taining at least one P–C or P–XR bond ( $\text{X} = \text{O}, \text{S}, \text{N}$ ; R is a hydrocarbon substituent), in which phosphorus has a coordination number of 3 ( $\text{P}^{\text{III}}$ ) or 4 ( $\text{P}^{\text{IV}}$ ). The structures of low-coordinate phosphorus compounds (see Refs 14–25) and phosphorus-containing heterocycles<sup>26–31</sup> are beyond the scope of this review. Metal complexes containing OPCs are also not included in the review, because this large and specific area of organophosphorus chemistry deserves a separate analysis.

The review summarises the results of theoretical conformational analyses of OPCs performed primarily in the last 10–15 years and covers inclusively data published up to mid-2003. In addition, the most important and high-priority studies and reviews in the field of experimental and theoretical conformational analysis of organophosphorus compounds published earlier are considered.

## II. Conformational analysis of tri- and tetracoordinate phosphorus compounds

### 1. Internal rotation about P–C(sp<sup>3</sup>) bonds

The first reviews<sup>5,8</sup> on the conformations of acyclic organophosphorus compounds, in which the  $\text{P}^{\text{III}}$  and  $\text{P}^{\text{IV}}$  atoms are bound to various organogen atoms, were published 20 years ago. The results analysed in these reviews were obtained primarily by experimental methods and semiempirical quantum-chemical calculations (in rare cases, by *ab initio* calculations for a few simple molecules). Conformational studies in this field were accompanied by generalisation and critical analysis of the considerable amount of experimental data obtained by gas electron diffraction, X-ray diffraction analysis, IR, UV, Raman and NMR spectroscopy and quantum-chemical calculations. Along with these general physical methods, a comparison and analysis of experimental dipole moments, the dipole moments calculated according to the vector-additive scheme (hereafter, the dipole moment method) and data on electric-field-induced birefringence (hereafter, the Kerr effect method) play an important role in conformational studies. Photoelectron spectroscopy also makes a great contribution to investigations of conformational equilibria.

The main characteristic features of internal rotation about P—C(sp<sup>3</sup>) bonds in OPCs were revealed. The internal rotation about the P—C(sp<sup>3</sup>) bond has a threefold barrier due to the tetrahedral environment of the carbon atom involved in this bond. From the very beginning, conformational analysis of OPCs assumed that the staggered *gauche* or *trans* conformations with respect to the P—C(sp<sup>3</sup>) bond were the most stable,<sup>5</sup> by analogy with the C(sp<sup>3</sup>)—C(sp<sup>3</sup>) bond (although the eclipsed *cis* conformation was initially also considered because of a lack of data). The Newman projections of the stable conformations of OPCs are shown below.<sup>5</sup>

According to current opinion, staggered *gauche* (synclinal) or *trans* (antiperiplanar) conformations with respect to the P—C(sp<sup>3</sup>) bond are favourable for most OPCs.

This situation occurs regardless of the coordination state of the phosphorus atom (P<sup>III</sup> or P<sup>IV</sup>) and the presence of one, two or three such bonds in OPC molecules. At the same time, specific interactions (for example, intramolecular hydrogen bonding) and conjugation effects (for example, in the O=P—O—Si bond system) can stabilise the eclipsed *cis* (synperiplanar) conformation.

The ratio of the various rotamers and the factors responsible for their stabilisation are determined by the balance between intramolecular repulsive and attractive forces, *i.e.*, from the sum of Coulombic interactions between the dipoles, steric and orientation interactions, intramolecular electronic effects, *etc.* It should be noted that the general and relative stabilities of favourable conformers are, with rare exception, independent of the aggregation state of the compounds under study (crystals, liquids or solutions). The conformations observed in crystals are almost always retained in liquid and solution states, although several staggered rotamers often co-exist in the liquid phase, and the conformational pattern becomes more diverse.

In the last 15 years, the relative stabilities of the conformations of organophosphorus molecules which differ in angle of rotation about the P—C(sp<sup>3</sup>) bond, have been extensively studied by semiempirical and *ab initio* quantum-chemical methods.<sup>32–44</sup> In some studies,<sup>34–36</sup> the spectroscopic and structural data for phosphine oxides and phosphine sulfides were analysed using the semiempirical MNDO/H method, and the conclusion was drawn that this method provides a satisfactory general description of the geometry and various physicochemical characteristics of OPCs. The results of experimental conformational analysis (the temperature dependence of the conformational stability estimated by IR spectroscopy) agree closely with the results of theoretical conformational analysis (*ab initio* calculations) of the ethyldifluorophosphine obtained by Durig *et al.*<sup>38,39</sup> The staggered *gauche* and *trans* conformations are favourable for this compound, the energy difference being small (0.23 ± 0.02 kcal mol<sup>–1</sup>).

Earlier experimental (IR and Raman spectra) conformational analysis and semiempirical calculations, carried out by this research group for the ClCH<sub>2</sub>PF<sub>2</sub>,<sup>43</sup> EtP(S)Cl<sub>2</sub> and CD<sub>3</sub>CH<sub>2</sub>P(S)Cl<sub>2</sub> molecules,<sup>32</sup> led to the same principal results. All these compounds are characterised by the staggered *gauche* (C<sub>1</sub> symmetry) and *trans* (C<sub>s</sub> symmetry) conformations the *gauche* conformer being more stable. In the solid state, the latter conformer is the major one, whereas the *gauche* ⇌ *trans* conformational equilibrium occurs in the liquid state; however, the *gauche* conformation is more stable (the energy difference is 0.60 kcal mol<sup>–1</sup>).<sup>32</sup> The heights of the barriers to rotation about the P—C(sp<sup>3</sup>) bond in EtP(S)Cl<sub>2</sub> (2.22 kcal mol<sup>–1</sup>) and CD<sub>3</sub>CH<sub>2</sub>P(S)Cl<sub>2</sub> (2.71 kcal mol<sup>–1</sup>) estimated in the cited study are consistent with the earlier data.

*Ab initio* calculations of the rotation about the P—C(sp<sup>3</sup>) bond in carbanions stabilised by pentavalent phosphorus<sup>37</sup> demonstrated that in the presence of electronegative substituents, the rotation barriers are higher in compounds containing P=S groups, whereas in the presence of electropositive substituents, the rotation barriers are higher in compounds containing P=O groups. The results of X-ray diffraction studies and theoretical conformational analysis (*ab initio* and semiempirical calculations) of 1-alkoxyethyldiphenylphosphine oxide<sup>33</sup> are also in good agreement with each other.

A recent study of the EtPH<sub>2</sub> molecule<sup>40</sup> by *ab initio* methods using the HF, MP2, BLYP and B3LYP basis sets showed that internal rotation about the P—C(sp<sup>3</sup>) bond gives rise to the two most stable conformers when the methyl group is in *trans* and *gauche* orientations relative to the lone electron pair of the P<sup>III</sup> atom. The optimised structural parameters agree well with the data obtained by microwave spectroscopy. The results of gas electron diffraction and various *ab initio* calculations for bis(trichlorosilyl)-*tert*-butylphosphine are also in satisfactory agreement with each other,<sup>42</sup> although the structure is distorted and the environment of the silicon and carbon atoms deviates from the ideal tetrahedral coordination. The vibrational frequencies of methylphosphine CH<sub>3</sub>PH<sub>2</sub> and its deuterated derivatives were calculated using the Gaussian 98 program (HF, MP2 and DFT/B3LYP/6-311G\*\*), and the results compared with IR spectroscopic data.<sup>44</sup>

Theoretical conformational analysis of a wide range of typical (from the point of view of competition between Coulombic and steric interactions) substituted phosphine oxides R<sup>1</sup>R<sup>2</sup>P(O)CH<sub>2</sub>X (R<sup>1</sup> = R<sup>2</sup> = Me, Et, Pr<sup>i</sup>, Bu<sup>t</sup>, Ph; X = Me, CN, Ph, Cl) was carried out by the semiempirical PM3 method.<sup>45,46</sup> This method adequately reproduced the structural characteristics determined by gas electron diffraction and X-ray diffraction analysis for trialkylphosphine oxides. The corresponding sulfides, selenides and tellurides<sup>47</sup> also demonstrated satisfactory agreement with spectroscopic data. For the phosphine oxides under consideration, calculations adequately interpreted the abundant experimental data (dipole moments, Kerr constants, vibrational spectra of compounds in different aggregation states and solvents at different temperatures) and predicted a noncontradictory set of stable conformations. In particular, the population of the conformation with P=O and C—X bonds in a *trans* orientation was found to decrease as the volumes of the substituents at the phosphorus atom and the methylene group increased.

Data on dialkyl and alkylaryl derivatives R<sup>1</sup>R<sup>2</sup>P(O)CH<sub>2</sub>X containing the above-mentioned substituents retrieved from the Cambridge Structural Database are scarce. Nevertheless, it was noted<sup>45,46</sup> that the conformations of P<sup>IV</sup>—C(sp<sup>3</sup>) with the C—X bond in the *gauche* orientation with respect to the phosphoryl P=O group and the X—C—P—O angles varying from 30° to 60° are statistically most probable taking into account the known crystal structures. The histograms of the torsion angles in phosphine oxides containing the CP(Ph)(O)CH<sub>2</sub>X fragment (Fig. 1) show that, in the crystalline compounds, the orientation of the plane of the arene ring relative to the P=O bond (characterised by the τ<sub>2</sub> angle) is close to an eclipsed conformation. According to the results of gas electron diffraction, an analogous situation is observed for mono- and diaryl-substituted phosphine oxides in the gas phase.<sup>48</sup>

Experimental (X-ray diffraction study, IR spectroscopy, dipole moments) and theoretical (PM3) conformational analysis of the bis(methoxycarbonylmethyl)phenylphosphine oxide molecule PhP(O)(CH<sub>2</sub>CO<sub>2</sub>Me)<sub>2</sub> demonstrated that the synclinal (*gauche*) orientation of the substituents relative to the P—C(sp<sup>3</sup>) and C(sp<sup>3</sup>)—C(sp<sup>2</sup>) bonds prevails in both the crystal and solution states.<sup>49</sup> *Ab initio* calculations (HF, DFT, MP2) of the molecular geometry of related phosphonates (RO)<sub>2</sub>P(O)CH<sub>2</sub>C(O)X, where X = Me, EtS, Ph or Et<sub>2</sub>N, also predicted the staggered *gauche* orientation of the CH<sub>2</sub>—P bond relative to the carbonyl group.<sup>50</sup>

**Figure 1.** Histograms of the torsion angles in phosphine oxide molecules containing the CP(Ar)(O)CH<sub>2</sub>X fragment; the data were retrieved from the Cambridge Structural Database; (a) is the OPCX angle ( $\tau_1$ ), (b) is the ArPO ( $\tau_2$ ) angle (see the text).

As mentioned above, a comparison of the calculated data with the experimental results (IR, microwave and Raman spectroscopy, gas electron diffraction, X-ray diffraction analysis, dipole moments) of conformational analysis for a wide range of OPCs containing one P<sup>III</sup>–C bond,<sup>51–59</sup> one P<sup>IV</sup>–C bond,<sup>60–68</sup> two P<sup>IV</sup>–C bonds<sup>69</sup> or three P<sup>IV</sup>–C bonds<sup>70,71</sup> led to the conclusion that these compounds adopt staggered *gauche* and *trans* conformations regardless of the valence state of the phosphorus atom, the number of internal rotation axes and the aggregation state. For example, *ab initio* calculations for the EtPCl<sub>2</sub> molecule (HF/6-31G\*\*) predicted the classical *gauche* conformation with a torsion angle  $\varphi = 60^\circ$ ; the *trans* conformation being 2.09 kcal mol<sup>-1</sup> less stable. In molecules of other compounds, the *gauche* or *trans* conformation can be stabilised in accordance with the steric and electronic effects of their substituents.

In recent years, interesting conformational analysis results were obtained for OPCs containing the bulky fullerene substituent.<sup>72–77</sup> In the study,<sup>77</sup> the electronic and spatial structure of a new fullerene derivative, phosphorylated methanofullerene C<sub>60</sub>C(CO<sub>2</sub>Me)[P(O)(OMe)<sub>2</sub>], was calculated by density functional theory (DFT/PBE/TZ2P) using the exchange-correlation Perdew–Burke–Ernzerhof (PBE) functional<sup>78</sup> and the three-exponent basis set including two polarisation functions (TZ2P) implemented in the PRIRODA program.<sup>79</sup> The calculations demonstrated that the most stable conformations of phosphorylated methanofullerene are characterised by the Coulombic interaction between the phosphoryl oxygen atom and one carbon atom of fullerene and by polarisation of this fragment, resulting in asymmetry of the bond lengths and atomic charges in the C<sub>60</sub> cluster. The C–C bond lengths in the cisoid polyene fragments

<sup>a</sup> –*ac* is (–)-antichiral, *ac* is (+)-antichiral, *sp* is synperiplanar. <sup>b</sup>  $E$  in the DFT/PBE/TZ2P method,  $\Delta H$  in the PM3 method.

adjacent to the *exo*-coordinated C–C bond of the fullerene cage were found to alternate and the differences in the bond lengths decreased with increasing distance from the *exo*-coordinated carbon atoms. The internal rotation of the P(O)(OMe)<sub>2</sub> group about the C<sub>60</sub>C–P bond leads to the three most stable conformations (Table 3), two of which are antichiral (–*ac* and *ac*) with C–C–P = O torsion angles of  $-144^\circ$  and  $148^\circ$ , respectively. These conformations are more stable ( $\Delta E = 0$  and 0.74 kcal mol<sup>-1</sup>).<sup>8</sup> In the third, less stable, synperiplanar (*sp*) conformation ( $\Delta E = 2.06$  kcal mol<sup>-1</sup>), the orientation of the C–C and P–O bonds corresponds to a distorted (toward the *cis* orientation) *gauche* conformation (the C–C–P = O torsion angle is  $23^\circ$ ).

The theoretical study<sup>75</sup> of internal rotation about the P–C bonds in C<sub>60</sub>C[P(O)(OMe)<sub>2</sub>]<sub>2</sub> virtually reproduced the situation observed in the previous study<sup>77</sup> for phosphorus-containing fullerene C<sub>60</sub>C(CO<sub>2</sub>Me)[P(O)(OMe)<sub>2</sub>]. In this case, two antichiral conformations were also found to be most stable, whereas the third most stable conformation was the *gauche* form distorted toward the *cis* orientation (the C–C–P = O torsion angle is  $23^\circ$ ) (Fig. 2). The difference in the results<sup>75</sup> obtained by the DFT/PBE/TZ2P and PM3 methods is attributable to the fact that the stabilising through-space interaction between the phosphoryl group and the C<sub>60</sub> cage, which is reproduced at the DFT/PBE/TZ2P level of theory, is weakly pronounced in calculations by the semiempirical PM3 method. For the MeP(O)(OMe)<sub>2</sub> compound, the *gg* and –*g*–*g* conformers are equivalent, whereas the *ac* and –*ac* (*gg* and –*g*–*g*) conformers of the C<sub>60</sub>C(CO<sub>2</sub>Me). [P(O)(OMe)<sub>2</sub>] molecule differ substantially in energy due to the asymmetrically oriented CO<sub>2</sub>Me group. In the stable conformations of the C<sub>60</sub>CPhY<sup>76</sup> and C<sub>60</sub>CY<sub>2</sub> compounds<sup>75</sup> and the C<sub>60</sub>(CY)<sub>2</sub> bis-adducts,<sup>74</sup> where Y = P(O)(OR)<sub>2</sub>, an additional

**Figure 2.** Stable conformations of phosphorylated methanofullerene C<sub>60</sub>C[P(O)(OMe)<sub>2</sub>]<sub>2</sub> calculated by the DFT/PBE/TZ2P method.<sup>75</sup>

§ Hereafter,  $\Delta E$  is the energy difference between the molecular conformation under consideration and the most stable conformer.

intramolecular coordination of the phosphoryl group to the fullerene cage is observed.

As mentioned above, analogous favourable conformations are also typical of other OPCs. Therefore, the addition of even such a bulky substituent as the fullerene fragment to the phosphorus atom has only a slight effect on the relative stabilities of different conformations of these compounds. For rotation about the P–C(sp<sup>3</sup>) bonds, staggered (or slightly distorted) conformations remain energetically most favourable for a wide range of compounds.

## 2. Internal rotation about the P–C(sp<sup>2</sup>)(alkene) bond

Most organophosphorus compounds containing a bond between the P atom and alkene fragments are liquids with high boiling points. Hence, methods providing information on their molecular structures in solution are of particular importance. Experimental conformational analysis of OPCs with the P–C(sp<sup>2</sup>)(alkene) bond has been carried out by gas electron diffraction, the Kerr effect method, the dipole moment method, vibrational spectroscopy and NMR spectroscopy. In solutions and in the gas phase, favourable conformations of vinylphosphonic acid dichloride CH<sub>2</sub>=CH–P(O)Cl<sub>2</sub>, divinylphosphinic acid dichloride (CH<sub>2</sub>=CH)<sub>2</sub>–P(O)Cl and vinylphosphonic acid difluoride CH<sub>2</sub>=CH–P(O)F<sub>2</sub> are those which contain C=C and P=O bonds in the *s-cis* orientation or similar conformations, in which these bonds are virtually coplanar.<sup>5</sup> The cisoid structure of the CH<sub>2</sub>=CH–P(O)XY fragment is attributable to steric repulsions between the substituents at the P<sup>IV</sup> atom and the methylene group, not involving electron conjugation. In contrast, the *s-trans* conformation is observed in styrenephosphonic acid difluoride PhCH<sub>2</sub>=CH–P(O)F<sub>2</sub>. Apparently, there is conjugation in this compound due to which the *trans* conformation becomes the most favourable.<sup>5</sup>

In more recent experimental studies,<sup>80–87</sup> the energetically favourable conformations of P<sup>III</sup> derivatives were found to contain the alkene fragments in the *cis* orientation with respect to the lone electron pair of the phosphorus atom. In these systems, the *trans* conformation can be present as the minor component. In  $\alpha$ -cyanostyrenephosphonates,  $\alpha$ - and  $\beta$ -substituted vinylphosphonates and other derivatives of alkenylphosphonic acids (results obtained by the dipole moment method, IR and NMR spectroscopy using lanthanide-shift reagents), the favourability of either *s-cis* or *s-trans* conformations is controlled by electrostatic factors. In all cases, structures with interacting dipoles in an antiparallel orientation are more stable.<sup>5</sup>

Semiempirical calculations (CNDO/2) for the CH<sub>2</sub>=CH–P(O)Cl<sub>2</sub> molecule<sup>88</sup> demonstrated that the dependence of the total energy of this compound on the angle between the O–P<sup>IV</sup>–C and P<sup>IV</sup>–C–C planes has a deep minimum corresponding to the *s-cis* conformation ( $\varphi = 0^\circ$ ) and a shallow minimum at  $\varphi = 180^\circ$  (*s-trans* conformation). In polar solvents, the *s-trans* conformation may become more stable, whereas the molecule adopts the *s-cis* conformation in the gas phase. More recent *ab initio* calculations for phosphorylated ethylenes CH<sub>2</sub>=CH–P(O)Cl<sub>2</sub>, CH<sub>2</sub>=CH–P(S)Cl<sub>2</sub>, CH<sub>2</sub>=CH–P(O)F<sub>2</sub>, CH<sub>2</sub>=CH–P(O)FMe, CH<sub>2</sub>=CH–P(O)Me<sub>2</sub> and CH<sub>2</sub>=CH–PCl<sub>2</sub> using the 4-31G basis set<sup>89,90</sup> confirmed the earlier conclusion that the *s-cis* conformation is favourable for these compounds. This conformation is also supported by the calculated dependences of the total energy (Fig. 3) and the parameters of the regression relation between the experimental and calculated ionisation potentials (IP) on the angle of internal rotation about the P–C bond. By contrast, calculations for dichlorovinylphosphonate and vinylphosphonic acid using the 6-31G\* basis set<sup>91</sup> and for some other derivatives of phosphonic acids (vinyl-, propenyl-, bromoalkenyl- and cyanoalkenylphosphonic acids and their diethyl esters) using the STO-3G basis set<sup>92</sup> gave two minima on the potential energy surface corresponding to the *s-cis* conformation, a distorted *s-trans-gauche* conformation

**Figure 3.** Dependence of the energies of the CH<sub>2</sub>=CHPCl<sub>2</sub> (1) and CH<sub>2</sub>=CHP(O)Cl (2) molecules on the torsion angle about the P–C bond.<sup>90</sup>

and two transition states with low barriers to rotation about the P–C(sp<sup>2</sup>) bond.

In the study,<sup>92</sup> the P=O bond in these compounds was demonstrated to be polarised and characterised by weak  $\pi$ -conjugation between the C=C and P=O groups. In the cited study, alkenylphosphonic acid derivatives were investigated by UV, IR, Raman and NMR (<sup>1</sup>H, <sup>31</sup>P, <sup>13</sup>C) spectroscopy, and it was concluded that the conformational equilibria were shifted toward the *s-cis* conformation [from 87% in the CH<sub>2</sub>=CH–P(O)(OH)<sub>2</sub> molecule to 99% in the MeCH=CH–P(O)Cl<sub>2</sub> molecule]. A distorted *s-trans-gauche* conformation was considered as the second most probable conformer. The energy difference between the conformers varied from 0.22 kcal mol<sup>–1</sup> in the *E* isomer of NC–CH=CH–P(O)(OMe)<sub>2</sub> to 2.81 kcal mol<sup>–1</sup> in the MeCH=CH–P(O)Cl<sub>2</sub> molecule.

The results of *ab initio* calculations for the CH<sub>2</sub>=CHPH<sub>2</sub>,<sup>88</sup> CH<sub>2</sub>=CHPF<sub>2</sub> (see Ref. 93) and CH<sub>2</sub>=CHPCl<sub>2</sub> molecules<sup>91,93</sup> are in complete agreement with experiment<sup>94</sup> (rotational spectra, the molecular constants and the dipole moment of vinylphosphine CH<sub>2</sub>=CHPH<sub>2</sub>) and indicate that these compounds adopt *s-cis* conformations. In these conformations, the lone electron pair of the phosphorus atom is parallel to the plane of the  $\pi$  system, hindering conjugation between these fragments. In the studies,<sup>91,93</sup> the form containing eclipsed C=C and P–Cl bonds was found as the minor conformation.

According to orbital models of donor-acceptor interactions (Fig. 4), the favourable conformation of vinyl derivatives of P<sup>III</sup> is determined by competition between the n(P)– $\pi^*(\text{PX}_2)$  and  $\pi(\text{C}=\text{C})$ – $\pi^*(\text{PX}_2)$  interactions. The former interaction stabilises the conjugated *gauche* conformation, whereas the latter stabilises the *cis* and *trans* conformations. In molecules containing electron-withdrawing substituents X at the P atom, the  $\pi(\text{C}=\text{C})$ – $\pi^*(\text{PX}_2)$  donor-acceptor interaction plays the major role, stabilises the *cis* conformation and is responsible for the  $\pi$ -acceptor character of the PX<sub>2</sub> fragment.<sup>93,95–97</sup>

A comparison of the vertical ionisation potentials of the EtPCl<sub>2</sub> [IP<sub>n(P)</sub> = 9.70, IP<sub>n(Cl)</sub> = 11.57 eV] and CH<sub>2</sub>=CHPCl<sub>2</sub> [IP<sub>n(P)</sub> = 9.84, IP <sub>$\pi(\text{C}=\text{C})$</sub>  = 10.86 and IP<sub>n(Cl)</sub> = 11.53 eV] molecules, which were determined from the photoelectron spectra,<sup>95</sup> also provides evidence that dichlorovinylphosphine adopts predominantly the *s-cis* conformation, in which there is no conjugation between the lone electron pair of the P atom and the  $\pi$  system of the C=C bond. In the electron-conjugated *s-trans* conformation, the first ionisation potential would be expected to decrease due to mixing of the n and  $\pi$  orbitals; however, an opposite situation is observed. Interestingly, theoretical conformational analysis of the related CH<sub>2</sub>=CHXMe molecules (X = O, S or Se) by *ab initio* methods including correlation energy at the MP2/

**Figure 4.** The key orbitals of dichlorovinylphosphine and their interactions in the *cis* conformation.<sup>95</sup> The calculated energies (eV) are given.

6-31G\* and MP2/6-311G\*\* levels of theory,<sup>98</sup> also predicted the *s-cis* conformation as the major one, characterised by a deep minimum in the energy curve.

The results of modern *ab initio* calculations (DFT/B3LYP/6-311++G\*\*) for the molecules  $\text{CH}_2=\text{CHP}(\text{O})\text{Cl}_2$  and  $\text{CH}_2=\text{CHP}(\text{O})\text{F}_2$  are virtually identical to the results of gas electron diffraction.<sup>88,93,99</sup> The calculations demonstrated that the *s-cis* conformation, in which the phosphoryl group eclipses the vinyl group, is stable at room temperature. It should be noted that the *gauche* rather than *s-trans* conformation (which was evident from the experimental data) was proposed<sup>99</sup> as the second possible form in the conformational equilibrium.

The mechanisms of electron conjugation between the vinyl and  $\text{PCl}_2$  fragments were considered in a study,<sup>90</sup> where the photoelectron spectra of phosphorylated ethylenes  $\text{Cl}_2\text{PCH}=\text{CH}_2$ ,  $\text{Cl}_2\text{P}(\text{O})\text{CH}=\text{CH}_2$  and  $\text{Cl}_2\text{P}(\text{S})\text{CH}=\text{CH}_2$  were analysed and *ab initio* calculations using the 4-31G basis set were carried out (see above). It was concluded that the *cis* and *trans* conformations of these compounds are stabilised by the  $\pi(\text{C}=\text{C})-\pi^*(\text{PCl}_2)$  and  $\pi^*(\text{C}=\text{C})-\pi(\text{PCl}_2)$  interactions involving the  $\pi$  system of the  $\text{C}=\text{C}$  double bond and the pseudo- $\pi$  orbitals of the  $\text{PCl}_2$  fragment. As a result of this interaction, the energies of the  $\pi$  and  $\pi^*$  orbitals of the vinyl fragment, unlike the energy of the  $\pi(\text{PCl}_2)$  orbital, depend only slightly on the angle of internal rotation about the  $\text{P}-\text{C}$  bond.

In another study,<sup>100</sup> the photoelectron spectroscopic data were compared with the results of calculations for phosphorylated allenes and ethylenes ( $\text{Me}_2\text{N})_2\text{P}(\text{O})\text{CH}=\text{C}=\text{CH}_2$ ,  $\text{Cl}_2\text{P}(\text{O})\text{CH}=\text{C}=\text{CH}_2$ ,  $\text{Cl}_2\text{P}(\text{O})\text{CH}=\text{C}=\text{CMe}_2$ ,  $(\text{MeO})_2\text{P}(\text{O})\text{CH}=\text{C}=\text{CH}_2$ ,  $(\text{MeO})_2\text{P}(\text{O})\text{CH}=\text{C}=\text{CMe}_2$ ,  $\text{Me}_2\text{P}(\text{O})\text{CH}=\text{C}=\text{CMe}_2$ ,  $\text{Cl}_2\text{P}(\text{O})\text{CH}=\text{CH}_2$  and  $\text{Cl}_2\text{P}(\text{S})\text{CH}=\text{CH}_2$ , which were performed using the 3G, 3G\*, 4-31G and 4-31G\* basis sets. It was demonstrated that at least the 4-31G split-valence basis set is required to achieve the proportionality of the calculated orbital energies  $\epsilon_m$  to the experimental ionisation potentials  $\text{IP}_m$  in phosphorylated allenes and alkenes. An increase in the energy of the  $\pi(\text{C}=\text{C})$  orbital in the molecules under consideration, compared to the energy of the same orbital in the ethylene molecule, is associated predominantly with the inductive effect of the  $\text{P}(\text{O})\text{Cl}_2$  and  $\text{P}(\text{S})\text{Cl}_2$  groups.

In polyfunctional alka-1,3-diene-2-phosphonates, coplanarity and consequently conjugation in the alka-1,3-diene fragment are disrupted.<sup>101</sup> This is evident from both experimental studies (IR and  $^1\text{H}$  and  $^{31}\text{P}$  NMR spectroscopy) of these compounds and semiempirical CNDO/2 calculations. The energetically most favourable conformation was found to correspond to rotation about the central  $\text{C}-\text{C}$  bond in the 1,3-diene fragment of the

chain by a torsion angle of  $\varphi = 75^\circ$  (in fact, the *gauche* conformation). Hence, alkadienephosphonates containing a branched carbon skeleton should be considered as molecules with two isolated fragments, *viz.*, the chlorovinyl and vinylphosphonate groups. By contrast, 3-chlorobuta-1,3-dienephosphonates are electron-conjugated systems.

Experimental and theoretical conformational analysis of 2-phosphorus-substituted acrylonitriles by various methods (X-ray diffraction analysis, IR spectroscopy, dipole moments, quantum-chemical calculations) provides a detailed and non-

<sup>a</sup> In  $\text{kcal mol}^{-1}$ .

contradictory description of their structures in the individual state and solution.<sup>102</sup> Calculations using B3LYP/6-31G(d) hybrid density functional theory justified the favourability of the *Z-s-cis* arrangement of the hydroxy and diphenylenephosphine oxide substituents relative to the C=C bond in the molecules under consideration, the conformation being stabilised by intramolecular hydrogen bonding. Table 4 gives the relative energies and polarities of the possible conformers of  $\alpha$ -cyano- $\beta$ -furyl- $\beta$ -hydroxyvinylidiphenylphosphine oxide. Analysis of the relative energies of the geometric isomers provides unambiguous evidence that the *Z* configuration is favourable; the conformers with the C=C bond in the *s-cis* orientation with respect to the P=O (or P=S) bond correspond to the global energy minimum.

Quantum-chemical calculations of the polarities were carried out for phosphorus-containing acrylonitriles<sup>102</sup> (EtO)<sub>2</sub>P(O).C(CN)=C(OH)(2-Fu), Me(EtO)P(O)C(CN)=C(OH)(2-Fu), Ph<sub>2</sub>P(O)C(CN)=C(OH)(2-Fu) (where 2-Fu is the 2-furyl substituent) and also for Ph<sub>2</sub>P(O)C(CN)=C(OH)Me and Ph<sub>2</sub>P(S)C(CN)=C(OH)Me in benzene as the solvent used to determine the dipole moments of these compounds. In these calculations, the influence of the solvent was taken into account using the isodensity polarised continuum model (IPCM).<sup>103</sup> The calculated dipole moments do not differ significantly from their values in the gas phase and are in good agreement with the experimental values measured in solution. These results along with the spectroscopic data indicate that there are no strong interactions between the above compounds and benzene.

### 3. Internal rotation about the P—C(sp<sup>2</sup>)(carbonyl) bond

Data on rotations about the P—C(sp<sup>2</sup>)(carbonyl) bond are scarce in the literature. Experimental data on the structures of acylphosphine oxides and the corresponding phosphonates and aroylphosphines (dipole moments, <sup>13</sup>C NMR spectra) are indicative of a virtually ananameric equilibrium (*i.e.*, an equilibrium, in which one conformer is predominant) between the *s-cis* and *s-trans* conformations, the percentage of the latter form being as high as 90%–95%.<sup>5</sup> For other OPCs containing a P—C(sp<sup>2</sup>)(carbonyl) bond (triacylphosphines), *ab initio* and semiempirical calculations of the barriers to rotation about the P—C bond give similar estimates (~5 kcal mol<sup>-1</sup>).<sup>104</sup> The authors of the cited study believed that semiempirical calculations (CNDO/2) of the barriers to pyramidal inversion of the P<sup>III</sup> atom in these compounds gave a more reasonable estimate (14.4 kcal mol<sup>-1</sup>) than *ab initio* calculations with the minimum STO 3G basis set (28.9 kcal mol<sup>-1</sup>).

### 4. Internal rotation about the P—C(sp<sup>2</sup>)(phenyl) bond

The conformational state of OPCs containing P—Ph bonds have received the most attention. A review<sup>5</sup> has summarised considerable experimental data on the conformations of these compounds obtained by the above-mentioned physical methods. Simultaneously, researchers examined the possibility of conjugation between unsaturated fragments at the phosphorus atom and the lone electron pair of P<sup>III</sup>(3+) atoms or the P=Y bond (Y = O, S) of P<sup>IV</sup>(5+) compounds (the formal oxidation states of phosphorus are given in parentheses). Since questions about the relative orientations of the benzene ring and lone electron pair of the P atom, and of the benzene ring and P=Y bond are interrelated, they are generally considered simultaneously.

The structure of phenylphosphine PhPH<sub>2</sub> was studied<sup>105</sup> by gas electron diffraction and quantum chemistry (*ab initio* HF/6-31G\* and B3LYP/6-31G\* calculations). Calculations at the HF/6-31G\* level of theory predicted the bisecting conformation (**B**) for the PhPH<sub>2</sub> molecule characterised by the LEP—P—C—C torsion angle  $\varphi = 0^\circ$ , whereas calculations at the B3LYP/6-31G\* level predicted the skewed conformation (**C**) with the asymmetrically arranged phenyl substituent and angle  $\varphi = 20^\circ$ . Electron diffraction data were interpreted using the results of calculations by the HF/6-31G\* method, and some geometric parameters of the molecule were taken from the quantum-chemical data.

The results of numerous studies of phenylphosphine and its derivatives PhPXY by photoelectron spectroscopy using the data from semiempirical calculations were summarised in a monograph.<sup>106</sup> Photoelectron spectroscopy demonstrated that the lone electron pair of the phosphorus atom in the PhPCl<sub>2</sub> molecule lies in the plane of the phenyl group, *i.e.*, it is orthogonal to the orbitals of the benzene  $\pi$  system. Due to the absence of the  $n-\pi$  interaction, the photoelectron spectrum showed no splitting of the  $\pi$  levels of the arene fragment. However, this splitting was observed in the photoelectron spectrum of PhPH<sub>2</sub>, indicative of a considerable contribution of conformation **A**. It should be noted that if the spectra were interpreted in terms of the free internal rotation model about the P—C bond instead of the model of discrete conformers (which is conventionally used in the conformational analysis of OPCs), the theoretical spectrum and band splitting would also be consistent with experimental data.

By contrast, calculations using the Hartree–Fock method (HF/6-31G\*, HF/6-31G\*\* and HF/6-311G\*\*) for the PhPH<sub>2</sub> molecule gave the total energy minimum for the bisecting conformation **B** and the saddle point for structure **A** (the rotation barriers are 1.25, 1.06 and 1.06 kcal mol<sup>-1</sup>, respectively). Calculations including correlation energy at the B3LYP/6-31G\* and DFT/PBE/TZ2P levels of theory predicted the skewed structures **C** with  $\varphi$  angles of 20° and 45°, respectively, as the favourable conformations. Structures **A** and **B** correspond to saddle points on the potential energy surface with imaginary frequencies of 82 and 73 cm<sup>-1</sup>, respectively. The barriers to internal rotation are low and similar in height (~0.2 kcal mol<sup>-1</sup>). On the whole, aromatic derivatives of elements of row three of the Periodic Table (such as PhPH<sub>2</sub> or PhSH) are characterised by low barriers to internal rotation and high conformational flexibility. It is this factor that accounts in part for the contradictory experimental data.

In the above-cited review,<sup>7</sup> intramolecular electronic interactions in tri- and tetracoordinate phosphorus compounds were analysed on the basis of available structural data, and an example of the forced coplanar orientation of the lone electron pair of the P atom and the  $\pi$  orbitals of the phenyl group was given. In compounds containing 1,3,2-dioxaphosphine (Y = O) or 1,3,2-dithiaphosphine (Y = S) rings, strong 1,3-*syn*-axial interactions between the H atoms at positions 4 and 6 of the heterocycle and the *ortho*-H atoms of the axial phenyl group are responsible for the rotation of the arene ring by an angle of 90° with respect to the symmetry plane of the molecule in which the lone electron pair of the P atom lies. In this conformation,  $n,\pi$  conjugation is theoretically possible, but weak.

A systematic consideration of the steric and electronic characteristics of bonds involving P<sup>III</sup> and P<sup>IV</sup> demonstrated that specific orbital interactions between the arene fragment and the low-lying unoccupied  $\pi^*$  and  $\sigma^*$  orbitals of the bonds with phosphorus are of great importance. In a study,<sup>7</sup> an appropriate classification, in our opinion, of the structural features of OPCs was proposed in the context of the perturbation theory. The nature of the orbital effects discussed in this study is closely related to the conformational characteristics of the interacting orbitals. For example,  $n,\sigma^*$  hyperconjugation plays the major role in the case of a *trans* orientation of the lone electron pair and

polarised  $\sigma$  bond, the acceptor properties of which are most pronounced in the presence of destabilising n,n repulsion between the lone electron pairs of the adjacent heteroatoms involved ( $\alpha$  effect). In the case of a parallel orientation of the  $\pi$  orbitals of the benzene ring and pseudo- $\pi^*$  orbitals of the  $PX_2$  fragment, the n, $\sigma^*$  interaction in arylphosphines  $ArPX_2$  plays the major role and stabilises the bisecting conformation. The same structural features are observed in molecules containing P—O—Ar fragments.

A recent study<sup>107</sup> of the molecular structure of triphenylphosphine by gas electron diffraction and *ab initio* calculations at the HF/6-31G\* level of theory demonstrated that the  $Ph_3P$  molecule has  $C_3$  symmetry with a torsion angle  $\varphi$  of 32(3)°. The structure of the diphenylphosphine molecule  $Ph_2PH$  determined by gas electron diffraction and *ab initio* calculations at the same level of theory<sup>108</sup> is asymmetrical, the torsion angles at the P—C bonds being 65(7)° and 154(7)°.

It should be noted that the favourable structural factors are necessary but insufficient to account for the occurrence of p, $\pi$  interactions alone. Apparently, the assumption of the presence of these interactions with the  $P^{III}$  atoms in OPCs should be considered with caution taking into account the reasons stated in the debated papers<sup>109–111</sup> and analysis of this problem in the reviews.<sup>5,7</sup> In particular, the authors of the study<sup>112</sup> reasoned that UV spectroscopy is sometimes unsuitable for the detection of p, $\pi$  conjugation. Nevertheless, several examples<sup>7,113</sup> show that, in favourable molecular conformations, this conjugation can be revealed by quantum-chemical methods.

For example, *ab initio* calculations<sup>113</sup> at the HF/6-31G(d,p) level of theory of the geometry and electronic structures of triphenylphosphine, phenylphosphabicyclo[3.3.1]nonane and the [4.2.1]-isomer of the latter demonstrated that steric repulsion of the bicyclononane fragment causes the phenyl substituent at phosphorus to be located perpendicular to the lone electron pair (Fig. 5). This orientation is favourable for n, $\pi$  conjugation, which, in the authors' opinion, is responsible for high catalytic activity of both of the phosphorus-containing bicyclononanes. The sterically unhindered  $PhPH_2$  and  $Me_2PPh$  molecules do not adopt this conformation and, correspondingly, their catalytic activity is low.<sup>113</sup> The calculated geometric parameters of the molecules agree well with X-ray diffraction data.

**Figure 5.** Stable conformations of phenylphosphabicyclo[3.3.1]nonane (a) and phenylphosphabicyclo[4.2.1]nonane (b).<sup>113</sup>

Semiempirical calculations,<sup>114</sup> where the angle of rotation of the  $PX_2$  group relative to the plane of the benzene ring was varied, also predicted the bisecting conformation as being the major one for the  $PhPF_2$ ,  $PhPCl_2$  and  $PhP(CN)_2$  molecules. However, the authors of this study suggested that there is an equilibrium between two of the conformations of  $PhPH_2$  and  $PhPMe_2$ , and an n, $\pi$  interaction can occur in one of these.

In an earlier study,<sup>115</sup> theoretical conformational analysis of the  $R_2PPh$  ( $R = H, F, Cl, Br, I, Me, Et, Pr^i, Bu^t$ ) and  $MeXPPh$  ( $X = H, F, Cl, Br$ ) molecules by the atom–atom potential method revealed flat minima in all conformational energy curves corresponding to the bisecting conformer. This provides evidence that the orientation of the Ph groups can be varied about the bisecting  $R_2P$  (or  $MePX$ ) plane within  $\pm 20^\circ$ , even in the case of di-*tert*-butylphenylphosphine. Therefore, the conformations of the above phenylphosphines do not rule out an insignificant p, $\pi$  interaction in these systems. Nevertheless, the conformations of aryl-substi-

tuted OPCs favourable for p, $\pi$  interactions (and, correspondingly, for the manifestation of these interactions in the spectra and properties) in this class of compounds are exceptions to this rule.

Semiempirical (CNDO/2, INDO, MINDO/3) calculations for the structures of diphenyl- and triphenylphosphines predicted the conformations that are unfavourable for conjugation between the lone electron pair of the phosphorus atom and the  $\pi$  system of the benzene ring.<sup>116</sup> Analysis of the results of semiempirical quantum-chemical calculations and spectroscopic characteristics (UV, IR, Raman) of *p*-carboxyphenyl-substituted dialkylphosphines and dialkylamines *p*- $HOOCC_6H_4EME_2$  ( $E = P, N$ ) showed that in the orthogonal conformation, the p, $\pi$  conjugation with the Ph fragment for a  $Me_2P$  group is half as strong as that observed for a  $Me_2N$  group, and, if the conformational equilibrium is not considered, this conjugation is weaker by a factor of 3–4.<sup>117</sup> Semiempirical (MNDO) and *ab initio* (HF, MP2) calculations for the  $RPCL_2$  ( $R = Me, ClCH_2, CF_3, CCl_3$ ) and  $ArPCL_2$  molecules and investigations of these compounds by  $^{35}Cl$  NQR spectroscopy led the authors of the study<sup>118</sup> to conclude that enhancement of steric interactions between the R and Cl substituents (the  $PCl_2$  group) and between the Ar and Cl at the  $P^{III}$  atom results in an increase in the s character of the lone electron pair of the chlorine atom. In a recent study,<sup>119</sup> the influence of the substituents on the structure of aromatic phosphines was investigated by the *ab initio* [MP2/6-311++G(U)B3LYP/6-31G(d)] method, and the P—X bond dissociation energies of *para*- and *meta*-substituted phenylphosphines *p*- $YC_6H_4PHX$  and *m*- $YC_6H_4PHX$  ( $X = H, F, Cl; Y = H, Me, NH_2, NMe_2, OMe, OH, SMe, etc.$ ) were evaluated.

Cyano derivatives of tri- and tetracoordinate phosphorus with one or two Ph substituents [ $PhP(CN)_2$ ,  $Ph_2PCN$ ,  $Ph(Et)PCN$ ,  $Ph_2P(O)CN$ ] were studied by the Kerr effect and dipole moment methods. These studies revealed structures in which the planes of the benzene rings virtually eclipse the lone electron pair of the phosphorus atom [ $PhP(CN)_2$ ,  $\varphi = 70^\circ$ ] or the phosphoryl group [ $Ph_2P(O)CN$ ,  $\varphi = 60^\circ$ ]. This excludes the possibility of efficient overlapping of the lone electron pair of the P atom with the  $\pi$  system of the benzene ring.<sup>120</sup> Therefore, it was experimentally demonstrated that the introduction of a strongly electron-withdrawing and small nitrile group directly at the phosphorus atom had no effect on the conformational behaviour of the phenyl fragments at the  $P^{III}$  and  $P^{IV}$  atoms and is not manifested in intramolecular electronic interactions involving these atoms. More recent<sup>121</sup> semiempirical (PM3) and *ab initio* (RHF/6-31G\*\*) calculations for the above-mentioned molecules also provided evidence that nearly-bisecting conformations are energetically favourable (Fig. 6).

The possibility of conjugation between the  $\pi$ -electron system and the lone electron pairs of  $P^{III}$  and  $P^{IV}$  atoms was actively discussed in the 1970s and 1980s. More recent studies did not confirm the initial assumption (which was made by many researchers) that trivalent phosphorus compounds, like nitrogen compounds, should be stabilised by p, $\pi$  conjugation. Tsvetkov and Kabachnik<sup>122</sup> analysed considerable experimental data and concluded that this conjugation in arylphosphines was inhibited. Later on,<sup>123</sup> dimethylphenylphosphine was studied by gas electron diffraction and IR and Raman spectroscopy. The authors of the cited study assumed the presence (along with that of an orthogonal conformer) of up to 30% of a conformer in which the mutual arrangement of the Ph group and the lone electron pair

**Figure 6.** Newman projections of the stable conformers of dicyanophenylphosphine (a) and cyanodiphenylphosphine (b).<sup>121</sup>

of the  $P^{III}$  atom was favourable for conjugation. It was noted that the energy difference between these conformers was as small as  $0.40\text{--}0.63\text{ kcal mol}^{-1}$ , and the shape of the internal rotation potential was determined primarily by steric interactions. Compared to these interactions,  $p,\pi$  conjugation is substantially weaker, if existent at all. The same conclusion was reached in a study<sup>124</sup> based on the results of IR, X-ray fluorescence and Raman spectroscopy. Therefore, the following conclusion can be drawn from all the available data: both experimental methods and calculations demonstrate that conformations favourable for most  $P^{III}$  compounds containing one aryl substituent are those in which the aromatic ring is coplanar with the lone electron pair of the phosphorus atom, hindering  $p,\pi$  conjugation.

In monoaryl derivatives of  $P^{IV}(5+)$ , the arene ring is coplanar with the  $P=O$  and  $P=S$  bonds, which is favourable for its conjugation to the phosphorus-containing group. In contrast, steric interactions play a decisive role in diaryl- and triaryl-containing OPCs (regardless of the valence state of the phosphorus atom) and the least hindered conformations become favourable. This is evident from both experimental data and the results of *ab initio* calculations. Recall that calculations by the atom–atom potential method performed by Baranov, Dashevskii, Medved' and Kabachnik more than 20 years ago<sup>125, 126</sup> predicted, on the whole, the same conformational pattern.

Without discussing the role of d orbitals in the formation of bonds involving phosphorus in detail, we shall give several examples. Estimations of the contribution of d-orbital interactions in the  $Ph_2P(Y)C_6H_4OH-o$  molecules ( $Y = O, S$  or  $Se$ ) by semiempirical methods (CNDO/2, CNDO/C)<sup>127</sup> showed that the  $d(P) \leftarrow s,p(O,S,Se)$  charge transfers calculated from the overlap populations of phosphorus, sulfur and selenium AOs are substantially larger than the  $s,p(P) \rightarrow d(S,Se)$  back bonding. The occurrence of strong electronic interactions between the PY groups and aromatic fragments in these molecules was also confirmed by CNDO/C calculations of the electronic spectra of these compounds. However, in an earlier study,<sup>128</sup> where the electronic structures of selected OPCs containing phosphoryl groups were analysed by similar methods (CNDO/2 and INDO) and these data were compared with the results of *ab initio* calculations, it was inferred that the d orbitals played a negligible role in binding. Therefore, estimations of the contribution of d-AOs of P atoms to OPC bond systems by semiempirical methods often give contradictory results.

## 5. Internal rotation about P–O and P–S bonds

Experimental studies<sup>5, 129–152</sup> have demonstrated that internal rotation about P–O, P–S and P–Se single bonds in tri- and tetracoordinate phosphorus compounds (scarce data) is, in principle, similar to internal rotation about  $P-C(sp^3)$  bonds. However, there are substantial differences in their conformational behaviour due to anomeric  $n-\sigma^*$  interactions between the lone pairs of the heteroatoms (O, S, Se) and the antibonding orbitals of the adjacent P–X bonds involving the phosphorus atom.

