the macrokinetics of exothermic reactions revealed that the reaction front temperature exceeds the adiabatic temperature (Fig. 14). A part of these results obtained in experimental studies of solid propellant block formation was reported some later.[222] Nevertheless, combustion in the condensed phase is usually modelled assuming that reaction front propagation can be described similarly to gas-phase combustion[8, 223] and the steady-state combustion models ignore experimentally detected excess of enthalpy in the combustion wave, which leads to superadiabatic temperatures.

To some extent the simplified mathematical treatment of EM combustion can be explained by the lack of the kinetic parameters relevant to complexity of the multistage EM decomposition over a wide temperature interval. Nevertheless, note that almost all correctly posed problems can be solved using modern powerful computers and experimental techniques. For instance, a modern strategy of modelling well-developed turbulent flows of multicomponent reactive gases with allowance for interrelations between the chemical kinetics and turbulent transfer was reported.[224]

Recently, advances were also made in studies of combustion of mixed fuels. These studies intensively use computer simulation of processes proceeding in the gas phase and condensed phase. Numerical analysis of combustion of a model fuel based on 1,3,5-trinitro-1,3,5-triazacyclohexane and glycidyl azide polymer has been reported.[225] Four oxidiser and binder decomposition reactions were taken into account for the condensed phase while the kinetic scheme for the gas phase included a total of 532 reactions involving seventy-four compounds.

V. Stability prediction of energetic materials

Explosives, solid propellants and powders are thermodynamically unstable materials due to occurrence of chemical reactions and physical processes in these substances.[8, 226] This requires the EM service life to be assessed with a rather high accuracy because untimely replacement of items made of EMs causes unreasonable expenditures. Explosive demolition requires that precautions be taken, often being an environmental hazard.

The warranty period of items made of EMs can be determined empirically or semiempirically but mathematical modelling is thought to be more efficient.[9, 226] A scheme of modelling of complex physicochemical processes was first developed to study thermal explosions. It involves phenomenological studies of the process, aimed at identification of the most important factors responsible for the changes in the practically valuable properties of EMs; construction of physicochemical and mathematical models of the process; experimental determination of parameters of particular stages; calculations and comparison of the results obtained with the results of full-scale tests to evaluate the accuracy of prediction, *etc*.

No mathematical model suitable for correct description of all (most important) physicochemical and physicomechanical processes proceeding in the course of production and storage of items made of EMs is available as yet. A relevant procedure for assessment of the warranty period of items made of EMs based on mathematical modelling has also not been elaborated so far. It was proposed[8] to characterise the stabilities of solid fuels and of the cast and pressed charges by the time taken to reach a degree of decomposition of 0.02% during the reprocessing step and storage life of the composition (in this case all gaseous products are dissolved in the condensed phase and development of internal pressure, pore formation and swelling of items are impossible). According to this concept, the extent of changes in the service life of items made of EMs are solely determined by the after-effects of gas evolution in the course of decomposition (increase in internal pressure, pore formation and swelling of items). Calculations of the tolerable degree of decomposition were carried out ignoring gas diffusion and the presence of atmospheric gases dissolved in the condensed phase.

This method of determination of stability criteria for EMs and items made of them has neither practical nor theoretical substantiation. The development of internal pressure, pore formation and swelling of items owing to gas evolution in the course of EM decomposition have not been studied even phenomenologically, the effect of these parameters on the operating characteristics has not been established and no quantitative relationships between them and the degree of decomposition was found, though porosimetry techniques for the condensed phase are well known (*e.g.*, positron annihilation and NMR spectroscopy). A small variation of porosity during decomposition is permissible, because pressed items made of explosives are characterised by a nearly 5% initial porosity. The service life of most solid propellants depends on the changes in their physicomechanical characteristics due to the binder degradation, which often proceeds without gas evolution.[227, 228] If an item made of solid propellants is subject to shrinkage or temperature stress, an increase (within certain limits) in the volume of the solid propellant due to gas evolution and pore formation is useful, because it reduces or even completely relieves stress.

The predictive power of the proposed unexperimented procedure for the determination of stability criterion is low. The authors noted that this criterion can vary within the limits of two orders of magnitude for the same composition. In practice, low accuracy of prediction is to some extent compensated by prolongation of the warranty period based on the results of full-scale tests of the items after expiration date. The 'benefit' from the prolongation of the warranty period is of course imaginary. Nevertheless, for obvious reasons this does not favour improvement of service life assessment procedures.

Temperature is not the sole factor determining the stability of items made of EMs.[226] The rate of a decomposition reaction also depends on different kinds of radiation (X-ray, UV, *etc.*), on the mechanical stress, on the presence of moisture and other compounds in the environment, *etc*. The influence of these factors on the EM decomposition and on the stability of items made of EMs has been studied much poorer than the thermal effects.

Instability of the shape and size of items made of EMs can be due to not only thermal decomposition but also incompleteness of phase separation in the course of crystallisation, thermodynamically nonequilibrium conformation of polymer chains and other physical factors.[226, 229]

Solving the problem of stability prediction for EMs requires a great body of data and takes a long time. For instance, in the USA the service life of rocket engines is evaluated by statistical treatment of the results of accelerated cyclic load tests of engines belonging to groups with different storage lifes. This allows one to attain engine failure in admissible and predictable time.[230, 231] Direct comparison of the results of calculations with the behaviour of the item under operating conditions requires too long time. However, differences between the test results and the life expectancy can be due to not only ignoration of some operation factors but also to a change in the mechanism of the process under operating conditions. For instance, if two competing concurrent processes (breakdown of cross-links and cross-linking) proceed in a polymer network, the dependence of the stress – strain properties on time has the form

$$Y = \alpha\exp(-k_1 t) - \beta\exp(-k_2 t) + Y_0,$$

where k_1 and k_2 are the rate constants for breakdown of cross-links and cross-linking, respectively, and Y_0, α and β are constants. If $k_1 < k_2$ under test conditions, the dependence $Y(t)$ passes through a minimum; otherwise ($k_1 > k_2$), it passes through a maximum. Extrapolation with allowance for the behaviour of the function $Y(t)$ in the initial period of tests can introduce gross errors.[226] Changes in the stress – strain state of the composite due to the difference between the binder and filler thermal expansion coefficients and temperature-induced changes in the mechanism of the interaction between the oxidiser decomposition products and binder can also introduce large errors when using a similar extrapolation.

A combined prediction procedure involving alternate 'placing' of a material or an item under accelerated test conditions and under operating conditions is nearly free from these drawbacks.[9]

At present, NMR imaging techniques have been intensively developed. They permit imaging of internal structure of a material and monitoring of its state immediately under operating conditions.[87, 232–235] NMR images are in essence multidimensional NMR spectra. For instance, NMR imaging permits non-destructive real-time monitoring of the dynamics of physical and chemical processes by measuring the spatial distribution of concentration in any section of the sample. Large objects are studied using surface coils [233] or devices combining an RF coil and a magnetic field source.

VI. Conclusion

The kinetic and mechanistic studies of EM decomposition aimed at solving important practical and theoretical problems are far from being completed. This is to a great extent due to the fact that the scientific and methodological potentials of modern chemical physics (in particular, chemical kinetics) and solid state physics are still little used in the EM decomposition studies. An optimum research strategy must involve joint kinetic and mechanistic studies of complex chemical reactions. This can be done using various efficient methods of determination of the composition of reaction mixtures and the evolution of reactant concentrations in the course of reaction. However, the decomposition mechanism of explosives is usually studied out of the context of the kinetics of elementary decomposition stages while the kinetic parameters are as a rule determined using methods of formal kinetics. However, these methods are little informative and therefore cannot be used for the determination of the rate constants for elementary stages of multistage processes.

Computer simulation of the decomposition of explosives as a means of controlling the mechanism reliability is only coming in practice, being performed taking simple model compounds as examples. The kinetics and mechanism of the decomposition of explosives in the condensed phase are very poorly studied because improved methods of investigation of the supramolecular structure of liquid and solid explosives characterised by rather high spatial and temporal resolution are almost not employed. Information on the supramolecular structure of the condensed phase and its evolution in the course of reaction is ignored. The true rate constants for the primary steps of decomposition (leave alone the rate constants for all elementary stages of the process) have not been determined as yet even for in-service explosives and solid propellant oxidisers and the corresponding decomposition mechanisms are not substantiated. The aforesaid suggests that the available methods of theoretical chemistry have considerable promise for the determination of the kinetics and mechanism of thermal decomposition of EMs. The highest efficiency can be attained in joint studies carried out using these methods and modern experimental techniques.

Usually, solid propellant binders are polymer networks with a complex multilevel structure. The chemical, topological and supramolecular structure of such polymers and composites based on them can be investigated using modern efficient and theoretically substantiated approaches. A number of methods for studying the structure of the free volume subsystem of the polymer network are available. This allows the decomposition kinetics of polymer networks and composites exposed to the action of various external factors to be studied, the most unstable structural blocks to be determined and efficient methods of stability improvement to be elaborated. However, the new techniques are very rarely used in studies of the degradation and stabilisation of solid propellants; the decomposition of solid propellants is studied using methods of formal kinetics.

The most important problem, prediction of stability of EMs, is still to be solved. The proposed criterion for stability of these materials (limitation on the tolerable degree of conversion during the reprocessing time and the storage life to a value of 0.02%) is not substantiated. In this situation the best way is to use of a combined prediction procedure and NMR techniques that allow the state of items made of EMs to be monitored immediately under operating conditions.

Mathematical modelling of combustion is performed using simple steady-state models and a number of essential assumptions. This is due to the lack of kinetic parameters relevant to the actual complexity of EM decomposition over a wide temperature interval. Powerful modern computers allow almost all correctly posed problems in the field of mathematical modelling of EM combustion to be solved.

Modern analytical thermooptical spectroscopy

M A Proskurnin, M Yu Kononets

Contents

I.	Introduction	1143
II.	General characterisation of thermooptical spectroscopy methods	1144
III.	Fields of application of analytical thermooptical spectroscopy	1152
IV.	Study of interfaces in condensed systems	1161
V.	Conclusion	1165

Abstract. The review surveys the main lines of research in thermooptical spectroscopy related directly or indirectly to analytical chemistry. The advantages and drawbacks of thermooptical spectroscopy methods are considered. Particular attention is given to the coupling of thermooptical spectroscopy to chromatography, flow analysis techniques, capillary electrophoresis, *etc*. Prospects for the development of analytical thermooptical spectroscopy are discussed. The bibliography includes 606 references.

I. Introduction

A pioneering study on analytical thermooptical spectroscopy [1] was published 25 years ago. In this time, the development of an analytical method is considerable and its status compared with other methods also change. The characteristic feature of the recent studies in the field of thermooptical spectroscopy is that researchers turn from the 'reproduction' of spectrophotometric procedures to a search for specific thermooptical methods of analysis.[2 – 17] It should be noted that not only the most commonly used thermal lens spectrometry but also such methods as mirage spectroscopy,[2, 5, 7, 8] the thermal prism technique,[4, 5, 16] photothermal refraction spectrometry [2, 4, 7, 8, 10, 11, 16] and photothermal interferometry [4, 17] have attracted increasing attention. In the period from 1997 to 2002, the distribution of methods used in studies in the field of thermooptical spectroscopy was as follows: thermal lens spectrometry, 43%; photothermal deflection, 27%; photothermal radiometry, 12%; photothermal displacement, 9%; photothermal interferometry, 4%; thermal lens microscopy, 4%; photothermal refraction spectrometry, 1%. Hence, it is evident that a new line of investigation, *viz*., analytical thermooptical spectroscopy, has evolved. There is a pronounced tendency to use thermooptical methods in fundamental studies, where their advantages as non-destructive highly sensitive methods of molecular light absorption spectroscopy are most obvious.[6, 15, 17, 18] In the period from 1998 to 2003, the number of studies devoted to thermooptical methods has steadily increased by approximately 300 papers *per annum* (Fig. 1).

In the present review, we analyse state-of-the-art thermooptical spectroscopy and its applications in analytical chemistry and related fields in the last 10 – 15 years. The coupling of thermooptical spectroscopy to other modern analysis methods (primarily, to chromatography, flow analysis methods, capillary electrophoresis, kinetic methods) enables one to extend the range of compounds that can be detected and to enhance the sensitivity of measurements. The review covers new fields of application of thermooptical spectroscopy in analytical chemistry and chemical analysis, such as the design of compact photothermal and photometric devices (chemical microchips and integrated microanalysis systems) on the basis of thermooptical detection, analysis of medical and biological samples and molecular analysis of surface- and volume-absorbing solid substances. In our opinion, the review of the main methods and applications of modern thermooptical spectroscopy will be of interest not only to analytical chemists but also to researchers in physical chemistry, biochemistry, surface chemistry and physics and laser chemistry.

II. General characterisation of thermooptical spectroscopy methods

1. Theoretical fundamentals of thermooptical spectroscopy

Methods of thermooptical (photothermal) spectroscopy are based on measurements of refractive index changes induced by electromagnetic radiation absorption (Fig. 2).[2–5,7,8]

All thermooptical methods are based on the conversion of absorbed radiation into heat. Initially, an irradiated sample absorbs radiation which is accompanied by transition of its atoms or molecules into the excited state. Then, the excited state relaxes back to the ground state. Relaxation can follow several paths. For purposes of thermooptical spectroscopy, radiationless non-radiative relaxation accompanied by the conversion of absorbed radiation into heat is of most interest. The spatial temperature distribution in an irradiated sample corresponds to the spatial energy distribution in incident radiation. The temperature distribution, in turn, gives rise to optical anisotropy, *viz*., a non-uniform spatial refractive index distribution. The refractive index distribution causes a change in the optical path length, resulting in the formation of an optical element. The characteristics of this element provide a basis of a photothermal signal.

For thermooptical spectroscopy methods, not only high intensity of laser radiation but also its mode composition, *viz*., a particular spatial energy distribution in the beam, is of considerable importance. In this case, the photothermal effect is regular. In a medium, which is isotropic before irradiation, this effect leads to the formation of an optical element similar in action to a lens, a prism, a diffraction grating, *etc*.[2,4,6,7] Data on thermooptical elements, measured signals, methods of their detection and the fields of application are given in Table 1.

The theory of thermooptical spectroscopy can be divided into three parts describing the following stages:[4]

(1) absorption of excitation radiation to form the temperature field;

(2) formation of the refractive index field in accordance with the temperature distribution;

(3) influence of the thermooptical element on transmitted radiation.

The key problem is to calculate the temperature change, which depends most substantially on the thermooptical properties of a sample and its thermal and optical structure. A calculation of the changes in the probe beam after it passes through a thermooptical element is a trivial problem. Methods for its solution have been developed in detail.[4]

Let us consider a finite thickness sample irradiated with a laser beam in the TEM_{00} mode (the Gaussian intensity distribution across the TEM_{00} mode), *i.e*., with the beam with radial symmetry of intensity. This beam is described by the expression[4]

$$I(r) = \frac{2P_e}{\pi\omega_{0e}^2}\exp\left(-\frac{2r^2}{\omega_{0e}^2}\right), \quad (1)$$

where $I(r)$ and P_e are the intensity at a distance r from the centre of the beam and the total power of the excitation beam, respectively, and ω_{0e} is the excitation-beam waist radius. The spatial heat distribution in the sample in the absence of radiation losses is defined by the three-dimensional differential equation of thermal diffusion

$$C_P\rho\frac{d}{dt}\left[\Delta T(r,z,t)\right] - k\nabla^2\left[\Delta T(r,z,t)\right] = Q(r,z,t). \quad (2)$$

Here C_P is the heat capacity, ρ is the density of the medium, k is the thermal conductivity coefficient, $\Delta T(r,z,t)$ is the change in the sample temperature with respect to the initial level (the temperature of the environmental medium), z is the coordinate along the axis coinciding with the beam propagation direction, t is the time, $Q(r,z,t)$ is the heat released upon absorption of laser radiation in the TEM_{00} mode per unit of volume in a unit of time

$$Q(r,z,t) = 2\pi\alpha(z)I(r)r\mathrm{d}r, \quad (3)$$

where $\alpha(z)$ is the linear absorptivity of the sample.

Various other processes can easily be taken into account by introducing additional terms in the thermal diffusion equation. For a particular experiment, the characteristic features are specified by the boundary conditions necessary for solving the heat transfer equation. By choosing appropriate conditions, one can reduce the dimensionality of the thermal diffusion equation. The solution of this equation is the spatial and time dependences of the temperature rise in the excitation region $\Delta T(r,z,t)$. The solution of the thermal diffusion equation is expressed in terms of Green's function formalism.[4] In studies with the use of pulse lasers, the heat transfer is often ignored because the time of thermal wave propagation is substantially longer than the laser pulse duration. In this case, the spatial temperature distribution in the sample is assumed to be exactly consistent with the spatial energy distribution in the incident pulse.[4] In experiments using a continuous radiation source, the signal is, on the contrary, formed predominantly through heat transfer.

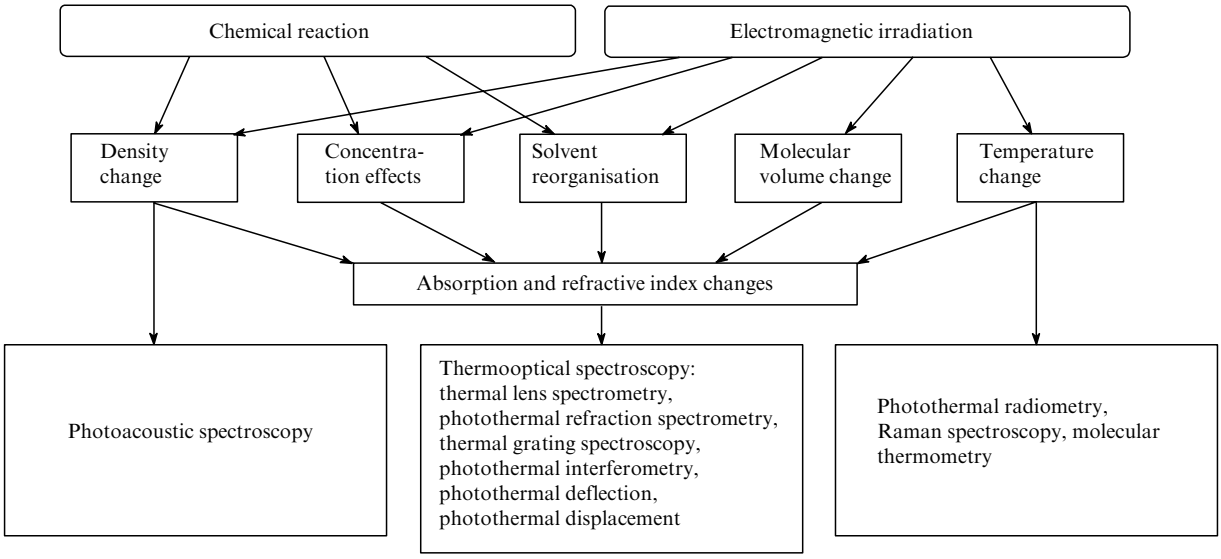

Figure 2. Main photothermal effects, which occur in condensed media irradiated with a laser, and methods for their detection.

Table 1. Main thermooptical methods and their characterisation.

Method	Thermooptical element	Signal	Detector	Objects; fields of application
Thermal lens spectrometry	divergent spherical lens	changes in the probe beam divergence (lens focal distance)	photodiode, photoelectron multiplier or multichannel photodetector	analytical determination of microamounts, detectors in chromatography, remote probing
Time-resolved thermal lens spectrometry	divergent spherical lens	slope of a time evolution curve of a thermal lens	photodiode, photoelectron multiplier	liquids and gases; a detector in chromatography
Photothermal refraction spectrometry	divergent cylindrical lens	changes in the probe beam divergence (lens focal distance)	photodiode, photoelectron multiplier or multichannel photodetector	liquids; probe analysis, analysis of small-volume samples (10^{-12}–10^{-14} litre), detectors in chromatography and capillary electrophoresis
Photothermal deflection (mirage effect)	pseudoprism in a medium in direct contact with a sample	probe-beam deflection	position-sensitive detector	gases, surfaces of condensed media; detectors in capillary electrophoresis
Photothermal displacement	mirror (bending of the sample surface)	spatial probe beam displacement	the same	surface and subsurface flaw detection
Photothermal radiometry	temperature fluctuations on the sample surface	surface thermal radiation	IR detector, lock-in amplifier	remote probing of surfaces, studies of fast processes
Photothermal microscopy	changes in refractive index distribution	amplitude and phase of the probe beam or thermal lens signal	scanning photodetector	microscopic analysis of surfaces, biological cultures and tissues, *in situ* analyses
Thermal grating spectroscopy	spatial diffraction grating	diffraction pattern in probe beam	the same	condensed media; studies of reaction mechanisms
Photothermal interferometry	changes in refractive index distribution	amplitude and phase of probe beam	Mach–Zehnder, Fabry–Perot, Jamin–Lebedev interferometers	flow rate measurements, surface absorption measurements, studies of DNA and proteins

The refractive index distribution $n(r,z,t)$, *i.e.*, the thermooptical element as such, is generally described by the following approximate equation:[19]

$$n(r,z,t) \approx n_0 + \frac{\mathrm{d}n}{\mathrm{d}T}\Delta T(r,z,t), \tag{4}$$

where n_0 is the refractive index of the non-excited sample. In the simplest case, the optical-path length change depends only on the refractive index (for example, in liquids). However, for solid samples, an additional increase in the optical path length due to expansion on heating is sometimes taken into account. In this case, the thermal expansion profile of the sample in the excitation region corresponds to the intensity profile of the incident radiation. This effect is described by a general equation of the optical path length (s) [17, 20]

$$\frac{\mathrm{d}s}{\mathrm{d}Q} = \frac{1}{\rho C_P}\frac{\mathrm{d}s}{\mathrm{d}T}. \tag{5}$$

The temperature dependence of the optical path length is related to the refractive index change $n(T)$ and the sample elongation $l(T)$ by the equation

$$s(T) = n(T)l(T).$$

The distribution of the optical-path length change (or the refractive index change) determines the phase shift of probe electromagnetic radiation passing through the excitation region. The phase shift is accompanied by a change in the radiation intensity distribution in the detector plane. Changes in the probe beam intensity in the detector plane are most accurately estimated by methods of diffraction optics. In this approach, the precise solution is found by solving the Huygens–Fresnel superposition integral. The direct solution of the system of Eqns (2)–(5) is very complex and cumbersome. The simplest expressions can be obtained with the use of the Fresnel and Fraunhofer approximations in diffraction processes, which involve detection in the near-field and far-field regions, respectively. Along with the diffraction model for the photothermal signal, simpler models, for example, a parabolic model [19] and a paraxial aberration model,[4] are sometimes used in thermal lens spectrometry.

From the above it follows that the mathematical apparatus of thermooptical spectroscopy is very complex. Hence, it is generally impossible to deduce an exact, simple and clear expression for a photothermal signal in analytical form. In practice, numerical methods are often used for simulation of a signal.

The theory of thermooptical spectroscopy of solid substances and heterogeneous materials differs substantially from the theory of thermooptical spectroscopy of homogeneous samples. Heat propagates in different layers or regions of solid matter and can also go to the gas or liquid surrounding the sample. To describe the resulting temperature change, it is necessary to simulate thermal diffusion.[4]

The complexity of three-dimensional thermal diffusion and the temperature and refractive-index changes taking place in solid samples forced researchers to search for alternative way to describe of a photothermal signal.[4] It is assumed that, first, spatial anisotropy of the refractive index, responsible for a photothermal signal, is not necessarily determined by the source intensity but depends much more substantially on the anisotropy of the sample. Second, it is generally impossible to obtain an exact solution of the thermal diffusion equation for a given geometry of the optical scheme.[4] To the contrary, this geometry is determined by the heterogeneous nature of the sample and the excitation source. In the next step, the chosen scheme can be used for studying thermal diffusion and the resulting temperature and refractive-index changes according to a standard procedure.[4] The three-dimensional structure of the material under study is revealed using experimental data and information, which is obtained by solving

the equation for specially chosen geometric conditions, rather than by solving thermal diffusion equations for a specific geometry of the optical scheme, which is usually done in studies of homogeneous samples.[4]

2. Thermal lens spectrometry

Of all the thermooptical methods, thermal lens spectrometry has gained the widest acceptance.[1–18, 21–71] This method is based on the periodic formation of a lens-like element in a medium that absorbs laser radiation with the TEM_{00} mode. The focal distance of the resulting thermal lens depends on the absorbance of the sample. The main advantages of this method are as follows: first, it allows one to study samples in different aggregate states and perform remote measurements and, second, it requires relatively simple equipment. The thermal lens signal depends on the temperature gradient of the refractive index and the thermal conductivity coefficient of the medium. The strongest thermal lens effects are observed in non-polar and low-polarity organic liquids.[3] It should be emphasised that this is also typical of other photothermal effects. Physical models of the thermal lens effect have been developed in detail.[54–60]

In conventional thermal lens spectrometry, two laser beams are coaxial (a spherical lens). The scheme of formation and detection of a thermal lens signal is presented in Fig. 3. If the formation of the thermal lens is completed, the stationary thermal lens signal (ϑ) is calculated as either a change in the probe beam intensity at the detector

$$\vartheta \equiv \frac{I_p(0) - I_p(\infty)}{I_p(\infty)}, \tag{6}$$

where $I_p(0)$ is the intensity at the centre of the probe beam reaching the detector at the initial moment $t = 0$, before the formation of the thermal lens; $I_p(\infty)$ is the intensity at the centre of the probe beam after completion of the formation of the thermal lens ($t \to \infty$), or as a relative broadening of the probe beam in the detector plane

$$\vartheta = \frac{\omega_{2p}^2(\infty) - \omega_{2p}^2(0)}{\omega_{2p}^2(\infty)}. \tag{7}$$

Time evolution of the thermal lens in a sample during one cycle of operation of a chopper (a modulator) of the excitation beam (or a single laser pulse) is described by a time-resolved thermal lens signal, which is the instantaneous relative intensity of the probe beam at the centre of the detector, $I_p(t)/I_p(0)$. The probe beam absorption in a sample is assumed to be negligible.

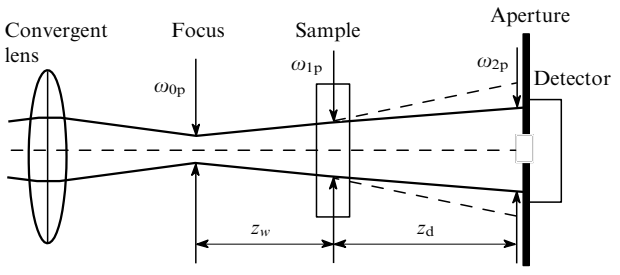

Figure 3. Diagram showing propagation of the probe beam; ω_{0p}, ω_{1p}, ω_{2p} are the radii of the probe beam in the waist, at the sample and in the plane of the detector, respectively; z_w is the distance between the probe laser waist and the sample; z_d is the distance between the sample and the plane of the detector.

In the case of liquids and isotropic solid substances, the thermal lens signal is usually described using the diffraction theory, in terms of which the relation between the thermal lens signal and the absorbance of the sample is expressed as follows:

$$\vartheta = (1 - 2.303AE_0P_eB)^2 - 1, \tag{8}$$

where A is the absorbance of the sample, P_e is the power of excitation radiation, E_0 is the thermal-lens enhancement factor (an increase in sensitivity compared to conventional spectrophotometry) for a unity power of excitation radiation

$$E_0 = -\frac{dn/dT}{\lambda_e k}, \tag{9}$$

(dn/dT is the temperature gradient of the refractive index, λ_e is the wavelength of the excitation laser, k is the thermal conductivity coefficient), B is the geometrical constant of a thermal lens spectrometer

$$B = \frac{1}{2}\operatorname{arctg}\left(\frac{2mV}{1 + 2m + V^2}\right), \tag{10}$$

V is the distance between the probe beam waist and the cell with a sample (in units of confocal distances of the probe laser)

$$V = \frac{z_\omega}{z_{cp}} + \frac{z_{cp}}{z_d}\left[\left(\frac{z_\omega}{z_{cp}}\right)^2 + 1\right], \tag{11}$$

m is the area ratio of the cross-sections of the probe and excitation beams in the sample

$$m = \left(\frac{\omega_{1p}}{\omega_{0e}}\right)^2 = \left(\frac{\omega_{0p}}{\omega_{0e}}\right)^2\left[1 + \left(\frac{z_\omega}{z_{cp}}\right)^2\right]^2, \tag{12}$$

where ω_{0e} and ω_{0p} are the waist radii of the excitation and probe lasers, respectively, z_{cp} is the confocal parameter of the probe laser.

For non-isotropic solid substances, the diffraction model of the thermal lens effect is inapplicable, because an analytical expression for neither a time-resolved lens signal nor a stationary thermal lens signal can be deduced.[72]

Quantitative measurements of the thermal lens effect enable one to evaluate the absorbance up to $y \times 10^{-8}$ and the concentration up to $y \times 10^{-12} - y \times 10^{-10}$ mol litre^{-1} (see Refs 6, 13, 21–43, 58, 62–71, 73–93). On the whole, the sensitivity of thermal lens spectrometry is 2–4 orders of magnitude higher than that of conventional spectrophotometry.

For isotropic samples, the time-resolved thermal lens signal is described in terms of the diffraction model by the following expression:

$$\frac{I_p(t)}{I_p(0)} = \left(1 - \frac{2.303E_0P_eA}{2} \times \right. \tag{13}$$

$$\left. \times \operatorname{arctg}\left\{\frac{2mV}{[(1 + 2m)^2 + V^2]t_c/2t + 1 + 2m + V^2}\right\}\right)^2 +$$

$$+\left(\frac{2.303E_0P_eA}{4}\ln\left\{\frac{[1 + 2m/(1 + 2t/t_c)]^2 + V^2}{(1 + 2m)^2 + V^2}\right\}\right)^2,$$

where t_c is the characteristic time constant of the thermal lens

$$t_c = \frac{\omega_{0e}^2}{4D}, \tag{14}$$

D is the thermal diffusivity of the sample.

Time-resolved thermal lens spectrometry is based on the time evolution of the focal distance of the thermal lens. The response time of the method is 0.1–1 ms, which is approximately an order of magnitude shorter than that achieved in stationary thermal lens measurements.[78, 94–98] Time-resolved thermal lens spectrometry is used for the detection in chromatography or studies of kinetic processes.

Presently, a differential (dual-cell) modification of thermal lens spectrometry is under development. In this method, the background signal is compensated by the formation of a thermal lens in two cells placed sequentially. The second cell containing a reference solution is placed symmetrically in front of the excitation laser waist.[30, 99–105] The thermal lens signal formed in this cell [see Eqn (6)] is proportional to absorption of impurities responsible for the background signal. The thermal lens signal in the second cell can be represented as the sum of the thermal lens signals of the analyte component and the background. The divergent thermal lens formed in this cell can be considered as a superposition of two thermal lenses, whose focal distances depend on absorption of the analyte components and impurities. Hence, the thermal lens effect in the first cell compensates for broadening of the probe beam, which occurs due to absorption of impurities in the second cell containing the solution analysed. In this case, the signal depends only on absorption of the component analysed in the second cell. Advantages of two-cell measurements over the conventional single-cell method is evidenced by the fact that the detection limit of iron(II) by its reaction with 1,10-phenanthroline is five times lower (20 nmol litre^{-1}), and the minimum quantifiable concentration is almost ten times lower (40 nmol litre^{-1}).[99]

3. Photothermal refraction

Crossed-beam thermal lens spectrometry or photothermal refraction is based on the optical scheme of thermal lens measurements, in which the excitation and probe laser beams are mutually perpendicular (a cylindrical lens).[49, 106–111] Although the sensitivity characteristics of this method are analogous to those of thermal lens spectrometry, photothermal refraction makes it possible to detect absolute amounts as low as several tens of molecules of absorbing substances in the volume from $y \times 10^{-18}$ to $y \times 10^{-15}$ litre (a crossing region).

Due to a high spatial resolution, photothermal refraction is used in capillary chromatography, capillary electrophoresis methods and local analysis of liquids.[49, 106–117] However, equipment required for the optical schemes of photothermal refraction are more cumbersome compared to that used in the parallel-beam scheme, and these optical schemes are characterised by a substantially more complex mathematical model, which describes the relationship between the signal recorded and the geometric parameters of the optical scheme. Besides, this mode of recording the thermal lens signal is inconvenient for performing analyses in a volume larger than 0.1 ml, because the energy of the excitation laser beam reaching the crossing region substantially decreases as the absorbance of the sample and the optical path length increase, resulting in narrowing of a region of the linear dependence of the refractometric signal (a linearity region).[118]

The use of the thermal lens detection in the near-field region (the sample-to-detector distance is 10 cm) gave additional impetus to the development of photothermal refraction.[109–111] Further investigation demonstrated that detection under these conditions corresponds to detection in capillaries, because the edge effects caused by interference of the probe laser beam at capillary walls are eliminated, and the measurement reproducibility is substantially improved. In addition, this approach employs compact apparatus, which made it possible to create a detector prototype for capillary electrophoresis (Fig. 4).

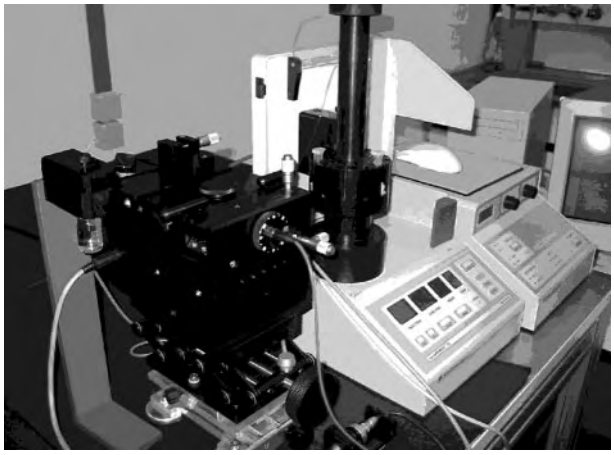

Figure 4. Photograph of a detector prototype for capillary electrophoresis based on photothermal refraction spectrometry.
The photograph courtesy of Drs W Faubel (Karlsruhe Research Centre, Germany) and U Puell (Marburg University, Germany).

4. Total internal reflection thermal lens spectroscopy

Thermal lens spectrometry under conditions of total internal reflection [an analogue of total internal reflection fluorescence spectroscopy] is a powerful tool for studying interfaces (liquid–liquid, liquid–solid, *etc.*) when nanogram amounts of reagents are used.[119, 120] However, this method has little use. The method is based on providing conditions under which the laser beam inducing a thermal lens undergoes total internal reflection from the interface. This allows the detection of photothermal effects, which appear virtually only at the interface. Taking into account that thermal lens spectrometry as a method of molecular absorption spectroscopy is suitable for a larger number of compounds compared to fluorescence, this method has great potential although it is still in its infancy.

5. Photothermal deflection and photothermal displacement

Mirage-effect spectroscopy (thermal deflection spectroscopy, thermal prism)[5, 51, 121–153] and photothermal displacement spectroscopy (thermal mirror)[154–170] are the next most commonly used methods after thermal lens spectrometry. These methods are most widely employed in a purely thermal modification using excitation with IR radiation, which is associated primarily with investigations of semiconducting and polymer materials. These methods are only partially used in experiments on selective excitation in the optical range.

These methods are based on the changes in the optical characteristics of the surface and subsurface layers of the medium caused by heating of a sample with an excitation laser (Fig. 5). In a liquid or gaseous medium, which exists in direct contact with the sample, the thermooptical element is formed. The latter acts as a prism on the radiation propagating along the sample surface. This process is accompanied by thermal deformation of the irradiated surface, resulting in its bending. The probe laser beam, which passes parallel to the surface (a mirage effect) or is incident on the surface at a particular angle (a thermal mirror), is deflected by the thermal prism at a definite angle from the initial direction or is

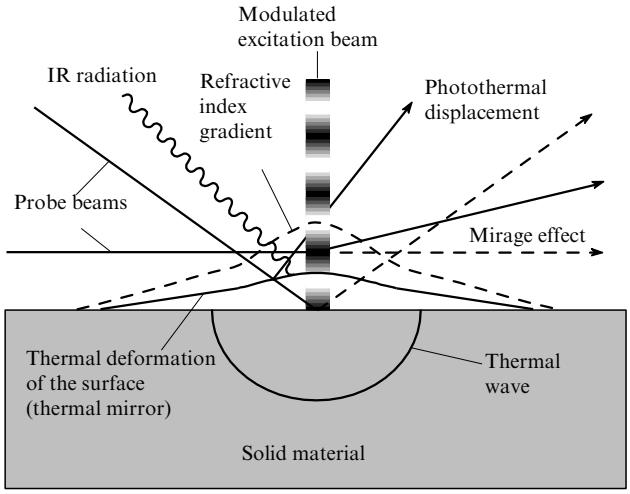

Figure 5. Thermooptical effects under laser excitation of the surface.

reflected from the bent surface and broadened. The perturbations caused by heating are associated with the absorbing ability and thermal properties of the surface under study and depend on the thermal properties (heat capacity, thermal conductivity) of the environmental medium. The scheme of the appearance of the above-described photothermal effects is shown in Fig. 5.

In mirage and photothermal displacement spectroscopy, optical position-sensitive detectors, for example, photodiode matrices and video cameras, are generally used. The angle ϕ (or a distance) at which the probe beam is deflected can serve as an analytical signal. This signal is called the amplitude signal, because it characterises the displacement amplitude of the probe beam relative to the non-excited state of the surface.

There are a number of equations describing the photothermal deflection. The form of these equations depends on the aim of a particular study and the phase state of the medium under study. In investigations of the surfaces of solid materials and gaseous media, the following equation is used:[5]

$$\phi = -\frac{\mathrm{d}n}{\mathrm{d}T}\frac{\alpha l P_\mathrm{e}}{\pi^2\psi\rho C_\mathrm{P}\omega_{\mathrm{e}0}^2}\left(-\frac{2x_0}{\omega_{\mathrm{e}0}^2}\right)\exp\left(-\frac{x_0}{\omega_{\mathrm{e}0}^2}\right). \qquad (15)$$

This equation is valid if the excitation and probe beams are mutually perpendicular (Scheme 1). In studies of weakly absorbing media, the propagation directions of the excitation and probe beams in samples form an acute angle (Scheme 2). In this case, the following equation is valid:[4]

$$\phi = -\frac{\mathrm{d}n}{\mathrm{d}T}\frac{\alpha l P_\mathrm{e}}{2\pi k x_0}\left\{2\exp\left[-\frac{2x_0^2}{\omega_{\mathrm{e}0}^2(1+1/\psi t_\mathrm{c})}\right]- \qquad (16)$$

$$-\exp\left[-\frac{2x_0^2}{\omega_{\mathrm{e}0}^2(1+2/\psi t_\mathrm{c})}\right]-\exp\left(-\frac{2x_0}{\omega_{\mathrm{e}0}^2}\right)\right\}.$$

Here α is the linear absorptivity of the sample layer giving rise to a photothermal signal; l is the thickness of the absorbing layer; ψ is the chopper frequency; x_0 is the so-called interaction distance, *viz*., the distance between the surface of the sample and the parallel-arranged probe beam (displacement of the probe beam) for Scheme 1 or the distance between the optical axes of the beams for Scheme 2.

The refractive index field induced by heating is responsible for the phase change of the displaced beam relative to the incident beam. The observed phase difference is called the phase signal. This signal is recorded by a lock-in amplifier connected to a position-sensitive detector. The spatial resolution of measurements is related to the size of the beam cross-section of the excitation laser, which, in turn, is limited by the wavelength of the excitation beam.

These methods have some specific features. For example, the mirage effect appears in the surrounding medium rather than in the sample. In this connection, measurements by the mirage spectroscopy are not carried out *in vacuo*. The possibilities of determining the concentrations of solid substances in gases, in particular, in air, are limited by their thermooptical characteristics. Hence, an auxiliary liquid possessing appropriate thermooptical properties is often applied on the surface to strengthen the thermal prism. However, this approach has drawbacks associated with the difficulty of choosing such liquids (it is necessary to exclude completely an interaction of the liquid with the material under study).

Of all theoretical models of the formation of a photothermal signal, the model of the mirage effect has been best developed. In the method of photothermal mirror, simulation of the thermal deformation of the surface is a much more complicated problem. In addition, the probe beam deflected by the deformed excited surface can be additionally deflected due to the presence of the refractive index field in the surrounding medium (if measurements are carried out not in vacuum). As a result, calculations become even more complicated.

Nowadays, mirage spectroscopy is one of the most convenient and commonly used thermooptical methods for studying surfaces with very high or very low light absorption. Generally, this method is used for microscopic studies and flaw detection in semiconductors,[171] metals[172,173] and various optical materials.[174–176] Mirage spectroscopy is rarely employed in analytical chemistry as a highly sensitive method of molecular absorption spectroscopy.

Mirage spectroscopy is used in immunoassay adsorption analysis with isolation of a specially coloured antigen–antibody complex on the surface of a solid substrate followed by detection of surface absorption.[177–179] This method is used also in thin-layer chromatography for detection of the absorption profile along the elution profile.[180–182] The new application of mirage spectroscopy for analysis by thin-layer chromatography[183] is limited to measurements with the use of non-selective excitation. However, mirage spectroscopy is not considered as a solo analytical method for the detection of surface absorption. The study[183] was aimed only at estimating the deep concentration profile in the chromatographic zone based on the determination of the surface properties by several thermooptical methods, including mirage spectroscopy. Besides, mirage spectroscopy is used in capillary chromatography.[149–153,184]

6. Photothermal radiometry

Photothermal radiometry is based on measurements of IR radiation from the sample surface after its irradiation with a laser beam (see Fig. 5).[185–214] The amount of emitted energy is proportional to the absorptivity of the sample. In photothermal radiometry, the rate of time evolution of the signal is substantially higher than that in mirage spectroscopy and the thermal-mirror technique, because the time required for evolution of surface deformation and the temperature gradient in the surrounding medium is longer than the thermal relaxation time determining the onset of emission of IR radiation from a heated sample. Semiconducting energy-dispersive detectors are used for rapid and highly sensitive measurements of emitted IR radiation. The possibilities of photothermal radiometry are most evident in studies of semiconducting materials and in IR tomography of biological tissues, including *in vivo* studies. The advantages of photothermal radiometry are the possibility of remote probing, simplicity of experimental equipment and, what is most important, high time resolution (10^{-7}–10^{-8} s). The latter fact allows one to measure absorption spectra of intermediates and study fast processes. Photothermal radiometry is used for determining the absorptivities of thin films, coatings and biological tissues of living organisms.[191,199–206] Theoretical models for photothermal radiometry are constructed on the basis of one-dimensional heat transfer and the law of blackbody radiation. However, the majority of real systems show substantial deviations from the model approximations, which complicates the interpretation of experimental data. These approximations are best suitable for analysis of semiconductors using laser radiation, whose wavelength is larger than the semiconductor band gap. In this case, the signal (thermal radiation) is generated by a plasma wave rather than by a thermal wave, and experiments correspond closely to the model of blackbody radiation.

7. Photothermal microscopy

Photothermal microscopy has been created in the course of the development of thermal lens spectrometry. In this case, the optical set-up of a thermal lens spectrometer is included in the scheme of measurements of an optical microscope.[178,215–232] Photothermal microscopy is used primarily in biological studies as a non-destructive method for investigating cell functioning and in medicine for diagnostic purposes. Depending on the conditions (virus activity, impairment of cellular functions, *etc*.), the optical

characteristics of cytoplasm can differ from those of cell nuclei, which are easily detected with a photothermal microscope.

Photothermal microscopy enables one to study the characteristic features of reaction pathways with the use of nanogram amounts of reagents. This method can be combined with microflow analysis and microchromatography. The further use of the results of these investigations is directly associated with the development of microflow injection analysis, microelectrophoresis and, on the whole, integrated microanalysis systems.[216–231] Photothermal microscopy can also be used for studying reactions under conditions of integrated microanalysis systems (detection of trace concentrations, investigations of mirochannels, microflows, *etc*.) and as a detection method.

8. Photothermal interferometry

Another group of thermooptical spectroscopy methods includes photothermal interferometry and related methods.[189, 233–245] In these methods, a three-dimensional pattern (an amplitude and a phase) of the probe beam recorded on an interferometer (Mach–Zehnder, Fabry–Perot or Jamin–Lebedev) serves as an analytical signal.[239, 246, 247] These methods allow one to determine the local absorption distribution on the surface and in subsurface layers. The sensitivity of photothermal interferometry is the highest of all thermooptical methods (the weakest signal is determined by quantum noise of an interferometer, the absorbance is $y \times 10^{-10}$) and allows the determination of highly absorbing compounds in amounts up to individual molecules. In addition to chemical analysis, photothermal interferometry is employed to study the hydrodynamics of liquids and gases, determine the rates of microflows with high precision, and establish nucleotide sequences in DNA and amino acid sequences in proteins.[242, 245] The amplitude signal in photothermal interferometry is calculated by the equation

$$\phi = \frac{\pi^2}{2}\sqrt{\frac{D}{\psi}}\,\frac{\omega_{e0}^2}{\lambda_p}\,\frac{\partial n}{\partial T}\,\frac{\alpha l}{k}\,P_e\left|\mathrm{erfc}\left(\sqrt{\frac{\psi}{D}\,\frac{\omega_e^2+\omega_{e0}^2}{8}}\;e^{i\pi/4}\right)\right|, \qquad (17)$$

where λ_p is the probe beam wavelength.

Photothermal spectroscopy holds promise for measuring ultralow light absorption in solid materials for laser and fibre-optical techniques, which was confirmed by studies.[239, 240, 248–251] To measure the rates of liquid and gas flows with a sensitivity up to $y \times 10^{-6}$ cm s^{-1}, an optical thermal anemometer was devised.[249–251] An apparatus was created for separate measurements of the bulk and surface light absorption in materials for power optics. This apparatus is successfully used for monitoring low absorption ($y \times 10^{-5}$ cm^{-1}) in ZnSe and ZnSe-based optical elements.

9. Thermal diffraction spectroscopy

Thermal diffraction spectroscopy is based on the spatial periodic refractive index change in a medium caused by the photothermal effect, which is induced by absorption of the excitation beam energy.[252–261] In this case, the thermooptical element behaves as a diffraction grating, and the diffraction pattern produced by the probe beam serves as a signal. This method requires very complex equipment and is used for solving special problems, in particular, for testing the quality of laser optics (spatial distribution of microelements in optical materials) and for studying fast processes (energy transfer in crystals, photochemical processes, structural vibrations of crystal lattices).[254, 257, 260, 262–267]

One promising line of investigation for the use of thermal diffraction spectroscopy is concerned with chemical kinetics and reaction mechanisms. The method allows one to separate diffusion processes and chemical reactions, because the total signal of these processes can be considered as a superposition of short-lived and long-lived diffraction gratings.