By the mid-1980s, semiempirical quantum-chemical calculations had been carried out for a series of OPCs containing P–O and P–S bonds. A few publications on *ab initio* calculations were also reported (these studies are considered in other reviews<sup>5, 7</sup>). In most cases, the staggered *gauche* or *trans* conformations are favourable for acyclic OPCs regardless of the coordination of the phosphorus atom ( $P^{III}$  or  $P^{IV}$ ), the nature of the heteroatom bound to phosphorus and the number of internal rotation axes.<sup>5</sup> In the case of internal rotation about exocyclic P–X bonds ( $X = O, S, Se$ ), the staggered conformations of 1,3,2-dioxaphosphorinanes are also more stable, regardless of the nature of the heteroatom adjacent to the phosphorus.<sup>5, 27</sup> In solutions of 1,3,2-dioxaphospholanes, the general characteristic features are responsible for a *cis* orientation of irregular (*i.e.*, those having additional degrees of freedom associated with their own internal rotation) exocyclic substituents with respect to the lone electron pair of phosphorus atom or the  $P=O$  and  $P=S$  bonds.<sup>5</sup>

Exceptions to these rules are attributable to additional intramolecular interactions (hydrogen bonds, high dipole moments at the adjacent atoms, *etc.*).<sup>5</sup> In one review,<sup>153</sup> it was noted that  $P^{III}$  derivatives are characterised by stabilisation of one conformer, whereas an equilibrium between several rotamers is often observed for  $P^{IV}$  compounds. The differences in conformations of the molecules in the gas phase, liquid state (solution) and in crystals can be associated with crystal packing forces. In most examples, the conformation observed in crystal form is also present as one of the components of the conformational equilibrium in the liquid state and solution. However, this is not always the case, and the major conformers in solution can differ from the molecular conformation found in crystals.

### a. Molecules with one internal rotation axis

Semiempirical quantum-chemical methods predict that the staggered *gauche* and (or) *trans* conformations of  $MeOPF_2$  and  $MeOPCl_2$  molecules are favourable,<sup>154–156</sup> which is in agreement with the gas electron diffraction data and dipole moment measurements. The geometric parameters of difluoromethoxyphosphine calculated by *ab initio* methods<sup>157</sup> agree well with the corresponding experimental parameters. Semiempirical calculations (CNDO/2) for thio derivatives of trivalent phosphorus acids, such as  $Cl_2PSMe$ ,  $Et_2PSMe$ ,  $MeP(SMe)_2$  and  $P(SET)_3$ , revealed a conformational equilibrium between the staggered synclinal and antiperiplanar conformations resulting from rotation about the P–S bond.<sup>156, 158</sup> This is consistent with the experimental dipole moment and Kerr constant data as well as with the vibrational spectra of these compounds.<sup>5</sup>

At least four staggered *gauche* and *trans* conformations were found for dichloropropyl and dichloroisopropyl thiophosphites  $Pr^n-S-PCl_2$  and  $Pr^i-S-PCl_2$  by Raman spectroscopy and quantum-chemical calculations.<sup>159</sup> In this case, as in the case of rotation about the  $P-C(sp^3)$  bonds (see Section II.1), only one conformer with the lone pair of the P atom in the *trans* orientation with respect to the C–S bond is present in crystals, whereas in the liquid state and solution, rotation about the P–S, S–C and C–C bonds leads to dynamic equilibrium between synclinal and antiperiplanar conformations. It was also noted that variation in length and branching of the alkyl substituent at sulfur in a series of thiophosphites  $RS-PCl_2$  ( $R$  is alkyl) does not lead to a qualitative change in barriers to internal rotation about the P–S bond, *i.e.*, the conformation with a *trans*-R–S bond relative to the lone pair of the P atom remains energetically favourable for all members of the series.

Several studies have been devoted to *ab initio* calculations of the structures of fluorophosphinates  $R'(F)P(O)OR$ , where  $R = Me, Pr^i, CH(Me)Bu^i$ , cyclo- $C_6H_{11}$  and  $R' = Me, Et$ .<sup>160, 161</sup> Calculations at all the levels of theory used in these studies [RHF/6-31G(d), MP2/6-31G(d), B3LYP/6-31(d), 3-21G\*] revealed one stable staggered conformer in which the O–C(R) bond is perpendicular to the P–F bond due to the anomeric effect. Figure 7 shows the potential energy curve for internal rotation about the P–O(R) bond in these molecules. The  $^{31}P$  and  $^{13}C$  NMR spectra of  $Me(F)P(O)OMe$  are also indicative of the occurrence of one stable conformer.<sup>160</sup> (In the cited study, the earlier interpretation of electron diffraction data was corrected.)

It should be noted that *ab initio* calculations of the molecular structures of methyl hypophosphite  $H_2P(O)OMe$ , dimethyl phosphite  $HP(O)(OMe)_2$  and trimethyl phosphite using different basis sets (STO-3G\*, 3-21G\* and 4-31G\*) gave different results.<sup>162</sup> The relative energies of stable conformers resulting from internal rotation about the P–O bond and the changes in the dipole moments of the methyl hypophosphite and dimethyl phosphite molecules depending on the  $O=P-O-Me$  torsion angle were calculated using the STO-3G\* basis set. These calculations showed that there was a conformational equilibrium between two forms, with the *cis* conformation predominating. Calculations using alternative basis sets predicted that the *trans* conformation was more stable. It was noted that the energy difference

**Figure 7.** The curve of the potential energy of rotation about the P–O bond (directed perpendicular to the plane of the page) for the MeOP(O)FMe compound.<sup>160</sup>

The geometric parameters were fully optimised at the B3LYP/6-31G\* level of theory, except for the C–P–O–C torsion angle.

$\Delta E$  between the conformers was insignificant ( $0.08 \text{ kcal mol}^{-1}$  for methyl hypophosphite and dimethyl phosphite and  $0.9 \text{ kcal mol}^{-1}$  for trimethyl phosphite). *Ab initio* calculations (RHF/6-31G\*) for the MeOP(CN)<sub>2</sub> and MeP(O)(CN)<sub>2</sub> molecules, which were carried out<sup>163</sup> to study the tautomeric and conformational stability of these compounds, revealed a deep minimum for the *trans* configuration of Me–O–P–LEP in dicyanomethoxyphosphine (Fig. 8). In contrast, three minima corresponding to the staggered *gauche* and *trans* conformations of dicyanomethylphosphine oxide are observed in the potential curve.

Analogous results were obtained for dicyanomethoxyphosphine in the study,<sup>121</sup> where the *trans*-Me–O–P–LEP structure was demonstrated to be the favourable conformation with the lowest energy, regardless of the method used for calculation (PM3, RHF/6-31G\*\*). This conclusion is in complete agreement

**Figure 8.** Potential curves of the internal rotation about the P–O bond and barriers to transition for the MeOP(CN)<sub>2</sub> and MeOP(NC)<sub>2</sub> molecules calculated by the MP2/6-31G\* method.

The potential barriers calculated at the RHF/6-31G\* level<sup>164</sup> are given in parentheses.

with experimental data<sup>165</sup> and with the results of other *ab initio* calculations,<sup>164</sup> including electron correlation (MP2 = FULL/6-31G\*). In the latter case, a deep minimum was found in the potential curve of internal rotation, corresponding to the *trans* arrangement of the MeO group with respect to the lone pair of the P atom.

It should be emphasised that the *trans* conformer appeared to be favourable for MeOP(CN)<sub>2</sub> regardless of the quantum-chemical method used [PM3 and 6-31G\*\*,<sup>121</sup> 6-31G\* and MP2 = FULL/6-31G\* (see Ref. 164)]. Stabilisation of the *trans* conformation of this compound is, apparently, associated with two factors acting in the same direction, *viz.*, Coulombic attraction between the oppositely directed P → CN and Me → O dipoles and the *gauche* effect. Apparently, due to the presence of the polar P–CN fragment with a large charge separation, interactions between the polar bonds play a major role in the stabilisation of conformations. The staggered *gauche* and *trans* conformations also result from rotation about the P–O bonds in phosphonite (MeO)<sub>2</sub>PCN and phosphonate (MeO)<sub>2</sub>P(O)CN.<sup>121</sup> Therefore, in some cases the favourable conformations with respect to the P–O bond can be transferred to related OPC molecules containing two or three identical internal rotation axes.

Somewhat unexpected results were obtained<sup>166</sup> in *ab initio* calculations of the molecular structure, conformational stability, vibrational frequencies and intensities of the absorption bands in the IR and Raman spectra of methyl dimethylphosphinite Me<sub>2</sub>POMe. Internal rotation about the P–O bond gives rise to two favourable conformers with the lone electron pair of the P atom in ‘nearly *cis*’ and ‘nearly *trans*’ orientations relative to the methyl group, the *cisoid* structure being more stable by more than  $1.5 \text{ kcal mol}^{-1}$ . Similar results were obtained in photoelectron spectroscopy and semiempirical quantum-chemical calculations (MNDO and INDO) for the Me<sub>2</sub>P–XMe compounds, where X = S or Se (and their arsenic analogues).<sup>167</sup> For these compounds, intermediate conformations with the  $\varphi$  angle varying between 0° and 180° rather than the ideal *cis* or *trans* conformations are stabilised. A study of the molecular structures of Me<sub>2</sub>PSMe and Ph<sub>2</sub>PSet by photoelectron spectroscopy in combination with quantum chemistry (CNDO/2 and *ab initio* calculations using various basis sets from 3G to 6-31G)<sup>168</sup> also led the authors to conclude that dimethyl methylthiophosphinite adopts a distorted (toward *cis*) *gauche* conformation with a torsion angle of 32°.

Semiempirical calculations demonstrated that methyl di(thio-methyl) phosphonite MeP(SMe)<sub>2</sub> with two internal rotation axes also adopts an ‘intermediate’ favourable conformation, in which the Me–P–S–Me torsion angles have similar values (17° and 14°).<sup>168</sup> If the photoelectron spectrum of this compound is modelled by an equilibrium between two conformations, the *gt* conformation with torsion angles of –45° and 180°, should be included. This is in complete agreement with the results of calculations using the HF/6-31G\*\* and DFT methods at the B3LYP/6-31G\*\* and PBE/TZ2P levels of theory (Table 5). The conformational equilibrium of phenyl di(thioethyl) phosphonite, which also has two internal rotation axes about the P–S bond, always includes the *g*<sub>1</sub>*g*<sub>2</sub> conformation, in agreement with the earlier experimental data.<sup>168</sup>

The existence of distorted conformations of OPCs in the case of a flat potential energy curve for the internal rotation about the P–O bond was demonstrated in principle by semiempirical quantum-chemical calculations performed by Gorenstein *et al.*<sup>169</sup> in the 1970s.

*Ab initio* calculations for the methyl phosphinate Me<sub>2</sub>P(O)OMe, dimethyl phosphite HP(O)(OMe)<sub>2</sub> and dimethyl phosphonates MeP(O)(OMe)<sub>2</sub>, (MeO)<sub>2</sub>P(O)CH<sub>2</sub>OH and (MeO)<sub>2</sub>P(O)CH(OH)CMe<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub> (HF/6-31G\*\*, B3LYP/6-31G\* and DFT/PBE/TZ2P), performed by one of the authors of this review, showed that, regardless of the number of P–O bonds (one or two) in these compounds and the basis set used in calculations, *gauche* (one internal rotation axis) or *gauche,gauche*

**Table 5.** Relative energies ( $\Delta E/\text{kcal mol}^{-1}$ ) of the stable conformers of the  $\text{P}(\text{OMe})_3$ ,  $\text{Me}_2\text{PSMe}$ ,  $\text{MeP}(\text{SMe})_2$  and  $\text{P}(\text{SMe})_3$  molecules (HF/6-31G\*\* and DFT methods at the B3LYP/6-31G\*\* and PBE/TZ2P levels of theory).<sup>a</sup>

<sup>a</sup> V V Zverev, unpublished data.

(two internal rotation axes) conformations are the most favourable rotamers. These conformations are characterised by energy minima in the potential curves, in complete agreement with the experimental data.

In contrast, *ab initio* HF/6-31G\*\* calculations<sup>170</sup> and calculations including electron correlation (see Tables 1 and 2) for phosphorus acids  $\text{H}_2\text{POH}$ ,  $\text{H}_2\text{P}(\text{O})\text{OH}$  and  $\text{H}_2\text{P}(\text{S})\text{OH}$  led to three different situations. The eclipsed *cis* and *trans* conformations were found for  $\text{H}_2\text{POH}$ , the staggered *gauche* and *trans* conformations were revealed for  $\text{H}_2\text{P}(\text{O})\text{SH}$ , whereas the energy difference between the *cis* and *gauche* conformations of  $\text{H}_2\text{P}(\text{S})\text{OH}$  is negligibly small. In the vicinity of *cis*–*gauche* conformations, the potential energy surface resembles a plateau. Unlike the neutral  $\text{H}_2\text{POH}$  molecule, the most favourable conformation of the radical cation of this compound is *gauche*. The inclusion of the solvent effect in calculations using the SCRf HF/6-31G\*\* method was demonstrated to lead to the elongation of the  $\text{P}=\text{O}$  bond and slight changes in the geometric parameters.<sup>170</sup> The calculated energies of the rearrangement of the molecule and solvation shell upon ionisation are slightly higher than the experimental values.

An analysis of normal vibrations in the IR and Raman spectra of phosphorodichloridates  $\text{R}(\text{CH}_2)_2\text{O}-\text{PCl}_2$  ( $\text{R} = \text{Et}, \text{OMe}, \text{Cl}, \text{SCN}$ ) and molecular mechanics calculations<sup>171–173</sup> demonstrated that the *anti* (*trans*) and *gauche* conformers with respect to the  $\text{P}-\text{O}$  and  $\text{C}-\text{O}$  bonds are favourable for alkoxy groups. The energy differences between these conformations are small (0.9  $\text{kcal mol}^{-1}$  for the  $\text{P}-\text{O}$  bond and 0.8  $\text{kcal mol}^{-1}$  for the  $\text{C}-\text{O}$  bond). In the liquid state, *gauche* conformations are favourable. At low temperatures, for  $\text{R} = \text{Cl}$ , these conformations are frozen out and the *trans* conformer becomes the most stable. In the liquid state, all compounds are characterised by a conformational equilibrium between the *gauche* conformation (A) and ‘bent’ conformation (B). In various studies,<sup>171–173</sup> it has been suggested that there is an additional intramolecular interaction between the phosphorus and oxygen (sulfur, chlorine) atoms in the latter conformer.

## b. Molecules with two and three internal rotation axes

Semiempirical [MNDO and CNDO/2(s,p,d)] calculations of dialkyl phosphites  $(\text{RO})_2\text{P}(\text{O})\text{H}$  ( $\text{R} = \text{Me}, \text{Et}, \text{Pr}, \text{Bu}, \text{C}_5\text{H}_{11}, \text{C}_6\text{H}_{13}$ ) substantiated the fact that the staggered *gauche* and *trans* conformations are energetically favourable, regardless of the method used.<sup>174</sup> Interestingly, a very small energy difference between the major conformer and the second most energetically favourable conformer (0.06 eV) was obtained in all approximations. An analogous conclusion about stability of the staggered *gauche*, *gauche* (*gg*) and *trans*, *gauche* (*tg*) conformations was drawn in an earlier experimental study of dimethyl phosphite and its deuterated analogue.<sup>175</sup> These conformations were evident from vibrational spectra measured at different temperatures, in different aggregation states and in solvents of different polarity and concentration, and were supported by force constant calculations.

Similar results were obtained by semiempirical calculations for trialkyl phosphate molecules<sup>176, 177</sup> (an equilibrium mixture of  $\text{C}_3$  and  $\text{C}_1$  rotamers). The conformational equilibrium was also evident from photoelectron spectra. In the cited study, a new assignment of the bands in the spectra was made and the ionisation potentials were refined. In continuation of these studies, the first five ionisation potentials were determined by mathematical processing, and the conformational inhomogeneity of samples was found to influence the photoelectron spectra of trimethyl and triethyl phosphates.<sup>178</sup> In the spectra of more complex phosphates, the contributions of different conformers became indistinguishable because of overlapping of the bands corresponding to the  $n_\sigma$  and  $\sigma$  orbitals of similar energies.

The conformational equilibrium between rotamers of trimethyl phosphate with  $\text{C}_3$ ,  $\text{C}_1$  and  $\text{C}_s$  symmetry corresponding to three minima on the potential energy surface (PES) was found in the study<sup>179</sup> with the use of *ab initio* methods (6-31G\* and 6-31G\*\* basis sets). The energy of the conformer with  $\text{C}_1$  symmetry is higher than that with  $\text{C}_3$  symmetry by 0.56  $\text{kcal mol}^{-1}$ , and the energy of the  $\text{C}_s$  conformer is higher than that of the  $\text{C}_3$  conformer by 1.43  $\text{kcal mol}^{-1}$ . The study of triethyl phosphate<sup>180</sup> by the semiempirical AM1 method and IR spectroscopy revealed two conformers with  $\text{C}_1$  symmetry.

Theoretical conformational analysis was carried out for a wide range of tetravalent phosphorus compounds containing one, two or three  $\text{P}-\text{O}$  rotation axes:  $\text{H}_2\text{P}(\text{O})\text{OH}$ ,  $\text{HP}(\text{O})(\text{OH})_2$ ,  $(\text{HO})_3\text{PO}$ ,  $\text{MeP}(\text{O})(\text{OH})_2$ ,  $\text{HP}(\text{O})(\text{OMe})_2$ ,  $\text{Me}_2\text{P}(\text{O})\text{OMe}$ ,  $\text{Me}_3\text{P}(\text{O})$ ,  $\text{MeP}(\text{O})(\text{OMe})_2$  and  $(\text{MeO})_3\text{PO}$ .<sup>181, 182</sup> In the study,<sup>181</sup> the authors used the molecular mechanics method (MM3) and parameters chosen from the results of *ab initio* calculations of the conformations of several phosphates (HF/6-31G\*\*). Figure 9 shows the plots of the relative energies of dimethyl phosphinate and trimethyl phosphate vs. the angle of rotation about the  $\text{P}-\text{O}$  bond. The *gauche* and *trans* conformations appeared to be favourable for these esters, whereas the *cis* conformation was favourable for dimethylphosphinic acid.

The possibility of  $\text{P}^{\text{IV}}$  acids adopting eclipsed conformations was also discussed above. It should be noted that the *cis* conformation of dimethylphosphinic acid and analogous compounds was found only in calculations by the Hartree–Fock method, whereas calculations by the MP2, MP4 and DFT methods using the correlation energy density functional predicted that the lowest energy corresponds to the staggered *gauche* structures, and the saddle point on the potential energy surface corresponds to the *cis* conformation (see Table 2). The parametrisation of the MM3 force field on the basis of *ab initio* calculations at the RHF/6-31G\* level of theory includes all the errors of the latter method. Here we are dealing with the relative energies of the conformations rather

**Figure 9.** Rotation profiles [HF/6-31G\*\* (1) and MM3 parameterised from the results of HF/6-31G\*\* calculations (2)] for the O=P–O–Me fragment in methyl dimethylphosphinate (a) and trimethyl phosphate (b).<sup>181</sup>

than with a considerable deformation of the overall calculated potential surface.

*Ab initio* MP2/6-31 + G\* and MP2/6-31G\* calculations for the methyl phosphinate, dimethyl phosphonate, trimethyl phosphate and hypophosphorous, phosphorous and phosphoric acids revealed<sup>182</sup> the global minimum in the energy curve for R–O–P=O torsion angles of 35–58° corresponding to the *gauche* conformation (in some cases, the conformation is slightly distorted towards the *cis* conformation). Analogous results were obtained for P<sup>IV</sup> compounds at other levels of theory (see Tables 2 and 6). Phosphorous and phosphoric acids are characterised by the presence of a second minimum at 180° (a *trans* conformation). The barrier to rotation about the P–O bond was estimated at 5 kcal mol<sup>–1</sup>. Calculations using the molecular mechanics method including interactions of the lone electron pairs for dialkyl phosphites (RO)<sub>2</sub>P(O)H demonstrated that these molecules can adopt at least two stable conformations of similar energy,<sup>184</sup> one of which is the above-mentioned *gauche* conformation distorted toward the *cis* conformation.

Conformational analysis of dimethyl phosphite in aqueous solution by the DFT method<sup>185</sup> demonstrated that solvent reorganisation plays an important role in the conformational

equilibrium between the *gauche,gauche* and *gauche,trans* conformations favourable for these compounds. In these calculations, the solvent was taken into account by the isodensity polarised continuum model (IPCM). Conformational analysis of this compound in the pure liquid state (dielectric permeability  $\epsilon = 34.3$ ) and in carbon tetrachloride by the *ab initio* self-consistent reaction field (SCRf) method with a fixed cavity, in which the solute is embedded, at the HF/6-31G\*\* level of theory, also showed that solvent reorganisation plays an important role in the equilibrium between the above-mentioned conformations (Table 6). The molar fractions of the conformers of dimethyl phosphite in polar solvents calculated by the SCRf method are equal to their empirical values and account for the kinetic data of this compound's homolytic reactions.<sup>183</sup>

The results of theoretical studies of the conformations of the HP(O)(OMe)<sub>2</sub> molecule by the Hartree–Fock method were compared with the results obtained using density functional theory (see Table 6).<sup>77,183</sup>

Calculations of the conformations of HP(O)(OMe)<sub>2</sub>, MeP(O)(OMe)<sub>2</sub> and C<sub>60</sub>C(CO<sub>2</sub>Me)[P(O)(OMe)<sub>2</sub>] using the PM3 method predicted that the –*gg* orientation of the methoxy groups relative to the P=O bond (which is directed perpendicular to the plane of the figure) corresponds to the most stable conformation.

The –*gt* and *tt* conformers are less stable, and their energies are lower than that of the –*gg* conformation by 2 and 4 kcal mol<sup>–1</sup>, respectively. However, *ab initio* calculations at HF/6-31G\* and MP2/6-31G\* levels and by the density functional theory with two different exchange-correlation functionals for HP(O)(OMe)<sub>2</sub> demonstrated that the *gg* rather than –*gg* conformation is most stable, whereas the energies of the less stable –*gt* and *gt* conformers are lower than that of the *gg* by ~2 kcal mol<sup>–1</sup>. Analogous results were obtained for MeP(O)(OMe)<sub>2</sub>. Analysis of the potential energy surfaces for the (MeO)<sub>2</sub>P(O)H and MeP(O)(OMe)<sub>2</sub> molecules showed<sup>77</sup> that the *gg* and –*gg* structures correspond to stationary points, but only one of these points is a local minimum (–*gg* according to calculations by the PM3 method and *gg* according to calculations by *ab initio* and DFT methods), whereas the second conformation is characterised by a saddle point (*gg* and –*gg* according to calculations by the PM3 and *ab initio* methods, respectively).

Semiempirical calculations (AM1, PM3) for *O,O*-di(isopropyl) isoxazolinophosphonate, in combination with the dipole moment method, demonstrated the favourability of the staggered *gauche* and *trans* conformations.<sup>186</sup> These recent results agree well with the experimental and calculated data reported in the preceding review.<sup>5</sup>

Examination of the photoelectron spectra and electronic structures of (MeO)<sub>3</sub>P, (MeO)<sub>2</sub>PNCO, MeOP(NCO)<sub>2</sub> and P(NCO)<sub>3</sub> by *ab initio* methods using the STO-3G basis set<sup>187</sup> showed an increase in the first ionisation potential corresponding to the n(P) orbital and in the second ionisation potential corre-

**Table 6.** Relative energies (kcal mol<sup>–1</sup>) and torsion angles OPOC(1) ( $\varphi_1$ ) and OPOC(2) ( $\varphi_2$ ) (deg) of different conformers of the dimethyl phosphite molecule HP(O)(OMe)<sub>2</sub> in the gas phase and in a solution with a dielectric permeability of  $\epsilon = 34.3$ .<sup>77,183</sup>

sponding to the  $n(\text{O})$  orbital, which is gradually transformed into  $\pi(\text{NCO})$  in a series from trimethyl phosphite to triisocyanatophosphine. The non-additive change in the first ionisation potential in this series of compounds, which was noted by the authors of the cited study, is attributable to the fact that the isocyanate group initially replaces the *gauche*-methoxy group on going from trimethyl phosphite to dimethyl isocyanatophosphonite and then replaces the *trans*-methoxy group on going to methyl diisocyanatophosphinite and triisocyanatophosphine. The results of *ab initio* calculations for the  $(\text{MeO})_3\text{P}$  and  $(\text{MeS})_n\text{PMe}_{3-n}$  molecules performed in this study (see Table 5) are consistent with the earlier experimental data (the Kerr effect, dipole moments, vibrational spectroscopy, gas electron diffraction).

Investigation of selenophosphate  $(\text{MeO})_3\text{P}=\text{Se}$  by the DFT method (6-311 + G\*\*) and temperature-dependent vibrational spectroscopy revealed an equilibrium between conformations<sup>188</sup> of  $C_3$  and  $C_1$  symmetry. Calculations by the DFT method with the 6-31G\* basis set for the dicharged dimethyl diphosphate anion<sup>189</sup> demonstrated that staggered conformations resulting from rotation about its P–O bonds are favourable for this anion, the synclinal (*sc*) conformation being more stable than the antiperiplanar (*ap*) conformation due to the anomeric effect.

Vibrational spectroscopy (IR and Raman) and *ab initio* calculations (HF/6-31G\*) revealed<sup>190</sup> the staggered *gauche* and *trans* conformations of the modified oligonucleotide chains  $[\text{MeOCH}_2-\text{P}(\text{O})\text{OMe}]_n$ ; the experimental results were in good agreement with theoretical data. Orbital interactions in the stable and metastable conformations of the dimethyl phosphate anion  $(\text{MeO})_2\text{P}(\text{O})\text{O}^-$  were considered, and the favourability of the staggered *gauche*, *gauche* and *trans*, *gauche* conformations was accounted for by stereoelectronic effects.<sup>191</sup> The key geometric parameters of phosphoric acid derivatives were determined by *ab initio* methods [HF/6-31G\*\*, B3LYP/6-31G(d), EDF1/6-31 + G(d), B3LYP/6-31 + G(d,p)].<sup>192, 193</sup> For the  $(\text{EtO})_2\text{P}(\text{O})\text{CH}_2\text{C}(\text{O})\text{X}$  compounds (X = Me, Ph, OEt,  $\text{NEt}_2$ , SEt), the results of the calculations were compared with experimental spectroscopic data (IR and  $^{13}\text{C}$  NMR).

Investigation of the vibrational spectra and conformations of phosphorus dithio acids by the molecular mechanics method<sup>194</sup> showed that the conformational equilibrium is shifted to the *trans* and *gauche* conformations of *O,O*-dimethyl dithiophosphate due to rotation about the P–O bonds. For *O,O*-diethyl dithiophosphate, only the *gauche* orientation of the C–O bonds (in the ethoxy substituents) relative to the P=S group was found. The

crystals of the former compound are composed of two staggered conformers, whereas the latter compound is conformationally homogeneous in the solid state.

Experimental and theoretical conformational analysis of silyl, germyl and stannyl derivatives of *O,O*-dialkyl dithiophosphates gave interesting results.<sup>195</sup> Photoelectron spectroscopy and calculations (*ab initio*, MNDO and PM3) for  $(\text{RO})_2\text{P}(\text{S})\text{S}-\text{EMe}_3$  (R = Me, Et, Pr<sup>i</sup>; E = Si, Ge, Sn) demonstrated that the *gauche* and *trans* conformations of the E–S–P=S fragments are favourable. This conclusion is consistent with the results of the earlier experimental conformational studies of acyclic derivatives of phosphorus dithio acids and *O,O*-dialkyl *S*-triethylstannyldithiophosphates (dipole moments, the Kerr effect, vibrational spectra).<sup>196–198</sup>

Therefore, semiempirical methods and most *ab initio* methods provide evidence for a threefold barrier to rotation about the P–O bond in OPCs, which is consistent with experimental data on the staggered synclinal and antiperiplanar conformations. It should be noted that this principal fact is virtually independent of the coordination state of the phosphorus atom, the number of internal rotation axes of the molecule and the nature of the substituents at the P atom. The conformational behaviour of various molecules differs primarily in the presence or absence of a conformational equilibrium between staggered conformations. For some molecules, synclinal conformations (+*sc* or –*sc*) are stabilised, whereas antiperiplanar (*ap*) conformations are stable for other molecules. In the presence of two or more internal rotation axes, the conformational equilibrium between two or several energetically favourable and least sterically hindered staggered conformers is, as a rule, observed.

Intramolecular electronic interactions in OPCs have been studied most thoroughly by theoretical methods for tri- and tetracoordinate phosphorus cyanides. The relative contributions of the interactions between the cyano group, on the one hand, and the lone electron pair of the phosphorus atom and the phosphoryl group, on the other hand, to stabilisation of the conformers of phosphorus cyanides were examined.<sup>121</sup> Unlike the  $n, \pi$  conjugation between the lone pair of the phosphorus atom and the benzene ring, this interaction in the P–C $\equiv$ N system is sterically unhindered. Figure 10 shows the correlation diagram of the energies of the frontier MOs for favourable conformations of the  $\text{MeO}-\text{P}(\text{CN})_2$  (*t*),  $\text{Ph}-\text{P}(\text{CN})_2$  (*c*),  $\text{Ph}_2\text{P}(\text{O})\text{CN}$  (–*gc*) and  $(\text{MeO})_2\text{P}(\text{O})\text{CN}$  (*g-g*) molecules and the hydrocyanic acid molecule. In the favourable *trans* conformation of  $\text{MeO}-\text{P}(\text{CN})_2$ , the

Figure 10. Correlation diagram of the HOMO energies for the stable conformations of phosphorus cyanides and HCN.<sup>121</sup>

highest occupied molecular orbital (HOMO), which is predominantly  $n(\text{P})$  in character, is additionally stabilised by the  $n(\text{P})-\sigma^*(\text{O}-\text{C})$  hyperconjugation interaction, absent in the eclipsed structure of  $\text{Ph}-\text{P}(\text{CN})_2$ . This is also evident from a decrease in the effective charge on the phosphorus atom from 1.05 in methoxydicyanophosphine to 0.79 in phenyl dicyanophosphine. Analysis of the energies and compositions of the frontier MOs showed that interactions between the  $n(\text{P})$  and  $\pi(\text{C}\equiv\text{N})$  orbitals are absent in  $\text{MeO}-\text{P}(\text{CN})_2$  and  $\text{Ph}-\text{P}(\text{CN})_2$ , and the interactions between the  $p_\pi(\text{O})$  and  $\pi(\text{C}\equiv\text{N})$  orbitals are absent in  $\text{Ph}_2\text{P}(\text{O})\text{CN}$  and  $(\text{MeO})_2\text{P}(\text{O})\text{CN}$ . In addition, all of the above-mentioned favourable conformations are characterised by a low population of  $d_{\pi^*}$ -AOs on the phosphorus atom, which indicates that there are no interactions between these orbitals and the orbitals of the substituents with suitable symmetry. Therefore, it can be concluded that interactions between the cyano group and the lone pair of the phosphorus atom, its  $d$  orbitals or the phosphoryl group make no contribution to stabilisation of the favourable conformers of phosphorus cyanides. Apparently, the nitrile group in the  $\text{P}-\text{CN}$  fragment behaves predominantly as a  $\sigma$  acceptor and does not exhibit  $\pi$ -acceptor properties.

The relationship between the conformations of OPCs and their reactivity has been studied in detail by photoelectron spectroscopy. At the Arbuzov Institute of Organic and Physical Chemistry (Kazan, Russia), the ionisation potentials of about 170 various organic uniconordinate, dicoordinate and tricoordinate phosphorus compounds (which comprise about one-half of all the data published in the literature) were determined by photoelectron spectroscopy in combination with quantum-chemical calculations.<sup>106</sup> The relationships between the ionisation potentials and the molecular structures, in particular, the bond and torsion angles, were revealed.

The ionisation potentials of the favourable and less stable conformations of selected OPCs are given in Table 7. The dependence of conformation on ionisation potential was found, and the regression relationship between the vertical ionisation potentials and the molecular orbital energies, calculated by varying the geometric parameters, was optimised:<sup>106, 168</sup>

$$\text{IP}_m = a\varepsilon_m + b,$$

where  $\varepsilon_m$  are the energies of the highest occupied orbitals.<sup>90, 97, 168, 187</sup> For the molecules under study, the conformations predicted by optimisation of the total energy of the molecule and the regression relationship were similar, but the latter approach was less sensitive to the calculation method.

In the publication,<sup>168</sup> a procedure was described for theoretical simulation of the photoelectron spectra of systems consisting of two conformers. The molecular orbital energies scaled from the experimental ionisation potentials of favourable conformers and their regression relationships can also be used to estimate the ionisation potentials of unstable conformations. The latter are not detected by photoelectron spectroscopy. However, in specific cases, these values can determine the reactivity of molecules.

## 6. Internal rotation about P–N and P–P bonds

Experimental and selected calculated data on the conformations and barriers to internal rotation about P–N bonds published before 1982 were summarised in a review.<sup>5</sup> The results of semi-empirical and *ab initio* calculations for OPCs with P–N bonds were analysed in several studies.<sup>199–207</sup> Apparently, this is in part attributable to the complexity of the systems under consideration because of internal rotation about this bond often being accompanied by a change in the configuration at the nitrogen atom. For example, it was noted<sup>208</sup> that topomerisation in aminophosphines is a complex process involving simultaneous rotation about the P–N bond and possible inversion of configuration at the N atom.

Substituents at the  $\text{N}(\text{sp}^3)$  atom increase the height of the barrier to internal rotation due to destabilising steric repulsions in its pyramidal environment. On the contrary, substituents at the P atom decrease this barrier because they induce the pyramidal

<sup>a</sup> In kcal mol<sup>–1</sup>.

<sup>b</sup>  $r$  is the correlation coefficient of the regression equation  $\text{IP} = a\varepsilon + b$ , where  $\varepsilon$  are the energies of the highest occupied molecular orbitals.

<sup>c</sup> A and B are respectively the conjugated and bisecting conformations of phenylphosphine.

configuration of the nitrogen atom. *Ab initio* calculations demonstrated<sup>208</sup> that a change in the torsion angle of the  $\text{LEP}-\text{N}-\text{P}-\text{LEP}$  fragment from 90° to 180° leads to a change in the configuration at the nitrogen atom from trigonal-planar to pyramidal with close to tetrahedral bond angles. Rotation of the amide group about the P–N bond is hindered, and the barrier height was estimated<sup>202</sup> to be approximately 6.5 kcal mol<sup>–1</sup>. The complexity of the equilibrium set of configurations results in an ambiguous interpretation of the photoelectron spectra of phosphoramidates.<sup>201</sup>

*Ab initio* calculations performed in recent years have provided an essential supplement to our knowledge about internal rotation about P–N bonds. For acid amides of Group V elements,  $\text{E}(\text{NMe}_2)_3$  ( $\text{E} = \text{As}, \text{Sb}, \text{P}$ ), a comparative study of the structures and favourable conformations was performed by electron diffraction and quantum-chemical methods.<sup>209</sup> The structural parameters are intended for use in compiling electronic databases, calculating the physicochemical properties of molecules and constructing a theory of reactivities for this class of compounds.

The use of the results of *ab initio* quantum-chemical calculations (HF/6-31G\*) and spectroscopic data for the interpretation of electron diffraction data made it possible to determine the geometric parameters and force fields for two stable rotamers of the  $\text{Me}_2\text{N}-\text{PCl}_2$  molecule: *gauche* ( $C_1$  symmetry) and *trans* ( $C_s$  symmetry).<sup>210</sup> For the energetically much more favourable *gauche* conformer, the vibrational spectra of undeuterated and completely deuterated isotopomers of  $\text{Me}_2\text{N}-\text{PCl}_2$  were reliably interpreted for the first time in the cited study. Gas electron diffraction data were analysed and the equilibrium geometric parameters of the molecules evaluated, taking into account the non-linear kinematic effect in first-order perturbation theory, which led to the conclusion that the  $\text{Me}_2\text{N}$  group has a non-planar equilibrium configuration.

In the study,<sup>211</sup> the effects of the electronic and steric factors on the structures of mono-, di- and triaminophosphines and dialkylaminophosphines were investigated by *ab initio* methods, providing evidence that the orthogonal conformation of the LEP–P–N–LEP fragment ( $\varphi = \pm 90^\circ$ ) is energetically more favourable. The *anti* conformation ( $\varphi = 180^\circ$ ) can occur as a minor structure. Tris(dimethylamino)phosphine can adopt a *syn* conformation. Therefore, the structures of the aminophosphines considered in the cited study were determined by interactions between the lone electron pairs of the phosphorus and nitrogen atoms, the hybridisation of the nitrogen atom and the steric requirements of the substituents.

It should be noted that the structure of the tris(dimethylamino)phosphine molecule has been debated for three decades and studied many times by gas electron diffraction using semiempirical and *ab initio* calculations.<sup>200, 203, 204</sup> *Ab initio* calculations revealed two stable conformations with  $C_3$  and  $C_s$  symmetry, the latter being more stable by 7 kcal mol<sup>-1</sup>. The electron diffraction study demonstrated that two of the NMe<sub>2</sub> groups in the  $C_s$  conformation are oriented so that the lone electron pairs of the nitrogen atoms [N(2) and N(3) in Fig. 11] are approximately perpendicular to the lone electron pair of the P atom, and the lone pair of the third NMe<sub>2</sub> fragment is positioned antiparallel with respect to the lone pair of the P atom. The environment of the N atom in the third fragment is essentially pyramidal (the sum of the bond angles is 337°), whereas two other nitrogen atoms have a flattened configuration (the sum of the bond angles is 353°). In the study,<sup>203</sup> it was hypothesised that the equilibrium  $C_s$ -symmetric structure is stabilised due to the anomeric effect, *i.e.*, due to overlapping of the lone electron pairs of the N(2) and N(3) atoms with the antibonding  $\sigma^*$  orbital of the P–N(1) bond (Fig. 11). The cited study has summed up the discussion and probably proposed an adequate model for this complicated conformational system.

**Figure 11.** Perspective model of the  $C_s$ -symmetric conformation of the P(NMe<sub>2</sub>)<sub>3</sub> molecule based on the results of gas electron diffraction and *ab initio* calculations.<sup>203</sup>

Data on internal rotation about P–P bonds are scarce. *Ab initio* calculations for the 1,1-difluorophosphine (H<sub>2</sub>P–PF<sub>2</sub>) molecule revealed<sup>212</sup> the existence of the staggered *trans* and *gauche* conformations, separated by a barrier of 0.9 kcal mol<sup>-1</sup>. Previously, the *trans* and *gauche* conformers of the Me<sub>2</sub>P–PMe<sub>2</sub> molecule had been detected by photoelectron spectroscopy by varying the temperature from 20 to –252 °C.<sup>213</sup>

### III. Conclusion

Modern quantum chemistry combined with the results of physicochemical methods of investigation provides a reliable theoretical basis for many general chemical features in terms of orbitals and electronic configurations.<sup>214</sup> Moreover, modern aspects of the theory, such as the structures of metastable intermediate particles, the compositions and geometries of molecular associates, the shapes of potential surfaces, *etc.*, give impetus to experimental

investigations and the development of new concepts.<sup>¶</sup> However, a search for stable conformers of molecules, analysis of their relative stabilities and examination of the shapes of their barriers to internal rotation are complicated physicochemical problems, which remain, in many respects, unresolved.

In recent years, the molecular structures of OPCs have been re-investigated more thoroughly by various experimental methods (gas electron diffraction, vibrational and photoelectron spectroscopy, the dipole moment method, *etc.*) and quantum-chemical calculations. The results of calculations using extended basis sets including correlation effects are in some respects similar to the results of high-precision experiments; they also require generalisation and explanation in terms of approximate models and theories. The main aim of each systematic conformational study is to draw generalisations which have predictive capabilities and allow one to exclude steps that give unambiguous and predictable results. An important problem is to reveal the general and specific features in the body of data and determine their place in general chemical theory.

It can be stated that experimental and theoretical results obtained by the conformational analysis of relatively simple OPCs (for example, OPCs containing one internal rotation axis) adequately describe sets of conformers resulting from internal rotation about P–C, P–O and P–S bonds. The data considered in this review demonstrate that the staggered *gauche* and *trans* conformations are favourable for OPCs, which is also true for molecules of classical organic compounds. The occurrence of eclipsed conformations is attributable to the structural features of particular molecules and these require special theoretical analysis.

The structures of more complex compounds with several internal rotation axes (particularly, if these axes belong to different atoms) cannot necessarily be unambiguously determined, even using physical methods combined with calculations. The spatial and electronic structures of polyfunctional OPCs (in which intramolecular interactions can give rise to unusual conformations) and OPCs containing P in low coordination states were poorly studied. Experimental and theoretical data on these compounds are scarce. Quantum-chemical studies of OPCs in solution are few in number. In addition to the above-considered publications on the theoretical conformational analysis of phosphorus-substituted acrylonitriles<sup>102</sup> and studies of a number of the simplest phosphorus compounds and their radical cations by *ab initio* self-consistent reaction field calculations,<sup>170</sup> several investigations also dealt with the conformational composition and reactivity of dimethyl phosphite in the gas phase and solvents of varying polarity<sup>183</sup> and with the conformational composition and spin properties of iminoxyl radicals containing the phosphine oxide substituent.<sup>216, 217</sup>

When using calculated data, it should be remembered that semiempirical quantum-chemical methods, which, on the whole, correctly reproduce the structures and conformations of organic molecules, can give large errors in their estimates of the geometric parameters and relative stabilities of OPCs. With certain exceptions, this is also true for *ab initio* calculations. In Section II.5, it was demonstrated that calculations for the H<sub>2</sub>P(O)OH molecule by the Hartree–Fock method using the rather large 6-31G\*\* basis set predicted the eclipsed *cis* conformation; however, this result is reproduced in the single-determinant approximation only for particular basis sets, whereas various modes of inclusion of electron correlation always predict a skewed conformation. On the other hand, transition structures on potential energy surfaces (saddle points with one imaginary frequency), *i.e.*, the peaks of the

<sup>¶</sup> In a recent theoretical study,<sup>215</sup> it was stated that the staggered conformation of the ethane molecule, which has been studied many times by various methods is, contrary to popular opinion, determined by superconjugation of the C–H bonds rather than by steric repulsions between hydrogen atoms.

barriers to internal rotation, generally correspond to the  $C_s$ -symmetric *cis* conformations for P–O and P–S bonds. Nevertheless, for H<sub>2</sub>POH, H<sub>2</sub>PSH and some other molecules, conformations with the eclipsed lone electron pair of the phosphorus atom are predicted at several levels of theory.

The relative stabilities of the *gauche* and *trans* conformations of the X<sub>2</sub>PCH=CH<sub>2</sub> or X<sub>2</sub>POMe molecules are, apparently, determined from competition between the  $n(\text{P})-\pi^*(\text{PX}_2)$  and  $\pi(\text{C}=\text{C})-\pi^*(\text{PX}_2)$  donor–acceptor interactions (see Fig. 4). In molecules containing electron-withdrawing PX<sub>2</sub> groups, the  $\pi(\text{C}=\text{C})-\pi^*(\text{PX}_2)$  donor–acceptor interactions stabilise the *trans* conformation. Compounds H<sub>2</sub>POH, H<sub>2</sub>PCH=CH<sub>2</sub> and H<sub>2</sub>PPh belong to an intermediate type, in which competitive interactions are of similar magnitudes and the conformers have similar energies. Calculations by the Hartree–Fock method using the 3-21G\*, 6-311G\*\* and 6-311(2d,2p) basis sets demonstrated that the *trans* conformation of these molecules is more stable, whereas calculations with the 6-31G\*, 6-31G\*\*, 6-31+G\* and 6-31+G\*\* basis sets predicted the *cis* conformation as the more stable. A further extension of the basis set up to 6-311++(3d,3p) results in a zero energy difference between the conformers. Calculations including of electron correlation at different levels of theory predict the *cis* conformation as the favourable one; however, an extension of the basis set decreases the energy difference between the *cis* and *trans* conformers.

These data suggest that investigations of the relative stabilities of conformers with similar energies and the correct treatment of eclipsed conformations requires the use of quantum-chemical methods at the maximum possible levels of theory with inclusion of electron correlations at the MP2, B3LYP or PBE level (see Tables 1, 2 and 6). However, the principal limitations of the model of discrete conformers are manifested in compounds with low barriers to internal rotation. Examples of these limitations encountered in the conformational analysis of the PhPH<sub>2</sub> molecule were considered in Section II.4.

The predictive capabilities of quantum chemistry and its role in modern conformational analysis are still debated.<sup>218</sup> In Scerri's opinion,<sup>219</sup> quantum theory often simulates and interprets (although at a very high level) experimental data (for example, spectroscopic characteristics and geometric parameters of the molecules) rather than gives predictions. At the same time, it was noted that the reliability of quantum-chemical predictions increases.<sup>218</sup> For example, a review<sup>220</sup> where the use of various versions of the Gaussian package for describing ion-molecular processes was considered, gave examples of the refinement of experimental data using the results of quantum-chemical calculations, which made it possible to reveal and eliminate errors in the measurements. The direct relationship between the quantum-chemical theory and conformational analysis of OPCs is clearly demonstrated by the evolution of views on the structure of the Cl<sub>2</sub>POMe molecule discussed in the study.<sup>221</sup> In the period from 1974 to 1994, the initial views on the *cis* conformation of this molecule were revised first in favour of the *gauche* conformer and then in favour of the *trans* conformer, which is sterically hindered but stabilised by electronic factors, according to calculated data.

On the whole, conformational analysis of organoelement compounds is in its infancy. A general system for determining the conformations of such compounds, which could allow one to reveal the characteristic features of internal rotation about any chemical bond in an arbitrary environment, so far is only qualitatively developed. For many organoelement compounds, conformational data are lacking, often for objective reasons (instability of compounds, the impossibility of preparing their solutions, etc.). However, experimental and theoretical studies are opening up new possibilities for the development of conformational analysis as a necessary step in routes to the synthesis of compounds possessing specified physical, chemical and biological properties, to explain of the reactivities of such compounds and to elucidate their reaction mechanisms.

This review has been written with the financial support of the Federal Program 'Leading Scientific Schools' (Grant NSh-750.2003.3) and the Russian Foundation for Basic Research (Project No. 03-07-90092).

**Abstract.** Some important aspects of the use of selective methods in NMR spectroscopy for interpreting the spectra of complex multicomponent systems, measuring the spin–spin coupling constants and determining the structure of compounds are discussed. Procedures for recording selective spectra and the application of selective radiofrequency pulses together with magnetic field gradient pulses are described. Practical methods for suppression of water signals in the study of biological samples are considered. The bibliography includes 198 references.

## I. Introduction

NMR spectroscopy belongs to the most efficient methods of investigation of the liquid, solid and liquid-crystalline states of matter.<sup>1</sup> Correctly interpreted NMR spectra give a clear picture of the molecular conformations, internuclear and intermolecular distances, angles and bond properties and information on the molecular dynamics. Usually, the most significant information is extracted from three main parameters of an NMR spectrum, namely, the chemical shift, spin–spin coupling constant and nuclear spin relaxation rate.<sup>2–6</sup> However, these parameters cannot always be measured immediately from the spectrum. This is due to low sensitivity of NMR spectroscopy owing to very small transition energy differences ( $\sim 10^{-6}$  eV) between nuclear energy levels and to the low natural abundance and gyromagnetic ratios of many nuclei. Often, these factors act in line with one another.

Yet another problem consists of the overlap of resonance signals, which is particularly typical of the spectra of large molecules and complex systems. As an example, let us compare resonances of two widely used nuclei, <sup>1</sup>H and <sup>13</sup>C. <sup>1</sup>H NMR spectroscopy is characterised by higher sensitivity due to both high natural abundance of the <sup>1</sup>H isotope (99.98%) and high gyromagnetic ratio [26.75 rad (s T)<sup>−1</sup>]. However, the width of the <sup>1</sup>H NMR spectrum is about 20 ppm while signals of most organic compounds are observed in an interval of around 8 ppm. <sup>13</sup>C resonances are observed in a much wider region of chemical shifts (200 ppm), signals being relatively well-resolved. However, the natural abundance of this isotope is low (1.1% of the total content of carbon isotopes) and its gyromagnetic ratio is low (0.25 of the gyromagnetic ratio of the <sup>1</sup>H isotope). Therefore, <sup>13</sup>C NMR spectroscopy is less sensitive. Using higher magnetic fields allows the sensitivity and resolution to be enhanced. However, <sup>1</sup>H NMR spectra of complex samples (*e.g.*, biological liquids and tissue extracts) remain overcrowded even at a frequency of 800 MHz,<sup>7</sup> such ultrahigh-field systems being too expensive. An alternative approach to enhancement of the sensitivity and spectral resolution is based on design of new pulse sequences for selective detection of particular signals.

At present, NMR methodology concerns not only the known and continuously revisable two-dimensional (2D) and three-dimensional (3D) pulse methods but also two more avenues. One of them is associated with the use of selective radiofrequency (RF) pulses<sup>8–10</sup> while the other employs pulsed magnetic field gradients (PFG), which improve the spectra by selecting appropriate coherent superpositions of different states of the nuclear spin system (from this point on, coherences).<sup>11–13</sup> Both methods, their advantages and drawbacks have been well documented.<sup>8–13</sup> Often, methods based on the use of selective RF pulses only are complicated by artifacts arising from long pulse durations. To suppress unwanted responses, phase cycling is needed. Experiments with selective pulses require a skilled operator; interpretation of the resulting spectrum is often unobvious and therefore the corresponding techniques are of limited use. In the case of PFG, no phase cycling is needed and the duration of experiments is

<sup>†</sup> Dedicated to Academician Vladimir Minkin on the occasion of his 70th birthday.

shortened by a factor of nearly five. The most promising approaches combine both these methods.<sup>14, 15</sup>

Combining selective RF pulses and pulsed field gradients began only recently but this gave good results.

## II. Selective pulses

The function of selective pulses<sup>8–10</sup> is to excite or invert certain resonances, either singlets or multiplets (sometimes, these can be subspectra within the same spectrum or single lines within a multiplet). The structure of organic compounds is determined using selective pulses, which allow the dimension of the problem to be reduced from 3D to 2D or from 2D to 1D in one experiment and necessary information to be obtained during a shorter time period with a rather high resolution.

Three general problems arise when using selective pulses. The first problem is associated with a rather long duration of such pulses, which is three orders of magnitude longer than the duration of non-selective ‘hard’ pulses. The selectivity obtained nearly equals the inverse pulse duration. For instance, excitation of a multiplet of spectral width 50 Hz requires a selective pulse of about ~20 ms long to be applied. Eagerness for selectivity enhancement can lead to considerable relaxation loss within the pulse sequence.

The second problem concerns the shape of the selective pulse profile. An ‘ideal pulse’ must have a rectangular envelope uniformly filled with the carrier radiofrequency. In the framework of the consecutive response theory the excitation profile can be calculated using the direct Fourier transform of the pulse shape from the frequency domain to the time domain and *vice versa*. However, the consecutive response theory is valid only for very weak excitation; therefore, the shape design of new selective pulses, which is usually performed using iterative methods, must involve an experimental stage. The most widely used shaped pulses are shown in Fig. 1. Application of a rectangular, Gaussian and sinc-type pulse creates a sinc-type, Gaussian and rectangular excitation profile, respectively.

**Figure 1.** RF pulse shapes and corresponding excitation profiles. Pulse: rectangular (a), Gaussian (b) and sinc (c); DFT stands for direct Fourier transform.

The third problem is concerned with the phase change of the selective pulse. Unfortunately, the excitation phase varies within the chosen width of a selective pulse. Therefore, excitation of a multiplet by a selective pulse can lead to a complex spectral pattern, because first-order phase correction is impossible. Pulse sequence designers mostly aim their efforts at generating short selective pulses with a constant phase and a smooth envelope within the semicircle. However, this problem has no exact solution and therefore it is necessary to find approximate solutions.

In principle, it is possible to determine the excitation profile and the phase change of the pulses employed. This requires a successive variation of the repetition frequency of a selective pulse in the frequency region of interest; however, the procedure is very time-consuming. Hwang and Shaka<sup>16</sup> reported an experiment with pulsed magnetic field gradients employed to ‘visualise’ the shape of a selective excitation pulse (Fig. 2). The pulse sequence used is inappropriate for solving structural chemical tasks; however, it exhibits many features of widely used pulse sequences. Experiments were carried out with the spin echo gradient sequence. When the selective pulse is on, a magnetic field gradient is applied to reproduce the image of the frequency distribution,

**Figure 2.** The RF pulse sequence (a) and PFG sequence (b) used for determination of the excitation profiles of 90° pulses. d1 is the relaxation delay, p1 is the selective 90° pulse, p2 is the 180° pulse, g1 and g2 are the rectangular pulse gradients and aq is the acquisition time.

which is read out during the data acquisition time, *i.e.*, during the last time interval.

The phases of the 90° Gaussian and sinc pulses change their signs, whereas the semi-Gaussian pulse has good phase characteristics and a good excitation profile for the *x*-magnetisation only. BURP<sup>15</sup> (Band-selective Uniform Response Pure-phase Pulses) type pulses are characterised by a very good phase mode. These ‘soft’ pulses are designed for refocussing the magnetisation trajectory in such a way that the natural divergence between the fast and slow components of the magnetisation vector is corrected. These pulses transfer the magnetisation to the +*y* axis in the whole range of resonance offsets, *i.e.*, shifts of the resonances from zero.

A 180° Gaussian pulse provides a good selectivity and phase mode due to the action of a REBURP (Refocused Band-selective Uniform Response Pure-phase) composite pulse. It should be noted that old spectrometers having no envelope shape storage modules can operate with modern pulses that can be programmed using the DANTE (Delays Alternating with Nutation for Tailored Excitation) sequence.<sup>17, 18</sup>

Prior to using selective pulses, the operator has to calibrate the excitation profiles. A detailed description of calibration procedures was reported by Braun *et al.*<sup>19</sup> The procedures are much like those used in the calibration of ‘hard’ pulses. The main difference is that determination of the duration of the 180° pulse only requires damping of the RF power. One should keep in mind that damping ‘operates’ in the logarithmic scale. Therefore, experiments with old instruments, which have no software for matching the initial phases of pulses within the same pulse sequence, require a check of either the phase of the selective 90° RF pulse or, at least, the phase of the 90° pulses with the phases of ‘hard’ 90° pulses at the same power. If both pulses are applied within the same pulse sequence, the difference in the corresponding phase programme must be set every time.

## III. Pulsed magnetic field gradients ‡

Selection of coherences using pulsed magnetic field gradients has been studied in detail.<sup>11–13</sup> The field gradient applied along the *z* axis causes a *z*-dependence of the resonance frequencies and thus the phase dependence of the magnetisation (Fig. 3). If the gradient

‡ The abbreviations of the NMR techniques employing pulsed magnetic field gradients are as follows: GRASP (Gradient Accelerated Spectroscopy) and ge (gradient enhanced). It is more appropriate to use the gs (gradient selection) abbreviation, which has been commonly accepted. Actually, the magnetic field gradients ‘select’ desired and ‘ignore’ undesired coherences; therefore, this term seems to be the best to reflect the essence of all the known gradient experiments.

**Figure 3.** The action of pulsed magnetic field gradient. Application of the gradient  $g_z$  causes dephasing, which is rephased by applying the gradient  $-g_z$ .

pulse has a limited intensity and duration, switching it off will be followed by precession of identical spins at their initial frequencies with the gradient-set phases. A signal detected at this stage will at best have the shape of a broadened absorption signal. Applying the second field gradient pulse of the opposite sign will result in a conventional NMR spectrum. Therefore, dephasing caused by the first gradient can be rephased by applying the second gradient, which is identical to the first one but has the opposite sign.

Practical implementation of this principle offers great prospects. Dephasing and rephasing depend on the gyromagnetic ratio and coherence orders at the instant of application of the gradient pulse; therefore, one can readily select coherences by changing their orders between the gradients set by the RF pulses. If selective RF pulses are applied between two gradients, only the coherences created by these pulses contribute to the resulting signal.

The use of magnetic field gradient pulses can be best considered using the coherence transfer diagram, which is based on the shift operators  $I^+$  and  $I^-$ . From the expression

$$I_x = \frac{1}{2}(I^+ + I^-) \quad (1)$$

it can be seen that the excitation by a  $90^\circ$  pulse can cause both a decrease and an increase in the coherence level (Fig. 4).

In performing a theoretical description it is assumed that the NMR spectrometers set the  $I^-$  level. Therefore, the RF pulses for detection using a pulse sequence must be chosen in such a way that the coherence trajectory arrives at this level. Here, the field gradient pulses must be distributed in a fashion that excludes other possible trajectories. To select the desired coherence, the following condition must be met:

$$\sum_{i=1} p_i \gamma_i g_i \geq 0, \quad (2)$$

**Figure 4.** Coherence pathway diagram for the excitation by a single RF pulse.

where  $p_i$  is the order of the  $i$ th coherence, a  $\gamma_i$  is the effective gyromagnetic coefficient, which exists during the action of  $i$ th pulse gradient  $g_i$ . All gradient pulses are assumed to have the same duration and shape.

Figure 5 presents a typical result of the gradient strength measurements using the pulse sequence shown in Fig. 6. The possibility of using the field gradient pulses depends on the degree of improvement of the spectrometer hardware.

**Figure 5.** Results of measurements of the magnetic field gradient strength in a water sample (a Teflon disk of diameter 2 mm was placed at the centre of the sample);<sup>18</sup>  $\delta_H$  is the chemical shift of protons.

**Figure 6.** The RF pulse sequence (a) and PFG sequence (b) used for determination of the magnetic field gradient strength. For notations, see Fig. 2.

#### IV. Selective methods with inverse detection

Usually, the function of selective methods is to determine the structure of organic compounds. Below we will consider only the  $^{13}\text{C}-^1\text{H}$  groups (though other groups, *e.g.*,  $\text{NH}$ ,  $\text{NH}_2$  and  $\text{NH}_3$  can also be considered). There are five main types of spin systems, namely, those of methyl ( $^{13}\text{CH}_3$ ), methylene ( $^{13}\text{CH}_2$ ) and methyne ( $^{13}\text{CH}$ ) groups, quaternary  $^{13}\text{C}$  atoms and all protons attached to  $^{12}\text{C}$ , O, N, *etc.* rather than  $^{13}\text{C}$ . The multiplicity of the  $^{13}\text{C}$  resonances depends on the number of attached protons. Because of this, particular  $^{13}\text{CH}_n$  groups are characterised by different precession rates of scalar coupling, possible highest orders of multiquantum coherences and corresponding angles and phases of RF pulses. These features are used in spectral editing for selective detection of  $^1\text{H}$  and  $^{13}\text{C}$  signals. At present, spectral editing is used in  $^{13}\text{C}$  NMR spectroscopy as a routine technique for assignment of C, CH,  $\text{CH}_2$  and  $\text{CH}_3$  signals.

Pulse methods comprise the APT (Attached Proton Test),<sup>20–23</sup> SEMUT (Subspectral Editing Using a Multiple-Quantum Trap),<sup>24,25</sup> RELAY (Relayed Correlation Spectroscopy),<sup>26,27</sup> INEPT (Insensitive Nuclei Enhanced by Polarisation Transfer),<sup>28,29</sup> DEPT (Distortionless Enhancement by Polarisation Transfer)<sup>30–32</sup> and PENDANT (Polarisation Enhancement During Attached Nucleus Testing)<sup>33</sup> techniques. An important role in spectral editing is played by various  $J$  precession effects in  $\text{CH}_n$  groups. For instance, in the INEPT

experiments the signal intensities of different  $\text{CH}_n$  groups depend on time and  $J$  precession angle, which is proportional to the number,  $n$ , of attached protons. In the case of the DEPT pulse sequence spectral editing is performed using specific angles of the coherence transfer pulses that are applied on double-quantum and zero-quantum coherences containing a total of  $n + 1$  spins.

In these methods, the magnetisation is transferred from  $^1\text{H}$  to  $^{13}\text{C}$  and theoretically the sensitivity of the  $^{13}\text{C}$  nuclei must increase by a factor of four<sup>2</sup> due to both pre-saturation of  $^1\text{H}$ -coherences<sup>21,22</sup> and the use of different pulse sequences.<sup>26–33</sup> In addition, the pulse sequences creating the transfer of  $^1\text{H}$ -polarisation are used in 2D heteronuclear correlation experiments,<sup>34</sup> in which the proton and carbon signals are in the  $F_1$  and  $F_2$  dimensions, respectively.

A large number of communications on the use of heteronuclear filtering for simplification of  $^1\text{H}$  NMR spectra has been reported in the last decade.<sup>35–50</sup> One of these methods is known as inverse detection NMR spectroscopy or NMR spectroscopy with proton detection. It is characterised by high sensitivity, because of the use of  $^1\text{H}$  nuclei with high gyromagnetic ratio for both coherence creation and detection.<sup>4</sup>

Heteronuclear single-quantum or multiquantum coherences are incorporated in the middle of most of the pulse sequences based on the INEPT and DEPT with inverse signal detection (inverse DEPT and inverse INEPT).<sup>35–37</sup>

The RELAY pulse sequence<sup>38</sup> uses two  $90^\circ$  ( $^1\text{H}$ ) pulses for selective excitation of  $^{13}\text{CH}_n$  group coherences.<sup>26,27</sup>

Using specific methods, one can easily obtain  $^1\text{H}$  NMR subspectra of  $^{13}\text{CH}_2$  ( $^{13}\text{CH}$  or  $^{13}\text{CH}_3$ ) groups only. Obtaining the spectrum of  $^{13}\text{CH}$  groups is a non-trivial task because the  $^{13}\text{CH}$  and  $^{13}\text{CH}_3$  spin systems have the same phases. A method for recording selective spectra of  $^{13}\text{CH}_n$  groups with minimum phase and intensity distortions was proposed.<sup>46</sup> It is based on the principle of Quantum Filtering of Maximum Order (MAXY).<sup>43–47</sup> In the MAXY experiments the spin systems of  $^{13}\text{CH}_n$  groups are excited to corresponding maximum possible (for a given group) order of heteronuclear multiquantum coherence (second order for  $^{13}\text{CH}$ , third order for  $^{13}\text{CH}_2$  and fourth order for  $^{13}\text{CH}_3$ ). This provides the possibility of selective observation of signals of one, two or all three groups. Selectivity can be achieved by using both phase cycling and pulsed field gradients.

## 1. DEPT and INEPT experiments

The possibility of editing the spin system in the DEPT and INEPT experiments is attained by using a corresponding angle for one pulse in the DEPT sequence or the precession angle  $\pi J\tau$  ( $J$  is the spin–spin coupling constant and  $\tau$  is the time interval between pulses) of the heteronuclear coupling in the INEPT experiments. The pulse angles ( $\psi = \beta$ , DEPT) and precession angles ( $\psi = \pi J\tau$ , INEPT) affect the signal intensities of different  $^{13}\text{CH}_n$  groups. The signal intensity depends on  $\sin(\psi)$  for  $^{13}\text{CH}$ , on  $\sin(2\psi)$  for  $^{13}\text{CH}_2$  and on  $(3/4)(\sin 3\psi + \sin \psi)$  for  $^{13}\text{CH}_3$ . Analogous principles are implemented in the DEPT and INEPT methods with inverse detection.

By specifying the delays and pulse angles and using the inverse-DEPT or inverse-INEPT sequences, a number of spectra are obtained. Then, by subtracting (adding) the spectra one gets the edited spectra of  $^{13}\text{CH}_n$  groups; however, the signal intensities become distorted (Table 1).

In the inverse-DEPT sequence (Fig. 7), the  $\beta_y$  pulse is applied to heteronuclear zero-quantum and double-quantum coherences  $2S_yI_x$  ( $^{13}\text{CH}$ ),  $4S_xI_xI_z$  ( $^{13}\text{CH}_2$ ) and  $8S_yI_xI_zI_z$  ( $^{13}\text{CH}_3$ ) and the products of the operators, which remain the same as before application of the  $\beta_y$  pulse, contribute to the signals observed.

The dependences of the signal intensities of the groups mentioned above are as follows:

for  $^{13}\text{CH}$  groups

$$2S_yI_x \xrightarrow{\beta_y} 2S_yI_x \cos \beta, \quad (3)$$

**Table 1.** Combination of NMR spectra for obtaining  $^1\text{H}$  subspectra of individual  $^{13}\text{CH}_n$  groups using the inverse DEPT sequence with the pulse angles  $\beta = 60^\circ$  (I),  $120^\circ$  (II) and  $180^\circ$  (III).<sup>35–37</sup>

| Spin system        | Signal intensity (rel.u.) |       |      | Combination                                       | Intensity ratio | Number of runs |
|--------------------|---------------------------|-------|------|---------------------------------------------------|-----------------|----------------|
|                    | I                         | II    | III  |                                                   |                 |                |
| $^{13}\text{CH}$   | 0.5                       | −0.5  | −1.0 | $0.111(\text{I}) - \text{II} - 0.555(\text{III})$ | 1.0             | 3              |
| $^{13}\text{CH}_2$ | −1.0                      | −1.0  | 2.0  | $\text{I} + \text{II}$                            | 2.0             | 2              |
| $^{13}\text{CH}_3$ | −1.875                    | 1.875 | −3.0 | $\text{I} + 0.5 \text{ III}$                      | 3.3             | 2              |

**Figure 7.** The inverse DEPT (a) and inverse INEPT (b) pulse sequences.  $I$  and  $S$  are the spins of a coupled system  $IS$ ;  $\Delta$  are the time intervals between pulses;  $\beta_y$  is the pulse applied along the  $y$  axis;  $\phi_1$  and  $\phi_2$  are the flip angles for the first and second pulse, respectively; GARP are the Globally-optimised, Alternating-phase Rectangular Pulses for Broad-band Decoupling.

Here and in Figs 9–14, 16, 18, 20–22, 24, 26 and 27 the filled and open rectangles denote the  $90^\circ$  and  $180^\circ$  pulses, respectively.

for  $^{13}\text{CH}_2$  groups

$$4S_xI_xI_z \xrightarrow{\beta_y} 4S_xI_xI_z \cos 2\beta,$$

and for  $^{13}\text{CH}_3$  groups

$$-8S_yI_xI_zI_z \xrightarrow{\beta_y} -2S_yI_xI_zI_z(3\cos 3\beta + \cos \beta).$$

When using the inverse-INEPT sequence and the spin–spin interaction Hamiltonian in the form  $\pi J_{IS}\tau(2S_yI_z)$  ( $J_{IS}$  is the spin–spin coupling constant between nuclei with the spins  $I$  and  $S$ ), intensity modulation occurs during the interval  $\tau$  in the middle of the pulse sequence. The expressions for the signals observed before and after the evolution of the system caused by the spin–spin interaction have the form:

for  $^{13}\text{CH}$

$$2S_yI_x \xrightarrow{\pi J_{IS}\tau(2S_yI_z)} 2S_yI_z \cos \psi, \quad (4)$$

**Figure 8.**  $^{13}\text{CH}$  (1),  $^{13}\text{CH}_2$  (2) and  $^{13}\text{CH}_3$  (3) signal intensities plotted vs. pulse angle  $\beta$  (inverse DEPT) (1), evolution time  $\tau$  (inverse INEPT) (2) and pulse phase  $\phi_2$  (MAXY) (3).

for  $^{13}\text{CH}_2$

$$2 S_y I_z \xrightarrow{\pi J \tau (2 S_y I_z)} 2 S_y I_z \cos 2\psi,$$

and for  $^{13}\text{CH}_3$

$$2 S_y I_x \xrightarrow{\pi J \tau (2 S_y I_x)} 2 S_y I_x \frac{1}{4} (\cos 3\psi + \cos \psi).$$

Figure 8 presents the signal intensities of different spin systems plotted vs. the relative pulse angle ( $\psi = \beta$ , inverse-DEPT), evolution time ( $\psi = \tau$ , inverse-INEPT) and pulse phase ( $\psi = \phi_2$ , MAXY). Signals of the  $^{13}\text{CH}$ ,  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  groups can be separated using the  $60^\circ$ ,  $120^\circ$  and  $180^\circ$  pulses, respectively (inverse-DEPT), or the evolution times equal to  $1/3J$ ,  $2/3J$  and  $1/J$ , respectively (inverse-INEPT).

## 2. Selective experiments based on the MAXY sequence

The MAXY sequence (Fig. 9a) includes excitation of the spin ( $^{13}\text{CH}_n$ ) systems to the maximum possible quantum order using the following pulse scheme:  $90_x^\circ(I) - \Delta - 90_x^\circ(S) 180_x^\circ(I) - \Delta - 90_x^\circ(I)$  (where  $\Delta = 1/2J$ ).<sup>46, 47</sup>

**Figure 9.** MAXY pulse sequence without (a) and with PFG (b).

Since the maximum possible quantum level of each different spin system is different, it is possible to convert all transitions, or any transition, to observable  $^1\text{H}$  single-quantum coherence. Spectral editing can be achieved by using multiple-quantum proton read pulses with different phases ( $\theta$ ) as in, e.g., the RELAY sequence<sup>26, 27</sup> or different flip angles ( $\beta$ ) as in the DEPT sequence.<sup>30, 31</sup> But it is also possible to use simply  $pmx$ - or  $\pm y$ -phases (i.e., phases associated with the positive or negative direction of the pulses along the coordinate axes) because this provides the highest signal intensity.

### a. Spectral selection using phase cycling

When using a sequence of  $90_\theta^\circ(I) - \Delta - 90_{\phi_2}^\circ(S) 180_\phi^\circ(I) - \Delta$  ( $\phi = \theta/2$ ) all multiple-quantum coherences can be converted to observable magnetisation:<sup>47</sup>

$$+ 2 I_x S_y \xrightarrow{90_\theta^\circ(I) - \Delta - 180_\phi^\circ(I) 90_{\phi_2}^\circ(S) - \Delta} I_y \cos \theta, \quad (5)$$

for  $^{13}\text{CH}_2$

$$+ 2 I_x I_y S_x \xrightarrow{90_\theta^\circ(I) - \Delta - 180_\phi^\circ(I) 90_{\phi_2}^\circ(S) - \Delta} I_y \cos 2\theta,$$

and for  $^{13}\text{CH}_3$

$$- 8 I_x I_y I_z S_y \xrightarrow{90_\theta^\circ(I) - \Delta - 180_\phi^\circ(I) 90_{\phi_2}^\circ(S) - \Delta} (1/4) I_y (3 \cos 3\theta + \cos \theta).$$

The pulse  $90^\circ(I_\theta)$  converts part of the magnetisation to zero-quantum and double-quantum coherences with intensities proportional to  $\cos n\theta$ . The expression for a  $^{13}\text{CH}_3$  group contains two terms proportional to  $\cos 3\theta$  and  $\cos \theta$  with intensity ratios of 3 : 1, respectively, and which correspond to the  $^1\text{H}$  triple-quantum coherence of  $8 I_x I_y I_z$ . The desired resonances can be selected by phase cycling the  $90^\circ(\theta)$  pulse with  $\theta = 180^\circ/n$ , where  $n$  is the number of attached protons. An advantage in this procedure is that resonances of protons not bound to  $^{13}\text{C}$  can be better suppressed by further cycling of the receiver phase. The phase cycling programmes for selection of  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  resonances via  $^1\text{H}$  double-quantum and triple-quantum coherences are listed in Table 2.

**Table 2.** Phase cycling programmes for selective observation of  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  resonances with the MAXY sequence.

| Phase    | For $^{13}\text{CH}_2$                                                           | Phase    | For $^{13}\text{CH}_3$                                                                  |
|----------|----------------------------------------------------------------------------------|----------|-----------------------------------------------------------------------------------------|
| $\phi_1$ | $0^\circ, 180^\circ$                                                             | $\phi_1$ | $0^\circ, 180^\circ$                                                                    |
| $\phi_2$ | $0^\circ, 0^\circ, 180^\circ, 180^\circ$                                         | $\phi_2$ | $0^\circ, 0^\circ, 180^\circ, 180^\circ$                                                |
| $\theta$ | $(0^\circ)_4, (90^\circ)_4, (180^\circ)_4, (270^\circ)_4$                        | $\theta$ | $(0^\circ)_4, (60^\circ)_4, (120^\circ)_4, (180^\circ)_4, (240^\circ)_4, (300^\circ)_4$ |

**Note.** The subscripts denote the numbers of cycles.

It is interesting that mathematical expressions for the observable signals for the inverse-DEPT, inverse-INEPT and MAXY sequences have the same form [see Eqns (4) and Fig. 8].

It is possible to obtain subspectra of the  $\text{CH}_3$  and  $\text{CH}_2$  groups by choosing appropriate  $\phi$  values (see Table 2). This can be done by phase cycling in the MAXY experiments because the variable is the read pulse phase ( $\theta$ ). When using inverse-DEPT and inverse-INEPT methods, the variables are the pulse flip angles and times, respectively, and the task becomes much more complicated.

**Table 3.** Combination of NMR spectra for obtaining  $^1\text{H}$  subspectra of individual  $^{13}\text{CH}_n$  groups using the MAXY sequence with the pulse angles  $\beta = 0^\circ$  (I),  $90^\circ$  (II),  $270^\circ$  (III).<sup>43–47</sup>

| Spin system        | Signal intensity (rel. u.) |    |     |          |          | Combination of spectra | Intensity ratio | Number of runs |
|--------------------|----------------------------|----|-----|----------|----------|------------------------|-----------------|----------------|
|                    | I                          | II | III | II + III | II – III |                        |                 |                |

| $^{13}\text{CH}_3$ | 0                          | 3  | 3   | 3        | 0        | II + III – I           | 3.0             | 2              |

**b. Spectral selection using a  $\beta_x(I)$  pulse**

If a  $\beta(I)$  pulse is applied along the  $x$  axis, it will convert part of the magnetisation heteronuclear zero-quantum and double-quantum coherence, which is then transferred to  $I$ -spin single-quantum coherence by the pulse following a delay  $\Delta$ . The data acquisition starts after a delay of  $\Delta$  and results in in-phase (correct) absorption lineshapes for all spins with the intensities proportional to  $\sin\beta$  (for  $^{13}\text{CH}_2$ ) or  $\sin^2\beta$  (for  $^{13}\text{CH}_3$ ); the exception is the  $^{13}\text{CH}$  group, which is not affected by the  $\beta_x(I)$  pulse:

for  $^{13}\text{CH}$

$$+ 2 I_x S_y \xrightarrow{\beta_x(I)} + 2 I_x S_y \xrightarrow{\Delta - 180^\circ_x(I) 90^\circ_x(S) - \Delta} + I_y, \quad (6)$$

for  $^{13}\text{CH}_2$

$$+ 4 I_x I_y S_x \xrightarrow{\beta_x(I)} + 4 I_x I_z S_z \sin\beta \xrightarrow{\Delta - 180^\circ_x(I) 90^\circ_x(S) - \Delta} + I_y \sin\beta,$$

for  $^{13}\text{CH}_3$

$$- 8 I_x I_y I_z S_y \xrightarrow{\beta_x(I)} - 8 I_x I_z S_z \sin^2\beta \xrightarrow{\Delta - 180^\circ_x(I) 90^\circ_x(S) - \Delta} + I_y \sin^2\beta.$$

When studying the dependence of the signal intensities on the pulse flip angle ( $\beta_x$ ), the flip angles of  $0^\circ$ ,  $180^\circ$ ,  $90^\circ$  and  $270^\circ$  are particularly interesting because at these angles the intensities reach extrema, which can be used for spectral editing. If a  $0^\circ$  or  $180^\circ$   $^1\text{H}$  read pulse is used, only  $^{13}\text{CH}$  resonances can be observed. The efficiency of suppression of  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  signals is very high, because these groups are in the multiple-quantum coherence states and all protons not bound to  $^{13}\text{C}$  will have only longitudinal magnetisation.

A  $90^\circ$  or  $270^\circ$   $^1\text{H}$  read pulse will convert the coherence of  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  groups to heteronuclear zero-quantum and double-quantum coherences and thus make it possible to get the true intensity (for  $\beta = 90^\circ$ , all signals in the spectrum are positive, whereas for  $\beta = 270^\circ$ , only  $^{13}\text{CH}_2$  signals are negative). This provides a way to edit the spectra by phase cycling, because the  $90^\circ$  and  $270^\circ$  flip angles are equivalent to a  $90^\circ$  pulse with phases of  $x$  and  $-x$  directions. As a result, if the receiver phase is shifted (subtraction of spectra), one gets the subspectrum of  $^{13}\text{CH}_2$  groups only; otherwise if the receiver phase is fixed (addition of spectra), the subspectrum of  $^{13}\text{CH}$  and  $^{13}\text{CH}_3$  groups together is observed.

**c. Spectral selection using a  $\beta_y(I)$  pulse**

Yet another method of obtaining the  $^{13}\text{CH}$  and  $^{13}\text{CH}_2$  subspectra involves the use of a  $\beta(I)$  read pulse applied only along the  $y$  axis. The effect of such a pulse is shown in Eqns (7):

for  $^{13}\text{CH}$

$$+ 2 I_x S_y \xrightarrow{\beta_y(I)} + 2 I_x S_y \xrightarrow{\Delta - 180^\circ_x(I) 90^\circ_x(S) - \Delta} + I_y \cos\beta, \quad (7)$$

for  $^{13}\text{CH}_2$

$$+ 4 I_x I_y S_x \xrightarrow{\beta_y(I)} + 4 I_x I_z S_z \sin\beta \xrightarrow{\Delta - 180^\circ_x(I) 90^\circ_x(S) - \Delta} + I_y \sin\beta,$$

for  $^{13}\text{CH}_3$

$$\begin{aligned} - 8 I_x I_y I_z S_y \xrightarrow{\beta_y(I)} - 8 I_y I_z S_z \sin\beta \xrightarrow{\Delta - 180^\circ_x(I) 90^\circ_x(S) - \Delta} \\ \longrightarrow + 8 I_y I_z S_z \sin\beta. \end{aligned}$$

Note that the coherence of  $^{13}\text{CH}_3$  groups cannot be converted to observable magnetisation by a read pulse applied along the  $y$  axis.

The intensities of  $^{13}\text{CH}$  and  $^{13}\text{CH}_2$  group resonances vary in proportion to  $\cos\beta$  and  $\sin\beta$ , respectively. Therefore, a  $90^\circ$  pulse along the  $y$  axis allows the subspectrum of the  $^{13}\text{CH}_2$  group to be selected. The editing scheme for MAXY  $^1\text{H}$  NMR spectra using spectrum addition or subtraction with  $\beta$  pulses is given in Table 3.

**d. The use of pulsed magnetic field gradients**

An advantage of the MAXY method over the inverse-DEPT and inverse-INEPT techniques is that selective detection of resonance signals can be achieved using pulsed magnetic field gradients.<sup>46–50</sup> This was shown to provide enhanced performance in many pulse sequences. In the MAXY experiments, the spin systems  $^{13}\text{CH}_n$  are excited to their highest possible quantum levels. In this case it is possible to observe subspectra of individual  $^{13}\text{CH}_n$  groups using PFG because the phase of the multiple-quantum coherence is proportional to the quantum order of the coherence. The quantum orders of all  $^{13}\text{CH}_n$  systems are the same in both the inverse-DEPT and inverse-INEPT experiments; therefore, pulsed magnetic field gradients cannot be used for selective detection. The PFG-MAXY pulse sequence is shown in Fig. 9b. Here, two pulses are used, with the first one applied during the first  $\Delta$  delay period and the second one applied immediately after the last  $90^\circ(S)$  transfer pulse, the field gradients having the values of  $g_1$  and  $g_2$ , respectively. The overall effect of the action of the PFGs can be written as follows:

for  $^{13}\text{CH}$

$$A_1 = \frac{1}{2} \cos[\pi(\gamma_H + \gamma_C)g_1\delta + \pi\gamma_H g_2\delta],$$

for  $^{13}\text{CH}_2$

$$A_2 = \frac{1}{2} \cos[\pi(2\gamma_H + \gamma_C)g_1\delta + \pi\gamma_H g_2\delta],$$

and for  $^{13}\text{CH}_3$

$$\begin{aligned} A_3 = \frac{3}{8} \cos[\pi(3\gamma_H + \gamma_C)g_1\delta + \pi\gamma_H g_2\delta] + \\ + \frac{1}{8} \cos[\pi(\gamma_H + \gamma_C)g_1\delta + \pi\gamma_H g_2\delta], \end{aligned}$$

where  $g$  and  $\delta$  are the gradient strength and duration of the PFG pulse, respectively. The first gradient pulse usually causes a phase shift proportional to the quantum order ( $n\gamma_H + \gamma_C$ ), where  $n$  is the number of attached protons in the  $^{13}\text{CH}_n$  groups. The effect of the first gradient pulse can be compensated by the second gradient pulse. By choosing an appropriate strength for the second gradient it is possible to selectively detect individual spin systems. When the same gradient shape and duration are used, the gradient strengths must be as follows:

for  $^{13}\text{CH}$

$$g_2 : g_1 = (\gamma_H + \gamma_C) : \gamma_H = -5 : 4, \quad (8)$$

for  $^{13}\text{CH}_2$

$$g_2 : g_1 = (2\gamma_H + \gamma_C) : \gamma_H = -9 : 4,$$

and for  $^{13}\text{CH}_3$

$$g_2:g_1 = (3\gamma_{\text{H}} + \gamma_{\text{C}}):\gamma_{\text{H}} = -13:4.$$

Selective detection using PFG is accompanied by a 50% decrease in signal intensity. Moreover, any molecular self-diffusion processes can cause a signal attenuation on the multiple-quantum coherence, which is proportional to the square of the quantum order.<sup>51</sup>

The application of the MAXY method can be useful in the case of complex NMR spectra, *e.g.*, those of peptides or proteins, or biological fluids and tissue extracts. A general problem in the NMR studies of such objects is the overlap of signals (often, even if a very high magnetic field strength was used). Generally, the assignment of most spectral lines requires an extensive use of 2D NMR spectroscopy methods.<sup>7</sup> As an initial stage in the line assignment procedure before carrying out time-consuming 2D NMR experiments, it is useful to determine which lines correspond to  $^{13}\text{CH}$ ,  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  groups. The NMR spectra can be essentially simplified by suppression of water signals. This approach facilitates both signal assignment and structural studies of complex molecules.

### 3. MAXY-Based selective 2D NMR methods

Two-dimensional correlation NMR spectroscopy is a modern method used for signal assignment in the NMR spectra. It is based on a general approach in which the magnetisation is transferred from one spin to another through spin–spin coupling, chemical exchange or cross-relaxation. In the case of  $^1\text{H}$ – $^1\text{H}$  correlations, especially for macromolecules, signal overlap can present a serious problem and thus limit the application of the technique. A possible solution to such problem is to use the editing capabilities of the RELAY,<sup>23,24</sup> INEPT<sup>25,26</sup> and DEPT<sup>27–29</sup> methods in the experiments on heteronuclear correlation<sup>36,41,46,48,52</sup> and homonuclear correlation.<sup>34,37–39,44–47</sup> Signal overlap can be reduced owing to multiplicity selection and enhanced resolution of the 2D NMR spectra.

2D MAXY-Based pulse sequences are shown in Fig. 10.<sup>44</sup> In the time axis, the increment time ( $t_1$ ) is placed at the centre, at the position where the  $^{13}\text{CH}_n$  spin systems are in their highest quantum states. The  $180^\circ$  ( $^{13}\text{C}$ ) pulse in the middle of the evolution period interchanges the quantum order and refocusses the  $^{13}\text{C}$  chemical shift evolution in such a way that only  $^1\text{H}$  chemical shifts have single-quantum coherence (SQ) for  $^{13}\text{CH}$ , pure double-quantum coherence (DQ) for  $^{13}\text{CH}_2$  and both triple-quantum (TQ) and single-quantum coherences for  $^{13}\text{CH}_3$  groups.

A composite  $180^\circ$  ( $^{13}\text{C}$ ) pulse can be utilised for suppression of undesired resonances in the  $^{13}\text{C}$  spectral region, especially in the case of molecules containing aromatic and aliphatic carbon atoms. Thus, at the end of period  $t_1$ , the intensities of observable signals will be proportional to:<sup>44</sup>

$$-2 I_x S_y \cos(2\pi\delta t_1) \Pi \cos(\pi J_j t_1)$$

for  $^{13}\text{CH}$ ,

$$-4 I_x I_y S_x \cos(4\pi\delta t_1) \Pi \cos(2\pi J_j t_1)$$

for  $^{13}\text{CH}_2$ , and

$$+2 I_x I_y S_y [3\cos(6\pi\delta t_1) + \cos(2\pi\delta t_1)] \Pi \cos^3(\pi J_j t_1) \text{ for } ^{13}\text{CH}_3.$$

Here  $\delta$  represents the proton chemical shifts,  $J_j$  is the  $j$ th spin–spin coupling constant and  $\Pi \cos(\pi J_j t_1)$  represents passive  $^1\text{H}$ – $^1\text{H}$  couplings evolving during  $t_1$ . It should be noted that the precession frequency of the  $^{13}\text{CH}_n$  groups is proportional to the number,  $n$ , of the attached protons. Selective detection of the subspectra of the individual  $^{13}\text{CH}_n$  groups can be achieved using the same technique as that used in the 1D experiments. Moreover, with a suitable acquisition mode, such as TPPI (Time-proportional Phase Incrementation),<sup>51</sup> it is possible to separate resonances from different  $^{13}\text{CH}_n$  groups.<sup>44</sup>

**Figure 10.** Pulse sequences based on 2D MAXY. 2D MAXY–COSY (Correlation Spectroscopy) (a), 2D MAXY–TOCSY (Total Correlation Spectroscopy) (b) and 2D MAXY–NOESY (Nuclear Overhauser Effect and Exchange Spectroscopy) (c). MLEV-16 stands for M Levitt's Composite pulse Decoupling Sequence;  $t_1$  is the increment time and  $t_m$  is the mixing time.

**Coherence separation using TPPI.** The TPPI method is widely used in phase-sensitive 2D experiments to achieve quadrature detection in the  $F_1$  dimension.<sup>51</sup> In the 2D MAXY experiments, TPPI acquisition is achieved by increasing the phase of the mixing pulses  $90^\circ\phi$  ( $^1\text{H}$ ) and  $180^\circ\phi$  ( $^1\text{H}$ ) with an increment of  $90^\circ$  and  $45^\circ$ , respectively, starting from  $0^\circ$  for the non-selective experiment. The increase in the mixing pulse phase by  $90^\circ$  shifts the phase by  $-90^\circ$  for SQ, by  $-180^\circ$  for DQ and by  $-270^\circ$  ( $+90^\circ$ ) for TQ, which is equivalent to the carrier frequency change<sup>4</sup> for the corresponding coherence. Thus, any quantum coherence can be separated and labelled by its carrier frequency or the number of protons in the  $^{13}\text{CH}_n$  groups. These changes can be seen after each phase increment (Table 4).

The  $90^\circ$  increment of the phase  $2\pi\delta t_1$  causes the functions  $\cos(2\pi\delta t_1)$  and  $\sin(2\pi\delta t_1)$  of the  $^1\text{H}$  single-quantum and triple-quantum coherences to be observed in alternating experiments with different sign cycling ( $++--$  for SQ and  $+-+ -$  for TQ) corresponding to the  $-90^\circ$  and  $+90^\circ$  phase changes. Those of homonuclear double-quantum coherences of the  $^{13}\text{CH}_2$  systems are always  $\cos(2\pi\delta t_1)$  terms with the signs  $(+ - + -)$  because of the  $180^\circ$  phase change in frequency. The signals of the  $^1\text{H}$  protons not attached to  $^{13}\text{C}$  are unaffected by the TPPI scheme. After appropriate Fourier transformation, the single-quantum coherence peaks of  $^{13}\text{CH}$  and  $^{13}\text{CH}_3$  groups appear along a  $45^\circ$  diagonal and the triple-quantum signals appear along a  $-71.56^\circ$  line in the  $F_1$  dimension. The peaks corresponding to the double-quantum and zero-quantum coherences appear at

$$\omega' = |\omega_1 + \omega_2|,$$

**Table 4.** Change in the quantum coherence on phase change.

| Spin system                   | Phase 0°                                                               | Phase 90°                                                              | Phase 180°                                                             | Phase 270°                                                             |
|-------------------------------|------------------------------------------------------------------------|------------------------------------------------------------------------|------------------------------------------------------------------------|------------------------------------------------------------------------|
| <sup>13</sup> CH              | + $I_y \cos(2\pi\delta t_1)$                                           | + $I_y \sin(2\pi\delta t_1)$                                           | - $I_y \cos(2\pi\delta t_1)$                                           | - $I_y \sin(2\pi\delta t_1)$                                           |
| <sup>13</sup> CH <sub>2</sub> | + $(I_{1y} + I_{2y}) \cos[2\pi(\delta_1 + \delta_2)t_1]$               | - $(I_{1y} + I_{2y}) \cos[2\pi(\delta_1 + \delta_2)t_1]$               | + $(I_{1y} + I_{2y}) \cos[2\pi(\delta_1 + \delta_2)t_1]$               | - $(I_{1y} + I_{2y}) \cos[2\pi(\delta_1 + \delta_2)t_1]$               |
| <sup>13</sup> CH <sub>3</sub> | + $(9/4)I_y \cos(6\pi\delta t_1)$<br>+ $(3/4)I_y \cos(2\pi\delta t_1)$ | - $(9/4)I_y \sin(6\pi\delta t_1)$<br>+ $(3/4)I_y \sin(2\pi\delta t_1)$ | - $(9/4)I_y \cos(6\pi\delta t_1)$<br>- $(3/4)I_y \cos(2\pi\delta t_1)$ | + $(9/4)I_y \sin(6\pi\delta t_1)$<br>- $(3/4)I_y \sin(2\pi\delta t_1)$ |

( $\omega_1$  and  $\omega_2$  are the chemical shift frequencies of the single-quantum coherences) with respect to the carrier frequency at the highest and lowest positions in the  $F_1$  spectral window. Therefore, the complete spectrum is divided into four parts in the  $F_1$  dimension. The upper part is the DQ COSY-spectrum of <sup>13</sup>CH<sub>2</sub> protons, the middle part is the COSY-spectrum of <sup>13</sup>CH and <sup>13</sup>CH<sub>3</sub> protons and the lower part is the TQ COSY-spectrum of <sup>13</sup>CH<sub>3</sub> protons and any unsuppressed resonances of XH<sub>n</sub> (X ≠ <sup>13</sup>C) groups (ZQ-spectrum) lying along the bottom line in the  $F_1$  dimension. The positions of <sup>13</sup>CH<sub>2</sub> and XH<sub>n</sub> signals can be exchanged by decreasing the phase of the 90°(<sup>1</sup>H) pulse and increasing the phase of the 180°(<sup>1</sup>H) pulse with 45° and 90° increments, respectively. Generally, this leads to an increase in the observable signal in proportion to  $I_y \cos(m\pi) \cos(n2\pi\delta t_1 - nm\pi/2)$ , where  $m$  is the number of phase increments. For selective measurements, the TPPI scheme can be applied to the 90°(<sup>1</sup>H) and 180°(<sup>1</sup>H) pulses with phase increments of 90°/ $n$  and 90°/2*n*, respectively.

**MAXY-TOCSY.** The magnetisation transfer from a spin ( $I_i$ ) to its coupling partners  $I_j$  can be achieved by the homonuclear Hartmann-Hahn mechanism.<sup>51, 53–58</sup> This can be done with ease by adding a TOCSY magnetisation transfer step before the data acquisition.<sup>44</sup>

**MAXY-NOESY.** When a 90°(<sup>1</sup>H)- $t_m$ -90°(<sup>1</sup>H) scheme is inserted before data acquisition, it is possible to obtain cross-peaks due to nuclear Overhauser effect (NOE) or chemical exchange.<sup>44</sup> For a <sup>12</sup>C-<sup>1</sup>H<sub>A</sub>-<sup>13</sup>C-<sup>1</sup>H<sub>B</sub> spin system, the first pulse will convert the coherence to longitudinal magnetisation as  $I_{zB}$  and  $I_{zA} \cos(\omega t_1)$ , respectively. The NOE magnetisation transfer occurs during the mixing of different states of the coupled spin system. The final 90°(<sup>1</sup>H) pulse re-establishes the single-quantum coherence of spin  $I$ . The observed NOE cross-peak corresponding to coherence transfer from the H<sub>B</sub> proton to the H<sub>A</sub> proton is defined as

$$I_A = I \cos(\omega_B t_1) \frac{\sigma_{AB}}{(\lambda_1 - \lambda_2) [\exp(-\lambda_1 t_m) - \exp(-\lambda_2 t_m)]},$$

where  $\lambda_{1,2} = (1/2)\{(R_A + R_B) \pm [(R_A - R_B)^2 + 4\sigma_{AB}\sigma_{BA}]^{1/2}\}$ ,  $\sigma_{AB}$  and  $\sigma_{BA}$  are the cross-relaxation rates from spin A to spin B (AB) and from spin B to spin A (BA), respectively,  $R$  is the longitudinal relaxation rate including all terms except for the cross-relaxation rate  $\sigma_{AB}$ . To calculate the maximum possible NOE, one must differentiate this equation with respect to  $t_m$ . Suppose that

$$R_A = R_B = 2\sigma_{AB} = 2\sigma_{BA},$$

$$\lambda_1 = 3\sigma,$$

$$\lambda_2 = \sigma.$$

Then one gets

$$t_m(\max) = \frac{\ln 3}{2\sigma} \approx 1.1 T_1.$$

If

$$\frac{\sigma_{AB}}{\lambda_1 - \lambda_2} = 0.5,$$

the maximum NOE enhancement is

$$I_{\text{cross}}(\max) = -0.19 I_{zB}(t_1).$$

The MAXY-TOCSY and MAXY-NOESY spectra can provide information on the type of the spin system provided that two spins are involved in a dipole-dipole coupling.

#### 4. Selective $J$ -resolved 1D NMR spectroscopy.

##### MAXY-JRES

Using  $J$ -resolved NMR spectroscopy, it is possible to separate the chemical shifts and the spin-spin coupling constants into the  $F_1$  and  $F_2$  dimensions, respectively,<sup>3, 59</sup> and thus obtain a broadband-decoupled 1D NMR spectrum from the projection on the  $F_2$  dimension. However, for complex samples (e.g., biological fluids<sup>60, 61</sup>), the method is of limited use because of strong overlap of NMR resonances. Procedures used for spectral resolution enhancement and lineshape improvement include pseudo-echo-weighting,<sup>62</sup> 'time-reversal'<sup>63</sup> and other techniques,<sup>64, 65</sup> specific data processing<sup>65, 66</sup> and the 3D JRES-COSY NMR spectroscopy<sup>67, 68</sup> (here, JRES stands for J Relay Selective). The MAXY approach can be successfully employed for obtaining individual JRES-spectra of <sup>13</sup>CH, <sup>13</sup>CH<sub>2</sub> and <sup>13</sup>CH<sub>3</sub> groups.<sup>45</sup> The MAXY-JRES pulse sequence is shown in Fig. 11. An advantage of the MAXY technique is the possibility of using magnetic field gradient pulses for separation of the subspectra of CH<sub>n</sub> groups. The gradient strength ratios,  $g_1 : g_2 : g_3 : g_4$ , are as follows:

Nonselective <sup>13</sup>CH + <sup>13</sup>CH<sub>3</sub>    <sup>13</sup>CH    <sup>13</sup>CH<sub>2</sub>    <sup>13</sup>CH<sub>3</sub>  
tive spectrum

1 : 1 : 4 : 5    1 : (-1) : 2 : 4    1 : (-1) : 2 : 4    1 : (-1) : 2 : 6    1 : (-1) : 2 : 8

**Figure 11.** The RF pulse sequence (a) and PFG sequence (b) in the MAXY-JRES experiments.

The delay  $\Delta$  is  $1/(2 J_{CH})$ ;  $\tau$  is the short delay for compensation of the pulse phase,  $t_1$  is the increase in the magnetisation evolution time. The pulse phase cycling scheme is as follows:  $\phi_1 = 0^\circ$ ;  $\phi_2 = 90^\circ$ ;  $\phi_3 = 0^\circ, 180^\circ$ ;  $\phi_4 = 0^\circ, 0^\circ, 180^\circ, 180^\circ$ .