A modification of the thermal diffraction method, *viz*., photothermal IR microspectroscopy, employs a microthermometer as a probe, which is used in atomic-force microscopy and thermal microscopy.[268, 269] In a photothermal microscope (unlike an atomic-force microscope), a probe of this type serves both as a thermometer and a heater, which allows the simultaneous detection of surface samples and samples of subsurface layers.[262] The instrument can be use both for measuring photothermal spectra at a given point (region) of samples based on the results of surface scanning in the mode of atomic-force microscopy and for obtaining photothermal samples, in which the signal is proportional to the concentrations of substances that absorb at the excitation wavelength. An important feature of photothermal IR microspectroscopy employing a thermoprobe is that this method, unlike other photothermal methods, is not restricted by the diffraction limit of spatial resolution.[267] Interestingly, photothermal measurements, scanning thermal microscopy, thermomechanometry or thermocalorimetry can be combined in the same instrument, because all these studies are carried out with the use of a Wollaston thermoprobe.[270] Photothermal microscopy provides better spatial resolution compared to conventional measurements using Fourier-transform IR spectroscopy.[267] Such photothermal measurements are used for studying composite materials, biological samples (hair, cells), in particular, for examining microprobing of drugs and the influence of antioxidants on cell functioning.[267–270]

10. Characteristic features of thermooptical spectroscopy methods

The characteristic features of thermooptical spectroscopy methods can be divided into six main groups.

The first group includes characteristics related to high sensitivity. Modern methods for recording the absorbed energy allows the determination of the temperature, volume or refractive-index changes corresponding to absorption of $y \times 10^{-8}$–$y \times 10^{-10}$ absorbance units, which is 4–6 orders of magnitude lower than the sensitivity of conventional spectrophotometric methods.[1–10, 46, 59, 74, 86] In addition to high instrumental sensitivity, thermooptical spectroscopy is characterised by a wide linear dynamic range of measurements (for thermal lens spectrometry, this range is up to 6–8 orders[4, 6, 11, 18, 90]). However, highly sensitive analytical methods have drawbacks, which are associated primarily with the purity of reagents and solvents, the problem of test experiments, laborious sampling, sample preparation, *etc*.

The second group includes characteristics reflecting the distinguishing features of thermooptical spectroscopy as a method of molecular absorption spectroscopy. The advantages of the latter are diversity of substances (including organic compounds) which can be detected, the possibility of investigating samples in different aggregate states, well-developed methods and numerous procedures for sample preparation and non-destructive determination (which allows one to analyse biological samples, for example, living cells), the possibility of performing remote analysis[21] and determinations in flow.[8, 10, 42, 43, 46, 178] However, thermooptical spectroscopy has all drawbacks of conventional spectrophotometry (primarily, spectral non-selectivity).

The third group includes the parameters of thermooptical spectroscopy as calorimetric methods. The common feature of these methods is the extraction of information on the composition and properties of the analyte by recording absorbed radiation and taking into account the attendant changes in the physical and (or) thermodynamic parameters. The absorbed energy can be measured using various modes of detection: acoustic (acoustic wave formation, gas pressure changes), interferometric, refractometric (refractive index changes), optical (measurements of the intensities of transmitted or absorbed radiation), thermometric (contact temperature control), direct calorimetric (direct detection of thermal radiation) or extensometric (changes in the sample size).

The fourth group includes the characteristics of thermooptical spectroscopy, such as power characteristics (the signal is proportional to the incident radiation intensity) and geometric characteristics (the signal depends on the geometry of the optical scheme).

These properties are not unique (recall photoacoustic spectroscopy). The advantage is that the dynamic range can be even more extended (up to 8 – 10 orders of magnitude) by varying the power of the radiation source.[27 – 33, 91 – 93, 271] However, the strong dependence of the thermal lens signal on the geometric parameters (positions of the laser beam waists, cells containing samples and the detector) leads to a serious problem of measurement reproducibility.[55, 58, 59, 80, 272, 273] In addition, not only sensitivity and reproducibility but also the linear range of the signal depends on the geometric parameters of the optical scheme.[59, 274 – 279]

The fifth group of parameters, which characterise the main distinguishing features of thermooptical spectroscopy, is associated with the use of lasers as powerful intense sources of monochromatic coherent radiation. As a result, the number of effects induced by interaction of radiation with an absorbing medium sharply increases. In addition to sample heating, researchers face the photochemical effects (which can play both positive and negative roles), the simultaneous manifestation of the photothermal effect and luminescence, *etc.*[3, 6, 280 – 284] It should be noted that the influence of laser radiation on samples in thermooptical experiments is poorly understood.

The sixth group includes parameters reflecting the unique properties of thermooptical spectroscopy. In relation to this connection, let us mention several important factors.

1. In thermooptical spectroscopy, the laser mode structure is the most important characteristic of laser radiation. Due to regularity of this distribution for the observed photothermal effect, it is possible to construct the precise mathematical model, which relates the strength of the effect (for example, the focal distance of the resulting thermal lens) to the concentration of absorbing components of the system.[6, 55, 56, 239]

2. The solvent plays a decisive role in thermooptical spectroscopy because when a medium is heated its parameter change, for example, refractive index and density. For example, a particular (chemically inert) absorbing compound is characterised by photothermal signals in organic and aqueous media, which differ by several orders of magnitude.[271] Methods of thermooptical spectroscopy are successfully used for determining the above-mentioned characteristics of solvents.[285 – 291]

3. It should be emphasised that the photothermal effects are local in character. They do not cover the overall volume of the sample, but only a small region around the excitation laser beam. This gives rise to strong convection of the liquid, which can lead to blurring and periodic oscillations of the signal.[292] However, the period of convective oscillations can provide important information on the photothermal properties of substances.[293, 294] Another consequence of the local character of the photothermal effects is that chemical processes in the heated portion of the solution can be either accelerated or decelerated (due to heating, photochemical reactions, *etc.*), resulting in a change in the concentration gradient and the formation of diffusion flows of substances.

Evidently, the above classification of the characteristics is tentative, but it gives an insight into the problems associated with the development of analytical thermooptical methods. When describing the features of these methods and classifying these characteristics, we used the principle 'from general to special'. It should be noted that only the first three groups of characteristics were considered in the literature concerned with the problems, advantages and drawbacks of analytical thermooptical spectroscopy, although (strange as it may seem) these characteristics are not unique for thermooptical spectroscopy and are met with in other methods. The last three groups of characteristics are generally ignored considering their well-known drawbacks, which decrease the efficiency of the method, or regarding them as personal techniques used by researchers. As a result, the true place of thermooptical spectroscopy among analytical methods is actually an open question.

In our opinion, this view is incorrect, because specific effects manifested in thermooptical experiments, such as the simultaneous detection of several analytical signals, and the employment of photothermal effects as an active component of the analytical method rather than as a passive mode of detection will presumably provide the basis for a 'special line' of the development of analytical thermooptical spectroscopy. It is encouraging that virtually all most important recent studies have been aimed at developing or, at least, searching for new approaches to methodology, sample preparation and measurements of the signals.[9 – 18, 50 – 54, 58, 112 – 117, 119, 120, 216 – 232, 239, 274, 282, 295 – 297]

11. Apparatus for thermooptical measurements

Dual-laser (dual-beam) optical set-ups have gained wide acceptance in thermooptical spectroscopy. In these schemes, a thermooptical element is formed in a sample under the action of one beam (the excitation beam), and the change in the characteristics of the second (probe) beam serves as an analytical signal.[4 – 10, 54 – 71, 184, 298 – 309] Correspondingly, the excitation laser wavelength is chosen at the absorption maximum, and the probe beam wavelength is, on the contrary, chosen at the absorption minimum. Since thermooptical methods belong to power methods, powerful continuous wave lasers (argon ion, krypton ion, helium cadmium, *etc.*) or pulsed lasers (Nd : YAG, CO, nitrogen, eximer, *etc.*) are used for excitation. It should be noted that thermooptical methods are not limited to the use of laser radiation. However, the use of laser radiation allows one to substantially enhance the effects, which, in fact, appear upon any interaction of radiation with matter. Sources of IR, UV and visible radiation with a continuous spectrum (xenon lamps) are also employed.[295] In this case, the regularity of the intensity profile of excitation radiation is achieved by using absorbing spatial filters.

The basic diagram of thermooptical measurements is shown in Fig. 6. Various methods employ radically different systems for beam focusing and convergence. In all thermooptical methods, the signal depends on the geometry of the optical set-up. Hence, careful adjustment and calibration of a thermooptical spectrometer are required before experiments, and the parameters should be frequently monitored during the course of measurements. A system for synchronisation, which provides synchronisation of the onset of the formation of a thermooptical element and the onset of signal accumulation, most commonly consists of either a mechanical or electromechanical chopper (for beam modulation of an excitation continuous wave laser), a controlling block (a lock-in amplifier or a sampling integrator) and a photodiode. The function of the reference signal is to record the current power of the excitation laser and normalise the signal.

The uniqueness of a thermooptical spectrometer is that the signal contains information only on light absorption of a sample, but the measurement technique allows one to use this instrument simultaneously as, for example, a nephelometer or a refractometer. Hence, a thermooptical spectrometer is a multipurpose instrument, which can provide much more information compared

to its spectrophotometric analogue. As an example we refer to thermal lens fluorimetric procedures for the determination of picogram amounts of transition metal complexes and a combined thermooptical refractometric detector for liquid chromatography. The merit of the latter is that it can be used for the simultaneous determination of compounds of different nature at nanogram levels (for example, the determination of metal chelates and polysaccharides without their preliminary derivatisation).[239, 248]

Let us consider a typical thermal lens spectrometer[58, 59] (Fig. 7). A thermal lens is induced in a cell with an Innova 90-6 argon ion laser *1* (Coherent, USA) with a lasing wavelength of 514.5 nm (TEM_{00} mode, the maximum power is 1.5 W). An SP-106-1 helium neon laser (Spectra Physics, USA) is used as the probe laser *2* with a lasing wavelength of 632.8 nm (TEM_{00} mode, the power is 10 mW). The beams of both lasers are initially vertically polarised. After an optical rotator *3* (model 310A, Spectra Physics, USA), the horizontally polarised excitation laser beam passes through a mechanical modulator (chopper) *4*. A part of the beam energy is directed to a FD-7K power monitoring photodiode *6* using a plate *5*. An amplifier *7* converts the current from the photodiode into a voltage and directs the signal to the second channel of an analogue-to-digital converter and a digital-to-analogue converter (ADC–DAC) board *8* installed on an IBM PC/AT *9*. To synchronise the detection system with the operation mode of the modulator, a part of the radiation energy of the excitation laser is allocated to a lock-in photodiode *11* using a plate *10*. The signal passes to a synchronisation block *12*. The latter forms a pulse, which coincides with the moment of the opening of the chopper. The pulse passes to the ADC–DAC board of the computer. This pulse corresponds to the onset of the formation of a thermal lens in the cell and serves as a signal for the beginning of a new cycle of data reading. The chopper is controlled by a computer through a converter *8* and a synchronisation block *12*. The excitation laser beam, which is focused by a lens *13*, passes through a plane-parallel plate *14* (which is used for fine tuning of the beams in the cell) and a Glan prism *15* and is directed to a cell *16*. The probe laser beam is sent through a system of mirrors *17* and *18* and a focusing lens *19* to the Glan prism, where it is reflected and goes to the cell. A dichroic mirror *20* serves for the preliminary separation of the excitation and probe laser beams and makes it possible to get rid of an additional thermal lens, which could be induced by a highly absorbing filter *21*. The helium neon laser beam, which bears information on light absorption by the sample, passes through an 2-mm aperture *22* located on an optical axis of the system and falls on a FD-7K photodiode *23*. The signal from the photodiode is converted by an amplifier *24* and goes to an ADC–DAC converter of the computer.

Photothermal detectors for capillary electrophoresis on the basis of photothermal refraction in the near-field region (Fresnel diffraction) have been extensively developed in recent years. A prototype of such detectors for high-performance capillary electrophoresis was devised at the Karlsruhe Research Centre (Germany)[113, 114, 310, 311] (see Fig. 4).

The scheme of a typical instrument for mirage spectroscopy[112–115] is shown in Fig. 8. This instrument consists of a probe monoblock equipped with a position-sensitive recording system (Phototherm Dr. Petry Gmbh, Germany). Excitation is performed with a Nd : YAG laser (ADLAS DPY 321, Germany) at wavelengths of 1064 and 532 nm; the maximum radiation power is 50 mW. A helium neon laser (Melles Griot, USA) with a power of 5 mW and a wavelength of 632.8 nm is used as the probe laser. The scanning system allows one to study samples of sizes of 2×2 cm at 1 μm resolution. The chopper frequency of the excitation source varies from 10 to 1000 Hz, which corresponds to heating of a sample layer with a depth from 1 nm to 1 μm. The signal recording system is equipped with a position-sensitive detector and a lock-in amplifier. The deflection amplitude (the amplitude signal) and the path difference (the phase signal) of the probe beam are recorded.

Photothermal IR microspectroscopy employs a modified Fourier-transform IR spectrometer. To ensure thermooptical measurements, the modulated beam from an IR spectrometer heats a sample. Heating is detected by a thermal probe. The output signal from the spectrometer returns to the input of the spectrometer, which makes it possible to record photothermal interferograms. In the scanning mode, a thermal probe is mounted on a positioning system (most often on an atomic-force microscope).[262]

As mentioned above, the main idea of photothermal interferometry consists of measuring the optical path length changes caused by a photothermal modulation of the refractive index. Compared to other photothermal methods used for detecting thermal perturbations of the optical parameters of a medium, *viz.*, photothermal deflection spectroscopy and thermal lens spectrometry, the phase method provides higher sensitivity and stability of measurements. However, in spite of substantial potential advantages, the phase method has little practical application. This is associated with the fact that commonly used Michelson and Mach–Zehnder interferometers are rather complex instruments, which are very sensitive to the environmental conditions and require tedious tuning. A photothermal detector on the basis of polarisation and fibre-optic interferometers, which has been

devised in recent years, can be used in liquid chromatography and capillary electrophoresis.[239, 240, 248–251, 312, 313]

A diagram indicating the main features of a thermooptical interferometer based on a Jamin–Lebedev polarisation interferometer is presented in Fig. 9. Doubled-frequency radiation of a Nd:YAG laser *2* (532 nm, 25 mW) is used for excitation. A semiconducting laser *1* (680 nm, 10 mW) serves as a source of probe radiation. The diameter of the probe beam in cell *3* is 100 mm. The detector operates simultaneously in photothermal and refractometric modes. In the latter case, non-periodic changes in the refractive index of a liquid flowing through the detector are measured. The corresponding signal induced by changes in the mobile phase in a chromatographic system *5–9* is formed in a feedback system. In the photothermal mode, the presence of an absorbing analyte in the cell leads to a temperature rise and, consequently, to an increase in the refractive index, whose variations are proportional to the modulation frequency of the excitation beam. This gives rise to an additional phase signal, which modulates the polarisation state in the second Savart plate *11*. This modulation amplitude is analysed using a Wollaston prism *13* and is measured with the use of photodiodes *14* and *15*, which are connected to a lock-in amplifier *16* incorporated into the interferometer.[239, 240, 248, 250, 312, 313]

The results of studies confirmed that this model can serve as a basis for the construction of commercial detectors. The minimum absorbance detected with this instrument is 2×10^{-10}; the sensitivity is 1000–10 000 times higher than that of conventional spectrophotometers and is 10–100 times higher than that of thermal lens spectrometers; the detection limits are about a few picograms per millilitre; the linear dynamic measurement range is about five orders of magnitude.[239, 240, 248, 250, 312, 313]

The first commercial instrument based on integrated microanalysis systems, *viz*., an ITLM-10 thermal lens microscope (Institute of Microchemical Technology, Japan),[314] was specially designed for applications associated with chemical microchips (Fig. 10). The instrument employs a dual-beam parallel scheme of thermal lens measurements involving an excitation laser with a wavelength of 532 nm (50 mW) modulated with a frequency of 1 kHz and a probe laser with a wavelength of 670 nm (1 mW). A silicon photodiode connected to a lock-in amplifier serves as a detector. The dimensions of the instrument are $650 \times 280 \times 550$ mm and its weight is 25 kg. The provisional price of the instrument equipped with accessories (micropumps, microheaters, *etc*.) is ~ $70 000. The IMT Company (Japan) has designed about 300 modifications of glass and plastic chips for the determination of trace amounts of various substances. This instrument finds an ever increasing use in a combination of thermal lens spectrometry with chemical microchips.[314–319] Models for the simultaneous detection of a thermooptical signal and fluorescence and a portable thermal lens microscope are at the development stage.

III. Fields of application of analytical thermooptical spectroscopy

More than a thousand of papers, several monographs[2–5, 297] and numerous reviews[6–17, 115, 116, 220, 278, 279, 308, 320–322] concerned (in one way or another) with applications of thermooptical spectroscopy have been published. More than half of these publications were devoted to studies in the field of analytical and physical chemistry. Thermooptical spectroscopy has various applications regarding signal recording systems, purposes and subjects of investigation.

Analytical studies of gases by thermooptical methods are scarce.[111, 233, 323–336] Photoacoustic methods prove to be much more convenient, sensitive and fast in studies of gaseous media. Because of this, we do not consider this field of application in the present review. The possibilities of thermooptical methods in the determination of physicochemical parameters and the development of analytical applications are most evident in the analysis of condensed media.

Studies of volume-absorbing solids are limited to transparent substances. An important task is to search for and study new laser active media.[337–348] These studies dealt primarily with the balance between the appearance of fluorescence and the thermal lens effect in the solid matter that generates laser radiation. This problem has been considered in detail in several publications.[17, 320, 349]

1. Stages of the development of analytical thermooptical spectroscopy

There are three stages of the development of thermooptical spectroscopy, each next stage being performed at a higher qualitative level and their role in analytical chemistry being increased.

The publication of the classical study [1] can be considered as the beginning of the first stage. It is characterised by the simplest way of using thermooptical spectroscopy in analytical chemistry. In this stage, the available spectrophotometric procedures were simply extended to the thermooptical detection of absorption. During a long period of time, this approach prevailed, because it combined reliable conventional spectrophotometric procedures and high instrumental sensitivity of thermooptical instruments.[2, 7, 8, 272, 350] Nowadays, more than half of thermooptical procedures for analysis are still based on this approach. This approach is very fruitful both for determining various compounds from their own absorption and in the situation where the detection limit cannot be improved due to instrumental characteristics of a spectrophotometric instrument (Refs 1, 4, 7, 8, 21, 22, 63, 73–82, 272, 273, 295, 350–357).

However, by the late 1980s, evidence showed that the available photometric procedures could not be used for detecting compounds, whose concentrations were 2–4 orders of magnitude lower than those, for which these procedures have been designed.[2, 4, 23–26, 83–87] In addition to a serious problem associated with the purity of reagents, it is necessary to take into account changes in the conditions of complex formation and real redox potentials.[18] These changes can give rise to new side processes, which affect the reaction pathway.[4, 7, 27–38, 87–93] Hence, a demand arose for modifications of spectrophotometric methods. This gave impetus to the second stage of the development of thermooptical spectroscopy, which reached its peak in the early 1990s. The main aim of studies carried out at this stage was to enhance the sensitivity by both modifying chemical systems and optimising the optical set-up of an instrument. At the same stage, researchers began to design combined methods (primarily, chromato-thermooptical methods).[4, 16, 23, 36–40]

The modern stage began in the late 1990s. This stage is characterised by the development of unique applications (not necessarily photometric), which employ the combined influence of laser radiation and thermooptical effects on the system under study. The development of this approach is accompanied by an increase in the fraction of applied combined analytical (chromatographic,[41, 42] kinetic,[43, 44] electrophoretic [45, 46]) and non-analytical (for example, highly precise measurements of flow rates or sizes of colloidal particles [47–49]) methods. Growing interest in this line of investigation is evidenced by a large number of studies (in 2003, it reached a record value) and research groups working in this field (about 76 groups in 25 countries, Fig. 11) as well as by a qualitative change in the aims of studies. In 1986, journals publishing research papers in the field of analytical chemistry contained primarily studies devoted to instrumental characteristics of thermooptical measurements, mathematical processing, *etc*., whereas 75% of present-day publications are devoted to applied aspects (Table 2) and are based on specific features of thermooptical spectroscopy.[9, 13, 16, 50–53] In the following sections, we will try to explain the factors responsible for such substantial changes.

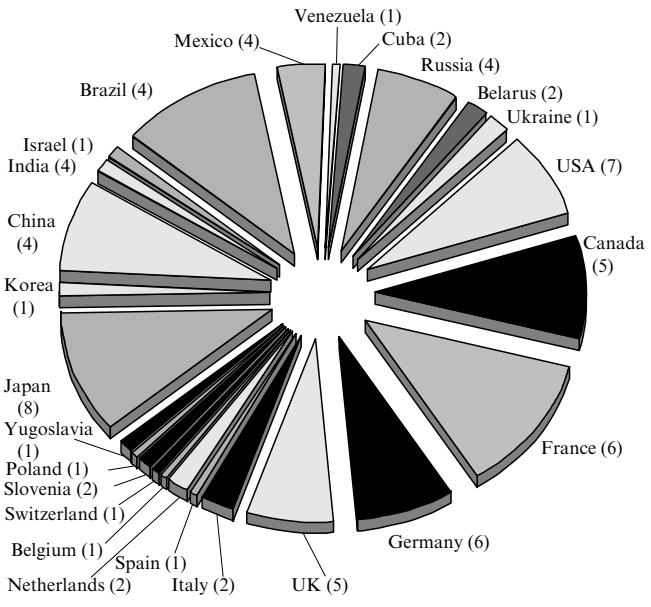

Figure 11. Diagram of the distribution of studies in the field of thermooptical spectroscopy by country in 2002.
The numbers of research groups working with this problem are given in parentheses.

Table 2. Distribution (in %) of studies in the field of thermooptical spectroscopy by main lines of investigation.

Line of investigation	Year		
	1986	1997	2000
Design and optimisation of instruments	39	11	17
Development of methods for analysis	23	41	27
Combined analytical methods	18	22	31
Other applied studies	20	26	25

2. Use of spectrophotometric procedures

Thermooptical spectroscopy allows one to determine optical densities at levels as low as 10^{-8} (see Refs 4–6 and 297). For most compounds, the detection limits are 10^{-10}– 10^{-9} mol litre^{-1} (the absorbance is from $y \times 10^{-7}$ to $y \times 10^{-6}$).[21, 22, 38, 76, 77, 353, 354] Even higher sensitivites (detection limits are from $y \times 10^{-12}$ to $y \times 10^{-10}$ mol litre^{-1}) were achieved in some studies.[355, 356, 358–360] The main advantage of thermooptical methods is the possibility of measuring absorption of ultrasmall amounts of substances in volumes of about $y \times 10^{-15}$–$y \times 10^{-9}$ litre due to small diameters of focused laser beams.[72, 112–116, 167, 189, 191, 239, 261, 321, 322, 361–375] In studies by crossed-beam thermal lens spectrometry, the detection limit of iron(II) involved in the complex with 1,10-phenanthroline was 120 molecules in a volume of 0.2 pl, which was determined by the crossing region of the laser beams in a cell.[356] In addition, a series of recent studies were devoted to the use of thermal lens microscopy in microflow analysis of substances and for the detection in capillary electrophoresis, where the detection limits were as low as zepto- (10^{-21} mol) and yoctomolar (10^{-24} mol) levels (in other words, individual molecules were detected) (Refs 178, 215–227, 296, 325, 376, 377).

Numerous studies were concerned with compounds, which served as models for either estimating the instrumental sensitivity of spectrometers (or signal recording systems),[1, 3, 6, 272, 350–354, 356] or examining the influence of solvents on the thermal lens effect.[1, 73–75, 273, 352–354, 357] For this purpose, the following simple and stable compounds, which are resistant to laser radiation, were chosen: a solution of molecular iodine in carbon tetrachloride,[73, 272, 351, 355, 357, 358, 378] aqueous solutions of presynthesised copper(II) complexes with EDTA [272] and acetylacetone,[77] iron(II) complexes with 1,10-phenanthroline [22, 78, 79, 272, 273, 357] or its analogues [273, 352] and cobalt(II) complexes with 1-(2-pyridylazo)-2-naphthol [77] and ethylenediamine.[73, 351]

Some researchers attempted to apply known spectrophotometric procedures without modifications to thermooptical spec-

troscopy,[22, 26, 85, 108, 354, 356] which led to a decrease in the detection limits, but did not allow the researchers to gain the most benefit from the method. The successive formation of a thermal lens under irradiation at two or more wavelengths made it possible to determine microamounts of compounds, whose maxima of absorption bands differ by 10–20 nm, in the case of their simultaneous presence in the sample.[61, 62, 81]

Thermooptical spectroscopy methods were used for determining various organic compounds, primarily, those containing nitrogen or sulfur.[32–36, 69, 71, 184, 379] In addition to studies of artificial mixtures serving for comparison of different modes of chromatographic separation, several studies were devoted to analysis of natural substances,[21, 26, 36, 37] in particular, to analysis of industrial and household dyes,[306] and examination of the possibility of controlling products of organic synthesis.[25] Studies dealing with the determination of proteins at a level of 1–100 ng[26, 38, 66, 76, 85, 304, 379] and amino acids at concentrations of $y \times 10^{-15}$–$y \times 10^{-12}$ mol litre^{-1} also deserve attention.[108, 301, 380, 381] Procedures were developed for the thermal lens detection of nanogram amounts of particular high-priority biological and medical samples (theophylline,[88, 89] phenols,[382] acetyl choline,[383] *p*-aminophenol[384–386]).

Modifications of the known spectrophotometric procedures taking into account the characteristic features of thermal lens spectrometry is the most rational way of devising analytical thermal lens procedures for the determination of different classes of compounds. In recent years, studies of real substances have become typical of analytical chemistry.

Many studies in the latter field associated with a combination of the thermooptical detection and the known separation and concentration methods are considered below. Here let us mention the following applications of thermal lens spectrometry: the determination of iron(II) in blood plasma using bathophenanthroline at a concentration of $y \times 10^{-7}$ mol litre^{-1};[373] the evaluation of the total concentrations of soluble organic compounds in sea water;[34] the determination of iron(III) and aluminium in natural waters[387, 388] and pesticides in waters, vegetables and food;[389, 390] and the detection of P-, Si-, S- and N-containing compounds in real substances.[54]

Investigations of the characteristic features of the photometric determination of phosphorus and silicon from the formation of heteropoly compounds and application of intracavity thermal lens spectrometry made it possible to detect these elements in various substances (inorganic acids of special purity grade, semiconducting materials, *etc.*) at a level of 50–100 pg ml^{-1}.[2, 24, 86, 87, 298, 353] Procedures were developed for the detection of cobalt, nickel and iron with the use of nitrosonaphthol,[90] dimethylglyoxime[91] and 1,10-phenanthroline.[92] A combination of reliable photometric methods and a universal methodology for devising thermal lens procedures made it possible to achieve the detection limits of 0.2–10 pg ml^{-1} and the quantifiable concentration ranges from 3 to 5 orders of magnitude.

The development of a methodological basis of measurements, a consideration of thermodynamic and kinetic factors, which affect the selectivity and sensitivity of the detection and minimisation of test experiments substantially improve the metrological characteristics of thermal lens procedures for the detection of various compounds.[228, 229, 232, 274, 276, 283, 382, 391–406] These procedures were used for determining molybdenum[27] and copper[401] in sea water, cobalt,[90] nickel[91, 93] and iron[92, 93] in highly pure water, bismuth[28] and cobalt[90, 93] in highly pure metals and nickel in nickel-containing heteropoly compounds, which are used as active compounds in chemical sensor elements for the detection of ammonia in the atmosphere.[407] The use of thermal lens spectrometry allows one to reduce the number of stages of analysis of heteropoly compounds and increase the accuracy of the determination of nickel.

In recent years, new possibilities of thermooptical spectroscopy have attracted considerable attention. Besides, pioneering studies were carried out within the framework of conventional photometric experiments. For example, the advantages and drawbacks of photometric thermooptical measurements compared to classical spectrophotometric measurements were considered by researchers from the University of Lyon (France) (Refs 9, 57, 364, 367, 371, 373, 408–411). In addition to high instrumental sensitivity, thermooptical spectroscopy is characterised by having a substantially smaller dependence on light scattering and the possibility of detecting trace amounts of elements in samples. It should be noted that a photothermal spectrum does not coincide with the corresponding classical absorption spectrum (in particular, in the case of rare-earth metals),[412] which provides the basis for developing more selective and sensitive procedures for the detection of trace amounts of compounds. For example, procedures were designed to detect uranium(VI), neodymium(III) and praseodymium(III) at a level of 10^{-6}–10^{-5} mol litre^{-1} (Refs 24, 30, 413, 414).

Procedures for the determination of trace amounts, which cannot be used within the framework of conventional spectrophotometry (for example, for the determination of metals inolved in aqua complexes), deserve attention.[29, 43, 77, 86, 87, 353, 357] Studies devoted to thermal lens techniques for the detection of individual rare-earth metals and their mixtures[30, 31, 62, 70, 80] are of most interest. In this case, virtually no additional sample preparation is required, because absorption bands of aqua complexes of rare-earth metals are rather narrow, due to which they can be selectively determined in soils,[30] waters[80, 81] and uranium fuel[70] at a level of $y \times 10^{-7}$–$y \times 10^{-6}$ mol ml^{-1}. Dual-beam thermal lens spectrometry made it possible to determine the composition of a mixture of neodymium and erbium involved in aqua complexes at a level of $y \times 10^{-4}$ mol ml^{-1} against the background of a 50-fold excess of nickel glycinate.[62]

Accumulation of thermal energy in the sample under study was demonstrated to play an important role in the thermal lens detection of trace amounts of compounds, which adversely affect the accuracy of the determination.[32] Hence, it is necessary to optimise the set-up of a thermal lens spectrometer compared to the set-up of model measurements to provide the best sensitivity and reproducibility of thermooptical measurements of real samples.[32]

In recent years, successful attempts were made to extend the range of samples investigated by thermooptical spectroscopy. Procedures for the photometric determination of pyrogenic endotoxins from the main functional regions of their molecules (polysaccharides, lipids, the core region) were applied to the thermal lens detection of a total concentration of endotoxins in Pyrogenal and in an endotoxin sample from *E.coli* 0113 : H10, which is used for standardisation of biological assays. The detection limit of lipopolysaccharides is 70 ng ml^{-1}, which is comparable to the sensitivity of biological assays.[415–417] Let us also mention a method for the simultaneous evaluation of the concentration of hydroxy groups, the temperature and flow rate in the flame from the data of one experiment using thermooptical deflection spectroscopy,[418] where other methods do not work.[418]

a. Selectivity change

It is known that an increase in instrumental sensitivity imposes heavier demands upon the sample preparation. This problem, which is associated primarily with non-selective absorption, is typical of all highly sensitive methods. Hence, it is of first importance that the reagents and solvents be pure and the signal of the test experiment be low. However, a change in the reaction conditions in going to nanogram amounts of the reagents can lead to a substantial increase in selectivity of the thermal lens detection compared to the spectrophotometric method.

Let us consider several examples. It is known that the results of the spectrophotometric determination of bismuth by the iodide method are most affected by lead, tin, copper and antimony,[419–422] because poorly soluble iodides and sulfates of these elements are formed under the reaction conditions. The thermal lens detection of bismuth proved to be much more selective. Under new conditions, precipitates of poorly soluble compounds

are not formed and the selectivity is determined by absorption of metal iodide complexes.[423–425] The adverse effect of copper(II) on the determination of bismuth by the thermal lens method is much weaker than that in the case of spectrophotometric measurements and is manifested at concentrations four times as high as those in the case of monovalent copper ions. This effect can be due to the fact that the formation of copper(II) sulfate complexes cannot be ignored in dilute solutions containing sulfuric acid at a concentration of 0.02 mol litre^{-1}. These complexes inhibit reduction of copper(II) with iodide but do not hinder the detection of bismuth. Therefore, copper(II) is masked, which is manifested only in the determination of trace amounts of bismuth by the thermal lens technique.[403] The hindering effect of nickel, which is observed in the case of determination of iron with the use of 1,10-phenanthroline, also vanishes in going from micro- to nanogram concentrations of the reagents. This could be attributable to the fact that the nickel(II) complex is inert and is not formed in a sufficient amount during the sample preparation (20–25 min) at a level of $y \times 10^{-7}$ mol litre^{-1}.[392]

b. Sensitivity change

It is commonly assumed that sensitivity characteristics (detection limits, lowest quantifiable concentrations) depend primarily on the instrumental sensitivity of a thermooptical spectrometer (the laser radiation power and geometry of the optical scheme) as well as on the thermooptical characteristics of the medium [see Eqn (9)].[2, 4, 58, 276–279] However, a change in chemical interactions with decreasing concentration can enhance the sensitivity of the thermooptical determination of compounds in trace amounts.

For example, the lowest concentration of bismuth detectable by spectrophotometric and thermal lens techniques is 600 and 0.5 ng ml^{-1}, *i.e.*, the sensitivity increases by a factor of 1200.[18, 403] The thermal-lens enhancement factor E_0 is 160. The relatively low sensitivity of the spectrophotometric determination could be attributable to the fact that in the vicinity of the determination limit, an excess of potassium iodide is oxidised with atmospheric oxygen to form free iodine, which impairs the measurement reproducibility. In thermal lens measurements (because there is a large excess of ascorbic acid and a smaller amount of iodide), this fact can be ignored.[403]

The sensitivity of thermal lens measurements is additionally increased due to an increase in the degree of completeness of the analytical reaction at nanogram level. The real sensitivity coefficient of the thermal lens determination of phenols with the use of the azo-coupling reaction with *p*-nitrophenyl diazonium[382] increases by a factor of $\sim$100 compared to the spectrophotometric determination, and calculations according to Eqn (9) give an increase by a factor of 35–40. This is associated with the fact that the azo-coupling reaction is not completed under the conditions of spectrophotometric measurements (0.5 mg ml^{-1} of *p*-nitrophenyl diazonium, 0.1–1 μg ml^{-1} of the phenol); the yield of the product is $\sim$50%. Under the conditions of thermal lens measurements (0.01 mg ml^{-1} of *p*-nitrophenyl diazonium, 1–10 ng ml^{-1} of the phenol), the reaction is completed by 95%–99%, because the sensitivity of the determination is additionally increased by a factor of two.[382]

3. Determination of the fundamental characteristics of reactions at trace levels of components

A decrease in the concentration level of the reacting components is accompanied by a substantial change in the reaction conditions and different analytical effects.[27, 28, 32–36, 69, 71, 88–93, 184, 379, 400] This fact can be used for determining the reaction parameters, such as stability constants, acid dissociation constants, *etc*. It should be noted that measurements are carried in substantially more dilute solutions compared to those used in conventional spectrophotometry, which provides better measurement reproducibility.

Data on the thermodynamics and kinetics of the complex formation of nano- and picogram amounts of transition metal complexes with 1,10-phenanthroline, dioximes and diethyl dithiocarbaminates were collected based on the results of thermal lens experiments.[403–407, 426] The methods were developed for calculations of the overall and stepwise stability constants, characteristic rate constants, molar absorptivities (including those of intermediate complexes), acid dissociation constants and other characteristics obtained from thermal lens experiments.[18, 392, 403–407, 426] These studies showed that stability constants determined by thermal lens spectrometry have a higher accuracy, their values being one–two orders of magnitude lower than the stability constants determined by conventional spectrophotometry and potentiometry. When evaluating the stability constants by thermal lens spectrometry, one must take into account the changes in the kinetic characteristics of the reaction under study when changing from micro- to nanogram concentrations of the reacting components.[405, 406]

Thermal lens spectrometry provides a possibility of determining stepwise complexation constants (at concentration levels of components of $y \times 10^{-6}$–$y \times 10^{-8}$ mol litre^{-1}) in systems, where conventional methods do not work.[401, 402] In particular, the characteristic features of the complex formation in the bismuth(III)–iodide system can be judged at nanogram level from the stepwise stability constants evaluated by thermal lens spectrometry. In the case of copper(I) bis(1,10-phenanthrolinate), the stepwise stability constants can be determined by thermal lens spectrometry in more dilute solutions (large relative excesses of a competitive ligand, *viz*., acetonitrile, without changes in the composition of the medium).[401]

4. Kinetic applications

One of the modern trends in the development of thermooptical spectroscopy is the combination of thermooptical, kinetic and catalytic methods of analysis.[43, 44, 376, 427–447] The main advantage of this combination is the formation of a selective chemical analytical signal and its highly sensitive thermooptical detection. Also, the kinetic measurements have better reproducibility compared to stationary thermooptical measurements, because the accuracy of the determination is substantially improved.[44, 432] Another advantage of thermooptical spectroscopy is that it can be used for both the analytical determination and calculation of the kinetic constants.

Studies of the kinetics of interaction of metal ions with natural ligands (fulvic acids, humic acids, zeolites) and various photometric reagents in the presence of these natural ligands are among the most interesting applications.[387, 388] In these studies, procedures were designed for the determination of submicrogram amounts of copper, nickel, iron and aluminium in natural waters. These studies examined also the fundamental parameters of chemical interactions of the components in complex systems at trace levels. In particular, thermal lens spectrometry was used for measuring the characteristic rate constants with an accuracy of $\pm$0.001; the total absorbance change in the system was $>$0.003. The influence of light scattering on the thermooptical determination of metals and organic compounds was demonstrated [388] to be substantially smaller than that in classical photometric experiments. Studies of the reaction mechanisms of iron(II) tetrakis(4-sulfonatophenyl)porphyrin with carbon monoxide by photothermal deflection spectroscopy and the development of a procedure for the determination of carbon monoxide in biological samples[448] are interesting applications of thermooptical spectroscopy. The characteristic rate constants and activation enthalpies of the reaction were evaluated.

It should be emphasised that thermooptical spectroscopy can be used for studying both processes with very low quantum yields of fluorescence and processes characterised by substantial fluorescence of the products or reaction components. In the latter case, the results of thermooptical experiments supplement data

from luminescence spectroscopy, which allows one to characterise the reaction mechanism in much more detail and develop procedures for the simultaneous determination of several compounds in one experiment.[399] Undoubtedly, the main application of thermooptical spectroscopy is its use for enhancing the sensitivity of kinetic methods. The determination of nitrite ions and nitrate reductase by single-laser thermal lens spectrometry (argon laser, 514.5 nm, 800 mW) in an aqueous medium with a detection limit of 9 pg ml^{-1} (9×10^{-10} mass%) deserves attention.[43, 449] Compared to spectrophotometry, the detection limit was reduced by a factor of 20. The conditions of the thermal lens determination of *p*-aminophenol in paracetamol samples provide a detection limit of 100 ng ml^{-1}, which is an order of magnitude better than that obtained in most spectrophotometric and chromatographic procedures. Dual-beam kinetic measurements of a thermal lens signal (the excitation argon ion laser, 514.5 and 457.9 nm, 30 mW; the probe helium neon laser) were used for analysing binary gaseous mixtures.[61] The selectivity is provided by measuring the ratio of signals obtained at different wavelengths. The study,[442] in which the concentrations of heavy metals were determined in ancient animal remains, is yet another illustration of the possibilities of thermooptical spectroscopy.

The iron(II) complex with 1,10-phenanthroline (ferroin) is widely employed as a catalyst in the Belousov–Zhabotinsky oscillatory reaction.[450, 451] Bromide selective electrodes are most often used for monitoring the course of the oscillatory process.[452, 453] The bromate Belousov–Zhabotinsky oscillator, which was created on the basis of malonic acid as an organic substrate and iron(II) 1,10-phenanthrolinate as a catalyst and an indicator of the reaction pathway, was investigated.[391] The dependence of the physicochemical parameters of the reaction (the oscillation period, the lifetime of the system) on the starting concentrations of the reagents and the effect of additives of inhibiting ions on the system were examined. Under new conditions, the oscillation amplitude was demonstrated to increase compared to the oscillation amplitude under the conditions of spectrophotometric studies due to an increase in the fraction of ferroin involved in the reaction (the overall concentration of iron decreases), and the reproducibility of the oscillation period is improved.[391] The kinetics of the Belousov–Zhabotinsky reaction can be reliably monitored by thermooptical spectroscopy at iron concentrations of $y \times 10^{-6}$ mol litre^{-1} (which is impossible in studies using of most other procedures [454]), and the oscillation period can serve as an analytical signal.[391]

In recent years, a number of studies concerned with analytical applications of thermooptical spectroscopy have investigated of the enzyme kinetics. For example, a thermooptical biosensor for pesticides was designed on the basis of acetylcholine esterase.[389, 390] As a result, the time of analysis of organophosphate pesticides (paraoxon, chlorpyrifos, diazinon) and carbamate pesticides (carbaryl, carbofuran) was decreased to 15 min. The detection limits of pesticides were $y \times 10^{-7}$–$y \times 10^{-5}$ g litre^{-1}. The thermal lens method for the determination of pesticides was demonstrated to be rather inexpensive and does not require thorough sample preparation even for such complex substances as agricultural cultures.[390] In the study,[273] thermal lens spectrometry was used in combination with the enzymatic kinetic determination of dopamine with polyphenyl oxidase.

On the whole, the above examples demonstrate that a combination of thermooptical spectroscopy with kinetic methods of analysis holds promise. Particular new methods can be characterised as kinetic methods coupled with the thermooptical detection. In these methods, a detector plays a passive role. In applications which are not limited to the thermooptical detection of absorption, combinations of kinetic and thermooptical methods show unusual possibilities due to the use of thermooptical effects rather than their consequences (absorbance measurements). For example, new signals allow one to solve problems, which are otherwise impossible to solve.

In the diagram showing formation of analytical signals presented in Fig. 12, the following three groups of sources of analytical information can be distinguished: (1) photometric [the formation of coloured products, a usual slope (α) of the initial region of the kinetic curve]; (2) thermooptical (changes in the thermooptical characteristics of the medium, convective oscillations, auto-acceleration of coagulation of colloidal products); (3) sources directly dependent on laser radiation (temperature effects, photoinduced effects, *etc*.). For example, we can go from simple photometric thermooptical measurements, which are described by the equation,

$$\vartheta(c) \propto A\,(c), \tag{18}$$

to

$$\vartheta(c) \propto E_0(c)A(c), \tag{19}$$

where the factor $E_0(c)$ [see Eqn (9)] reflects the dependence of the thermooptical properties of the sample on the concentrations of the reaction products. Hence, $\mathrm{d}E_0(c)/\mathrm{d}t$ is a new analytical signal.

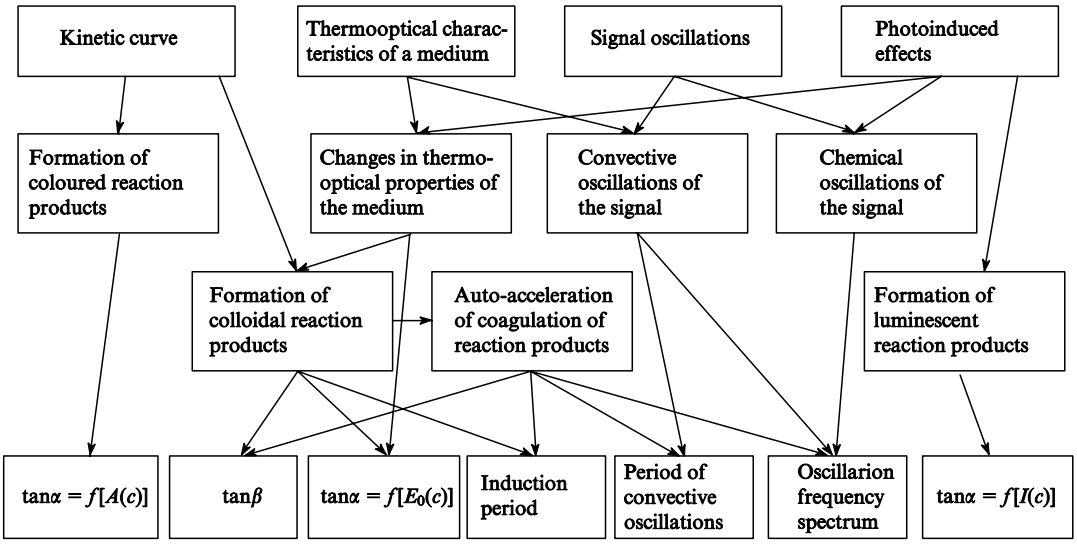

Figure 12. Scheme of formation of analytical signals in the kinetic thermal lens detection.
A is absorbance, α, β are slopes of kinetic curves.

In some cases, the thermooptical sensitivity $E_0(c)$ plays the major role. In particular, the spectrophotometric detection is inapplicable to the simultaneous determination of resorcinol and pyrocatechol by oxidation of bromate ions, because the molar absorptivity of the reaction products of resorcinol is no higher than 500 litre mol^{-1} cm^{-1}. Under the same conditions, the thermal-lens kinetic curves are characterised by good reproducibility and the detection limit of resorcinol in the absence of pyrocatechol is 5×10^{-5} mol $litre^{-1}$. Calculations showed that the factor $E_0(c)$ makes the major contribution to an increase in sensitivity of thermal lens measurements: the rate ratio $E_0(c)/dt : dA(c)/dt$ is 25 : 1. Therefore, the enhancement of sensitivity of thermal lens spectrometry due to changes in the thermooptical properties of the medium makes it possible to determine compounds, which cannot be detected by spectrophotometric methods.[283, 398, 399] In the case of the purely thermooptical detection, the kinetic equation takes the form

$$\vartheta(c) \propto E_0(c)A, \qquad (20)$$

where A = const. In other words, the equation is true if the reaction products do not absorb at the wavelength of the exciting radiation, and only thermooptical characteristics of a sample vary in the course of the reaction. In this case, the sensitivity of thermal lens measurements is provided by the addition of inert absorbing compounds. The range of compounds determined by kinetic methods can be substantially extended.

It was demonstrated that certain effects (changes in the thermooptical characteristics, auto-acceleration of coagulation of colloidal solutions of the reaction products in the region of thermal lens formation, a change in the period of convective oscillations of the thermal lens signal, *etc.*) can be used for determining the reaction components at trace levels. Components of mixtures can be determined by thermal lens spectrometry simultaneously (unlike spectrophotometric methods) due to the appearance of new analytical signals. In spite of an obvious complication of the system, the sensitivity of thermal lens measurements increases with no sacrifice in reproducibility.[384, 398]

Kinetic thermal lens measurements are used for measuring spectra of intermediate states. The changes in the enthalpies of the ketone and enol forms of 7-hydroxyquinone were evaluated by thermal lens spectrometry. The enol form was demonstrated to prevail in the ground state, whereas the ketone form prevails in the excited singlet state.[455] The quantum yield of the formation and the lifetime of the triplet state of pyridine in the liquid phase were measured [456] under two-photon excitation. In both cited studies, information was extracted from the analysis of the fast and slow components of the thermal lens signal after laser pulse absorption. The absolute quantum yield and the lifetime of singlet molecular oxygen sensitised by haematoporphyrin in ethanol were also estimated from the analysis of these components.[457]

Specific effects, which are directly associated with the nature of the thermal lens effect and, primarily, with the changes in the thermooptical and colloidal properties of the medium, are manifested in thermal lens measurements performed in systems involving an oxidiser (bromate or periodate ions), an organic reducing agent (aromatic amines or phenols), a catalyst (vanadium ions) and an activator (phenols, hydroxy acids).[458]

To conclude of this section, let us consider the kinetic effects observed only in thermal lens studies of known analytical reactions. Investigations of the stability of transition metal complexes with 1,10-phenanthroline by thermal lens spectrometry showed that the rate of formation of the iron(II) complex with 1,10-phenanthroline at pH 0–2 decreased substantially,[392] which was not observed in spectrophotometric studies.[459] Even more substantial differences in the results were found in studies of stability of iron(II) tris(1,10-phenanthrolinate) by thermal lens spectrometry and spectrophotometry. In spectrophotometric studies, the pH range for the formation of the complex coincides with the pH range of its decomposition, whereas at iron concentrations of $y \times 10^{-7}$ mol $litre^{-1}$ the complex decomposes at pH 1 only after one day, which differs from dissociation of ferroin at a concentration of $y \times 10^{-5}$ mol $litre^{-1}$.[460–462] A change in kinetic stability of the iron(II) complex with 1,10-phenanthroline at low pH can have an analytical application. Since the iron(III) complex is formed in an even more alkaline medium,[463] iron(II) can be determined in the presence of iron(III).