The selective spectrum of a  $^{13}\text{CH}_n$  group can also be obtained using the phase cycling scheme.

## 5. 2D correlation NMR spectroscopy of geminal protons

Using a 2D method, which shows correlations only between geminal protons of methylene groups, it is possible to simplify both a COSY spectrum and signal assignment.<sup>37, 38, 44, 47</sup> Two pulse sequences were reported,<sup>37</sup> named gem-COSY-MQ (Fig. 12a) and gem-COSY-PT (Fig. 12b) and based on the inverse-DEPT-90 (see Ref. 31) and inverse-INEPT-1/(2 $J_{\text{CH}}$ ) (see Ref. 33) techniques, respectively. The techniques were modified in such a fashion that the  $\text{H} \rightarrow ^{13}\text{C} \rightarrow \text{H}$  magnetisation transfer was restricted to one-bond couplings. For a spin system  $I_1-S-I_2$ , the initial  $90^\circ(I)$  excitation pulse creates negative magnetisation along the  $y$ -axis of the  $I_1$  spin ( $-I_{1y}$ ) in both pulse sequences.<sup>37</sup> After the evolution and mixing periods, the expressions for the observable signals are as follows:

gem-COSY-MQ

$$\sigma = -I_{2y}\cos(2\pi\delta_1 t_1)\cos(\pi J_{12} t_1)\Pi\cos(\pi J_{1j} t_1) + 2I_{1x}I_{2z}\cos(2\pi\delta_1 t_1)\sin(\pi J_{12} t_1)\Pi\cos(\pi J_{1j} t_1), \quad (9)$$

gem-COSY-PT

$$\sigma = -I_{2x}\cos(2\pi\delta_1 t_1)\cos(\pi J_{12} t_1)\Pi\cos(\pi J_{1j} t_1) - 2I_{1z}I_{2y}\cos(2\pi\delta_1 t_1)\sin(\pi J_{12} t_1)\Pi\cos(\pi J_{1j} t_1) \quad (10)$$

( $\sigma$  is the density operator). Equation (10) describes the double magnetisation transfer  $I_1 \rightarrow S \rightarrow I_2$ , which gives rise to a cross-peak equivalent to an analogous peak in the COSY spectrum, except that it has an in-phase doublet pattern ( $J_{12}$ ) in both frequency dimensions. Equation (10) describes the magnetisation back-transfer  $I_1 \rightarrow S \rightarrow I_1$ , which gives rise to a double diagonal

**Figure 12.** gem-COSY-MQ (a), gem-COSY-PT (Polarisation Transfer) (b) and gem-COSY (c) pulse sequences based on the MAXY sequence.

dispersion peak with antiphase splitting ( $J_{12}$ ). Passive  $^1\text{H}-^1\text{H}$  coupling described by the term  $\Pi\cos(\pi J_{1j} t_1)$  has the same meaning as in conventional correlation spectroscopy.<sup>37</sup> An alternative method of obtaining gem-COSY spectra involves modification of the 2D MAXY pulse sequence (Fig. 12c).<sup>44, 47</sup> If a  $90_x(^1\text{H})-\Delta-90_x(^{13}\text{C})180_x(^1\text{H})-\Delta-90_y(^1\text{H})$  is used, the  $^{13}\text{CH}_n$  spin systems will be excited to the second maximum possible quantum order ( $n$  for  $^{13}\text{CH}_n$  or  $n-1$  for  $^1\text{H}$ ) as shown below:

for  $^{13}\text{CH}$

$$I_z \rightarrow +2I_z S_y \text{ (SQ)},$$

for  $^{13}\text{CH}_2$

$$I_{1z} \rightarrow -4I_{1z}I_{2x}S_x \text{ (DQ)},$$

for  $^{13}\text{CH}_3$

$$I_z \rightarrow -8I_xI_xI_zS_y \text{ (TQ)}.$$

The modification of the MAXY pulse sequence is that the second  $90_y(^1\text{H})$  pulse is applied along the  $y$  axis; therefore, the spin- $I_1$  coherence is transferred to  $I_2$  during the preparation period. At the end of the coherence evolution time, we get:

for  $^{13}\text{CH}$  (SQ)

$$+2I_z S_y,$$

for  $^{13}\text{CH}_2$  (DQ)

$$4I_{1z}I_{2y}S_x\cos(2\pi\delta_2 t_1)\cos(\pi J_{12} t_1) \cdot \Pi\cos(\pi J_{1j} t_1) + 2I_{2y}S_x\cos(2\pi\delta_2 t_1)\sin(\pi J_{12} t_1),$$

for  $^{13}\text{CH}_3$  (TQ)

$$-8I_yI_yI_zS_y\sin^2(2\pi\delta_2 t_1)\Pi\cos^2(\pi J_{1j} t_1).$$

After the mixing scheme  $90_x(^1\text{H})-\Delta-90_x(^{13}\text{C})-180_x(^1\text{H})-\Delta$ , the observable single-quantum coherence is:

$$+I_y \text{ for } ^{13}\text{CH},$$

$$+I_{1y}\cos(2\pi\delta_2 t_1)\cos(\pi J_{12} t_1)\Pi\cos(\pi J_{1j} t_1) - 2I_zI_{2x}\cos(2\pi\delta_2 t_1)\sin(\pi J_{12} t_1) \text{ for } ^{13}\text{CH}_2$$

and

$$-(1/2)I_y[\cos(4\pi\delta_2 t_1) + 1]\Pi\cos^2(\pi J_{1j} t_1) \text{ for } ^{13}\text{CH}_3.$$

Signals of  $^{13}\text{CH}$  groups appear in the zero-frequency region along the bottom line in the  $F_1$  dimension and signals of a  $^{13}\text{CH}_3$  group will appear as two peaks corresponding to double-quantum and zero-quantum coherences with the same initial intensity in the  $F_1$  dimension. For  $^{13}\text{CH}_2$  groups, the first term describes the  $I_1 \rightarrow I_2 S(t_1) \rightarrow I_1(t_2)$  transfer, which gives rise to a cross-peak equivalent to that in a conventional COSY spectrum with the exception that multiplets are in-phase in both measurements. The second term describes the  $I_1 \rightarrow I_2 S(t_1) \rightarrow I_2(t_2)$  transfer responsible for the appearance of diagonal peaks with dispersion doublet lineshapes. If the phase of the last  $90_y(^1\text{H})$  pulse alternates about the  $x$  axis, the sign of the  $\text{CH}_2$  cross-peak is the same, whereas the signs of the peaks of other groups are altered. This offers yet another way of obtaining diagonal peak suppressed gem-COSY spectra, as in the 2D MAXY NMR spectrum.

The TOCSY and NOESY transfers can also be used in the gem-COSY experiments. The MAXY method provides a better suppression of diagonal peaks compared to the original MQ method. Proton signals of  $^{13}\text{CH}$ ,  $^{13}\text{CH}_2$  and  $^{13}\text{CH}_3$  groups are observed separately in different parts of the spectrum.  $^{13}\text{CH}_2$  group protons give a normal gem-COSY spectrum.  $^{13}\text{CH}_3$  proton signals appear at the right lower region of the spectrum.  $^{13}\text{CH}$  proton peaks are along the bottom line of the spectrum together with zero-quantum coherence correlation of  $^{13}\text{CH}_3$  protons. 2D correlation NMR spectroscopy of geminal protons appeared to be useful for analysis of the spectra of large molecules<sup>47</sup> and provides an alternative method of editing  $^1\text{H}$  NMR spectra.

## 6. Spin–spin coupling constants measurement using MAXY-based experiments

The spin–spin coupling constant is one of the most important parameters in NMR spectroscopy and has been widely used in conformational analysis of complex molecules and in structural modelling.<sup>2, 4, 69–74</sup>

For the first-order spectra of symmetrical systems the spin–spin coupling constants can be measured directly in the NMR spectrum. However, in the case of complex molecules, line assignment is very difficult because of signal overlap.

Using the MAXY method, it is possible to obtain 2D NMR subspectra of individual  $^{13}\text{CH}_n$  groups or separate the spectra into different spectral regions according to the number,  $n$ , of the protons bonded to  $^{13}\text{C}$ , thus resulting in appreciable reduction of signal overlap. For instance, the 2D MAXY technique was used to determine the spin–spin coupling constants in the neurotensin molecule.<sup>75</sup> Although neurotensin is a relatively short peptide, proton signals in its  $^1\text{H}$  NMR spectrum are strongly overlapped, especially in the low-frequency region. The use of the 2D MAXY method with correlation of only  $^{13}\text{CH}_2$  groups permits resolution enhancement of most overlapped peaks including the  $\beta$ -proton peaks.

## V. Measurements of self-diffusion coefficients

At present, self-diffusion coefficients are very often measured using the pulsed magnetic field gradient technique according to Stejskal and Tanner.<sup>76</sup>

Once the Longitudinal Eddy Current Delay (LED) pulse sequence was designed and the concept of diffusion-ordered spectroscopy proposed, it became possible to determine the diffusion coefficients associated with each resonance signal in the high-resolution NMR spectrum. Therefore, researchers expressed increased interest in measuring diffusion coefficients using NMR spectroscopy.<sup>77–87</sup> The diffusion coefficients thus determined were used in, *e.g.*, experimental studies on the vesicle size distribution in phospholipids,<sup>82</sup> molecular mass distribution in polymers,<sup>83</sup> in analysing complex mixtures of cell extracts,<sup>85</sup> protein association,<sup>86</sup> aggregation of insulin molecules<sup>87</sup> and protein binding with drugs.<sup>88–107</sup> Editing 1D and 2D NMR spectra of biological fluids, based on differences in the molecular diffusion coefficients and relaxation times, is possible using the DIRE (Diffusion Relaxation) and DETOCY (Delay TOCSY) techniques<sup>108</sup> and improved 2D methods of the HETCOR (Heteronuclear Correlation Spectroscopy), COSY and NOESY types.<sup>109–111</sup>

In an original PFG–SE (Pulsed Field Gradient Spin Echo) experiment, signal attenuation can be written as follows<sup>76</sup>

$$\ln \frac{A(g)}{A(0)} = -\gamma^2 D \left[ \frac{2g_0^2 \tau^3}{3} + gg_0 \delta \left( \frac{3\tau^2}{2} - \frac{\delta^2}{6} \right) + g^2 \delta^2 \left( \Delta - \frac{\delta}{3} \right) \right] - \frac{2\tau}{T_2}. \quad (11)$$

Here  $A(g)$  and  $A(0)$  are the signal intensities in the presence and in the absence of PFG,  $\gamma$  is the magnetogyric ratio for a given spin,  $D$  is the diffusion coefficient,  $g_0$  is the steady magnetic field gradient,  $g$  and  $\delta$  are the strength and duration of the rectangular gradient pulse,  $\Delta$  is the time interval between the starting points of two gradient pulses (diffusion time),  $2\tau$  is the time at which spin echo occurs and  $T_2$  is the transverse relaxation time. If

$$g_0^2 = \tau^3 \ll g^2 \delta^2 \Delta,$$

Eqn (11) is simplified

$$\ln \frac{A(g)}{A(0)} = -\gamma^2 D g^2 \delta^2 \left( \Delta - \frac{\delta}{3} \right) - \frac{2\tau}{T_2}. \quad (12)$$

This equation is known as the Stejskal–Tanner equation for diffusion coefficient measurement.

Having obtained a number of spectra using different gradient strengths and plotted  $\ln A$  vs.  $\gamma^2 g^2 \delta^2 (\Delta - \delta/3)$ , one gets a straight line with the slope equal to the self-diffusion coefficient. In order to determine the exact  $D$  values, one must attenuate the NMR signal. This can be achieved using a wide range of gradient pulses. For slowly diffusing particles the gradient strength can be of the order of 1000 to 2000 mT m<sup>−1</sup>.

Alternating eddy flows that can be induced in a sample under study in the course of experiments complicate exact detection of the NMR signal.<sup>112</sup> It is also possible to obtain the same range of  $\gamma^2 g^2 \delta^2 (\Delta - \delta/3)$  values using small gradients with compensation of alternating eddy flows owing to longer diffusion time.<sup>113, 114</sup> However, this can lead to a decrease in sensitivity due to spin relaxation.<sup>113</sup>

Another way of increasing gradient strength is to use the dependence of the dephasing/rephasing of gradient pulses on the quantum order of the spin systems affected<sup>115</sup> by the gradients during the multiple-quantum sequence. In this case the effective magnetogyric ratio  $\gamma_{\text{ef}}$  is the sum of the values,  $\gamma$ , of the spins involved in coherence. For a homonuclear double-quantum sequence one has  $\gamma_{\text{ef}} = 2\gamma$ ; therefore, the gradient strength is doubled while the measurable diffusion coefficient decreases by a factor of four.<sup>116–120</sup> Diffusion spread of longitudinal spin orders  $2I_z I_z$  and  $4I_z I_z I_z$  normal to the gradient direction was studied.<sup>118, 119</sup> It was shown that the effective magnetogyric ratios are equal to  $2\gamma$  and 0 for the  $2I_z I_z$  system and to  $3\gamma$  and  $\gamma$  for the  $4I_z I_z I_z$  system.

The MAXY method was modified<sup>43–46, 121–123</sup> to determine diffusion-induced changes in the maximum quantum order of the spin operator  $8I_x I_y I_z S_y$  for the  $^{13}\text{C}^1\text{H}_3$  ( $SI_3$ ) spin system. This system is characterised by four magnetogyric ratios, namely,  $(3\gamma_{\text{H}} + \gamma_{\text{C}})$ ,  $(3\gamma_{\text{H}} - \gamma_{\text{C}})$ ,  $(\gamma_{\text{H}} + \gamma_{\text{C}})$  and  $(\gamma_{\text{H}} - \gamma_{\text{C}})$ , corresponding to four multiple-quantum levels composed of possible combinations of individual spin states. The multiple-quantum coherences (each of them can be obtained individually using pulsed field gradients) can be converted to observable single-quantum coherences. Diffusion-induced changes in each coherence can also be measured individually.<sup>43–46</sup>

An original technique<sup>124</sup> permits reduction of the duration of the 3D NMR experiments; the corresponding pulse sequence is given in Fig. 13. The modification of the MAXY sequence consists of addition of a diffusion time and diffusion gradient

**Figure 13.** The RF pulse sequence (a) and PFG sequence (b) used in the modified MAXY diffusion coefficient measurement technique.

The pulse phases in the rotating frame are along the  $x$  axis until otherwise specified, *i.e.*,  $\phi_1 = x$ ,  $x$ ,  $x$ ,  $-x$ ,  $-x$ ;  $\phi_2 = -y$ ,  $y$ ,  $y$ ,  $-y$ . The delay time  $\tau$  is 3.85 ms, the time interval  $\Delta$  is set to 50 ms; FID stands for Free Induction Decay. For notations  $g_c$ ,  $g_d$ ,  $g_s$  and  $g_r$ , see text.

pulses (encoding gradient  $g_e$  and decoding gradient  $g_d$ ). The coherence-selective and read pulse strengths ( $g_s$  and  $g_r$ , respectively) are chosen according to the desired quantum order and fixed. The interval  $\tau$  is set to  $1/(2^1 J_{SI})$ ; this delay period is too short for significant homonuclear  $J$  precession to occur.<sup>125</sup>

This pulse sequence was used in the diffusion coefficient measurements in studies of D,L-alanine.<sup>126</sup>

Most diffusion coefficient measurement techniques<sup>127</sup> are comparatively time-consuming because they include either a series of NMR experiments or a 2D DOSY (Diffusion-Order Spectroscopy) experiment. A 1D DOSY method<sup>128</sup> for the determination of diffusion coefficients in a single experiment (scan) involves spatial variation of the parameters of a conventional STE (Stimulated Echo) pulse sequence<sup>78</sup> in such a manner that all the scans necessary for the determination of diffusion coefficient could be performed simultaneously in different regions of the sample. The spectrum is recorded in the presence of a weak read gradient and therefore the lineshape contains the necessary information. For well-resolved spectra with high signal-to-noise ratio the method allows the duration of the experiment to be shortened by an order of magnitude (to 1 s), which is important in studies of those samples whose state rapidly changes with time.

Diffusion, relaxation and the spin–spin coupling precession directly affect the accuracy of measurements of coefficients. The larger the  $\Delta$  value, the smaller the gradient strength or duration; however, signal attenuation due to transverse relaxation  $\exp(-\Delta/T_2^*)$  leads to a decrease in the signal-to-noise ratio. To compensate for the loss of sensitivity, it is necessary to obtain a larger number of spectra, which increases the duration of the experiment.

Thus, methods based on the MAXY sequence can be successfully implemented on spectrometers with low gradient strength and low magnetic field for measuring small diffusion coefficients (in macromolecules and molecular ensembles). Signal attenuation due to self-diffusion can be observed simultaneously for all coherences using 2D NMR spectroscopy or for a certain coherence using magnetic field gradient pulses. In the case of systems with natural abundance of  $^{13}\text{C}$  the sensitivity of such methods is

low. However, they can be suitable for measuring the diffusion coefficients of  $^{13}\text{C}$ -labelled molecules in complex mixtures such as biological fluids or cell extracts.

Now consider again Eqn (11). If the condition  $g_0^2 \tau^3 \ll g^2 \delta^2 \Delta$  is not met, the effect of the steady gradient must be accounted for. There are two factors that have a negative effect on the accuracy of measurements; these are the steady gradient and thermal convection. The steady gradient is due to inhomogeneity of the static magnetic field in the sample, which can be eliminated using the spin echo technique.<sup>88–90</sup> This approach is widely used in transverse relaxation time measurements. Thermal convection particularly manifests itself if experiments are carried out at high temperatures.

To obtain reliable values of metabolite diffusion coefficients in biological fluids, the diffusion coefficients must be measured at physiological temperature.<sup>80,81</sup> Since in most NMR spectrometers the temperature is maintained with an upstream gas (nitrogen or air) flow, a temperature gradient is created in the sample, which is responsible for the onset of convection flow. In addition, time-dependent temperature gradients are created when the gradient pulses are switched on and off.

Problems associated with convection were analysed by Carr and Purcell<sup>91</sup> in the early studies of the spin echo effect and diffusion. In the multiple spin-echo gradient experiments carried out in the presence of convection flows the amplitudes of the even echo signals are larger than those of the odd signals. This is due to the fact that the effect of thermal convection during the odd echo is compensated for during the even echo. Therefore, the simplest method is to measure only the even echo signals. This approach was implemented in the PFG–STE method and its versions involving doubling of the pulse sequence.<sup>93,94</sup> It should be noted that the diffusion gradients in the PFG–STE pulse sequence and its versions, such as LED, act for coherence selection, as in gradient enhanced NMR spectroscopy.

The use of coherence-selective gradients causes the sensitivity of the method to be halved. Doubling the STE and LED sequences again halves the sensitivity so it totally decreases by a factor of four. This is equivalent to shortening of the transverse relaxation

**Figure 14.** The RF pulse sequences and the PFG sequences used in the spin-echo (SE) methods for diffusion coefficient measurements (a), MSE (Multiple Spin Echo) (b) and DMSE (c).

time by a factor of  $1.4 T_2$ . The  $T_2$  times of metabolite spins in biological fluids lie between a few hundreds of milliseconds and a few seconds; therefore, one can expect that a compensation technique based on the double PFG–SE sequence for diffusion times shorter than  $T_2$  will be more sensitive than the coherence transfer method.

In the Carr–Purcell–Meiboom–Gill (CPMG) method<sup>97,98</sup> the spin echo is used for  $T_2$  measurements at a spin stabilisation time of up to a few seconds under conditions of minimum phase distortions. Using this technique, it is possible to obtain a homogeneous static magnetic field (steady gradients) and compensate for artifacts that appear due to distortions of the  $180^\circ$  pulses. Based on the CPMG sequence, a pulse sequence was created for measuring diffusion coefficients in the presence of steady gradients and thermal convection (Fig. 14*a*). Bipolar pulses were used instead of the gradient pulse (Fig. 14*b*). In addition, a multiple spin-echo pulse sequence was implemented instead of a single  $180^\circ$  pulse, which permits operation with long diffusion times. The last pulse before data acquisition removes the dispersion component from the detected signal. This pulse scheme is doubled and therefore was named DMSE (Double Magnetic Spin Echo, Fig. 14*c*). To ensure bipolar gradient pulses, a  $180^\circ$  pulse is incorporated in the middle of the sequence. Theoretical description and the results of tests with human blood plasma and human seminal fluid were reported recently.<sup>123</sup> The results were compared with the data obtained using the BP–LED (Bipolarisation LED)<sup>100</sup> and MSE methods. The temperature dependence of diffusion coefficients obtained using these three pulse sequences are shown in Fig. 15.

**Figure 15.** Temperature dependence of water diffusion coefficients measured using the BP–LED (1), MSE (2), DMSE (3) and other (4) methods in the range 298.2–323.2 K.

The DMSE technique permits efficient suppression of thermal convection,<sup>123</sup> being unaffected by the steady gradients. Incorporation of the CPMG sequence into the DMSE sequence allows one to operate with long diffusion times and suppress broad NMR peaks with short transverse relaxation time  $T_2$ . This possibility of spectral editing makes the DMSE technique suitable for studying the molecular mobility in complex systems. Among the other advantages of this method are good lineshapes and base line and efficient suppression of water signals.

## VI. Observation of ‘underwater’ signals. RECUR NMR technique

Efficient suppression of water signals is of crucial importance in NMR spectroscopy of complex systems.<sup>58</sup> The main efficiency criteria are as follows:

- high degree of suppression of the water peak, which is five to six orders of magnitude more intense than the peaks of the molecules under study,
- high selectivity to the signals appearing near the water peak

and

- short duration of the solvent signal suppression sequence in order to minimise the magnetisation transfer to the exchanging protons.

Among the methods designed to meet these criteria, the WET (Water Eliminated Transfer)<sup>129</sup> and WATERGATE (Water Gate)<sup>130</sup> techniques can be pointed out. The best, with respect to all criteria, is the modified WATERGATE method.<sup>131</sup> However, these schemes have a common drawback consisting of suppression of ‘underwater’ peaks.

Attempts at solving this problem in studies of macromolecules included taking into account the longitudinal relaxation time ( $T_1$ ) difference between water and the macromolecule. This means that by choosing an appropriate recovery time, which follows the inversion scheme, it is possible to observe the signals of macromolecules.<sup>132</sup>  $T_1$ -Editing was performed using the heteronuclear multiple quantum coherence (HMQC) method modified by incorporating magnetic field gradients.<sup>133</sup> The approach is efficient in natural abundance  $^{13}\text{C}$  or  $^{15}\text{N}$  studies. If the repetition time of experiments is short, the water signal can be partly suppressed owing to longer relaxation time compared to the relaxation times of the macromolecule. HMQC, HSQC (Heteronuclear Single Quantum Coherence) and magnetic field gradient experiments give satisfactory results and there is no need for further suppression of water signals. However, a long pre-delay time is required in studies of small molecules and therefore both water signals and  $^{12}\text{CH}$  signals must be additionally suppressed using the Bilinear Rotation Decoupling (BIRD) sequence. One can also use diffusion filtering for attenuation of the signals of diffusing water as in, e.g., the DRYCLEAN (Dry Clean) technique.<sup>134</sup> However, these approaches are inapplicable in studies of small metabolite molecules in biological fluids due to similar  $T_1$  values and diffusion coefficients for the molecules in question and water protons.

A number of methods based on the relaxation time  $T_2$  differences between water signals and signals of the molecules under study are also used. They are particularly efficient if the relaxation time  $T_2$  of the water signal can be reduced by, e.g., adding paramagnetic impurities.<sup>135</sup>

Some techniques were designed in order to avoid difficulties that appear when the desired signal of proton A is masked by other proton signals and thus cannot be selectively excited. The key feature of these methods is selective excitation of the second proton B coupled to the desired proton A. The magnetisation is transferred from B and A using the COSY or TOCSY sequence and the second selective pulse excites the proton A (e.g., NOE or ROE, or Rotating-frame Overhauser Effect). Using appropriate magnetic field gradient pulses, it is possible to eliminate undesired coherences in this scheme. Such methods<sup>136–140</sup> were named gs-1D CONO (COSY–NOESY), gs-1D TONO (TOCSY–NOESY) and gs-1D TORO [TOCSY–ROESY (Rotating-frame Overhauser Effect Spectroscopy)]. There are also the gs-1D ROTO and gs-1D RORO techniques which begin with the ROESY transfer. However, one should keep in mind that if a pulse sequence includes a number of selective pulses, long duration of these pulses can complicate experiments owing to long relaxation of useful signal.

A method of ‘underwater’ signal recovery using magnetisation transferred NMR spectroscopy, named RECUR NMR (Recovery of ‘Underwater’ Resonances NMR), was proposed.<sup>138</sup> The technique is based on a modified WATERGATE suppression scheme followed by magnetisation transfer. This method offers considerable advantages over other techniques.<sup>136,139</sup> Water signal suppression occurs involving a double WATERGATE sequence with a five-lobe composite pulse (W5), as shown in Fig. 16*a*.

The ‘underwater’ signals can be recovered using both the TOCSY and ROESY sequences which execute magnetisation back-transfer to the ‘underwater’ signals using scalar or dipole–dipole couplings, respectively, in 1D RECUR–TOCSY experiments (Fig. 16*b*). It should be noted that both coherence transfer

**Figure 16.** Conventional WATERGATE-W5 two-pulse sequence (a), 1D RECUR-TOCSY pulse sequence (b) and 2D RECUR-ROESY pulse sequence (c) containing the MLEV-17 spin stabilisation pulse sequence or a long pulse to create a TOCSY or ROESY type magnetisation transfer for recovery of 'underwater' signals; the RECUR-JRES and RECUR-CPMG pulse sequences (d).

schemes lead to in-phase magnetisation. This makes it possible to measure the ROE buildup rate in 1D NMR experiments using the pulse sequence shown in Fig. 16b or in 2D NMR experiments (Fig. 16c). By incorporating the CPMG sequence before the data acquisition step (see Fig. 16d, RECUR-CPMG) one can measure the transverse relaxation times of any underwater resonance. If a single spin echo technique is employed instead of this scheme, the pulse sequence can be implemented in  $^1\text{H}$ - $^1\text{H}$  homonuclear JRES NMR spectroscopy (RECUR-JRES).

The pulse sequence shown in Fig. 16c differs from the WATERGATE-TOCSY and WATERGATE-ROESY<sup>136,139</sup> sequences, in which the WATERGATE module follows the magnetisation transfer scheme. These methods involve suppression of 'underwater' signals and permit 2D NMR spectroscopy studies of macromolecules. But they cannot be implemented in 1D NMR spectroscopy experiments and prevent the ROE buildup rate or  $T_2$  of the 'underwater' signals from being measured.

The RECUR method was tested<sup>138</sup> using a 4 : 1 model mixture of D-glucose (20 mg ml<sup>-1</sup>) and D-galactose (5 mg ml<sup>-1</sup>) in 1 : 1 H<sub>2</sub>O-D<sub>2</sub>O solution. NMR spectra with and without water signal suppression, obtained using the double WATERGATE sequence, are shown in Fig. 17a,b. After TOCSY (Fig. 17c) or ROESY (Fig. 17d) magnetisation transfer with mixing times of 80 ms and 1.5 s, respectively, the 'underwater' signals are completely recovered. TOCSY magnetisation transfer occurs more efficiently. However, in the absence or in the presence of a weak spin-spin coupling the RECUR-ROESY method is optimum.

At a sufficiently high concentration of the substance under study, NMR resonances of individual CH<sub>n</sub> groups (e.g. CH<sub>3</sub>) can be recovered using the MAXY sequence.<sup>43,44</sup> The proton

**Figure 17.** 1D NMR spectra of D-glucose and D-galactose obtained without (a) and with (b) water signal suppression using the WATERGATE double pulse sequence.

H(1) proton 'underwater' signals completely recovered using the RECUR-TOCSY (c) and RECUR-ROESY (d) methods.

spin-spin relaxation times obtained using the RECUR-CPMG sequence are as follows:<sup>138</sup>

| Compound | β-Glucose | β-Galactose | α-Glucose | α-Galactose |
|----------|-----------|-------------|-----------|-------------|
| Time/s   | 1.1       | 1.5         | 1.3       | 1.3         |

The 2D RECUR-ROESY NMR technique was used in studies of a human blood plasma sample to determine the internuclear distance in the glucose molecule.<sup>138</sup>

The RECUR-TOCSY and ROESY methods can also be used for spectral editing. For instance, at a spin stabilisation time of 70 ms it is possible to observe signals of the most flexible structural fragments of lipoproteins. Extension of this time to 700 ms causes an appreciable weakening of these signals while the signals from small metabolite molecules become less suppressed owing to comparatively longer relaxation times. When analysing 2D JRES NMR spectra, this approach allows visualisation of all peaks from small molecules, including the 'underwater' signals. The TOCSY or ROESY techniques allow the  $T_2$ , internuclear ROE and ROE buildup rate to be measured, which is important in molecular structure and dynamics studies.

## VII. Homonuclear selective methods

### 1. Selective COSY experiments

Combining selective and conventional 'hard' pulses in a single experiment permits design of a new approach, which can conveniently be exemplified by the COSY sequence.<sup>141-143</sup>

The pulse sequence shown in Fig. 18 was used in the study of brucine (Fig. 19). The coherence diagram shows that the selective 90° pulse creates coherences  $I^+$  and  $I^-$ . The antiphase magnetisation,  $2I_{H1}I_{H2z}$ , of proton 2 coupled to the first excited proton  $I_{H1}$  evolves during the d2 delay time equal to  $(1/2)J(\text{H,H})$ . Then, a 'hard' 90° pulse p2 converts it to  $2I_{H1z}I_{H2y}$ . Thus, in the data acquisition step the phase magnetisations of all the brucine protons (see Fig. 19) coupled to the selectively excited proton

**Figure 18.** The RF pulse sequence (a), PFG sequence (b) and coherence pathway (c) in the selective gs-COSY experiment.<sup>144</sup> Transition of the spin system from a lower to a higher energy level is denoted by '+1' and the reverse transition is denoted by '-1'.

**Figure 19.** Brucine spectra obtained using the selective COSY sequence.<sup>16</sup> Selective excitation of H(14) (a), selective excitation of H(15 $\beta$ ) (b) (residual artifacts are asterisked) and conventional selective COSY spectrum (c).

evolve and can be recorded. In contrast to a conventional 2D COSY experiment, selective COSY experiments allow the NMR spectrum to be recorded rather accurately, because by applying a selective pulse only one row in the COSY matrix is measured. A 'hard'  $90^\circ$  pulse creates a transverse magnetisation of all nuclei; therefore, their signals can be suppressed using a phase cycling scheme with a minimum number of steps (two). In particular, this concerns strong signals, *e.g.*, those of methyl or methoxyl groups, which precludes analysis of multiplet signals. The problem can be solved in the PFG experiments. Application

of the gradient g1 causes dephasing of all coherences  $I^+$  and  $I^-$ . A 'hard'  $90^\circ$  pulse acts on the  $I^+$  and  $I^-$  coherences as follows:

$$I^+ \xrightarrow{90^\circ I} \frac{1}{2}(I^+ + I^-) + iI_z,$$

$$I^- \xrightarrow{90^\circ I} \frac{1}{2}(I^+ + I^-) - iI_z.$$

Here  $I^-$  is the observable coherence. It must be phase shifted by the negative gradient applied after the 'hard' pulse that can give rise to random artifacts in the 1D COSY spectrum. Signals created by the 'hard' pulse will be completely dephased by the second gradient.

It should be noted that gradients follow the upper trajectory (signals from the lower trajectory never reach the receiver). Therefore, gradient experiments with the same number of scans can be accompanied by a twofold decrease in signal intensity. When carrying out experiments on modern spectrometers, this is not an unsolvable problem because of rather high proton sensitivity in studies of conventional organic compounds. Another drawback of this pulse sequence is the use of a finite-duration gradient immediately before data acquisition, which leads to a large phase coefficient. The drawback can be overcome in two ways, (i) using a linear back-prediction proposed by Bernstein and Trimble<sup>141</sup> and (ii) by incorporating the gradient pulse into the data acquisition interval. In selective COSY experiments, an individual multiplet structure is usually of greater interest than a complete 1D NMR spectrum; therefore, it is more appropriate to adjust the phase of each multiplet individually.

## 2. Selective TOCSY method

Another selective excitation technique was proposed<sup>143</sup> for selective TOCSY experiments (Fig. 20). Initially, all protons are excited by a 'hard'  $90^\circ$  pulse and then dephased after the gradient pulse g1. Then, a selective RF  $180^\circ$  pulse changes the coherence order of the desired proton and the subsequently applied gradients g2 and g3 cause rephasing. A practical advantage of this method is that the selective  $180^\circ$  pulse can be calibrated much more easily than the selective  $90^\circ$  pulse. Moreover, it can be shown that the phase of the selective  $180^\circ$  pulses relative to the phase of the 'hard' pulses is of no significance. This allows the use of selective pulses

**Figure 20.** RF pulse sequence (a), PFG sequence (b) and the selective-pulse excited (c) and non-excited (d) coherence pathways in the gs-SELTOCSY (Selective TOCSY) experiments.

for which the carrier frequency is chosen to be slightly different from the basic frequency. Therefore, only one frequency can be used when changing the frequency range of the spectral window and all the protons under study. The second gradient is followed by the MLEV-16 spin stabilising scheme, which serves for retention of coherence order. The last gradient is rephased by applying a 'delay – 180° pulse – tailored gradient pulses' sequence. However, these methods are inappropriate for solving problems arising due to the mixing of the antiphase components within the same multiplet. As a consequence, a correct determination of the spin – spin coupling constants is complicated.

### 3. Double PFG echo spectroscopy

A number of methods use selective pulses and gradients for filtering unwanted magnetisations rather than excitation of particular signals. For instance, the WATERGATE technique<sup>144</sup> employs the pulse sequence shown in Fig. 21.

**Figure 21.** The RF pulse sequence (a) and PFG sequence (b) for the WATERGATE technique of water signal suppression.

To suppress an unwanted signal (often, water signal), two PFGs are applied along with a 'hard' 180° pulse (p3) and a selective 180° pulse. The last pulse is often composed of two 90° pulses, p2 and p4. Therefore the water resonance is affected by the effective 360° pulse, while all other signals are excited by the 180° pulse only, thus being influenced by two gradients of the same sign. A few versions of this method use a binomial sequence instead of selective pulses. The WATERGATE strategy was employed in some techniques known as PHOGSY (Pulse Heteronuclear Gradient Spectroscopy). They permit detection of bound water molecules in proteins.<sup>145–148</sup>

Hwang and Shaka<sup>16</sup> showed that the use of the double pulse sequence shown in Fig. 21 improves both suppression and the phase mode; however, the 'cost' of such improvements is a decrease in the total magnetisation relaxation during the action time of two identical sets of gradient pulses.

The pulse sequence shown in Fig. 21 can be used for improving other pulsed methods. Some of them appeared to be fruitful for organic chemistry, *e.g.*, difference NOE spectroscopy. Gradient Overhauser effect spectroscopy (GOESY)<sup>149</sup> appeared to be a major improvement over the double pulse field gradient spin echo (DPFGSE) technique.

If the inversion rate of a molecule is such that the NOE effects become insignificant or vanish, rotating-frame experiments are usually carried out, with spins blocked by a weak RF-field. There are a number of selective methods, which also employ a spin blockade, *e.g.*, Gradient Rotation Overhauser Effect Spectroscopy (GROESY).<sup>150</sup> This approach is similar to the 1D TOCSY method; however, here the spin blockade is much weaker. Such sequences are included in the selective retranslated COSY scheme.<sup>150–156</sup>

### 4. NMR studies of C – C coupling

INADEQUATE (Incredible Natural Abundance Double Quantum Transfer Experiment) type methods are used in studies of C – C spin – spin couplings, spin system connectivities and for molecular structure analysis (in the case of long-range couplings). 2D INADEQUATE experiments are a source of valuable information in studies of organic compounds.<sup>157</sup> In practice, experimenters often have very small amounts of compounds under study. To obtain correct results in 2D INADEQUATE experiments, the resulting <sup>13</sup>C NMR spectrum must exhibit a signal-to-noise ratio of at least 30 : 1 after a single 90° pulse. The selective 1D INADEQUATE method is called SELINQUATE (Selective INADEQUATE);<sup>158</sup> it can be implemented with ease because only one row in the 2D matrix is to be measured when using a carbon-selective pulse. However, the major problem in this method is suppression of false signals from the molecules having only one <sup>13</sup>C atom. The spin – spin coupling constant <sup>1</sup>J(C,C) is of the order of 40 Hz and corresponding signals can be detected with ease even if the main signal is incompletely suppressed. This is insignificant if the SELINQUATE technique is used to determine the spin system connectivity, but is of crucial importance if the method is used for measuring the <sup>2</sup>J or <sup>3</sup>J constants.

The use of magnetic field gradient pulse sequences permits improvement of the INADEQUATE technique. Willker and Leibfritz<sup>142</sup> first demonstrated the principle used in the H,H-COSY experiments with labelled <sup>13</sup>C atoms. In this case the double-quantum filter is not employed because it nearly halves the sensitivity. The method was called GRECCO (Gradient Enhanced Measurement of Carbon Coupling);<sup>159</sup> the corresponding pulse sequence is shown in Fig. 22.

**Figure 22.** RF pulse sequence (a), PFG sequence (b) and the selective (c) and non-selective (d) coherence pathways in the GRECCO method. WALTZ-16 is the decoupling sequence and CPD stands for Cross Polarisation Decoupling.

The most important problem is to reduce the cross-polarisation (CP) to the desired carbon atoms. Selective inversion of coherence pathways is achieved using a Gaussian selective  $180^\circ$  pulse. The evolution period of duration  $(1/2)J_{CC}$  (typically, 83 ms) is followed by a Gaussian  $180^\circ$  pulse of duration lying between 10 and 50 ms. A 'hard'  $90^\circ$  ( $^{13}\text{C}$ ) pulse transfers the magnetisation between coupled spins. The gradient ratio  $g1:g2:g3$  serves to select the magnetisations inverted by the Gaussian pulse. The corresponding coherence pathway is shown in Fig. 22c. The coherence pathway given in Fig. 22d is valid for the remaining carbon coherences; it changes under the action of three gradients. The three-gradient set provides a complete suppression. This combination of semiselective CP method and the frequency selective coherence pathway selection under the action of the  $180^\circ$  pulse is used to achieve selective polarisation from proton to carbon.

Weigelt and Otting<sup>160</sup> succeeded in suppressing all unwanted signals using PFG in proton detected INADEQUATE experiments.

An ADEQUATE (Astonishingly Sensitive Double Quantum Transfer Experiment) pulse sequence for observation of  $^{13}\text{C}$ – $^{13}\text{C}$  couplings in natural compounds has been introduced recently.<sup>161</sup> It permits observation of through-bond carbon–carbon couplings for up to six bonds (Fig. 23). The method provides a greater amount of information compared to, *e.g.*, the HMBC (Heteronuclear Multiple-Bond Correlation) method. Depending on the delay time, the HMBC technique allows through-bond correlations for 4–5 bonds to be observed; however, experiments with the most typical delay times of 50–80 ms make it possible to observe through-bond correlations only for 2–3 bonds. A salient feature of the ADEQUATE method is the use of adiabatic pulses with  $\omega_1$ -defocussing (distribution of the components of the spin–spin coupling constants over the first dimension). This permits analysis of the spectra obtained in the same way as in the HMBC method. Some versions of this technique were successfully used for exact measurement of  $^{13}\text{C}$ – $^{13}\text{C}$  spin–spin coupling constants (see Ref. 162) and determination of  $^{13}\text{C}$  signal multiplicities (see Ref. 163).

**Figure 23.** Scheme of correlations that can be obtained in different ADEQUATE experiments.

## VIII. Heteronuclear experiments

Probing carbon nuclei allows emergence of masked proton signals. Initially, a particular carbon atom is excited and then the magnetisation is transferred to a proton, which is accompanied by significant loss of the carbon magnetisation. In this case, the main problem also consists of suppression of signals of the protons coupled to  $^{13}\text{C}$ . Recently, numerous methods have been developed, which permit selective excitation of any proton through an

appropriate coupled carbon atom and subsequent transfer of the magnetisation from the proton to the  $^{13}\text{C}$  nucleus through scalar coupling.<sup>161–172</sup> The advantage of such methods is a high sensitivity.<sup>4</sup>

During excitation of a carbon atom under study the protons must be decoupled in order to ensure a single carbon signal and thus a high selectivity. To excite a chosen carbon atom, one must use a selective  $180^\circ$  pulse because it can be calibrated with ease and no phase coherence with other 'hard' carbon-selective pulses is needed.

Suppression of unwanted coherences and selective excitation of protons coupled to the chosen  $^{13}\text{C}$  atom is more efficient in the presence of PFG. To avoid relaxation losses, the pulse sequence must be as short as possible.

An HMQC-based SELINCOR (Selective Incredible Correlation) sequence<sup>161</sup> (Fig. 24) is probably the first sequence including carbon-selective excitation pulses. When using the conventional inverse-INEPT sequence, the magnetisation is back-transferred to protons and the rephasing gradient 'selects' the necessary pathway.

A conventional SELINCOR module appeared to be a universal tool in the spectroscopist's hands. More recent methods (COSY,<sup>170</sup> TOCSY,<sup>173</sup> NOESY<sup>174</sup> and ROESY) use a selectively excited proton in order to create the 1D and 2D NMR spectra of those signals that are uncoupled from other signals. Figure 25 presents a number of spectra reported by Parella *et al.*<sup>174</sup>

An interesting feature is manifestation of the NOE effect between chemically equivalent protons in, *e.g.*, symmetrical

**Figure 24.** The RF pulse sequence (a), PFG sequence (b) and coherence pathway (c) in the gs-SELINCOR experiment.

The technique employs a  $180^\circ$  carbon selective pulse with a selected coherence pathway (solid line). d1 is the relaxation delay; p1, p3 and p4 are the  $90^\circ$  pulses; p2 and p5 are the  $180^\circ$  proton pulses; p6 and p9 are the  $180^\circ$  carbon pulses; p7 is the  $180^\circ$  carbon selective pulse; p8 is the  $180^\circ$  carbon pulse; g1–g4 are sinusoidal pulsed gradients; and dec is the decoupling.

**Figure 25.**  $^1\text{H}$  NMR spectra of saccharose obtained using different versions of the gs-HSQC pulse sequence.<sup>174</sup> HSQC-ROESY (a), HSQC-NOESY (b), HSQC-TOCSY (c), HSQC+2 RELAY (d), HSQC+3 RELAY (e), HSQC+4 RELAY (f), HSQC-COSY+r+z (g) (r is refocussing, z is filtering), HSQC-COSY (h), HSQC-lr (i) (lr is long range), HSQC/D (j), HSQC/C (k), and HSQC (l). The furanose and pyranose ring hydrogens are labelled by the unprimed and primed figures, respectively.

molecules. The effect can be detected using the SELINCOR technique followed by NOE transfer. Two protons can be discriminated<sup>175</sup> by allowing one of them to couple with  $^{13}\text{C}$ . Pulsed field gradients can also be used provided that the spin-spin coupling constant is allowed. This permits measurement of proton-proton couplings when the proton signals are overlapped or masked by other signals.<sup>137</sup>

In addition to the methods shown in Fig. 25 there is yet another method of determination of the magnitude and sign of C-H coupling constants. The technique named  $\alpha/\beta$ -gs-SELINCOR-TOCSY<sup>176,177</sup> is a version of the approaches considered above.

The SELINCOR sequence can be modified with two 'soft' pulses. The first pulse excites a proton-decoupled carbon signal and the second one determines the spin state. The last ( $^1\text{H}$ ) pulse in the HSQC sequence creates multiple-quantum coherences ( $I^+S^+$ ,  $I^-S^+$ ,  $I^+S^-$  and  $I^-S^-$ ).

The method takes into account selective creation of the coherence of the protons coupled to a particular carbon atom (in the  $\alpha$ - or  $\beta$ -spin state). Then, the MLEV-16 composite pulse transfers this coherence from the protons to the carbon atom during the time interval between the second and third pulses of the TOCSY sequence. Proton coherence created using the  $\beta$ -gs-SELINCOR technique will be distributed over all protons belonging to the same coupled system. All proton signals are filtered and the separation between them is equal to the halved long-range H-C spin-spin coupling constant. Determination of this spin-spin coupling constant requires setting the time interval between corresponding signals.

Heteronuclear NOE effects can be useful in structural analysis of natural compounds. Traditionally, these effects are studied by either 2D HOESY spectroscopy or 1D NMR spectroscopy using selective irradiation of certain protons and measurement of the heteronuclear difference NOE spectrum. The use of magnetic field gradient pulses permits suppression of signals of the  $^{12}\text{C}$ -coupled protons to such a degree that weak heteronuclear NOE effects will be observed in proton detection. Besides, proton detection provides a sensitivity gain. The method based on the use of both selective RF pulses and PFG was introduced by Stott and Keeler<sup>178</sup> and named HETGOESY (Heteronuclear Gradient Overhauser Effect Spectroscopy). The main pulse sequence employed in this technique is shown in Fig. 26. The vitality of the technique was proved in studies of gibberellic acid. The

p16 is the 180° phosphorus selective pulse. The g1 and g2 gradients are applied in the echo–antiecho method.

approach provides a way of solving one of the most stubborn problems, namely, signal assignment of quaternary carbon atoms.

Often, the subjects of biochemical studies and investigations of organometallic compounds are molecules containing more than one atom (nucleus Y) in the heterocycle. Such molecules can be studied by 3D NMR spectroscopy using 3D <sup>1</sup>H NMR spectra and the <sup>13</sup>C and <sup>31</sup>P frequencies (see Refs 178–181). However, this technique is very time-consuming and offers a limited resolution. A selective triple resonance (SELTRIP) experiment<sup>181</sup> combines a 2D HSQC NMR technique and a selective 90° (Y) pulse in order to reduce the dimension of the problem to 2D. A modified version (gs-SELTRIP) of SELTRIP experiments is illustrated in Fig. 27.<sup>182</sup>

## IX. Two-dimensional correlation experiments based on heteronuclear *J*-cross-polarisation

Modern versions of the HSQC method<sup>183</sup> can be used in multi-dimensional NMR experiments based on the same principles. A widely used, improved HSQC–PEP (Pulse Enhancement Polarisation) scheme<sup>184</sup> offers the following advantages: (i) coherence selection by PFG; (ii) a maximum sensitivity and optimisable resolution obtained by combining the echo–antiecho and PEP techniques; (iii) efficient suppression of solvent signals, achieved either using PFG (solely) or water flip-back; (iv) wide use of various pairs of NMR active nuclei; (v) applicability to both natural abundance studies of natural compounds and investigations of labelled biomolecules; and (vi) flexibility in incorporating new modules into the pulse sequence.

Design of modified HSQC techniques for selective manipulation of the spin state  $\alpha$  and/or  $\beta$  has become a fruitful approach in multidimensional NMR spectroscopy. For instance, the well-known Exclusive Correlation Spectroscopy (E.COSY)<sup>185</sup> is widely used in the determination of homonuclear and heteronuclear spin–spin coupling constants in labelled biomolecules. To determine the sign and magnitude of very small spin–spin coupling constants, one has to measure the relative offset between cross-peaks corresponding to the spin states  $\alpha$  and/or  $\beta$  in the E.COSY spectra. Recently, numerous versions of the HSQC

method have been reported, which allow selection of only  $\alpha$  or only  $\beta$  spin state in individual 2D NMR spectra. A simple example is provided by HSQC- $\alpha/\beta$  experiments,<sup>186</sup> in which the second part of the retro-INEPT pulse sequence of a conventional HSQC–PEP experiment<sup>187</sup> is shortened to a single 90° pulse. This shortened module selects two different coherences, one in the form of an in-phase multiplet and the second in the form of an antiphase multiplet. Simultaneous addition or subtraction of this coherence before the data acquisition stage permits selection of the  $\alpha$ - or  $\beta$ -component, respectively, with retention of maximum sensitivity. This experiment allows one to obtain edited 2D correlation NMR spectra containing only one of the two multiplet signals. The spin state can be selected during the indirect evolution time; this is a coupled edited <sup>1</sup>H–X correlation NMR experiment named  $\alpha/\beta$ -HSQC (or IPAP experiment).<sup>188</sup> The major advantage of this method is that transverse relaxation during indirect X-measurement is not as critical as in the case of <sup>1</sup>H-measurement in studies of large biomolecules. Both approaches can be combined in a single  $\alpha/\beta$ -HSQC- $\alpha/\beta$  experiment, with the best example provided by the popular TROSY technique.<sup>189</sup> NMR experiments with editing are widely used for measuring scalar and residual dipolar coupling constants and specifying basic principles of modern NMR methods of structural and dynamics studies of large biomolecules in high-strength magnetic fields.

Correlation NMR experiments provide an attractive alternative to conventional HSQC experiments.<sup>190</sup> A feature of the pulse sequences proposed in that study is the use of heteronuclear cross-polarisation (HCP) for the magnetisation transfer from nucleus X to <sup>1</sup>H and/or from <sup>1</sup>H to X instead of a conventional INEPT sequence. The idea of using HCP in studies of isotropic fluids is not new. Relevant theoretical aspects have been documented (see, e.g., Refs 191 and 192), including applications to protein<sup>193</sup> and nucleic acid studies.<sup>194</sup> During the last decade, analogous NMR experiments (HMQC and HSQC) have been routine tools in studies of both small molecules and large labelled and unlabelled biomolecules.

Unlike free precession <sup>1</sup>H–X-correlation experiments, HCP-experiments are based on synchronous application of two magnetic fields to both nuclei, <sup>1</sup>H (spin *I*) and X (spin *S*), and on achievement of maximum heteronuclear coherence transfer provided that the so-called Hartmann–Hahn condition is met.<sup>195</sup>

According to theoretical predictions, the HCP-based experiments<sup>190</sup> must exhibit a maximum sensitivity due to selection and combination of two different magnetisations. The anisotropy of heteronuclear coherence transfer involving HCP mixing processes is demonstrated by strong dependence of the transfer mechanism on the relative phase between the input magnetisation and the HCP mixing sequence. A number of similar pulse schemes have been designed for simple and selective manipulation of various coherences available before and after the HCP mixing. Such schemes are characterised by high sensitivity, good stability to RF field inhomogeneities, better (compared to HSQC experiments) behaviour of the spin system in the relaxation and chemical exchange processes, versatility and possibility of being slightly modified.

The use of novel, optimised, ultrabroadband heteronuclear cross-polarisation sequences including improved multiple-pulse sequences or adiabatic pulses and HCP-based strategies presents an alternative to the most popular HSQC pulse schemes. In addition, various HCP modules can be incorporated into multi-dimensional NMR experiments as efficient preparation and mixing modules.

## X. Combined use of selective and non-selective excitation in NMR experiments

A method of studying molecular dynamics processes was proposed.<sup>196</sup> The technique involves excitation of a single nucleus in a coupled spin system using the Multiplet-Selective Excitation (MUSEX) pulse sequence.<sup>197</sup> The usefulness of the method

**Table 5.** Versions of the MUSEX COSY technique.<sup>196</sup>

| Version                   | Pulse sequence                                                                                                                                                         | 2D spectral pattern |

| SP(A)–NSP<br>MUSEX COSY   | $90_x^\circ(A) - t_1 - 90_x^\circ - t_2$<br>$\sigma_4^{\text{expl}} = I_{Ay} S_A^1 C_J^1 S_A^2 C_J^2 +$<br>$+ I_{By} S_A^1 S_J^1 S_B^2 S_J^2 - I_{By} C_B^2 C_J^2$     |                     |
| SP(A)–SP(A)<br>MUSEX COSY | $90_x^\circ(A) - t_1 - 90_x^\circ(A) - t_2$<br>$\sigma_4^{\text{expl}} = I_{Ay} C_A^1 S_J^1 C_A^2 S_J^2 +$<br>$+ I_{Ay} S_A^1 C_J^1 S_B^2 C_J^2$                       |                     |
| SP(A)–SP(B)<br>MUSEX COSY | $90_x^\circ(A) - t_1 - 90_x^\circ(B) - t_2$<br>$\sigma_4^{\text{expl}} = -I_{Ay} C_A^1 C_J^1 C_A^2 C_J^2 +$<br>$+ I_{Ay} S_A^1 C_J^1 S_B^2 C_J^2 - I_{By} C_B^2 C_J^2$ |                     |

**Note.** Here and in Table 6 we use the following notations: NSP is the non-selective pulse; SP(A(B)) is the selective pulse exciting the A or B nuclei, respectively;  $C_{A(B)}^{1(2),\tau} = \cos \Omega_{A(B)} t_{1(2)}$ ;  $C_J^{1(2),\tau} = \cos \pi J_{AB} t_{1(2)}$ ;  $S_{A(B)}^{1(2),\tau} = \sin \Omega_{A(B)} t_{1(2)}$ ;  $S_J^{1(2),\tau} = \sin \pi J_{AB} t_{1(2)}$ ; filled circles in the 2D spectral patterns denote positive intensity;  $t_1$  and  $t_2$  are variable time intervals, and  $\tau$  is a constant time interval.

consists of minimisation of information loss on the spin–spin coupling, which favours simplification of detection technique and signal assignment in spin systems. This requires experiments with combined selective and non-selective excitation.

Consider the behaviour of a weakly coupled AB spin system under the action of a two-pulse MUSEX COSY sequence.<sup>196</sup> The case of two non-selective pulses presents a well-known conventional COSY experiment.<sup>4,197</sup> It is of interest to consider all possible combinations of selective and non-selective pulses. Table 5 schematically depicts 2D NMR spectra with explicitly observable components.

NSP–SP(A) MUSEX COSY experiments allow the NMR spectral pattern to be simplified without loss of information on the spin–spin coupling (here,  $J$ -cross-peaks are absent because of selective excitation).

The SP(A)–SP(A) MUSEX COSY technique can be implemented in EXSY experiments used in chemical exchange studies.

The SP(A)–SP(B) MUSEX COSY method can be useful for obtaining information on the spin–spin coupling between any two spins in a multiple-spin system.

Non-selective NMR spectra often include a number of regions with overlapped multiplet signals, which leads to ambiguity in the interpretation of such spectra. A particular value of the approach<sup>196</sup> is the possibility of avoiding this ambiguity. MUSEX experiments allow the size of the data array to be reduced and the duration of experiments to be shortened. The techniques mentioned above are applicable to all types of 2D experiments. Table 6 lists all observable components for spin A and provides their schematic representation in the form of a 2D NMR spectrum for the three-pulse sequences containing a complete set of possible combinations of non-selective and multiplet-selective pulses. Excitation of spin B gives rise to an axial doublet in the NMR spectrum. A distinctive feature of the experiments consists of the use of alternating spin excitation (ALEX) using the MUSEX

**Table 6.** 2D subspectral patterns.<sup>196, 198</sup>

| Number | Pulse sequence                                                     | 2D spectral pattern |
|--------|--------------------------------------------------------------------|---------------------|
| 1      | $90_x^\circ(B) - t_1 - 90_x^\circ(A) - \tau - 90_x^\circ(A) - t_2$ |                     |
| 2      | $90_x^\circ(A) - t_1 - 90_x^\circ(A) - \tau - 90_x^\circ(B) - t_2$ |                     |
| 3      | $90_x^\circ(B) - t_1 - 90_x^\circ(B) - \tau - 90_x^\circ(A) - t_2$ |                     |

**Note.** Open circles in the 2D spectral patterns denote negative intensity.

sequence. All calculations were carried out using the operator product formalism, as in the MUSEX COSY method.

The pulse sequences 1 and 2 allow visualisation of each coupling in a multiplet system. The pulse sequence 1 can be used in a stepwise manner for identification of all coupled partners in a complex spin system, because the MUSEX COSY experiments allow all couplings to be followed simultaneously. The pulse sequence 2 is convenient for studying relaxation mechanisms. The resulting NMR spectrum (pulse sequence 3) exhibits a spin-A diagonal peak appearing as a result of interference of eight components, of which four components are single-quantum coherences and the remaining components were transferred from double-quantum and zero-quantum coherences. In this case the first two pulses represent the ALEX COSY technique and the last B-nucleus pulse is used as the detection pulse. With an appropriately adjusted phase, two resonance lines for the diagonal peaks can disappear, thus leaving only diagonal lines.

\* \* \*

At present, NMR spectroscopy offers a variety of methods which permit identification and investigation of the structure and dynamics of complex biomolecules and biosystems. Advantages in these studies are to a great extent due to both design of new hardware and the use of various selective methods. Combining radiofrequency pulses and magnetic field gradient pulses allowed a number of problems arising in the experiments with selective pulses (in particular, the problem of selection of desired coherences) to be solved. One can expect that some of these methods will become routine techniques in NMR spectroscopy of organic compounds, because often they give a fast and detailed answer to those questions that were unanswerable a few years ago.

The review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 03-03-32296, 04-03-96807 and 04-03-81028).

**Abstract.** Data on the synthetic routes to substituted 1,2,3-triazoles, including those containing functional groups, based on cyclisation of various nitrogen compounds published during the last 15 years are described. Examples of using new triazole derivatives in agrochemistry, medicine and engineering are given. The bibliography includes 583 references.

## I. Introduction

The 1,2,3-triazole (*v*-triazole) heterocyclic system has been known for more than one hundred years. The synthesis of the first representatives of these compounds was reported in the late 19th century by Pechmann;<sup>1</sup> during the subsequent decades, several routes to various substituted triazoles, including polyfunctional ones, have been developed. The results of synthetic studies have been reported in a number of publications, the most recent of which are reviews;<sup>2–19</sup> the structures, properties and chemical transformations of 1,2,3-triazole and its derivatives are considered in some sections of monographs.<sup>14, 20, 21</sup> In the last two decades, the chemistry of 1,2,3-triazoles has gained a new impetus to the development due to the discovery of diverse biological activities of many triazole derivatives. The number of patents dealing with the use of these derivatives as drugs and agrochemicals has grown. This has attracted the attention of researchers to the development of new and perfection of the known methods for the synthesis of triazole derivatives.

The triazole ring itself is relatively stable, which allows one to carry out various chemical modifications of substituents and functional groups. These modifications are usually carried out by standard synthetic methods, which are fully reflected in the monographs cited above. However, on treatment with strong bases or highly nucleophilic reagents (as well as on thermolysis and photolysis), the triazole ring can open to give reactive intermediates, which undergo diverse chemical transformations to yield new carbo- and heterocyclic structures.<sup>22</sup> These problems

are considered in a large number of publications from the last decade, for example, the works.<sup>23–37</sup>

This review covers the data dealing with the formation of the 1,2,3-triazole ring published mainly from 1986 to 2002.

The methods of formation of a heterocyclic system are usually considered in terms of the closure of particular bonds in pre-arranged structural blocks. Within the framework of this approach, the information on triazole synthesis can be classified into four sections dealing with the methods of formation of particular bonds of the triazole ring, namely, the N(1)–N(2), C(5)–N(1) [or C(4)–N(3)], C(5)–N(1) and C(4)–N(3) bonds; and the C(4)–C(5) and N(1)–N(2) bonds.

In some cases, researchers propose original methods for the synthesis of triazole systems. However, by considering the step-wise mechanisms of relevant reactions, one can often assign them formally to one of the above groups.

## II. Methods of formation of the N(1)–N(2) bond

### 1. Condensation of amines with $\alpha$ -diazocarbonyl compounds

A possible way of formation of a triazole ring is the reaction of amines with  $\alpha$ -diazodicarbonyl compounds, which proceeds through intermediate  $\alpha$ -diazoidimines. Since  $\alpha$ -diazoidimines are highly reactive, they readily cyclise into isomeric 1*H*-1,2,3-triazoles even during their synthesis. The diazo derivatives of 1,3-dicarbonyl or other compounds with an active methylene group can act as triazole precursors.<sup>38</sup>

The simplest derivative of  $\alpha$ -diazo- $\beta$ -oxoaldehydes, namely, the diazo derivative of malonodialdehyde, condenses with aniline hydrochloride to give 1-phenyltriazole-4-carbaldehyde in a high yield.<sup>39</sup> However, other  $\alpha$ -diazo- $\beta$ -oxoaldehydes have long been poorly accessible. It has been found recently<sup>40</sup> that 2-azido-1-ethylpyridinium tetrafluoroborate transfers the diazo group onto various  $\beta$ -oxoaldehydes **1** in the presence of bases with retention of the aldehyde function. These reactions underlay a general method for the synthesis of  $\alpha$ -diazo- $\beta$ -oxoaldehydes **2**, which were used to prepare 1-substituted 4-acyltriazoles **3**.<sup>41–45</sup> The diazomethyl ketone  $R^1C(O)CH=N_2$  impurity formed at the diazotisation stage did not influence the subsequent synthesis of acyltriazoles. Ammonia, aliphatic and aromatic amines, hydroxylamine and semicarbazide were involved in the condensation with  $\alpha$ -diazo- $\beta$ -

*Uspekhi Khimii* 73 (4) 369–410 (2005); translated by Z P Bobkova

oxoaldehydes.<sup>41</sup> An advantage of this method is the formation of only one regioisomer, because condensation is directed at the more electrophilic formyl group rather than the acyl group. With hydroxylamine or semicarbazide, triazole oximes or semicarbazones **3** are formed in some cases

$R^1 = \text{Me, EtO, 2,4-Cl}_2\text{C}_6\text{H}_3, 2,4\text{-Br}_2\text{C}_6\text{H}_3$ ;  $R^2 = \text{H, Pr}^i, \text{Bu}^i, \text{Ph, 1-naphthyl (Naph), 4-ClC}_6\text{H}_4, 2,4\text{-Cl}_2\text{C}_6\text{H}_3, 3,4\text{-Cl}_2\text{C}_6\text{H}_3, 2,4\text{-Br}_2\text{C}_6\text{H}_3, 2,4,6\text{-Me}_3\text{C}_6\text{H}_2, \text{HO, EtO, NH}_2\text{CONH}$ .

When diazo  $\beta$ -oxoesters **4** react with hydroxylamine<sup>46</sup> or with aniline and methylamine,<sup>47</sup> the ester group is retained in the triazole **5** molecule.

$R = \text{Me, Ph, OH}$ .

This method has also been used to prepare hetaryltriazoles, for example, methyl 1-(5-pyrazolyl)triazole-4-carboxylate.<sup>48</sup>

Carbonyl derivatives of  $\alpha$ -diazooacetonitrile **6** [ $X = \text{RC(O)}$ ] readily cyclise under the action of hydrogen halides to give 4-acyl-5-halotriazoles **7**,<sup>49</sup> the yields of which (45%–94%) depend on the nature of the halogen and the substituent. This method was used to prepare 5-chlorotriazole derivatives with amide, urethane,<sup>50</sup> and phosphoryl groups.<sup>51</sup>

$X = \text{RC(O)}$ :  $\text{Hal} = \text{Cl, Br, I}$ ;  $R = \text{EtO, NH}_2, \text{MeNH, Ph}$ ;  
 $X = (\text{RO})_2\text{P(O)}$ :  $\text{Hal} = \text{Cl}$ ;  $R = \text{Me}$  (62%),  $\text{Et}$  (86%).

Detailed study of the reaction has shown that the scope of its application is limited to diazo compounds that have only  $\alpha$ -carbonyl or  $\alpha$ -phosphoryl groups.<sup>52</sup> The reaction mechanism formally includes two steps, in particular, the addition of hydrogen halide to  $\alpha$ -carbonyldiazonitrile to give intermediate  $\alpha$ -diazohalimine, which then undergoes a heteroelectrocyclic process yielding 5-halotriazole. In essence, cyclisation of  $\alpha$ -carbonyldiazonitriles can be considered as a series of tandem pseudopericyclic processes.<sup>52</sup>

Triazoles can be obtained from  $\alpha$ -aminodiazocompounds if the molecule does not contain any other nucleophilic centres. For example, the cyclisation route of diazo(lithio)trimethylsilylmethane **8** depends on the nature of the substituent  $X$ : for  $X = \text{Alk}$  or  $\text{Ar}$ , the reaction gives 4-trimethylsilyltriazoles **9**, while in the

presence of electron-withdrawing substituents, 3-trimethylsilyltriazoles **10** are formed most often.<sup>53, 54</sup>

$R^1 = \text{Me, Ph}$ ;  $R^2 = \text{Et, Ph}$ ;  $X = \text{Alk, Ar, Ac, EtO}_2\text{C, NC, PhSO}_2, (\text{EtO})_2\text{PO}$ .

Recyclisation of 4-oxypyrido[*a*]pyrimidinyldiazonium **11** in the presence of alcoholates resulting in alkyl 1-(2-pyridyl)triazole-4-carboxylates **12** can be assigned to the same type of reaction.<sup>55</sup>

$R = \text{Me, Et, Pr}^n, \text{Bu}^n, n\text{-C}_5\text{H}_{11}$ .

Similarly, 3-amino-4*H*-pyrimido[1,2-*b*]pyridazin-4-ones are converted into the corresponding 1-(pyridazin-2-yl)triazole-4-carboxylates.<sup>56</sup> Diazotisation of 7 $\beta$ -aminocephalosporin sulfones also gives a 1,2,3-triazole derivative. The opening of the  $\beta$ -lactam ring and the attack by the diazonium cation on the nitrogen atom are the key steps in this process.<sup>57</sup>

Cyclisation of diazo compounds of this type containing amide, amidine or imidate groups is a convenient method for the preparation of polyfunctional derivatives of triazole. An example is the synthesis of 4-substituted 1-(arylideneamino)triazol-5-olates **13**.<sup>58</sup>

$\text{Ar} = 4\text{-FC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$ .

If the molecule of the diazo compound contains a cyano group, apart from the above-listed groups, base-induced cyclisation occurs through attack by the terminal nitrogen atom of the diazo group on the nucleophilic nitrogen atom of the amide to give 4-cyanotriazol-5-olates **14**. When primary amines are used, amine addition to the cyano group takes place giving rise to  $\alpha$ -diazo-*N*-alkylamidines **15**, whose cyclisation involves the amidine nitrogen atom and results in 1-alkyl-5-amino-4-carbamoyltriazoles **16**.<sup>59</sup>

Cyclisation of amidine **17** containing different substituents at nitrogen atoms affords either one of isomers **18**, **19** or their mixture, depending on the nature of the radicals  $R^1$  and  $R^2$  (see Ref. 60).

$R^1 = \text{H, Me; } R^2 = \text{Me, Bn, 2-Py, 4-MeC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4$ ;  
 $Y = \text{NH}_2, \text{MeNH, EtO}$ .

For example, in the case of  $R^1 = \text{H}$ ,  $R^2 = \text{Bn}$ , and  $Y = \text{NH}_2$  regioisomer **18** is formed in 74% yield, while with  $R^2 = 2\text{-pyridyl}$ , the reaction route changes, triazole **19** becoming the predominant product (yield 83%). In the case of  $R^1 = \text{Me}$ ,  $R^2 = \text{Bn}$ ,  $Y = \text{NHMe}$ , the reaction mixture contains both isomers (yield 56%).<sup>60</sup>

Triazoles **20a** and **21a** have been prepared through the  $\alpha$ -diazomalonamide derivative of cyanoacetic acid *N*-benzylidenetriazide<sup>61</sup> using the transformation sequence shown in Scheme 1 (pathway *a*).

Similar 2-(*N*-methylcarbamoyl)- (**22b**) and 2-ethoxycarbonyl derivatives (**22c**) react with tosyl azide and sodium ethoxide immediately to give sodium salts of hydroxytriazoles **21** (pathway *b*) rather than intermediate diazo compounds.<sup>61</sup> The use of diazo transfer to these hydrazides is impossible due to a side reaction involving the hydrazide group. However, arylmethylidene-protected acetohydrazides react with tosyl azide (pathway *c*) to be smoothly converted into the sodium salts of 1-(arylmethylidene-amino)hydroxytriazoles **20b,c**.<sup>62</sup> It has been noted that in the case of carbamoyl derivatives, no isomeric triazoles resulting from

cyclisation at the nitrogen atom of the amide group are formed. Acidification of aqueous solutions of sodium salts yields 5-hydroxytriazoles, which occur in equilibrium with the open forms of diazo compounds.<sup>63–65</sup> After removal of the benzylidene protection and upon acidification, 1-aminotriazoles **21a–c** also mainly exist as the open form of diazo compounds.<sup>59</sup>

The mechanism of heterocyclisation of 2-cyanoacetamides into 5-hydroxytriazoles has been studied in detail.<sup>66,67</sup> It was shown that 2-diazo-2-cyanoacetamides undergo partial cyclisation on refluxing in ethanol in which the equilibrium between the cyclic and open forms is rapidly established, whereas in the case of diazomalonodiamide, the equilibrium is established very slowly. In polar solvents, the equilibrium shifts towards cyclic forms. The position of the equilibrium depends only slightly on the electronic and steric properties of the substituent at the carboxamide nitrogen atom, although electron-withdrawing substituents have been noted to destabilise to some extent the cyclic structure.<sup>67</sup> On the basis of experimental values of the activation energy of the cyclisation, the  $\rho$  reaction parameters and the kinetic isotope effects, together with the results of theoretical calculations, it has been concluded that the cyclisation mechanisms of *N*-aryl and *N*-alkyl derivatives of diazocynoacetamides are different. In the former case, the reaction starts with proton elimination from the amide nitrogen atom of *N*-aryl derivatives **23** to give imidolate anion **24**, which then isomerises and cyclises into triazolate anion **25** by an electrocyclic mechanism. The process ends in the protonation of the triazolate anion to give 5-hydroxytriazole.<sup>67</sup> These transformations have been considered in a review.<sup>68</sup>

$\text{Ar} = \text{Ph, 4-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 4\text{-EtO}_2\text{CC}_6\text{H}_4$ .

Apparently, cyclisation of *N*-sulfonyldiazomalonamides [ $\text{ArSO}_2\text{NHCOC}(=\text{N}_2)\text{CONHSO}_2\text{Ar}$ ] to 1-sulfonyltriazoles occurs in a similar way.<sup>69</sup>

Meanwhile, in the case of *N*-alkyl derivatives **26**, which have a lower NH-acidity, the substituents rotate around the C–N bond to give cyclic zwitterionic structure **27** (monorotatory mechanism).<sup>67</sup>

Scheme 1

$X = \text{CN, Y} = \text{NH}_2$  (**a**);  $Y = \text{H; } X = \text{MeNHC}$  (**b**),  $\text{CO}_2\text{Et}$  (**c**).

Alk = H, Me, n-C<sub>6</sub>H<sub>13</sub>, Bn.

Proceeding from the ability of triazoles to undergo easy cleavage of the heterocycle to be converted into linear diazo compounds, researchers<sup>64,69</sup> have developed a method for the synthesis of 4-substituted 1-alkyl-5-hydroxytriazoles **28** from more readily available 1-aryl derivatives **29**.<sup>65,70</sup> The rearrangement proceeds on refluxing the starting triazole in ethanol and includes the following steps: triazole ring opening, isomerisation of diazoacetamide and triazole ring closure.

The ability of 5-amino-1,2,3-thiadiazoles to isomerise into 5-mercaptotriazoles has been used in the synthesis of 1-amino-4-R-5-thiolates **30** from the corresponding 5-chlorothiadiiazoles **31** on treatment with excess hydrazine.<sup>71–73</sup> In the case of the ethoxycarbonyl derivative **31c**, the reaction proceeds at room temperature, whereas for derivatives **31a,b**, replacement of the chlorine atoms in thiadiazole requires heating. When the resulting thiolate **30** is treated with an acid, triazole ring transformation takes place to give hydrazinothiadiazole.<sup>71</sup>

R = H (a), Ph (b), CO<sub>2</sub>Et (c).

On treatment of 5-morpholino-1,2,3-thiadiazole-4-carbaldehyde with primary amines, the imine readily undergoes the Conforth rearrangement, being converted into 1-R-4-morpholinothiocabonyl-1,2,3-triazole.<sup>74</sup> The tandem Conforth rearrangement was carried out in the reaction of thiadiazole-4-carbaldehyde **32** with 1-amino-4-carbamoyltriazol-5-olate **33**.<sup>75</sup>

Recently, a new method for triazole synthesis has been reported in which the heterocycle is formed *via* diazo transfer.<sup>76</sup> Using the reaction of 3-diazo-2-one (**34**) with N-substituted enaminocarbonyl compounds **35** as an example, a process mechanism has been proposed.

R = Me, Bu<sup>t</sup>; X = Me, EtO; a is PhH or PhMe,  $\Delta$ .

This reaction has been carried out for not only various enaminones,<sup>76</sup> but also for 3-diazo derivatives of 5-nitrooxyindole, 1-methyl-5-nitro-oxyindole and 5,7-dinitro-oxyindole as substrates.<sup>76,77</sup>

## 2. Cyclisation of nitrogen derivatives of 1,2-dicarbonyl compounds

This pathway to 1,2,3-triazoles was first proposed by Pechmann<sup>78</sup> and later developed by many researchers. It was shown that heating bishydrazones or bissemicarbazones of  $\alpha$ -dicarbonyl compounds in the presence of oxidants such as MnO<sub>2</sub>, HgO, Hg(OAc)<sub>2</sub>, FeCl<sub>3</sub>, NiO<sub>2</sub>, CuCl, CuSO<sub>4</sub>, and Pb(OAc)<sub>4</sub> gives rise to substituted triazoles. The process includes the complexation stage and subsequent cyclisation in which a metal compound in a reduced state is eliminated. The transformations of  $\alpha$ -diketone bissemicarbazones **36** into 1-ureidotriazoles **37** on treatment with lead tetraacetate has been studied:<sup>79</sup>

R = H, Me, Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-BrC<sub>6</sub>H<sub>4</sub>.

The product yields in this cyclisation are usually relatively low. Despite a number of modifications, this method has not received wide use.<sup>2</sup> Nevertheless, substituted 2H-triazoles can be synthesised in this way.<sup>14,15</sup> Thus the oxidation of glyoxal phenylosazone **38** yields bis(phenylazo)ethylene, which is then converted into 2-phenyltriazole **39** on treatment with FeCl<sub>3</sub>, CuCl or CuSO<sub>4</sub>, but the yields do not exceed 50%. The optimal conditions for this

reaction were chosen, namely, heating of a mixture of osazone, CuCl and anhydrous CaCl<sub>2</sub> with continuous evaporation of the product *in vacuo*; the yield of 2-phenyltriazole **39** was thus increased to 75%.<sup>80</sup>

An example of the preparation of bis(triazol-2-yl)-substituted arylenes using  $\alpha$ -diketones and arylenebis(hydrazines) has been reported.<sup>81</sup> Proceeding from D-arabinose osazone, 2-(3-nitrophenyl)-4-( $\beta$ -D-erythrofuranosyl)triazole has been synthesised.<sup>82</sup> The potential of using osazones of low-molecular-weight carbohydrates for the preparation of heterocyclic compounds, including 1,2,3-triazole derivatives, is described in a review.<sup>83</sup>

Heating of aroyl cyanides with phenylhydrazine (ratio 1 : 2) results in 4-amino-5-aryl-2-phenyltriazoles **40**.<sup>84</sup> The researchers assume that the reaction proceeds through the formation of intermediate  $\alpha$ -amino- $\alpha'$ -arylglyoxal bis(phenylhydrazones) **41**, which cyclise with the loss of an aniline molecule.

Ar = Ph, 3-MeC<sub>6</sub>H<sub>4</sub>, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

The intermediate product of phenylhydrazine addition at the C $\equiv$ N bond (compound **42**) has been isolated in a similar transformation of 2-oxocycanoacetanilide phenylhydrazones **43**.<sup>85</sup>

The oxidative cyclisation of analogous arylhydrazones of 2-oxocycanoacetamides has resulted in the synthesis of a series of 4-amino-2-aryl-5-cyanotriazoles,<sup>86</sup> and the reaction of acyl cyanides with methylhydrazine gave 4-amino-5-aryl-2-methyltriazoles.<sup>87</sup>

In the case of dimethylglyoxal bishydrazones with *N*-aryl and *N'*-benzoyl groups (compound **44**), oxidation with lead tetraacetate results in rather stable triazole derivatives of the ylide type **45**.<sup>28</sup> These compounds are additionally stabilised due to negative charge delocalisation involving the carbonyl group.

Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

Note that cyclisation of *N*-unsubstituted phenylglyoxal bishydrazones furnishes 1-amino-4-phenyltriazole.<sup>14</sup>

The oxidation of asymmetric dimethylglyoxal aroylhydrazones yielding isomeric *N*-(4,5-dimethyltriazol-1-yl)arylcarboximido acids has been considered.<sup>88</sup> The oxidative cyclisation of bis(acetylhydrazones) of 1,2-dicarbonyl compounds results in the formation of 1-(*N*-acetyl)- and *N,N*-bis(acetylamino)triazoles.<sup>89</sup>

It is noteworthy that cyclisation of the bishydrazones of polyfluorinated diketone **46** induced by bromine or sulfuryl chloride at room temperature gives only 1-amino-4-hexafluoroisopropyl-5-trifluoromethyltriazole **47**.<sup>90, 91</sup>

(a) Br<sub>2</sub>, CH<sub>2</sub>Cl<sub>2</sub>; (b) SO<sub>2</sub>Cl<sub>2</sub>, CaCl<sub>2</sub>.

Cyclisation giving triazole with a more electron-withdrawing group at the 5-position also takes place during the oxidation of (5-hydroperfluoropentyl)glyoxal bishydrazones on treatment with SeO<sub>2</sub>.<sup>92</sup> Under more rigorous conditions, compound **46** was converted into a deamination product, namely, 4,5-disubstituted 2*H*-triazole **48**.<sup>93</sup> The formation of only one regioisomer of 1-phenylsulfonyltetrahydrobenzotriazole is observed in the reaction of methyl derivatives of cyclohexane-1,2-diones with phenylsulfonylhydrazine.<sup>94</sup>

The oxidative cyclisation of  $\alpha$ -arylhyaazono ketone anils affords 1,2-diaryltriazolium derivatives,<sup>95</sup> while that of  $\alpha$ -hydroxyimino ketones results in the corresponding triazole *N*-oxides.<sup>96</sup> This method was used to prepare a series of 5-acyltriazole *N*-oxides **49**.<sup>97</sup>

Y = Ar: X = COMe, C<sub>6</sub>H<sub>5</sub> (**49**); X = Me, Y = ArCO (**50**);  
Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

When *N*-arylhyaazonos of  $\alpha$ -hydroxyimino ketones are used in this reaction, migration of the aroyl group to the oxygen atom takes place in the intermediate *N*-oxides **50** to give triazoles **51**.<sup>98</sup>

The oxidative cyclisation of (*N*-phenylhydrazono)oximes of ethyl acetoacetate on treatment with MnO<sub>2</sub> affords different isomers of 4(5)-methyl-2-phenyl-5(4)-ethoxycarbonyltriazole *N*-oxide depending on the position of the oximino and hydrazono groups in the initial compound.<sup>99</sup> This method has been used to prepare symmetric 4,5-disubstituted 2-phenyltriazole 1-oxides **52**. Cyclisation induced by other oxidants, *i.e.*, *N*-iodosuccinimide or copper sulfate, shows a higher efficiency of the latter compound (the yield exceeds 90% almost in all cases).<sup>100</sup>

R = Ph, 2-MeC<sub>6</sub>H<sub>4</sub>, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 1-Naph, cyclo-C<sub>6</sub>H<sub>11</sub> (Cy).

The same reagent was used to prepare 1-(benzyloxy)triazole **53** from *O*-benzyloxime glyoxal monohydrazones.<sup>101</sup> The possibility of debenzoylation of triazole **53** to give unsubstituted 1-hydroxytriazole was demonstrated.

It is worth noting that 1-hydroxy-1*H*-triazoles and their O-derivatives have attracted the attention of researchers as new condensing reagents in the peptide synthesis, which are able to suppress racemisation and other side reactions. To study the properties of compounds of this class, a series of new 1-hydroxytriazole derivatives have been prepared<sup>46, 102</sup> by different synthetic routes. Alkyl- and aryl-substituted 1-hydroxytriazoles **54** were synthesised by treatment of 1,2-diketone *N*-tosylhydrazone oxime **55** with sodium ethoxide with subsequent short-term refluxing in diglyme.<sup>46</sup>

R = Me, Ph, 4-MeOC<sub>6</sub>H<sub>4</sub>.

This method proved to be inapplicable for the synthesis of 1-hydroxy-1*H*-triazole with an ester group (R = CO<sub>2</sub>Me); this compound was prepared by cyclisation of the oxime of ethyl diazoacetoacetate.<sup>46</sup>

The cyclisation of phenylhydrazone oximes **56** induced by dehydrating agents (Ac<sub>2</sub>O, SOCl<sub>2</sub>) affords 2-phenyltriazoles **57** with an unsubstituted 1-position.<sup>103</sup>

Ar<sup>1</sup> = Ph, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>; Ar<sup>2</sup> = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 2-MeOC<sub>6</sub>H<sub>4</sub>, 2-ClC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 2,4-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>.

Similarly, aroyl glyoxal 1,2-bis(phenylhydrazones) [ArCOC(=NNHPh)CH(=NNHPh), where Ar = Ph, 2-furyl] are converted into 4-aryl-2-phenyltriazoles.<sup>104</sup> This route was used to synthesise 4-nitro-2-phenyltriazole **58** from 2-nitro-2-phenylhydrazonoacetoxime **59**.<sup>105</sup> It is noteworthy<sup>106</sup> that in the oxidative cyclisation {K<sub>3</sub>[Fe(CN)<sub>6</sub>], KOH, dioxane}, this oxime results in triazole with an *N*-oxide group at the 1-position.

However, 2-nitro-2-phenylhydrazonoacetamidoxime forms 4-amino-5-nitro-2-phenyltriazole only on heating with urea.<sup>105</sup> On coupling of 2-nitroacetaldehyde oxime with 1,2,4-triazole-3-diazonium salts followed by the cyclisation of the corresponding hydrazonoacetaldehyde oximes, 4-nitro-2-(1,2,4-triazol-3-yl)-1,2,3-triazoles were prepared.<sup>107, 108</sup>

Several approaches have been proposed to obtain unsubstituted triazole. Harada *et al.*<sup>109</sup> carried out cyclisation of glyoxal monoxime monohydrazone on treatment with acetic anhydride, and the resulting 2-acetyltriazole was subjected to alcoholysis.

Unsubstituted triazole is formed in the reaction of tosylhydrazine with a mixture of ammonia and glyoxal on heating in aqueous methanol<sup>110</sup> or on bubbling ammonia into water or into an organic solvent.<sup>111</sup> A two-step method based on the reaction of dichloroacetaldehyde with sulfonylhydrazines with the subsequent cyclisation of the resulting hydrazone **60** under the action of ammonia has been developed.<sup>112</sup> A drawback of this approach is related to the use of toxic dichloroacetaldehyde and its proneness to polymerisation. The procedure modified by other researchers<sup>113</sup> does not imply the isolation of the intermediate hydrazone and provides triazole **61** (R<sup>2</sup> = H) in 55% yield. By introducing aliphatic, aromatic or heteroaromatic amines into this reaction instead of ammonia, a series of 1-substituted triazoles **61** have been obtained. The solvents used were water, alcohols, acetonitrile, dioxane, DMSO, or DMF.<sup>113, 114</sup>

R<sup>1</sup> = R<sup>3</sup>CO, R<sup>3</sup>SO<sub>2</sub>; R<sup>3</sup> = Me, Et, Pr<sup>n</sup>, Pr<sup>i</sup>, Bu<sup>n</sup>, Ph, XC<sub>6</sub>H<sub>4</sub> (X = Alk, AlkO, Cl, Br, NO<sub>2</sub>); R<sup>2</sup> = H, Alk, Ar, Het.

This method was utilised to prepare 1,1'-bitriazole.<sup>115</sup> 1-Aminotriazole served as the amino component; it was prepared by treatment of arylsulfonylhydrazone of dichloroacetaldehyde with hydrazine hydrate in the presence of Et<sub>3</sub>N (PrOH, 40 °C, yield 65%)<sup>116, 117</sup> or by cyclisation of glyoxal bishydrazone in aqueous hydrogen peroxide in the presence of catalytic amounts of transition metal oxides.<sup>118</sup>

Similarly, reactions of methyl- and benzylamine with 1,1-dichloroacetone tosylhydrazone afford 1-methyl(or benzyl)-4-methyltriazoles in high yields, while the reactions with chloral tosylhydrazone give the corresponding 5-amino-substituted triazoles.<sup>119</sup> The reaction of ω,ω-dichloroacetophenone with tosylhydrazine resulted in 1-tosylamino-4-phenyltriazole (yield 20%).<sup>119</sup>

By the reactions of hydrazones of substituted ω-bromoacetophenones **62** with benzylideneaniline in the presence of Et<sub>3</sub>N, mixtures of aryl-substituted tetrahydrotriazines **63** and 4-aryl-1-phenyltriazoles **64** have been obtained.<sup>120</sup>

Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-BrC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

The thermally induced ring transformation in phenylhydrazones of 3-acetylisoaxazoles **65** to give 4-acetonyl-2-phenyltriazoles **66** can be assigned to the same Section. The subsequent nitrosation, transition of oximino derivatives into arylhydrazones and treatment of these products with PCl<sub>5</sub> yield 2,2'-diaryl-4,4'-bistriazoles **67**.<sup>121</sup> Substituted phenylhydrazones of acetylisoaxazoles undergo the same transformations.

Ar = Ph, 2-ClC<sub>6</sub>H<sub>4</sub>, 3-ClC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 2-BrC<sub>6</sub>H<sub>4</sub>, 3-BrC<sub>6</sub>H<sub>4</sub>, 4-BrC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>; Am<sup>i</sup> is isoamyl.

1-Aryl-4,4-diazidopyrazolin-5-ones **68** open the pyrazoline ring at room temperature in the presence of alkali to give the intermediate hydrazidiazide, which cyclises into 2-aryl-4-carboxy-1,2,3-triazole-5-carboxylic acids with nitrogen extrusion.<sup>122</sup> Subsequently, other researchers have shown that if amines or alkoxides are introduced into the reaction instead of alkali, the reaction gives the corresponding derivatives of acid **69**.<sup>123</sup> The same products can be prepared by the reaction of NaN<sub>3</sub> with arylazovinyl halide **70**, which is formed upon ring opening in dihalopyrazolinone **71** on treatment with bases.

R<sup>1</sup> = Me, Ph; Ar = Ph, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>; X = NH<sub>2</sub>, EtNH, EtO;  
R<sup>2</sup>, R<sup>3</sup> = Alk.

The formation of the triazole ring on heating 1,2-bis(*N*-methoxy-*N*-nitrosoamino)ethane **72** (R<sup>1</sup> = R<sup>2</sup> = H) has been described.<sup>124</sup> On treatment with sodium methoxide, *N*-oxide **73** is converted into 2-hydroxytriazole **74**.<sup>124</sup>

If 1,2-dialkyl-substituted 1,2-bis(*N*-alkoxy-*N*-nitrosoamino)ethanes **72** (R<sup>1</sup> = Alk, R<sup>2</sup> = H) are introduced in this reaction, 4,5-dialkyl-2-hydroxytriazoles **74** (R<sup>1</sup> = Alk) are produced. In the case of tetrasubstituted *N*-alkoxy derivatives **72** (R<sup>1</sup> = R<sup>2</sup> = Alk), the reaction stops after the formation of 1-alkoxy-4,5-dihydrotriazole 2-oxide **73**.<sup>125</sup>

Proceeding from readily available 3,4-dinitrofuroxan, a new method for the synthesis of 4-amino-substituted 5-nitro-2*R*-triazole 1-oxides **75** via *N*-alkylamino derivatives **76** has been developed.<sup>126–128</sup>

R<sup>1</sup> = H, Me, Et, HO(CH<sub>2</sub>)<sub>2</sub>, NC(CH<sub>2</sub>)<sub>2</sub>; R<sup>2</sup> = Me, Et, CH<sub>2</sub> = CHCH<sub>2</sub>.

These transformations occur similarly to the recyclisation of benzofuroxans into 1,2,3-triazole oxides under the action of acylanilide anions.<sup>129, 130</sup>

5-Chloro-1,2,3-thiadiazole-4-carbaldehyde reacts with a number of amines to give 1-substituted triazole-4-thiocarboxamides **77**. The mechanism proposed for ring transformation includes the formation of imino derivatives, thiadiazole ring opening at the N–S bond, and triazole ring closure.<sup>131</sup>

R = Me, Et, Bn, Ph, 4-MeOC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, NH<sub>2</sub>, O(CH<sub>2</sub>CH<sub>2</sub>)<sub>2</sub>N.

The mechanism of recyclisation of 3-benzoyl-5-phenyl-1,2,4-oxadiazole arylhydrazones into 2-aryl-4-benzoylamino-5-phenyl-1,2,3-triazoles depends on the nature of substituents in arylhydrazone.<sup>132, 133</sup>

### 3. Cyclisation of *ortho*-disubstituted nitrogen derivatives of aromatic compounds

The presence of two nitrogen-containing functional groups in the *ortho*-position of the benzene ring allows the use of these compounds for construction of the benzotriazole system. Depending on the nature of the groups and the reagents used, the intramolecular cyclisation can yield different substituted benzotriazoles, in particular, *N*-oxides and *N*-hydroxy derivatives.<sup>14</sup> Data on the reductive cyclisation of *o*-nitrophenylazobenzenes **78** into 2-arylbenzotriazoles **79** on treatment with SmI<sub>2</sub> have been published recently.<sup>134</sup> The putative reaction mechanism includes the reduction of the nitro group to the nitroso group, intramolecular cyclisation to give 2-arylbenzotriazole 1-oxide and its subsequent deoxygenation.

R<sup>1</sup>, R<sup>2</sup> = H, Cl; Ar = 2-HO-5-MeC<sub>6</sub>H<sub>3</sub>, 2-HO-3,5-Bu<sub>2</sub>C<sub>6</sub>H<sub>2</sub>.

The electrochemical reduction of 2-hydroxy-5-methyl-2'-nitroazobenzene during the preparation of 2-(2*H*-benzotriazol-2-

Scheme 2

R–R = Me<sub>2</sub>, (CH<sub>2</sub>)<sub>5</sub>, (CH<sub>2</sub>)<sub>2</sub>O(CH<sub>2</sub>)<sub>2</sub>; Ar = Ph, 3,4-Cl<sub>2</sub>C<sub>6</sub>H<sub>3</sub>.

yl)-4-methylphenol (known as the light stabiliser Benazol-P) proceeds in a similar way.<sup>135</sup>

The synthesis of 1*H*,5*H*-benzo[1,2-*d*:4,5-*d'*]bistriazole **80**, which is converted into 1,5- and 1,7-diamino derivatives upon amination, has been accomplished using diazotisation of the diacetyl derivative of tetraaminobenzene.<sup>136</sup>

This method underlies the synthesis of a series of 1-(4-carboxamidotriazol-5-yl)benzotriazoles **81**.<sup>137</sup>

R = H, Me, MeO, F, Cl, CF<sub>3</sub>.

and the regioselective synthesis of 9-substituted 8-azaguanines **82**.<sup>138, 139</sup>

4-Diazopyrazoles **83**, which are prepared by diazotisation of *N*-alkyl-*N'*-(4-aminopyrazol-5-yl)ureas proved to be convenient synthons for the construction of various heterocyclic systems, for example, pyrazolo[4,5-*d*]triazole.<sup>140</sup>

R = Me, Bn.

Diazotisation of 4-dialkylamino-5-aminopyrimidines **84** in an acidic aqueous medium results in opening of the pyrimidine ring followed by attack by the diazo group on a nitrogen atom. This affords triazoles of different structures, depending on the substituent at the 6-position of pyrimidine.<sup>141</sup> For example, in the presence of 6-MeO or 6-ArCH<sub>2</sub>S groups in the pyrimidine ring, only 4(5)-carboxamidotriazoles **85** are formed, whereas in the case of the 6-Cl substituent, cyano- and carboxamidotriazoles have also been isolated as minor products (Scheme 2).

The anodic oxidation of 2-arylazo-3-aminocrotonitrile to 2-aryl-4-cyanotriazole<sup>142</sup> and oxidative cyclisation of pyrazole azo compounds containing an amino group can be assigned to the same type of triazole ring construction.<sup>143</sup>

Het = 2-Py, thiazol-2-yl, pyrazol-5-yl.

A similar method has been used to synthesise derivatives of benzotriazole and more complex fused systems,<sup>144, 145</sup> including those containing several triazole rings, for example, heterocyclic compound **86**.<sup>146</sup>

A review<sup>147</sup> has been devoted to the closure of the triazole ring in 2-acylazine hydrazones. The triazoloazinium cations thus formed tend to undergo cleavage of the six-membered ring on treatment with nucleophilic agents. For pyrimidine **87**, this sequence can be represented as follows:

NBS is *N*-bromosuccinimide.

The transformation of annelated 1,2,4-triazin-3-one into the corresponding 1,2,3-triazole induced by *N*-chlorosuccinimide (NCS) has been described;<sup>148</sup> by analogy with the ring transformations known previously,<sup>149</sup> this process includes *N*-chlorination, azine ring opening and triazole ring closure followed by the removal of chlorine.

A thermal rearrangement of 4,4'-diacetamido-3,3'-azodifuroxans **88** has been detected.<sup>150</sup> The presence of acetamide groups in the starting azodifuroxan was shown to be a necessary condition for this process. According to the reaction mechanism proposed by the researchers, two successive rearrangements take place. The first one is the transformation of one furoxan ring into a 1,2,4-oxadiazole ring with O(1)–N(5) bond cleavage and formation of the nitromethylene fragment, while the second ring transformation gives rise to a new bond of the triazole ring. Isomerisation of the furoxan fragment is possible at the final stage, resulting in the formation of two isomeric products.

R = H, Me.

4-Acetylamino-3-arylazofuroxans undergo the same cascade rearrangement in an alkaline medium to give 2-aryl-4-acetylamino-5-nitro-2*H*-triazoles (Ar = 4-MeOC<sub>6</sub>H<sub>4</sub>, 4-EtOC<sub>6</sub>H<sub>4</sub>, 2,4-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, 2,4,6-Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>),<sup>151</sup> while 4-acetyl(or benzoyl)-3-methylfuroxan phenylhydrazones are transformed on heating into

5-acetyl-4-methyl(or phenyl)-2-phenyl-2*H*-triazole 1-oxide oximes.<sup>152</sup>

The reaction of *vic*-chlorinated 1- or 2-arylaazonaphthalenes with sodium azide can also be ascribed to this type of reaction. In both cases, 2-aryl-2*H*-naphtho[1,2-*c*]triazoles **89** are formed.<sup>153</sup>

Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 2-ClC<sub>6</sub>H<sub>4</sub>, 3-ClC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-BrC<sub>6</sub>H<sub>4</sub>, 2-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 3-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

Triphenylphosphine-induced cyclisation of 2,3-diazo-1,4-naphthoquinone **90** prepared *in situ* has been reported.<sup>154,155</sup> The reaction proceeds smoothly, the yield of 2-aminobenzotriazole **91** being nearly quantitative.

Although the reaction mechanism has not been studied in detail, it is assumed that PPh<sub>3</sub> adds to the terminal nitrogen of the azide group according to the Staudinger reaction type, while the second nitrogen atom of the same group attacks the neighbouring azide group. This is accompanied by elimination of a nitrogen molecule, which is really observed in experiments. Thus, this reaction is similar to thermal and photochemical intramolecular cyclisations of aryl azides which involve neighbouring unsaturated substituents.<sup>154</sup>

### III. Methods of formation of the C(5)–N(1) or C(4)–N(3) bond

This group of reactions includes examples of intramolecular cyclisation of cyano-containing triazenes.