5. Use of thermooptical methods in flow analysis, high-performance liquid chromatography and capillary electrophoresis

Thermooptical spectroscopy holds considerable promise and is finding rapidly increasing analytical use for detection in HPLC, capillary electrophoresis, continuous flow and flow-injection analysis. The main advantage of this approach is the possibility of combining selective separation of the analyte components and their highly sensitive non-destructive detection in one instrument.

A large number of studies were devoted to the coupling of thermal lens spectrometry with HPLC (Refs 4, 6, 23, 36–43, 49, 106–111, 178, 377–379, 393, 408, 409, 464–480), capillary electrophoresis (Refs 45, 46, 112–116, 310, 311, 380, 381, 481–504) and various modes of flow-injection analysis.[73, 117, 389, 394, 395, 444, 505–510] Several reviews have dealt with these problems.[8, 10, 23, 84, 115, 220, 468, 471]

a. Flow analysis

Flow-injection analysis is an important area of application of thermal lens spectrometry.[73, 117, 394, 444, 505, 507–509] No universal detectors were designed for this analysis, and the choice of the detection method depends primarily on the purpose of a particular investigation. In flow-injection systems, the flow rates are generally 1–5 ml min^{-1}. In these experiments, peristaltic pumps are used instead of plunger pumps, which are employed in HPLC. Hence, noise, which is caused by flow pulsations and masks the thermooptical effect, is the most serious problem associated with the use of photothermal detectors. Nevertheless, due to the highly sensitive detection of absorption in automated analysis of solutions, thermooptical spectroscopy can be considered as one of the most promising detection methods in flow-injection analysis.

Models of changes in the thermal lens signal under flow conditions were proposed.[56, 58, 73, 78, 297] The thermal lens method was devised for the flow determination of Cu(II), Co(II), Fe(III), Bi(III), Nd(III), Pr(III), Al(III), Cr(III), Mn(II), Zn(II) and Pb(II) by the reaction with Xylenol Orange at pH 4.5 in aqueous solutions.[394] The influence of the reactor length and its temperature on the sensitivity and reproducibility of measurements was examined. The detection limits are $y \times 10^{-7}$ mol $litre^{-1}$, the quantifiable concentration ranges are $\sim$1.5 orders of magnitude.[394, 395] The absorbance can be measured in flow up to 1×10^{-6} using a dual-beam scheme (argon laser, 458 nm, 100 mW).[58, 59] The detection limit achieved in the colorimetric determination of iron(II) as a complex with 1,10-phenanthroline was 40 pg of iron in 100 μl of a sample at a flow rate of 0.5 ml min^{-1}. Organic dyes were detected at levels of $y \times 10^{-7}$ mol $litre^{-1}$ by flow-injection analysis coupled with photothermal refraction spectrometry.

b. High-performance liquid chromatography

A large number of combined analytical procedures employ thermooptical methods and HPLC. Universal spectrophotometric methods are widely used for detection in HPLC. In this case, the sensitivity is determined by the optical path length in a detector cell. The sensitivity of such detectors decreases substantially in going to capillary and microcolumn chromatographic systems. If a capillary is several micrometers in length, a conventional photometric detector actually does not work.

On the whole, thermooptical spectroscopy works well in HPLC. The main advantages of this method, *viz.*, high sensitivity and a small detectable volume, have been exploited in the majority of liquid chromatographic methods. As a rule, photothermal detectors decrease the detection limits by two–three orders of

magnitude compared to analogous methods employing the spectrophotometric detection.[11, 16, 58, 297]

A dual-beam optical scheme of thermal lens measurements with a coaxial arrangement of the excitation and probe beams in a detector cell is successfully employed in high-performance liquid chromatography. This method was used for determining various organic and inorganic compounds.[11, 389, 468, 469, 475, 505, 506, 511, 512] The sensitivity achieved in ion chromatography is more than three orders of magnitude higher than that of the photometric detection.[312, 313]

An attempt was made not only to create a model of a thermooptical detector for HPLC but also to devise algorithms of data collection and processing which are specific for the conditions of thermooptical detection in chromatography.[312, 313, 393, 397, 513] The optical set-up of a thermal lens spectrometer was optimised taking into account expert estimates,[274] according to which a substantial gain in spectrometer sensitivity is achieved for all optical schemes.

Most studies performed by thermal lens spectrometry coupled with HPLC were devoted to analysis of organic compounds. A combination of HPLC with the thermal lens detection was used to detect amino acids,[108, 474] nitro derivatives of aromatic compounds,[378, 514, 515] catecholamines[478, 479] and carotenoids (Refs 408, 475, 511). Thermal lens spectrometry, photothermal refraction spectrometry and other thermooptical methods are employed for constructing detectors for chromatographic analysis of organic compounds. The thermooptical detection in capillaries gives better results compared to those obtained with the use of standard cells due to the absence of liquid turbulence in the detection region. Dabsyl derivatives of amino acids were detected by reverse-phase HPLC coupled with photothermal refraction at a level of 10^{-15} mol litre^{-1}. In addition, thermooptical detectors are employed in analysis of dye compositions and for the quality control of products of industrial organic synthesis.

The detection of inorganic compounds has been studied less. After separation, cobalt(II), copper(II), manganese(II), nickel(II), iron(III), zinc(II) and lead(II) cations were determined by ion chromatography according to the post-column reaction with 4-(2-pyridylazo)resorcinol.[516] The influence of noise from a flow reactor on fluctuations of the thermal lens signal was examined.[517] A method was proposed for the determination of trace amounts of elements by HPLC coupled with the thermal lens detection. Procedures were developed for the detection of neodymium and uranium at nanogram levels.[518] Double-beam thermal lens spectrometry was used for detecting chromium(III) and chromium(VI).[42] In this case, pre-column derivatisation of chromium(III) with pyridine-2,6-dicarboxylic acid and of chromium(VI) with diphenylcarbazide was used. The detection limits of chromium(III) and chromium(VI) were 30 and 0.3 ng ml^{-1}, respectively.[42, 512, 519]

Various modifications of the thermal lens technique were used in combination with capillary liquid chromatography.[149–153, 184, 409, 473, 476, 477] In this mode of HPLC, crossed-beam thermooptical systems (photothermal refraction and mirage spectroscopy) are generally used for the detection. A prerequisite to the use of such systems in capillary liquid chromatography is the possibility of measuring the thermooptical characteristics of samples of very small volumes (as small as $y \times 10^{-9}$ litre). This method was used for detecting amino acids as dabsyl derivatives at femtomole levels (10^{-15} mol).[108] Other thermooptical spectroscopy methods were also employed in capillary liquid chromatography. For example, nitropyrene and dinitropyrenes were determined with the use of a pulsed photothermal refractometer as a detection system.[379]

In spite of the large number of studies devoted to applications of thermooptical spectroscopy in HPLC, there are no universal combined methods. Studies dealing with the complex and comprehensive examination of the possibility of combining HPLC with thermooptical detection methods are scarce. Nevertheless, taking into account the characteristic features of both methods,[112–117, 377, 464–467, 469, 472, 475, 480] their combination would be expected to provide a basis for devising a new analytical method.

Thermooptical methods are also used for the highly sensitive detection required in thin-layer chromatography.[33, 500, 520] A photothermal detector for this chromatographic method was constructed on the basis of the mirage effect induced by pulsed laser radiation.[33]

c. Capillary electrophoresis

Nowadays, thermooptical spectroscopy is being extensively employed as a detection method in capillary electrophoresis.[108, 115, 116, 297, 301, 310, 380, 381, 473, 481–491, 493, 496–500] This combined method has a wide application in the detection of amino acids.[108, 116, 301, 380, 381, 482–488] The determination of amino acids as their dabsyl derivatives at a level of 10^{-12} mol litre^{-1} was described.[380] Unlike HPLC and flow analysis, not all detection methods are suitable for this separation method. Thermooptical methods (thermal lens spectrometry, photothermal refraction spectroscopy and the thermal prism method) are among the best detection methods in capillary electrophoresis. After the reaction with 4′-(dimethylamino)azobenzene-4-sulfonyl chloride, amino acids were determined at a level of several attomoles by probe capillary electrophoresis coupled with the thermooptical detection.[381, 501] Twelve amino acids were determined using the thermooptical detection during 13.5 min.[496] The detection limits were $\sim 10^{-7}$ mol litre^{-1} (or 100 fg in an injected volume of 0.6 nl). The authors of the cited study emphasised that the linearity range was substantially larger than that achieved in the spectrophotometric detection and covers more than four orders of magnitude. In the study,[521] traces of amino acids (tryptophane and phenylalanine) were detected without derivatisation at a level of tens of femtomoles by the photothermally induced capillary vibration method at the second harmonic wavelength of an argon ion laser (257.2 nm, 5 mW). In this study, the results of determination of vitamin B_2 were also reported; the detection limit at the excitation wavelength (476 nm) was 80 attomoles (the absorbance was 1.8×10^{-7}), which is three orders of magnitude larger than the detection limits reached with the use of alternative methods for absorption measurements.[521]

Methods of thermooptical spectroscopy are employed also for the detection of other organic and biologically active compounds, such as components of food additives,[466] proteins,[486] nucleotides,[485] metabolism products[492] and pesticides.[243] It should also be noted that thermooptical spectroscopy was used to determine the sequences of amino acids in DNA, peptides, *etc*.[522] In recent years, a number of studies were devoted to the determination of drugs, primarily, of antidepressants.[310, 523]

Methods of thermooptical spectroscopy are widely used also in inorganic analysis, for example, for the simultaneous detection of cations and anions (involved in coloured compounds) at levels of 10^{-12}–10^{-10} mol litre^{-1}.[493] In analysis of real samples, thermal lens spectrometry in the near-field region was employed for the determination of iron and nickel using 1,10-phenanthroline[311] and bathophenanthroline,[524] respectively. For iron, the detection limit was 4×10^{-8} mol litre^{-1}.[310]

As demonstrated above, the main processes attendant on the formation of thermooptical elements (heat transfer and the formation of the temperature profile of the refractive index) are directly related to the thermooptical characteristics of the medium (thermal conductivity, heat capacity, the temperature gradient of the refractive index). Changes in the latter provide the possibility to control the signal. For example, the sensitivity of thermal lens detection in capillary electrophoresis using an aqueous-acetonitrile mixture or an aqueous-methanolic mixture increases by an order or half-order of magnitude, respectively, compared to that achieved in the case of aqueous buffer solutions. The experimental data agree well with the results of calculations. Under the above-considered conditions, the detection limits of a number of organic compounds (phenol and aniline derivatives) are 10^{-8}–10^{-7} mol litre^{-1}.[310]

6. Microanalytical systems

A recent trend is to miniaturise instruments and equipment for chemical analysis and integrate all stages of analysis (sampling, sample preparation, separation, concentration processes, analytical reactions and measurements of an analytical signal) in one small (supercompact) device. Presently, such devices (called 'microanalytical systems' (micro-Total Analysis System, μTAS) or 'laboratories on a chip') are used for solving various problems of analytical chemistry, biochemistry, synthetic chemistry and biotechnology.[220,525] Chemical microchips are generally constructed with the use of state-of-the-art microtechnologies, and they often have a planar geometry. Glasses, quartz, various plastics, silicon and (more rarely) metals serve as materials for microchips. As a rule, a microchip scheme includes reservoirs for reagents, reaction circuits or microvessels, microcolumns or capillaries and communications with linear sizes of $y \times 10^{-9}$–$y \times 10^{-4}$ m.[232,443–445] In addition, micropumps, voltage sources and electrodes can be integrated into a microchip.[525] In some cases, a detector is also integrated into a microchip, although a microchip contains only a detection zone (generally optical) and an interface equipped with an external detector.[525]

A consequence of miniaturisation of analytical detection systems and their integration in a single device is a decrease in the volumes of samples (to $y \times 10^{-10}$ litre), reagents, solvents and wastes (to $y \times 10^{-6}$–$y \times 10^{-7}$ litre) and reduction of the analysis time compared to conventional analytical instruments. In addition, the principal distinguishing features of chemical microchips are that they differ (compared to macrosystems) in the conditions of heat and mass transfer and separation in microchannels, which provides the possibility to construct unique analytical devices and devise new procedures.

Due to a tendency to combine advantages of microchips (integration, compactness, the possibility of using the modern achievements of flow-injection analysis, capillary electrophoresis, HPLC, *etc*.) and detection by thermooptical spectroscopy (sensitivity, locality, high response rate), many studies devoted to microchips were performed with the use of thermooptical spectroscopy (Fig. 13), and the detection limits were declared to be several molecules or tens of molecules.[219,224,325,376,377]

The main fields of application of integrated microanalysis systems are as follows: (1) analytical chemistry (immunoassay methods, capillary electrophoresis, flow-injection analysis, extraction processes, enzymatic catalysis); (2) synthetic chemistry (transfer reactions at the liquid–liquid interface, influence of thermal, electrical and magnetic fields on reactions in microchannels, polymerisation); (3) studies in the field of cell biochemistry. Photothermal deflection spectroscopy, thermal lens microscopy and wavelength-tunable thermal lens microscopy are employed as the main instrumental approaches. The major achievements are associated with the detection of individual molecules, studies of the nanospace and spectroscopy of the liquid–liquid interface. Let us illustrate the above with typical example.

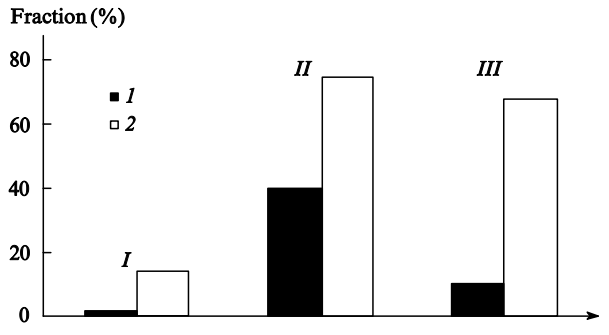

Figure 13. Distribution of studies in the field of thermooptical spectroscopy using macro- (*1*) and microsystems (*2*).
I — applied spectroscopy, *II* — analytical chemistry, *III* — commercial studies.

Methods of thermal lens microscopy were used in microflow-injection analysis of L-ascorbic and dehydroascorbic acids by reduction of iron(III) in the presence of 1,10-phenanthroline[228] and analysis of epinephrine and other catecholamines by their oxidation with sodium periodate.[526] The detection limit of ascorbic acid was 1×10^{-7} mol litre^{-1} (the absolute quantifiable amount of the compound was 3×10^{-20} mol), which is at least one-and-a-half orders of magnitude lower than the determination limit of this acid by capillary electrophoresis coupled with the electrochemical detection[527] and surpasses the known pharmacological method in sensitivity.[528] The procedure was used to determine ascorbic acid in urine and pharmaceutical samples.[228] The sensitivity of detection of catecholamines was as high as $y \times 10^{-6}$ g litre^{-1}, which allows one to use microflow analysis coupled with the thermooptical detection in clinical analysis. The method was employed for the determination of epinephrine, norepinephrine, dopamine and L-dopa in injection samples.[526]

An integrated microanalysis system equipped with a thermal lens detector and an additional IR laser was used for the rapid monitoring of enzyme reactions in flow.[444] Photothermal heating of a liquid flow in a small volume (5 nl) made it possible to heat and cool analyte solutions at rates of 50–60 K s^{-1}, which are an order of magnitude higher than that achieved in conventional heaters and 3–6 times higher than the heating rate of electrothermal microheaters. In enzyme reactions of hydrogen peroxide with 4-aminoantipyrine and *N*-ethyl-(*N*-oxy-3-sulfopropyl)-*m*-toluidine in the presence of horseradish peroxidase, the concentration of substrates can be determined by the thermooptical techniques with a time resolution of 0.6 s at a level of $y \times 10^{-4}$ mol litre^{-1}. In this case, the formation of reaction products depends completely on heating the flow with an IR laser beam and can be determined with high reliability.[444] The minimum reaction volume and the minimum quantifiable amount of the reaction products are 10 nl and 100 fmol, respectively.[445]

A microsystem equipped with a scanning thermal lens microscope deserves attention.[529] This microsystem was employed to study processes in a cell *in vivo*. It should be noted that nonfluorescent reagents can be used, and the detection does not require markers. The spatial resolution of the instrument is 1 μm, and the minimum absolute quantifiable amount of a compound (cytochromes in mitochondria) is 10^{-22} mol.[529]

A microimmunoassay analysis system coupled with the thermooptical detection was used for determining the oncofetal antigen, which serves as a marker of pancreatic cancer.[222] A specially designed microchip, was partially filled with polystyrene granules containing immobilised antibodies to this antigen. A sample of blood plasma with the marker under investigation and a solution containing free antibodies and antibodies immobilised on colloidal gold particles were passed through a microchannel. An interaction gave rise to complexes of the antigen with three antibodies immobilised on the surface of granules, whose concentration was measured on a thermal lens microscope. The determination limit of the oncofetal antigen was an order of magnitude lower than the limit achieved in an immunoassay (ELISA).[530] The results obtained in clinical tests were in good agreement with the results of the determination of the antigen by conventional methods. Analogously, an immunoassay combined with the thermooptical detection on chemical microchips was used for determining human immunoglobulin in blood[446] and gamma interferon.[481] In these experiments, the analysis time was halved due to the use of microanalytical systems. The time of determination of the oncofetal antigen was reduced from 24 to 1 h. In all cases, the detection is characterised by very simple procedures, which are presently under clinical tests.

The possibilities of thermal lens spectrometry coupled with microanalytical fluid devices are also well exemplified by studies of molecular transport in a three-phase water–cyclohexane–water flow system (in a microchannel, the thickness of the organic

phase sandwiched between two aqueous systems, was 64 μm).[510] Under these conditions, the distribution parameters of Methyl Red were determined.[510] Such experiments can be carried out only with the use of integrated microanalysis systems (under these conditions, an organic phase exhibits membrane properties). As in the above-described case, non-fluorescent compounds can be used, which substantially extends the scope of this method. In particular, a theoretical model of molecular transport through a liquid organic membrane under microflow conditions was proposed in the study.[531] This model can find use in biochemical investigations.

A number of recent studies have been aimed at designing microanalytical systems, which combined, for example, flow-injection analysis and immunoassays,[222, 481] capillary electrophoresis and the detection on a microchip by thermal lens microscopy [315] and the detection with the use of interferometer-based microsystems.[532]

Full spectrum lamps were used in the study [315] for inducing a regular thermooptical effect. In this case, a thermooptical element is formed not due to a spatial distribution of the intensity in the incident beam but due to formation of the heat outflow profile as a result of a specially chosen shape of a microchannel in a microchip. In this case, the thermooptical detection is the only possible way of forming an analytical signal, and a thermal lens detector is completely integrated in a microanalysis system.

A combination of thermooptical spectroscopy and integrated microanalysis systems is employed not only in analytical and bioanalytical investigations but also for the synthesis of compounds in a microflow with the thermooptical detection of the products in a real-time mode.[218, 219, 223, 316, 317, 533, 534] These methods are based primarily on two-phase systems under flow conditions giving rise to coloured reaction products at the interface and the thermooptical detection of the compounds in the organic phase. These methods are characterised by high selectivity of reactions at the interface and high sensitivity of thermooptical detection in organic media. In particular, this combination of methods was proposed for use in studies of azo-coupling reactions [218] and alkylation.[317]

Of analytical applications within the framework of this approach, a selective method for the detection of potassium and sodium ions is worthy of notice.[223] This method is based on the formation of a two-phase system in a microchannel. The organic phase in this system contains the ions under study, whereas the organic phase is composed of several solutions of ionophores added successively. The solutions contain also a lipophylic non-selective acid – base indicator. The ionophores selectively interact with the ions (in the case under consideration, valinomycin reacts with potassium ions, and dibenzo-16-crown-5 derivatives react with sodium ions). Interactions of ionophores with the ions lead to extraction of the latter into the organic phase, resulting in a change in the colour of the indicator, and the ions are detected using a thermal lens microscope.[219] In addition to high sensitivity of detection, this approach is fast, which is an obvious advantage over an optrode detector.[535] The thermooptical detection in microchannels is characterised by a short diffusion time and rapid response of the thermooptical detector (the overall time of analysis is 8 s).[219] In the case of an optrode, the system response is rather slow because of slow diffusion of the ions in the optrode membrane. In addition, a micromode of measurements allows one to use substantially smaller amounts of expensive reagents. In particular, the detection of subnanogram amounts of potassium and sodium necessitates 0.5 μl an organic solution of the reagent. For one test, 2 ng of ionophores and 3 ng of an indicator are required. On the whole, the thermooptical detection leads to an increase in the sensitivity of determination of sodium and potassium by an order of magnitude compared to that achieved with the use of an optrode detector.[535]

7. Specific fields of application of thermooptical methods

a. Role of the solvent. Non-photometric thermooptical spectroscopy

The highest sensitivity, *i.e.*, the maximum factor E_0 [see Eqn (9)], can be achieved by choosing a medium characterised by a high temperature refractive index and low thermal conductivity. In this respect, aqueous solutions are inferior to non-polar solvents (benzene, carbon tetrachloride, saturated hydrocarbons) as a medium for thermal lens measurements. For example, low concentrations of 9-nitroanthracene were determined in various solvents, and the detection sensitivity in n-pentane was demonstrated to be twice as high as that in methanol and 40 times higher than that in water.[536]

However, water has a number of advantages, because it is available, can be easily purified and serves as a convenient reaction medium. It should also be taken into account that fluctuations of the thermal lens signal in aqueous solutions are much weaker than those in organic solvents.[93] As a result, the determination limits in aqueous solutions are lower than those in organic solvents.[93, 271]

Aqueous-organic mixtures can be considered as solvents of choice for thermooptical measurements. On the one hand, convenient conditions for both the sample preparation and the photometric reaction in an aqueous medium are provided. On the other hand, high values of the E_0 factor ($3-5$ mW^{-1}) typical of organic liquids are achieved.[396, 537] As an example, Fig. 14 shows the ranges of detectable concentrations of the same compound in aqueous, organic and aqueous-organic media.[271]

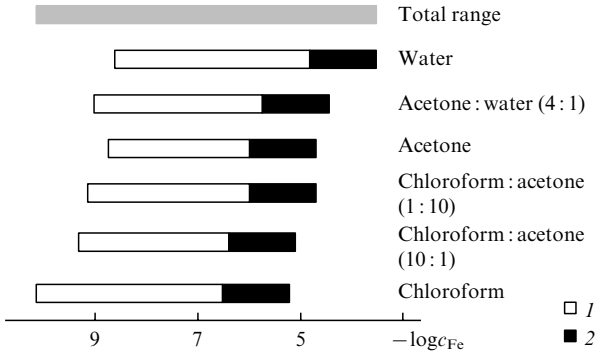

Figure 14. Ranges of quantifiable concentrations of iron(II) tris(1,10-phenanthrolinate) by thermal lens spectrometry in various solvents; the power of laser radiation inducing a thermal lens is 400 (*1*) and 40 mW (*2*).[271]

Due to the fact that the sensitivity of thermooptical measurements depends on the characteristics of the medium, thermooptical spectroscopy can be used for determining characteristics of the medium, such as the thermal conductivity, viscosity, density and the temperature dependence of the refractive index.[285–288] The results of determination of these characteristics for benzene, toluene, carbon disulfide, acetone, methanol and white Burgundy wine from the time evolution of the thermal lens signal correspond to the reference data.[286] Dual-beam thermal lens spectrometry was used to measure the thermal conductivity coefficients of krypton, carbon dioxide, methane, ethane, propane and butane.[288]

It was demonstrated that trace amounts of colourless organic compounds in water can be determined with the use of the thermal lens signal as a function of thermooptical characteristics of a medium (the thermal conductivity, viscosity, density, the temperature dependence of the refractive index, *etc.*) rather than as an analogue of the absorbance. For example, the determination limits of ethanol and DMSO thus determined are 0.05 and 0.04 mass %, respectively.[513]

b. Photochemical thermooptical spectroscopy

The high power and intensity of laser radiation in thermooptical spectroscopy are responsible for initiation of photochemical processes involving reaction products and reagents (Refs 281–284, 411, 430, 440, 538–545). These effects were observed often.[440, 538–540, 542, 543] However, they have attracted considerable attention only in recent years. One of the pioneering series of studies was devoted to photoreduction of complex heteropoly acids of phosphorus and silicon in ethanolic solutions giving rise to bright coloured reduced forms of heteropoly acids (the determination limits $y \times 10^{-9} - y \times 10^{-8}$ g ml^{-1}, see Refs 298 and 546).

Thermal lens spectrometry can be used to study the kinetics of photodecomposition and the formation of radicals in various solvents. For example, the photochemical reaction involving the 2-naphthylmethyl radical was discovered,[430] and the behaviour of benzophenone in acetonitrile and propan-2-ol was investigated.[545]

Photochemical thermooptical spectroscopy is used to determine the thermodynamic characteristics (the enthalpy, entropy and free energy) of chemical processes and to control the parameters of chemical reactions by varying the intensity of excitation laser radiation.[455, 538, 541, 547] Procedures in which the thermooptical detection is coupled with a method for concentrating an analyte component photoinduced by the laser beam,[548] photocatalysis and photocoagulation [398, 399, 549] are similar to the above-described thermooptical measurements.

c. Thermooptical cytometry

Two studies [550, 551] have laid the groundwork for thermooptical cytometry. The method is based on measurements of the response of living cells to short-time heating induced by a laser pulse. Elements of the theory of thermooptical microscopy in a pulsed mode of operation of an excitation laser were developed. The method was used for non-destructive control of living cells,[552–554] control of selective photothermolysis, investigations of DNA and studies of defects and impurities in ultrapure optics and semiconductors. This method can be performed in modes of thermal lens spectrometry, photothermal deflection spectroscopy and photothermal radiometry.

8. Colloidal systems

a. Coarsely dispersed colloidal systems †

Coarsely dispersed systems, *viz*., coarse slurries, suspensions and emulsions, are most often used in thermooptical measurements.[4, 18, 37, 38] Several studies [54, 295, 529, 555, 556] were concerned with measurements of thermooptical deflection of the probe laser beam from the reflecting surface formed by large suspension particles. In the case of spontaneous formation of coarsely dispersed systems, the efficient power of the excitation beam decreases proportionally to the number of reflecting particles and, consequently, the detection sensitivity decreases, which limits the use of these systems in analytical practice.[398, 399]

b. Finely dispersed colloidal systems

Finely dispersed systems with particle sizes $y \times 10^{-7} - y \times 10^{-9}$ m also affect the sensitivity of thermooptical detection. In this respect, surfactants are of considerable interest (Refs 4, 18, 47, 397, 410, 536, 537, 557). A micellar mechanism of modifications of thermooptical properties of a medium involves an increase in the temperature gradient of the refractive index and a decrease in the thermal conductivity coefficient due to disruption of the rigid water structure.[558]

In the study,[557] the concentrations of the hydrophilic salt TbCl were determined using surfactants, which form micelles with the analyte in non-polar solvents. The thermal lens signal corresponding to the absorbance of 1×10^{-7} was recorded. The simultaneous determination by fluorescence spectroscopy and the thermal lens techniques demonstrated that the determination limits of tetracycline in the presence of Triton X-100 are three times lower than those in the absence of the surfactant.[410] The micellar effect in aqueous solutions was examined in the study of 9-nitroanthracene.[536] Being highly soluble both in polar and non-polar solvents at concentrations lower than $y \times 10^{-7}$ mol litre^{-1}, this compound was chosen for testing the validity of the assumption that the change in the thermal lens signal depends only on the thermooptical characteristics of the medium. The mechanism of interaction of this signal with surfactants of different nature was elucidated and it was noted that the thermal lens signal strength is proportional to the degree of hydrophobicity of the environment of the molecule.[536] This fact was confirmed by the data obtained in the study of 9-nitroanthracene derivatives. The presence of long hydrocarbon chains is favourable for higher solubilisation, which leads to a substantial increase in the signal strength.[536]

It was demonstrated [47] that microemulsions can be studied by thermal lens spectrometry. Microemulsions of differently charged particles were studied above and below their percolation threshold. Microemulsions of negatively charged particles are subjected to percolation at rather high concentrations of surfactants (30%), and the thermal lens signal is independent of the water content. Apparently, microemulsions consist of small reverse micelles, and this structure exists both above and below the percolation threshold. In contrast, percolation of microemulsions of positively charged particles occurs at relatively lower concentrations of surfactants (10%), and the thermal lens signal depends on the concentration of water in the system.[47] Consequently, the structure of these microemulsions changes upon percolation, and these microemulsions above the percolation threshold consist of large bound aggregates or two-dimensional structures.[47]

It was proved [557] that an increase in the thermal lens signal upon the addition of surfactants occurs primarily due to an increase in dn/dT of the solution. The influence of surfactants and various dissolved compounds on the water structure can be characterised by the following two parameters: the temperature at which $dn/dT = 0$, and the temperature dependence d^2n/dT^2. These parameters decrease upon the addition of substances disrupting the water structure (for example, of urea), whereas the addition of, for example, *tert*-butyl alcohol leads to an increase in these parameters.[47, 557] The molecular structure of the surfactant plays an important role in the observed effect. A reduction of water structurisation is more pronounced when a surfactant exists in the micellar rather than monomeric form.[557] The disruption of the water structure in the presence of surfactants, such as polyoxyethylene lauric ester (**1**), hexadecyltrimethylammonium bromide (**2**), 3-(*N*-dodecyl-*N*,*N*-dimethylammonium)propane-1-sulfonic acid (**3**) or sodium dodecylsulfate (**4**), was examined. At concentrations of a surfactant lower than the critical micelle concentration, this effect decreases in the series **1** > **2** > **3** > **4**. For micellar solutions, **1** > **2** = **3** = **4**.

The characteristic features of thermooptical non-linearity in cast films of polymer-encapsulated nematic liquid crystals were studied experimentally. The dynamics of changes in the light transmission of the film on heating of liquid crystal drops by a laser radiation pulse was examined.[559]

IV. Study of interfaces in condensed systems

Photothermal methods have wide application in studies of interfaces in condensed heterogeneous systems.[176] They are virtually the only methods suitable for non-contact studies of the thermal and optical properties of condensed phases. The use of photothermal methods in studies of interfaces is dictated primarily by the necessity of solving a number of important problems [158, 173, 560–563] associated with experiment planning. The characteristic features of photothermal methods were efficiently

† This section deals with colloidal systems, in which liquids serve as a dispersion medium. In the case of colloidal systems, thermooptical spectroscopy examines changes in the macroproperties of solutions caused by changes in the number and size of colloidal particles.[4]

used in specific investigations concerned with the dynamics of absorption processes [119, 183, 564–577] and the extraction equilibrium in microspace.[219, 223, 531] Non-transparent solid samples with smooth and rough surfaces [158, 172, 173, 212, 563, 578–586] and transparent substances, including transparent films (Refs 174, 562, 587–594), were also studied by these methods. Modern apparatus allows one to perform two- and even three-dimensional surface imaging.[174, 579, 583, 593]

1. Physical models

Simulation of experiments with consideration for all characteristic features of the system under examination and apparatus employed gives the best results. The main results in this field are concerned with the solid–gas (air) interfaces. The influence of the form of the energy profile in a pulse on the thermal response was examined by the mirage effect method,[158] and the theoretical data were compared with the experimental results with and without considering this form. Investigation of a gold (1.5 μm)/tetrahedral amorphous carbon (80 nm) coating on a silicon substrate demonstrated that the thermal properties of carbon are virtually independent of the pulse form, whereas the correct characterisation of the thermal properties of gold requires that the pulse form of the incident laser radiation be taken into account. This approach simplifies the mathematical apparatus for the description of multilayer structures of semiconducting products.[560, 561]

A model for simulation of the photothermal beam deflection (for a perpendicular crossed-beam configuration of an instrument) in samples, including weakly absorbing thin films on substrates with high light absorption, was considered in the study.[562] The model was employed to determine the thermal conductivity of thin films on substrates. The influence of the intersection angle of the excitation and probe beams at the sample, the modulation frequency of the excitation beam, the thickness and absorption of the thin film and the thermal properties of the substrate on the thermal conductivity of thin films was discussed. This method proved to be suitable for thermal conductivity measurements of thin films with high thermal conductivity, for example, of diamond and diamond-like carbon films deposited on substrates with relatively low thermal conductivity at low modulation frequencies.

The crossed-beam configuration of the optical scheme of photothermal deflection was investigated.[173] Equations describing the probe beam deflection were deduced. In particular, the role of the incident angle of the probe beam [see Eqn (16)] was demonstrated to be analogous to the role of the height at which this beam passes above the surface in photothermal deflection measurements employing the parallel configuration of the probe beam [see Eqn (15)]. An analogy between these two configurations was found by comparing the dependences of the signals on the incident angle and the height at which the probe beam passes. To confirm the results of theoretical calculations, photothermal deflection measurements on invar samples were performed (since this compound has a small thermal expansion coefficient, a thermally induced surface displacement in a limited range of the incident angles can be ignored).

A new model of the laser-induced thermal lens on the surface of semiconducting materials was devised.[563] The model is based on the Fresnel diffraction theory and other photothermal effects, such as photothermal deflection, the thermal lens effect and photoreflection. According to this model, the photothermal reflection makes the major contribution to the detectable signal and the diffraction pattern, but the air-thermal lens effect at low modulation frequencies and the photothermal reflection at high frequencies are also significant. It was demonstrated that the sensitivity can be enhanced by choosing an optimum position of the sample, which depends on the modulation frequency.

2. Adsorption

The surface of a gold film electrode (a polycrystalline gold film of thickness 1 μm on a polymer substrate) was studied [564] by the transient reflecting grating method. The thermal response to both the formation of a double layer and oxidation at anode potentials above +1 V and the acoustic response only to the formation of an oxide film were detected using a cyclic potential scan in 0.05–0.1 M solutions of acids (HCl, HClO). The thickness of the oxide film varied from one to several monolayers. Thermal grating spectroscopy proved to be more sensitive than other photothermal and photoacoustic methods. However, attempts to describe the observed phenomena in terms of a simple model based on enhancement of oxygen adsorption at anode potentials failed.

A highly sensitive method for the detection of antigens on the blood cell surface by thermal lens microscopy was considered in the study.[565] Colloidal gold coated with antibodies was used for staining leukocyte membrane antigens. Human leukocyte antigens on lymphocytes and mononuclear leukocytes were observed by thermal lens microscopy. Antigens of particular chromosomes on lymphocytes were detected and determined for a single cell. Antigen mapping studies were carried out on mononuclear leukocytes. Thermal lens microscopy allows one to perform non-degrading biochemical studies directly on living cell membranes.

Studies of sorption of various classes of model compounds on a series of sorbents showed that thermal lens spectrometry is suitable for investigations of adsorption of nanogram amounts of these compounds by measuring their residual concentrations in solution. The sorption kinetics were studied, adsorption isotherms were constructed and characterised, and the maximum adsorption and the conditional adsorption coefficient were determined.[566]

It was demonstrated that thermal lens spectrometry can be used to study adsorption on low-capacity sorbents (chemical glass and quartz). Thermal lens spectrometry was applied for the direct determination of the concentration of iron(II) tris(1,10-phenanthrolinate) on the quartz surface upon adsorption from aqueous solutions. It is possible to determine quantitatively the concentrations to about pmol litre^{-1} [$\sim$0.01 monolayer for adsorption of iron(II) tris(1,10-phenanthrolinate) on quartz glass] and the absolute amounts of about tens of attomoles.[566, 570] The limiting sensitivity of thermal lens determination is $\sim$100 times higher than that of diffuse reflection measurements under the same conditions. The adsorption characteristics of iron(II) tris(1,10-phenanthrolinate) and nickel(II) dimethylglyoximate from aqueous and aqueous-ethanolic solutions on laboratory glass were evaluated at nanogram levels of the sorbate in solution, and the surface concentrations of irreversible and reversible sorption centres were estimated.[407, 570] The process is most adequately described by the Freundlich equation for monomolecular adsorption.[568]

It was shown that thermal lens spectrometry is suitable for investigating of the continuity and surface concentrations of molecular layers grafted onto the quartz glass surface [567, 569, 595, 596] and for the direct detection of the dye Reactivrot B5A on the glass substrate.[567] The method allows one to perform quantitative determinations up to a monolayer of the grafted dye. Rapid ($\sim$5 min) laser-induced photodestruction of the grafted dye was observed for the first time.[567]

Investigation of adsorption of the dye acridine orange at the quartz glass–water interface by total internal reflection thermal lens spectrometry demonstrated [119] that the thermal lens effect is induced only by the penetrating wave. The adsorption depth profile can be obtained. The determination limit of the dye Sudan II in acetone is 3.0×10^{-5} absorbance units (the 2s criterion, the concentration of the dye was 3.8×10^{-5} mol litre^{-1}), which is hundreds of times lower than that achieved by the attenuated total reflection method. Under these experimental conditions, adsorption of the dye acridine orange on silanol groups of glass was observed. The adsorption isotherm is consistent with the Langmuir model.

Adsorption of diphilic surfactants at the water–hexane interface was studied [571] by surface thermal lens spectrometry. A thin thermal lens was observed for the diphilic molecules of 10-(1-pyrene)decanoic and 4-(1-pyrene)butanoic acids present at the

hexane – phosphate buffer solution interface. This method gives a linear response to the number of molecules; the detection limit is ~ 0.01 monolayer.

A procedure was proposed [572] for studying liquid – liquid interfaces. This method is called total internal reflection optical beam deflection (OBD). A comparison with total internal reflection thermal lens spectrometry [571] demonstrated that the background noise in the OBD method is substantially lower. The fact is that the probe beam in thermal lens measurements should be precisely focused onto the centre of the excitation region at the interface. In this case, even small variations in the conditions affect the background signal. In OBD measurements, the probe beam passes at a particular distance from the interface in an isotropic medium, due to which it is less dependent on the accuracy of tuning and external conditions. The maximum sensitivity is reached when the probe beam passes in dodecane in the vicinity of the interface (due to the higher sensitivity enhancement factor for dodecane compared to that for water). The method was used to examine the complex formation of iron(II) with 4,7-diphenyl-1,10-phenanthroline upon the contact of an aqueous solution of iron with a dodecane solution of the ligand. The detection limit (the 3*s* criterion), which is 750 molecules per 1 μm^2 or 2.8×10^{-6} absorbance units, is ~ 3 orders of magnitude lower than the detection limit provided by total internal reflection thermal lens spectrometry.

Adsorption of asphaltenes on glass substrates was studied by photothermal deflection and displacement spectroscopy.[573, 574] Adsorption isotherms for asphaltenes were measured at room temperature in toluene on a glass substrate.[573, 574] Multilayer adsorption was detected in three experiments, where the time of the contact was longer than 3 days. The isotherms measured during short periods of time show a linear dependence of adsorption on the concentration.[573] In the case of an appropriate ratio of the radii of the excitation and probe beams at the sample surface, an analytical signal can be measured by a single photodiode.[574]

A series of studies by Japanese researchers were concerned with the dynamics of diffusion and isomerisation of coloured compounds. They examined *N*-(4-methoxybenzylidene)-4-*p*-butylaniline (MBBA) in ethanol [575, 576] and other organic solvents,[576] in experiments with total internal reflection of the probe beam and the vertical direction of the excitation beam and studied spiropyran at the water – air [577] and solid – liquid [576] interfaces by the transient reflecting grating method. Surfaces of pure and polystyrene-coated sapphire [575, 576] and porous glass [576] were investigated. In the presence of a molecular layer of spiropyran, diffusion of molecules and their aggregates was demonstrated to occur at the water – air interface (fast and slow components of a biexponential decrease in the signals).[577] Studies with MBBA showed that the surface strongly catalyses isomerisation. This fact was confirmed by measurements in porous glass.[575, 576]

The possibilities of photothermal deflection spectroscopy and photothermal radiometry were examined as applied to characterisation of plates, which are used in thin-layer chromatography to determine the surface and depth distributions of various compounds on a sorbent.[183] Photothermal radiometry proved to be of little use for characterisation of thin-layer chromatograms. The observed low reproducibility of measurements is presumably associated with poor reproducibility of the separation conditions and inhomogeneity of different chromatographic plates.

3. Semiconductors

Semiconducting materials are most often studied by photothermal deflection methods (mirage effect) [578 – 580] and photothermal radiometry.[212, 581, 582] The photothermal reflection technique [583] and surface thermal lens spectrometry are also used for these purposes.[563]

The nature of surface defects in insulator films and defects between a-Si : H and insulator layers were examined [578] by ESR and photothermal deflection spectroscopy. The surface defect densities for a-Si : H, a-$SiN_{1.7}$: H and a-SiO were estimated from the dependence of the ESR signal intensity on the thickness. The surface state density in a-$SiN_{1.7}$: H/a-Si:H and a-SiO_2/a-Si : H was evaluated by analysis of the layered structure of thin layers. For an a-Si : H film, the results obtained by ESR agree well with the results of photothermal deflection spectroscopy. However, defects in a-$SiN_{1.7}$: H and a-SiO_2 films were not observed by the photothermal deflection technique in spite of the fact that their concentrations were virtually equal to that in a-Si : H films. The reason is that the spectral range of excitation of a photothermal spectrometer does not coincide with the absorption range of defects in a-$SiN_{1.7}$: H and a-SiO films. Defects in these structures were demonstrated to appear in the course of the plasma surface reaction and are located on the a-Si:H side of the interface. A combination of these methods holds promise. Thus, the energy distribution of defects can be studied by photothermal deflection spectroscopy, and their chemical environment can be revealed by ESR. Therefore, these methods supplement each other.

Non-contact imaging of the buried structures in air was performed by the photothermal deflection technique.[579] The method was employed to analyse layered CdTe (50 nm)/glass (0.15 mm)/carbon black (10 μm) samples. Photothermal amplitude and phase images of optically nontransparent buried structures were obtained. The phase images were more smooth and regular. The thermal diffusivity and the absorptivity of the material were calculated from the amplitude and phase parameters of the photothermal image. The thermal diffusivity of buried structures can be determined (non-destructively) from the data on photothermal deflections at two modulation frequencies.

The thermal conductivity, adhesion and mechanical stress in diamond films, which were synthesised on a ceramic aluminium nitride substrate, were studied.[580] The thermal conductivity of this composite was examined by photothermal deflection spectroscopy. It was found that this parameter is 73% larger than the thermal conductivity of pure aluminium nitride. Scanning electron microscopy and Raman spectroscopy revealed the influence of a diamond film on the thermal conductivity of samples. Unusual stability and very high adhesion of a diamond film to an aluminium nitride substrate are associated with the formation of an aluminium carbide underlayer in the synthesis of a diamond film. It was noted that diamond-coated aluminium nitride substrates are promising materials for heat removal from semiconducting electronic devices.

Photothermal radiometry was demostrated to be suitable for non-contact temperature measurements of semiconductors.[212] This method can be used to measure the temperature of high-alloy silicon samples, but it is necessary to find experimental conditions to minimise the effect of formation of electron – hole pairs (for example, to use a low modulation frequency of the excitation laser). The latter effect can be eliminated by using a laser, whose wavelength is smaller than the energy gap width of the semiconductor. For semiconductors characterised by a very short lifetime of electron – hole pairs, this effect is insignificant and has virtually no influence on the measurements.

In the study,[581] the non-contact diagnostics of the SiO_2/Si interface was carried out by photothermal radiometry. Two silicon plates containing aluminium and silicon gate metal-oxide-semiconductor structures were analysed by this method. Diffusion of charge carriers, their lifetime and the surface recombination rate were examined. The activation energies measured by two photothermal methods have close values, which are 0.15 – 0.17 and 0.21 eV lower than the lower limit of the conduction band for plates with aluminium and silicon gate devices, respectively.

Three-dimensional photothermal radiometric microscopy was employed in non-contact non-destructive studies of electron transfer in integrated schemes of lithographed silicon plates.[582] The surface resolution was 20 μm. It was demonstrated that scribeline photothermal probing can be efficiently used for non-contact monitoring of local changes in the lifetime of charge

carriers, which provides a way of determining contaminations and plate damage during the manufacture of integrated devices.

The structure of a metal-oxide-semiconductor insulated-gate field-effect transistor (MOSFET) was studied by reflection microscopy.[583] In the optical range for probing of the gate surface, the resolution was ~ 1 μm, and the constituent electro- and thermal reflections were found in the signal. Depending on the configuration of the gate valve, six different types of images with different sharpness can be obtained. In the cited study, it was also demonstrated that this method is suitable for the detection of subsurface effects.

4. Non-transparent films

Electron transitions in C_{60} under the influence of oxygen were investigated.[584] Absorption of atmospheric oxygen was demonstrated to impair dark conductivity and photoconductivity of C_{60} films. Light absorption was measured at 300 and 77 K by the photothermal deflection method. A new method, *viz*., photothermal bending, was described in the literature.[584] Absorption of excitation laser radiation which is incident perpendicular to the film surface leads to expansion of the external absorbing layer of the sample fixed at one end, resulting in bending of the sample, which is accompanied by a change in the reflection angle of the probe laser beam. This method can be used *in vacuo* (this is of considerable importance in studies of materials sensitive to an environmental medium). The method is also sensitive to temperature changes; however, it is applicable only to thin samples.

Two schemes of photothermal deflections were used to study a non-transparent film deposited on Corning 7059 glass substrates.[585] At low modulation frequencies, both schemes give similar results and it is preferable to detect the phase shift, because it is less affected by the thermal thickness of the sample.

The photothermal deflection method was employed for the non-destructive non-contact study of artificial and natural copper patina.[172] This approach is used in non-destructive analysis of ancient copper production.

Photothermal radiometry was used to characterise nickel-pigmented aluminium oxide solar cells.[586] After heating of a sample with a modulated laser beam, thermal radiation emission was measured as a dependence on the modulation frequency in a range from 10 Hz to 10 kHz. The experimental results were described by a simple one-dimensional model, which made it possible to estimate the thermal parameters of light-absorbing coatings. The radiation ability measured by conventional methods was compared with that determined by photothermal radiometry.

5. Weakly absorbing films

The optical and thermal properties of defect polycrystalline boron-doped diamond films were investigated.[587, 588] The absorptivities of thin (< 10 μm) diamond films cannot be determined by conventional methods because of a small film thickness and large scattering due to surface roughness. Both problems can be overcome by determining the absorptivity from the results of measurements of heat adsorbed by the surface using photothermal deflection spectroscopy. The method was used to study defects and impurities in polycrystalline diamond. Absorption, which is caused by local structures that appear upon implantation of polycrystalline diamond films, and reduction after annealing were observed for the first time.

An application of surface thermal lens spectrometry to investigations of weakly absorbing films was proposed in the study.[579] The results were compared with the data from photothermal deflection spectroscopy. Laser-induced deformation is considered as a bent mirror, which either focuses or defocuses the probe beam depending on the geometry used. Surface thermal lens spectrometry does not require the precise tuning of the probe beam and has the same high sensitivity as photothermal deflection spectroscopy. The exact size and shape of the region deformed upon excitation can be observed with a CCD camera. This fact is of considerable importance in studies of thermal expansion and absorbance. The reproducibility of measurements increases by a factor of ~ 5. The spatial resolution depends only on the size of the excitation beam, which can be focused to a submicrometre size by near-field photothermal microscopy. The above advantages were exemplified by studies of adsorption and characterisation of defects of weakly absorbing films of titanium(IV), tantalum(V), zirconium(IV) and silicon(IV) oxides on the surface of BK7 glass. The accuracy of the detection of absorbance is retained down to 2.6×10^{-6}.

Photothermal displacement spectroscopy was used to examine defects and attendant damages of coatings of optical elements under high-power pulsed laser irradiation, for example, in photolithographic devices.[590] Multilayer Al_2O_3/SiO_2 coatings on quartz glass, which reflect strongly at 248 nm, were investigated.

Photothermal deflection spectroscopy was used to study transparent amorphous diamond-like graphite films deposited on the quartz surface.[591] These films are resistant to damages and are transparent in the visible region.

A series of studies [174, 592, 593] were concerned with the properties of polymer materials for waveguides. The photothermal deflection spectra of non-oxidised polyalkylthiophenes containing alkyl side chains of different lengths were measured in the near-field IR region.[592] This field is used in non-linear optical waveguides. Fluorination of polyalkylthiophenes does not lead to a noticeable improvement of the waveguide properties (for example, in a range of 1700–1800 nm). Besides, purification from iron trichloride is required; otherwise, such materials are unsuitable for the construction of non-linear optical devices. The best wavelength range for waveguide materials is about 1300 nm.

Photothermal beam deflection imaging of the refractive index structure was described in the publications.[174, 593] Poly(methyl methacrylate) (PMMA) and polythiophene containing the dissolved dye Disperse Red 1 were studied. A mixture of PMMA with the dye was analysed by the laser photodecomposition technique.[593] The refractive index distribution in the polymer was determined. The method, in essence, is to examine the absorption spectrum changes caused by decomposition and subsequent image contrast reversal due to the corresponding change in the excitation beam wavelength. Images of integrated waveguide devices constructed from PMMA and polythiophene were obtained by photodecomposition and photothermal deflection on a photolithographic instrument. Structures of dimensions > 50 μm were resolved. Attempts to image structures of dimensions < 30 μm by the photothermal deflection technique failed. Photothermal displacement spectroscopy would be expected to overcome this limitation.

Scanning photothermal deflection was compared with scanning photothermal displacement.[174] A 20% solution of the dye Disperse Red 1 in PMMA was examined. Two methods show similar depth resolution. Data on photothermal deflection are rather easy to interpret due to a simple relation between the signal and excitation source power. Due to enhancement of the signal by an auxiliary liquid, images with an acceptable signal/noise ratio can be obtained even at low excitation power. However, immersion of a sample into an auxiliary liquid may be a drawback if the latter cannot be removed after the experiment. Besides, signal accumulation time is large due to a rather low chopping frequency.

To interpret the results of photothermal displacement spectroscopy, numerous factors should be taken into account. The convexity theory is complex and is additionally complicated in the case of focused-beam excitation. For thin samples, a convexity is formed primarily in the substrate. Hence, it is necessary to know the distribution of the thermal and optical properties of the substrate. The advantages are a high rate of signal accumulation (due to a high chopping frequency) and the possibility of performing analysis in air. Hence, it was concluded that the photothermal deflection method is more convenient for studying polymer films (due to higher reproducibility of the results) compared to the photothermal displacement technique.[174]

Amorphous graphite films, which were prepared on polystyrene under its irradiation with He^+ and H^+ ions, were analysed in the study.[594] These films are used in particular types of protective coatings. The photothermal deflection method was employed to record an absorption spectrum in a wavelength range from 1.2 to 2.0 μm. The mechanical, electrical and optical properties of such films depend on the ratio between the contents of the sp^2- and sp^3-hybridised carbon atoms. The changes occurring in the film can readily be observed from evolution of particular overtones in the absorption spectrum in the above-mentioned range.

V. Conclusion

When considering the development of analytical thermooptical spectroscopy, it is necessary to mention a considerable contribution of the research team headed by Professors V I Grishko and I G Yudelevich (A V Nikolaev Institute of Inorganic Chemistry of the Siberian Branch of the Russian Academy of Sciences, Novosibirsk), who laid the groundwork for analytical investigations in the field of thermal lens spectrometry. Initial studies using thermooptical spectroscopy methods have been concerned with chemical interactions at low concentrations of reacting compounds. The metrological characteristics of the method have been comprehensively evaluated, and its possibilities in the determination of traces of organic and inorganic compounds have been examined.[82, 86, 87, 106, 298, 353, 541, 546] In addition, this research team published the only Russian monograph [2] (and the first monograph in the world), which was completely devoted not only to the physics of the thermooptical phenomena but also to instrumental possibilities of thermal lens spectrometry and (which is of most importance) to its analytical applications. The results of the studies performed by this research group in the field of thermooptical spectroscopy were so voluminous that they are still being published (even ten years after the completion of their research).[359]

Nowadays, thermooptical methods for analysis are being developed and used in leading research centres in Russia and Former Soviet Republics, such as M V Lomonosov Moscow State University,[313, 401, 402, 548, 595–600] St Petersburg State University,[218, 229, 232, 443–445, 510, 531] Institute of Physics of Microstructures of the Russian Academy of Sciences (Nizhnii Novgorod),[239, 240, 248–251, 313] A V Lykov Institute of Heat and Mass Transfer (Minsk, Republic of Belarus),[552–554] N E Bauman Moscow State Technical University,[5, 552, 554] L V Kirensky Institute of Physics of the Siberian Branch of the Russian Academy of Sciences (Krasnoyarsk) [559] and Dnepropetrovsk State University (Ukraine).[601] Considerable experience has been gained in the field of thermooptical spectroscopy. Numerous studies were published, many of which made a considerable contribution to the theory and practice of thermooptical investigations.

The section 'Thermooptical Methods' was included in the Handbook 'Analytical Chemistry' (Ed. Yu A Zolotov, Nauka, Moscow, 1998, 2d edition). This is the only example of the inclusion of information a review format on thermooptical methods in a handbook for university students. Nowadays, the fundamentals of thermooptical spectroscopy are included in training courses of the Departments of Physics [602] and Chemistry (the Chair of Analytical Chemistry, the training course 'Analytical Chemistry',[603] and the Chair of Laser Chemistry, the training course 'Introduction to Laser Chemistry' [604]) of Moscow State University, St Petersburg State University (the training course 'Physical Fundamentals of Optical Methods of Analysis of Substances and Materials') [605] and Krasnoyarsk State University (the Chair of Physical Chemistry, the training courses 'Materials Science and Technology of New Materials' and 'Modern Methods of Analysis').[606]

In conclusion, it should be noted that, in addition to high sensitivity, methods of thermooptical spectroscopy provide much more information than spectrophotometric methods. This makes it possible to increase substantially the range of the problems, which can be solved. Apparently, the main advantages of thermooptical methods (the possibility of the simultaneous detection of several analytical signals and the use of specific effects not as a passive way of detecting but as an active component of new analytical methods) will assist the development of analytical thermooptical spectroscopy.

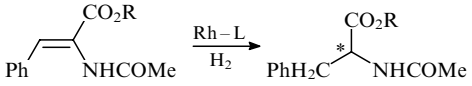
Abstract. The recently published data on the dependence of the configuration of the reaction product on the structure of a catalytic metal complex (or an intermediate determining the asymmetric induction) in asymmetric catalytic reactions of hydrogen-transfer hydrogenation of acetophenone, hydroformylation of styrene, allylic alkylation of 1,3-diphenylprop-2-enyl acetate and alkylation of benzaldehyde with dialkylzinc are systematised. The applicabilities of octant and quadrant projections of the complexes are compared in order to establish the relationships between their structures and the enantioselectivities of the reactions. The known mechanisms of asymmetric induction in these reactions are discussed with regard to the C_1 or C_2 symmetry of the catalytic complex. The reasons for a decrease in the enantioselectivities of hydrogen-transfer hydrogenation, hydroformylation and alkylation by dialkylzinc [in the absence of $Ti(OPr^i)_4$] when performed with complexes with chiral C_2-symmetric ligands (as compared with complexes with asymmetric ligands) are considered. The bibliography includes 435 references.

I. Introduction

Asymmetric catalysis is undergoing a period of explosive development as can be evidenced from the increasing number of publications (see the monographs [1–5] and the most recent reviews [6–23]) and financial support of this field of research. The interest of the pharmaceutical industry in asymmetric catalysis stems from its possible use for the preparation of enantiomerically pure drug components. In 1996 – 1998, the annual expenditures for their production increased from US $ 73 bln to 96 bln.[24] The number of publications devoted to the theoretical aspects of asymmetric homogeneous catalysis was steadily increased correspondingly.

Studies into the mechanisms of asymmetric reactions on metal-complex catalysts that yield products with great enantiomeric excess (*ee*) attract special attention. The hydrogenation of enamides of α-acetamidocinnamic acid derivatives, on rhodium phosphine complexes is especially well-studied.[6]



In the 1980's, following a publication by Galpern and Brown (for Ref. 6), it was thought that the predominant mechanism of this reaction is characterised by the following features:

(1) the first reaction step yields two intermediate complexes with the substrate, *viz*., minor and major, the concentration of the former being order of magnitude lower than that of the latter;

(2) the asymmetric induction occurs in the subsequent transformation of the intermediate;

(3) the major enantiomeric product is formed predominantly *via* the minor intermediate, since the rate of its reaction exceeds that *via* the major intermediate by three orders of magnitude.

However, a recently postulated alternative mechanism [25, 26] entails the formation of a hydride complex in the first step, the asymmetric induction as a result of substrate coordination and the formation of the predominant enantiomer of the reaction product *via* the major intermediate.

This discussion is not yet complete, since both mechanisms of reactions on rhodium [27, 28] and ruthenium complexes [28, 29] have advocates of their own. Presumably, the reaction mechanism depends on the nature of the catalytic complex with different phosphine ligands. However, the similarity of the dependences of the product configuration on the structure of the catalytic complex [10] (see Section II) is rather in favour of a single mechanism.

The character of the asymmetric induction step is the key difference between the aforesaid mechanisms. However, even if the asymmetric induction occurs in different reaction steps, this does not always account for the differences in the configurations of the reaction products. The dependence mentioned above is consistent with either mechanism on the assumption of a random coincidence of the product configuration in the case of one or another asymmetric induction step. Formally, only the second mechanism fits well into the most popular concept on the interaction of a chiral complex with a substrate commonly

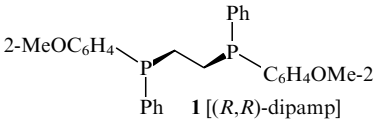
† Dedicated to the memory of Prof. G Snatzke.

known as a 'key–lock' mechanism. The overwhelming majority of configurational models used in asymmetric homogeneous catalysis also fit into this model.

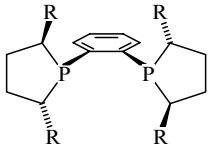
The construction of configurational models, *i.e.*, determination of simple relationships between the configurations of asymmetric catalystic reaction products and those of chiral metal complexes that play the role of the catalysts attracts special attention.

II. Configurational models in asymmetric homogeneous catalysis

Knowles [30] who studied the hydrogenation of α-acetamidoacrylic acid in the presence of the Rh–dipamp complex (**1**) recommended that the so-called quadrant diagram was used to determine the efficient and non-efficient coordination variants of an enamide in a hypothetical transition complex.[6, 10]

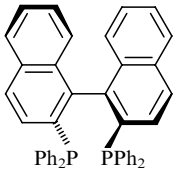


1 [(*R*,*R*)-dipamp]



2 [(*R*,*R*)-duphos]

R = Me, Et, Pr^n.



3 [(*R*)-binap]

This diagram is based on the arrangement of the phosphine phenyl groups (with the edge or the plane facing the viewer) in the precursor of the catalytic complex as established by X-ray diffraction spectroscopy. [31] According to this diagram, the substituents of a coordinated substrate that fall into the quadrants blocked by the phenyl groups of the ligand turned edgewise to the viewer encounter with a greater steric hindrance. A similar diagram with two blocked diagonal quadrants (Fig. 1) was used by Burk *et al.*[11, 32, 33] to rationalise the enantioselectivity of enamide hydrogenation in the presence of the Rh–duphos complex (**2**). The results of computations based on this model [27] were in good agreement with the experimental data.

A similar graphical approach based on a sector diagram was developed for the consideration of hydrogenation of β-keto esters,[34, 35] β-keto sulfonates [36] and other β-keto derivatives [7] on the Ru–binap complex (**3**).[10] Whereas the Ru–(*R*)-binap complex catalyses the formation of *R*-alcohols, the Ru–(*S*)-binap complex favours the formation of *S*-hydroxy derivatives. Pfaltz *et al.*[37–39] used a projection of a catalytic complex and a substrate coordinated by this complex, which is similar to the quadrant projection, to establish the preferential coordination of the substrate and, correspondingly, the configuration of the product formed upon reduction of α,β-unsaturated esters and amides with sodium cyanoborohydride in the presence of an *in situ* generated complex $CoCl_2$–**4**.

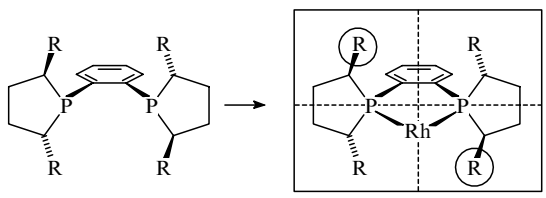


Figure 1. Shielding of diagonal quadrants in a rhodium complex with (*R*,*R*)-duphos in the hydrogenation of enamides.[11, 32]

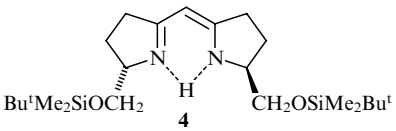


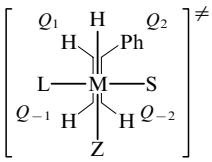
4

The transition-state model [40] of yet another popular asymmetric reaction, *viz.*, hydroformylation on rhodium and palladium complexes (Section IV), is based on the quadrant projection of a chiral complex. Within the framework of this model, asymmetric induction takes place in the substrate coordination step as is tacitly accepted for other intermediates mentioned above. This model is based on the following assumptions:

(1) an activated complex resulting in the formation of a metal–alkenyl intermediate possesses the highest free energy;

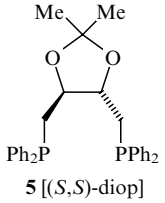
(2) in the transitions state, the double bond of the substrate is approximately coplanar with the bond between the metal and hydrogen.

The transition state is displayed as a projection of a complex onto a plane perpendicular to the direction of approach of the substrate to the metal atom. The ligands L and S and the reagent Z differ in size: L > S, Z > H (*e.g.*, Z = CO). The metal–ligand bonds form quadrants differing in the degree of occupation of space with these ligand fragments. The four variants of the distribution patterns of substrate substituents between the quadrants depending on substrate orientation correspond to four intermediate states characterised by different values of free activation energies (Q). The predominant orientation of styrene shown in the scheme corresponds to the arrangement of the ligands and the ratios of Q.

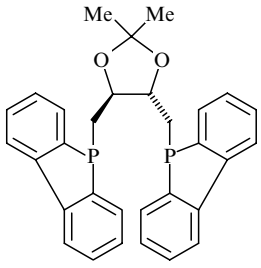


M is metal, $Q_{-1} > Q_{-2} \gg Q_1 > Q_2$.

The distribution of the molecular masses of the ligands between the quandrants, especially for C_2-symmetric bidentate ligands, such as diop (**5**) and dbp-diop (**6**), for which this model has been constructed (for rhodium [40–42] and platinum [41, 43–45] complexes), remains unclear.



5 [(*S*,*S*)-diop]



6 [(*S*,*S*)-dbp-diop]

Besides, this model does not take into account the fact that the enantiomeric outcome of the reactions carried out on rhodium and platinum catalysts can be different even if the same ligands are used.[41, 46] The experimental proof of this model showed that the predicted isomeric compositions of the reaction products and the configuration of the chiral product do not often coincide with the experimental data.[47] This fact was also acknowledged by the authors.[40, 41]

In practice, the relative positions of the ligands L and S in the transition state are deduced from the results of hydroformylation of a simple substrate;[47] therefore, the model under consideration is more explanatory than predictive.

A combination of quantum-chemical calculations and the molecular mechanics method was used in the construction of yet

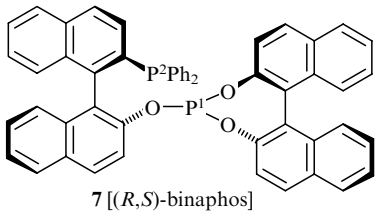
another semiquantitative model of this reaction.[48] Experimental data suggest a trigonal-bipyramidal structure of an intermediate with a coordinated alkene.[49] The admissions underlying this model are very similar to those used in the previous model:

(1) the double bond of the substrate is coplanar with the apical bond M – H;

(2) the substrate coordination step is responsible for the regioselectivity and enantioselectivity;

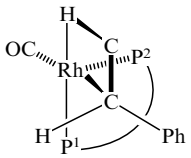
(3) this step is irreversible.

It has previously been established [48] that this model provides an adequate interpretation of the data on hydroformylation of alkenes in the presence of the Rh – (*R*,*S*)-binaphos complex (**7**).[49]

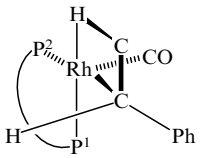


7 [(*R*,*S*)-binaphos]

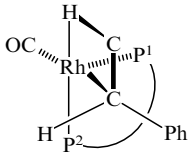
With styrene as a substrate, four intermediates (**A** – **D**) are possible.



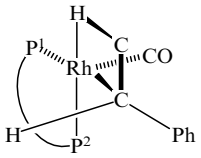
A



B



C

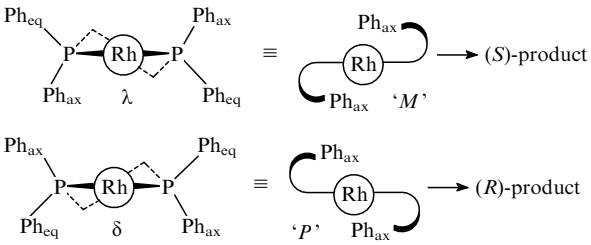


D

The coincidence of the calculated value of *ee* and the product configuration with the experimental results is achieved only with the intermediate **A**. A drawback of this model is that another intermediate can be more preferable for ligands having different structures. The calculated data should be compared each time with the experimental results; hence, this model also has a limited predictive potential.

Simpler literal rules for the dependence of the product configuration on the complex structure have been proposed. The relationship between the configurations of the enamide hydrogenation products and the conformations of the five-membered chelate rings in the rhodium complexes with bis(diphenylphosphine) ligands were simultaneously and independently established by Kagan [50] and by Pavlov and Klabunovskii.[51 – 53]

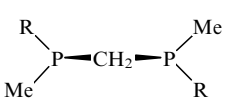
In this case, the folded conformations, λ and δ, were formed due to the presence, in the ring, of bulky substituents at one or two chiral carbon atoms. The conformation λ of the chelate ring results in (*S*)-, whereas the conformation δ yields the (*R*)-enantiomer of the reaction product.



This model was further extended to rhodium complexes used for enamide hydrogenation with seven-membered chelate rings in the λ-twist-chair and δ-twist-chair conformations.[10, 52 – 56] Similar dependences were found for hydrosilylation,[10, 55] cross-coupling [10, 57, 58] and allylic alkylation [59] on Rh, Ni, Pd, *etc.* complexes.

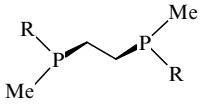
As the enantioselectivity of this reaction is directly related not to the conformation, but rather to the chiral arrangement of the phosphine phenyl groups determined by this conformation,[60, 61] a more general expression for the same dependence which is based on a conventionalised image of a helix loop can be used.‡ In this case, the indices '*P*' and '*M*' describe the chiral arrangement of molecular masses of two pairs of phosphine phenyl groups in the complex.

For simplicity's sake, this regularity can be described by the dependence [10] λ('*M*') – (*S*), δ('*P*') – (*R*). Obviously, it is the use of '*P*'/'*M*'-indices only that is applicable in the case of enamide hydrogenation on rhodium phosphine complexes where the chirality of the ligands is determined either by the chiral phosphorus atoms [(*R* ,*R*)-miniphos (**8**),[62] (*R*,*R*)-bisP* (**9**) [63]] or by four chiral carbon atoms located pairwise in two rings containing phosphorus atoms [(*S*,*S*)-bpe (**10**), (*R*,*R*)-**2**].[32]



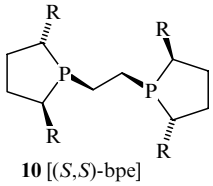
8 [(*R*,*R*)-miniphos]

R = Pr^i, Bu^t, cyclo-C_6H_{11}, Ph.



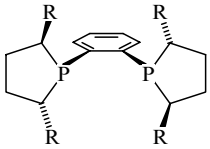
9 [(*R*,*R*)-bisP*]

R = Bu^t, Et_3C, 1-adamantyl, *etc.*

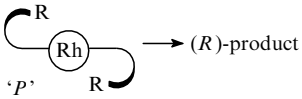


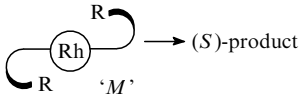
10 [(*S*,*S*)-bpe]

R = Me, Et, Pr^n, Pr^i.



2 (R = Me, Et, Pr^n).





In the case of rhodium complexes with the ligands **8** and **9**, the indices are given with respect to substituents R bulkier than the methyl group, whereas those for the complexes with ligands **10** and **2** are determined from the substituents facing the viewer.

Hydrogenation of methyl α-acetamidocinnamate in the presence of the rhodium complexes with the ligands **10** – **17** and **1** obeys the regularity '*M*' – (*S*), '*P*' – (*R*) (Table 1). Thus, this concept may have a predictive potential.

The enantioselectivities of the hydrogenation reactions of α-acetamidocinnamic acid derivatives in the presence of the complexes Rh – **2**,[32] Rh – **10** and Rh – (**11** – **13**) are virtually the same. Thus, additional chiral carbon atoms in the ligand more remote from the metal atom in the chelate complex than the carbon atoms in the substituents that determine the chirality in the quadrant projection, have no effect on the enantiodiscrimination. The change in the configuration of the chiral donor phosphorus atom in the 'hybrid' ligand **17** has a much more pronounced effect on the value (but not the sign) of the enantioselectivity.

In total, more than 80 structural variants of chiral ligands [10] involved in the hydrogenation of enamides on rhodium complexes have been considered. All of them (with the exception of several deviations which have a specific explanation of their own) obey the above-mentioned regularity. Unfortunately, the involvement of a rhodium complex containing a cyclophane bis(diphenylphos-

‡ Quotation marks are used in this case to denote the helicity indices.

Table 1. Hydrogenation of methyl α-acetamidocinnamate in the presence of Rh complexes with the ligands **10** – **17**.

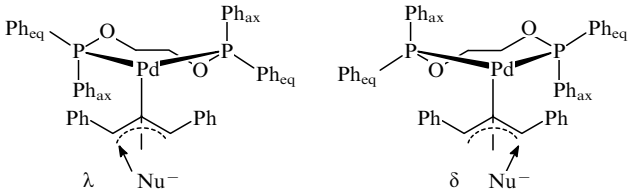
Note. Hereinafter Fcd is ferrocenylene.

phine) ligand with planar chirality [70] cannot adequately be analysed due to the lack of X-ray diffraction data.

A model of configurational relationships based on the conformations of the intermediates was employed in the study of allylic alkylation products of 1,3-diphenylprop-2-enyl acetate (Section V) by a diethyl malonate anion in the presence of a bis(diphenylphosphinite) palladium complex.[59, 71]



It was found that the λ-conformation of the intermediate favours the formation of the *S*-product, whereas the δ-conformation yields the *R*-enantiomer.

A more general configurational model considers the arrangement of the complex in the space of the quadrant (Fig. 2).[72, 73]

The regions determining the complex chirality are marked by the indices *Pr* (plus region) and *Mr* (minus region); the configuration of the reaction product depends on the region *Pr* or *Mr* where the ligand fragments fall. This model has found experimental support in that the dependence *Mr* – (*R*), *Pr* – (*S*) was observed in the allylic alkylation of 1,3-diphenylprop-2-enyl acetate by a diethyl malonate anion catalysed by palladium complexes with iminophosphine, diphosphine and diamine ligands.[72] However, the choice of this reaction is not quite suitable. In terms of this model, the asymmetric induction occurs in the substrate coordination step (the 'key – lock'-type interaction). However, the asymmetric induction step of this reaction does not coincide with the substrate coordination step (see Section V). Therefore, this model is applicable to such reactions as ketone hydrogen-transfer hydrogenation and to certain enamide hydrogenation, ketone hydrosilylation reactions, *etc*., where the asymmetric induction occurs in the substrate coordination.[6] A drawback of this model is that the space in front of the metal atom is not taken into consideration. The model is inapplicable to complexes with ligands, the bulky fragments of which face the viewer (see Fig. 2) and are nearer to it than the metal atom. Indeed, the complexes with ligands **18** and **19**, **20** and **21** (see Table 2) possess different *Pr*/*Mr*-chiralities, but the configuration of the allylic alkylation product of 1,3-diphenylprop-2-enyl acetate by a diethyl malonate anion is similar in these pairs.§ As a matter of fact, two phenyl groups in the

§ The conformations employed in the construction of complexes using molecular models corresponded to more favourable equatorial positions of bulky substituents in the chelate rings.[76, 77]

Table 2. Comparison of the configurational models *Pr*/*Mr* and Pr^{oct}/Mr^{oct} in the allylic alkylation of 1,3-diphenylprop-2-enyl acetate by diethyl malonate anion under the action of palladium complexes with diamines.[74, 75]

Ligand	Complex	*ee* (%) (product configuration)	Location of substituents in octants	Chirality in configurational models	
				Pr/*Mr*	Pr^{oct}/Mr^{oct}
 **18**		> 99 (*S*)	FL(+), FR(+), RR(+), RL(+)	*Mr*	Pr^{oct}
 **19**		89–91 (*S*)	RL(+), RR(+)	*Pr*	Pr^{oct}
 **20**		64 (*R*)	RL(−), RR(−)	*Mr*	Mr^{oct}
 **21**		48 (*R*)	FL(−), FR(−), RL(−), RR(−)	*Pr*	Mr^{oct}

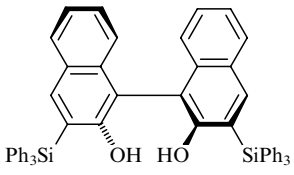
Note. Hereinafter, the following designations are used: Mr^{oct} (minus region octants); FL(−), frontal left (−); FR(−), frontal right (−); RL(−), rear left (−); RR(−), rear right (−) octants; Pr^{oct} (plus region octants), FL(+), frontal left (+); FR(+), frontal right (+); RL(+), rear left (+); RR(+), rear right (+) octants.

complexes with ligands **18** and **21** are located beyond quadrants that contain the chelate rings and that are limited by a plane passing through the metal atom perpendicular to the symmetry axis C_2. In the case of complexes with ligands **19** and **20**, the alkyl groups remain within the quadrants. In the framework of the *Pr*/*Mr* model, the complexes Pd–**18** and Pd–**20**, Pd–**19** and Pd–**21** are identical pairwise. Nevertheless, the configurations of the corresponding reaction products are different. It may thus be concluded that the escape of the substituent from the limits of the above-mentioned space changes the chirality sign. However, in this case the octant projection with the opposite signs of the frontal and rear octants¶ (Fig. 3) becomes applicable and the configurational *Mr*/*Pr* model is considered as a particular case of the configurational model based on the octant projection (the Mr^{oct}/Pr^{oct} model) for those complexes with ligands which do not escape the space of the rear octants.

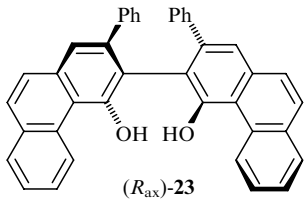
As can be seen from Table 2, the Mr^{oct}/Pr^{oct} model is more adequate to the experimentally determined enantioselectivity of this reaction.

Cycloaddition of cyclopentadiene to methacrolein catalysed by the *in situ* formed complexes Al–**22** and Al–**23** is yet another example of the difference between the models *Mr*/*Pr* and Mr^{oct}/Pr^{oct}.[80]

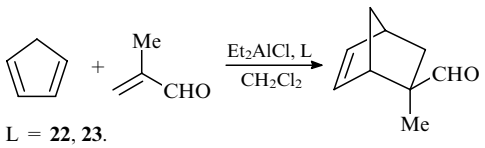
¶ By analogy with the octant projection used for the description of the chiral environment of the carbonyl chromophore in cyclohexanone based on data from circular dichroism.[78, 79]



(R_{ax})-**22**



(R_{ax})-**23**



L = **22**, **23**.

Complex	The sign of optical rotation of the cycloaddition product	*ee* (%)	Chirality in configurational models	Location of substituents in octants
(R_{ax})-**22**	−	17	*Pr*, Pr^{oct}	RL(+), RR(+)
(R_{ax})-**23**	+	97	*Mr*, Mr^{oct}	FL(−), FR(−)

The silicon atoms in the octant projection of the molecular model of the Al–**22** complex fall into the rear positive octants close to the plane separating the frontal and rear octants; hence, the low enantiomeric excess of the reaction product is explicable. The terminal fragments of the phenanthrene units of the ligand in

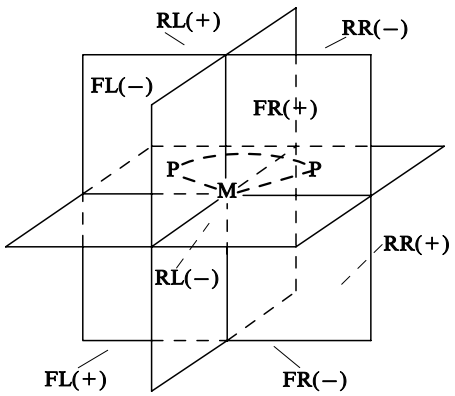


Figure 3. The octant projection of the Pd complexes **18**–**21**. The designations of the types and signs of the octants as in Legend to Table 2.

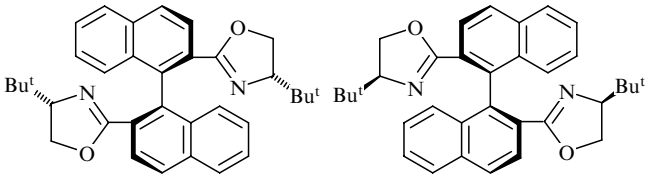
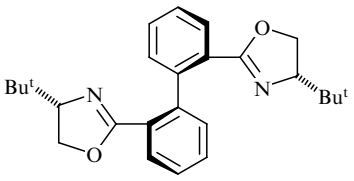
the projection of the complex Al–**23** lie in the frontal negative octants, which suggests a change in the chirality sign in comparison with the previous case. This observation is consistent with the experimental data[80] and suggests that the results obtained are better rationalised in terms of the Pr^{oct}/Mr^{oct} model than in terms of the Pr/Mr model.

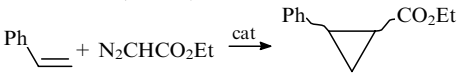
Cyclopropanation of styrene with ethyl diazoacetate in the presence of complexes CuOTf–**24** (see Ref. 81) and CuOTf–**25** (Ref. 82) is yet another illustrative example of the applicability of the octant model to the estimation of enantioselectivity.



(S_{ax},*S*,*S*)-**24** (R_{ax},*S*,*S*)-**24**



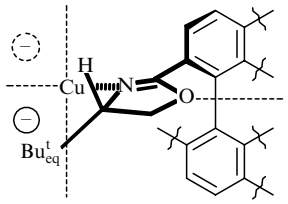
(S_{ax},*S*,*S*)-**25**



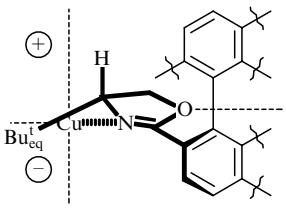
Catalyst	Isomer of ethyl 2-phenylcyclopropanecarboxylate	*ee* (%) (see †)
(S_{ax},*S*,*S*)-**24**	*trans*-(1*R*,2*R*)	87
	cis-(1*R*,2*S*)	86
(R_{ax},*S*,*S*)-**24**	*trans*-(1*S*,2*S*)	3
	cis-(1*S*,2*R*)	3
(S_{ax},*S*,*S*)-**25**	*trans*-(1*R*,2*R*)	71
	cis-(1*R*,2*S*)	84

† Chromatographic analysis of the cyclopropanation products on columns with chiral phases gives the ratio of the enantiomeric pairs *trans*-(1*S*,2*S*)/*trans*-(1*R*,2*R*) and *cis*-(1*S*,2*R*)/*cis*-(1*R*,2*S*). Therefore, the enantioselectivity of the reaction is usually expressed by *ee* values and the total ratio of the *trans*/*cis* products. If the reaction is carried out with chiral esters, the value of the diastereomeric excess [*de* (%)] is sometimes used.

The lateral projections of the first two complexes are shown below. In the projection of the Cu–(S_{ax},*S*,*S*)-**24** complex, the Bu^t_{eq} groups lie in the frontal negative octants (for simplicity's sake, the second dihydrooxazole ring in each complex is omitted). In the projection of the second complex, these groups are localised in the vicinity of the plane separating the frontal octants with the opposite signs. Presumably, such a border location is the reason for the extremely low (3%) enantioselectivity of the reaction catalysed by this complex.

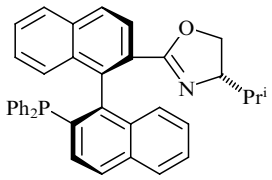


Cu-(S_{ax},*S*,*S*)-**24**

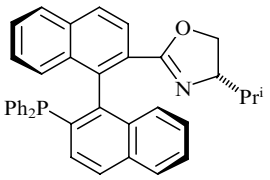


Cu-(R_{ax},*S*,*S*)-**24**

A comparison of the contributions of different types of chirality to the enantioselectivity gives rather controversial results. On the one hand, the dominant role of the axial chirality in the dihydrooxazole ring (in comparison with the central chirality) in the cyclopropanation reaction [Cu–(S_{ax},*S*,*S*)-**24** and Cu–(R_{ax},*S*,*S*)-**24**] leaves no doubt (see Ref. 81). On the other hand, the contribution of the axial chirality caused by the difference between the dinaphthyl and diphenyl systems in analogous complexes Cu–(S_{ax},*S*,*S*)-**24** (see Ref. 81) and Cu–(S_{ax},*S*,*S*)-**25** (see Ref. 82) in the same reaction is very small. As regards the central chirality of the carbon and phosphorus atoms in the complexes[69] Rh–(*S*,*S*,*S*,*S*,*S*p)-**17** and Rh–(*S*,*S*,*S*,*S*,*R*p)-**17** employed for hydrogenation (see Table 1), the data available do not allow an unambiguous conclusion. The dominant role of the axial chirality in comparison with the central chirality in the dihydroxazole fragment in the allylic alkylation of 1,3-diphenylprop-2-enyl acetate can be judged from the example of the palladium complexes with ligands (S_{ax},*S*)-**26** [(*S*), 28%] and (R_{ax},*S*)-**26** [(*R*), 86%].[83, 84]



(S_{ax},*S*)-**26**



(R_{ax},*S*)-**26**

However, even a qualitative estimation of the contribution of one or another type of chirality is not always possible.[8] Generally speaking, estimation of contributions of different types of chirality of catalytic complexes to enantioselectivity can be regarded as a formal approach to the problem. Enantioselectivity is provided by spatial fixation of bulky groups of the ligand that being nearest to the donor atoms form the chiral environment of the metal atom. In other words, the ligand molecule within a catalytic complex plays the role of a template.

The octant projections and the 'Pr^{oct} (Mr^{oct})–product configuration' relationship cannot be regarded as the quantitative reflection of the stereochemistry of these complexes. These projections simply show the probable distribution of the groups that determine the chirality of the metal environment. These results were obtained from the analysis of molecular models, *viz*., Dreiding stereomodels ('Büchi Laboratoriums-Technik AG') or the published X-ray diffraction data and calculations.

The description of the real stereochemistry of a complex suitable for predicting both the configuration of the product and *ee* is possible only if exact spatial coordinates of the environment of the bulky groups that form the chiral environment of the metal atom under the reaction conditions are known. Unfortunately, X-ray diffraction data, *e.g*., on transition metal chiral chelate

complexes,[61] can hardly be used as a reliable basis in the construction of quantitative models of the type 'structural elements of complex – *ee* and product configuration'. Equalisation of molecular parameters of complexes in crystal to those in solution is probably unjustified. However, this approach gives positive results when using relative values, such as changes in certain complex parameters due to the presence of ligands with similar structures. Thus, it has been found[85] that in the case of an asymmetric Diels–Alder reaction where acrylates react with cyclopentadiene in the presence of the Ti–2,2′-biaryldiol complex the dependence of *ee* of the *endo*-adduct on the torsion angle of the biaryl passes through a maximum. A similar dependence exists between *ee* and the calculated parameter 'chirality content of molecule' (CCM), used as a quantitative measure of chirality of the given chiraphore‡ (in this case, of the biaryl fragment).[86] Correspondingly, a linear dependence exists between CCM and the dihedral angle. This testifies to the non-linear dependence between CCM and the experimentally determined *ee* value of the reaction product.[86] Most probably, the introduction of the parameter CCM[87] opens up a new way of predicting the magnitude and sign of enantioselectivity on the basis of calculations.

The majority of quantitative theoretical approaches dealing with asymmetric homogeneous catalytic reactions catalysed by metal complexes are based on computations that employ different programs and methods for different reactions and catalysts. The correspondence of the calculated parameters to the experimental results is considered as evidence in favour of a suggested mechanism. Recently, calculations have been carried out for the hydrogenation of enamides in the presence of the Rh–**2** complex;[27] for hydrogen-transfer hydrogenation of ketones catalysed by Rh–diamine,[88,89] Ru–*N*-tosylethylenediamine[90] or Ru–amino alcohol complexes,[90–92] for cyclopropanation of styrene on the complex Cu–*N*,*N*′-dimethylmalonaldiimine,[93] *etc*.

Although the use of the configurational models *Pr*/*Mr* or Pr^{oct}/Mr^{oct} is a qualitative approach, it provides a simple tool for predicting the sign of asymmetric induction and its interpretation. Many additional examples in which these models were compared can be mentioned. However, this is more appropriate in the subsequent analysis of the most extensively studied reactions catalysed by metal complexes (see Sections III–VII).

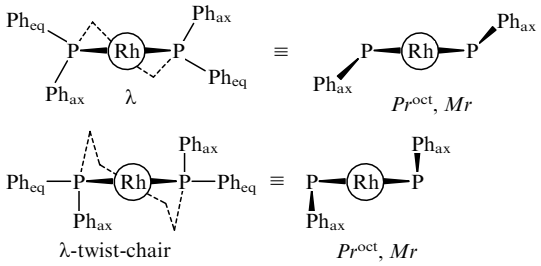
The octant projection localisation of the chiral C_2-symmetric metallacycle containing two identical donor atoms is shown in Fig. 3. The following conditions should be met when octant projections are used. In defining the sign of the octant determining the chirality, preference is given to the substituent nearest to the donor atom. Other conditions being the same, the preference is given to a bulkier substituent ($Bu^t > Pr^i > Pr^n > Et > Me$; $Bu^tCH_2 > Ph > Bn$, *etc*.). For different substituents at the same atom of the metallacycle of the complex not affecting the sign of the asymmetric induction, the complex with a substituent, which ensures the maximum value of *ee* of the reaction product, is allowed for. If the changes in the reaction conditions (*e.g*., solvent, temperature, additional reagent, *etc*.) do not cause any reversal of the product configuration, they are excluded from consideration.

Additional conditions should be met in order to unify the approach to the description of this model. In the octant projection (a view from the metal side) of an asymmetric metallacycle containing two identical donor atoms, the atom with a substituent determining the octant sign (which is closer to the donor atom or is bulkier) occupies a right-sided position; in the presence of two different donor atoms, the inferior (as regards its atomic number) atom takes a right-sided position; preference is given to the substituent or the environment of the left (senior) donor atom.

It is necessary that the last three requirements are met for the standardisation of the subjects that are analysed. The requirement for the unification is extended to the choice of relevant data for a concrete substrate in reactions carried out under maximally similar conditions.

‡ By analogy with the terms 'chromophore' and 'pharmacophore'.

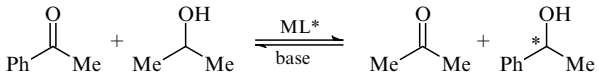
Determination of octant projections of various complexes is based on the use of molecular models or X-ray diffraction data. For example, the octant projections of bis(diphenylphosphine) complexes were obtained on the basis of data on the λ- and δ- as well as λ- and δ-twist-chair conformations of five- and seven-membered rhodium chelate complexes.[10]



This projection shows only axial phenyl substituents. They fall completely into the corresponding octants, whereas the equatorial substituents lie at the border between two opposite octants. Therefore, the chirality of a complex is determined from the position of the axial substituents in the octants.

III. Hydrogen-transfer hydrogenation of acetophenone catalysed by metal complexes

Hydrogenation of aromatic ketones is one of the simplest asymmetric reactions catalysed by metal complexes with different chiral ligands.[16,94,95]



A comparison of the '*Pr*(*Mr*)–product configuration' and '$Pr^{oct}(Mr^{oct})$–product configuration' relationships for the hydrogen-transfer hydrogenation of acetophenone in the presence of rhodium and iridium complexes is presented in Table 3. Those complexes with bidentate ligands are considered where the spatial configurations of the bulky groups adjacent to the metal atom that determine its chiral environment are established on the basis of molecular models or using X-ray diffraction. As can be seen, the relationships Pr^{oct}–(*S*), Mr^{oct}–(*R*) and *Pr*–(*R*), *Mr*–(*S*) are observed in 60% and 53% of cases, respectively. An analysis of other complexes including ruthenium complexes (Table 4) revealed that the relationships Pr^{oct}–(*R*), Mr^{oct}–(*S*) and *Pr*–(*R*), *Mr*–(*S*) are observed in 70% and 80% of cases.

Special attention in Tables 3 and 4 should be paid to the relatively low enantioselectivity of reactions in the presence of complexes with chiral C_2-symmetric ligands. The *ee* values of the reaction product increase significantly on going to complexes with asymmetric ligands. At the first glance, this conclusion is contradictory to the high enantioselectivity of acetophenone hydrogenation catalysed by complexes containing chiral C_2-symmetric tri- and tetradentate ligands **56**–**59**[119–123] (Table 5).§ However, as can be seen from Table 5, the *ee* values and the configurations of the products formed in the presence of complexes with these ligands and of complexes with ligands which represent 'monomeric' analogues of these complexes, are virtually identical, which probably suggests that it is on these asymmetric 'monomeric' fragments that the reaction occurs. Indeed, excessive shielding of the metal atom, which fulfils the catalytic function, with bulky groups of tri- and tetradentate ligands prevents substrate coordination. Besides, the results of molecular model studies suggest that considerable stress is required for the ligand **59** to be coordinated

§ In the presence of some complexes with chiral C_2-symmetric tridentate ligands, this reaction proceeds with low enantioselectivity ($ee_{max} \leqslant 45\%-48\%$).[124,125]

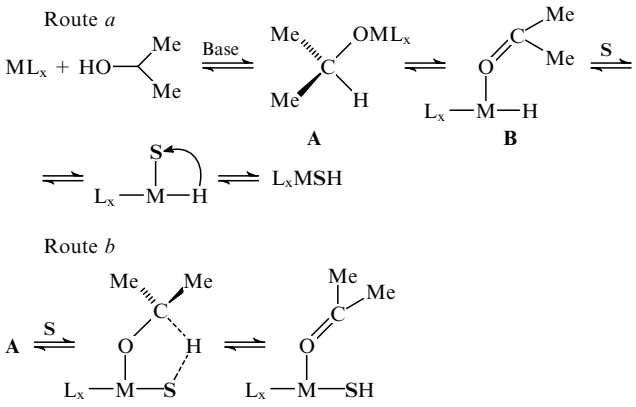
within the complex through all the four donor atoms. A similar assumption based on a larger body of experimental evidence according to which complexes with asymmetric fragments (but not complexes with chiral C_2-symmetric tri- and tetradentate ligands) are involved in the catalytic reaction will be considered in Section VII.

The position of substituents in certain complexes is sometimes difficult to establish with the use of molecular models, although asymmetric hydrogenation of acetophenone on these complexes proceeds with sufficiently high enantioselectivity.[126–134]

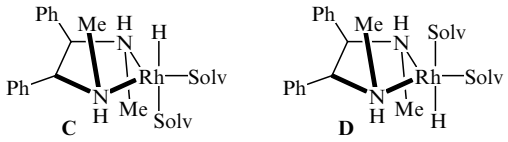
Two mechanisms of the hydrogen-transfer hydrogenation of ketones are currently being considered,[6,95,105] *viz*., route *a* (hydride route) and route *b* (direct hydrogen transfer) (Scheme 1).

Route *a* seems to be more substantiated,[97] since the hydride intermediate **B**, which adds the substrate, was detected experimentally.[135] According to DFT calculations,[89] the structure of the metallacycle containing stereogenic nitrogen atoms (the symmetry axis C_2) is the most stable in the case of the chiral C_2-symmetric ligand. By illustration, in the case of (*R*,*R*)-*N*,*N*′-dimethyl-1,2-diphenylethylenediamine (*R*,*R*)-**28** and the catalytic system

Scheme 1

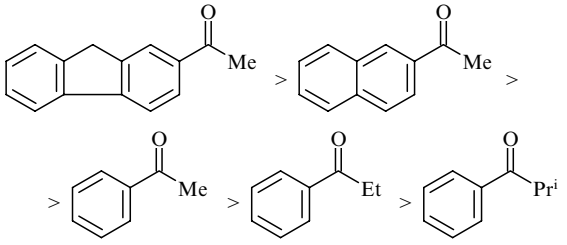


[RhCl(COD)]$_2$–(*R*,*R*)-**28** (COD is cycloocta-1,5-diene) the structures **C** and **D** can be formed.



If structures **C** and **D** are at equilibrium and the asymmetric induction in the substrate coordination step proceeds at a slower rate, the substrate can recognise the chiral environment of the metal atom as a C_2-symmetric environment.