Recently, a new approach to the synthesis of iminodihydrotriazole 1-oxides **92**, namely, KOH-induced cyclisation of cyano-containing aromatic and heterocyclic triazene 1-oxides **93**, has been proposed.<sup>156,157</sup> A possible sequence of transformations includes base-induced formation of an anionic centre on N(3) of the triazene oxide fragment and nucleophilic attack by this centre on the electron-deficient carbon atom of the nitrile group. In the case of 3-(het)aryltriazene 1-oxides containing an active hydrogen atom in the α-position to the cyano and triazene oxide groups, the iminodihydrotriazole 1-oxides **92** (R<sup>1</sup> = H) formed are isomerised into the *N*-oxides of aminotriazoles **94**.

Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-BrC<sub>6</sub>H<sub>4</sub>, 1,2,4-triazol-3-yl; R<sup>1</sup> = R<sup>2</sup> = Me; R<sup>1</sup>–R<sup>2</sup> = (CH<sub>2</sub>)<sub>5</sub>.

Formally, the rearrangement of unstable 1,2,3,4-tetrahydro-1,2,3,4-tetrazine **95**, which is formed upon the reaction of azoalkene **96** with dimethyl azodicarboxylate and is converted into 1,5-dihydro-2*H*-triazole **97** already during the reaction, can also be classified as the method in question for 1,2,3-triazole ring formation. The product **97** eliminates methyl carbamate on treatment with trifluoroacetic acid (TFA) to give 2,4,5-trisubstituted 2*H*-triazole **98** in 80% yield.<sup>158</sup>

#### IV. Methods of formation of two C–N bonds

This group of reactions is used most often to prepare the triazole system and can be exemplified by the largest number of cases. This approach is based on 1,3-dipolar cycloaddition of organic azides to unsaturated compounds.

##### 1. Reactions of azides with substituted acetylenes

The published examples of reactions of azides with alkynes, resulting in triazole derivatives, are rather numerous. It is expedient to start this Section by considering reactions of inorganic azides, which were the first to be used in this method for triazole synthesis. Unsubstituted 1,2,3-triazole was first prepared in a relatively low yield by the addition of HN<sub>3</sub> to acetylene at 100 °C in a sealed tube under an elevated pressure;<sup>159</sup> subsequently, conditions were chosen to bring the product yield up to 86%.<sup>160</sup> Recently, it has been shown<sup>161</sup> that phenylacetylene reacts with dimethylammonium azide to give a mixture of 4-phenyltriazole and 5-phenyltetrazole.

The presence of an amide or an acyl group in phenylacetylene **99** (R = Ph) allows the reaction with sodium azide to be carried out with heating in DMF; the reaction gives 5-amido- or 5-acyl-triazoles **100** (R = Ph), respectively, in high yields.<sup>162–165</sup>

R = Ph; X = NH<sub>2</sub>, CH<sub>2</sub>COAr; Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>;  
R = CH<sub>2</sub>NAIk<sub>2</sub>, X = NH<sub>2</sub>.

In the case of 3-(*N,N*-dialkylaminomethyl)propiolamides **99** (R = CH<sub>2</sub>NAIk<sub>2</sub>, X = NH<sub>2</sub>), carboxamidotriazoles **100** (R = CH<sub>2</sub>NAIk<sub>2</sub>) are also formed. This was used for the design of complex biologically active compounds containing a triazole ring with secondary aminomethyl substituents.<sup>166, 167</sup>

Triazole derivatives have also been synthesised under the same conditions by the reaction of NaN<sub>3</sub> with acetylenic aldehydes,<sup>168</sup>

1-alkylthio-2-chloroacetylenes<sup>169</sup> and esters of long-chain oxoacetylenic fatty acids.<sup>170</sup> The use of hydrogen azide or metal azides in the cycloaddition results in 1,2,3-triazoles unsubstituted at the ring nitrogen atom. However, conduction of these reactions, especially on a preparative scale, is associated with a risk of explosion. The safety aspects for the work with sodium azide on an industrial scale, in particular, in the production of 1,2,3-triazoles, have been discussed in a brief review.<sup>171</sup> The use of trimethylsilyl azide as the reagent reduces the risk and allows one to synthesise 1-trimethylsilyltriazoles, from which the silyl group can subsequently be removed.<sup>172</sup>

The azide group bound in the complex with Mn(I) **101** proved to undergo cycloaddition to dimethyl acetylenedicarboxylate (DMAD) at room temperature. This yields (under kinetic control) 1-triazolate complex **102**, which is converted into thermodynamically more stable 2-triazolate complex **103**.<sup>173</sup> Treatment of this product with HCl results in triazole-4,5-dicarboxylic acid **104**.

The phenylpalladium(II) azide complex shows a similar behaviour in the reaction with DMAD.<sup>174</sup> A series of 2-allyltriazoles have been obtained in a three-component condensation of allyl methyl carbonate, trimethylsilyl azide and a substituted acetylene catalysed by a Pd(0) complex. Presumably, a  $\pi$ -allylpalladium azide complex is formed first; then it undergoes 1,3-dipolar cycloaddition at the triple bond to give 1-( $\eta^3$ -allylpalladium)triazoles; these rearrange to 2-( $\eta^3$ -allylpalladium)triazoles, which are converted into 2-substituted triazoles, formed in moderate yields, through reductive elimination of Pd(0).<sup>175</sup>

The cycloaddition to a triple bond proceeds more easily with organic azides than with inorganic ones, especially when the alkyne molecule contains substituents.<sup>2</sup> This reaction underlies the development of synthetic routes to numerous N-substituted 1,2,3-triazoles. For instance, substituted 1-trityltriazoles have been prepared by the reaction of acetylene with sterically hindered trityl azides carried out by heating in various organic solvents under a pressure of up to 20 kg cm<sup>–2</sup>.<sup>176</sup>

The cycloaddition of aryl azides and benzyl azides to substituted acetylenes containing electron-withdrawing groups proceeds most easily.<sup>18</sup> In the case of symmetric alkynes **105** (X = Y), one product is formed, while the reactions with asymmetric alkynes **105** (X ≠ Y) may yield both regioisomers **106** and **107**.<sup>177</sup>

R = Ph, Bn; X = H, CO<sub>2</sub>Me; Y = Ph, CO<sub>2</sub>Me, CO<sub>2</sub>Et;  
R = 4-C<sub>5</sub>F<sub>4</sub>N; X = H, Y = Ph; R = Ph(CH<sub>2</sub>)<sub>n</sub>; X = H,  
Y = CONHBn; n = 1, 3.

The formation of both regioisomers has also been noted for the reactions of pentafluorophenyl azide and 4-azidotetrafluoropyridine with phenylacetylene<sup>178</sup> and benzyl azide and 3-phenylpropyl azide with acetylenic amides **105** (X = H, Y = CONHBn).<sup>179</sup> In the last-mentioned case, the 1,4-regioiso-

mers **107** were formed in substantially predominant amounts, which was attributed to lower steric strain in these compounds compared to the 1,5-isomers **106**.

Dimethyl acetylenedicarboxylate is often used as the starting alkyne, and then the chemical modification of both ester groups is carried out for the preparation of various 4,5-bifunctional 1-aryl-triazoles.<sup>180–183</sup> Diazido- and triazidomethanes readily react with DMAD to afford bis- and tris(triazol-1-yl)methanes; however, in the latter compound, one triazole ring isomerises (apparently, through a 1,5-sigmatropic CH-shift).<sup>184</sup>

E = CO<sub>2</sub>Me.

Acetylene dicarboxylic acid diamide is much less reactive than DMAD and requires more rigorous conditions to be involved in reactions with organic azides.<sup>18, 179, 185</sup>

The hydroxymethyl and chloromethyl acetylene derivatives **105** (X = Y = CH<sub>2</sub>OH, CH<sub>2</sub>Cl) have been made to react with aryl azides containing various substituents in the ring (Cl, Br, MeO, NO<sub>2</sub>).<sup>180, 186</sup> The functional groups were utilised for further modifications of the triazoles.

The influence of the electronic nature of the substituents in the acetylene molecule on the regiochemistry of the cycloaddition of aromatic azides can be illustrated in relation to the use of phenoxyacetylene and methylpropiolate as dipolarophiles; this results in 1-aryl-substituted 5-phenoxytriazoles<sup>187</sup> and 4-methoxycarbonyltriazoles.<sup>188, 189</sup>

The nitrogen heteroallene cations **108** (1,3-diaza-2-azoniaallene salts) can also enter into cycloaddition with substituted acetylenes, giving rise to 1,2,3-triazolium salts **109**.<sup>190, 191</sup>

R<sup>1</sup> = 4-MeC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 2,4,6-Cl<sub>3</sub>C<sub>6</sub>H<sub>2</sub>; R<sup>2</sup> = R<sup>3</sup> = H, Me, Et, Bu<sup>n</sup>, Bu<sup>t</sup>, HOCH<sub>2</sub>, ClCH<sub>2</sub>, Ph, CO<sub>2</sub>Me.

A large series of 4,5-disubstituted and 4(5)-monosubstituted 1-benzyltriazoles have been prepared on the basis of substituted benzyl azides RC<sub>6</sub>H<sub>4</sub>CH<sub>2</sub>N<sub>3</sub>, where R = H, 2-Me, 3-Me, 4-Me, 3-MeO, 4-MeO, 2-Cl, 3-Cl, 4-Cl, 2-Br, 3-Br, 4-Br, 2-NO<sub>2</sub>, 3-NO<sub>2</sub>, and 4-NO<sub>2</sub>, which were made to react with DMAD, phenylacetylene and ethyl propiolate.<sup>177</sup> It was shown that the reaction of benzyl azides with unsubstituted ethyl propiolate, unlike the reaction with phenylacetylene, is strictly regioselective, giving rise to 1-benzyl-4-ethoxycarbonyltriazoles. However, when a terminal group is introduced into the ethyl propiolate, both regioisomers are formed. Thus the cyclocondensation of ethyl 4-aryl-4-hydroxybut-2-ynoates **110** with 4-methoxybenzyl azide gives, most often, mixtures of ethyl 1-(4-methoxybenzyl)triazole-4(5)-carbox-

ylates **111** and **112** in ~1 : 1 ratio. Only in two cases was the ratio different (3 : 1 for X = NO<sub>2</sub>, Y = U = H, Z = NHAc and 1 : 1.5 for X = NHCOOCH<sub>2</sub>Ph, Y = U = H, Z = CF<sub>3</sub>).<sup>192</sup>

X = NO<sub>2</sub>, NHCO<sub>2</sub>CH<sub>2</sub>Ph; Y = H, Me, MeO; Z = H, Me, CF<sub>3</sub>, MeO, Pr<sup>i</sup>O, NHAc, NHCO<sub>2</sub>Bu<sup>t</sup>; U = H, Me, MeO, Pr<sup>i</sup>O, MeOCH<sub>2</sub>O.

The cyclisation of substituted 2-fluorobenzyl azides with acetylenic acid derivatives **105** (X = H, Y = CO<sub>2</sub>H, CONH<sub>2</sub>; X = Y = CO<sub>2</sub>Me; X = Y = CONH<sub>2</sub>) has been carried out on heating in toluene, dioxane or DMSO.<sup>193, 194</sup>

The influence of solvents on the course of 1,3-dipolar cycloaddition of di-*tert*-butylacetylenedicarboxylate **105a** to substituted benzyl azides and the concomitant transformations of ester groups in the triazole ring has been studied.<sup>195</sup>

Z = H, 2-Me, 3-Me, 4-Me, 3-MeO, 4-MeO, 2-Cl, 3-Cl, 4-Cl, 2-Br, 3-Br, 4-Br, 2-NO<sub>2</sub>, 3-NO<sub>2</sub>, 4-NO<sub>2</sub>; R = Me (**b**), Et (**c**).

It was found that the reaction proceeds much more slowly in boiling benzene or THF than in methanol or ethanol and results in the expected 4,5-bis-*tert*-butyl esters **113** (yields 73%–94%). However, long-term refluxing of functionally substituted benzyl azides (Z ≠ H, Me) in alcohols results in trans-esterification with partial decarboxylation. This affords 4-alkoxycarbonyltriazoles **114**, whose formation has been confirmed by alternative synthesis from alkynes **105b,c** (yields 88%–95%).

Protected acetylenedicarboxaldehydes can be involved in reactions with azides. During the reactions, the acetal protection is removed. For example, bis[(4,5-diformyltriazol-1-yl)methyl]benzene acetal has been obtained from bis(azidomethyl)benzene and acetylenedicarboxaldehyde bis(diethyl acetal).<sup>196</sup>

Using the same azide, bis(triazolylmethyl)benzene has been prepared with dibenzoylacetylene as the dipolarophile.<sup>197</sup> 4,5-Diaroyloxymethyl-1-phenyltriazoles are produced from phenyl azide and symmetric bis(aroxyloxymethyl) derivatives of acetylene **105** (X = Y = CH<sub>2</sub>OCOAr).<sup>198</sup> In the case of monosubstituted acetylenes **105** (X = H; Y = CH<sub>2</sub>OCOAr, CH<sub>2</sub>OAr, CH<sub>2</sub>OH), the reaction gives mixtures of 4- and 5-substituted 1-aryltriazole isomers, for example, compounds **115** and **116** (see the studies<sup>199–201</sup>) with predominance of the former compound.

R = H, Me, F, Cl, Br, I, NO<sub>2</sub>.

Propargylthio derivatives also react with organic azides. 1-Pyrazolyl-2-propargylthiobenzoimidazole was converted into the corresponding triazolylmethylthiobenzoimidazole derivative.<sup>202</sup> The synthesis of 1-[(triazol-1-yl)methyl]-1,5-benzodiazepine by the reaction of 1-propargyl-4-phenyl-1,5-benzodiazepin-2-one with benzyl azide has been reported.<sup>203</sup>

The cycloaddition reaction of substituted trifluoromethylphenylacetylenes with aryl azides **117** showed a high regioselectivity; as expected,<sup>204</sup> the 4-CF<sub>3</sub> regioisomer **118** predominated in all cases. This was confirmed by quantum-chemical calculations for the frontier orbitals of the reacting species.<sup>205, 206</sup>

| R <sup>1</sup>    | R <sup>2</sup>      | The ratio <b>118</b> : <b>119</b> |
|-------------------|---------------------|-----------------------------------|
| 2-Cl              | H                   | 93 : 7                            |
| 4-Cl              | H                   | 82 : 18                           |
| 4-NO <sub>2</sub> | H                   | 72 : 28                           |
| 4-MeO             | H                   | 80 : 20                           |
| 4-NH <sub>2</sub> | H                   | 88 : 12                           |
| 4-NO <sub>2</sub> | 2,6-Cl <sub>2</sub> | 71 : 29                           |
| 4-MeO             | 2,6-Cl <sub>2</sub> | 79 : 21                           |
| 4-Cl              | 4-NO <sub>2</sub>   | 80 : 20                           |

The calculations showed that on introduction of an electron-withdrawing CF<sub>3</sub> group, the reaction obeys orbital control and the transition state leading to regioisomer **118** becomes preferred. It is noteworthy that the theory of frontier orbitals is not always able to predict quantitatively the isomer ratio. For this purpose, it is proposed to calculate the local electron density indices in terms of electron density functional theory, which are sensitive to changes in the chemical potential upon the introduction of substituents.<sup>207</sup>

Although the nature of the substituents in both phenyl groups has little influence on the cycloaddition regioselectivity, it does influence the reaction rate (the presence of electron-withdrawing NO<sub>2</sub> group in the azide molecule retards the process).<sup>204</sup>

The reaction of pentafluorophenylacetylene with aryl azides affords only the 1,4-regioisomer, which corresponds to the electron density distribution in the reacting molecules;<sup>208</sup> the reaction of conjugated trifluoromethyldiacetylenes with phenyl azide involves only one triple bond, which carries the CF<sub>3</sub> group, and also results in one 1,4-isomer.<sup>208</sup>

The similar effect of an electron-withdrawing substituent (CO<sub>2</sub>Alk) at the triple bond of the alkyne on the regioselectivity of cycloaddition with phenyl azide is also observed for methyl 3-phenylpropiolate and methylbut-2-ynoate, which were converted into 4- and 5-methoxycarbonyl-substituted triazoles in 66 : 34 and 70 : 30 ratios, respectively.<sup>209</sup> A similar result has been

obtained in reactions of a chiral azide, 1-[(*R*)-3-azido-3-cyclohexylpropanoyl]pyrrolidin-2-ol, with methyl propiolate and ethyl but-2-ynoate<sup>210</sup> and a number of aryl azides with methyl 4-oxo(or hydroxy)but-2-ynoates.<sup>211, 212</sup> However, in the case of 1-phenylseleno-2-(*p*-tolylsulfonyl)acetylene, triazole with the tosyl group at the 5-position is formed predominantly.<sup>213</sup>

The bulky Me<sub>3</sub>Si group in the acetylene molecule is favourable for the formation of 1-(het)aryl-4-trimethylsilyltriazoles in the reaction of trimethylsilylacetylene **105** (X = H, Y = SiMe<sub>3</sub>) with aryl azides and azido derivatives of seleno(thio)phene.<sup>214, 215</sup> These examples were used to establish the logarithmic dependence of the reaction rate on the pressure and to select the optimal conditions for the preparation of 1,4-disubstituted triazoles (20 °C, ~1 GPa).<sup>216</sup> The presence of the bulky tertiary substituent in the propargylamine **120** molecule is also favourable for the formation of only 4-substituted 1-phenyltriazole **121** in a high yield.<sup>217</sup>

Steric factors may be responsible for the predominant formation of 4-substituted 1-phenyltriazoles upon the reaction of phenyl azide with *tert*-butyl 2-(*tert*-butyloxycarbonylamino)-4-oxohex-5-ynoate<sup>218, 219</sup> and trimethylstannylacetylene.<sup>220</sup> A similar result has been obtained in the reaction of phenyl azide with 3-propargylquinazolones **122**.<sup>221</sup>

R = H, Me, Ph.

Thus, 1,3-dipolar cycloaddition of aliphatic and aromatic azides to terminal alkynes under kinetic control conditions results in the corresponding 1,4-disubstituted triazoles.

The formation of an unusual isomer was detected in the reaction with a symmetrical alkyne. Monitoring of the reaction of the triisopropylsilyl ether of the enol of 3-azido cyclohexanone **123** with DMAD in boiling CH<sub>2</sub>Cl<sub>2</sub> has shown that 1-cyclohexenol triazole derivative **124** is formed initially; after 17 h, the presence of substantial amounts of the 2-isomer **125** can be detected (the yields are 27% and 45%, respectively); after 72 h, only triazole **125** remains in the reaction mixture.<sup>222</sup>

This fact suggests that 1-substituted triazole **124** is ionised under the given conditions followed by recombination of ions into thermodynamically more stable 2-isomer **125**. The suggestion is based on new theoretical and experimental data on triazole<sup>223, 224</sup> and benzotriazole<sup>225, 226</sup> tautomerism.

Cycloaddition of 1-naphthyl azides to symmetrical disubstituted alkynes also proceeds under relatively mild conditions to give 4,5-disubstituted 1-naphthyltriazole **126**,<sup>182</sup> whereas the reaction with asymmetric alkynes yields predominantly 4-substituted 1-naphthyltriazole **127**.<sup>24, 227</sup> Thus in the reaction of 1-naphthyl azide with ethyl propiolate, the yield of the 4-ethoxycarbonyl

derivative **127** ( $R^1 = R^2 = \text{H}$ ,  $R^3 = \text{CO}_2\text{Et}$ ) amounts to 71%, and the yield of 5-regioisomer **128** ( $R^1 = R^2 = \text{H}$ ,  $R^3 = \text{CO}_2\text{Et}$ ) is only 18%.<sup>227</sup>

$R^1 = \text{H}$ , Me;  $R^2 = R^3 = \text{CO}_2\text{Et}$ ;  $R^2 = \text{H}$ ,  $R^3 = \text{CO}_2\text{Et}$ ;  
 $R^2 = \text{Me}$ ,  $R^3 = \text{CO}_2\text{Me}$ .

In the presence of two azido groups located in the *peri*-positions, the reaction with diethyl acetylenedicarboxylate proceeds in several stages: first, two isomeric monotriazolynaphthalenes **129** are formed, the 4-ethoxycarbonyl derivative ( $Y = \text{H}$ ,  $X = \text{CO}_2\text{Et}$ ) being the predominant isomer; on long-term keeping of the reaction mixture, a mixture of 1,8-ditriazolynaphthalenes **130** is formed.<sup>227</sup>

| X                  | Y                  | Z                  | U                  | Yield of <b>130</b> (%) <sup>a</sup> |
|--------------------|--------------------|--------------------|--------------------|--------------------------------------|
| CO <sub>2</sub> Et | H                  | H                  | CO <sub>2</sub> Et | 52                                   |
| CO <sub>2</sub> Et | H                  | CO <sub>2</sub> Et | H                  | 24                                   |
| H                  | CO <sub>2</sub> Et | CO <sub>2</sub> Et | H                  | 2                                    |

<sup>a</sup> For  $R^1 = R^2 = \text{Et}$ .

Various dialkyl acetylenedicarboxylates ( $R^1 \neq R^2$ ) have been employed in the cyclocondensation with 1,8-diazidonaphthalene. The subsequent chemical transformations of the azide and ester groups gave rise to diverse functional derivatives **130**.<sup>227–229</sup>

Recently, it has been found that Cu(I)-catalysed cycloaddition of azides to terminal acetylenes is regiospecific and gives 1,4-disubstituted triazoles.<sup>230–236</sup> The use of encapsulation techniques in the reaction of phenyl azide with phenylacetylene made it possible not only to increase appreciably the reaction rate but also to obtain the only isomer, 1,4-diphenyltriazole.<sup>237</sup>

A new, in principle, method for regiocontrol of the dipolar cycloaddition, based on the chemical recognition principle, has

been proposed.<sup>238</sup> The method implies selective spatial fixation of the reacting molecules of a dipolar compound and a dipolarophile. A crown ether fragment (in the azide molecule) and a terminal ammonium group (in the substituted acetylene molecule) are used as the structural blocks than ensure the chemical recognition. Due to the formation of a bound complex between these blocks, the cycloaddition becomes pseudo-intramolecular, which facilitates the reaction and markedly increases the regioselectivity (only 3% of the second regioisomer) compared to the model reaction carried out without complex formation (in this case, up to 43% of the second isomer is formed).<sup>238</sup>

Heterocyclic azides have also been used in reactions with acetylene derivatives, for example, 6-azido-2,3-diphenylindole,<sup>239</sup> tetrathiafulvalene azido derivatives,<sup>240</sup> fluoroquinolonecarboxylic acid azido derivatives<sup>241</sup> and azidobenzo[*b*]thiophenes.<sup>214, 242</sup> 9-Azidoacridine reacts with alkynes to give regioisomers of 9-(4,5-disubstituted 1*H*-1,2,3-triazol-1-yl)acridines; only in the case of trimethylsilylacetylene, does the reaction proceed regioselectively.<sup>243</sup> The attempts to introduce acetylene and its homologues into the reaction with 5- and 6-azido-2-methylbenzothiazoles did not lead to the desired outcome, whereas the use of more reactive organomagnesium derivatives  $\text{RC}\equiv\text{CMgBr}$  ( $R = \text{Me}$ ,  $\text{Ph}$ ) (Iotsich complexes) made it possible to obtain the corresponding 1,5-disubstituted triazoles.<sup>244</sup>

For azido derivatives of azines, the influence of additional factors on the cycloaddition reaction has been noted. On the one hand, the electron-withdrawing properties of the heterocycle favour polarisation of the azide fragment. On the other hand, in the case of  $\alpha$ -isomers, there exists a tautomeric equilibrium between the azidoazine and the cyclic form, tetrazoloazine, the stability of which is determined by the nature and the positions of substituents in the azine ring. The influence of these factors accounts for the different reactivities of substituted 2-azidopyridines **131** upon reaction with DMAD. Previously, it has been shown<sup>245</sup> that 2-azido-6-chloropyridine **131** ( $R^1 = \text{Cl}$ ,  $R^2 = \text{H}$ ) forms the corresponding 1-pyridyltriazole **132** ( $R^1 = \text{Cl}$ ,  $R^2 = \text{H}$ ) in boiling chloroform, whereas unsubstituted 2-azidopyridine and its 5-derivatives ( $R^1 = \text{H}$ ;  $R^2 = \text{H}$ ,  $\text{Br}$ ,  $\text{NO}_2$ ) react with DMAD only on strong heating in the absence of a solvent. The reaction of 2-azidopyridine with methyl propiolate ( $X = \text{H}$ ,  $Y = \text{CO}_2\text{Me}$ ) and diphenylacetylene ( $X = Y = \text{Ph}$ ) proceeds in a similar way.<sup>246</sup> The 6- $\text{CF}_3$  derivative reacts with phenylacetylene to give a mixture of 4- and 5-regioisomers in  $\sim 1:1$  ratio.<sup>247</sup>

$R^1 = \text{H}$ ,  $\text{Cl}$ ,  $\text{CF}_3$ ;  $R^2 = \text{H}$ ,  $\text{Br}$ ,  $\text{NO}_2$ ;  $X = Y = \text{CO}_2\text{Me}$ ;  $X = Y = \text{Ph}$ ;  
 $X = \text{H}$ ;  $Y = \text{CO}_2\text{Me}$ ,  $\text{Ph}$ .

According to a publication,<sup>248</sup> 4- and 6-substituted (by  $\text{Cl}$ ,  $\text{Br}$ ,  $\text{CF}_3$ ) 2-azidopyridines form 1-pyridyl-4-methoxycarbonyltriazoles in high yields on refluxing with methyl propiolate in  $\text{CHCl}_3$ . 4-Azidotetrafluoropyridine reacts with diphenylacetylene on heating in  $\text{CCl}_4$ ; however, the yield of the cycloadduct is very low under these conditions.<sup>249</sup>

The reaction of azido derivatives of pyrimidine and pyrazine with DMAD and methyl propiolate takes place under milder conditions than the reaction with azidopyridines due to the stronger electron-withdrawing properties of the heterocycle.<sup>246, 250</sup> 3,6-Diazidopyridazine **133a** reacts with transformation of only one azido group even under drastic conditions, because the second azido group exists predominantly in the cyclic tetrazole form (tautomer **133b**).<sup>250</sup>

2- and 4-Azidopyrimidines **134**, containing a phenyl and/or *o*-hydroxyphenyl group in the heterocycle react with DMAD, phenylacetylene and propargyl alcohol to give substituted 1-pyrimidyltriazoles in 70%–90% yields. It was found that conducting the reaction at 140 °C in the presence of excess alkyne is optimal, whereas on heating in solvents, the reaction time markedly increases.<sup>251</sup>

Y = CH, Z = N; Y = N, Z = CH; R<sup>1</sup>, R<sup>2</sup> = H, Ph, 2-HOC<sub>6</sub>H<sub>4</sub>;  
X = Ph, CH<sub>2</sub>OH.

On the basis of cycloaddition of 6-azidouracils to DMAD and phenylacetylene, a method for the synthesis of new potentially biologically active triazolyluracils has been developed.<sup>252</sup> This reaction readily proceeds on refluxing in toluene and the product yields are high. Recently, it has been shown that a broad range of mono- and bis(triazolyl)pyrimidines can be synthesised on the basis of diazidopyrimidines and acetylenic dipolarophiles. The presence of an active azido group in the pyrimidine ring of the monosubstituted derivatives permits the nucleophilic substitution of this group by various functional groups. Moreover, azidation of triazolylpyrimidines demonstrated nucleofugacity of the 1*H*-1,2,3-triazolyl fragment,<sup>253</sup> whose mobility is governed by the nature of substituents in the pyrimidine and triazole rings (Scheme 3). The researchers cited found an unusual reaction of

bis(triazolyl)pyrimidine **135** with acetylacetone, which can be formally considered as replacement of two carbon fragments of DMAD by the corresponding fragments of 'dehydrated' acetylacetone ('Ac–C≡C–Me') to give compound **136** (see Section IV.3).

When the pyridine ring contains three azide groups at the 2-, 4- and 6-positions, the route and level of the cycloaddition depend to a large extent on the nature of the dipolarophile. Using triazido-pyridine **137** as an example, it was found that two DMAD molecules easily add to 2- and 6-azido groups yielding bis(triazolyl)pyridine **138a** in a high yield.<sup>254–256</sup>

On the basis of quantum-chemical calculations (PM3), it has been shown that the electron densities on the frontier orbitals are different for the  $\alpha$ - and  $\gamma$ -azide groups in molecule **137a**. For example, the HOMO has a high orbital density on the  $\alpha$ -azide group and a low density on the  $\gamma$ -analogue, which results in reactions with electron-deficient dipolarophiles (for example, DMAD) at the azide group in the 2-position. Conversely, the higher orbital density on the  $\gamma$ -azide group in the LUMO of molecule **137a** is favourable for reactions with electron-enriched dipolarophiles (for example, with norbornene) to give aziridine. It also follows from the calculations that the presence of the triazolyl group in molecule **139a** does not change the situation significantly, and therefore, the reaction with DMAD further involves the second  $\alpha$ -azido group.<sup>255</sup> A similar reaction of a more electron-deficient dicyano-substituted pyridine **137b** with DMAD stops after the formation of the monoadduct 2,4-diazido-6-triazolyl-3,5-dicyanopyridine **139b** (yield 34%).<sup>257</sup> The thermal reaction of

Scheme 3

Acac is acetylacetone.

4-azido-2,6-bis-(2-pyridyl)pyridine with DMAD gives the 2*H*-azirine derivative rather than triazole.<sup>258</sup>

7-*R*-8-Azidoquinolines (*R* = H, Me) readily react with DMAD and dehydrobenzene to give esters of 1-(8-quinolyl)triazole-4,5-dicarboxylic acids and benzotriazole, respectively, in high yields.<sup>259</sup>

On heating with symmetric alkynes (*X* = *Y*), 4-azido-6-methyl-2*H*-pyran-2-one **140** gives disubstituted triazolypyrones **141** in high yields.<sup>260</sup> In the case of phenylacetylene (*X* = H, *Y* = Ph), the reaction products contain both regioisomers, 5-phenyl-substituted triazole **141** (*Y* = 5-Ph) somewhat predominating over the 4-regioisomer **141** (*Y* = 4-Ph), whereas ethoxyacetylene (*X* = H, *Y* = OEt) furnishes only 5-ethoxytriazole **141** (*Y* = 5-OEt).<sup>260</sup>

*X* = *Y* = Ph; *X* = *Y* = CH<sub>2</sub>OH; *X* = H, *Y* = Ph; *X* = H, *Y* = OEt.

A series of 4-(triazol-1-yl)-2*H*-benzopyran-2-ones have been prepared by cyclocondensation of 7-diethylamino-4-azidobenzopyranone with mono- and disubstituted acetylenes (H, Ph, CH<sub>2</sub>Cl and CH<sub>2</sub>OH as substituents).<sup>261</sup>

Examples of the synthesis of azolytriazoles have been reported. 5-Azidopyrazoles **142** were used for the synthesis of pyrazolyltriazoles. It was found that the reaction with methyl propiolate takes place on refluxing the reactants in acetonitrile or toluene; 4-regioisomers predominated in the reaction products.<sup>48, 262</sup> The cyclocondensation with DMAD occurs in the usual way; dipolarophiles such as phenylacetylene, ethyl phenylpropiolate and ethyltrimethylsilyl propiolate proved insufficiently reactive and did not enter into this reaction.<sup>262</sup>

*R* = Ph (45%); H, Bu<sup>t</sup> (79%–86%).

2-Azidoimidazole has not been involved into the reaction with methyl propiolate even in boiling toluene,<sup>262</sup> whereas 5-azido-2-aryl-4-trifluoromethylthiazoles (Ar = 2-thienyl, 2-furyl, 4-MeC<sub>6</sub>H<sub>4</sub>) form mixtures of the corresponding substituted (triazol-1-yl)thiazoles.<sup>263, 264</sup>

The synthesis of some (triazol-1-yl)oxazolines<sup>265</sup> and furazans<sup>266, 267</sup> have been described. In relation to the reaction of 3-azido-4-aminofurazan with ethoxycarbonylacetylenes, it was shown that the use of an ionic liquid as the reaction medium shortens the time of synthesis several-fold.<sup>268</sup>

Despite the fact that examples of the use of various alkynes and azides in 1,3-dipolar cycloadditions are quite diverse and have been considered previously in many publications, the range of reagents used to prepare new triazole derivatives has been markedly extended in recent years. For example, dehydrobenzenes and 2,3-dehydronaphthalene generated in the reaction mixture *in situ* have been used in this reaction as dipolarophiles. This resulted in the synthesis of a series of substituted 1-naphthylbenzotriazoles and 1-(2-methyl-1-naphthyl)naphtho[2,3-*c*]triazole.<sup>259</sup>

Various alkyl azides<sup>269–272</sup> and amidoalkyl azides **143**<sup>273</sup> have been made to react with asymmetric acetylene derivatives. This was found to give predominantly 1,4-disubstituted triazoles **144**. An exception is acetophenone triphenylphosphorus ylide

(formally, the latent form of phenylacetylene), which reacts with amidoalkyl azides **143** to give the corresponding 5-phenyl isomers **145** in high yields.<sup>273</sup>

*R* = Ph (**a**), 2-MeC<sub>6</sub>H<sub>4</sub> (**b**), 4-MeC<sub>6</sub>H<sub>4</sub> (**c**), 2-ClC<sub>6</sub>H<sub>4</sub> (**d**), 4-ClC<sub>6</sub>H<sub>4</sub> (**e**), Bn (**f**).

The earlier attempts to involve fluorinated alkyl azides into cycloaddition with diphenylacetylene have failed.<sup>274</sup> However, recently, reactions of 2*H*-perfluoropropyl azide **146a** and methyl 3-azidoperfluoropropionate with various acetylene derivatives have been carried out.<sup>275</sup> The reaction with monosubstituted acetylenes is carried out in an autoclave with heating to 90–130 °C, while that with disubstituted acetylenes is carried out at 170 °C. The regioselectivity of cycloaddition (ratio of **147**:**148** isomers) depends on the type of substituents in the reactants.

*X* = Bu<sup>n</sup>, Ph, CO<sub>2</sub>Me, SiMe<sub>3</sub>; *Y* = H, Ph, CO<sub>2</sub>Me;  
*R*<sub>F</sub> = CF<sub>3</sub>CHFCF<sub>2</sub> (**a**), MeO<sub>2</sub>C(CF<sub>2</sub>)<sub>2</sub> (**b**).

| <i>X</i>           | <i>Y</i>           | Yields (%)  |             |
|--------------------|--------------------|-------------|-------------|
|                    |                    | <b>147a</b> | <b>148a</b> |

Derivatives of α-azido-α-amino acids have also been used as substrates in reactions with dipolarophiles.<sup>276, 277</sup> Esters of α-amino-α-(triazol-1-yl)phosphonic acid **149** are readily formed upon condensation of diethyl α-azido-α-aminophosphonic acid **150** with alkynes.<sup>278, 279</sup> In the case of monosubstituted acetylenes (*X* = H; *Y* = Bu, CH<sub>2</sub>Cl, CH<sub>2</sub>Br), the 1,4-disubstituted triazole to 1,5-isomer ratio in the reaction products varies from 2:1 to 5:1; in other cases, the 5-regioisomer is detected in only minor amounts.

*R* = PhCO, CO<sub>2</sub>CH<sub>2</sub>CCl<sub>3</sub>; *X* = H, Ph, CO<sub>2</sub>Me; *Y* = Bu<sup>n</sup>, CH<sub>2</sub>Cl, CH<sub>2</sub>Br, PrCH(OH), Ph, CO<sub>2</sub>Me, CO<sub>2</sub>Et.

Several publications are devoted to cycloaddition to alkynes of other phosphorus-containing azides: ω-azidoalkyltriphenylphosphonium bromides<sup>280</sup> and azidomethylphosphonates.<sup>281–284</sup> From 2-azido-3-hydroxy-1-phenylphospholane 1-oxides **151**, a number of optically active triazole derivatives have been prepared.<sup>285–290</sup>

R = H, Alk; X, Y = H, Alk, CO<sub>2</sub>Alk.

The influence of spatial factors on the regioselectivity of the cycloaddition to asymmetrical alkynes has been studied in relation to the reaction of the azidomethyl derivative of sulfone **152**.<sup>291</sup> The regioselectivity was found to be controlled by the steric effects of the substituents X and Y. As the substituent bulk increases in the series H < Ph < Bu<sup>t</sup> < Me<sub>3</sub>Si, the ratio of the regioisomers in the reaction products varies in parallel, except for the Me<sub>3</sub>Si group. The steric effect of the last-mentioned group acts in the same direction as the electronic effect, whose role is to stabilise the induced positive charge on the acetylene β-carbon atom in the transition state. Both effects promote the formation of 4-trimethylsilyl isomers as the only products in high yields. An increase in the pressure to 10 kbar increases substantially the reaction rate.<sup>291</sup>

X = H: Y = CO<sub>2</sub>Me, SiMe<sub>3</sub>, SO<sub>2</sub>Ph; X = Ph, Y = CO<sub>2</sub>Et;

X = Bu<sup>t</sup>, Y = SO<sub>2</sub>Ph; X = SiMe<sub>3</sub>: Y = CO<sub>2</sub>Me, SO<sub>2</sub>Ph, SO<sub>2</sub>NMe<sub>2</sub>.

The 1,3-dipolar cycloaddition of the substituted alkoxyethyl azides **153** to symmetrical and asymmetrical alkynes has been used to prepare an extensive series of 1-alkoxyethyltriazole derivatives.<sup>292</sup> The yields of the isolated compounds varied from 11% to 95%; the low yields can be attributed to the low thermal stability of the starting alkyl azides.

R = HO(CH<sub>2</sub>)<sub>2</sub>, MeO<sub>2</sub>C(CH<sub>2</sub>)<sub>2</sub>, BnO(CH<sub>2</sub>)<sub>2</sub>, (BnOCH<sub>2</sub>)<sub>2</sub>CH,  
BnO(BnOCH<sub>2</sub>)CHCH<sub>2</sub>; X = CO<sub>2</sub>Me, Ph, 4-ClC<sub>6</sub>H<sub>4</sub>, 2-Py.

X = Ph (**a**), C<sup>o</sup>Ph (**b**); n = 1, 2.

Interesting results have been obtained<sup>293</sup> by refluxing 2-(4-pyridyl)ethyl azide **154** with substituted alkynes in toluene. In the case of phenylacetylene, a mixture of 4- and 5-phenyl-2-(4-pyridyl)ethyltriazole **155** was synthesised (regioisomer ratio 1 : 2, quantitative yield). If the reaction is carried out with diphenylacetylene, 4,5-diphenyltriazole **156a** is formed in a relatively low yield. In the case of dibenzoylacetylene, in addition to 4,5-dibenzoyl derivative **156b**, the rearrangement product **157b** was obtained (yield 8%, **156b** : **157b** = 4 : 1). The compounds **155**, **156a**, which are quaternised at the pyridine nitrogen atom, undergo the retro-Michael rearrangement to give 1-unsubstituted triazoles (Scheme 4).<sup>293</sup>

The synthesis of a number of β-lactams containing a triazolyl group from the corresponding azides has been described.<sup>294</sup> New-type homo-C-nucleosides have been obtained by the 1,3-dipolar cycloaddition of trimethylsilylacetylene to the azide groups of 4-amino-6-(ribofuranosyl)azidomethylpyrimidine **158** epimers.<sup>295, 296</sup>

Tr is triphenylmethyl (trityl).

Quite a few examples of using this strategy for the preparation of glycosylated triazoles from azido derivatives are documented. Thus on refluxing in toluene with DMAD, acetylated 1-azidoglycopyranosyl cyanide **159** gives the cycloaddition product in a good yield.<sup>297–299</sup>

Scheme 4

Under the same conditions, DMAD reacts with 3-azido-3-deoxy- $\alpha$ -D-glucufuranose derivatives<sup>298,300</sup> and with 6-azido-6-deoxycyclodextrins.<sup>301,302</sup> The reactions of acetylated cellobiosyl, lactosyl, maltosyl and melibiosyl azides with various esters of acetylenedicarboxylic acid affords the corresponding 1-glycobiosyltriazaolones, which were used in the synthesis of oligosaccharides and anthracycline antibiotics.<sup>303</sup>

The reactions of 5-azido-5-deoxy- $\alpha$ -D-xylofuranose derivatives, methyl 5-azido-5-deoxy- $\beta$ -D-ribofuranoside and other azido sugars with various acetylene derivatives were carried out to prepare nucleoside analogues containing triazole as the nitrogenous base.<sup>19, 231, 232, 304–315</sup> The other compounds used as substrates in the reaction with alkynes include 3'-azido-2',3'-dideoxythymidine and 3'-azido-2',3'-dideoxyuridine,<sup>185,316</sup> 3'-azido-3'-deoxythymidine and 5'-azido-5'-deoxythymidine,<sup>317,318</sup> as well as azido derivatives of acyclonucleosides<sup>319</sup> and the carbocyclic analogue of furanose.<sup>320</sup>

The cycloaddition using a soluble polymer (based on polyethylene glycol succinate) with one of the reactants attached to it, either azide (for example, 5-azido-5-deoxy-1,2-*O*-isopropylidene- $\alpha$ -D-xylofuranose) or acetylene (for example, propargyl alcohol), has been proposed.<sup>306</sup> Except for the reaction of polymer-supported azide with diphenylacetylene, both versions of this process give products in quantitative yields. The product is removed from the polymer support by treatment of the methanol solution with excess ammonia followed by ether precipitation of the polymer.

The reaction of organic azides with alkynes allows the use of broad ranges of both reactants. For example, various acetylene derivatives containing heterocyclic fragments were used as dipolarophiles. Pyrimido[1,2,3-*cd*]purine-8,10-dione **160** as the acetylene derivative and a number of organic azides were made to react to give 2-(4- and 5-triazolyl) derivatives (~1:1) of heterocyclic system **161**.<sup>321</sup>

R = HOCH<sub>2</sub>, HOCH<sub>2</sub>CH(OH), HOCH<sub>2</sub>(CHOH)<sub>2</sub>CH(OH), CO<sub>2</sub>Me, Ph.

The reaction of 9-propargylguanidine with AcOCH<sub>2</sub>.CH<sub>2</sub>OCH<sub>2</sub>N<sub>3</sub> affords the 1,4- and 1,5-regioisomers in a 7:3 ratio (overall yield 71%).<sup>322</sup> The use of a ZnCl<sub>2</sub>-doped natural phosphate as the catalyst allows one to shorten the reaction time by an order of magnitude without changing the yield and the isomer composition.

The dipolar 1,3-cycloaddition has been used successfully to synthesise triazole derivatives of various classes of large molecules and some polymers, in particular, crown ethers,<sup>323,324</sup> rotaxanes,<sup>325–327</sup> pseudorotaxanes,<sup>328</sup> dendrimers<sup>329</sup> and polystyrenes.<sup>236</sup>

N-substituted histidine analogues have been obtained by the reaction of azides with C-propargylglycine, while reactions with terminal alkynes containing peptide residues gave peptidotriazoles.<sup>230</sup> This strategy has found application as a tool for studying proteins, for example, the protein shell of the plant mosaic virus<sup>330</sup> and a number of enzymes.<sup>331</sup> The reaction between N-protected propargylamine and the azide obtained from D-leucine is a route to cyclic peptides with triazole fragments capable of self-organisation and formation of peptide nanotubes.<sup>234</sup>

Numerous examples of the use of phosphorus-containing alkynes in reactions with azides have been described. 4,5-Disubstituted triazoles have been prepared on the basis of symmetric disubstituted acetylenes with diphenyl and thiophosphinoyl

groups.<sup>332,333</sup> Phosphorus ylides containing an  $\alpha$ -oxo group in the chain (Wittig reagents, see above) behave similarly to electron-enriched acetylenes; they react with organic azides to give the corresponding triazoles.<sup>2,8,273</sup> This method has been used to obtain two benzoyl triazole isomers based on acetone triphenylphosphorus ylide (acetylmethyltriphenylphosphorane).<sup>334</sup> In a similar reaction with *o*- and *m*-phthalimidobenzoyl azides, 4-methyltriazaolones **162** are formed in high yields. Presumably, the azide adds to the enol form of the ylide and this is followed by elimination of a triphenylphosphine oxide molecule.

X = 2- and 3-phthalimido.

It was shown that the preparation of 1-aryl-5-substituted triazoles from aryl azides and phosphonium ylides is sharply accelerated when the reactions are initiated by microwave irradiation of the reactant mixture supported on SiO<sub>2</sub>.<sup>335</sup>

The reaction of the 3-quinuclidine analogue of the Wittig reagent **163** with 3-nitrobenzoyl azide has yielded a product that was debenzoylated during chromatography on Al<sub>2</sub>O<sub>3</sub>, being converted into N-unsubstituted (3-quinuclidinyl) triazole **164**.<sup>336</sup>

The use of glycosyl azides as substrates in the cycloaddition of 2-oxoalkylenetriphenylphosphoranes has been reported.<sup>337</sup> Azido derivatives of 5,6-diphenyl-*as*-triazine **165** and its phenanthrene analogue react with acetylmethylenetriphenylphosphorane **166** (R<sup>3</sup> = Ac) being converted into 1-azinyl-5-methyltriazaolones **167** in high yields.<sup>338</sup> However, the replacement of the acetyl substituent in the phosphorane by the ethoxycarbonyl group results in the formation of only iminophosphoranes **168**. In the latter case, ethyl diazoacetate is also formed in 70% yield.<sup>338</sup>

R<sup>1</sup> = R<sup>2</sup> = Ph, R<sup>1</sup>–R<sup>2</sup> = *o,o'*-biphenylene, R<sup>3</sup> = Ac, CO<sub>2</sub>Et.

5-Substituted 1-[1-(diethoxyphosphonyl)alkyl]triazaolones are formed in good yields in the reaction of diethyl 1-azidoalkylphosphonates with 2-oxoalkylenetriphenylphosphoranes.<sup>339</sup> Acetyl- and benzoylphosphoranes were transformed into 4 $\beta$ -(triazol-1-yl)podophyllotoxin derivatives to study their cytotoxic properties.<sup>340</sup>

Worth mentioning are numerous examples of the combination of two functions, an azide group and a triple bond linked by an at least three-carbon bridge in one molecule. The cyclisation of the azide obtained from enyne **169** allows the synthesis of annelated triazole systems, for example, pyrrolotriazole **170**.<sup>341</sup>

$R^1, R^2, R^3, R^4, R^5 = H, Me; R^2-R^3 = (CH_2)_4$ .

A similar result has been attained in the case of a saturated chain of three carbon atoms.<sup>210</sup>

If the azide group and the triple bond are separated in the molecule by only a methylene group, the presence of nucleophilic agents is needed for cyclisation. Thus treatment of bromobutyne **171** or iodoallene **172** with sodium azide in alcohol at room temperature affords a mixture of 4-(1-azido-1-methylethyl)-1*H*-triazole **173** and 4-(1-alkoxy-1-methylethyl)-1*H*-triazole **174**.<sup>342</sup>

$R = Me, Et$ .

The mechanism of the reaction that includes the rearrangement of propargyl azide **175** to short-lived allenyl azide **176**, which rapidly forms triazafulvene **177**, has been studied.<sup>342</sup> The last-mentioned product adds a nucleophilic molecule at the exocyclic double bond, being converted into the final product.