We have obtained some experimental evidence[6,99] in favour of the asymmetric induction of hydrogen-transfer hydrogenation of aromatic ketones during their coordination on rhodium and iridium complexes [Rh–(*R*,*R*)-**30**, Rh–(*S*,*S*)-**30**, Ir–(*R*,*R*)-**30**, *etc*.].

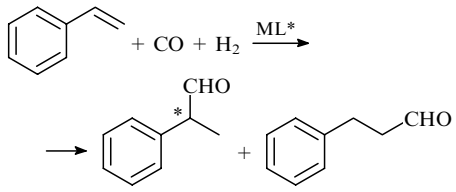


The order of changes in the *ee* values of the reaction products in the ketone series suggests that enantiodiscrimination by catalytic complexes correlates with the molecular sizes of substituents in prochiral aromatic ketones. The direct proportionality between these parameters is in favour of the asymmetric induction in the direct interaction of the catalytic complex with the substrate (ketone), *i.e*., during the coordination of the substrate.

Thus, the enantioselectivity of the hydrogen-transfer hydrogenation of acetophenone on rhodium, iridium and ruthenium complexes depends on the symmetry of a catalytic complex. Complexes with chiral C_1-symmetric (asymmetric) ligands manifest higher enantioselectivity than complexes with chiral C_2-symmetric ligands. Probably, the asymmetric induction takes place in the coordination of the carbonyl group of the ketone by the C_2-symmetric chiral hydride complex (in the case of a C_2-symmetric starting complex). In complexes with asymmetric ligands, the asymmetric induction is controlled by the asymmetric hydride complex. In some other reactions,[6] asymmetric intermediates also ensure high enantioselectivity.

IV. Catalytic hydroformylation of styrene in the presence of metal complexes

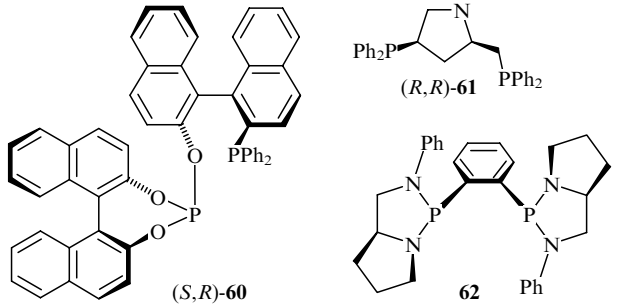
Hydroformylation of alkenes on chiral metal complexes is one of the most prominent industrially important reactions in asymmetric catalysis.[3, 47, 136–138] Several types of such reactions exist that differ in the positions of the double bonds in alkenes and the pathway of formation of chiral carbon atoms in the reaction products. Hydroformylation of styrene is especially well studied.



Platinum and rhodium complexes with phosphine and phosphinite ligands as catalysts provide the highest enantioselectivity.

Correlation of the *ee* values and the configurations of the products with the arrangement of the substituents which determine the chiralities of the corresponding complexes in the octants (the octant projection) or quadrants (the quadrant projection) suggests that the regularities $Mr^{oct}-(S)$, $Pr^{oct}-(R)$ and $Pr-(S)$, $Mr-(R)$ are fulfilled similarly in both cases for both platinum [40, 41, 45, 139–145] and rhodium complexes.[41, 46, 146, 147]

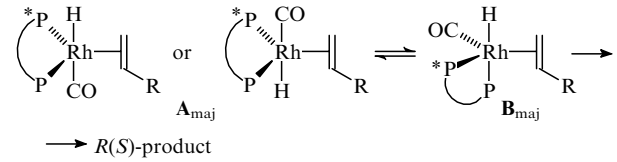
A comparison of enantioselectivities in the hydroformylation of styrene catalysed by rhodium complexes with chiral C_2-symmetric ligands and chiral C_1-symmetric (asymmetric) ligands revealed that as in the hydrogen-transfer hydrogenation, complexes containing C_2-symmetric ligands [148–154] are noticeably less enantioselective than complexes with asymmetric ligands [115, 155–162] of the type (*S*,*R*)-**60** (*ee* = 94%) or (*R*,*R*)-**61** (*ee* > 96%).[161, 162]

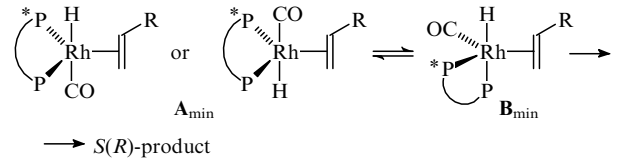


The lack of enantioselectivity in the reaction catalysed by a rhodium complex with the chiral C_2-symmetric ligand **62** (*ee* = 0) is especially surprising.[153] This ligand manifests a virtually ideal C_2-symmetry due to the conformational rigidity of the bicyclic systems at the donor phosphorus atoms.

For complexes with sulfur-containing bidentate ligands [163, 164] or ligands based on donor sulfur and phosphorus atoms,[165] or phosphorus and nitrogen atoms [166, 167] or bis(dialkylphosphine) complexes,[168] the enantioselectivity of styrene hydroformylation is rather low.

The known mechanisms of asymmetric hydroformylation of alkenes on rhodium diphosphine complexes [136, 154] suggest competition between two pairs of diastereomeric intermediates **A** and **B**,[169] which have the shape of trigonal bipyramids.



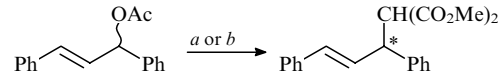


These intermediates determining the direction of the asymmetric induction represent constituents of stereoisomeric minor and major cycles. If the starting compounds represent chiral C_2-symmetric complexes and the equilibrium is established rather quickly, the chiral fragments of the intermediates $\mathbf{A}_{maj}$ and $\mathbf{A}_{min}$ are considered to be C_2-symmetric with respect to the coordination substrate.

Thus, the enantioselectivities of alkene hydroformylation on rhodium diphosphine complexes and hydrogen-transfer hydrogenation of ketones on rhodium, iridium and ruthenium complexes are determined by the symmetry of the catalytic complex. Chiral C_1-symmetric (asymmetric) complexes provide higher enantioselectivity in comparison with chiral C_2-symmetric complexes.[170] Apparently, the asymmetric induction occurs in the coordination of alkenes on chiral C_2-symmetric intermediates, the starting complex being chiral and C_2 -symmetric. In complexes containing asymmetric ligands, the asymmetric induction is effected by the asymmetric intermediate. Similar to other reactions,[6] asymmetric intermediates provide higher enantioselectivity.

V. Allylic alkylation catalysed by palladium complexes

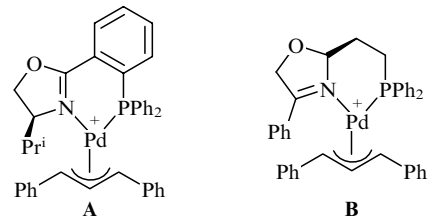
Among other asymmetric allylic alkylation reactions catalysed by palladium complexes,[171–176] the reaction with 1,3-diphenylprop-2-enyl acetate is especially well-studied.



(*a*) $[Ph(\eta^3\text{-}C_3H_5)Cl]_2$/L*, $NaCH(CO_2Me)_2$; (*b*) $[Pd(\eta^3\text{-}C_3H_5Cl]_2$/L*, $CH_2(CO_2Me)_2$, *N,O*-bis(trimethylsilyl)acetamide, AcOK.

Although the reaction product probably does not represent a valuable synthon, this reaction is very popular for a number of reasons. First, large dimensions of both the substrate and the nucleophile molecules ensure a high level of discrimination of the reaction in the presence of a catalytic complex and, as a consequence, its high enantioselectivity. Second, the nature of palladium as a complex-forming metal allows the use of diverse ligands that do not reduce the catalytic properties of the complex in this reaction.

In the allylic alkylation of 1,3-diphenylprop-2-enyl acetate with diethyl malonate in the presence of palladium complexes with several ligands, a series of intermediates with a coordinated allylic substrate was isolated and their structures were established by X-ray diffraction analysis.[177–179] The bulky, spatially extended molecule of the coordinated substrate in these intermediates shifts the ligand fragments to the rear octants (the octant projection). However, such a shift should be considered as a trend rather than a rule. Thus the phenyl substituent in the oxazoline ligand fragment of the complex **B** falls into the frontal octant.[179]

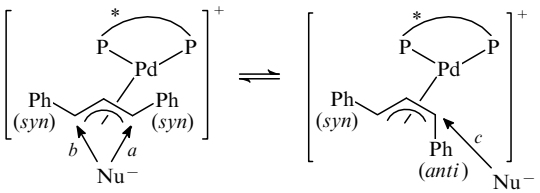


As the asymmetric induction takes place in the attack of the nucleophile on the intermediate containing a coordinated allylic group (see below), the distribution of substituents in the octants should be estimated for these intermediates. The projections and the distributions of substituents in palladium chiral C_2-symmetric diphosphine and diphosphinite complexes in the octants and quadrants as well as *ee* values and the configuration of the allylic alkylation product of 1,3-diphenylprop-2-enyl acetate by diethyl malonate in the presence of these complexes are listed in Table 6. As can be seen, in 70% of cases the formation of allylic alkylation products conforms to the rule: Pr^{oct}–(*S*), Mr^{oct}–(*R*). The configurational model *Pr*/*Mr*–(*S*)/(*R*) is fulfilled with a ~50% probability, *i.e.*, the rule based on quadrant projections is inapplicable to this case.

The enantioselectivity of the reaction catalysed by palladium diphosphinite complexes depends, to a large measure, on the nature of the substituents at the phosphorus atoms of the ligand (see data from the complexes Pd–**66**, Table 6).

The enantioselectivity of this reaction can be explained by steric and electronic factors, *e.g.*, the effects of substituents on the relative activities of two terminal allylic positions attacked by a nucleophile (Scheme 2, routes *a*, *b*) or *syn*,*syn*/*syn*,*anti*-isomerism (Scheme 2, route *c*).[71]

Scheme 2



All three routes are associated with changes in the product configuration. The contribution of steric factors due to the energy gain in the case of the equatorial position of bulky substituents in the chelate ring (*cf.* Ref. 77) is presumably [71] compensated for by the effects of electronic factors. It is rather difficult to detect electronic effects in the background of the steric effects in reactions carried out in the presence of complexes with ligands that form seven-membered chelate rings [71] because of the high conformational labilities of these complexes.

Table 6. Allylic alkylation of 1,3-diphenylprop-2-enyl acetate with diethyl malonate in the presence of palladium chiral C_2-symmetric diphosphine and diphosphinite complexes.

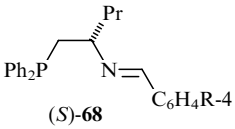
Note. Cy is cyclohexyl. [a] Calculation (see Ref. 182). [b] X-Ray diffraction data.[59]

The ligand **68** forms a palladium complex with a conformationally more rigid five-membered metallacycle; therefore, it represents a more convenient subject for this study.[183]

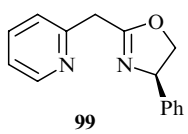


(*S*)-**68**

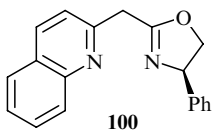
R	H	CO_2Me	CF_3	Me	OMe	NMe_2
ee, %	52 (*R*)	19 (*R*)	38 (*R*)	74 (*R*)	85 (*R*)	92 (*R*)

It has been found that electron-withdrawing groups decrease enantioselectivity, while electron-donor groups increase it. The effects of purely electronic factors on the enantioselectivity can be judged from a comparison of ligands with 4-CF_3 and 4-Me groups. Their steric effects are virtually similar, but *ee* values are significantly different. Hence, electronic factors influence *ee*, but not the product configuration.

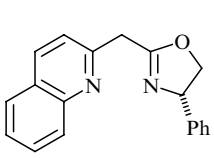
The data on the allylic alkylation of 1,3-diphenylprop-2-enyl acetate by diethyl malonate in the presence of conformationally rigid Pd complexes are summarised in Table 7. The positions of the substituents in the ligands can be determined using molecular models and based on the data for the complexes the structures of which were established by X-ray diffraction analysis or by calculations.



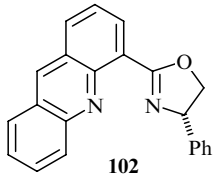
99



100



101



102

Ligand	*ee* (%)	Product configuration
(*R*)-**99**	16	*R*
(*R*)-**100**	78	*S*
(*S*)-**101**	75	*R*
(*S*)-**102**	34	*R*

The sign of enantioselectivity for the complexes with the ligands (*R*)-**100**, (*S*)-**101** and (*S*)-**102**[190] not included in Table 7 is opposite to that expected based on the corresponding data for the complexes Pd–**80** (see Table 7) and Pd–**99**. It is suggested[190] that two diastereomeric intermediates, **A** and **B** (Scheme 3), exist, which are converted into the π-complexes **C**–**F** by four different routes. Different reactivities of these intermediates also contribute to the stereochemistry of the reaction products. The intermediates **C** and **E** are preferable for complexes with ligands of the type **99**, whereas the intermediates **D** or **F** are more typical of complexes with ligands of the type **100**. This is due to the steric interactions of the left chiral centre in the complexes **C** and **E** containing an isoquinoline fragment. The transition from the complex **C** to **D** or from **E** to **F** should be accompanied by configurational changes in the reaction product, which is the case.

As can be seen from Table 7, the dependences Pr^{oct}–(*S*), Mr^{oct}–(*R*) and *Pr*–(*S*), *Mr*–(*R*) are fulfilled in 95% and 80% of cases, respectively. Besides, the model *Pr*/*Mr* is inapplicable in a few cases (see ligands **89**–**91**). Therefore, the octant model is preferable for this reaction.

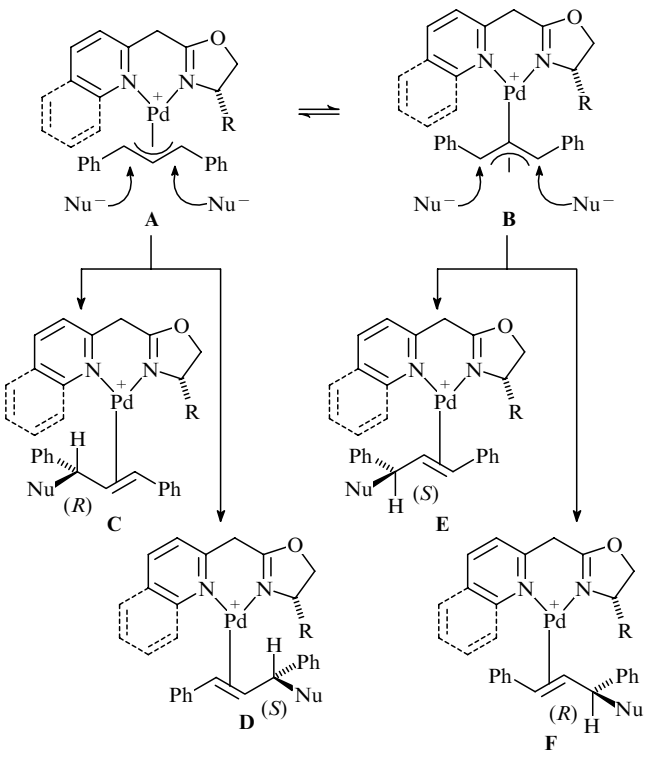
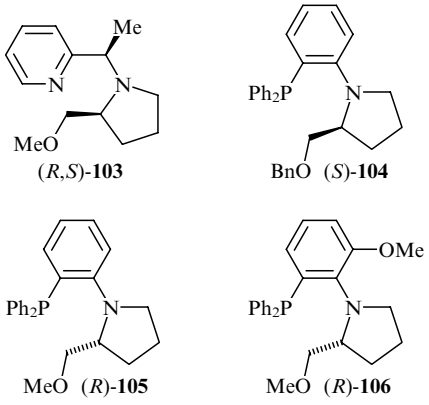
The enantioselectivities of the majority of the complexes with ligands listed in Table 7 are close to 90% or higher. All these ligands confer higher conformational rigidity on the chelate rings formed due to the presence of aromatic or oxazoline substituents in the metallacycle.

For the majority of cases, the higher the enantioselectivity of the reaction in the presence of a complex, the larger is the molecular volume of the chirality-determining substituent in the conformationally rigid chelate ring of the complex (only the most efficient substituents are listed in Table 7).

If a chiral centre is located at the donor atom of the ring, as in the case of the ligands **103**–**105**, the coordination of the ligand by the metal atom results in the formation of two stereoisomeric complexes.

Scheme 3

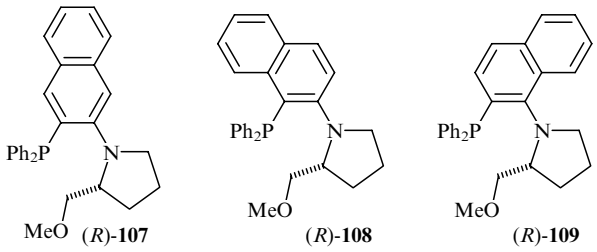




Ligand	*ee* (%)	Product configuration	Ref.
(*R*,*S*)-**103**	6	*S*	214
(*S*)-**104**	36	*S*	215
(*R*)-**105**	49	*R*	215
(*R*)-**106**	85	*R*	216

The substituents in such stereoisomers can fall into octants bearing opposite signs; therefore, it is expected that the reaction enantioselectivity cannot be too high, which is the case. However, the introduction of an additional substituent preventing free rotation around the C–N bond (ligand **106**) causes a sharp increase in the enantioselectivity.

A similar situation is observed for complexes with the ligands **107**–**109**.[215]



Ligand	*ee* (%)	Product configuration
(*R*)-**107**	24	*R*
(*R*)-**108**	39	*R*
(*R*)-**109**	74	*R*

The arrangement of the naphthyl rings in the ligand **109** hinders the free rotation of the pyrrolidine fragment to the largest extent if compared with compounds **107** and **108**; therefore, the enantioselectivity of the reaction is higher in this case.

Bidentate ligands of the cyclophane [217] and ferrocene [218] series have been described, which appear to be too bulky to allow the analysis of the octant projections of the complexes based on them.

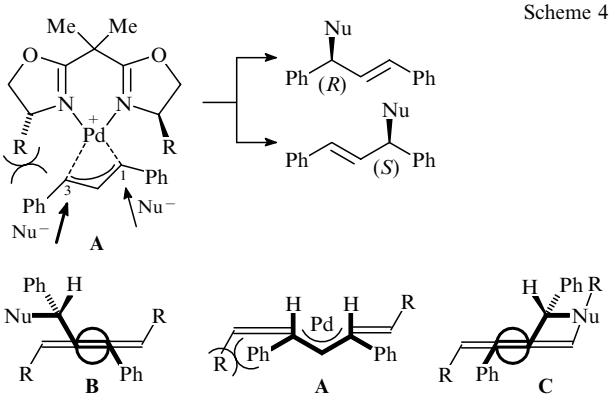
The enantioselectivity of the allylic alkylation catalysed by conformationally rigid palladium complexes depends only slightly on reaction conditions. For example, the *ee* value of the reaction product formed in the presence of the Pd–**84** complex depends only slightly on the nature of the cation in MOAc.[198] The enantioselectivity is virtually independent of either the precursor of the catalytic complex and the solvent or of temperature and reaction time.

Some ligand complexes provide sufficiently high reaction enantioselectivity, but their octant projections are difficult to establish for a number of reasons. For some complexes containing bulky tetradentate C_2-symmetric,[72, 73, 219–223] tridentate asymmetric [72, 196, 224] and tetradentate asymmetric [225] ligands, X-ray diffraction data are lacking. Complexes with some bi- and tridentate ligands [194, 216, 226, 227] manifest rotational isomerism as in the case of the ligands **103**–**109**. Bi-, tri- and tetradentate C_1- and C_2-symmetric ligands of some other complexes [221, 224, 225, 228–236] have too bulky backbones and determination of their octant projections is ambiguous.

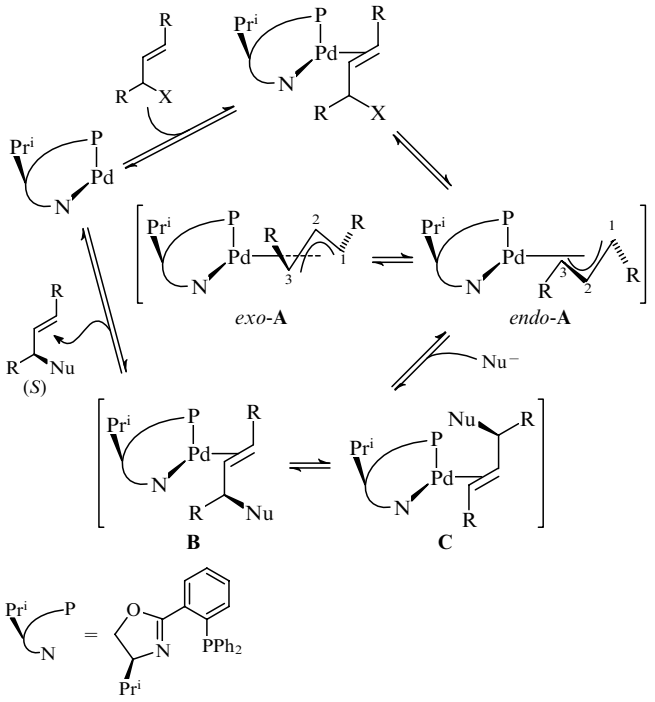
The mechanism of allylic alkylation includes oxidative addition of the allylic group to a Pd(0) complex to yield diastereomeric π-allylic intermediates (see Schemes 2 and 3), which are at equilibrium (the π–δ–π-mechanism), and their subsequent attack by a nucleophile from the side opposite to the coordinated palladium.[75, 171, 185, 237–239] The irreversible oxidative addition of the allylic group occurs much faster than the nucleophilic attack. The rate of the epimerisation of π-allylic intermediates is also by one or two orders of magnitude higher.[237] Therefore, the attack by a nucleophile is the limiting and, simultaneously, the asymmetric induction step. The latter is controlled by an asymmetric π-allylic intermediate irrespective of whether the starting palladium complex is asymmetric or chiral C_2-symmetric. The predominant enantiomer of the reaction product, which determines its configuration,[237] is formed *via* a π-allylic intermediate, which is in excess.

An alternative opinion[75, 185] consists of the following: if the starting complex is chiral and C_2-symmetric, the enantiomerism of the major product is determined by the competition between the positions C(1) and C(3) of the coordinated allylic substituents subject to the attack by the nucleophile in a single reaction intermediate. This is exemplified by the complex Pd–(*R*)-**70** (Scheme 4). The square-planar geometry of this intermediate was confirmed by X-ray diffraction analysis.[185] The intermediates

Scheme 4



Scheme 5



of reactions catalysed by other palladium complexes have similar structures.[174, 200, 240–242] The enantioselectivity is determined by the regioselectivity of the nucleophilic attack on the (1,3-diphenylallyl)palladium intermediate at positions C(3) or C(1). X-Ray diffraction and ^{13}C NMR spectroscopic data suggest that the Pd–C(3) bond is longer than the Pd–C(1) bond, presumably due to the steric interaction of the allylic phenyl group at the C(3) atom with the neighbouring benzyl group (R) in the dihydroxazole ring of the ligand **70**. The elongation of the bond increases the reactivity of the allylic substituent at position C(3) and favours its attack by the nucleophile at this position. The configuration of the reaction product [*ee* = 88% (*R*)] is consistent with this interpretation. Analogous considerations were employed in the analysis of reactions with other chiral C_2-symmetric complexes.[75] However, the concept of the regioselective activation of palladium–allylic bonds differs from that suggesting that the enantioselectivity is determined by the direct interaction of the chiral ligand with the nucleophile.[243–247]

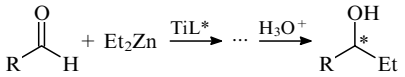
An alternative interpretation of enantioselectivity is based on the differences in the thermodynamic stabilities of the Pd(0) complexes **B** and **C** with the product the existence of which was recently confirmed experimentally (see Scheme 4).[238] As regards stereochemistry, the intermediate **B**, which favours the formation of the (*R*)-product, is undoubtedly more stable than the intermediate **C**.

If asymmetric complexes contain different donor atoms as in, *e.g.*, the complex Pd–**83**, two (1,3-diphenylallyl)palladium intermediates are in equilibrium.[238] The catalytic cycle of the allylic alkylation reaction catalysed by the Pd–**83** complex [R = Ph, X = OAc, Nu = $CH(CO_2Me)_2$] is shown in Scheme 5. The attack by the nucleophile at positions C(1) or C(3) of the intermediates *exo*-**A** and *endo*-**A** corresponds to the four possible reaction routes two of which, *viz.*, the attack at position C(3) of the intermediate *exo*-**A** and at position C(1) of the intermediate *endo*-**A**, should yield the *S*-enantiomer, which is the case. The intermediate **B** was identified experimentally by NMR spectroscopy,[238] therefore, it it assumed that the predominant reaction route involves a nucleophilic attack at the *trans*-position relative to the phosphorus atom in the intermediate *exo*-**A**. This conclusion is in keeping with the allylic alkylation mechanism proposed for reactions catalysed by other asymmetric palladium complexes.[178, 200, 239–248]

Thus, the asymmetric induction in the allylic alkylation catalysed by palladium chiral C_2-symmetric complexes takes place either in the step of the chiral intermediate, which has lost its C_2-symmetry after coordination to the substrate (see Scheme 4, intermediate **A**), or during the conversions of chiral intermediates (see Scheme 5) which are also devoid of the symmetry elements (except for C_1). In this case, palladium complexes containing both chiral C_2-symmetric ligands and chiral C_1-symmetric (asymmetric) ligands ensure high (up to 98%–99%) enantioselectivity of this reaction.

VI. Alkylation of benzaldehyde with dialkylzinc catalysed by titanium complexes

The formation of optically active alcohols in reactions of aldehydes with diethylzinc at low temperatures in the presence of *in situ* generated titanium chiral complexes is a well-studied reaction.[9, 17, 249, 250]



The reaction of benzaldehyde with diethylzinc in the presence of titanium complexes with chiral diols, sulfonamides and phosphoramides has been studied in especially great detail (Table 8). The experimental results suggest that the regularities Pr^{oct}–(*R*), Mr^{oct}–(*S*) and *Pr*–(*R*), *Mr*–(*S*) are fulfilled with a probability of 97%.

The same probability of fulfilment (87%) of the dependences based on the use of octant and quadrant projections [Pr^{oct}–(*S*), Mr^{oct}–(*R*) and *Pr*–(*S*), *Mr*–(*R*)] was also observed in the alkylation of benzaldehyde with diethylzinc in the presence of titanium asymmetric complexes with amino alcohols, *N*-sulfonylamino alcohols and *N*-thiophosphoramido alcohols (Table 9).

A hypothetical catalytic cycle of alkylation of benzaldehyde with diethylzinc in the presence of titanium complexes with *N*-substituted diamines is shown in Scheme 6.[266] Presumably, the intermediate **A** is the key species. This reacts with the aldehyde to give dialkoxytitanate **B**, which regenerates the key intermediate **A** in such a way that the catalytic cycle is closed. According to this scheme, the asymmetric induction takes place in the interaction of the aldehyde with the asymmetric complex irrespective of the symmetry (C_1 or C_2) of the starting catalytic complex. The maximum values of *ee* for the alkylation of benzaldehyde catalysed by Ti complexes with chiral C_2- and C_1-symmetric ligands are nearly identical (up to 98%).

Table 8. Asymmetric alkylation of benzaldehyde (**S**) with diethylzinc in the presence of titanium complexes with chiral diols, sulfonamides and phosphoramides.

It is of note that the feasibility of the configurational model (Pr^{oct}/Mr^{oct} or Pr/Mr) in the alkylation of benzaldehyde in the presence of titanium complexes with various chiral C_1- and C_2-symmetric ligands is very high (up to 93%). This testifies to a similarity of the reaction mechanisms in both cases and corrobo-

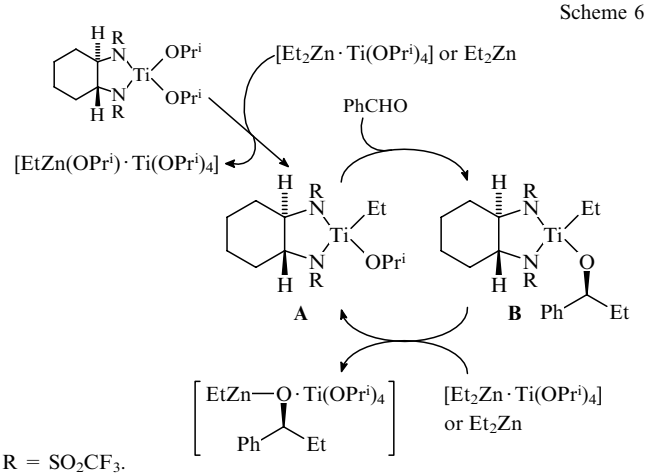
rates the conclusion that the maximum enantioselectivity of this reaction does not depend on the symmetry of the ligand.

Scheme 6



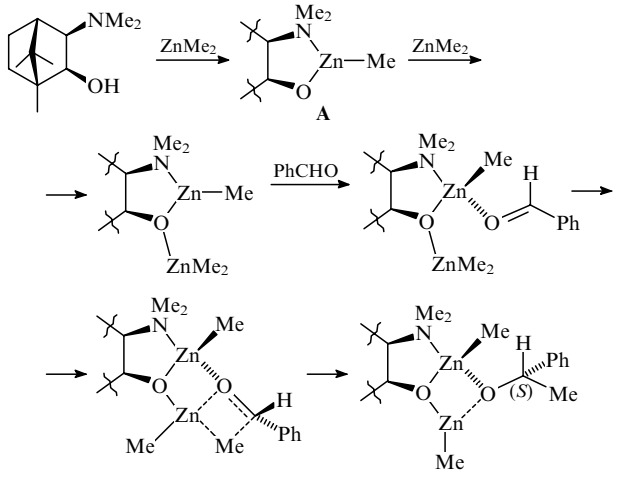
R = SO_2CF_3.

VII. Alkylation of benzaldehyde with dialkylzinc in the presence of amino alcohols and related compounds

In the asymmetric alkylation of aldehydes with dialkylzinc (see Refs 9, 17, 249 and 250), chiral amino alcohols, amido alcohols, diamines, diols, amino thiols, disulfides and diselenides represented components of *in situ* generated catalytic systems. The reaction of benzaldehyde with diethylzinc is a standard reaction, but in this case it is carried out in the absence of $Ti(OPr^i)_4$. As can be judged from the number of compounds tested as chiral ligands, this reaction seems to be a leader among other asymmetric reactions.

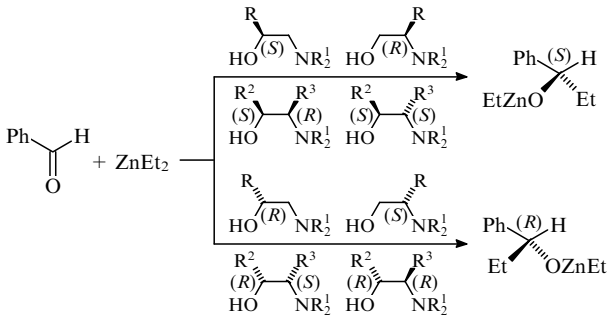
Experimental and theoretical studies into the mechanism of the reaction of dialkylzinc with benzaldehyde in the presence of amino alcohols have made it possible to establish the order of formation of intermediates [3, 9, 277–281] (Scheme 7). The first step includes the formation of the chelate zinc complex **A** with an amino alcohol, which determines the stereochemistry of its further conversions. The configurational relationships between the

Scheme 7



amino-alcohol ligand and the reaction product are described by the scheme (Scheme 8) proposed by Noyori *et al.*[249]

Scheme 8



This scheme is based on a large body of experimental evidence [282–344] and reflects adequately the relationship between the product and ligand configurations. A comparison of configurational models for the reaction of dialkylzinc with benzaldehyde in the presence of amino alcohols,[304–316, 333] which provide the maximum enantioselectivity of the reaction, is given in Table 10. The data from Table 10 and the analysis of experimental data [282–344] suggest that the regularities $Pr^{oct} \rightarrow (S)$, $Mr^{oct} \rightarrow (R)$ and $Pr \rightarrow (S)$, $Mr \rightarrow (R)$ are equally observed in nearly 93% of cases. However, in contrast to the octant model, the quadrant

projection model can be applied to a limited number of ligands only. The quadrant model is inapplicable to reactions in the presence of complexes with the ligands **148**–**151** and **153**–**157** due to location of coordinated ligand fragments in the quadrants with opposite signs.

Here, as in other cases (see, *e.g.*, Tables 3–7), the overwhelming majority of complexes that ensure high enantioselectivity of the reaction possess conformational rigidity. These include five-membered chelate complexes with bulky substituents (Ph, Bu^t, Pr^i) the conformational rigidity of the chelate ring which is

[a] This reaction occurs in the presence of 4-ClC_6H_4CHO.

provided by a more advantageous equatorial position of the substituent [77] (complexes with the ligands **139** – **145**). The conformational rigidities of many efficient complexes are enhanced owing to the incorporation of one of the bonds of the first chelate ring into the second ring (complexes with the ligands **146** – **156**). Complexes with atropoisomeric ligands (*e.g.*, the ligand **157**) constitute a special group.

Octant projections can be constructed for a small group of complexes with chiral amino thiols, which represent thio analogues of the ligands **139** – **143** and **145**.[306, 326, 345 – 354] All of them have the same structural features as the amino alcohol-containing complexes. It is therefore not surprising that reactions catalysed by these complexes follow the same regularities, *viz.*, $Pr^{oct}\rightarrow(S)$, $Mr^{oct}\rightarrow(R)$ and $Pr\rightarrow(S)$, $Mr\rightarrow(R)$, with a high degree of probability (~90%).

A comparison of chiral C_2-symmetric tetradentate ligands (which are rather few in number) (Table 11) with their asymmetric 'monomeric' bidentate counterparts has shown that the involvement of all these ligands in the reaction is largely due to the involvement of their 'monomeric' asymmetric fragments. A comparison of the experimental results obtained with the complexes with both 'monomeric' and the corresponding 'dimeric' ligands revealed a virtually complete coincidence of the *ee* values and the

Table 12. Asymmetric alkylation of benzaldehyde with diethylzinc in the presence of chiral C_2-symmetric tridentate ligands and their asymmetric analogues.[358]

 (*S*,*S*)-**176**	65 (*S*)	 (*R*,*R*)-**177**	67 (*R*)
 (*S*,*S*)-**178**	55 (*S*)	 (*S*,*S*)-**179**	35 (*S*)
 (*S*,*S*)-**180**	93 (*S*)	 (*S*,*S*)-**181**	95 (*S*)

product configurations, which provides convincing evidence in favour of this conclusion.

An analysis of the data summarised in Table 12, which compares the results obtained in the presence of chiral C_2-symmetric tridentate ligands and their asymmetric analogues, corroborated this conclusion. The similarity of the *ee* values and the coincidence of the product configurations were observed in the majority of cases. This provides additional evidence in favour of the fact that the reaction in the presence of chiral C_2-symmetric tri- and tetradentate ligands involves their asymmetric bidentate fragments.

Thus, it is only asymmetric ligands that are effective in the asymmetric alkylation of benzaldehyde with diethylzinc in the absence of $Ti(OPr^i)_4$.

Successful implementation of asymmetric reactions in the presence of chiral C_2-symmetric ligands requires the presence of $Ti(OPr^i)_4$ in the catalytic system (see Table 8).

Unfortunately, the applicability of the above-described regularities to a large number of complexes cannot be estimated because their octant projections are too difficult to establish.

In some cases,[359–365] the problem arises as to whether the chiral centre is located in the side chain of the ligand or the complex contains a ring spiro-fused to the metallacycle.[319,366–373] Because of the ambiguity of determination of the octant projection, complexes with bulky tri- and tetradentate ligands cannot be considered.[362,368,371,374–388] However, the tetradentate C_2-symmetric ligands **166**–**175** were included in Table 11, because there is evidence that their bidentate fragments are involved in the catalysis as components of the corresponding complexes. For complexes with ligands containing bulky fragments[306,383] that rotate around the C–C bond in their side chains, the octant projection cannot be established at all. Complexes with several seven-membered metallacycles[389–392] contain $(CH_2)_2$ fragments, and their octant projections cannot be unambiguously determined because of the conformational lability of the coordinated ligand. The octant projections of the complexes the ligands in which form eight-membered (and larger-sized) metallacycles[393,394] as well as of some other complexes[285,372,376,395–397] cannot be reliably determined either.

The mechanism of asymmetric induction in the alkylation of benzaldehyde with diethylzinc in the presence of chiral C_2-symmetric ligands will be discussed in the next Section.

VIII. Complexes with chiral C_2-symmetric ligands as the asymmetry inductors

Previously, it was concluded[6] that the intermediate responsible for the asymmetric induction in some asymmetric reactions is asymmetric irrespective of the symmetry of the starting complex. This conclusion was made in the analysis of mechanisms of such reactions as hydrogenation of amino acid precursors and hydrosilylation of ketones in the presence of chiral metal complexes. In other words, in the catalysis by complexes containing C_2-symmetric ligands the C_2-symmetry is lost in the step preceding the asymmetric induction. High enantioselectivity can be achieved with the use of complexes with both asymmetric and chiral C_2-symmetric ligands as catalysts. A similar conclusion was made in the analysis of allylic alkylation, cyclopropanation, the Diels–Alder reactions and benzaldehyde alkylation with dialkylzinc on titanium complexes.

Complexes with chiral C_2-symmetric and asymmetric ligands manifest different efficiencies in the hydrogen-transfer hydrogenation of acetophenone and hydroformylation of styrene. Complexes with asymmetric ligands provide higher enantioselectivities (see Sections III and IV). Presumably, this can be related to the C_2-symmetry of the intermediate responsible for the asymmetric induction (in the case of chiral C_2-symmetric complexes).

The presence or the absence of titanium complexes in the catalytic system influences significantly the enantioselectivity of the alkylation of benzaldehyde with dialkylzinc in the presence of chiral C_2-symmetric ligands (Table 13). In all the cases studied,

the enantioselectivity is highly enhanced in the presence of $Ti(OPr^i)_4$ in the catalytic system.

The data on the addition of diethylzinc to benzaldehyde in the presence of chiral ligands with a C_2-symmetry axis passing through the donor nitrogen atom are presented in Table 14. In C_2-symmetric fragments of the ligands **188**–**190**, one of the oxygen atoms can be coordinated with the catalyst (in contrast to the ligands **185** and **186** which are devoid of such an ability due to the shielding of the oxygen atoms by bulky groups). As a result, the *ee* value increases from 10(20)% to 90(95)% (the ligand **187** [400, 401] occupies an intermediate position). An analysis of molecular models revealed that the zinc atom can coordinate not only the donor atoms of the ligands [O(S) and N], but also the oxygen atom of one of two identical and C_2-symmetric groups in the nitrogen-containing ring. Under these conditions, the second group becomes inaccessible for the coordination. The C_2-symmetry of the catalytic complex is lost as a result of additional coordination of the oxygen atom of only one of the chiral C_2-symmetric groups of the ligand by the zinc atom. Complexes with similar ligands that are incapable of such coordination and therefore manifest higher symmetry appear to be less enantioselective as catalysts.

The reaction catalysed by chiral C_2-symmetric titanium complexes proceeds *via* the asymmetric intermediate **A** (see Scheme 7). Based on calorimetric studies, a catalytic model has been proposed for the reaction catalysed by complexes with asymmetric ligands of the type **191** and **192** (Scheme 9). According to this scheme, the asymmetric induction is realised in the **A** → **B** conversion step.

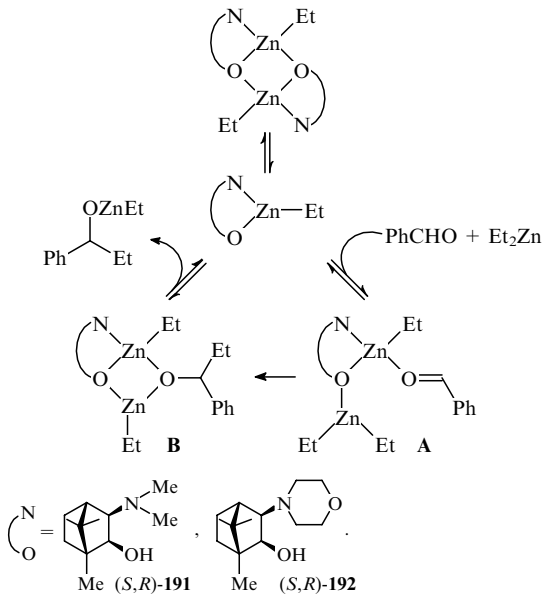
Scheme 9

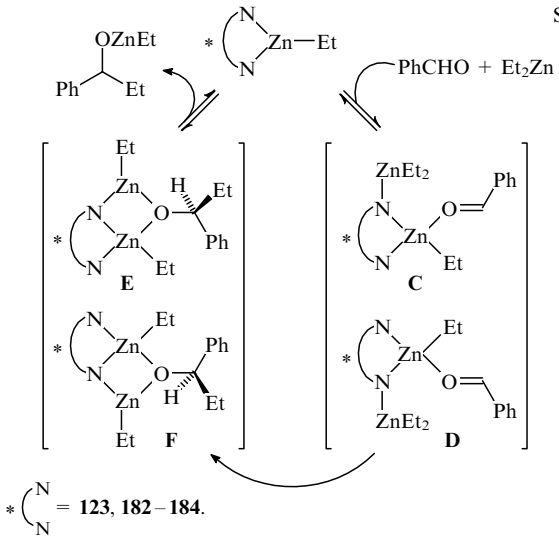


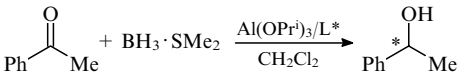
Extrapolation of this model to a reaction catalysed by complexes with chiral C_2-symmetric ligands of the type **123**, **182**–**184** (Scheme 10) demonstrates that in this case, too, the **A** → **B** step is responsible for asymmetric induction. The structures **C** and **D** determining the asymmetric induction are diastereomeric, but the immediate environments of the coordinated aldehyde in each of these intermediates represent enantiomeric species. Presumably, the difference in the concentrations of the diastereomers **E** and **F**, which favour the formation of different enantiomers of the reaction product, is small; therefore, the enantioselectivity of the reaction should be low which actually is the case.

Thus, the increase in enantioselectivity on going from a reaction in the presence of chiral C_2-symmetric ligands to a reaction catalysed by titanium complexes with these ligands (see Table 13), is due to the loss of C_2-symmetry by the intermediate. A deviation from this rule, which is manifested in moderate enantioselectivity in the presence of the chiral C_2-symmetric ligand **123** [*ee* = 54% (*S*)], can be attributed to the fact that the ideal C_2-symmetry is not realised in this case, presumably due to, *e.g.*, conformational distortions in the six-membered ring.

The reduction of acetophenone with borane in the presence of chiral C_2-symmetric atropoisomeric ligands becomes enantioselective upon the addition of $Al(OPr^i)_3$ to the reaction system (Table 15).[402]

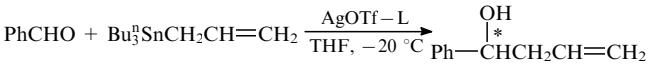
Scheme 10





The enhancement of the enantioselectivity of this reaction can be due to the same factors as in the alkylation of benzaldehyde with dialkylzinc in the presence of $Ti(OPr^i)_4$ and without it (see Table 13). Apparently, in contrast to the chiral C_2-symmetric reducing reagent based on borane and a ligand, the catalytic system generated *in situ* from borane, a chiral C_2-symmetric ligand and $Al(OPr^i)_3$, is asymmetric.

The loss of C_2-symmetry in the series of chiral ligands of the same type is accompanied by a drastic enhancement of the enantioselectivity of certain catalytic reactions. The allylation of aldehydes is an example.[403]



L	*ee* (%)	Product configuration
 (*R*,*R*)-**195**	9	*R*
 (*R*,*R*)-**196**	15	*R*
 (*R*)-**197**	52	*R*

The oxidation of sulfides is a striking example of high sensitivity of the enantioselectivity of a catalytic reaction to the C_2-symmetry of the chiral ligands.

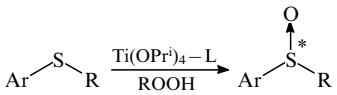
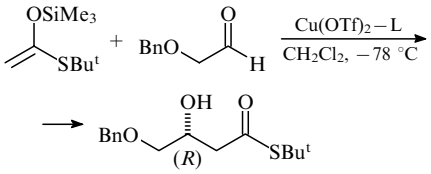
 (*R*)-**194**	93	0	97	10 (*R*)
(*R*)-**115**	91	0	95	71 (*S*)



As can be seen from Table 16, the enantioselectivity of this reaction depends on the structures of chiral diols as the ligands. A comparison of conformational rigidities of such ligands revealed that the possible conformational deviations from the ideal C_2-symmetry decrease in the following order: **198** < **199** ≪ **200** ≈ **201**. For the latter two ligands, the deviations are the greatest due to the free rotation of the Bu^t and Ph groups at the chiral carbon atoms around the C–C bond. This order coincides with the order of changes in *ee* of the reaction product formed in the presence of the same ligands (Table 16). Thus, in the sulfide oxidation these parameters are linearly interrelated.

The existence of such a relationship is confirmed by an analysis of numerous published data on asymmetric catalytic reactions. Contrary to expectations, the transition from a conformationally labile six-membered metallacycle to a more rigid seven-membered ring results in a radical decrease in the enantioselectivity of aldol condensation.[407]



Ligand L	 (*S*,*S*)-**202**	 (*S*,*S*)-**203**
ee (%) (product configuration)	64 (*R*)	0

In this case, this can be attributed to a more perfect C_2-symmetry of the complex with a seven-membered metallacycle. Similarly, lower enantioselectivity of aldehyde allylation corre-

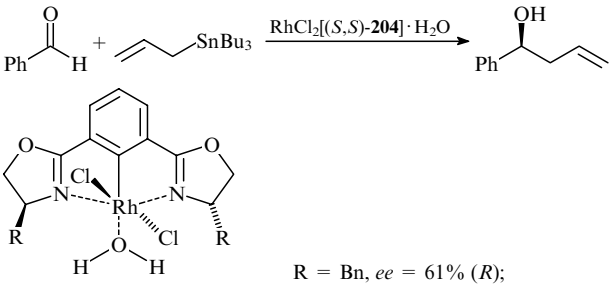
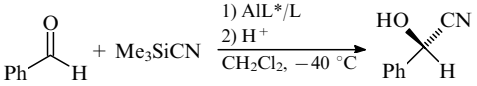
sponds to a more perfect C_2-symmetry of the complex $RhCl_2[(S,S)$-**204**$]\cdot H_2O$ (R = Ph) (in comparison with the symmetry of the same complex containing a benzyl substituent).[408]



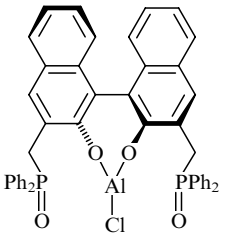
$RhCl_2[(S,S)$-**204**$]\cdot H_2O$

R = Bn, *ee* = 61% (*R*);
R = Ph, *ee* = 6% (*R*).

And, finally, there is evidence that the enhancement of enantioselectivity can be due to the loss, by the chiral C_2-symmetric catalytic complex, of the symmetry axis C_2. Numerous findings suggest that the enantioselectivity is enhanced upon addition of monodentate achiral auxiliary ligands (additives or co-catalysts) to the reaction mixture.[409] The cyanosilylation of aldehydes in the presence of Lewis acids as catalysts is a typical example of such a reaction.



For example, the reaction catalysed by the aluminium complex AlCl[(*S*)-**205**] in the presence of an achiral ligand proceeds with a much higher enantioselectivity.[410]



AlCl[(*S*)-**205**]

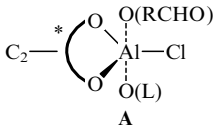
ee (%) (product configuration)	9 (*S*)	97 (*S*)	25 (*S*)	90 (*S*)

It is known that the intermediate **A**, which has the structure of a trigonal bipyramid, is formed in the presence of an achiral ligand.[411, 412]



A

In contrast to the complex formed in the absence of an additional ligand, in the intermediate **A** the symmetry axis C_2 is lost. Consequently, the enhancement of the enantioselectivity can be explained by the asymmetry of the intermediate **A**. A similar effect in the Mannich reaction is induced by an additional ligand.[413] A weaker effect is observed in the allylic alkylation reaction,[414] *etc.*[415] upon introduction of an achiral ligand. Numerous examples of the use of molecular sieves (MS 4 Å) for enhancement of the enantioselectivity of a catalytic reaction in the presence of chiral C_2-symmetric metallocomplexes are known (for more recent publications, see Refs 416 and 417). This effect can also be due to the loss of the C_2-symmetry by chiral C_2-symmetric complexes upon chemisorption on the surface of aluminosilicate. As a result, the asymmetric induction is realised in the step involving the asymmetric intermediate, *i.e.*, that devoid of any symmetry elements other than C_1.

Thus, the opinion[418] that chiral C_2-symmetric ligands are the most efficient asymmetry inductors should probably be considered in the context of a concrete reaction mechanism. For example, in such reactions as hydrogen-transfer hydrogenation of ketones, hydroformylation of styrene or alkylation of aldehydes with dialkylzinc [without the involvement of $Ti(OPr^i)_4$ or analogous complexes], these ligands are less efficient than asymmetric ligands. In reactions like sulfide oxidation, complexes with a chiral C_2-symmetric ligand act as asymmetry inductors, most probably due to the deviation from the ideal C_2-symmetry. Actually, in such cases it is the intermediate that becomes asymmetric due to the loss of the symmetry axis C_2 that is responsible for the asymmetric induction.

The abnormal inefficiency of complexes with chiral C_2-symmetric ligands as asymmetry inductors was observed earlier, *e.g.*, in hydroformylation reactions.[170] This was rationalised by the peculiarities of this reaction, but the true reason for this phenomenon seems to be more fundamental. Presumably, this effect is not confined to catalytic reactions only. Thus, our findings[419–421] and the results by other investigators[422–425] point to an abnormally low enantioselectivity of acetophenone reduction by lithium chiral dihydrides $[(O\ O)LiH_2]$¶ modified by the atropoisomeric ligands **41**, **110**, and **206**–**208**.

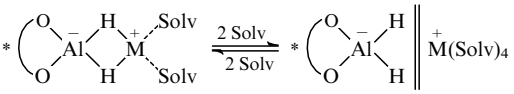
Ligand	*ee* (%) (product configuration)	Ref.	Ligand	*ee* (%) (product configuration)	Ref.
 (*R*)-**110** (binol)	2 (*R*) 0	422 420	 (*R*)-**208**	43 (*R*)	423
 (*R*)-**206**	9 (*R*)	423	 (*R*,*R*)-**41** (Ar = H, C_6H_4OMe-4)	78 (*R*)	425
 (*R*)-**207**	2 (*R*)	424			

Since the aluminium atom in $LiAlH_4$ has a tetrahedral environment, the structure of the dihydride anion based on these chiral C_2-symmetric ligands is close to ideal C_2-symmetric. The introduction of an ethyl group into the ligand **206** (giving the ligand **208**) increases the deviation of its C_2 symmetry from the ideal in comparison with the ligands **110**, **206** and **207**. It is this factor that is responsible for the moderate enantioselectivity of the dihydride containing the ligand **208**. Further enhancement of the enantioselectivity is observed upon transition to the ligand **41**,

¶ It was suggested[422] that the disproportionation of $Li(binol)AlH_2$ to $LiAlH_4$ and $LiAl(binol)_2$ was the reason for the low enantioselectivity of the reduction of ketones with this dihydride. Our experiments[420] showed that this was not the case: no disproportionation took place under the reaction conditions.

which has four phenyl groups that rotate around the $C-C_{Ph}$ bond and thus disturb the C_2-symmetry.

Both the non-modified hydrides $LiAlH_4$ and $NaAlH_4$ and diol-modified hydrides react with ketones in THF or diglyme, predominantly as contact and dissociated ion pairs.[426]



Solv is solvent.

Since the Li^+ cation is a stronger acid than Na^+, it can be expected that the bridging ring is more rigid in the case of Li; therefore, the violation of the C_2-symmetry in the case of lithium dihydride is less pronounced. In turn, the ring formed by the ligand in a planar monohydride based on AlH_3 is more strained than that in the dihydride based on $NaAlH_4$. Therefore, the C_2-symmetry of the latter is less perfect. We found that the *ee* values of the reduction products of substrates containing C=O and C=N groups are higher in the case where the C_2-symmetry of the hydride is violated to a greater extent [the ligand **209** represents an analogue of the ligand **41** (Ar = C_6H_4OMe-4)] (Table 17).

Table 17. Enantioselectivity in reduction with aluminium hydrides.[420, 421]

These data suggest that this phenomenon is versatile and is not confined to catalytic reactions.

IX. Conclusion

A comparison of the configurational models Mr^{oct}/Pr^{oct} and Mr/Pr, in the example of catalytic hydrogen-transfer hydrogenation, hydroformylation, allylic alkylation and alkylation of aldehydes with dialkylzinc and some other reactions, suggests that preference should be given to the former based on the octant projection.

The configurational relationships 'catalytic complex – reaction product' considered in this review are based on the analysis of octant and quadrant projections obtained from consideration of molecular models, X-ray diffraction data or calculations for certain structures. It is of note that both X-ray diffraction data and numerous calculations (to say nothing of molecular models) give purely probabilistic patterns of spatial arrangements of molecular fragments in real intermediates, especially under the reaction conditions. However, the accuracy of the estimation of the fulfillment of the regularity $Pr^{oct}-(S)$, $Mr^{oct}-(R)$ [or $Pr^{oct}-(R)$, $Mr^{oct}-(S)$] increases manifold with an increase in the number of variants under study. Having established such a regularity relative to a concrete substrate and a concrete reaction and knowing the configuration of the reaction product, its *ee* and reaction mechanism, one can get a better insight into the structure of an intermediate responsible for the asymmetric induction, especially if we take into consideration the fact that such an intermediate can be isolated and studied instrumentally in only a few catalytic reactions.

Thus, the judgement on the absolute configuration of the intermediate determining the asymmetric induction in the hydrogenation of enamides on rhodium bis(diphenylphosphine) complexes can be made exclusively by analogy with the structure of a stable diastereomeric intermediate present in excess in the reaction mixture. X-Ray diffraction analysis of the latter requires its preliminary isolation at low temperature,[427] *i.e.*, under the conditions where the ratio of the conformers changes drastically as can be evidenced from low-temperature circular dichroism data.[428] Moreover, the results of X-ray diffraction analysis of the complex in crystal from do not provide any relevant information about conformations of complexes in solution, since crystallisation forces are stronger than forces responsible for conformational changes. For example, the conformations of the ligand diop in crystals of the complexes Ir[(*S*,*S*)-(+)-diop](COD)Cl (see Ref. 429) and [(*R*,*R*)-(−)-diop]$NiCl_2$ (see Ref. 430) differ from the ideal twist-chair-λ and twist-chair-δ conformations which are more favourable. In the latter crystal, the distortions are so strong that the array of the phenyl groups determining the complex chirality becomes virtually symmetric with respect to the metal (the symmetry plane). If a complex retained such a conformation in solution in the asymmetric induction step, it would contradict the well-known rule of asymmetric catalysis ('no asymmetry without asymmetry'), since the cross-coupling in the presence of the same complex, [(*R*,*R*)-(−)-diop]$NiCl_2$, occurs enantioselectively.[431, 432]

It is of note that the interpretation of effects of metal complexes on the enantioselectivity in catalytic reactions using models Pr^{oct}/Mr^{oct} or Pr/Mr is based on static factors. These effects are steric in nature. An alternative explanation based on dynamic factors also exists. A recently proposed theory[433, 434] of the so-called chiral molecular recognition and induction is based on helical electronic effects in the chiral metallocomplex (catalyst) and the coordinating substrate. 'Handedness matching' of the signs of helical polarisability of a chiral catalyst and a coordinating substrate in enantioselective reactions should be met.

An optimistic prognosis of applicability of chiral C_2-symmetric compounds as asymmetry inductors has been made in the review[418] devoted to the phenomenon of asymmetric induction. The analysis made in the present review suggests that these prospects refer only to such reactions as enamide hydrogenation, allylic alkylation, alkylation with diethylzinc in the presence of $Ti(OPr^i)_4$ as well as cyclopropanation and the Diels–Alder reactions not considered in this review. It should also be noted that the use of the term 'chiral induction'[435] instead of the generally accepted term 'asymmetric induction' is incorrect, since the highest value of asymmetric induction is observed in the step of an asymmetric intermediate, *i.e.*, that devoid of any elements of symmetry (exception for C_1).

V.	Conclusion	1235

Abstract. Results of the experimental and theoretical investigations into hydrogen sorption by various carbon nanostructures, including fullerenes, single-walled and multi-walled nanotubes, nanofibres, nanographite and nanographite-based composites are surveyed. Results of a thermodynamic analysis of the most significant experimental data are presented. The emphasis is placed on the studies reporting the extremum sorption parameters. The thermodynamic and kinetic (diffusion) parameters and equations describing the sorption processes are refined. The prospects of the applications of new carbon nanomaterials for hydrogen storage in the automotive industry are discussed. The bibliography includes 206 references.

I. Introduction

Hydrogen represents a unique energy-rich fuel and highly efficient energy carrier.[1] The modern trends in the development of large-scale production of energy carriers and the automotive industry imply gradual replacement of non-renewable hydrocarbon fuels with hydrogen as an environmentally friendly processing product of water and biomass (which are renewable natural resources). This may only be achieved if either the problem of hydrogen storage and transportation † is successfully solved or autonomous systems for its *in situ* production are designed.

The governments of several countries have approved federal programmes aimed at the development of hydrogen-driven mobile motor vehicles. In the U.S., president Bush's initiative[2] has given a high priority to this programme. At the end of November 2003, the International Partnership for the Hydrogen Economy (IPHE) was founded, which joined 15 countries, including Russia. One of the major goals declared by the IPHE is the design of competitive affordable electric vehicles operated with hydrogen fuel cells by 2020. In December 2003, the Complex program of R&D activities in the field of hydrogen energetics and fuel cells was approved in Russia.[3] A prerequisite for all these programmes is the development of compact systems of hydrogen storage that would provide sufficiently fast desorption of hydrogen in a technically reasonable temperature range.[2,4–8]

According to the basic qualifying standards of the U.S. Department of Energy (DOE), the prospective stand-alone systems should store no less than 6.5 mass % or 62 kg m^{-3} of hydrogen (to guarantee a haul of $\sim$500 km) ‡ and operate with in the technologically acceptable temperature and time regimes to be commercially justified.§

The potential utility of carbon-based light sorbents for hydrogen storage was pointed out as early as in the 1960s. The best performance for cryoadsorption storage has been achieved for adsorbents based on low-density high-surface-area activated carbons, which also enabled purification of molecular hydrogen from admixtures. In particular, porous carbon AX-21, which is characterised by a specific surface area of 3000 m^2 g^{-1}, adsorbs up to 10 mass % (or 32 kg m^{-3}) of hydrogen at 77 K and 5 MPa (50 atm). However, the adsorption capacity of this material as well as of other activated carbons drops down to 0.5 mass % at room temperature and 7 MPa,[9,10] which is hardly acceptable for the automotive industry.

The interest of researchers in the hydrogen sorption by carbon materials has been rekindled following the discovery of new allotropic forms of carbon, *viz*., fullerenes, nanotubes, graphite nanofibres and other nanostructured carbon materials.[11–13] These carbon materials are composed of quasi-sp^2-hybridised carbon atoms assembled into closed spherical (fullerenes), non-spherical clusters or quasi-one-dimensional tubes seamlessly rolled-up from graphene sheets. Nanotubes are subdivided into single-walled (with a diameter of 1 – 2 nm) and multi-walled (with a diameter of 10 – 40 nm) species.[12,14–17] The latter may contain from 2 to 50 graphene layers. Graphite nanofibres are built up of graphite platelets stacked at different angles with respect to the

† According to estimates,[1] the long-distance transportation of hydrogen through the pipe lines at a pressure of 7 – 8 MPa (70 – 80 atm) is less expensive than the electric power transmission through the high-voltage lines.

‡ A typical motor vehicle requires $\sim$0.04 m^3 of a hydrocarbon fuel to travel 500 km, whereas an electric vehicle driven by a hydrogen fuel cell requires 2 – 4 kg of H_2 for the same haul.[4–6]

§ Networked or autonomous hydrogen storage systems should conform to common qualifying standards: ignition time $\sim$15 s, refueling time $<$ 5 min, working lifetime (no less than 500 cycles) at a fuel regeneration level no lower than 90%.

fibre axis (*i.e.*, parallel, perpendicular or in a herringbone arrangement). Typically, the fibres possess lengths of 5 – 100 μm and diameters of 1 – 500 nm.

The first experimental results reporting increased hydrogen sorption (5 mass % – 10 mass % under normal conditions) by a material consisting of single-walled carbon nanotubes were published in 1997.[18] Numerous investigations into hydrogen sorption by various carbon nanomaterials and their metal-doped modifications that followed have demonstrated that the required sorption capacity at room temperature and a reasonable pressure is difficult to achieve but is attainable, in principle.[4, 18 – 26] For instance, nanographite adsorbs hydrogen sufficiently well but its applications are hampered by typically high desorption temperatures.[22, 27 – 31] Furthermore, it turned out that the sorption capacities could be different by as much as two – three orders of magnitude even for closely related materials. In 1998, exceptionally high hydrogen sorption (up to 67 mass %) by graphite nanofibres (GNF) at room temperature and 12 MPa was reported.[32, 33] These communications evoked both great interest and many critical comments.[34 – 37]

Several factors can be responsible for the observed scatter in the experimental hydrogen sorption capacities by different carbon nanomaterials. The major reasons for the discrepancies in quantitative estimates of sorption properties of carbon nanomaterials include difficulties in the preparation of pure sorbents with a strictly defined microstructure, the lack of commonly adopted techniques for their attestation, complexity of physical and chemical processes in their interactions with hydrogen and dependence of these processes on the experimental conditions.[14, 34, 38 – 40] These, as well as a number of other aspects of the interactions of carbon sorbents with hydrogen, became a subject of vivid discussion at conferences during 2001 – 2004.[41 – 51] The same issues were analysed in a number of reviews devoted to fullerenes,[52] fullerites,[52, 53] carbon nanotubes, graphite nanofibres[14, 52, 54 – 57] and other carbon nanostructures[4, 14, 22, 58 – 62] (see also http://asyncbrain.baf.cz/sanatorium/1/h2fuel/).

Although some sceptics have pointed out that 'reliable data on carbon nanostructures are lacking and the experimental results are characterised by poor reproducibility', many researchers (for instance, see Refs 10, 14, 42 – 47, 51, 63 – 65) share the opinion that all aspects of the problem deserve a more accurate and thorough consideration and soundly propose to continue investigations within the scope of an international project 'Physicochemical fundamentals and prospects in the use of new carbon materials for hydrogen storage in automotive industry'.[48] The present review describes for the first time an original constructive analysis of thermodynamic and diffusion parameters as applied to a series of hydrogen – carbon sorbent systems that are characterised by the extremum characteristics of the sorption processes.

II. Experimental studies of hydrogen sorption by carbon nanostructures

Table 1 summarises experimental data on sorption (and storage) of hydrogen by various carbon nanomaterials (CNM), such as fullerenes, single- and multi-walled nanotubes (SWNT and MWNT, respectively), carbon and graphite nanofibres (CNF and GNF, respectively), nanographite and composites on its base and new types of nanostructures, such as fullerene-filled nanotubes ('peas in the pod'), nanobells, *etc*. Micrographs of some of these nanostructures are shown in Fig. 1. An analysis of the factors influencing the results of sorption capacity determination indicates that even carbon materials belonging to one type differ strongly from each other. For example, nanotubes synthesised using different methods can differ in purity, diameter, length, specific surface area, *etc*. The apparent sorption capacity of such materials is also strongly affected by the character of the chemical or thermal pretreatment of the samples and purity of hydrogen.[106]

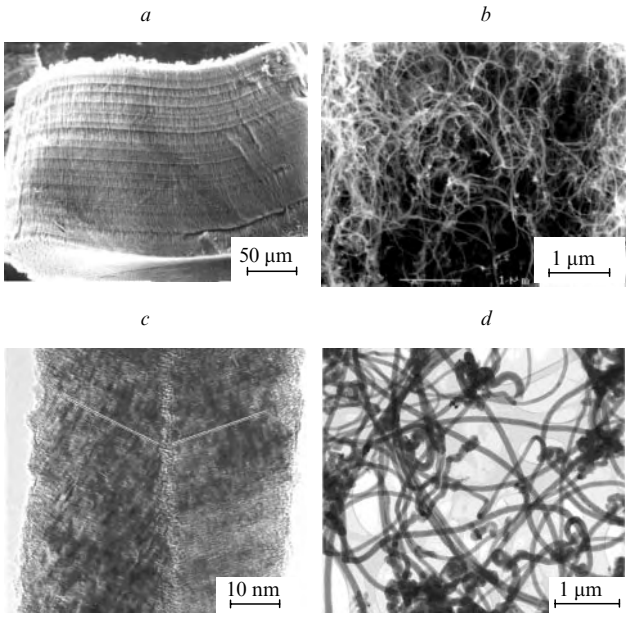

Figure 1. Micrographs of some carbon nanostructures.[32, 91] (*a*) A dense block of aligned (straightened) carbon nanotubes prepared by catalytic pyrolysis of ferrocene on a quartz support, (*b*) randomly oriented carbon nanotubes, (*c*) GNF composed of graphite platelets oriented at 45° (herringbone-type) with respect to the fibre axis, (*d*) GNF prepared by catalytic decomposition of an ethylene – hydrogen mixture.

Quantitative estimates of the sorption capacities discussed in the present review are based on several experimental techniques, such as volumetric analysis (VA), thermogravimetric analysis (TGA), temperature-programmed desorption (TPD) and thermodesorption spectroscopy (TDS). The apparent values of the sorption capacity of carbon nanomaterials can differ from the real ones if possible sources of the experimental errors are neglected.¶

In particular, in the case of volumetric analysis (*i.e.*, when a change in the volume or pressure of hydrogen due to sorption or desorption is measured), the following factors should be taken into account:

— temperature effects (that are especially significant for high-pressure experiments),

— thermal effects due to compression/decompression of the sorbent upon sorption/desorption of hydrogen,

— thermal effects due to nuclear spin transitions (changes in the ratio of ortho/para modifications of molecular hydrogen),

— the actual equilibration time,

— possible leaks in the experimental setup (which can strongly decrease the accuracy of determination of small changes in pressure).

Tibbetts *et al.*[38] studied sorption of hydrogen at 300 K and 10 MPa and estimated that a decrease in the temperature by 1° for a sample with a mass of 1 g in a volume of 1 litre necessitates that the pressure was increased by 33.3 kPa, which results in an apparent increase in the amount of absorbed hydrogen by 2.6 mass %. They found that filling of the chamber with hydrogen was accompanied by a jump-like increase in temperature by more than 25 °C and the system required about 100 min to equilibrate.

TGA and TDS data can become less accurate due to admixtures of water vapour and other gases in hydrogen (*e.g.*, sample No. 26 in Table 1).[39, 40] The experimental errors are often aggravated by insufficient purity of sorbents themselves (in particular, due to admixtures of catalysts).

¶ For a discussion concerning potential sources of the experimental errors, see, for instance, Refs 1, 34, 38, 56.

[a] RT is room temperature. [b] Adopted acronyms: VM is volumometry, TPD is temperature-programmed desorption, MS is mass spectrometry, ECM is electrochemical methods, TGA is thermogravimetric analysis, XRD is X-ray diffraction, QMS is quadrupole mass spectrometry, NEXAFS is Near-edge X-ray absorption fine structure. [c] Total amount of desorbed H_2 is 4.2 mass % (3.3 mass % at RT and 0.9 mass % upon heating). [d] Volume capacity is 68 kg m^{-3}. [e] Corrected data from Ref. 40, which reported overestimated values due to utilisation of humid hydrogen for similar samples. [f] CVD stands for chemical vapour deposition. [g] Desorption of hydrogen occurs upon heating to 573 K. [h] Total amount of desorbed H_2 is 45.09 mass %.

As can be seen from Table 1, DOE requirements to the parameters of hydrogen sorption by carbon nanostructures have been met in several cases (*e.g.*, sample Nos 11, 27, 32–34, 37, Table 1). In particular, hydrogen sorption capacity at room temperature and 12 MPa (measured using a Sieverts-type apparatus) has reached ~67 mass % (!) for specific GNF samples prepared by metal-catalysed (typically, Ni, Fe) pyrolysis of hydrocarbons at 723–1023 K (sample No. 32).[33] These fibres were composed of graphite platelets with lengths of 10–100 μm and thicknesses of 3–50 nm oriented parallel (tubular-type fibres), perpendicular (platelet-type fibres) and at an acute angle (herringbone-type fibres) with respect to the fibre axis; the minimum distance between the platelets was 0.335 nm. The authors of this study suggested [33] that the structures of these materials are ideally suited for hydrogen storage. Desorption occurred within 5–10 min. Later, the same authors in response to criticism from other researchers, noted [32] that a special thermal pretreatment of the fibres aimed at the removal of chemisorbed gases and water is necessary to provide reproducible results. Sorption capacity of the samples increased from 2 mass % to 40 mass % (sample No. 34, Table 1) as a result of an *in situ* thermal treatment in an inert gas.[32]

Attempts undertaken by several other research groups to reproduce these results failed despite the experimental conditions being strictly observed.[35, 36, 94, 107] Nevertheless, attainability of high sorption capacities for similar structures has been confirmed in other studies [20, 24, 95–97] (sample Nos 37, 38, 40, Table 1).

Recently, a continuous process for the synthesis of MWNT using hot-filament plasma-assisted chemical vapour deposition has been developed.[88] The structure of MWNT prepared using this method (sample No. 27, Table 1) differs from the ideal one and resembles to a certain extent that of the graphite nanofibres having graphite platelets with open ends. These materials are characterised by relatively high and reproducible sorption capacity (5 mass % – 7 mass %) at room temperature and moderate pressures (1 MPa). Annealing of the samples at 573 K and removal of admixtures of catalysts gave rise to an increase in the sorption capacity up to 13.8 mass %.

Note that volume density of hydrogen is also of importance for applications: it should be no less than 62 kg m^{-3}. According to estimates,[5] volume density of hydrogen sorbed by an array of nanotubes with a diameter of 2 nm can reach 54 kg m^{-3} assuming that density of the original nanotubes is ~1000 kg m^{-3}. Indeed, density of the standard carbon adsorbents lies in the range of 500–1000 kg m^{-3}, but that of CNT is typically significantly lower, *viz.*, 100–200 kg m^{-3}. Only pressed bundles of nanotubes had a density of ~330 kg m^{-3}, which corresponded to the volume density of absorbed hydrogen of 10–33 kg m^{-3} at a sorption capacity of 10 mass %. Recently developed methods for the compaction of CNT enable preparation of materials with a density of as high as ~800 kg m^{-3} (see Ref. 56) and even 1700 kg m^{-3} (see Ref. 83). In the latter case, promising results with respect to hydrogen sorption have been obtained: the volume density of hydrogen reached 68 kg m^{-3} at a sorption capacity of 4 mass % (sample No. 21, Table 1).

Not all the experimental results look so promising (see, for instance, data for sample Nos 5, 15, 20, 35, 36, Table 1). According to measurements [38] performed in a temperature and pressure range of 193–773 K and 3.5–11 MPa for nine samples including graphite flakes, activated carbon G-60 with a specific surface area of 700 m^2 g^{-1}, carbon wires (grown on a FeNiCu composite), graphitised carbon fibres, PYROGRAF fibres and MWNT with different diameters, the hydrogen sorption capacity at room temperature did not exceed 0.1 mass % at 3.5 MPa and 0.5 mass % at 11 MPa. All attempts to activate the samples did not give positive results. A study of hydrogen sorption by purified SWNT samples as well as by differently pretreated samples of SWNT, MWNT and GNF prepared using the CVD method [37] has given similar results: the maximum hydrogen uptake did not exceed 0.63 mass % at room temperature and 4.5 MPa.

One possible route to enhance sorption capacity of carbon nanomaterials is development of alternative synthetic approaches. A series of experimental studies (see, for instance, reviews [108, 109]) has shown that a high sorption capacity can be achieved by implantation of atoms or ions of hydrogen isotopes with a kinetic energy on the order of 10 keV into graphite or by sputtering of graphite (or another graphite material) with a hydrogen plasma. In the latter case, amorphous 'a-C : H' films are deposited onto metallic walls of the plasmatron. Such films are characterised by a high tritium content (T/C ≈ 0.5–0.7), which corresponds to a sorption capacity of 4.2 mass % – 5.8 mass % (recalculated for the same protium content).

The prospects of the application of less typical forms of nanostructured carbon as hydrogen sorbents were recently discussed by Rawat *et al.*[110] They synthesised liquid crystals of carbon doped with carbon nanofibres and found that sorption of hydrogen by the material increased linearly in a pressure range of 0.3–0.6 MPa (at 77 K) and reached 3.5 mass % at 0.6 MPa (that is the maximum pressure achievable with their experimental setup); extrapolation of the experimental results to a pressure of 2.5 MPa gave a sorption capacity of 6.5 mass %. A new class of 'pillared' materials based on nanographite and nanotubes doped with lithium was proposed [111] as potential hydrogen sorbents. These materials are characterised by an increased separation between layers of graphite or walls of nanotubes, which can enhance their sorption capacity. Unfortunately, for the moment, these materials exist only in theory although the authors proposed possible routes to their synthesis. According to estimates,[111] the hydrogen sorption capacity of these materials at room temperature and 2–5 MPa can reach as high as 6.0 mass % – 6.5 mass % (or 61.7–62.9 kg m^{-3}), depending on the exact structure.

Investigations into the electrochemical accumulation of hydrogen in carbon nanomaterials are also of great interest.[65, 72, 112–121] In the majority of cases, the measurements were conducted in a system of half-cells filled with 6–7 M KOH (as an electrolyte) at room temperature with the working electrode made of the respective metallised carbon nanomaterial. In this case, the charge/discharge processes, which occur on the working electrode, can be represented as:

$$\mathrm{CNM} + x\,\mathrm{H_2O} + \mathrm{e^-} \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} (\mathrm{CNM} + x\,\mathrm{H}) + x\,\mathrm{OH^-}\,.$$

A series of carbon materials including various CNT, SWNT and MWNT have been studied with respect to the electrochemical accumulation of hydrogen.[112] In this case, the hydrogen sorption capacity can reach 2.0 mass % at 298 K, partly due to metallic admixtures. For an SWNT sample, a discharge capacity of 316 mA h g^{-1} was achieved,[112] which corresponds to a hydrogen sorption capacity of 1.2 mass %. The capacity was virtually independent of the number of charge–discharge cycles. The most significant experimental and theoretical studies on the electrochemical sorption of hydrogen by carbon nanotubes (CNT) have been recently surveyed.[113] Good results were obtained for the CNF decorated with Ni–P alloy particles.[114] A high discharge capacity of 1625 mA h g^{-1} (which corresponds to a hydrogen sorption capacity of 5.7 mass %) was also obtained for the electrodes prepared by compacting a mixture of CNT, copper powder and polymer binder (polytetrafluoroethylene, or PTFE) taken in a mass proportion 1 : 5 : 3 into a nickel collector.[116] No doubt, the electrochemical accumulation of hydrogen in systems with carbon electrodes will find applications in the future,[65, 72] although development of the electrodes on the basis of less expensive activated carbons seems more promising due to a high cost of CNT.[119]

Different physical methods, such as NMR (see Refs 122–125), neutron scattering,[80, 126–135] ESR,[136] Raman scattering, are normally applied to elucidate the mechanisms of hydrogen accumulation in the storage systems under development.[137] In particular, it has been demonstrated that physisorption of hydro-

gen molecules by SWNT bundles at 200 K occurred predominantly in the internal channel-cavities,[128] although sorption centres were observed on the external surfaces of SWNT as well.[129] The ^{1}H NMR data [125] supported the presence of sorption centres both on the external surfaces of SWNT and in the internal channels (the authors observed mutual diffusion of hydrogen molecules between the two types of the centres). An analysis of the ESR spectra indicates that hydrogen adsorbs dominantly on admixtures since the signal caused by admixtures attenuates upon hydrogen adsorption. In the case of an MWNT sample synthesised without metal catalysts, the experimental data were interpreted as evidence for the direct interaction of hydrogen with the walls of the tubes.[136] An analysis of the Raman scattering spectra for an H_2–MWNT system has revealed an influence of the method used for the synthesis of the MWNT on the hydrogen uptake and confirmed that hydrogen can be adsorbed not only in the molecular form but in the dissociated atomic form as well.[137]

III. Theoretical studies of physisorption and chemisorption

The great interest to the problems of hydrogen storage has promoted numerous theoretical investigtions into the interactions of molecular and atomic hydrogen with carbon nanostructures. This interest was to a large extent stimulated by impressive results obtained in the field of spherical carbon clusters and nanosized tubes [12, 15, 16] as well as by the relative simplicity of the species being adsorbed and availability of efficient computational methods (advantages and disadvantages of the modern computational approaches have been analysed elsewhere [138, 139]). Table 2 summarises the theoretical results obtained using different models, which are of greatest importance for the following discussion. Supplementary information may be found elsewhere,[4, 14, 56, 57, 61] in particular, in two recent reviews (Refs 138, 152).

All theoretical studies can be formally subdivided into two main groups. The first group of studies analyses idealised models of physisorption of molecular hydrogen whereas the second group elucidates the mechanisms of chemisorption of molecular and atomic hydrogen.

1. Physisorption of molecular hydrogen by carbon nanomaterials

The Monte Carlo method, classical molecular mechanics algorithms and approved sets of empirical potentials were applied to simulate physisorption of hydrogen by carbon nanostructures.[57, 94, 140, 142, 144, 153–155] Additionally, some of the simulations explicitly took into account the quantum effects.[139, 141, 144, 155] Virtually in all simulations, calculated sorption capacities of isolated ideal single-walled nanotubes with cylindrical pores as well as of graphite nanofibers with slot-like pores agree with the experimental data at 77 K but do not support the possibility of detection of a high sorption capacity at 300 K (see Table 2).

Figure 2 depicts schematically different areas of a bundle of SWNT available to adsorption of molecular hydrogen.[155, 156]

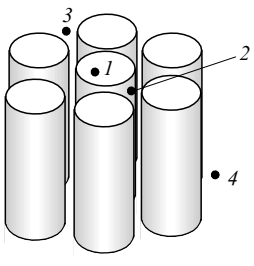

Figure 2. Sorption of hydrogen by an SWNT bundle.[155, 156]
(*1*) Inside the nanotube, (*2*) in the channels between the nanotubes, (*3*) in a 'groove', (*4*) on the outer surface of the bundle.

According to calculations of sorption of molecular hydrogen within the density functional theory (DFT), the inner space of the nanotubes, their outer surfaces and channels between them can be involved in the sorption process.[157] Adsorption in channels and slots is favoured over the adsorption on individual nanotubes.[156] An explicit account for the curvature of the surface of SWNT (which is of especially great importance for nanotubes with small diameters) indicates [158] that adsorption on the internal surface of the tube is energetically less favourable than that on the external surface. The probability of adsorption in extremely narrow channels between the tubes is also quite low (sample No. 9, Table 2).[135]

An increase in the sorption capacity can be achieved by optimising the size of the nanotubes and their arrangement within bundles.[140, 144, 145] Two typical types of arrangement of CNT in a bundle are shown in Fig. 3 [142] (samples No. 3, 9, 10, 11, Table 2). Probably, the arrangement of CNT giving rise to bundles with a triangular cross-section can ensure fairly high sorption levels even at room temperature provided that some specific conditions are met (sample No. 11, Table 2).[145] Changes in the parameters of the lattice formed by parallel bundles of single- or multi-walled nanotubes due to hydrogen sorption have been analysed by Cabli *et al.*[159, 160] and Gordilio *et al.*[161] Sorption capacity of SWNT bundles at 298 K and 12 MPa can be enhanced by 40% by doping them with alkali metals (sample No. 12, Table 2).[57]

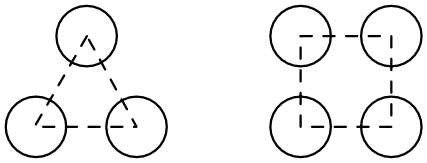

Figure 3. Bundles of CNT with triangular and square cross-sections.[142]

The results of simulations of molecular hydrogen sorption inside SWNT in a wide temperature (20–300 K) and pressure (up to 20 MPa) ranges [139] are of special note. An analysis of the computational data obtained within the density functional theory showed that changes in the external pressure can induce a series of first-order phase tranitions accompanied by abrupt changes in the density of adsorbed hydrogen. According to estimates,[139] the amount of adsorbed hydrogen at 290 K and 10 MPa does not exceed 0.42 mass % (sample No. 6, Table 2). A simulation of the interactions in the system H_2–SWNT using molecular dynamics methods and density functional theory has confirmed that molecular hydrogen adsorbed inside SWNT can undergo condensation to form quasi-one-dimensional crystal lattices at low temperature or one-dimensional associates with a variable density at high temperature.[162]

Recently, the effects exerted by a surface chemical modification of SWNT on hydrogen physisorption have been elucidated [143] (sample No. 8, Table 2). According to simulations based on a combination of the Monte Carlo and molecular dynamics methods, oxidation (which opens holes in the walls of the nanotubes) increases the sorption capacity whereas the presence of the surface C–H groups results in its decrease.

In summary, the above investigations clearly indicate that physisorption alone cannot be responsible for the high values of sorption capacities at high temperatures observed experimentally.

2. Interaction of atomic hydrogen with carbon nanostructures

There are a number of experimental facts that imply that the interaction of hydrogen with graphite and related carbon nanostructures cannot be reduced to a mere physisorption of molecular hydrogen and a more complex process has to be considered. These include an unexpectedly low rate of sorption, stepwise desorption occurring with an increase in temperature and evident effects of

[b] Acronyms used: GCMC is Grand Canonical Monte Carlo, DFT is Density Functional Theory, MD is Molecular Dynamics, MM is Molecular Mechanics. [c] BTCS is bundles with a triangular cross-section. [d] BSCS is bundles with a square cross-section.

catalysts (for instance, Fe, Co or Ni), structural defects and other factors favouring dissociation of hydrogen molecules.[163, 164]

The use of the *ab initio* methods to study chemisorption is quite difficult due to the fact that a correct representation of the carbon nanostructure (*e.g.*, SWNT) requires a model containing approximately 200 atoms.[138] There are two principal ways to overcome this difficulty. The first one is based on the periodicity of the structure of SWNT, which makes it possible to adapt *ab initio* and DFT methods suitable for small systems to larger extended structures using periodic boundary conditions.[147, 165] The second way exploits the two-level approach, in which a relatively small but essential part of the system (*i.e.*, its active site) is simulated at a high quantum-mechanical level, while the remainder is treated at a lower level (for example, using molecular mechanics methods). For instance, the active site of a closed SWNT was simulated by DFT using only 24 carbon atoms [146, 166] (sample No. 13, Table 2).

The first DFT calclulations [147] showed that sorption of hydrogen atoms occurs both inside and outside the SWNT (Fig. 4). Hydrogen atoms adsorbed inside the SWNT can assemble to molecules. Sorption capacity increases linearly with an increase in the diameter of nanotubes. Gravimetric capacity of the system H_2 – (10,10) SWNT † amounts to 14 mass % whereas volume capacity is 160 kg H_2 m^{-3}. Sorption capacity of the system

† The so-called chirality indices of nanotubes (n,m), which define orientation of the axes of a graphene sheet rolled-up into a nanotube with respect to the axes of the tube formed (for details, see, for instance, reviews [12, 15, 16]).

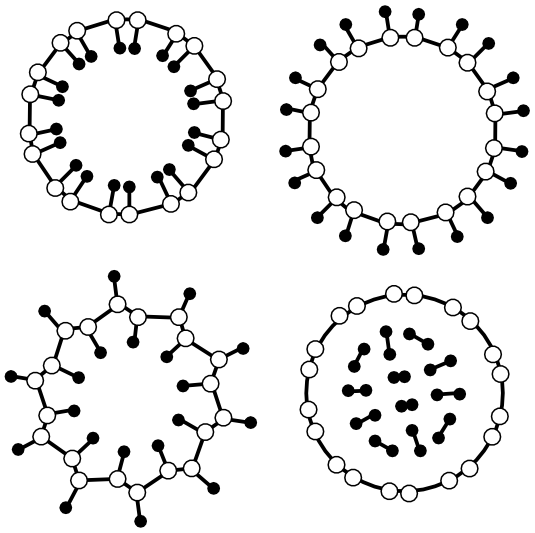

Figure 4. Hydrogen chemisorption centres in SWNT (a model representation, see text).[147]

H_2–MWNT is 7.7 mass % (sample No. 14, Table 2), which is close to the maximum theoretical value.

Bonding energies of an H atom to external surfaces of three types of SWNT, *i.e.*, (9,0), (5,5) (Fig. 5) and (10,0), for their coverage with hydrogen by 50% and 100% were calculated using DFT. It turned out that the hydrogen bonding energies are similar for all the three types of SWNT. For the (10,0) SWNT, another filling pattern, *i.e.*, 50% of H atoms bound to the internal surface and 50% bound to the external surface, was simulated. This filling mode proved to be the optimum one whereas the exclusive filling of the external surface was energetically unfavourable. It remains unclear, to what extent such a model can be achieved in practice, since no methods for the hydrogen insertion and extraction have been developed so far. The authors suggested[146, 166] that these stages can be accomplished using *ad hoc* catalysts initiating cleavage of the H—H and C—H bonds.

Similarly, according to calculations,[167] the system nanotube–H_2 has to be initiated catalytically or electrochemically prior to hydrogen sorption. Hydrogen chemisorption depends on the radius and chirality of the nanotube, as evidenced by the DFT simulation.[167] The threshold radius for the stability of nanotubes with hydrogen adsorbed on their external surface is 0.625 nm [note that it is nanotube (8,8) that have a close radius]. Measurements of photoinduced desorption of hydrogen from SWNT treated with atomic hydrogen[168] confirmed that the critical radii of curvature for chemisorption is $\sim$0.6 nm.

Figure 5. A model of a (5,5) SWNT with 50% coverage (as compared to the ultimate 'carbohydride' filling) with hydrogen (a stable structure).[146, 166]

Calculations at the DFT level have shown that a mechanical deformation of the nanotubes substantially affects the energy of their interaction with hydrogen atoms. An increase in the ellipticity of a nanotube (or a decrease in its radii of curvature) decreases the hydrogen bonding energy to a value typical of hydrogen sorption on a graphene sheet.[163, 169] A certain analogy between hydrogen sorption on a CNT and the basal plane of graphite was derived from *ab initio* calculations[163] (these results will be considered in more detail in the following section).

According to *ab initio* data,[170] dissociative chemisorption of molecular hydrogen from the gas phase on the surface of individual nanotubes is characterised by vanishingly low probability but in the case of a solid phase composed of bundles of nanotubes at a high hydrogen pressure, hydrogen molecules can dissociate forming simultaneously two C—H bonds on adjacent nanotubes. The adsorption is reversible: hydrogen desorbs if the high pressure is released. The experimental studies[19, 78] of hydrogen sorption by arrays of CNT have shown that the complete desorption requires at least 573 K.

In a series of papers,[148–150, 171–173] Ma and coworkers suggested a model describing the interactions of low-kinetic-energy hydrogen atoms (0.5–30 eV) with SWNT based on the molecular dynamics and, partially, *ab initio* calculations. According to their findings, the energy range of 1–3 eV is optimum for the sorption of hydrogen atoms on the external walls of the SWNT; hydrogen atoms with an energy of 4–14 eV are reflected from the walls whereas those with an energy of 16–25 eV are characterised by a high probability of penetrating through the side faces of the closed single-walled nanotubes and accumulating inside these capsules in the form of hydrogen molecules (Fig. 6). Owing to the high mechanical strength of nanotubes, hydrogen molecules can be concentrated therein up to densities exceeding by far that observed upon capillary condensation (sample No. 15, Table 2). According to estimates,[173] pressure of molecular hydrogen embedded into SWNT can reach as high values as 60 GPa. This hydrogen condensate inside individual SWNT, depending on hydrogen density and pressure, can undergo several phase transitions giving rise to different crystal lattices built up of hydrogen molecules.[172] If the pressure of hydrogen inside a (5,5) SWNT is 37.4 GPa, the bulk sorption capacity can reach 0.63 g cm^{-3}, which meets the requirements of the automotive industry. Potential ways to

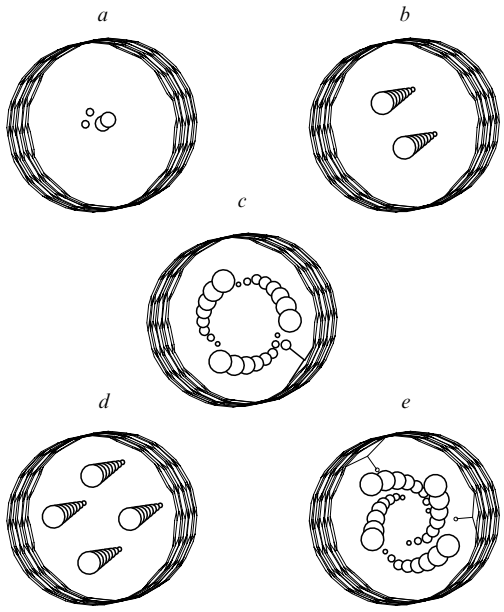

Figure 6. Arrangements of H_2 molecules inside a (5,5) SWNT at different volume densities of hydrogen.[148]
Volume density of hydrogen /kg m^{-3}: (*a*) 20, (*b*) 51, (*c*) 90, (*d*) 125, (*e*) 142.

practical achieving of such high hydrogen sorption levels by bundles of closed SWNT have been suggested as well as methods for hydrogen withdrawal through the walls of the nanotubes.[150, 174]

Recently, the first results of a semi-empirical study on the chemisorption of atomic hydrogen on a graphite sheet with structural defects have been published.[175] The authors used a modified (*i.e.*, not self-consistent) tight-binding model, which, in their opinion, described the chemical bonding between H and C atoms in real complex systems with sufficient accuracy and, at the same time, was simple enough to enable computer simulations.

In general, as correctly pointed out by Froundakis [138] and Tada *et al.*,[176] computer simulations of hydrogen adsorption on carbon nanomaterials conducted so far were successful only in rationalising a few first elementary steps of the overall process. Therefore, any step beyond the bounds of the idealised models would be indeed interesting but its practical implementation is challenging due to the necessity of bulk calculations. A search for conditions that would provide the optimum combination of thermodynamic and kinetic parameters of physisorption and chemisorption, is a current task for the development of hydrogen storage systems.[57, 59]

IV. A thermodynamic analysis of the experimental data

1. Methodology of the analysis

The similarity between the basic chemical structure elements of carbon nanomaterials under consideration and those of graphite implies that their interactions with hydrogen should obey some common rules. In order to elucidate these rules and factors governing the sorption capacities of the respective materials we applied the methods of thermodynamics of reversible processes and formal kinetics (the linear approximation of thermodynamics of irreversible processes). Earlier, we applied this methodology to an analysis of similar problems.[63, 177–180] The proposed methodology includes a new (simplified) procedure [63] for the evaluation of the diffusion coefficient based on the corresponding parameters of the thermodesorption peak and the characteristic length of the diffusion path. The proposed interpretation of the thermodynamic and kinetic (diffusion) parameters calculated in this way takes into account the results of theoretical studies of atomic hydrogen chemisorption by graphite and carbon nanostructures.[163]

2. Solubility, sorption and diffusion of deuterium in isotropic and pyrolytic graphites

Synthetic graphites are usually not single-crystalline materials. They are composed of small polycrystalline granules. One of the models proposed for such a spherical granule of isotropic graphite [181] is shown in Fig. 7. This granule has a size of ~ 2 μm (r_{gg}) and contains crystallite grains with sizes (r_{cg}) ranging from 0.03 μm to 0.2 μm.[182]

The equilibrium solubility of gaseous deuterium in the high-density ($\rho = 1.90$ g cm^{-3}) isotropic graphite ISO-880U (for the measurements, plates with a thickness of $l = 1$ mm were taken) at 1123–1323 K and 2.6–12.7 kPa is described by the following expression (the Sieverts isotherm)

$$x = \frac{D}{C} = 2.0 \times 10^{-7} \left(\frac{P_{D_2}}{P^{\circ}_{D_2}}\right)^{1/2} \exp\left(-\frac{\Delta H}{RT}\right), \quad (1)$$

where $\Delta H = -19 \pm 2$ kJ mol^{-1} is the standard enthalpy of dissolution of 0.5 mol of gaseous deuterium in graphite (the mean value for the above temperature range); P_{D_2} and $P^{\circ}_{D_2}$ are equilibrium and standard pressures of gaseous molecular deuterium at a specific temperature (expressed in Pa), respectively; $P^{\circ}_{D_2} = 1$ Pa.

Making use of the results obtained elsewhere [177, 179, 180] we can show that the expression (1) corresponds to the approximations of the ideal gas phase (hydrogen, deuterium) and the ideal solid solution, for which the infinitely dilute solution ($x^{\circ} \to 0$) can be taken as the standard state. Appropriateness of the approximation for the gas phase (within the temperature and pressure ranges of interest) can be verified using the semi-empirical equations of states for hydrogen.[1, 183] The applicability of the aforementioned approximation for the solid phase (*i.e.*, graphite and carbon nanomaterials) as well as effects of internal stresses and local deformations,[154, 184–187] which emerge upon dissolution of the gas in an inhomogeneous (defect-rich) solid phase, on the apparent solubility of the gas will be considered in the following sections as a part of the experimental data analysis.