This route was supported by an experiment with optically active 3-azido-3-methylbut-1-yne **175** ( $R^1 = H, R^2 = Me$ ), where complete product racemisation was observed. These transformations cannot be accomplished in an aprotic solvent such as chloroform. It was shown that in the absence of nucleophiles, propargyl azides polymerise as a result of intermolecular 1,3-dipolar cycloaddition. The ring closure in vinyl azides takes place only for  $\alpha$ -azidoenamines;<sup>343</sup> simple vinyl azides are not converted into triazoles<sup>344</sup> due to the low nucleophilicity of the C(5) atoms

and, in some cases, also an unfavourable geometry. The probability of cyclisation becomes higher for not only the vinyl azide carbanion but also for the allenyl azide anion owing to the presence of a p orbital at the central carbon atom of the allene system.<sup>342, 345</sup>

The transformation of various propargyl derivatives, first into propargyl azides **178** and then into triazoles is carried out with isolation of intermediate compounds, which makes this method of synthesis safe and convenient. However, it was shown that, depending on the structure of the starting compounds and on the conditions, the reaction may give isomeric allenenes and triazafulvenes, which react with nucleophiles to give isomeric N-unsubstituted triazoles,<sup>346</sup> for example, **179** and **180** (Scheme 5). This approach has been used to synthesise various biologically active compounds containing a triazole ring with secondary amino-methyl substituents.<sup>166, 347–349</sup>

Azidoaminoallenes **181**, which are formed as intermediate products in the reaction of phenylpropiolaldehyde aminals with trimethylsilyl azide, undergo intramolecular cyclisation to give 4-alkylidene-4*H*-triazoles **182**.<sup>350</sup>

$R^1 = EtOCH_2, Me_2NCH_2, Ph; R^2-R^3 = Me_2, (CH_2)_5, (CH_2)_2O(CH_2)_2, (CH_2)_2NMe(CH_2)_2$ .

Subsequently, several modifications of this method as applied to various allene systems, including those containing heterocyclic rings, have been developed.<sup>351</sup>

The intramolecular cyclisation of *ortho*-propargyloxy(or thio)-substituted phenyl azides **183**, which takes place on heating in toluene, affords annelated triazoles **184**.<sup>352</sup>

Scheme 5

X = O, S; R = H, HOCH<sub>2</sub>, MeOCH<sub>2</sub>, Ph.

The same approach was used to prepare a series of triazolo[1,5-*a*]benzodiazepinones **185**.<sup>353,354</sup> The key stages of the preparation of triazolo[1,5-*a*][1,4]benzodiazepin-6(4*H*)-one derivatives on a polymer support have been optimised.<sup>355</sup>

X = H, Cl, F, NO<sub>2</sub>, NH<sub>2</sub>; R = H, Me, Ph.

Other examples of intramolecular cyclisation involving an azide group and a triple bond present in various structures have been reported in original studies<sup>356–358</sup> and in a review.<sup>359</sup> Thus numerous annelated triazoles with a β-lactam fragment (for example, compounds **186–188**) have been obtained from azide derivatives of β-lactam antibiotics; these products can be used for subsequent structural modifications and as antibacterial agents.<sup>359</sup>

R<sup>1</sup>, R<sup>2</sup> = Alk; R<sup>3</sup>, R<sup>4</sup> = H, R<sup>5</sup> = Me (**188a**); R<sup>3</sup> = Bu<sup>t</sup>, R<sup>4</sup> = Alk, R<sup>5</sup> = H (**188b**).

The azide molecule entering into intramolecular 1,3-cycloaddition to give triazole can contain not only a triple bond but also a double bond, either C=C or C=N. Examples of such reactions are documented.<sup>360–365</sup>

Of particular interest as the initial components for the synthesis of the triazole ring are acetylene aldehydes and aldimines (1-aza-1,3-enynes).<sup>366</sup> Both inorganic (HN<sub>3</sub>, NaN<sub>3</sub>) and organic (R<sup>3</sup>N<sub>3</sub>) azides were found to add to acetylene aldimines **189** at the triple bond to give substituted triazoles containing a formyl or iminomethyl group at the 5-position.<sup>367–373</sup> The structure of the product depends on the nature of the azide.

Sodium azide adds to the triple bond of azaenynes in DMF even at –20 °C to give salts that are hydrolysed to formyltriazoles **190**. If the azaenynone contains a trimethylsilyl group (**189**, R<sup>1</sup> = Me<sub>3</sub>Si), this reaction is accompanied by desilylation to yield 5-formyltriazole **190** (R<sup>1</sup> = H), whereas the germanium analogue (**189**, R<sup>1</sup> = Et<sub>3</sub>Ge) retains the substituent. Hydrazoic acid adds chemospecifically to the aldimine triple bond. The reaction of acetylenic aldimines with organic azides occurs under much more drastic conditions and goes to completion only after long-term heating of the reactants in toluene. The addition is also chemospecific and involves the triple bond, the process regioselectivity increasing with an increase in the bulk of the substituent at the triple bond (from Ph to Bu<sup>t</sup>, Me<sub>3</sub>Si, and Et<sub>3</sub>Ge) and on passing from alkyl azides to aryl azides (Scheme 6).

Acetylenic silyl ketones react with various azides in boiling toluene as effective dipolarophiles to give mixtures of isomeric triazoles in which the 1,4-regioisomer markedly predominates.<sup>271</sup>

Desilylation of the resulting triazolylacysilanes induced by alkali furnishes the corresponding triazolecarboxaldehydes.

R = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, PhSCH<sub>2</sub>, Me<sub>3</sub>SiCO(CH<sub>2</sub>)<sub>2</sub>, Ad (1-adamantyl), benzo[*b*]thiophen-3-yl.

Dialdehydes of the triazole series can easily be obtained from diacetals **191**. These are formed on long-term heating of acetylenedicarbaldehyde bis(diethyl acetal) **192** with phenyl and alkyl azides in a sealed tube.<sup>374</sup>

R = n-C<sub>6</sub>H<sub>13</sub>, n-C<sub>10</sub>H<sub>21</sub>, Br, Ph.

However, in the case of more labile 2-azidonitrobenzene, the reaction with alkyne is usually carried out at a lower temperature to prevent the azide from decomposition and, hence, the reactivity of diacetal **192** is insufficient. The removal of the acetal protection from one aldehyde group allows one to transform (benzene, 55 °C) alkyne **105d** and 2-azidonitrobenzene into a mixture of two monosubstituted triazole-4,5-dicarboxaldehyde diethyl acetals **193** and **194** (R = 2-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>) in which isomer **193** predominates.<sup>375</sup> Similar mixtures were obtained from other azides under the same conditions. Acid hydrolysis of the mixtures (with azeotropic distillation of water with benzene) gives rise to 1-substituted dialdehydes **195**, which react with hydrazine hydrate yielding triazolo[4,5-*d*]pyridazines. These products can also be obtained directly from mixtures of compounds **193** and **194**.

R = Bn, Ph, 2-MeC<sub>6</sub>H<sub>4</sub>, 4-MeC<sub>6</sub>H<sub>4</sub>, 2-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

The addition of the azide anion to acetylene  $\beta$ -diketones carried out under drastic conditions (heating in DMF) is also chemospecific, involving the triple bond.<sup>165</sup> The yield of the resulting triazole diketones **196** reaches 60%–70%. As triazole dialdehydes, these polyfunctional compounds can be used in the synthesis of annelated heterocyclic systems. For example, on heating in sulfuric acid, compound **196** undergoes dehydration to give an annelated pyrrolone ring.

Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>.

The condensation of 1-aryl-2-phenylacetylenes (Ar = Ph, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>) with aryl azides (Ar = 2-ClC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 2-MeOC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>) takes place in boiling toluene to give mixtures of 4,5-regioisomers in which 1-aryl-4-aryl-5-phenyltriazole predominates.<sup>376, 377</sup> Only *o*-nitrophenyl azide does not enter into this reaction.<sup>377</sup>

It was shown that the addition of benzyl azide to diacetylene compounds in which triple bonds are separated by alkyl or aryl groups affords ditriazolyl derivatives as the only products. If the triple bonds are separated by a carbonyl group, NaN<sub>3</sub> adds to only one triple bond; benzyl azide taken in an equivalent amount forms the monoadduct, while a twofold amount results in the formation of mono- and diadduct isomers (Ref. 378).<sup>†</sup> However, terminal dicyanopolynes (for example, compounds **197**) with conjugated triple bonds react regioselectively with methyl azidoacetate to give the product of cycloaddition only to the terminal triple bond.<sup>379</sup>

## 2. Reactions of azides with alkenes

Compounds with double C=C bonds can also undergo 1,3-dipolar cycloaddition with azides, the reaction being highly regioselective.<sup>264</sup> This strategy is a key route to 4,5-dihydro-1*H*-1,2,3-triazoles (or  $\Delta^2$ -1,2,3-triazolines) including those labelled by <sup>13</sup>C and <sup>15</sup>N isotopes.<sup>380</sup> The preparation and chemical transformations of these heterocycles are the subjects of numerous

papers and several reviews (for example Refs 4, 25, 381). The systems containing a triazoline fragment are usually unstable and can decompose under ambient conditions being converted into aziridines (with elimination of a nitrogen molecule), diazo compounds, imines or enamines, or undergo intramolecular rearrangements.<sup>381</sup> For this reason, the formation of triazolines often cannot be detected during cyclocondensation. The stability of the triazoline ring can be increased by introducing stabilising substituents or by synthesising fused systems or conformationally stable complex structures.

When phenyl azide reacts with the simplest allene, propa-1,2-diene, the resulting methylenetriazolines are aromatised to 4- and 5-methyltriazolines formed in very low yields.<sup>345</sup>

Cascade synthesis of 1-substituted triazoles **198** starting from aryl iodide **199** containing an allene fragment has been performed. The process includes the following reaction sequence: palladium complex-catalysed cyclisation of allene into the iodomethyl derivative, reaction with sodium azide, cyclocondensation of the resulting organylmethyl azide with norbornadiene to an unstable triazoline and the retro-diene decomposition of the last-mentioned product.<sup>272</sup>

Examples of using other aryl iodides<sup>272</sup> and alkoxymethyl azides and their *S*-analogues<sup>292</sup> in a similar reaction with norbornadiene are also known.

The reaction of methyl azide with acrylic and crotonic acid derivatives is not stereospecific, resulting in triazolines which occur in equilibrium with their open forms, *i.e.*, aminodiazo compounds. In some cases, this reaction is complicated by the reactions of the latter compounds with the starting alkenes.<sup>382</sup> The presence of an electron-releasing substituent at the N(1) atom of the triazoline ring stabilises the molecule, while that at C(4) or C(5) has a destabilising effect.<sup>4</sup> The formation of unstable triazolines with electron-withdrawing substituents and easy opening of the triazoline ring is used to obtain new interesting structures, for example, compounds **200** and **201**.<sup>383, 384</sup>

Heating of thiobenzophenone or 9*H*-fluorene-9-thione with dimethyl fumarate and excess phenyl azide gave a mixture of diastereoisomeric thiiranes.<sup>385</sup> The researchers believe that this transformation involves triazoline derivative **202** as a reactive intermediate.

<sup>†</sup> The reactions of diacetylenes and their derivatives with sodium azide and organic azides are also considered in the review by I A Maretina, B A Trofimov *Adv. Heterocycl. Chem.* **82** 158 (2002).

R = Ph, R-R = *o,o'*-biphenylene.

The regioselectivity of the cycloaddition of aromatic azides to 5-substituted furan-2-ones was studied.<sup>386</sup> In those cases where thermally stable triazolines are formed, they can be dehydrogenated by treatment with oxidants such as  $\text{KMnO}_4$ ,<sup>387, 388</sup>  $\text{NiO}_2$ ,<sup>382</sup>  $\text{Br}_2$ <sup>389</sup> and  $\text{O}_2$ <sup>390</sup> to be converted into the corresponding triazoles. The presence in the same molecule of an azido group and a double bond bridged by several carbon atoms is favourable for intramolecular cyclisation.<sup>389, 391</sup>

The presence of a good leaving group, for example, Hal (Cl, Br), RO (R = H, Alk, Ar, Ac),  $\text{RSO}_n$  ( $n = 0, 1, 2$ ),  $\text{Alk}_2\text{N}$ ,  $\text{NO}_2$  or CN at the olefin double bond is favourable for regiospecific cycloaddition to azide. When the carbon atom next to the double bond bears a hydrogen atom (*i.e.*, in the presence of a  $\text{H}-\text{C}=\text{C}-\text{X}$  fragment, which is a latent alkyne), the formation of triazoline during the reaction is often followed by spontaneous ejection of this group with aromatisation of the triazole ring.

Below we consider reactions with azides classified according to the nature of the leaving group in the alkene.

The reaction of substituted benzyl azides with 2-chloroacrylonitrile, which is accompanied by HCl elimination, leads to 1-benzyltriazole-4-carbonitriles.<sup>392, 393</sup> The discovery of high biological activity and the possibility of practical use of 1-(2,6-difluorobenzyl)triazole-4-carboxamides<sup>194</sup> brought about the task of optimisation of the synthesis of their precursor, 4-cyano derivative **203** (Ar = 2,6- $\text{F}_2\text{C}_6\text{H}_3$ ), whose yield was increased to 98% by conducting the reaction in a two-phase system.<sup>392</sup> This procedure was extended to the synthesis of other 1-benzyl-4-cyanotriazoles **203** and 1-(het)aryl-4-cyanotriazoles.

Ar = Ph, 4-NCC $_6\text{H}_4$ , 2,6- $\text{F}_2\text{C}_6\text{H}_3$ .

The reaction of sodium azide with 2-aryl-4,4,4-trifluoro-3-chlorobut-2-enal yields 5-aryl-4-trifluoromethyltriazoles **204**.<sup>394</sup> The reaction mechanism proposed includes substitution of the azido group for the chlorine atom followed by attack by the terminal nitrogen of the azido group on the double bond of the aldehyde hydrate with elimination of formic acid.

X = H, 4-Br, 3- $\text{CF}_3$ , 4- $\text{CF}_3$ .

When the substrate contains two chloroacrolein groups connected by a *p*-phenylene bridge, the reaction gives 1,4-bis(4-trifluoromethyltriazol-5-yl)benzene.<sup>394</sup>

The reaction of (*Z*)-2- $\alpha$ -bromostyrylchromones with  $\text{NaN}_3$  in boiling DMF gives, in addition to the expected 4(5)-aryl-5(4)-(2-chromonyl)triazoles **205**, minor amounts of tetrazole derivatives **206**.<sup>395</sup> The latter products result from the reaction of the ketene imines, formed as side products, with  $\text{NaN}_3$ .

R = ; X = H, Cl.

1,3-Dipolar cycloaddition of aryl (or benzyl) azides to activated alkene **207** proceeds on moderate heating without solvents to give the corresponding 4-trifluoroacetyltriazoles **208** in high yields.<sup>396</sup> The presence of an active vicinal hydrogen atom in the intermediate triazoline **209** promotes elimination of the EtOH molecule.

$n = 0$ : Ar = 2-Me $\text{C}_6\text{H}_4$ , 4-Cl $\text{C}_6\text{H}_4$ ;  $n = 0, 1$ : Ar = Ph, 4-MeOC $_6\text{H}_4$ , 4-O $_2\text{NC}_6\text{H}_4$ .

Elimination of the EtOH molecule to give a triazole derivative was also observed on heating a mixture of azidothymidine and vinyl ethyl ether.<sup>185</sup>

5-Trifluoroacetyl-3,4-dihydro-2*H*-pyran proved to be inert with respect to benzyl azide even on strong heating.<sup>396</sup> However, when heated with  $\text{NaN}_3$  in AcOH, 2-trifluoromethylchromones substituted at the benzene ring and similar imines **210** give cycloadducts that are cleaved in an acid medium to give 4-aryltriazoles **211**.<sup>397</sup>

X = O, NH; R = Me, Cl,  $\text{NO}_2$ .

1-Pyridyltriazoles have been prepared in low yields by heating mixtures of vinyl acetate with various Cl- and  $\text{CF}_3$ -substituted isomeric azidopyridines.<sup>248</sup>

Reactions with a sulfur-containing leaving group are known. The parent triazole can be obtained in a yield of up to 55% on

heating an alkali metal azide or  $\text{Me}_3\text{SiN}_3$  with vinyl sulfoxide or vinyl sulfone ( $\text{RSO}_n\text{CH}=\text{CH}_2$ ;  $n = 1, 2$ ) in toluene.<sup>398</sup> A similar approach has been used to prepare 5-(4-hydroxyphenyl) derivatives of triazole-4-carboxamides<sup>399, 400</sup> and 4-perfluoroalkyltriazoles, containing residues of D-galactose and D-altrose derivatives (compounds **212**, **213**).<sup>401</sup>

$R = \text{Cy}$ ;  $R_F = n\text{-C}_4\text{F}_9, n\text{-C}_6\text{F}_{13}$ .

It was shown that a similar reaction can be carried out between 5-azidoxyfuranose and vinyl phenyl sulfoxide. The use of 1-(5-deoxy- $\alpha$ -D-xylofuranosyl)triazole azide grafted on a polymer (polyethylene glycol monomethyl ether) makes it possible to increase the yield from 68% to 94%.<sup>306</sup>

Examples of using various enamines with azides are encountered rather often in the literature. The 7-azido derivative of 6-fluoroquinolone-3-carboxylic acid **214** reacts with alkenes (norbornene, dicyclopentadiene and some enamines) to afford thermally unstable triazolyl adducts; only in the case of 1-morpholinocyclopentene, was the triazoline derivative **215** isolated together with side product 7-aminofluoroquinolone **216**.<sup>241</sup>

$R-R = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$ .

Aryl azides readily react with  $\alpha$ - and  $\beta$ -aminoacrylonitriles, but give different cycloaddition products. In the former case, spontaneous ejection of HCN from the intermediate triazoline takes place to give 1-aryl-5-aminotriazole **217**, and in the latter case, the corresponding amine is evolved and 1-aryl-4-cyanotriazole **218** is formed.<sup>402</sup> Fragments of secondary cyclic amines (pyrrolidine, piperidine and morpholine) were used as substituents in aminoacrylonitriles. In all cases, the yields of triazoles were 75%–95%. Despite the captodative character of  $\alpha$ -aminoacrylonitriles, their dipolarophilic properties in the cycloaddition are comparable with those of  $\beta$ -aminoacrylonitriles, which is inconsistent with their possible participation in the cyclisation of biradical intermediate species and confirms the one-step concerted Huisgen mechanism.<sup>402</sup>

$\text{Ar} = \text{Ph}, \text{MeC}_6\text{H}_4, 3\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 3\text{-O}_2\text{NC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4$ ;  
 $R-R = (\text{CH}_2)_4, (\text{CH}_2)_5, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$ .

When the nitroethylene molecule contains a morpholine residue, cycloaddition to the azide is accompanied by morpholine elimination with retention of the nitro group in the heterocycle.<sup>403–405</sup>

To prevent decomposition of the starting azide under the action of the evolved morpholine, the reaction is carried out in the presence of triethyl orthoformate.

In the reaction of 3-dimethylaminocrotonic acid, its esters or amides with mono-, di- or trinitrophenyl azides, the dimethylamine molecule is eliminated during cyclisation to give the corresponding 1-[( $\text{O}_2\text{N}$ ) $_n\text{C}_6\text{H}_{5-n}$ ]-triazole-4-carboxylic acid derivatives ( $n = 1-3$ ).<sup>406</sup>

The reactions of thiazole azides **219a–c** with enamines have been studied.<sup>264</sup> The reaction of 2-morpholinoprop-1-enyl phenyl ketone with 2-(2-thienyl)-5-azidothiazole **219a** occurs under very mild conditions with evolution of morpholine to yield 5-(triazol-1-yl)thiazole. Using derivatives **219b,c** as examples, it was shown that in the absence of a hydrogen atom at the enamine double bond, the triazoline ring easily loses a nitrogen molecule yielding a mixture of 5-aminothiazole derivatives. The reaction of methyl acrylate with azide **219c** affords 5-aziridinotriazole (Scheme 7).

Acyl azides react with alkenes in a similar way, although in some cases, the products of the Curtius rearrangement are formed in parallel.<sup>356</sup>

In some cases, a compound with the enamine fragment is used in the cyclisation as the dipolarophile.<sup>407–409</sup> 1,4-Disubstituted triazoles are formed as the result of ejection of the amine molecule from the triazoline that has already formed.<sup>410, 411</sup> Study of the kinetics of the reaction of aryl azides with methyl 3-pyrrolidinocrotonate **220** has shown that cycloaddition is a concerted asynchronous process controlled by the LUMO of the azide and the HOMO of the dipolarophile.<sup>412</sup>

An unusual rearrangement was found for the products of cycloaddition of heterocyclic acyl azides to aminoacrylate **220**, whereas in the reaction of the latter with methyl crotonate or methyl propiolate, no products of such a transformation were detected.<sup>413</sup>

Het = 2-furyl, 2-thienyl, selenophen-2-yl, thieno[3,2-*b*]thiophen-2-yl.

Scheme 7

R = 2-thienyl (**a**), 2-furyl (**b**), 4-MeC<sub>6</sub>H<sub>4</sub> (**c**).

A number of publications have been devoted to the cycloaddition of azidoalkylphosphonates **221** to enamines.<sup>282, 283, 414</sup> It was shown that, depending on the enamine structure, the reaction can either stop after the formation of 1-phosphorylmethyl-5-amino- $\Delta^2$ -triazolines **222** or afford bicyclic 1-phosphorylmethyl-triazole **223** via elimination of the amine molecule.<sup>414</sup>

R<sup>1</sup> = H, Me, Ph; R<sup>2</sup>–R<sup>3</sup> = (CH<sub>2</sub>)<sub>4</sub>, (CH<sub>2</sub>)<sub>2</sub>O(CH<sub>2</sub>)<sub>2</sub>.

Upon reaction with enamines — amino derivatives of unsaturated acid esters R<sup>1</sup>R<sup>2</sup>NCH=CHCO<sub>2</sub>Alk — substrates **221** are converted into 4-alkoxycarbonyl-1-phosphoryl-methyltriazoles.<sup>414</sup>

β-Amino-α,β-unsaturated carbonyl compounds **224** have been proposed for the synthesis of 4-acyltriazoles and alkyl triazole-4-carboxylates.<sup>415</sup>

R<sup>1</sup> = Bu<sup>n</sup>, n-C<sub>10</sub>H<sub>21</sub>, Bn, Ph, *p*-Tol; R<sup>2</sup> = Me, EtO; R<sup>3</sup> = Me, *p*-Tol.

| (R <sup>3</sup> = <i>p</i> -Tol) |                 |                                   |    |    |               |                 |     |

It was shown that reactions of **224** with tosyl (mesyl) azide are accompanied by the 'diazo transfer', *i.e.*, elimination of sulfonylamine and an attack by the diazo group on the enamine nitrogen. The reaction affords only one regioisomer of triazole **225**, whose yield depends on the reactant structure. It is noteworthy that the product yields are higher with mesyl azide.<sup>415</sup>

This strategy is also applicable for the solid-state synthesis of 4-carbamoyltriazoles **226**.<sup>416</sup>

(a)  $\text{TsN}_3$ ,  $\text{Pr}_4\text{NEt}$ ,  $\text{DMF}$ ; (b)  $\text{TFA}$ ,  $\text{CH}_2\text{Cl}_2$ ,  $20^\circ\text{C}$ ;

(P) is the polymer support;

R = CH<sub>2</sub>CO<sub>2</sub>Bn, CH<sub>2</sub>C<sub>6</sub>H<sub>4</sub>OMe-4, (CH<sub>2</sub>)<sub>2</sub>C<sub>6</sub>H<sub>4</sub>NO<sub>2</sub>-4.

It has been shown<sup>417</sup> that methyl 3-pyrrolidino-3-formylcrotonate dimethyl acetal is much more reactive in cycloaddition to 4-nitrophenyl azide than the cyclic analogue, namely, enaminofuranone.

The reaction of arylidene derivatives of *N*-acetylindoxyl **227** with hydrazoic acid proceeds as the nucleophilic addition of the N<sub>3</sub><sup>−</sup> anion to the C=C double bond accompanied by cleavage of the C–N bond followed by closure of the triazole ring.<sup>418–420</sup> The reaction takes place on heating substrate **227** with sodium azide in a DMSO–acetic acid mixture to give 4-(2-acetylaminobenzoyl)-5-aryltriazoles **228**.

R = Ph, 4-Pr<sup>i</sup>C<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 4-BrC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-Py.

However, benzylideneacetophenone and 1,2-dibenzoyl ethylene, which do not differ much in structure from enamide **227**, do not form triazole or triazoline derivatives when reacted with 2-(4-pyridyl)ethyl azide, the corresponding enaminoketones being formed instead.<sup>293</sup>

Acyl ketene amins can also act as active dipolarophiles in dipolar cycloaddition.<sup>421</sup> By reactions of acylketene amins **229** with tosyl azide, a series of 5-amino-4-acetyl-1,2,3-triazoles **230** and **231** substituted at the endo-N(1)- or exocyclic nitrogen have been synthesised (Scheme 8).<sup>422</sup>

The reaction takes place in THF at room temperature (only substrates **229b** require refluxing). The researchers believe that the reaction is accompanied by the Dimroth rearrangement of cycloadduct **232** formed initially with subsequent elimination of the TsNH<sub>2</sub> molecule. In the case of amins **229b,c**, the reaction is regioselective to give 5-R<sup>2</sup>NH-4-acyltriazoles **231**; in other cases, isomer mixtures were obtained.<sup>422</sup>

The reactions of similar morpholine or piperidine enaminals containing various electron-withdrawing groups with *p*-nitrophenyl azide resulted in the preparation of only 1-aryltriazoles

Scheme 8

R<sup>1</sup> = Me, Ph; R<sup>2</sup> = Ph (a), PhCO (b), 4,6-dimethylpyrimidin-2-yl (c).

| Aminal | R <sup>1</sup> | Yield (%) |     |

with the functional substituent at the 4-position of the heterocycle (compounds **233**).<sup>423</sup>

X = COMe, CPh, CO<sub>2</sub>Me, CO<sub>2</sub>Et, CO<sub>2</sub>Bn, Ts, NO<sub>2</sub>;  
R–R = (CH<sub>2</sub>)<sub>5</sub>, (CH<sub>2</sub>)<sub>2</sub>O(CH<sub>2</sub>)<sub>2</sub>.

In the general case, the reaction of aryl azides with cyclic acyl ketene amins can follow two pathways to give triazoles of two structural types: annelated and/or fully substituted,<sup>424, 425</sup> the product ratio being dependent on the nature of substituents in the reactants. These dependences were studied qualitatively for the reaction of *para*-substituted phenyl azides **234** with amins **235**, containing a *para*-substituted benzoyl fragment at the double bond. The reaction rate decreases with a decrease in the electron-withdrawing properties of the *para*-substituent Y in aryl azide in the series: NO<sub>2</sub> > Cl > H > OMe and in the electron-releasing properties of the substituent X in the enamine in the series OMe > Me > H > Cl (Scheme 9).<sup>424</sup>

All the enaminals studied react with 4-nitrophenyl azide very easily to give only fully substituted triazoles with two aryl groups **236** (yields 87%–97%) even at room temperature in dioxane. With other azides, the reaction is much slower; refluxing of reactants in dioxane gives product mixtures. In addition to triazoles **236** (yields 8%–71%), compounds **237** are formed, which include a fused triazole system with a bridgehead nitrogen atom (yields 6%–31%). On the basis of the results obtained, the researchers cited proposed a sequence of transformations (see Scheme 9) and concluded that enaminals of this structure react with aryl azides both as nucleophiles and as 1,3-dipolarophiles. In the former case, the terminal nitrogen atom of the azide group

Scheme 9

X = H, Me, MeO, Cl; Y = H, MeO, Cl, NO<sub>2</sub>; n = 1, 2.

attacks the β-carbon atom of enamine to give an adduct whose subsequent cyclisation and dehydration afford 1,4,5-trisubstituted triazole **236**. In the alternative process, enaminals react as usual dipolarophiles. The resulting adducts undergo the Dimroth rearrangement followed by deamination to give fused triazoles **237**.<sup>424</sup> The reaction with amins of benzoyl-substituted heterocyclic ketenes was also carried out using 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl azide,<sup>426, 427</sup> while protected ribosyl azide was used in the reaction with aryl ketene amins.<sup>428</sup>

Isopropylidenedihydrotetrazoles **238**, which contain an enamine fragment, also react with alkyl azides to give spiro compounds **239**. These products undergo [3 + 2]-cyclo-reversion during thermolysis to eject methyl azide. The final products **240** exist as mixtures of iminodihydrotriazole geometric isomers in which the *E*-isomer predominates.<sup>429</sup>

R = Me, CD<sub>3</sub>, CH<sub>2</sub>Bu<sup>t</sup>.

The aroyl derivatives of *S,S*- and *S,N*-acetals of polarised ketenes are also able to react with azides: on heating in DMSO with NaN<sub>3</sub>, the former are converted into 4-aroyle-5-methylthio-triazoles, while the latter give only 5-aroyletriazoles under the same conditions.<sup>430</sup> In addition, the aroyl derivatives of ketene *S,N*-acetals of ketenes **241** do not react with tosyl azide in boiling dioxane,<sup>431</sup> but they react in ethanol in the presence of alkali even

at room temperature. In this case, intermediate triazolines **242** eliminate MeSH and undergo the Dimroth rearrangement, resulting in 1-aryl-4-aryl-5-tosylaminotriazoles **243**. On treatment with sulfuric acid, the products give off the tosyl group, while the 5-aminotriazoles **244** thus produced undergo one more Dimroth rearrangement on refluxing in pyridine, being converted into substituted 5-anilinothiazoles **245**.<sup>431</sup>

R = Me, Et, Pr<sup>n</sup>, Pr<sup>i</sup>, Bu<sup>n</sup>, Cy, Bn, (EtO)<sub>2</sub>CHCH<sub>2</sub>, Ph;  
Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>.

The reaction of tosyl azide with aroyl derivatives of cyclic ketene *S,N*-acetals carried out under the same conditions (NaOH, EtOH) is accompanied by resinification, but this reaction performed by refluxing in dioxane gives annelated triazoles **246** in good yields.<sup>431</sup>

Ar = Ph (69%), 4-ClC<sub>6</sub>H<sub>4</sub> (60%), 4-MeOC<sub>6</sub>H<sub>4</sub> (65%).

If cyclic ketene *N,X*-acetals (X = Me<sub>2</sub>C, MeN, O, S) react with azides that possess enhanced electrophilicity, this yields unstable triazoline adducts, which immediately eliminate N<sub>2</sub>. Simultaneously, the triazoline ring is cleaved giving rise to other nitrogen-containing heterocycles.<sup>432</sup>

In the case of two geminal acceptor groups at the double bond (*e.g.*, alkene **247**), the reaction with organic azide proceeds with difficulty and gives, in addition to dihydrotriazole, a side acyclic enamine product, which is apparently formed upon rearrangement rather than upon triazoline decomposition.<sup>433</sup>

Ar = 4-MeOC<sub>6</sub>H<sub>4</sub>.

Alkenes that contain an electron-withdrawing nitro group at the double bond readily react with azides. Furan- and indole-based α,β-unsaturated ketones containing an α-nitro group have been used to prepare 4-hetaryl-5-acyltriazoles.<sup>434</sup> The reaction of α-nitroalkenes (R<sup>1</sup>CH = CR<sup>2</sup>NO<sub>2</sub>) with methyl and phenyl azides was found<sup>435, 436</sup> to give only 1-Me(Ph)-4-R<sup>2</sup>-4-NO<sub>2</sub>-5-R<sup>1</sup>-triazolines, which are converted into 1-Me(Ph)-4-R<sup>2</sup>-5-R<sup>1</sup>-triazoles after elimination of HNO<sub>2</sub>. The reactions of β-nitrostyrene and nitropropene homologues with the same azides give not only

isomeric 1- and 3-substituted triazoles containing no nitro group but also 1-substituted 4-nitrotriazole.<sup>437</sup> Apparently, this product results from oxidative cyclisation of the intermediate diazo compound PhCHNHR<sup>1</sup>C(NO<sub>2</sub>)=N<sub>2</sub>, which is the open form of the corresponding triazoline.<sup>437</sup>

Recently, it has been shown that the double bond in β-nitrostyrenes **248** can be involved in dipolar cycloaddition with elimination of a nitro group. This gave triazoles **249** in high yields.<sup>438</sup>

R is cyclohex-1-enyl; Ar = Ph, 4-MeOC<sub>6</sub>H<sub>4</sub>.

Of particular interest as the initial components for the synthesis of nitrotriazoles are *gem*-dinitroethylenes **250**, which are prepared either from alkyl dinitroacetate and the products of its transformation or starting from 1,1,1-trinitroalkanes.<sup>439–441</sup>

R = H, Me, Bu<sup>n</sup>, 4-MeC<sub>6</sub>H<sub>4</sub>, Me<sub>2</sub>N.

The reaction of tetranitrobutane-2,3-diol diacetates **251** with NaN<sub>3</sub> smoothly produces dinitro-substituted bis-triazole **252**, probably through the intermediate tetranitrobutadiene.<sup>440</sup>

R = H (67%), Br (34%).

Unlike the diacetate, the monoacetate of tetranitrobutanediol forms only one triazole ring under these conditions, which is confirmed by the subsequent oxidation of the product to 5-nitrotriazole-4-carboxylic acid.<sup>440</sup>

The reaction of vinylcyclopropenylruthenium complex **253** with excess Me<sub>3</sub>SiN<sub>3</sub> follows an unusual route, resulting in 4-ethyl-5-phenyltriazole.<sup>442</sup> Presumably, the addition of Me<sub>3</sub>Si to an exocyclic double bond is accompanied by cyclopropenyl ring opening. The presence of traces of water in the solvent promotes elimination of the silyl group from the intermediate and the formation of complex **254**. The repeated attack by Me<sub>3</sub>SiN<sub>3</sub> on the double bond of the intermediate results in the [3+2]-cycloaddition product, which is converted into a triazole ring after elimination of the cyanoruthenium fragment.<sup>442, 443</sup>

Cyclocondensation has been carried out for 3-aminoisothiazole 1,1-dioxide.<sup>444</sup> The reaction of these cyclic sulfones containing an amidine fragment yields a mixture of several products depending on the conditions. The highest yield (70%) of the bicyclic adduct, namely, dihydrogenated isothiazolo[4,5-*d*]tri-

azole **255**, was attained by using isothiazoline **256** or isothiazole **257** as the starting compounds.

Ar = 4-MeOC<sub>6</sub>H<sub>4</sub>.

Cations of nitrogen-containing heteroallenes (1,3-diaza-2-azoniaallene salts) can be introduced in cycloadditions as the 1,3-dipolar component; they react stereoselectively, for example, with glycals.<sup>445</sup>

### 3. Reactions of azides with CH-active compounds

Depending on the reaction mechanism and the nature of the activating groups [most often, C(O)R or C≡N], the key stages of these reactions can formally be considered as either ionic (the nucleophilic addition of a carbanion to the azide group) or azide cycloaddition to the olefin intermediate (enol or enolate) or to the C=C=NH fragment.

Back in 1902, Dimroth<sup>446</sup> performed the reaction of phenyl azide with ethyl acetoacetate in ethanol in the presence of EtONa and obtained 1-phenyl-5-methyltriazole-4-carboxylic acid. Subsequently, Huisgen *et al.*<sup>447</sup> successfully used ethyl formylacetate in this reaction and obtained 1-phenyltriazole-4-carboxylic acid.<sup>403</sup> Later, other organic azides and various dicarbonyl compounds containing CH-active groups (acetylacetone, ethyl malonate, acetoacetate and cyanoacetate, *etc.*) have been used to prepare substituted triazoles. Other examples of such reactions are documented in reviews.<sup>2,3,8</sup> The reaction of azides with cyanomethylenecarbonyl compounds has some specific features. Apart from aminotriazoles, products of reduction of the azido group were found in the reaction mixture; in several cases, these were the major components.

Previously, Olsen showed<sup>448</sup> that methyl (or benzyl) azide is capable of reactions with ketones in Bu<sup>t</sup>OH in the presence of Bu<sup>t</sup>OK to give 1-methyl(benzyl)-5-alkyl-5-hydroxytriazolines, which are readily dehydrated to the corresponding 5-alkyltriazoles. Later, acetaldehyde enolate was involved in cyclocondensation with some acetaldehyde arylazides to give 1-aryltriazoles in high yield (Scheme 10).<sup>449</sup>

Ar = C<sub>6</sub>H<sub>4</sub>R; R = H, 2-Me, 4-Me, 3-OMe, 4-OMe, 2-SMe, 2-SEt.

Only phenyl azides with electron-releasing substituents in the aromatic ring can be used in this reaction. This increases the stability of the triazoline ring and, hence, the equilibrium shifts from triazene ketone **258** towards hydroxytriazoline **259**, which is dehydrated on treatment with MeONa or Bu<sup>t</sup>OK. The reaction is complicated by side reactant destruction processes.

The reactions of organic azides with arylacetic esters can be exemplified by the reaction of phenyl azide with ethyl benzoxazolyl-2-acetate. This affords 1-phenyltriazol-5-olate **260**; attempts to isolate the product as a neutral compound resulted in triazole ring opening.<sup>450</sup>

The reaction of diethyl malonate **261a** with benzyl azides in DMSO<sup>451</sup> gives the corresponding 1-benzyl-5-hydroxy-4-ethoxycarbonyltriazoles. However, with ethyl phenylacetate **261b**, the yield of triazole was relatively low (8%), and esters **261c,d** did not react at all.

Ar = Ph, 4-MeOC<sub>6</sub>H<sub>4</sub>, 3,5-Cl<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; X = CO<sub>2</sub>Et (**a**), Ph (**b**), F (**c**), NO<sub>2</sub> (**d**).

Diethyl malonate reacts with aryl azides in EtOH in a similar way;<sup>187</sup> 4-nitrophenyl and tosyl azide react with alkyl malonates in HMPT to give 2-diazomalonates.<sup>452</sup>

Ethyl alkylidenemalonates react with NaN<sub>3</sub> in DMSO to give triazoles *via* intermediate 4,5-dihydrotriazoles and with benzyl azide to give 1-benzyl-4,5-dihydrotriazole. On treatment with Bu<sup>t</sup>OK in DMSO, the latter products undergo either aromatisation to triazoles, or deethoxycarbonylation without aromatisation, or lose nitrogen, being converted into ethyl (benzylamino)methylidenemalonates.<sup>453</sup>

The reaction of azides with 1,3-diketones allows the synthesis of triazole ketones. For example, benzyl azides react with acetylacetone to afford 1-substituted 4-acetyl-5-methyltriazoles in high yields (at R = Me **262** ≡ **263**); the reaction with benzoylacetone gives mixtures of two regioisomers, **262** and **263**, in a ~1:1.5 ratio.<sup>451</sup>

Ar = Ph, 3,5-Cl<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; R = Me, Ph.

Analogous reactions between 4-nitrophenyl azide and various 1,3-diketones and alkyl acetoacetates in HMPT resulted in the synthesis of carbonyl compounds with a triazole ring.<sup>452,454</sup> Ethyl 1-aryl-5-methyltriazole-4-carboxylates, formed upon reactions of the aryl azides  $\text{RC}_6\text{H}_4\text{N}_3$  (R = H, 2-Me, 3-Me, 4-Me, 2-MeO, 4-MeO, 2-Cl, 3-Cl, 4-Cl, 2-Br, 3-Br, 4-Br) with ethyl acetoacetate in the presence of EtONa, were subjected to alkaline hydrolysis giving rise to a series of the corresponding acids in 43%–80% yields.<sup>455</sup>

Phenyl azide reacts with methyl γ-methoxyacetoacetate in the presence of Et<sub>3</sub>N in boiling MeOH (the yield of methyl 5-methoxy-1-phenyltriazole-4-carboxylate is ≤24%<sup>201</sup>) and reacts with macrocyclic oxo ester **264** yielding 5-hydroxytriazole due to opening of the macrocycle.<sup>456</sup>

The reaction of 2-nitrophenyl azide with ethyl benzoylacetate affords the 1-nitrophenyl derivative of triazole **265**, which was used to prepare the triazolo[1,2-a]benzotriazole system **266**.<sup>457</sup>

A similar protocol was also realised for other carbonyl compounds.<sup>458, 459</sup>

$R^1 = \text{COPh}$ ,  $R^2 = \text{OEt}$ ;  $R^2 = \text{Me}$ :  $R^1 = \text{COMe}$ ,  $\text{CO}_2\text{Et}$ ,  $\text{Ph}$ .

The reaction of azides with CH-activated compounds has found wide use in the synthesis of polynuclear heterocyclic structures. The reactions of substituted azidofurazans with  $\beta$ -dicarbonyl compounds furnished a series of (triazol-1-yl)furazans **267** in high yields.<sup>460, 461</sup>

$R^1 = \text{Me}$ ,  $\text{Ph}$ ,  $\text{MeO}$ ,  $\text{NH}_2$ ;  $R^2 = \text{Me}$ ,  $\text{Et}$ ,  $\text{Pr}^n$ ,  $\text{MeOCH}_2$ ,  $\text{ClCH}_2$ ,  $\text{Ph}$ ;  
 $R^3 = \text{Me}$ ,  $\text{Ph}$ ,  $\text{MeO}$ ,  $\text{EtO}$ .

The predominant formation of one regioisomer is in line with the data on the reaction of 2-azidothiazoles with 1,3-dicarbonyl compounds.<sup>462</sup>

By condensing various  $\text{CF}_3$ -substituted 2- and 4-azidopyrimidines with  $\text{RC(O)CH}_2\text{CO}_2\text{Et}$  ( $R = \text{Me}$ ,  $\text{Ph}$ , 4-Py), a broad range of 1-pyridyl-5-methyl(or aryl)triazole-4-carboxylates have been prepared.<sup>247</sup>

Starting from 4-azidoquinolines, ethyl *p*-nitrobenzoylacetate and other  $\text{CH}_2$ -active compounds, a series of 1-(4-quinolyl)triazoles have been synthesised.<sup>463, 464</sup> 1-(Acridin-9-yl)-4-methoxycarbonyl-5-*R*-triazoles [ $R = \text{Me}$ ,  $\text{Et}$ ,  $\text{Pr}$ ,  $(\text{CH}_2)_4\text{Cl}$ ,  $\text{CH}_2\text{CO}_2\text{Me}$ ,  $\text{Ph}$ ] have been prepared from 9-azidoacridines. The regioselectivity of the base-catalysed reaction may be indicative of an ionic mechanism of the successive steps.<sup>36</sup>

Refluxing 3-azidophenanthro[9,10-*e*][1,2,4]triazine and ethyl acetoacetate produces, in a high yield, 1-hetaryl-5-methyltriazole-4-carboxylic acid, which is readily decarboxylated on heating above the melting point.<sup>338</sup>

The reaction of aryl azides with dimethyl acetonedicarboxylate carried out by refluxing the reactants in  $\text{MeOH}$  in the presence of  $\text{Et}_3\text{N}$  gave disubstituted triazoles **268**. Repeated treatment of these esters with tosyl azide under phase transfer catalysis conditions resulted in diazo derivatives at the methylene

group, triazoles **269**, which were converted into triazolylnorcaradienes **270** (in the *endo*-hetaryl, *exo*-methoxycarbonyl configuration) on heating in benzene.<sup>465</sup>

$\text{Ar} = \text{Ph}$ , 4- $\text{ClC}_6\text{H}_4$ , 4- $\text{BrC}_6\text{H}_4$ , 4- $\text{NO}_2\text{C}_6\text{H}_4$ , 4- $\text{MeCOC}_6\text{H}_4$ , 2,4- $\text{Cl}_2\text{C}_6\text{H}_3$ .

It has been shown<sup>466</sup> that the reaction of 2- and 4-azidopyrimidines with  $\beta$ -dicarbonyl compounds (acylacetones) in  $\text{EtOH}$  or dioxane in the presence of  $\text{Et}_3\text{N}$  gives 1-pyrimidinyl-4-acyl-1,2,3-triazoles in good yields. In the case of acetylacetone, the reaction of 2-aryl-4-azidopyrimidines gives rise to 4-acetyl-5-methyltriazoles (at  $R^2 = \text{Me}$ , **271**  $\equiv$  **272**), whereas in the case of benzoylacetone, mixtures containing equal amounts of regioisomers **271** and **272** are formed. The reaction rate depends on the nature of the substituent in the 2-aryl groups of pyrimidine. On the one hand, electron-releasing substituents retard the process; on the other hand, the most pronounced accelerating effect was noted for *o*-hydroxyphenyl derivatives, which form a strong intramolecular hydrogen bond between the hydroxyl group and the neighbouring pyrimidine nitrogen.<sup>466</sup>

$R^1 = \text{H}$ ,  $\text{Ph}$ ;  $\text{Ar} = \text{Ph}$ , 4- $\text{BrC}_6\text{H}_4$ , 2- $\text{HOC}_6\text{H}_4$ , 2- $\text{MeOC}_6\text{H}_4$ , 4- $\text{MeOC}_6\text{H}_4$ ;  
 $R^2 = \text{Me}$ ,  $\text{Ph}$ .

The reactions of (het)aryl azides with alkyl cyanoacetates give in some cases (het)arylamines as side products (the formal reduction of the azido group to the amino group). One factor directing the reaction along this pathway is the enhanced  $\text{CH}$ -acidity of the dipolarophile. When interpreting the experimental results, researchers consider two possible reaction pathways. Azide cycloaddition to the double bond of the enol form of the dipolarophile gives 5-hydroxytriazoline, while its open form, unstable triazene of type **258** (see Scheme 10), spontaneously decomposes to amine and diazo ketone (or diazo ester).<sup>38, 467, 468</sup>

When two azide groups are present at the 4- and 6-positions of the pyrimidine ring (compound **273**), the reaction with cyanoacetate does not lead to triazoles but stops after the formation of 4-azido-6-aminopyrimidine **274** (Scheme 11).<sup>469</sup>

When other  $\beta$ -dicarbonyl compounds are used (acetylacetone, ethyl acetoacetate and ethyl benzoylacetate), diazidopyrimidine **273** is converted into bis(triazolyl)pyrimidines, although completion of the reaction requires long-term refluxing. Only in one case, when 1 equivalent of acetylacetone is made to react with diazidopyrimidine **273**, 4-amino- and 4-azido-6-(triazol-1-yl)pyrimidines were detected in minor amounts apart from bis(triazolyl)pyrimidine **275**.<sup>469</sup>

However, in the reaction of diazido-1,3,5-triazines **276** with compounds having a reactive  $\text{CH}_2$  group, both azide substituents

Ar = 4-MeOC<sub>6</sub>H<sub>4</sub>; X = CO<sub>2</sub>Et, Ac;

(a) Et<sub>3</sub>N, DMF, 20 °C; (b) Et<sub>3</sub>N, EtOH, Δ.

can be transformed into amino groups due to the better acceptor properties of the heterocycle.<sup>468</sup>

Z = MeO, EtO, NH<sub>2</sub>; R = Me, EtO.

For azides with fragments having lower electron-withdrawing ability than pyrimidine and 1,3,5-triazine rings, 'diazo transfer' processes in the triazene and its decomposition (see Scheme 10) do not play a crucial role, the reaction being directed along the usual route to give 5-aminotriazoles. The reaction of phenyl azide with CH<sub>2</sub>-active compounds containing a cyano group was first performed by Dimroth.<sup>470</sup> The reaction does not follow a concerted mechanism; it starts with attack of the electrophilic terminal nitrogen atom of the azide on the anion derived from the cyanomethylene component, resulting in the formation of the intermediate triazene, in which the anionic nitrogen atom attacks the electrophilic carbon atom of the cyano group in the same molecule. 'Quenching' (protonation) of the anion and isomerisation of the imine produce the final product, namely, amino-triazole.<sup>3</sup>

R = Ph, CO<sub>2</sub>Alk, CONH<sub>2</sub>, CN.