Let us first consider the process of deuterium desorption from samples of isotropic graphite with a thickness of 1 mm. In the case of samples of isotropic graphite exposed to deuterium at $P_{D_2} = 60$ kPa and $T = 1173$ K (samples A) or 973 K (samples B) for 5 h, the temperature-programmed desorption curves (TPD) for a heating rate of $\upsilon = 0.17$ K s^{-1} manifest [63, 181] three peaks ‡ (Fig. 8) centred at $T_I \approx 445$ K, $T_{II} \approx 727$ K and $T_{III} \approx 1239$ K and at $T_I \approx 445$ K, $T_{II} \approx 760$ K and $T_{III} \approx 1193$ K for the samples A and B, respectively.

‡ However, one more peak *IV* ($T_{IV} \approx 973$ K) can be revealed, which is especially distinct for the samples deuterated at 673 K and 1173 K (Fig. 8). Also note that two peaks around T_I can be resolved for the samples deuterated at 673 K.

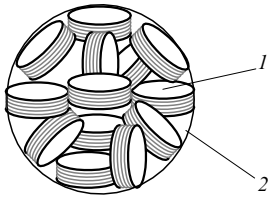

Figure 7. A model of a spherical granule of isotropic graphite [182] composed of independent crystallite grains.
(*1*) A crystallite grain, (*2*) a granule of isotropic graphite.

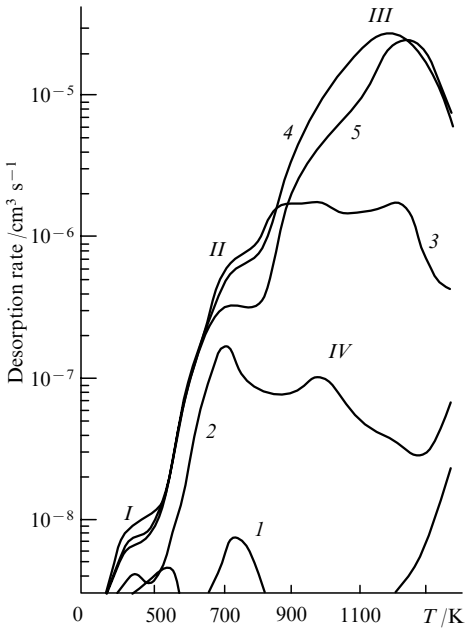

Figure 8. Temperature-programmed desorption of deuterium from isotropic graphite hydrogenated at different temperatures (curves *1* – *5*) (60 kPa, 5 h).[181]
Hydrogenation temperature /K: 473 (*1*), 673 (*2*), 773 (*3*), 973 (*4*) and 1173 (*5*) (for assignment of the TPD peaks *I*–*IV*, see text).

It was suggested [63, 181] that the peak *I* is due to desorption of deuterium molecules adsorbed on the surface of graphite granules, the peak *II* is due to deuterium molecules adsorbed on the surface of crystallite grains and the peak *III* is due to deuterium atoms absorbed (dissolved) in the crystallite grains. This assignment was based on the TPD data [181] obtained for isotropic graphite deuterated at 973 K, which showed that the amount of deuterium (x) desorbed during stages *I* and *II* was proportional to P_{D_2} whereas that desorbed during stage *III* was proportional to $(P_{D_2})^{1/2}$.

Furthermore, the amount of deuterium desorbed from the samples deuterated at 973 K and 60 kPa in the region corresponding to T_{III} was of the same order of magnitude as the equilibrium solubility ($x_{III} \approx 0.6\,x$); the amount of deuterium desorbed in the regions corresponding to T_{II} and T_I was smaller by two and four orders of magnitude, respectively. The equilibrium bulk solubility of deuterium in graphite was achieved only for the samples deuterated at 1173 K and 60 kPa (Fig. 8):[181] $x_{III} \approx x$, $x_{IV} \approx 1.1\times10^{-1}\,x$, $x_{II} \approx 1.5\times10^{-2}\,x$, $x_I \approx 3\times10^{-4}\,x$.

Taking into account that the position of the peak *II* (T_{II}) shifts depending on the thickness of the sample from 760 K (for a sample with a thickness of 1 mm) to 710 K (for a thinner sample with a thickness of $l = 0.45$ mm), annealing of the samples at 573–1173 K has a stepwise character and x_{II} linearly depends on P_{D_2}, Atsumi *et al.*[181] suggested that the peak *II* is due to one-dimensional diffusion of deuterium molecules from the adsorbed nanolayers on the surface of crystallite grains along the nanolayers towards the free external surface of the sample.

The diffusion coefficient as a function of temperature obeys the Arrhenius equation [181]

$$D_{II} = (D_0)_{II}\exp\left(-\frac{Q_{II}}{RT}\right)$$

with a preexponential factor $(D_0)_{II} = 1800$ cm^2 s^{-1} and an activation energy $Q_{II} = 120\pm5$ kJ mol^{-1}.

Taking into account that the peak *III* (in contrast to the peak *II*) does not shift with a decrease in the thickness of graphite samples, annealing of the samples has a stepwise character, x_{III} is proportional to $(P_{D_2})^{1/2}$ (see Ref. 181) and other experimental evidence, in particular, parameters of the bulk diffusion of hydrogen in graphite [188] and data on the sizes of polycrystalline granule grains (r_{gg}) and crystallite grains within these granules (r_{cg}),[108, 181, 182, 189] one may assume that the peak *III* is due to bulk diffusion (*i.e.*, diffusion occuring between the graphene sheets) of deuterium atoms dissolved in graphite crystallite micrograins towards the nearest boundaries of these grains. Temperature dependence of the diffusion coefficient D^*_{III} of hydrogen atoms in crystallite grains of isotropic graphite corrected as compared to the value given by Atsumi *et al.*[181] (see Ref. 188) can be represented in the following form:

$$D^*_{III} = (D^*_0)_{III}\exp\left(-\frac{Q_{III}}{RT}\right),$$

where $(D^*_0)_{III} \approx 3\times10^{-3}$ cm^2 s^{-1}, $Q_{III} = 250\pm10$ kJ mol^{-1}.

It should be stressed that in Ref. 188 (in contrast to Ref. 181) the diffusion coefficient was determined from the experimental data on the characteristic length of diffusion path. Therefore, we find it appropriate to correct the preexponential factor $(D_0)_{III} = 1.7$ cm^2 s^{-1} given in Ref. 181 using the data from Ref. 188. The uncorrected former value corresponds to a mean radius of the polycrystalline granule rather than the crystallite grains. The corrected $(D^*_0)_{III}$ is given by the following formula: $(D^*_0)_{III} = (D_0)_{III}\,(r_{cg}/r_{gg})^{1/2}$.

The characteristic length of diffusion path travelled by a deuterium molecule (L_{II}) corresponding to the peak *II* can be estimated using the following expression:

$$L_{II} \approx (D_{II}\,t)^{1/2} \approx \left(\frac{D_{II}\Delta T_{II}}{\upsilon}\right)^{1/2}, \qquad (2)$$

where $D_{II} = 4.3\times10^{-6}$ cm^2 s^{-1} (for $T_{II} = 727$ K); $t = \Delta T_{II}/\upsilon$ is the diffusion time [$\Delta T_{II} \approx 182$ K is the full width at half maximum of peak *II* (Fig. 8); $\upsilon = 0.17$ K s^{-1} (see Ref. 181)].

Substitution of these values for D_{II} and ΔT_{II} in Eqn (2) gives rise to the value of L_{II}, which agrees with the thickness of the samples (l)§ reported in Ref. 181. In this case, one may consider that the characteristic length of diffusion path (L) was determined experimentally based on the dependence of T_{II} on l.[181]

The apparent sizes of crystallite grains in polycrystalline granules, which correspond to the characteristic length of diffusion path travelled by deuterium atoms from a crystallite grain to its surface (peak *III*), can be estimated using the following expression:

$$L_{III} \approx r_{cg} \approx \left(\frac{D^*_{III}\Delta T_{III}}{\upsilon}\right)^{1/2}, \qquad (3)$$

where $D^*_{III} \approx 1\times10^{-13}$ cm^2 s^{-1} (for $T_{III} = 1239$ K), $\Delta T_{III} \approx 210$ K is the full width at half maximum of the peak *III*. The value of $r_{cg} \approx 0.1$ μm calculated in this way is in accord with the experimental data [108, 182] on the sizes of crystallite grains. These values of structural parameters $r_{cg} \approx 0.1$ μm and $r_{gg} \approx 2$ μm (from Ref. 189) are used below in the analysis and interpretation of the results by Atsumi *et al.*[181]

According to thermodynamic data (for $T \approx 1200$ K), experimental data on equilibrium solubility of deuterium in graphite [$x \approx x_{III} \sim (P_{D_2})^{1/2}, \Delta H$] [181] and diffusion parameters corresponding to the peak *III* [Q_{III}, $(D^*_0)_{III}$, L_{III}], the process of dissolution of gaseous molecular deuterium in graphite crystallite grains can be represented with the following scheme (dissociative chemisorption):[63, 181]

$$0.5\,D_2(\text{gas}) \rightleftharpoons D - 224\ \text{kJ mol}^{-1}, \qquad (4)$$

$$D \longrightarrow D(\text{gr.latt.}), \qquad (5)$$

$$D(\text{gr.latt.}) + C(\text{gr.ch.c.}) \rightleftharpoons DC(\text{gr.abs.}), \qquad (6)$$

$$0.5\,D_2(\text{gas}) + C(\text{gr.ch.c.}) \longrightarrow DC(\text{gr.abs.}) + 19\ \text{kJ mol}^{-1}, \qquad (7)$$

where D is a deuterium atom on the surface of a crystallite grain; D(gr.latt.) is a deuterium atom in the graphite lattice (away from chemisorption centres); C(gr.ch.c.) is an internal carbon chemisorption centre for deuterim in the graphite lattice capable of forming a chemisorbed complex DC; DC(gr.abs.) is a deuterim atom absorbed in the graphite lattice. The total process (7) is characterised by an enthalpy change $\Delta H_{(7)III} = \Delta H \approx -19$ kJ mol^{-1}.

The law of mass action for the reaction (7)

$$K_{III} = \frac{x_{III}/(x_{III})_{max}}{(P_{D_2}/P^\circ_{D_2})^{1/2}[1 - x_{III}/(x_{III})_{max}]} \qquad (8)$$

is transformed into the Sieverts–Langmuir adsorption isotherm:[177, 179]

$$\frac{x_{III}}{(x_{III})_{max}} = \frac{K_{III}(P_{D_2}/P^\circ_{D_2})^{1/2}}{1 + K_{III}(P_{D_2}/P^\circ_{D_2})^{1/2}}, \qquad (9)$$

where equilibrium constant (K_{III}) for the reaction (7) is given by:

$$K_{III} = \exp\left(\frac{\Delta S}{R}\right)\exp\left(-\frac{\Delta H}{RT}\right). \qquad (10)$$

Here, $(x_{III})_{max}$ denotes the maximum possible D/C ratio (or the fraction of internal chemisorption centres), $\Delta H = \Delta H_{(7)III} \approx -19$ kJ mol^{-1}, $\Delta S = \Delta S_{(7)III}$ is the standard change of entropy

§ A similar value $L_{II} \approx l$ is obtained if the diffusion problem is reformulated to an isothermal case (using the value of Q_{II} from Ref. 181).[190, 191]

for the reaction (7). If $x_{III} \ll (x_{III})_{max}$, Eqns (8)–(10) are transformed into the expression (1), *i.e.*, the Sieverts isotherm.

As follows from Eqns (1) and (8)–(10), $(x_{III})_{max} \exp(\Delta S/R) \approx 2 \times 10^{-7}$. For the ultimate (carbohydride) values of concentration $(x_{III})_{max} = 0.5$ (or 1.0),[146] $\Delta S/R \approx -14.7$ (or -15.4), which means that $\Delta S = \Delta S_{(7)III} \approx -122$ (or -128) J K^{-1} mol^{-1} [the latter value is close to the values of ΔS known for reactions similar to (7), see reference books [192–194]]. Within this approximation, the standard enthalpy ($\Delta H_{(7)III}$) and entropy ($\Delta S_{(7)III}$) of absorption for the reaction (7) are independent of the concentration of absorbed deuterium. Note that in this case, it is the concentrated solution ($x^{\circ}/x_{max} = 0.5$) that can be chosen as the standard state for the solid phase, then $\Delta H_{(7)III}$ and $\Delta S_{(7)III}$ in the expression (10) are constants.[177, 179]

Assuming that dissolution of deuterium atoms in the graphite lattice without involvement of chemisorption centres in stage (5) does not modify the enthalpy of the system [*i.e.*, $\Delta H_{(5)III} \approx 0$], the value of enthalpy determined from Eqns (4)–(7) is $\Delta H_{(6)III} \approx -243$ kJ mol^{-1}.

The factors essential for understanding of the mechanism underlying deuterium dissolution in crystallite grains are listed below:

— The calculated value of $\Delta H_{(6)III}$ is close in absolute value to the activation energy of bulk diffusion of deuterium atoms through the graphite crystallite grains but has the opposite sign ($Q_{III} = 250$ kJ mol^{-1}) (see Refs. 181, 188).

— The value of $\Delta H_{(6)III}$ is close to the energy of interaction of hydrogen atoms with the external surface of nanotubes belonging to types (5,5), (10,10), (10,0) and (9,0) calculated using the DFT method.[146, 147]

— The value of $\Delta H_{(6)III}$ is by 48 kJ mol^{-1} larger than the energy of interaction of hydrogen atoms with the graphene surface calculated using the DFT method [195] and the energy of hydrogen sorption on the basal plane of graphite according to the model F (Fig. 9, $\Delta H_F = -195$ kJ mol^{-1}) calculated using the *ab initio* molecular orbitals method.[163] Presumably, the discrepancies between the experimental and theoretical values of $\Delta H_{(6)III}$ are related to large errors associated with theoretical determination of the C–H bonding energy.

Furthermore, estimates for the chemisorption energy of hydrogen on the (0001) basal plane of graphite (models E and F) and on cleaved C–C bonds at (1010) zigzag-like (models D and H) and (1121) chair-like (models C and G) side planes of graphite (Fig. 9)¶ are available, which are sufficiently accurate and can be used to rationalise some parameters of the sorption processes corresponding to peaks *I*–*IV* (see Fig. 8).†

The aforementioned data clearly indicate that both bulk dissolution of D_2 and bulk diffusion of deuterium atoms through the crystallite grains of isotropic graphite (peak *III* in Fig. 8) contribute to the dissociative chemisorption of deuterium on active carbon sites with the absorption enthalpy of $\Delta H_{(abc)III} = \Delta H_{(6)III} \approx -Q_{III}$.

A model [177] of diffusion of hydrogen atoms through the graphite lattice accompanied by reversible capture of the diffusant by internal carbon chemisorption centres yields similar values of the thermodynamic ($\Delta H_{(6)III}$) and kinetic ($-Q_{III}$) parameters of the hydrogen absorption process. In this case, the diffusion activation energy is consumed predominantly to cleavage of the chemisorption bonds formed by the diffusant.

It might be assumed [63] that sorption of two hydrogen atoms on two adjacent centres on the basal plane (model F) generates

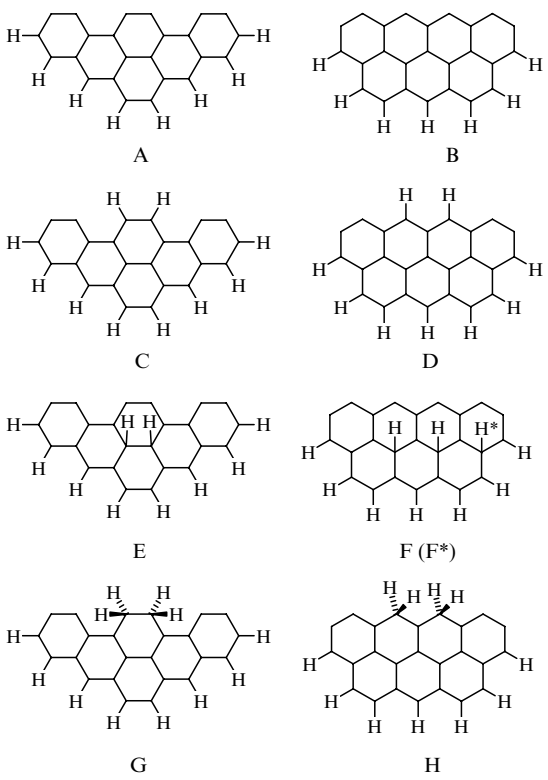

Figure 9. Models of hydrogen chemisorption on graphite (for description of the models, see text).[163]

new potential chemisorption centres for the next hydrogen atoms (third, fourth, *etc.*) on proximate carbon atoms of the graphene layer (model F*, Fig. 9). The energy of chemisorption for the additional hydrogen atoms on adjacent carbon atoms of the graphene layer (model F*) is likely characterised by a value similar to ΔH_F. For the model F*, according to results of Ref. 146 (sample No. 13, Table 2), $(x_{III})_{max} \approx 0.5$ [or $(x_{III})_{max} \approx 1.0$, if both sides of a graphene layer are considered]. The validity of such a model is justified by experimental data on the realisation of a high content of hydrogen isotopes in implanted graphite layers in the case of a-C : H-films (H/C $\approx 0.5-0.7$) [108, 109] and fullerites (H/C $\approx 0.6-0.95$).[19, 103]

Taking into account that the C–H (C–D) chemical bonds are characterised by saturability, directionality and localisation, it might be assumed that the expressions (8) and (9) can remain valid even for deuterium concentrations approaching the ultimate carbohydride values $(x_{III})_{max} \approx 0.5$ (or 1.0). An analysis of the experimental data on the amount of hydrogen isotopes absorbed in nanocrystalline graphite synthesised mechanochemically (see Section IV.6),[27, 29, 30] and on the hydrogen content in graphite nanofibres (see Section IV.9) [32, 33, 196] support the applicability of the model of chemisorption centres and ultimate concentrations $(x_{III})_{max}$ corresponding to a specific bulk carbohydride phase (H/C = 0.5–1.0) [146] to the description of hydrogen sorption by these materials.

Within the model [177] of bulk diffusion of deuterium (hydrogen) atoms through the graphite lattice accompanied by reversible capture of the diffusant by internal chemisorption centres [provided that the predominant fraction of the diffusant is localised in the absorption centres and $x_{III}/(x_{III})_{max} \ll 1$], the apparent diffusion coefficient (D^*_{III}) and activation enthalpy (energy) (Q_{III}) can be written as:

$$D^*_{III} \approx \frac{AD_{latt}}{K_{(6)III}}, \qquad (11)$$

¶ The model A in Fig. 9 corresponds to the basal plane with empty chair-like edge centres, the model B corresponds to the basal plane with empty zigzag-like edge centres.

† A comparison of the experimental values of ΔH (for peaks *I*–*IV*) with the theoretical values of E_{ad} makes it possible the most appropriate model (models C–H, Fig. 9) for description of the sorption process attributed to specific TPD peaks.

$$Q_{III} \approx Q_{\text{latt}} - \Delta H_{(6)III}, \quad (12)$$

where A = const, D_{latt} and Q_{latt} are the diffusion coefficient and the activation enthalpy (energy) for the diffusion of deuterium (hydrogen) atoms through the graphite lattice in the absence of capturing chemisorption centres, respectively; $K_{(6)III}$ is the equilibrium constant of the reaction (6) as applied to peak *III*. Here,

$$D_{\text{latt}} \approx (D_0)_{\text{latt}} \exp\left(-\frac{Q_{\text{latt}}}{RT}\right),$$

$$K_{(6)III} \approx B \exp\left(-\frac{\Delta H_{(6)III}}{RT}\right),$$

where $(D_0)_{\text{latt}}$ and B are preexponential factors.

The activation energy of diffusion of hydrogen atoms in nanostrucured graphite was estimated both experimentally [28] for a temperature range of 300–425 K ($Q_{\text{exp}} \approx 9.6$ kJ mol^{-1}) and theoretically [197] ($Q_{\text{theor}} \approx 1.5$ kJ mol^{-1}). The diffusion activation energy (Q) can be characterised by that small value only if the chemisorption centres are either absent or almost completely occupied, *i.e.*, if $Q = Q_{\text{latt}}$. Provided that Q_{latt} acquires such a value, the activation energy of diffusion of deuterium atoms through the graphite lattice [the expression (12)] approaches the enthalpy of desorption of deuterium atoms from graphite, *i.e.*, $Q_{III} \approx -\Delta H_{(6)III} = -\Delta H_{(\text{abs})III}$.

Taking into account the linear dependence of x_{II} on P_{D_2} and values of Q_{II} (as reported in Ref. 181), it might be assumed that the diffusion processes of deuterium sorption on graphite [181] associated with peak *II* are described by the following reactions:

$$D_2(\text{gas}) \longrightarrow D_2(\text{graph.}), \quad (13)$$

$$D_2(\text{graph.}) \rightleftharpoons 2D(\text{graph.}), \quad (14)$$

$$2D(\text{graph.}) + C(\text{ch.c.}) \rightleftharpoons D_2C(\text{ads.}), \quad (15)$$

$$D_2(\text{gas}) + C(\text{ch.c.}) \longrightarrow D_2C(\text{ads.}), \quad (16)$$

where D_2(graph.) and D(graph.) denote, respectively, a deuterium molecule or atom on the surface of graphite crystallite grains (away from chemisorption centres); C(ch.c.) is a carbon chemisorption centre that binds two deuterium atoms in graphite (potential formation of a D_2C complex) localised at the surface of the crystallite grains; D_2C(ads.) is a couple of deuterium atoms adsorbed on a carbon centre on the surface of the crystallite grains.

Our analysis shows that in many cases the rate of the first stage (13) of the process is diffusion-limited.

There is some evidence (see Refs 28, 197) suggesting that the activation energy for diffusion of deuterium molecules becomes negligibly small as compared to Q_{II} in the absence of chemisorption centres on the surface of crystallite grains.[181] In such a case, the apparent activation enthalpy (energy) for the diffusion of deuterium molecules along the surface of graphite crystallite grains (Q_{II}) should be similar to the standard change of enthalpy for the desorption of deuterium molecules from the surface of crystallite grains, which is the thermodynamic characteristics of a reaction reversed with respect to the reaction (16).

$$\Delta H_{(\text{ads})II} = \Delta H_{(16)II} \approx -Q_{II} = -120 \text{ kJ mol}^{-1}.$$

A similar situation is typical, for instance, of gas chromatography.[198]

The standard change of enthalpy for the reaction (14) at a temperature close to T_{II} can be written as $\Delta H_{(14)} \approx 2\Delta H_{(4)} \approx 450$ kJ mol^{-1} (see Refs 192–194), whereas the standard change of enthalpy for the reaction (15) can be written as $\Delta H_{(15)II} = \Delta H_{(16)II} - \Delta H_{(14)} - \Delta H_{(13)II} \approx -570 \pm 8$ kJ mol^{-1} [provided that $\Delta H_{(13)II} \approx 0$]. The experimentally measured value of $\Delta H_{(15)II}$ is similar to the theoretical value of energy of chemisorption of two hydrogen atoms on a zigzag-like edge carbon centre: $\Delta H_{\text{H}} = -540$ kJ mol^{-1} (model H, Fig. 9).[163] Taking into account that a zigzag-like edge carbon centre cannot adsorb an H_2 molecule, a scheme describing the process of chemisorption of two hydrogen atoms on such a centre should include stages (14) and (15), which correspond to a dissociative-associative adsorption.

The enthalpy of adsorption of deuterium molecules in intergranule nanoareas of graphite can be estimated from the experimental dependence of the area under the peak *I* (that is respective concentration) on deuteration temperature (1173 K and 973 K, Fig. 8) using the Henry adsorption isotherm equation.[181] The standard change of enthalpy for the reaction (16) as applied to the peak *I* is $\Delta H_{(16)I} = \Delta H_{(\text{abc})I} \approx -20 \pm 5$ kJ mol^{-1}, whereas the standards change of enthalpy for the reaction (15) is $\Delta H_{(15)I} = \Delta H_{(16)I} - \Delta H_{(14)} - \Delta H_{(13)I} \approx -465 \pm 7$ kJ mol^{-1} [provided that $\Delta H_{(14)} \approx 445$ kJ mol^{-1} (see Refs 192–194) and $\Delta H_{(13)I} \approx 0$]. The value of $\Delta H_{(15)I}$ obtained in this way is close to the theoretical value of energy of chemisorption of two hydrogen atoms on a chair-like edge carbon centre, which is $\Delta H_{\text{G}} = -480$ kJ mol^{-1} (model G, Fig. 9).[163] Taking into account that the chair-like centre cannot adsorb an H_2 (or D_2) molecule, the stages (14) and (15), which correspond to a dissociative-associative adsorption, should be included in the total chemisorption process.

Probably, any two nearest carbon atoms of graphene layers located at the surface of granules can also act as adsorption centres. Chemisorption of two hydrogen atoms on such a centre is characterised by an energy change of $\Delta H_{\text{F}} = -390$ kJ mol^{-1} (model F, Fig. 9),[163] which is in reasonable agreement with the experimental value of $\Delta H_{(15)I}$.‡ Formally, these centres correspond to potential chemisorbed complexes D_2C_2 (or H_2C_2). Taking this into account, Eqn (15) should be rewritten as:

$$2D(\text{graph.}) + 2\,C(\text{ch.c.}) \rightleftharpoons D_2C_2(\text{ads}). \quad (15a)$$

Since $T_I \ll T_{II}$ and processes associated with peaks *I* and *II* are characterised by identical lengths of diffusion path (L = 1 mm), it might be expected that [according to Eqn (2)] $Q_I < Q_{II}$.[181] The value of Q_I should be close to the standard change of enthalpy of desorption of deuterium molecules from the surface of granules, *i.e.*, $Q_I \approx \Delta H_{(\text{desorb})I} = -\Delta H_{(16)I} \approx 20$ kJ mol^{-1}. Within this formalism, the peak *I* corresponds to diffusion transfer of deuterium molecules from the surface of granules to the external surface of the sample accompanied by their reversible capture by carbon chemisorption centres (to form complexes D_2C or D_2C_2) in nanocavities between granules. The following equations can be applied to calculate the apparent diffusion coefficient of deuterium molecules (D_I) and effective solubility of deuterium ($x_I \approx$ D/C, where C is the total number of carbon atoms in the sample) on the surface of granules:

$$D_I = (D_0)_I \exp\left(-\frac{Q_I}{RT}\right) \approx \frac{AD_{\text{surf}}}{K_{(16)I}}, \quad (17)$$

$$x_I \approx 6\,\frac{\Delta r_I}{r_{\text{gg}}} x_{D_2 I}, \quad (18)$$

$$Q_I \approx -(\Delta H_{(14)I} + \Delta H_{(15)I}) \approx -\Delta H_{(16)I}, \quad (19)$$

$$K_{(16)I} = \frac{x_{D_2 I}/(x_{D_2 I})_{\max}}{(P_{D_2}/P^{\circ}_{D_2})[1 - x_{D_2 I}/(x_{D_2 I})_{\max}]}, \quad (20)$$

$$K_{(16)I} = \exp\left(\frac{\Delta S_{(16)I}}{R}\right)\exp\left(-\frac{\Delta H_{(16)I}}{RT}\right). \quad (21)$$

Here, A = const, D_{surf} is the diffusion coefficient of hydrogen molecules within the surface layer of granules in the absence of chemisorption centres, Δr_I is the effective thickness of the chem-

‡ A similar conclusion was derived from a comparison of the theoretical values of ΔH_{ads} (the models F and F*, Fig. 9) with the experimental values of $\Delta H_{(6)III}$.

isorbing layer on the surface of granules, $x_{D_2 I}$ is the local concentration of D_2 molecules (the ratio D_2/C^*, where D_2 and C^* are numbers of D_2 molecules and carbon atoms in the chemisorbing layer, respectively) on the surface of granules, $(x_{D_2 I})_{max}$ is the maximum concentration of D_2 molecules, $\Delta H_{(14)I}$ and $\Delta H_{(15)I}$ are the standard changes of enthalpy for the reactions (14) and (15), respectively, $\Delta H_{(16)I}$ and $\Delta S_{(16)I}$ are the standard changes of enthalpy and entropy for the reaction (16), respectively, $K_{(16)I}$ is the equilibrium constant for the reaction (16). The equation (20) represents the Henry–Langmuir adsorption isotherm. In the proximity of T_I ($T_I \approx 445$ K), the condition $D_I \approx L_I^2 \upsilon/\Delta T_I$ is met [equation similar to (2)], where $L_I \approx l = 1$ mm (the thickness of the samples).[181] If $x_{D_2 I}/(x_{D_2 I})_{max} \ll 1$, Eqn (20) is reduced to the Henry adsorption isotherm equation.

Substituting $Q_I \approx 20$ kJ mol^{-1} in Eqn (17) and using the expression $D_I \approx L_I^2 \upsilon/\Delta T_I$, one gets $(D_0)_I \approx 3 \times 10^{-3}$ cm^2 s^{-1}.

In order to estimate $x_{D_2 I}$ in the samples of isotropic graphite[181] after their exposure to hydrogen at $P_{D_2} = 60$ kPa and $T = 1173$ K, one can utilise the experimental value of $x_I(D/C) \approx 3 \times 10^{-4} x = 1.0 \times 10^{-7}$. Provided that $r_{gg} \approx 2$ μm and $\Delta r_I \approx$ 0.3 nm, Eqn (18) gives rise to the value $x_{D_2 I} \approx 1.3 \times 10^{-4}$. Within the model G (Fig. 9) for sorption complexes D_2C corresponding to the peak I,[181] it can be taken that $(x_{D_2 I})_{max} \approx 0.5$. Substituting $\Delta H_{(16)I} \approx -20$ kJ mol^{-1} in Eqns (20) and (21), one gets $\Delta S_{(16)I} \approx -180$ J K^{-1} mol^{-1} [the latter value is typical of chemical reactions similar to (16)[192–194]]. It might be assumed that for the D_2C_2 centres of type F (Fig. 9) at $(x_{D_2 I})_{max} \approx 0.25$, $\Delta S_{(16)I} \approx -170$ J K^{-1} mol^{-1}.

The respective expressions for the desorption process corresponding to the peak II can be written as:

$$D_{II} = (D_0)_{II} \exp\left(-\frac{Q_{II}}{RT}\right) \approx \frac{A' D'_{surf}}{K_{(16)II}}, \quad (22)$$

$$x_{II} \approx 6 \frac{\Delta r_{II}}{r_{cg}} x_{D_2 II}, \quad (23)$$

$$Q_{II} \approx -(\Delta H_{(14)II} + \Delta H_{(15)II}) \approx -\Delta H_{(16)II}, \quad (24)$$

$$K_{(16)II} = \frac{x_{D_2 II}/(x_{D_2 II})_{max}}{(P_{D_2}/P^{\circ}_{D_2})[1 - x_{D_2 II}/(x_{D_2 II})_{max}]}, \quad (25)$$

$$K_{(16)II} \approx \exp\left(\frac{\Delta S_{(16)II}}{R}\right) \exp\left(-\frac{\Delta H_{(16)II}}{RT}\right), \quad (26)$$

where respective parameters have similar physical meanings to those in the formulas (17)–(21) but correspond to peak II and $\Delta H_{(16)II} \approx -Q_{II} = -120$ kJ mol^{-1}.

Using the experimental value $x_{II} \approx 1.5 \times 10^{-2} x = 5.2 \times 10^{-6}$ and assuming that $r_{cg} \approx 0.1$ μm and $\Delta r_{II} \approx 0.3$ nm, one gets from Eqn (23) that $x_{D_2 II} \approx 4.0 \times 10^{-4}$. Similarly, using the values $\Delta H_{(16)II} \approx -120$ kJ mol^{-1} and $(x_{D_2 II})_{max} \approx 0.5$, one gets from Eqns (25) and (26) that $\Delta S_{(16)II} \approx -250$ J K^{-1} mol^{-1}.

According to our analysis, parameters of sorption and diffusion of deuterium in isotropic graphite,[181] which correspond to the peak IV (Fig. 8) are in satisfactory agreement with the respective parameters of sorption and diffusion of tritium in pyrolytic graphite§ (data from the review by Causey[109]).

In particular, the apparent enthalpy of activation of tritium diffusion[109] ($Q = 365 \pm 50$ kJ mol^{-1}) is close in absolute value (but opposite in sign) to the theoretical value of energy of chemisorption of a hydrogen atom on a chair-like ($\Delta H_C = -360$ kJ mol^{-1}, model C, Fig. 9)[163] or zigzag-like ($\Delta H_D = -380$ kJ mol^{-1}, model D, Fig. 9) edge carbon centre. The experimentally measured value of tritium dissolution enthalpy[109] ($\Delta H \approx -140$ kJ mol^{-1}) is close to the value of ΔH calculated for the reactions (4)–(7) based on the models C and D assuming that $\Delta H_{(4)} \approx 228$ kJ mol^{-1}: $\Delta H = \Delta H_{(7)IV} \approx \Delta H_{(4)} + \Delta H_{C(D)} \approx -132$ kJ mol^{-1} and -152 kJ mol^{-1} for the models C and D, respectively (see Refs 192–194). Thus, the experimental results[109] can be interpreted on the basis of Eqns (4)–(12) for the chemisorption centres belonging to types C and D (Fig. 9).

Assuming that the experimental data[181] corresponding to the peak IV (Fig. 8) for isotropic graphite can be described in a similar way, one can write:

$$\Delta H_{(7)IV} \approx \Delta H_{(4)} + \Delta H_{(6)IV}, \quad (27)$$

$$Q_{IV} \approx Q_T \approx -\Delta H_{(6)IV} \approx -\Delta H_C \approx -\Delta H_D, \quad (28)$$

where $\Delta H_{(7)IV}$ and $\Delta H_{(6)IV}$ are the standard enthalpy changes for the reactions (7) and (6) as applied to peak IV (Fig. 8); Q_{IV} is the apparent activation enthalpy (energy) for the diffusion process.

The effective diffusion coefficient of deuterium (tritium) atoms in graphite corresponding to the peak IV can be calculated according to the following equation:

$$D_{IV} \approx D_T = (D_0)_{IV} \exp\left(-\frac{Q_{IV}}{RT}\right),$$

where $(D_0)_{IV} \approx 620$ cm^2 s^{-1}, $Q_{IV} \approx Q_T \approx 365$ kJ mol^{-1} (data from Ref. 109).

For the graphite samples,[181] the desorption peak IV is characterised by the following values of parameters (Fig. 8): $T_{IV} \approx 973$ K, $\Delta T_{IV} \approx 140$ K, $x_{IV} \approx 0.11x \approx 3 \times 10^{-5}$. Substituting these values into the equation

$$L_{IV} \approx \left(\frac{D_{IV} \Delta T_{IV}}{\upsilon}\right)^{1/2}$$

it is possible to estimate the characteristic length of diffusion path of deuterium atoms ($L_{IV} \approx 1$ nm).

Sorption and diffusion parameters of the process corresponding to the peak IV are described by equations analogous to Eqns (8)–(12) for the peak III, thus giving rise to

$$\Delta S = \Delta S_{(7)IV}, \Delta H = \Delta H_{(7)IV} \approx -140 \text{ kJ mol}^{-1},$$

$$\Delta H_{(6)IV} \approx \Delta H_{C(D)} \approx -370 \text{ kJ mol}^{-1},$$

$$x_{IV} \approx \left(\frac{3 L_{IV}}{r_{cg}}\right) x_{DIV},$$

where x_{DIV} is the local concentration of deuterium atoms (D/C) absorbed in the graphite layer with the thickness L_{IV} in the proximity of boundaries of the crystallite grains, $(x_{DIV})_{max} \leqslant 0.5$.

It should be noted that the parameters calculated in this way for the peak IV (Fig. 8) require further refinement. However, even within the current approximation they give satisfactory explanation for the abrupt slowing-down of the diffusion process[181] upon isothermal deuteration of isotropic graphite at 473–773 K and 60 kPa as compared to the rate of deuterium desorption upon annealing of the samples hydrogenated at 973–1173 K extrapolated to the respective temperatures (Fig. 8).

In order to refine the parameters of the TPD peaks I–IV (Fig. 8) it would be reasonable to analyse a large array of the experimental data on sorption and diffusion of hydrogen in various graphite materials including graphite layers ion-implanted with hydrogen followed by neutron irradiation and a-C : H films.[108, 109]

Typically, absorption of hydrogen in graphite, *i.e.*, dissolution of hydrogen atoms in the graphite lattice (a bulk phenomenon) is contrasted[100] to hydrogen chemisorption on cleaved σ-bonds on the surface of the crystal, grain boundaries and dislocations

§ Pyrolytic graphite is routinely synthesised by pyrolysis of hydrocarbons. Depending on the experimental conditions and composition of the starting gas, crystals with different sizes and orientations can be prepared.

Table 3. Basic results of the analysis of data on sorption and diffusion of hydrogen (deuterium) in isotropic [181] and pyrolytic [109] graphites.

Experimental data (Fig. 8)	Models of		Reactions	Parameters of processes		Equations used for the calculations	Type of the adsorption isotherm
	sorption (Fig. 9)	diffusion		sorption	diffusion		
Peak *III*	Dissociative chemisorption (model F*)	Diffusion of deuterium atoms through the crystallite grains	(4)–(7)	$\Delta H = \Delta H_{(7)III} \approx -19$ kJ mol^{-1}, $\Delta S/R \approx -14.7$ (-15.4) for $(x_{III})_{max} = 0.5$ (1.0)	$(D_0^*)_{III} \approx 3 \times 10^{-3}$ cm^2 s^{-1}, $Q_{III} \approx$ 250 kJ mol^{-1}	(3), (8)–(12)	Sieverts–Langmuir [Eqns (8), (9)]
Peak *II*	Dissociative–associative chemisorption (model H)	Diffusion of deuterium molecules along the boundaries of the crystallite grains	(13)–(16)	$\Delta H_{(16)II} \approx -120$ kJ mol^{-1}, $\Delta S_{(16)II}/R \approx -30.0$ for $(x_{D_2II})_{max} = 0.5$	$(D_0)_{II} \approx$ 1800 cm^2 s^{-1}, $Q_{II} \approx$ 120 kJ mol^{-1}	(2), (22)–(26)	Henry–Langmuir [Eqn (25)]
Peak *I*	Dissociative-associative chemisorption (models G and/or F)	Diffusion of deuterium molecules along the boundaries of the granules	(13)–(16)	$\Delta H_{(16)I} \approx -20$ kJ mol^{-1}, $\Delta S_{(16)I}/R \approx -21.3$ for $(x_{D_2I})_{max} = 0.5$	$(D_0)_I \approx 3 \times 10^{-3}$ cm^2 s^{-1}, $Q_I \approx$ 20 kJ mol^{-1}	(17)–(21)	Henry–Langmuir [Eqn (20)]
Peak *IV*	Dissociative chemisorption (models C and/or D)	Diffusion of deuterium and tritium atoms through the intergrain nanoregions	(4)–(7)	$\Delta H_{(7)IV} \approx -140$ kJ mol^{-1}	$(D_0)_{IV} \approx$ 620 cm^2 s^{-1}, $Q_{IV} \approx$ 365 kJ mol^{-1}	(27), (28)	Sieverts–Langmuir [Eqns (8), (9)]

(surface phenomena). For this, it should be stressed that the peak *III* for isotropic graphite (see Fig. 8) corresponds to chemisorption of hydrogen atoms on the internal carbon centres located at the graphite ¶ basal planes.

The process of desorption [stage (6)] of single hydrogen (or deuterium) atoms dissolved between the graphene sheets within the graphite crystallite grains [181] corresponding to the peak *III* is not accompanied by abstraction of carbon atoms from the graphene sheets, since the desorption energy of a hydrogen atom [$-\Delta H_{(6)III} \approx 243$ kJ mol^{-1}] is three times smaller than the energy required to abstract a carbon atom from its three carbon neighbours in a graphene layer [$-3/2\,\Delta H_{(C-C)} \approx 730$ kJ mol^{-1}, model F*, Fig. 9].

In the case of peaks *I* and *IV* for graphite,[181] the desorption energy of hydrogen atoms [stages (15) or (6) $-\Delta H_{(15)I} \approx$ 465 kJ mol^{-1} (models G, F) or $-\Delta H_{(6)IV} \approx 370$ kJ mol^{-1} (models C, D)] are also smaller than the energy required to abstract a carbon atom from its neighbours (485 kJ mol^{-1} or 1460 kJ mol^{-1} for the peak *I* and 485 kJ mol^{-1} for the peak *IV*).

The opposite situation is observed in the case of the desorption of two hydrogen (deuterium) atoms adsorbed on the surface of the graphite crystallite grains [stage (15)][181] corresponding to the peak *II*, since the desorption energy of two hydrogen atoms [$-\Delta H_{(15)II} \approx 570$ kJ mol^{-1}, model H, Fig. 9] is larger than the abstraction energy of a carbon atoms from its two neighbours (485 kJ mol^{-1}). In this case, the desorption of hydrogen atoms can be accompanied by abstraction of carbon atoms followed by formation and desorption of hydrocarbon molecules (CH_4, C_2H_4, *etc*.).

* * *

This is supported by mass-spectrometric data,[181] which reveal concomitant liberation of methane (CD_4) from hydrogenated graphite samples. The total amount of liberated methane is three orders of magnitude smaller than the total amount of desorbed deuterium and constitutes ~10% of deuterium desorbed at T_{II}. Liberation of small amounts of hydrocarbons has also been detected in the course of hydrogen desorption from nanostructured graphite and carbon nanofibres (see Sections IV.6 and IV.9).

Thus, the following equation should be utilised in order to determine the effective deuterium (hydrogen) concentration in isotropic graphite [181] hydrogenated at a temperature and exposure sufficiently high to achieve the equilibrium state both inside the crystallite grains and granules and at their boundaries:

$$x_\Sigma(\mathrm{D/C}) = x_I + x_{II} + x_{III} + x_{IV}. \quad (29)$$

Relaxation times (τ_I, τ_{II}, τ_{III}, τ_{IV}) of diffusion processes corresponding to the TPD peaks *I*–*IV* for graphite [181] can be estimated on the basis of D_I, D_{II}, D^*_{III}, D_{IV} and characteristic lengths of diffusion path L_I, L_{II}, L_{III} and L_{IV}.

The major results concerning the analysis and interpretation of data on the sorption of hydrogen in isotropic [181] and pyrolytic [109] graphites are summarised in Table 3. These results are used below to analyse and rationalise some published data on hydrogen sorption by other carbon nanomaterials.

3. High-temperature sorption and diffusion of hydrogen in nanoporous carbon

This section analyses experimental data [67, 199, 200] on high-temperature hydrogen sorption by nanoporous carbon (NPC) composed of graphite-like microfragments joined together by a pyrocarbon binder.

The overall porosity of one of the investigated materials [67] reached ~70% (~40% of porosity was due to nanopores with a mean diameter of ~0.8 nm and the remaining 30% of porosity was due to pores with sizes in the range 0.2–1 μm), specific surface area of this sample (S_{sp}) was ~1200 m^2 g^{-1}.

For the temperature-programmed desorption measurements,[199] samples with a thickness of $l = 1$ mm (exposed to hydrogen at $P_{H_2} = 7.1$ MPa and $T = 523$ K for 3 h) were heated at a rate of $\upsilon = 7.5 \times 10^{-2}$ K s^{-1}. The TPD curves manifest three peaks (Fig. 10) centred at 753 K (peak *I*′), 923 K (peak *II*′) and 1193 K (peak *III*′). The total hydrogen concentration x_Σ in the studied samples was up to 0.16.

The peak *I*′ is comparable in its origin and parameters of the sorption and diffusion processes to those of the peak *II* (Table 3)

¶ Essentially, chemisorption can be involved also in the cases of nanostructured graphite and carbon nanofibres. For high concentrations of chemisorbed hydrogen in such materials, the interlayer separation between graphite layers is substantially increased, which is supported by the experimental X-ray diffraction data (see Sections IV.6 and IV.9).

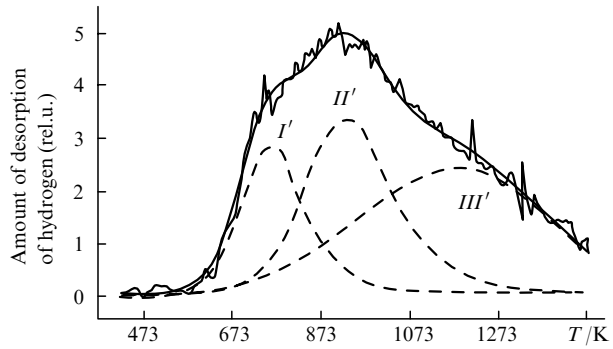

Figure 10. Temperature-programmed desorption of hydrogen from nanoporous carbon hydrogenated at 523 K and P_{H_2} = 7.1 MPa for 3 h (for assignment of the TPD peaks, see text).[199]
The experimental curve shown as a solid line, its components are shown as dashed lines.

for isotropic graphite discussed above.[181] Substitution of the experimental values of $T_{I'}$, $D_{II}(T_{I'})$, υ and $\Delta T_{I'}$ into Eqn (2) yields the length of diffusion path of hydrogen molecules ($L_{I'} \approx 1$ mm), which is in agreement with the thickness of the samples.[199] The hydrogen concentration corresponding to the peak I' [$x_{I'} \approx x_\Sigma(S_{I'}/S_\Sigma) \approx 0.04$] can be described with the expression (23) as well as expressions (25) and (26) (for 523 K and 7.1 MPa). Assuming $x_{II} \approx x_{I'}$ and $\Delta r_{II} \approx 0.3$ nm, the mean size (radius) of a nanograin in the NPC samples can be estimated as $r_{cg} \approx 10$ nm.[199]

The peak II' on the TPD curve for hydrogen desorption from NPC [199] is analogous to the peak *III* (Table 3) for isotropic graphite.[181] The mean size of nanograins for the NPC samples [199] estimated using Eqn (3) is 4 nm ($L_{III'}$) in satisfactory agreement with the aforementioned value of r_{cg}. The concentration of hydrogen corresponding to the peak II' [$x_{II'} \approx x_\Sigma(S_{II'}/S_\Sigma) \approx 0.06$] can be described using the expressions (8)–(10) (for 523 K and 7.1 MPa).

Presumably, the peak III' for NPC (see Ref. 199) is analogous to the peak *IV* (Table 3) for isotropic graphite.[181] Based on the equation similar to (3) and experimental values of $T_{III'}$, $D_{IV}(T_{III'})$, υ and $\Delta T_{III'}$, a value $L_{III'} \approx 190$ nm can be derived, which should characterise the mean linear size of areas of localisation of the corresponding chemisorption centres in the NPC samples.[199]

4. Parameters of hydrogen diffusion in nanostructured pyrolytic graphite

Recently,[68, 69, 201] experimental results on hydrogen thermodesorption from highly oriented pyrolytic graphite [108] exposed to atomic hydrogen at 323–363 K have been reported. This treatment resulted in emergence of surface nanohillocks with heights of 3–5 nm and diameters of 40–75 nm, which can be considered as a sort of nanostructuring of graphite. The nanohillocks disappeared after hydrogen desorption that proceeded as a first-order reaction.[69, 201] Probably, the nanohillocks are formed due to filling of nanocavities with gaseous molecular hydrogen at a high pressure ($P_{H_2} \approx 30$–50 MPa [68]). The TPD measurements (at a heating rate of υ = 25 K s^{-1}) revealed [69, 201] two dominant peaks: a peak α centred at $T_\alpha \approx 1123$ K ($\Delta T_\alpha \approx 180$ K, $S_\alpha/S_\Sigma \approx 0.45$, the activation energy of the process is $Q_\alpha \approx 230$ kJ mol^{-1}) and a peak β centred at $T_\beta \approx 1523$ K ($\Delta T_\beta \approx 250$ K, $S_\beta/S_\Sigma \approx 0.55$, $Q_\beta \approx 385$ kJ mol^{-1}).

The peak α can be attributed to bulk diffusion of hydrogen atoms dissolved in graphite through the nanocavities towards the external free surface of the samples.[68] It should be correlated with the peak *III* for isotropic graphite.[181] The length of the diffusion path (which, in this case, means the width of the nanocavity) is calculated based on Eqn (3), $L_\alpha \approx 4$ nm.

The peak β is analogous to the peak *IV* for isotropic graphite.[181] Using Eqn (3), the length of the diffusion path can be estimated as $L_\beta \approx 300$ nm, this value, effectively, characterises the mean linear size of the areas of localisation of the corresponding chemisorption centres in the samples.[69, 201]

5. Parameters of hydrogen diffusion and sorption in films of nanostructured carbon

Let us now consider experimental data [104, 105] on hydrogen sorption by films of nanostructured carbon prepared using ultrasound-assisted deposition of carbon clusters. The films had porous structures where the size distribution of pores peaked at 3.4 nm and the specific surface area of the samples was 665 m^2 g^{-1} (while volume of the samples was $\sim$0.9 mm^3). The samples hydrogenated at $T \approx 298$ K and P_{H_2} = 100 kPa revealed two dominant peaks in TPD (measured with a heating rate of υ = 0.33 K s^{-1}) with the following characteristics: peak α ($T_\alpha \approx 513$ K, $\Delta T_\alpha \approx 220$ K, $x_\alpha \approx 6 \times 10^{-2}$) and peak γ ($T_\gamma \approx 970$ K, $\Delta T_\gamma \approx 150$ K, $x_\gamma \approx x_\alpha$).

These values assume that peaks α and γ for nanostructured carbon [104, 105] are analogous to peaks *II* and *III* for isotropic graphite.[181] The lengths of diffusion path for hydrogen molecules and atoms can be derived from Eqns (2) and (3). The values obtained in this way, $L_\alpha \approx 9$ μm and $L_\gamma \approx 3$ nm, most probably characterise the mean thickness of the film [104, 105] and the size of the crystallite grains, respectively. The expressions (9), (10), (23), (25) and (26) (for $\sim$298 K and 100 kPA) give rise to the values of $x_{III} \approx 0.1$, which is close to x_γ, and the characteristic size of the crystallite grains $r_{cg} \approx 10$ nm, which is close to L_γ.

* * *

The analysis conducted above indicates that the parameters and equations (Table 3) proposed for characterisation of processes of hydrogen desorption from isotropic graphite [181] give a satisfactory description of the processes corresponding to analogous TPD peaks for a range of nanostructured carbon materials.[67–69, 104, 105, 199–201]

6. Parameters of hydrogen diffusion and sorption in mechanochemically synthesised nanocrystalline graphite

Let us now turn to experimental data [27, 29, 30] on hydrogen and deuterium sorption by mechanochemically synthesised nanocrystalline graphite. The starting material [27, 29] represented graphite powder composed of microgranules with a diameter of $l_{mg} \approx 200$ μm. The graphite powder was saturated with hydrogen (or deuterium) during its milling in a ball mill for 80 h at $T \approx 300$ K and $P_{H_2(D_2)}$ = 1.0 MPa. As a result, a material containing $x_\Sigma \approx 0.96$ of hydrogen was produced. The specific surface area of this sample after milling for 80 h was $S_{sp} \approx 10$ m^2 g^{-1}, which was close to its starting value.[27] For the graphite microgranules after milling for 2 hours, the linear size of nanocrystallites in the direction perpendicular to the graphene layers estimated from the width of peak (002) in the diffraction pattern was $l \approx 40$ nm.[29] The linear size of nanocrystallites ('nanograins') along the graphene layers for the microgranules after milling for 20–80 h was $l_{cg} \leqslant 4$ nm according to Raman scattering and neutron diffraction data.[29] The TPD curves measured for desorption of hydrogen (or deuterium) from these samples upon heating at a rate of υ = 0.33 K s^{-1} revealed two peaks (Fig. 11): a peak α ($T_\alpha \approx$ 730 K, $\Delta T_\alpha \approx$ 130 K, $S_\alpha/S_\Sigma \approx$ 0.8–0.6) and a peak β ($T_\beta \approx 1000$ K, $\Delta T_\beta \approx 30$ K, $S_\beta/S_\Sigma \approx 0.2$–$0.4$). Minor desorption peaks of hydrocarbons with masses of 16 (CH_4) and 28 (C_2H_4) were also detected [29] around T_α (Fig. 11 *a*). No extra peaks were detected around T_β. It is noteworthy that the peak β appears at the same temperature as the peak observed by differential thermal analysis (DTA) and attributed to recrystallisation of nanostructured graphite, which is characterised by the activation enthalpy of $Q_{recr} \approx 244$ kJ mol^{-1}.

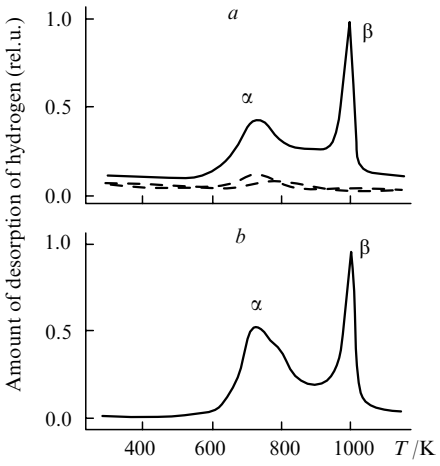

Figure 11. Temperature-programmed desorption of hydrogen (*a*) and deuterium (*b*) (solid lines) from nanocrystalline graphite saturated with hydrogen (or deuterium) during mechanochemical synthesis (1.0 MPa, 300 K, 80 h).[29]
The desorption curves of CH_4 and C_2H_4 are shown as dashed lines.

On the basis of neutron diffraction and Raman scattering data, Orima *et al.* suggested[27,29,30] that the peak α is due to desorption of chemically bound hydrogen (deuterium) whereas the peak β is due to desorption of hydrogen (deuterium) from the interlayer space of the crystallite grains. Therefore, peak β is analogous to peak *III* for isotropic graphite.[181] The length of diffusion path, which corresponds to the linear size of the crystallite grains or nanograins (l_{cg}), determined using Eqn (3) is $L_\beta \approx 2$ nm. This value agrees with the value $l_{cg} \leqslant 4$ nm found experimentally[29].

The calculated concentration of hydrogen $x_\beta \approx (S_\beta/S_\Sigma)x_\Sigma \approx 0.2-0.4$ is in agreement with the value $x_{III} \approx 0.2-0.3$ determined using Eqns (9) and (10) at $P_{D_2} = 1$ MPa and $T = 300$ K, which assumes that under the experimental conditions, the equilibrium bulk solubility of hydrogen (deuterium) in the graphite lattice is reached.[27,29]

The experimental and calculated values of bulk solubility of hydrogen (deuterium) in the graphite lattice[27,29] ($x_\beta \approx x_{III} \approx 0.2-0.4$) approach the ultimate (carbohydride) values of concentrations of occupied chemisorption DC centres in the graphene layers (Table 3).

Evidently, the peak α is due to diffusion of hydrogen (deuterium) molecules from the surface of the crystallite grains towards the external surface of the granules, *i.e.*, it corresponds to the peak *II* (Table 3) for isotropic graphite.[181]

The length of diffusion path L_α estimated using Eqn (2) is comparable to the diameter of graphite microgranules ($l_{mg} \approx 200$ μm) within the samples.[27,29]

The local concentration of hydrogen (deuterium) molecules $x_{D2\alpha}$ on the surface of the crystallite grains can be calculated using the following formula:

$$x_\alpha \approx 12\left(\frac{\Delta r}{l_{cg}}\right)x_{D_2\alpha}\,, \qquad (23a)$$

and the value $x_\alpha \approx (S_\alpha/S_\Sigma)x_\Sigma \approx 0.6-0.8$. Substitution of $\Delta r \approx 0.3$ nm and $l_{cg} \approx 3$ nm[29] in (23a) gives rise to the value of $x_{D2\alpha}$, which is close to the ultimate values of concentration of the chemisorption centres D_2C (model H, Fig. 9), which correspond to formation of a carbohydride adsorbed nanophase on the surface of the crystallite grains.

The above results, in particular, imply that the nanoareas at boundaries of the crystallite grains in nanostructured graphite[27,29] are similar to a certain extent to those of the crystallite micrograins in polycrystalline microgranules of isotropic graphite.[181]

It would be useful to note that such nanoareas at boundaries of crystallite grains are evidently formed upon milling of graphite[27,29] in a ball mill, *i.e.*, upon periodic high-speed plastic deformation of graphite, which results[178] in emergence of a high stationary dislocation density in the material being deformed. These dislocations apparently accelerate diffusion mass transfer of hydrogen in grapite during mechanochemical synthesis of these materials in the atmosphere of hydrogen.[27,29]

Kinetics of hydrogenation of graphite milled in a ball mill (*i.e.*, synthesised mechanochemically) can be formally described as a first-order reaction (Fig. 12):[63,178,202]

$$x_{\Sigma(t)} \approx x_{\Sigma 0}\left[1 - \exp\left(-\frac{t}{\tau_\Sigma}\right)\right]. \qquad (30)$$

Here, $x_{\Sigma(t)}$ is the mean deuterium concentration in the material subjected to milling (mechanochemical synthesis) for a time t; $x_{\Sigma 0}$ is the saturation concentration of deuterium in nanocrystalline graphite; τ_Σ is the relaxation time of diffusion process within the material during mechanochemical hydrogenation ($\tau_\Sigma \approx L_\Sigma^2/D_\Sigma$), where L_Σ is the distance travelled by deuterium in graphite upon mechanochemical synthesis, D_Σ is the apparent deuterium diffusion coefficient in graphite, $\tau_\Sigma \approx 16$ h. This yields a value $D_\Sigma \approx (L_\Sigma^2/\tau_\Sigma)$ that is larger by many orders of magnitude than D^*_{III} and by several orders of magnitude than D_{II}, estimated using the respective equations (see Table 3). Therefore, deuterium diffusion in graphite is abnormally accelerated during mechanochemical synthesis.

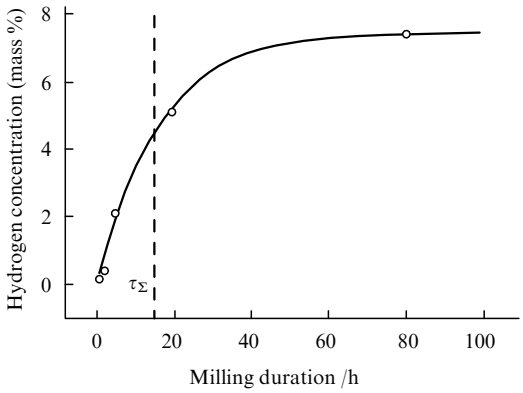

Figure 12. The kinetics of hydrogenation of nanostructured graphite during mechanochemical synthesis [$P_{D_2(H_2)} = 1$ MPa, $T = 300$ K].[27,29]

A series of samples of mechanochemically nanostructured graphite[27,28,124] hydrogenated up to $x_\Sigma \approx 0.96$ (according to Ref. 28) and $x_\Sigma \approx 0.24$, 0.31 and 0.96 (according to Ref. 124) has been studied using NMR. NMR spectra of the samples with $x_\Sigma \approx 0.96$ manifested two peaks suggestively attributed[27,28,124] to chemisorption of deuterium on defect areas (peak *1*) and physisorption of deuterium in the interlayer space (peak *2*).

Additionally, spin–lattice relaxation times of hydrogen atoms were measured[28,124] for the samples of mechanochemically nanostructured graphite (with $x_\Sigma \approx 0.96$, 0.31, 0.24) at 67.7 MHz in a temperature range of 300–425 K (the peak had the maximum intensity at ~390 K). Based on these experimental data, the enthalpy of activation of hydrogen diffusion in graphite (ΔH_a) was estimated as 9.6 kJ mol^{-1}. The authors attributed this 'suprisingly low' value of H_a to diffusion of hydrogen physisorbed between the graphene layers.

Taking into account the specific character of the NMR procedure utilised in the above studies[28,124], theoretical results (MD simulation)[197] concerning hydrogen diffusion between the graphene layers (in the absence of chemisorption centres) as well as the results of our analysis of published data,[27,29,30] it might be

assumed that the above value $\Delta H_a \approx 9.6$ kJ mol^{-1} characterises the enthalpy of activation [Q_{latt} in Eqn (12)] of diffusion of those hydrogen atoms located between the graphene layers, which have not been captured by the chemisorption centres. There are some reasons to suggest that the chemisorption centres capable of capturing the diffusant appeared completely occupied (up to the ultimate hydrocarbon concentrations H/C $\approx$ 1) under the experimental conditions.[28] This situation is equivalent to the lack of the chemisorption centres.[177, 203] The diffusion coefficient determined under such conditions should be close to D_{latt} [expression (11)]. Furthermore, it might be suggested that peaks *1* and *2* in the NMR spectra [28, 124] characterise the same processes as TPD the peaks α and β, respectively.[29, 31]

7. Hydrogen sorption and diffusion in bundles of single-walled carbon nanotubes

Hydrogen sorption by soot containing ~0.01 mass % – 0.02 mass % of SWNT bundles has been studied.[18] The bundles were composed of 7 – 14 SWNT (each tube had a diameter of ~ 1.2 nm and a length of ~ 5 μm). The soot samples (with a mass of ~1 mg) were exposed to hydrogen for 10 min at $P_{H_2} = 40$ kPa and $T = 273$ K (followed by quenching for 3 min at 133 K), then they were heated at a rate of $\upsilon = 1$ K s^{-1}. The TPD curves revealed two peaks (α and β) centred at ~150 K (peak α) and ~288 K (peak β characterised by the following parameters: $\Delta T_\beta = 50$ K, $x_\beta \approx 0.6 - 1.2$).† Based on additional TPD measurements with $\upsilon = 0.3 - 30$ K s^{-1}, the activation enthalpy of the process was determined ($Q_\beta = 19.6$ kJ mol^{-1}, peak β) according to the Kissinger procedure. The process was considered to be a first-order reaction.

The similarity between Q_β and Q_I (see Table 3) allows one to suggest that the diffusion process corresponding to the peak β is analogous to that attributed to the peak *I* for isotropic graphite.[181] Therefore, in order to estimate the length of diffusion path, Eqn (2) can be used, which yields $L_\beta \approx 70$ μm. This value is close to the thickness of the sample. Evidently, in this case, diffusion of hydrogen adsorbed by carbon nanotubes towards the external surface of the sample is accompanied by reversible capture of the diffusant by the chemisorption centres (traps) located on the nanotubes. Within this model, the apparent diffusion coefficient is described by the expression $D_{SWNT} \approx AD_{cap}/K_{(16)I} \approx D_I$ (A = const, D_{cap} is the capillary diffusion coefficient of hydrogen in the absence of chemisorbing traps) similar to Eqn (17).

Taking into account that the experimental values of specific surface area of SWNT samples [76, 204] are typically three – four times smaller than the theoretical value ($S_{sp} \approx 1300$ m^2 g^{-1}),[72] the experimental value x_β should be written in a modified form:

$$x_\beta \approx 2\,\Delta r\, S_{sp}\, \rho\, x_{H_2\beta} \qquad (18a)$$

Substitution of $S_{sp} \approx 400$ (or 1300 m^2 g^{-1}), $x_\beta \approx 0.6 - 1.2$, $\Delta r \approx 0.3$ nm and $\rho \approx 2$ g cm^{-3} (density of the material) [72, 192] into Eqn (18a) gives rise to $x_{H_2\beta} \approx 1.2 - 2.4$ (or 0.4 – 0.8).

For the sorption process corresponding to the peak *I*, Eqns (20) and (21) for $T = 273$ K and $P_{D_2} = 40$ kPa yield $x_{D_2 I} \approx 0.075$, which is substantially smaller than $x_{H_2\beta}$. Thus, it might be assumed that it is physisorption of hydrogen (*i.e.*, condensation of the adsorbate) that dominates in the SWNT samples [18] (peak β) rather than chemisorption as in the case of graphite [181] (peak *I*); to a certain extent, this could be promoted by additional quenching of the SWNT samples at 133 K.

A totally different situation occurs upon hydrogen adsorption on SWNT samples ($x_{SWNT} \approx 0.01$) and graphite powder ($x_{graph} \approx 0.01$) hydrogenated at $T = 295$ K and $P_{H_2} =$ 107 kPa.[85] In a pressure range from 5 kPa to 107 kPa (P_{H_2}), the adsorption process is described by the Henry isotherm, which represents a reduced form of the Henry – Langmuir isotherm [Eqn (20)] at near-zero filling of the sorption centres.

Substitution of the experimental values [85] S_{sp}(SWNT) $\approx$ 504 m^2 g^{-1} and S_{sp}(graph.) $\approx$ 60 m^2 g^{-1} into (18a) yields x_{H_2}(SWNT) ≈ 0.16 and x_{H_2}(graph) ≈ 0.12. Similarly, from Eqns (20) and (21) for $T = 295$ K and $P_{H_2} = 107$ kPa, it follows that $x_{D_2 I} \approx 0.09$, which is close to x_{H_2}(SWNT) and x_{H_2}(graph.). This implies that the mechanism and parameters of hydrogen (deuterium) adsorption by the SWNT and graphite samples [85] studied at a pressure of ~10 – 100 kPa and room temperature are similar to those of the chemisorption process attributed to the peak *I* (Table 3) for isotropic graphite.[181]

The sorption capacity of the graphite sample [85] at 295 K and 107 kPa recalculated for $S_{sp} = 1000$ m^2 g^{-1} is $c_S \approx 1.3$ mass %; the respective sorption capacity of the SWNT samples [85] at the same temperature and hydrogen pressure is $c_S \approx 1.9$ mass %. A similar value $c_S = 1.5 \pm 0.2$ mass % was obtained [72] for electrochemically hydrogenated SWNT and graphite samples with a specific surface area from 50 to 1200 m^2 g^{-1}, which strongly supports the surface character of the sorption processes.

Note that a significantly larger sorption capacity $c_S \approx 10$ mass % – 20 mass % (at 273 K and 40 kPa) was reported for another series of SWNT samples.[18] The reason for this discrepancy is either a strong overestimation of the experimental sorption capacity (by an order of magnitude) or localisation of the dominant fraction of the adsorbate in nanocavities between the tubes, *i.e.*, involvement of the physical mechanism of hydrogen sorption (condensation) under the experimental conditions. (It should also be kept in mind that the SWNT samples [18] were heavily contaminated with soot and subjected to an additional hydrogenation step at 133 K.)

Kinetics of hydrogenation (at $P_{H_2} = 0.1$ MPa and $T = 500$ K) and isothermal hydrogen desorption in a vacuum (at $T = 500$ K) were measured on pads (with a thickness of ~1 mm) composed of tangled bundles of SWNT (50 vol.% – 70 vol.%, diameter of bundles ~15 nm, diameter of nanotubes ~1.4 nm, $S_{sp} \approx 250 - 470$ m^2 g^{-1}, residual content of the catalyst 0.2, 2 and 6%) using the thermo-EMF method.[76] Both processes proceeded as first-order reactions with a relaxation time of $\tau \approx 1$ h. Assuming that the rate-limiting step of the process is diffusion of hydrogen molecules from the surface of the samples to the bulk with the parameters similar to those corresponding to the peak *I* for graphite [181] (Table 3), the estimated length of diffusion path [$L_I \approx (D_I \tau)^{1/2}$] appears similar to the thickness of the pads.

Kinetics of isothermal desorption of hydrogen from electrochemically hydrogenated cylindrical samples ($d = 7$ mm) prepared by cold compacting of a SWNT material (10 mg) mixed with gold powder (90 mg) was studied.[72] Hydrogen content in these SWNT samples reached 0.9 mass %. At 293 K, about half of the total hydrogen amount desorbs during first 10 h whereas the remaining part desorbs for $t_\Sigma \approx 200$ h.[72]

On the basis of diffusion parameters corresponding to the TPD peak *I* for isotropic graphite [181] (Table 3), one can estimate the diffusion coefficient at 293 K to be $D_I = 7.1 \times 10^{-7}$ cm^2 s^{-1}, which is close to $(d^2/t_\Sigma) \approx 6.8 \times 10^{-7}$ cm^2 s^{-1}. This means that it gives a satisfactory description for the process of hydrogen diffusion in such materials.[72]

The same study [72] reported results on hydrogen desorption from SWNT samples hydrogenated at 78 K and 0.2 MPa upon their heating with a rate of $\upsilon \approx 0.067$ K s^{-1} (in a temperature range from 78 K to 800 K) and from graphite samples hydrogenated at room temperature and 2 MPa (for 30 min) upon their cooling to 78 K. For both SWNT and graphite samples, three peaks were revealed [72] at ~105 K, ~136 K and ~300 K. The two latter peaks correspond evidently to peaks α (~150 K) and β (~288 K) observed for the aforementioned SWNT samples studied in Ref. 18. Additional peaks were revealed [72] at ~800 K for the SWNT samples and at ~650 K for the graphite samples,

† In the estimate [18] of sorption capacity of the SWNT samples, a possible involvement of soot and amorphous graphite abundant in the samples (their content reached 99.9 mass % – 99.8 mass %) was not taken into account, peak α was also neglected.

which, probably, can be correlated with peaks *II* and/or *IV* (Fig. 8) for isotropic graphite.[181]

Measurements of hydrogen desorption from samples composed of SWNT bundles, amorphous carbon and particles of a metal catalyst were reported.[34] The samples were first milled in a ball mill (for 24 h in an argon atmosphere) and then exposed to hydrogen for 15 min at $P_{D_2} = 80$ kPa and room temperature. According to electron microscopy,[34] the milling process results in the emergence of deformed areas (defects) in the structure of SWNT bundles and the formation of strongly bent or broken SWNT fibres. TPD curves of the hydrogenated SWNT samples treated in this way (measured at a heating rate of $\upsilon \approx 0.3$ K s^{-1} from $\sim$400 K to $\sim$850 K) reveal a single peak at $\sim$590 K, ($\Delta T \approx 75$ K, $x \approx 0.01$). Based on TPD measurements at different heating rates (from 0.03 to 0.3 K s^{-1}), the activation energy of the process was determined to be $Q_{SWNT} = 145 \pm 20$ kJ mol^{-1}.

The similarity between Q_{SWNT} and Q_{II} implies that the parameters of the diffusion process corresponding to the peak of hydrogen desorption from SWNT bundles[34] are analogous to those of the peak *II* for graphite (Table 3).[181] The length of diffusion path, which characterises the thickness of the samples, estimated from Eqn (2) is L(SWNT) $\approx$ 30 μm.

Within such a model, the apparent diffusion coefficient of hydrogen within the deformed SWNT bundles[34] upon their heating in a vacuum can be described using the following equation: $D_{SWNT} \approx AD_{cap}/K_{(16)II} \approx D_{II}$.

The value $x_{D2II} \approx 0.5$, calculated using Eqns (25) and (26) for 295 K and 80 kPa, can be further used to estimate the atomic (volume) fraction of the deformed areas (η_{II}) within the structure of SWNT bundles. From the expression $x \approx 2\eta_{II} x_{D2II}$, it follows that $\eta_{II} \approx 10^{-2}$. [Most probably, it is the H_2C chemisorption centres of type H (Fig. 9) that are localised in these deformed areas of the SWNT samples.[34]]

Another study[34] was devoted to SWNT, GNF and graphite samples hydrogenated using mechanochemical synthesis in a deuterium atmosphere (in a ball mill at $P_{D_2} =$ 0.9 MPa for 24 h). TPD measurements at a heating rate of $\upsilon \approx 0.08$ K s^{-1} in a temperature range from $\sim$300 K to $\sim$900 K, revealed[34] a peak centred at 740 K (that was distinct in the cases of SWNT and GNF samples but poorly resolved for the graphite samples) and a leading edge of a second peak (especially pronounced for the GNF samples) apparently centred in the range of 900–1100 K. Temperature positions of these peaks are close (taking into account different heating rates υ) to those of peaks α and β observed for the samples of nanostructured graphite[27,29] prepared mechanochemically in a deuterium atmosphere.

It would be useful to consider the experimental results[83] on volume (68 kg m^{-3}) and gravimetric ($x_{exp} \approx 0.48$) hydrogen sorption capacities of SWNT samples (pellets) characterised by S_{sp}(SWNTC) $\approx$ 110 m^2 g^{-1} hydrogenated at $\sim$11 MPa and 295 K. For these conditions, Eqn (18a) gives rise to the value x_{H_2}(SWNT) $\approx$ 3.6 (provided that $S_{sp} = 110$ m^2 g^{-1}) while Eqns (20) and (21)give rise to the value $x_{D_2I} \approx 0.48$, which is close to the ultimate (carbohydride) value (0.5). This discrepancy may be, firstly, due to strongly underestimated experimental specific surface area S_{sp}, which is smaller than the theoretical value by an order of magnitude (see Ref. 72); secondly, it may indicate condensation of the predominant fraction of the adsorbate in the nanocavities between the nanotubes, which is possible at such a high pressure.

Similar values of sorption capacity ($x \approx 0.5$–0.6) were reported in other studies[23,71] for the SWNT samples hydrogenated at 10 MPa and room temperature, which can thus be interpreted analogously.

The interaction of gaseous molecular hydrogen with purified SWNT samples (content of SWNT bundles was $\sim$90 mass %–95 mass %, diameter of the tubes was $\sim$1.38 nm) with the ends open using a chemical treatment with an NaOH aqueous solution was elucidated.[77] The samples with a mass of $\sim$1 g and volume of $\sim$1 cm^3 were hydrogenated at 1.5–9.0 MPa and room temperature ($\sim$295 K). The sorption capacity of the SWNT samples[77] in the case of hydrogenation at 9 MPa and 295 K was x(H/C) = 0.038. The experimental data[77] at $P_{H_2} =$ 1.5–9.0 MPa and $T = 295$ K are described by the Henry adsorption isotherm. TPD measurements with heating rates of $\upsilon = 0.17$ K s^{-1} and 0.017 K s^{-1} revealed peaks centred at $T \approx 508$ K and 374 K, respectively. The enthalpy of activation of the process (Q) determined using the Kissinger procedure was 20 kJ mol^{-1}.

Since the above value of Q coincides with the value of Q_I determined in an analysis of hydrogen desorption from the purified SWNT samples,[77] it is reasonable to utilise the diffusion and sorption parameters corresponding to the peak *I* for graphite (see Table 3).[181] The length of diffusion path calculated using the expression (2) is $L \approx 1$ mm, which corresponds to the thickness of the SWNT samples.[77] Similarly, sorption capacity can be estimated based on Eqns (20) and (21) for 295 K and 9 MPa as $x_{D_2I} \approx 0.47$, which approaches the ultimate (carbohydride) value.

The value x_{H_2}(SWNT) ≈ 0.08 calculated from Eqn (18a) using a typical value of S_{sp}(exp.) = 400 m^2 g^{-1} is substantially smaller than the aforementioned x_{D_2I}. This means that hydrogen sorption on the SWNT samples[77] cannot be described on the basis of the sorption parameters (Table 3) corresponding to the peak *I* for isotropic graphite.[181]

Hydrogen sorption on a new carbon nanomaterial, *viz*., single-walled nanotubes with cone-shaped (horn-like) ends, or nanohorns (SWNH), was studied.[100] The content of SWNH in the samples exceeded 95 mass % while metal catalysts and soot were virtually absent. The original SWNH samples ($S_{sp} \approx 308$ m^2 g^{-1}) and those treated with oxygen at 693 K for 10 min ($S'_{sp} \approx 1006$ m^2 g^{-1}) were tested. Both samples were hydrogenated at $\sim$0.1–6.5 MPa and 303 K. In both cases, the hydrogenation process obeyed the Henry adsorption isotherm (similar to Ref. 77). The sorption capacity of the oxidised samples at 6.5 MPa was $x_{ox} \approx 0.038$ whereas that of the original samples was $x_{init} \approx 0.014$. Substitution of typical experimental values of specific surface area for similar samples into the expression (18a) yields x_{H_2}(ox.) = 0.032 and x_{H_2}(init.) = 0.038. On the other hand, the value calculated using Eqns (20) and (21) for 303 K and 6.5 MPa, $x_{D_2I} = 0.46$ [which is close to the ultimate (carbohydride) value of 0.5], is larger than the above x_{H_2}(ox.) and x_{H_2}(init.) values by an order of magnitude.

These results are similar to those obtained in the above analysis of the experimental data from Ref. 77 but drastically different from those of Ref. 83. The latter results were obtained at a similarly high pressure for the SWNT samples that have not been purified from soot, amorphous carbon and particles of metal catalysts. Therefore, the presence of soot, amorphous carbon and metal catalyst in the SWNT samples strongly affects the overall sorption process.

8. Sorption and diffusion of hydrogen in multi-walled carbon nanotubes

Sorption of hydrogen by two types of MWNT samples (with a mass of $\sim$2 mg) having different structures were studied by Lee *et al*.[89] The samples were exposed to hydrogen for 5 h at 4 MPa and 300 K (with subsequent cooling down to 80 K) and then studied using TPD (at $\upsilon = 0.03$–0.08 K s^{-1}).

The first type (A) of the samples were composed of strongly bent nanotubes with strongly distorted graphene layers and partially blocked nanoholes. Side faces of the majority of the tubes were closed. External and internal diameters of the tubes were estimated[89] to be 10–30 nm and 5–15 nm, respectively, and the specific area amounted to S_{sp}(A) $\approx$ 174 m^2 g^{-1}. The samples A manifested two TPD peaks: a peak α_1 around 312 K ($\Delta T_{\alpha 1} \approx 18$ K, $\upsilon = 0.05$ K s^{-1}, $Q_{\alpha 1} \approx 18.5$ kJ mol^{-1}, $x_{\alpha 1} \approx 7.7 \times 10^{-2}$) and a peak β_1 around 419 K ($\Delta T_{\beta_1} \approx 8$ K, $\upsilon = 0.05$ K c^{-1}, $Q_{\beta 1} \approx 124.4$ kJ mol^{-1}, $x_{\beta 1} \approx 3.6 \times 10^{-3}$). The peak α_1 reappeared upon several consecutive cycles of hydro-

genation and heating of the samples whereas the peak β_1 did not reappear.

The samples B were composed of straightened, aligned MWNT with a less distorted structure as compared to the samples A. Nanoholes within the samples B were assembled into pores and side faces of the tubes remained open. The external and internal diameters of the tubes were $\sim$20 nm and $\sim$8 nm, respectively; specific surface area $S_{sp}(B) \approx 877$ m^2 g^{-1} [this value is several times larger than the theoretical value of the specific surface area (263 m^2 g^{-1}) [72] for ten-walled nanotubes]. The samples B manifested only one TPD peak (α_2) around 313 K ($\Delta T_{\alpha 2} \approx 7$ K, $\upsilon = 0.05$ K c^{-1}, $Q_{\alpha 2} \approx 16.5$ kJ mol^{-1}, $x_{\alpha 2} \approx 0.24$).[89]

The similarity between $Q_{\alpha 1}$ and $Q_{\alpha 2}$, on the one hand, and Q_I in graphite,[181] on the other hand, indicates that the parameters characterising the TPD peak *I* (Table 3) for isotropic graphite [181] can be used to describe peaks α_1 and α_2 for the MWNT samples.[89] The lengths of diffusion path $L_{\alpha 1}$ and $L_{\alpha 2}$, which characterise thickness of the samples, calculated on the basis of Eqn (2) are 130–200 μm.

The ratio $x_{\alpha 2}/x_{\alpha 1}$ is close to the ratio $S_{sp}(A)/S_{sp}(B)$, which is in agreement with the published results.[72, 81] The local concentration of hydrogen molecules within the adsorbed layers on the walls of the nanotubes calculated using Eqn (18a) is $\sim$0.2–0.3. For the experimental conditions used in Ref. 89, Eqns (20) and (21) yield $x_{D_2 I} \approx 0.4$. This value of $x_{D_2 I}$ is close to $x_{H_2 \alpha}$ calculated from the experimental data [*i.e.*, $x_{\alpha 1}$, $S_{sp}(A)$, $x_{\alpha 2}$, $S_{sp}(B)$] for the MWNT samples.[89]

The similarity between $Q_{\beta 1}$ and Q_{II} assumes that the peak β_1 for the samples A is analogous (with regard to diffusion parameters) to the peak *II* (Table 3) for isotropic graphite.[181] The absence of the peak β_1 in subsequent cycles of hydrogenation and annealing of the samples A [89] can be explained by curing of the deformational structural defects in these samples upon their first annealing. The length $L_{\beta 1} \approx 0.2$ μm calculated using Eqn (2) probably characterises the diffusion dimension of the distorted areas within the samples A.[89] The volume fraction of such distorted areas within the samples A with chemisorbing carbon 'centres' can be estimated using the equation $x_{\beta 1} = 2\eta_{\beta 1} x_{D_2 II}$, where $x_{D_2 II} \approx 0.5$ [as determined from the expressions (25) and (26)] to $\eta_{\beta 1} \approx 4 \times 10^{-3}$.

Sorption of hydrogen by MWNT samples at 10 MPa and room temperature was studied by Li *et al.*[90] They used two types of samples: one type of the samples (A) was characterised by numerous cracks in the external graphene layers (walls) of nanotubes even after annealing at 2473 K (for 2 h); another type (B) was characterised by crack-less graphene layers (walls) both before and after annealing at 2473 K (for 2 h). Sorption capacities (x) of the non-annealed samples A and B were 0.1 and 0.09, respectively whereas those of the annealed samples were 0.5 and 0.1, respectively.

Specific surface areas of the samples A and B [90] calculated using Eqns (18a), (20) and (21) are $\sim$520 m^2 g^{-1} and $\sim$110 m^2 g^{-1}, respectively. These calculated values of S_{sp} are within the range of typical values found experimentally for such materials, which implies that the process of hydrogen sorption on the MWNT samples [90] can be described using the parameters corresponding to the peak *I* for graphite.[181]

Sorption of hydrogen by MWNT samples with a diameter of 10–40 nm (predominantly with closed side faces) at 290 K and $P_{H_2} = 3$–10 MPa was studied by Cao *et al.*[91] They used two types of samples: samples A composed of straightened highly oriented nanotubes [tube density was up to $\sim 10^8$ mm^{-2}, thickness of some tube blocks was $h \approx 250$ μm, $S_{sp}(A) \approx 60$ m^2 g^{-1}] and samples B characterised by a random arrangement of the nanotubes [and variable nanoporosity, $S_{sp}(B) \approx 27$ m^2 g^{-1}].

For both types of the MWNT samples (A and B), the hydrogen uptake increased linearly with an increase in pressure P_{H_2} from 3 to 10 MPa.[91] Sorption capacities (x) of the samples A and B at 290 K and 10 MPa were $\sim$0.29 and $\sim$0.082, respectively. Hydrogenation of the samples A resulted in disappearance of pores in the size range of 10–100 nm and an increase in the number of pores in the size range of 2–10 nm, which can be due to development of local strains and deformations.[154, 184–187]

Sorption capacity x_{H_2}, determined using the expression (18a) and experimental values of $x(A)$, $x(B)$, $S_{sp}(A)$ and $S_{sp}(B)$ is 2.2–3.6, which is significantly larger than $x_{D_2 I} \approx 0.46$, estimated on the basis of Eqns (20) and (21) for 290 K and 10 MPa. Presumably, this discrepancy is due to inaccurate determination of the specific surface areas of the MWNT samples [91] (the experimental values of S_{sp} were measured using the BET adsorption isotherms of nitrogen rather than hydrogen at 77 K and thus were underestimated). The high values of x_{H_2} can be also explained by condensation of a large fraction of the adsorbate in the nanocavities between the tubes of the MWNT samples,[91] *i.e.*, domination of physisorption over chemisorption with the parameters corresponding to the peak *I* for graphite.[181]

Characteristics of hydrogen sorption on straightened (aligned) multi-walled nanotubes with a diameter of 50–100 nm and density of $\sim 10^8$–10^9 mm^{-2} were reported by Chen *et al.*[88] The samples were hydrogenated at $\sim$295 K and $\sim$0.1 MPa (or $\sim$1.0 MPa) up to hydrogen concentration $x_{exp} \approx 0.60$–0.84 (or 1.08–1.56), then treated with nitric acid and annealed at 673 K.

Upon heating of the hydrogenated samples (with a mass of $\sim$1 mg) from $\sim$295 K to 573 K with a rate of $\upsilon \approx 0.083$ K s^{-1}, several hydrogen desorption peaks were detected by mass spectrometry.[88] The major peak (about 90%) was centred at $T \approx 540$ K with a width at half maximum of $\Delta T \approx 45$ K, *i.e.*, the dominant fraction of adsorbed hydrogen was liberated from the MWNT samples at 500–600 K.[88]

The length of diffusion path of hydrogen estimated using Eqn (2) is $L \approx 15$ μm. This value is comparable with the mean length of the nanotubes and thickness of the MWNT samples.[88] This indicates that the diffusion process corresponding to the peak at 540 K for the MWNT samples [88] is characterised by parameters similar to those attributed to the peak *II* for graphite.[181]

Substitution of $x_{D_2 II} \approx 0.5$ calculated using Eqns (25) and (26) and the experimental value $0.9\,x_{exp} \approx 0.54$–0.76 into Eqn (18a) gives rise to $S_{sp} \approx 500$–700 m^2 g^{-1}, which is significantly larger than the ultimate theoretical value.[72] Therefore, it might be assumed that in this case, the dominant part of the adsorbate undergoes condensation in the nanocavities between the tubes of the MWNT samples.[88]

Chen et al. [88] noted that the cone-shaped structure of studied samples was different from that typical of ideal MWNT samples and rather similar to GNF samples.[32, 33, 205]

9. An analysis of abnormal data concerning hydrogen sorption by graphite nanofibres

In 1998, Chambers *et al.* published a sensational paper [33] on the possibility of hydrogen storage in a new materials, *viz.*, graphite nanofibres‡ with a specific structure. They reported that GNF samples with an oriented (at $\sim$45°) nanostructure are capable of sorbing an abnormally high amount of hydrogen ($x_\Sigma \approx 18.5$) at $P_{H_2} \approx 9.6$ MPa (final value) and $T = 298$ K.

Hydrogenation of the GNF samples lasted for 20 h (τ_Σ). Upon release of the pressure, the dominant fraction of adsorbed hydrogen ($x \approx 9.8$) desorbed during $\tau \approx 5$–10 min.

Chambers *et al.* [33] also hydrogenated a series of other materials, including palladium powder (up to final composition of $PdH_{2.2}$, which differs from the stoichiometry of stable Pd_2H and metastable $PdH_{1.1-1.3}$ palladium hidrides [177]) and $LaNi_5$. The sorption capacities of these materials were overestimated as well,

‡ The nanofibres with a length of $\sim$10–100 μm were composed of stacks of strictly oriented (parallel, perpendicular, or at an angle of $\sim$45° with respect to the stack axis) graphene platelets with a distance between the graphene sheets of $\geqslant$0.335 nm (which is close to the interlayer separation in graphite [181]) and a cross-section area of $\sim$0.3–5.0 nm^2. This material represented a system of spot-like nanopores with open ends.[33]

which, according to Nishimiya *et al.*,[85] can be considered as additional evidence for a systematic error in the measurements of hydrogen sorption by GNF performed by Chambers *et al.*[33] Results regarding hydrogenation of graphite (at $\sim$11 MPa and 298 K for $\sim$40 h) up to a concentration of $x_\Sigma \approx 0.57$ and activated carbon 'Norite' characterised by $S_{sp} \approx 1000$ m^2 g^{-1} up to a concentration of $x_\Sigma \approx 0.20$ were also significantly different from those reported by other groups.[35, 38, 72, 85, 141]

In a subsequent study of hydrogen sorption by GNF samples, the same group of authors [32] reported much lower values $x_\Sigma \approx 8.0$ (hydrogenation was performed at $P_{H_2} \approx 11.2$ MPa and 298 K for 24 h).§ Furthermore, the authors noted that achievement of such a high value of x_Σ required an additional short *in situ* annealing of the GNF samples at 473 K.

Followed by release of the high pressure and retention of the hydrogenated samples at 298 K for $\tau_\alpha \geqslant 10$ min giving rise to desorption of the dominant fraction of hydrogen ($x_\alpha \approx 5.9$, peak α), the GNF samples were heated again to $\sim$1223 K at a rate of $\upsilon \approx 0.17$ K s^{-1}. Upon this second heating, the TPD curve (Fig. 13) revealed two peaks (β and γ) centred at 880 K ($\Delta T_\beta \approx 245$ K, $x_\beta \approx 1.2$) and 1140 K ($\Delta T_\gamma \approx 205$ K, $x_\gamma \approx 0.9$). Around T_β, a concomitant liberation of gaseous hydrocarbons (CH_4, *etc.*) was detected.

A comparison of the TPD curves (Fig. 13) for the GNF samples hydrogenated at 11 MPa (curve *1*) and 0.1 MPa (curve *2*) shows that the sorption process corresponding to the peak β is described by the Henry – Langmuir adsorption isotherm and that corresponding to the peak γ is described by the Sieverts – Langmuir isotherm. The peak β is analogous to the peak *II* in the case of isotropic graphite,[181] whereas the peak γ is analogous to the peak *III*. Therefore, in order to calculate the respective length of diffusion path of hydrogen in the GNF samples (for peak β), one can utilise Eqn (2). The value $L_\beta \approx 0.4$ cm determined in this way corresponds to the linear size of the GNF sample ($l \approx 0.6 - 0.8$ cm).[32]

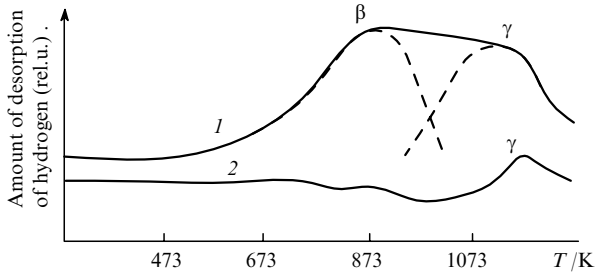

Figure 13. Temperature-programmed desorption of hydrogen from the GNF samples hydrogenated at 11.2 MPa (*1*) and 0.1 MPa (*2*) (for assignment of the TPD peaks, see text).
The experimental curves are shown as solid lines, individual components of the curve (*1*) are shown as dotted lines.

The value of sorption capacity $x_{H_{2\beta}}$ calculated using the equation $x_\beta \approx 12\,(\Delta r/d_{GNF})x_{H_2\beta}$ ($\Delta r \approx 0.2$ nm, $d_{GNF} \approx 1$ nm)[32] is $\sim$0.5. A similar value is obtained for x_{D_2II} on the basis of Eqns (25) and (26).

The experimental value x_γ is in fair agreement with the value $x_{III} \approx 0.6$ calculated using Eqns (9) and (10) for the peak *III* (Table 3). Also note that the values of x_γ, x_{III}, $x_{H_2\beta}$ and x_{D_2II} are close to the ultimate (carbohydride) values of $(x_{III})_{max}$ and $(x_{II})_{max}$.

The length of diffusion path ($L_\gamma \approx 50$ nm) estimated on the basis of parameters of the peak γ (for the GNF samples) according to Eqn (3) using D_{III} (Table 3) is significantly larger than $d_{GNF} \approx 1$ nm.[32, 33] There are two possible reasons for the difference between L_γ and d_{GNF}: either the value of diffusion coefficient used in the calculation of L_γ is overestimated ¶ or the value of d_{GNF} as determined in Ref. 32 is incorrect.† This can be due to the formation of a specific substructure (with a characteristic linear size of $\sim$1 – 3 nm) in the hydrogenated GNF samples [32] (having a fibre diameter of $\sim$50 nm), which disappears (due to curing) upon heating of the samples in the course of the TPD measurements. This suggestion is supported by the results of other studies,[32, 91] which revealed an abrupt decrease in the hydrogen concentration and a change in the size of nanopores within the hydrogenated GNF and MWNT samples and their reappearance upon heating.

It should be emphasised that the parameters of sorption and diffusion processes corresponding to peaks β and γ for the GNF samples [32] agree with those of processes corresponding to peaks α and β for nanocrystalline graphite [29] and are satisfactorily described by the parameters of peaks *II* and *III* for isotropic graphite (Table 3).[181]

The apparent diffusion coefficient of hydrogen in the GNF samples,[32] which characterises the process of desorption of the dominant fraction (x_α) of hydrogen at 298 K (peak α that appears just after release of the high pressure), can be estimated as $D_\alpha \approx (L^2/\tau_\alpha) \approx 2 \times 10^{-3}$ cm^2 s^{-1}. This value is larger by 3.5 orders of magnitude than D_I (peak *I*, Table 3) typical of graphite.[181] This strongly assumes different mechanisms of hydrogen sorption on GNF [32] and graphite [181] around T_α and T_I.

The sorption capacity corresponding to the peak α cannot be described using the parameters attributed to the peak *I* for isotropic graphite.[181] Thus, there are serious reasons validating the suggestion [32, 33] that the desorption process corresponding to the peak α is essentially due to the removal of hydrogen condensate from the nanocavities of the graphite nanofibres. Additionally, this is supported by the neutron diffraction data [4, 32] on abnormally high packing density (which exceeds that of hydrogen molecular crystals) of the adsorbate on the graphite surface and X-ray diffraction data [26] on an abnormally large increase (by 40%) in the interplane separation observed for the GNF samples hydrogenated at 9 GPa.

V. Conclusion

The comparative and constructive thermodynamic analyses of the experimental and theoretical data on the sorption of hydrogen by carbon nanomaterials in technically reasonable ranges of pressure and temperature confirm that the abnormally large scatter (up to three orders of magnitude) and poor reproducibility (or even lack of reproducibility) of the measurements of sorption capacities of these materials is caused by a number of factors, including complexity of the objects under study, variations in the microstructure (that strongly depends upon method used for the preparation of the sorbents) and conditions of physicochemical pretreatment and modes of hydrogenation of the samples, etc. The state-of-the-art in investigations into the interactions of hydrogen with graphite and carbon nanomaterials makes it possible to deliberately optimise synthetic conditions and modes of hydrogenation for such materials, which is an absolute prerequisuite for advancement towards creation of superadsorbents for hydrogen.

The authors are grateful to their colleagues, A K Chernysheva and E V Borisov, for the fruitful discussion of the results.

§ These data were neither confirmed by other researchers.

¶ It might be assumed that the diffusion coefficient of hydrogen atoms in the 'hydrocarbon phase' of GNF is smaller than that in the graphite lattice [181] with partially occupied carbon chemisorption centres, therefore, the value of D_{III} should not be used in a calculation of L_γ.

† There is experimental evidence [35, 71, 141, 142, 206] that the graphite nanofibres were characterised by a larger diameter ($d_{GNF} \approx 10 - 100$ nm) than that reported in Ref. 32.