This route is important from the synthetic standpoint;<sup>4</sup> however, its use is restricted due to the lability of both the starting compounds and the reaction products under the given conditions. For example, it is known that 1-substituted 5-aminotriazoles readily undergo the Dimroth rearrangement; therefore, to prevent this transformation, the reaction is usually carried out at a lower temperature. In some cases, the optimal condition is to perform the process at room temperature in the presence of Bu<sup>t</sup>OK in Bu<sup>n</sup>OH or anhydrous K<sub>2</sub>CO<sub>3</sub> in DMSO.<sup>451</sup>

The substituents of choice in the RCH<sub>2</sub>CN molecule are Ph, CO<sub>2</sub>Alk, CONH<sub>2</sub> and CN. Aryl and vinyl azides readily react with these cyano derivatives (examples are documented<sup>3,6,34,471</sup>), while HN<sub>3</sub> and acyl azides do not react. Benzyl and alkyl azides give ambiguous results. For example, in the above-mentioned reaction of benzyl azide with ethyl cyanoacetate (EtONa, EtOH, 20 °C), the yield of ethyl 1-benzyl-5-aminotriazole-4-carboxylate did not exceed 5%.<sup>472</sup> The yield was increased by increasing the reaction time (30%)<sup>473</sup> or by conducting it under an elevated pressure of 5 kbar (53%). The attempt to replace the solvent by DMSO was unsuccessful.<sup>451</sup> On refluxing phenylethyl azide in ethanol in the presence of EtONa, the yield of 5-aminotriazole was low.<sup>474</sup>

Various substituted phenyl azides were used for the synthesis of *N*-aryl-5-aminotriazoles.<sup>475</sup>

Ar = 3-ClC<sub>6</sub>H<sub>4</sub>, 3-F<sub>3</sub>CC<sub>6</sub>H<sub>4</sub>, 3-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 3-F<sub>3</sub>CSC<sub>6</sub>H<sub>4</sub>, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-FC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 4-F<sub>3</sub>CC<sub>6</sub>H<sub>4</sub>, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 2,4-Cl<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, 2,5-Cl<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, 3,4-Cl<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, 2,4,6-Cl<sub>2</sub>C<sub>6</sub>H<sub>2</sub>, 2-Cl-3-F-4-F<sub>3</sub>CC<sub>6</sub>H<sub>2</sub>.

Similar products have been obtained from hetaryl azides, for example, 4-azidopyridine and its *N*-oxide,<sup>26</sup> 6-azido-2,3-diphenyl-indole,<sup>239</sup> 5-azido-2-trifluoromethylpyrimidine.<sup>475</sup> Most often, the reaction is carried out at 0–20 °C to prevent the Dimroth rearrangement.

Other acetonitriles have also been used in reactions with azides. For example, 1,4-disubstituted 5-aminotriazoles **277** were prepared by the reaction of 4-nitrophenyl and 4-pyridyl azides with nitriles **278a–c** (condition *a*)<sup>26,76</sup> and benzyl azide with nitriles **278d,e** (condition *b*).<sup>476,477</sup>

R<sup>1</sup> = Bn, 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>, 4-Py, 4-Py-*N*-oxide; R<sup>2</sup> = CO<sub>2</sub>Me (**a**), Ph (**b**), 4-ClC<sub>6</sub>H<sub>4</sub> (**c**), 4-MeOC<sub>6</sub>H<sub>4</sub> (**d**), 4-MeC<sub>6</sub>H<sub>4</sub> (**e**);  
(a) MeONa, MeOH; (b) Bu<sup>t</sup>OK, THF.

1-(Acridin-9-yl)-5-amino-4-aryltriazoles (Ar = Ph, 2-ClC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 2-Py) and analogous 4-carbamoyltriazoles have been synthesised on the basis of 9-azido-acridines and cyano derivatives.<sup>36</sup>

Refluxing a mixture of 4-nitrophenyl azide and ethyl cyanoacetate in EtOH yielded the Dimroth rearrangement product, 5-arylamino derivative **279**.<sup>26</sup>

An analogous compound has been isolated, together with the product of its alkylation, in pronounced amounts in addition to the expected 5-amino-4-ethoxycarbonyl-1,2,3-triazole, upon the reaction of 1-naphthyl azide with ethyl cyanoacetate.<sup>478</sup>

The chemoselectivity of the reaction of phenyl azide with the cyanoketone group incorporated in a macrocyclic system depends on the type of the base.<sup>456</sup> In the presence of EtONa, the macrocycle in the intermediate adduct is cleaved to give 5-amino-4-ethoxycarbonyl-1,2,3-triazole **280** and the product of its intramolecular N-acylation **281** as an impurity. When NaH is used, acylation is intermolecular, giving rise to the product of O-acylation of the enol form of the starting cyanoketone **282**.<sup>456</sup>

The reaction of azides with cyanoacetamide proceeds smoothly giving the corresponding 5-amino-4-carboxamidotriazoles in high yields. Depending on the nature of the azide, the reaction is carried out in EtOH in the presence of EtONa at various temperatures (0–5 °C,<sup>479</sup> 20 °C<sup>474</sup> or 70 °C<sup>138</sup>), in DMF in the presence of KOH (0 °C)<sup>292</sup> or in DMSO in the presence of K<sub>2</sub>CO<sub>3</sub> (35–40 °C).<sup>451</sup> The resulting 5-amino-4-carbamoyl-1,2,3-triazoles are of interest as biologically active compounds<sup>480,481</sup> and the starting compounds for the synthesis of fused heterocyclic systems.<sup>8,482</sup> The preparation of these derivatives (**283**) by the reaction of substituted methyl azides with cyanoacetamide and their further transformation into 8-azapurines **284**, which are acyclic analogues of nucleosides, have been reported.<sup>292,483</sup>

R = BnO(CH<sub>2</sub>)<sub>2</sub>, (BnOCH<sub>2</sub>)<sub>2</sub>CH, BnO(BnOCH<sub>2</sub>)CHCH<sub>2</sub>; X = O, S.

5-Amino-4-carbamoyl-1,2,3-triazole 1-β-ribozide has been prepared in a similar way; it can be used to prepare 9-β-ribozides of 8-azahypoxanthines.<sup>484,485</sup> 2,9-Disubstituted 8-azapurin-6-ones were synthesised without isolation of intermediate triazoles.<sup>486</sup>

Of special interest from the synthetic standpoint is the reaction of the cyano carbanions RCH<sup>−</sup>CN with *ortho*-substituted aryl azides (substituents CN, NO<sub>2</sub>, CO<sub>2</sub>H). Previously, it was found that aminotriazole **285** formed *in situ* is involved in the formation of the new ring:<sup>487–489</sup> the amide anionic centre attacks the electrophilic centre of the *ortho*-substituent.

R = Ph, CO<sub>2</sub>Et, CONH<sub>2</sub>, CN.

When aryl azide (or benzyl azide) contains a carbonyl group, the cyclisation ends with the formation of substituted 4*H*-triazolo[1,5-*a*]quinazolinones **286** and their seven-membered analogues **287**, respectively.<sup>490–492</sup>

R = H, Et; Y = Ph, CONH<sub>2</sub>, CONHMe, CO<sub>2</sub>Et.

Azidocyano derivatives of five-membered nitrogen heterocycles react in this way with the anions derived from substituted acetamides, the subsequent transformations of the compounds formed being dependent on the nature of the heterocycle and the acetamide. For example, 5-azido-4-cyanopyrazole **288** is converted into different products when reacted with phenylacetone, cyanoacetamide and cyanoacetic acid and its esters.<sup>493</sup> Interestingly, the mechanism of the last-mentioned transformation includes opening of the triazole ring at the N–N bond, ejection of the nitrogen molecule and decarboxylation (Scheme 12).

In the reaction of 5-azido-4-cyanotriazoles **289** with substituted acetonitriles, it is possible to detect both tautomers of the product, namely, cyclic **290** and open **291** tautomers, whose ratio depends on the polarity of the medium and the nature of the substituent.<sup>494,495</sup>

Scheme 12

Subsequently, the scope of this reaction was extended. The reactions of various *ortho*-substituted aryl azides with the diethyl acetonedicarboxylate carbanion generated under the action of bases or an ion exchange resin in the OH-form have been studied.<sup>489</sup> The reactions take place in ethanol at room temperature. The side fragment in the intermediate 1-aryltriazole **292** interacts immediately with the *ortho*-substituent. The closure of the additional ring affords tricyclic system **293**.

The amino or hydroxy derivative of 1,2,3-triazolo[1,5-*a*][1,7]naphthyridine is formed in a similar way from azidopyridine containing a CN or a CO<sub>2</sub>Et group, respectively, when made to react with diethyl acetonedicarboxylate.<sup>489</sup>

Only in the case of 2-nitrophenyl azide, was 1-(2-nitrophenyl)-triazole isolated; it was reduced to the corresponding *o*-amino-phenyl derivative, which was refluxed in xylene containing some *p*-toluenesulfonic acid to give 1,2,3-triazolo[1,5-*a*]benzo[1,5]diazepin-6-one **292** in a quantitative yield<sup>489</sup>

Similar transformations have been employed in the synthesis of 8-aza-3-deazaguanine nucleosides; the reaction between protected glycosyl azides and dimethyl acetonedicarboxylate was carried out in DMSO in the presence of K<sub>2</sub>CO<sub>3</sub>.<sup>496</sup>

The behaviour of 5-azido-4-cyanoimidazole **294** in the reaction with compounds containing an active CH<sub>2</sub>-group differs from that presented above for the benzene and pyridine analogues. It was shown that, depending on the conditions of reactions with β-dicarbonyl compounds, either imidazolate (**295a**) or tetrazepinate salts (**296**) can be isolated; on treatment with HCl in tetrahydrofuran, these products are converted into the corresponding imidazolytriazole **295** in high yields.<sup>497</sup>

The outcome of the reaction of the same azide with malononitrile depends on the conditions of product isolation. It has been assumed<sup>497</sup> that imidazo[5,1-*d*][1,2,3,5]tetrazepinate salts play a key role in these transformations.

When the phenyl azide molecule contains an *o*-CHO group, the reaction pathway is determined by the conditions, in particular, by the solvent used. The reaction of 2-azidobenzaldehyde with substituted acetonitriles in EtOH in the presence of piperidine or EtONa results in tetrazolo[1,5-*a*]quinolines **297** (first, the Knoevenagel condensation takes place at the aldehyde group and only after that, does the 1,3-cycloaddition of the azide group to the  $C\equiv N$  bond of the intermediate nitrile occur). However, the same reaction in an aprotic solvent at 0 °C yields triazolo[1,5-*a*]quinazolines **298**.<sup>498</sup> With the protected aldehyde function (as the oxime or *N*-methylnitron), this reaction produces only triazolo[1,5-*a*]quinazolines **298**, irrespective of the conditions.<sup>498</sup>

The attempts to induce a regioselective attack by cyano carbanions on the carbonyl group in 2-azidoacetophenone failed, 5-methyltriazolo[1,5-*a*]quinazolines being isolated as the only products.<sup>489</sup>

The behaviour of mono- and dimethyl-6-azido-5-formyluracils towards ethyl cyanoacetate and malononitrile in ethanol is similar to that of 2-azidobenzaldehyde: in the presence of piperidine, only the corresponding tetrazolo[1',5':1,6]pyrido[2,3-*d*]pyrimidines are formed.<sup>499</sup>

The reaction of 3-azidothiophene-2-carboxaldehyde with substituted acetonitriles was carried out using the acetal protection of the aldehyde group in order to prevent the aldol-crotonic condensation. The protection was removed after the formation of aminotriazole; the condensation of the free aldehyde group with the amino group gave a pyrimidine ring in the tricyclic system **299**.<sup>488</sup>

The behaviour of two isomeric azido derivatives of benzo[*b*]thiophenealdehydes **300** and **301** towards 1,3-dicarbonyl compounds has been studied.<sup>500</sup> It was shown that only the 2-azido isomer **300**, does form triazole **302** (benzene, piperidine acetate as the catalyst) when made to react with acetylacetone, while in EtOH, reductive deazotisation takes place. The 3-azido isomer reacts with diethyl malonate, ethyl acetoacetate and acetylacetone to give 2-alkylidene derivatives of 3-azidobenzothiophene.<sup>500</sup>

If the (het)aryl azide molecule contains an ester group, instead of the aldehyde group, an amide fragment is formed in the resulting ring. This was shown using azidopyrrole **303** as an example. It was noted that the reaction products did not undergo the Dimroth rearrangement under classical conditions; only upon refluxing in the DMSO–water system, did phenyl derivative **304** rearrange to heterocycle **305** in a quantitative yield.<sup>501, 502</sup>

R = Ph, CN, CONH<sub>2</sub>.

To conclude the Section devoted to the methods of synthesis of triazoles from azides, it is pertinent to list once again the most advanced modifications of the experimental conditions used to carry out dipolar cycloaddition. Apart from the dependence on the nature of reactants, solvents and temperature, the rate and completeness of the reaction were found to depend markedly on the pressure in the reaction system.<sup>214, 216, 242, 291, 473</sup>

The use of ionic liquids as the reaction media allows one to sharply reduce the reaction time.<sup>268</sup> Cascade synthesis of 1-substituted triazoles from allene derivatives of aryl iodides, NaN<sub>3</sub> and norbornene has been carried out.<sup>272</sup> The reactions of organic azides with acetylene amides, azidomethylphosphonates with low-activated acetylenes and enamines and aryl azides with methyl-enephosphoranes have been successfully carried out in the absence of solvents on exposure to microwave radiation.<sup>179, 233, 283, 335</sup>

New methods the regiocontrol of dipolar cycloaddition include encapsulation conditions for the reactants<sup>237</sup> or the 'chemical recognition' principle (for example, the presence of the crown-ether fragment in the azide molecule and the terminal ammonium group in the substituted acetylene).<sup>238</sup> A series of substituted triazoles with a high degree of purity have been prepared by solid-state synthesis using polymer-supported 3-aminocrotonamides and tosyl azide,<sup>416</sup> 2-azidocarboxylic acids,<sup>503, 504</sup> 5-azido-4-hydroxyvaleric acid.<sup>505</sup> However, in this version, it is impossible to use low-reactivity compounds and it is inconvenient to monitor the reaction. It has been proposed to avoid these difficulties by using soluble polymers with grafted dipolarophiles.<sup>306, 506</sup> As a polymer of this type, monomethyl ether of polyethylene glycol with a molecular mass of 5000 (MeO-PEG 5000) was proposed. This polymer is soluble in many organic solvents, which allows one to monitor the cycloaddition using spectral methods. The removal of the target products from the polymer is accomplished under mild conditions by treatment with NaBH<sub>4</sub> in ethanol. Using this procedure, several carbohydrate triazole derivatives have been prepared.<sup>306, 506</sup> Another variant implies attachment of the azide function to a polymer and carrying out cyclocondensation with DMAD or terminal acetylenes containing Ph, CO<sub>2</sub>Me, CH<sub>2</sub>Cl, CH<sub>2</sub>Br, CH<sub>2</sub>OH or CH<sub>2</sub>CH<sub>2</sub>OH group. The reaction mixture is then treated with formic acid to isolate the regioisomers, namely, 4- and 5-substituted triazoles.<sup>507</sup> The solid-state combinatorial synthesis of substituted carboxamidotriazoles by successive treatment of supported 3-oxobutyramide with triethyl orthoformate and tosyl azide has been described.<sup>508</sup>

## V. Methods of formation of the C(4)–C(5) and N(1)–N(2) bonds

This line of research is not very popular in triazole synthesis. This is mainly limited to the condensation of diazo derivatives with compounds containing activated C=N bonds. It was found in the mid-20th century that metallated derivatives of diazoethane and phenyldiazomethane form 4,5-dimethyl- or 4,5-diphenyltriazoles, respectively.<sup>509, 510</sup> Some suggestions have been made concerning the reaction mechanism and the structures of intermediates but they have long remained unproved. In a recent publication,<sup>511</sup> the reaction of trimethylsilyldiazomethane with butyllithium was studied, the structure of the dimerisation product formed was determined and theoretical calculations were performed that made it possible to correct the existing views on the structure of the reacting species and the dimerisation mechanism. The general scheme includes the reaction between two dipolar diazomethane molecules, the formation of the lithium derivative of *N*-amino-triazole **306** and cleavage of the exocyclic N–N bond. Treatment of the reaction mixture with water results in disubstituted triazoles **307**.<sup>511</sup>

R = Me, Ph, Me<sub>3</sub>Si.

Phenyl isocyanate reacts with trimethylsilyldiazomethane in the presence of butyllithium to give 5-hydroxy-1-phenyltriazole.<sup>512</sup>

C-Metallated diazoalkanes are also capable of this type of cyclocondensation. Indeed, the  $\alpha$ -diazomethylzirconium complex reacts with phenyl and naphthyl isocyanates to give triazole derivatives.<sup>513</sup>

Isothiocyanates easily react with the lithium salt of trimethylsilyldiazomethane but the reaction pathway depends on the solvent used: 2-amino-1,3,4-thiadiazoles are formed in Et<sub>2</sub>O; only conducting the reaction in THF, does allow one to prepare 1-substituted 5-alkylthio-4-trimethylsilyltriazoles.<sup>514</sup> The Me<sub>3</sub>Si group is readily removed by refluxing of the reaction products with 10% KOH.

R<sup>1</sup> = Me, Bu<sup>n</sup>, Bn, Ph, CH<sub>2</sub> = CHCH<sub>2</sub>; R<sup>2</sup>X = MeI, BnBr.

4,5-Diaryltriazoles **308** are formed in the reaction of phenyl-diazomethane with substituted benzonitriles in the presence of Bu<sup>t</sup>OK according to the dipolar cycloaddition pattern to an activated C≡N bond.<sup>515</sup> The function of a base is to eliminate a proton in the cycloadduct to give anion **308a**, the treatment of which with an aqueous solution of an acid gives the corresponding triazole.

Ar = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 2-BrC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>.

It is noteworthy that azines of aromatic aldehydes (Bu<sup>t</sup>OK, DMSO, 20 °C) enter into a similar reaction to give symmetric 4,5-diaryltriazoles (Ar = Ph, 3-MeOC<sub>6</sub>H<sub>4</sub>, 4-ClC<sub>6</sub>H<sub>4</sub>), but the product yield does not exceed 40%.<sup>515</sup>

Other cyano derivatives in which the C≡N bond is activated can also react with diazo compounds. For example, cyanotrinitromethane reacts with methyl diazoacetate in ether at room temperature to give 5-methoxy-4-trinitromethyl-2*H*-triazole **309**, which undergoes N-alkylation on long-term storage in the reaction mixture.<sup>516, 517</sup>

2-Cyanochromone and its 7-chloro derivative reacts with excess diazomethane to give a set of three *N*-methylated triazoles **310–312** in which the 2-methyl derivatives **310** predominate.<sup>518</sup> Presumably, prototropic triazole is first formed and then it undergoes N-methylation. The reaction of diazomethane with nitrophthalonitriles proceeds in a similar way, but involving only one cyano group.<sup>519</sup>

In order to obtain N–N' bonded triazole rings, attempts have been made to involve *N*-arylideneaminotriazoles and diphenylnitrile imine in cycloaddition.<sup>520</sup> However, the C=N bond in *N*-arylideneaminotriazoles proved to be inactive and only in the case of Ar = 4-NO<sub>2</sub>C<sub>6</sub>H<sub>4</sub>, did the reaction give triaryltriazole isomers in satisfactory yields. Diphenylnitrile imine was generated *in situ* by treatment of *N*-phenylbenzoylhydrazonoyl chloride with triethylamine in an aprotic solvent (THF–benzene), and the suspension obtained in this way was kept at the boiling point of

the solvent mixture. Presumably, the reaction proceeds *via* isomeric cycloadducts, each of them decomposing with cleavage of the exocyclic N–N bond to give 1,2,3-triazole derivatives **313** and 1,2,4-triazole derivatives **314**, respectively.<sup>520</sup> The intermediate 4,5-dimethyltriazole **315** adds a second nitrile imine molecule (at the 1- or 2-position).

Ar = 4-O<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>.

## VI. Conclusion

The methods of synthesis of substituted 1,2,3-triazoles described in the review were used in the last decade to prepare a great diversity of compounds, the properties of which proved to be rather attractive for practical purposes, in particular, for the development of drugs and plant protection and growth control agents.

For example, it has been proposed to use polyunsaturated conjugated systems containing terminal 5-hydroxytriazole groups as dyes for photographic materials,<sup>512</sup> and bis(triazol-2-yl)-substituted arylenes with different bridging fragments, in organic electroluminescence devices.<sup>81</sup> (2*H*-Benzotriazol-2-yl)-4-methylphenol is known as the Benazol-P light stabiliser.<sup>135</sup> Fluorescing bleaching agents can be prepared on the basis of triazole derivatives.<sup>521</sup> In view of the substantial energy content of nitrogen derivatives, it has been proposed to use nitrotriazoles as components of explosive mixtures,<sup>107, 108, 522</sup> and 1,1'-bitriazole,<sup>115</sup> 1*H*-triazole and its 1-amino derivatives can be used as nitrogen generators for the automobile safety bags.<sup>523–526</sup>

1-Benzyl-4,5-dibenzoyl- and -4,5-dialkoxycarbonyltriazoles inhibit the corrosion of some metals in acid media,<sup>527–530</sup> 4-alkyl(hydroxy, nitroso, mercapto)-triazoles can also be used to protect aluminium and its alloys.<sup>531</sup>

In recent years, 1-hydroxy-1*H*-triazoles and their *O*-derivatives have attracted the attention of researchers engaged in the search for new coupling reagents for peptide synthesis to suppress racemisation.<sup>46, 102</sup> For instance, ethyl 1-hydroxytriazole-4-carboxylate can be used in combination with diisopropylcarbodiimide in solid-state peptide synthesis<sup>46, 532, 533</sup> and in combination with peptide hydrazides for the assembly of peptide segments.<sup>534, 535</sup>

Data on the biological action of triazole derivatives and the possible use of these compounds in agrochemistry, veterinary and medicine have been reported in a number of publications and patents. Particular aspects of the activity are considered in special reviews.<sup>14, 536–539</sup> 1-Aryl-5-phenoxytriazoles have been proposed as herbicides,<sup>187</sup> while a number of 2-[2-alkyl- and cycloalkyl(2*H*-triazol-4-yl)]acrylonitriles have been proposed as insecticides, nematocides and acaricides.<sup>540</sup> Some (het)aryltriazoles have shown high insecticide and pesticide activities,<sup>96, 247, 248, 541–543</sup> and halogen and haloalkyl derivatives of 1-(diarylmethyl)triazoles have exhibited insecticide properties.<sup>544</sup>

Triazolyl analogues of natural antibiotics have shown excellent antibacterial action.<sup>545, 546</sup> Antibacterial properties have also been found for triazolyl derivatives of esters of  $\beta$ -enamino acids,<sup>547</sup> 7 $\beta$ -(triazolyl-4-formamido)cephalosporins,<sup>548–550</sup> 4-aryl-1-[5-methyl-1-(4-chlorophenyl)triazole-4-carbonyl]thiosemicarbazides and their heterocyclic derivatives.<sup>551</sup> Antiinflammatory activities have been found for carboxamidotriazoles,<sup>400</sup> while sterically hindered 5-(4-hydroxyphenyl) derivatives of triazole-4-carboxylic acids and amides have proved active in the therapy of arthritis.<sup>399</sup> For 5-amino-4-carbamoyltriazoles,<sup>481</sup> dimethyl triazole-4,5-dicarboxylate with *N*-arylacetamide substituents<sup>552</sup> and some bistriazoles,<sup>553</sup> various types of antimicrobial activities have been found. 1-Benzyl-5-aminotriazoles constitute a new class of antiproliferative agents for the therapy of psoriasis and coccidiosis.<sup>554–557</sup>

1-Aryltriazole-4,5-dimethanol derivatives<sup>180</sup> and 1-(1-phenyltriazol-5-yl)alkyl-4(1*H*)-quinolones<sup>558</sup> possess a cytotoxic action, while 5-amino-1-[[3,5-dichloro-4-(chlorobenzoyl)phenyl]-methyl]-4-carboxamidotriazole exhibited anti-HIV action, along with cytotoxic properties.<sup>559–561</sup> Clinical investigations of the last-mentioned compound have demonstrated that it is well tolerated in the case of oral administration, decreases a tumour, and stabilises the patient's condition.<sup>537</sup> Some 5-amino-4-carboxamidotriazoles inhibit metastases,<sup>562–564</sup> and one of the 4 $\beta$ -(1-triazolyl)podophyllotoxins has demonstrated even stronger cytotoxic properties *in vivo* than the anticancer drug etoposide used in clinical practice.<sup>340</sup> Some triazole *N*-nucleosides also possess antitumour and antiviral properties.<sup>426, 565</sup> 17-(Triazol-1-yl)steroids induce a decrease in testosterone and dihydrotestosterone levels and can be used for the therapy of benign hypertrophy and prostatic cancer.<sup>566–568</sup>

Some substituted 1-(4-quinolyl)triazoles are analgesics, being superior to indometacin as regards this type of activity.<sup>463, 464</sup> For the series of fused diazepine systems, it has been shown that the neuroleptic properties are due to the presence of the 1,2,3-triazole fragment in the structure.<sup>569</sup> 1-Aryl-5-pyridyltriazoles have formed a new structural group of anticonvulsants, which are comparable in action with known clinical drugs and, in addition, possess a very low neurotoxicity.<sup>570, 571</sup> Fluorinated 1-arylalkyltriazoles also exhibit an antispasmodic action,<sup>193</sup> 4(5)-carboxamide and -alkylcarbamoyl derivatives have been recommended for the therapy of neuropathic diseases, in particular, epilepsy,<sup>572–575</sup> while triarylmethyltriazoles have been proposed for treatment of central nervous system diseases.<sup>176</sup>

A series of substituted 5-dimethylaminomethyltriazoles with (thio)morpholino groups in the heterocycle or in the side chain are antagonists of neurokinin receptors and exhibit the properties of opioid analgesics.<sup>576</sup> Preparations of this type have been proposed for the curing and prevention of inflammations, headaches and neuralgias.<sup>166, 347–349</sup> Some 4-piperidyl-substituted triazoles<sup>270</sup> and substituted triazolo[1,5-*a*]quinazolines<sup>577</sup> are active with respect to muscarin receptors and are of particular interest as drugs against Alzheimer's disease. Tricyclic benzoazepine compounds containing a carbamoyltriazole fragment can be used as antiallergic drugs.<sup>192, 578, 579</sup> Substituted amidinotriazoles showed an antihypertensive effect, while having low toxicity.<sup>141</sup> 5-(2-Nitroanilino)triazoles and 1-(4-carbamidotriazol-5-yl)benzotriazoles possess a vasodilatory action caused by activation of potassium channels.<sup>137, 480</sup>

Some 1-( $\beta$ -D-ribofuranosyl)-5-alkylcarbamoyltriazole derivatives<sup>337, 580, 581</sup> and carbocyclic analogues of ribavirin containing a 4-carbamoyltriazole fragment<sup>315</sup> showed high anti-HIV and antihepatitis activities.

Many publications are devoted to the interaction of functional derivatives of 1,2,3-triazole with various bioreceptors and enzymes but these studies are beyond the scope of this review. We would only like to note that triazole compounds are attractive components in biochemical and medical investigations, as they are formed in high yields in aqueous or aqueous-organic media from organic azides and terminal alkynes *via* Cu(I)-catalysed cyclo-

addition and are readily bound to biological targets through hydrogen bonds and dipole interactions, while still remaining chemically inert linkers.<sup>582, 583</sup>

| II. Linear polymethyleneamine alkaloids  | 381 |
| III. Cyclic polymethyleneamine alkaloids | 386 |

**Abstract.** The published data on the structures and biological activities of the plant alkaloids of the biogenic polymethyleneamine series, *viz.*, putrescine (1,4-diaminobutane), spermidine (1,8-diamino-4-azaoctane), and spermine (1,12-diamino-4,9-diazadodecane), are considered and systematised. The structures and biological activities of some synthetic analogues of these alkaloids are also presented. The bibliography includes 84 references.

## I. Introduction

The biogenic polymethylenepolyamines putrescine, spermidine and spermine have been identified in detectable amounts in all living cells.

These are natural amino acid metabolites in plants and animals<sup>1,2</sup> and are involved in many biological processes.<sup>1,3</sup> Valuable biological activities of biogenic polymethylenepolyamines gave impetus to the development of methods for their synthesis and the synthesis of their analogues.<sup>†</sup>

The natural polyamines occur as free aliphatic bases and structural elements of alkaloids commonly referred to as secondary metabolites.

This review is devoted to plant alkaloids with putrescine, spermidine or spermine fragments as their constituents. They play an essential role in different stages of plant development (flowering, fruit ripening, ageing, *etc.*), as well as in miscellaneous interactions of plants with the environment.<sup>4,5</sup> Depending on the nature of the parent polyamine, the alkaloids can be divided into

three groups, *viz.*, putrescine-borne polyamines, spermidine-borne polyamines and spermine-borne polyamines. Each of these groups is represented by both cyclic and linear compounds. A special group of alkaloids includes lactams.

The present review covers the literature published in 1992–2003 dealing with the description of methods for the isolation of this group of alkaloids from plants, determination of their structures and biological activities and structural modification aimed at the design of targeted-action medicines. References to previous publications are given where necessary.

It is common practice that trivial names of natural compounds derive from the names of plants they are isolated from. Some linear polymethyleneamine derivatives have no such names and the substitutive nomenclature is used where putrescine, spermidine or spermine are taken as parent compounds and the locants of the nitrogen atoms indicate their positions in the chain.

## II. Linear polymethyleneamine alkaloids

Linear alkaloids containing spermine, spermidine, putrescine or guanidinoputrescine fragments are represented by amides of various carboxylic acids (*N*-acylpolyamines). As a rule, these compounds contain only one polyamine constituent. The only exception is alkaloid tenuilobine isolated from plants of the *Oncinotis* genus (Apocynaceae), with contains both spermine and spermidine fragments.

The carboxylic acids most commonly found in linear spermine and spermidine derivatives include cinnamic acid and its derivatives, *e.g.*, *p*-coumaric (*p*-hydroxycinnamic), caffeic (3,4-dihydroxycinnamic), ferulic (4-hydroxy-3-methoxycinnamic), 3,4-dimethoxycinnamic and, less frequently, dihydrocinnamic acids.

Received 7 April 2004

*Uspekhi Khimii* 74 (4) 411–427 (2005); translated by R L Birnova

<sup>†</sup> Since recently, synthetic polymethyleneamine derivatives are considered as promising antitumour and anti-infectious agents.<sup>1</sup>

Some alkaloids contain benzoic and hexadecanedioic acids as carboxylic acid components. In addition to the foregoing carboxylic acids, linear putrescine derivatives contain aliphatic acids and carboxy derivatives of flavaglines,<sup>6</sup> cyclopenta[*bc*]benzopyrans (aglaines and aglaforbesines) and benzo[*b*]oxepins (forbaglines).

Cinnamamides are present in many higher plants.<sup>7,8</sup> They were found in the reproductive organs (anthers) as the main structural components of pollen and in some other parts of the plants. Their presence is associated with responses of plants to pathogenic factors, *e.g.*, viral or fungal infections.<sup>9</sup>

### 1. Linear spermine derivatives

Linear spermine derivatives are few in number. 1-(*N*-*p*-Coumaroyl)spermine (**1**) is the simplest representative of natural spermine amides.<sup>10</sup> Kukoamines A (**2**) and B (**3**) isolated from the root bark of *Lycium chinense* also belong to this group. These compounds contain dihydrocaffeic acid fragments.<sup>11</sup>

### 2. Linear spermidine derivatives

Linear spermidine derivatives include mono- (**4–6**), di- (**7–10**) and triacyl (**11–18**) derivatives of cinnamic acids.<sup>7,9,10,12–15</sup> Some spermidine amides isolated from plants are listed in Table 1. The monoamide **4** and its synthetic isomer (compound **5**) differing in the position of the central nitrogen atom in the chain result from acylation of the primary amino group. Diamides include compounds with all possible combinations of pairwise substitutions, *viz.*, N<sup>1</sup> and N<sup>5</sup>; N<sup>1</sup> and N<sup>10</sup>; N<sup>5</sup> and N<sup>10</sup>. In these compounds, fragments of the same acid (compounds **7–9**) or of different acids (compound **10**) serve as the substituents. Trisubstituted spermidine derivatives are the most numerous; in this case, too, the role of substituents is played by the same acid (compounds **11–13**) or two different acids (compounds **14–17**). The alkaloid **18** is the only spermidine alkaloid containing three different acyl substituents (coumaric, caffeic and ferulic acid fragments).

In addition to fragments of cinnamic acids, some linear spermidine derivatives contain fragments of other acids. Thus 5-*N*-benzoylspermidine (**6**)<sup>12</sup> (monoamide) and tenuilobine (**19**) (diamide), were isolated from the leaves of *Oncinotis tenuiloba* Stapf (Apocynaceae).<sup>16</sup> Compound **19** represents a diamide of hexadecanedioic acid and contains one spermine and one spermidine fragment. This was also isolated from the Central Asian plant *Salsola subaphylla*<sup>17</sup> and was named subaphylline.

**Table 1.** Linear alkaloids derived from spermidine.

| Alkaloid                           | R <sup>1</sup>      | R <sup>2</sup>      | R <sup>3</sup>      | Plant source                                                                            | Ref.     |

### 3. Linear putrescine derivatives

A characteristic feature of mono- and diacyl putrescine derivatives is diversity of substituents. Putrescine mono- and diamides isolated from plants are listed in Table 2.<sup>5,6,18–27</sup>

The aminoamides **20**, **21** and the diamides **22–25** contain 'standard' fragments of cinnamic, ferulic, coumaric and benzoic acids. The alkaloid **24** is known under two names, *viz.*, pyramidine (being isolated from *Aglaia pyramidata* Hance, syn. *Aglaia*

**Table 2.** Linear alkaloids derived from putrescine.

| Alkaloid | Trivial name                                 | R <sup>1</sup>                                                                      | R <sup>2</sup>                                                                      | Plant source                                                        | Ref.          |

|----------|----------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------|----------------|------------------------|------|
| 37, 38   | bisamide of the forbagline type <sup>b</sup> | <p>37: R<sup>3</sup> = R<sup>4</sup> = R<sup>5</sup> = H;<br/>38: R<sup>3</sup> = R<sup>4</sup> = Me; R<sup>5</sup> = glucosyl.</p> |                | <i>Agla. dasyclada</i> | 24   |

<sup>a</sup> Edulimide is a triamide with an additional Ac substituent at N<sup>6</sup>. <sup>b</sup> The names for structure types are indicated.

*silvestris*)<sup>6,21</sup> and haplamidine (being isolated from *Haplophyllum latifolium*).<sup>20</sup> It is noteworthy that haplamide (**25**) (putrescine dibenzoate) was isolated from the same plant.<sup>22</sup>

Putrescine diamides containing various aromatic and aliphatic acids were identified in plants of the *Aglaia* genus (Meliaceae). This genus comprises 130 dioecious arboreal and shrub species occurring predominantly in tropical and subtropical climatic zones. Depending on the structures of the substituents R<sup>1</sup> and R<sup>2</sup>, these compounds are categorised into two types. One of them includes compounds **26–30**,<sup>21,23–25</sup> which contain cinnamic acid or its derivatives as the substituent R<sup>1</sup> as well as two sulfur-containing methylthioacrylic acid diamides<sup>21,26</sup> [aglaithioduline (**31**) and aglaithioduline (**32**)] and edulimide (**33**).<sup>21,26</sup> The latter contains an acetyl group at the nitrogen atom as a third substituent and is the only representative of dihydrocinnamic acid imides in this group of compounds. Compounds containing aglaine (**34**, **35**), aglaforbesine (**36**) and forbagline (**37**, **38**) are related to the second type of diamides.<sup>21,23,24</sup> Diamides of the former type are accumulated predominantly in plant leaves, while structurally more complex amides are usually present in the bark.

The presence, in the same plant species, of different types of amides, which occurs quite often, suggests close biogenetic relationships between them. Thus the ability of dasyclamide **27** to be converted into diamides **35–38** upon cycloaddition with flavonoids suggests its role as a biosynthetic precursor of these compounds.<sup>24</sup>

#### 4. Linear guanidinoputrescine derivatives

Guanidinoputrescine, which is most likely formed upon enzymatic decarboxylation of arginine, undergoes further transformations. Sphaerophysine (**39**), the first guanidinoputrescine derivative with a simple structure, was isolated from the Central Asian plants *Sphaerophysa salsula* and *Smirnovia turkestanica*.<sup>28</sup> Sphaerophysine acetate and malonate, named smirnovine (**40**) and smirnovinine (**41**),<sup>29</sup> were also isolated from *Smirnovia turkestanica*.

R = H (**39**), C(O)Me (**40**), C(O)CH<sub>2</sub>CO<sub>2</sub>H (**41**).

More complex guanidinoputrescine derivatives containing a 3,4-dimethoxycinnamic acid fragment were found in the Venezuelan plant *Verbesina caracasana* Fries. One of them, viz., caracasanamide (**42**), was isolated as a mixture of *E*- and *Z*-forms.<sup>30,31</sup> The second compound, viz., caracasanediamide (**43**), represents a cyclobutane-type dimer of caracasanamide **42**<sup>31,32</sup> and yet

another is 1-(3,4-dimethoxycinnamoylamino)-4-guanidinobutane (**44**).<sup>33</sup>

The alkaloids (+)-hordatines A (**45**) and B (**46**), which contain a benzofuran core with two guanidinoputrescine residues as substituents, were isolated from barley (*Hordeum vulgare* L.) sprouts.<sup>34</sup>

Martinellinic acid (**47**) and its ester, martinelline (**48**), isolated from the roots of the tropical liana *Martinella iquitensis* have even more complex structures.<sup>35</sup> They contain a pyrroloquinoline backbone and several guanidino groups including a guanidinoputrescine group.

Of special note is the fact that no natural compounds with such a backbone have been reported hitherto.

### 5. Biological activities of linear alkaloids

Linear alkaloids manifest diverse kinds of biological activities. Thus the hypotensive activity kukoamine A (**2**) gave an impetus to the synthesis and assay of all of its regioisomers as potential hypotensive drugs.<sup>36</sup> Besides, this compound causes mixed-type inhibition of trypanothione reductase ( $K_i = 1.8 \mu\text{mol litre}^{-1}$  and  $K_{ii} = 13 \mu\text{mol litre}^{-1}$ ), a unique specific enzyme of protozoan parasites (trypanosomes, *Leishmania*). It is of note that kukoamine A has no effect on the human enzyme endowed with a similar protective function.

Synthetic mono- and diacyl, analogues kukoamine A based on spermine and spermidine also inhibit trypanothione reductase, however, with much lesser efficiency ( $K_i = 11-607 \mu\text{mol litre}^{-1}$ ).<sup>37</sup> Studies of inhibiting activities of a panel of kukoamine A-based inhibitors prepared by solid-phase combinatorial chemical synthesis have shown that the highest inhibiting activity is manifested by bis(5-bromoindol-3-ylacetyl)spermine (compound **49**) ( $K_i = 0.076 \mu\text{mol litre}^{-1}$ ).<sup>38</sup>

The monosubstituted alkaloids 1-(*N*-*p*-coumaroyl)spermine (**1**) and 1-(*N*-*p*-coumaroyl)spermidine (**4**) cause reversible dose-dependent inhibition of neuromuscular synapses in insects ( $IC_{50} = 70$  and  $60-200 \mu\text{mol litre}^{-1}$ , respectively), which opens a way to a better understanding of their role as a means of chemical self-protection of plants against pests. Structural analogues of these alkaloids, *viz.*, polyamines isolated from the toxins of *Nephila* spiders, produce irreversible blocking effects ( $IC_{50} = 0.1 \mu\text{mol litre}^{-1}$ ).<sup>10</sup>

The triamides **11**, **12** and **15** manifest fungicidal activities: they inhibit mycelial growth in the pathogenic fungus *Pyrenophora avenae* affecting oats leaves and protect barley seedlings against mildew.<sup>9</sup>

Among synthetic derivatives of tenuilobine **19**, isotenuilobine (**50**)<sup>39</sup> and the aromatic derivatives **51-55** are worthy of note.<sup>39</sup> The structural similarity of tenuilobine **19** to spider and wasp toxins widely known as potent inhibitors of CNS glutamate

**51:**  $\text{R}^1 = \text{Bu}^t$ ,  $\text{R}^2 = (\text{CH}_2)_2\text{C}(\text{O})\text{N}[(\text{CH}_2)_3\text{NH}_2](\text{CH}_2)_4\text{NH}_2$ ;

**52:**  $\text{R}^1 = \text{Bu}^t$ ,  $\text{R}^2 = (\text{CH}_2)_2\text{C}(\text{O})\text{N}[(\text{CH}_2)_3\text{NH}_2](\text{CH}_2)_4\text{NH}(\text{CH}_2)_3\text{NH}_2$ ;

**53:**  $\text{R}^1 = \text{Bu}^t$ ,  $\text{R}^2 = (\text{CH}_2)_2\text{C}(\text{O})\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}_2$ ;

**54:**  $\text{R}^1 = \text{R}^2 = (\text{CH}_2)_2\text{C}(\text{O})\text{N}[(\text{CH}_2)_3\text{NH}_2](\text{CH}_2)_4\text{NH}_2$ ;

**55:**  $\text{R}^1 = \text{R}^2 = (\text{CH}_2)_2\text{C}(\text{O})\text{N}[(\text{CH}_2)_3\text{NH}_2](\text{CH}_2)_4\text{NH}(\text{CH}_2)_3\text{NH}_2$ .

receptors provided a rationale for their biological testing as candidate inhibitors of ionotropic glutamate receptors. These studies are currently under way.<sup>40</sup>

Presumably symmetrical and non-symmetrical tenuilobine derivatives of hexadecanedioic acid and spermidine, spermine and their shorter-chain analogues inhibit polyamine transport. At present, methods for the synthesis of these compounds are developed and investigations into their ability to control polyamine metabolism are underway.<sup>41</sup>

Some disubstituted putrescines also possess biological activity. Thus compounds **22** and **23** cause reversible inhibition of  $\alpha$ -glucosidase,<sup>‡</sup> which is involved in carbohydrate catabolism. Studies on structure-activity relationships have shown that inhibiting activities of these compounds are determined by the presence of a hydroxy group in the aromatic ring.<sup>25</sup>

Non-cytotoxic concentrations of the sulfur-containing bis-amides aglaithioduline (**31**) and aglaithioduline (**32**) have little effect on the herpes simplex virus (types 1 and 2);<sup>26</sup> pyrimidine (**24**) manifests antileukemic activity *in vivo*.<sup>42</sup>

The identification of sphaerophysine (**39**) and the discovery of its hypotensive activity were of great consequence for the therapy of a hypertonic disease, being the first demonstration of high potential of guanidinoputrescine derivatives as efficient hypotensive drugs. Sphaerophysine benzoate<sup>8</sup> is successfully used in the therapy of hypertony and as a labour-stimulating agent in obstetrical-gynecological practice.<sup>43</sup> Smirnovine (**40**) also possesses hypotensive activity.<sup>45</sup>

Worthy of notice are water-soluble guanidinoputrescine derivatives caracasamide (**42**, *Z*-form) and caracasenediamide (**43**) endowed with hypotensive properties. Caracasamide (**42**) can be used in the therapy of moderate arterial hypertension; its therapeutic effect is commensurate with those of reserpine and papaverine. Caracasenediamide (**43**) exceeds compound **42** in hypotensive and antihypertensive activities and has no adverse side effects (*e.g.*, reflexive tachycardia or low cardiac inotropism) manifested by the majority of antihypertensive and vasodilating agents.<sup>31</sup>

Candidates for hypotensive drugs were also found among synthetic derivatives of compound **44** containing a modified diaminoalkane chain or a modified acyl moiety.<sup>33</sup> The derivative **56** containing an (*E*)-*p*-methoxycinnamic acid fragment produces a stronger hypotensive effect than compound **44**. The number of methylene groups in the diaminoalkyl chains of compounds of the type **57** does not influence their therapeutic activity. In pharma-

**56:**  $\text{R} = \text{H}$ ,  $n = 3$ ; **57:**  $\text{R} = \text{OMe}$ ,  $n = 1-5$ .

‡ In the past decade,  $\alpha$ -glucosidase inhibitors have been widely used as peroral hypoglycemic drugs in the therapy of diabetes, but a search for novel, safer inhibitors remains a topical task.

§ At present, sphaerophysine benzoate has no wide application.<sup>44</sup>

cological doses, all these compounds produced hypotensive and slightly positive inotropic effects devoid of substantial chronotropic and respiratory effects.

Hordatines A (**45**) and B (**46**) possess fungicide activities.<sup>34</sup>

There is evidence that the sap of two tropical liana species (of the genus *Martinea* Bignoniaceae), viz., *M. iquitosensis* A. Sampayo and *M. obovata* (HBK) Bureau et K. Schum, is used by representatives of thirteen different ethnolinguistic groups in nine countries of South America as a folk remedy against various eye diseases. Some native tribes residing in the Amazonian Region of Peru extract this sap from the root bark of *M. obovata*. One or two drops of such potion immediately eliminate inflammation in the eye infected by a parasitic microorganism (or a group of microorganisms, including Gram-positive and Gram-negative bacteria). Studies have shown that this effect is provided by martinellinic acid (**47**) and martinelline (**48**), the only natural non-peptide antagonists of B<sub>1</sub>- and B<sub>2</sub>-receptors of bradykinin (BK). It is noteworthy that martinelline (**48**) exceeds martinellinic acid (**47**) in activity. Thus, the sap from the root bark of *M. obovata* possess antiinflammatory and analgesic effects. Martinelline (**48**) is an antagonist of histaminergic,  $\alpha$ -adrenergic and muscarinic receptors, manifests moderate antibiotic activity and has little or no cytotoxic or lytic effect with respect to red blood cells. Such a happy combination of antiinflammatory, analgesic and antimicrobial actions makes this compound a valuable tool in the treatment of conjunctivitis.<sup>35</sup>

### III. Cyclic polymethyleneamine alkaloids

Yet another important class of polyamine alkaloids comprises cyclic compounds with polyamine backbones. These compounds can be divided into two main subtypes, viz., cycloputrescine derivatives (2-aminopyrrolidines) and macrocyclic (8–22-membered) lactams containing biogenic bases (mostly spermine and spermidine). Putrescine, spermidine and spermine are present in the ring systems either as a whole molecule or as a part thereof.

### 1. Cycloputrescine derivatives

Cycloputrescine derivatives are represented by pyrrolidine bisamide alkaloids, which rarely occur in nature and contain a 2-aminopyrrolidine group. By present, pyrrolidine bisamides have been identified only in plants of the *Aglaia* genus (Meliaceae). Some aminopyrrolidine bisamides isolated from these plants are listed in Table 3.

Depending on the structures of their substituents R<sup>1</sup> and R<sup>2</sup>, all aminopyrrolidine bisamides are divided into two types. Compounds **58**–**65** have simple structures and contain various carboxylic acid fragments as substituents R<sup>1</sup> and R<sup>2</sup>. In structurally more complex bisamides, the role of the substituent R<sup>2</sup> is played by carboxylic acids, while that of substituent R<sup>1</sup> is played by structural fragments, of the aglaine (**66**–**69**), aglaforbesine (**70**, **71**), forbagline (**72**, **73**), tapsakine (**74**) or tapoxepin types (**75**). Such complex bisamides are related to flavaglines and represent typical secondary metabolites of 30 investigated species of the genus *Aglaia*.<sup>6</sup> Presumably, the flavagline molecule consists of a flavonoid and a fragment of cinnamic acid. Flavaglines are represented by three structural types, viz., cyclopenta[*b*]benzofurans (rocaglamides,<sup>49</sup> aglaroxin A, pannelline), cyclopenta[*bc*]benzopyrans (aglaines, aglaforbesines, tapsakins) and benzo[*b*]oxepins (forbaglines, tapoxepins). The latter two types are related to polyamine derivatives. Possible biogenetic relationships between different types of flavaglines and putative mechanisms of their formation have been discussed.<sup>48</sup>

As a rule, the same plant species produces different types of bisamides. Different compositions of linear and cyclic bisamides in plants of the same species is interpreted as a 'survival strategy' preventing the adaptation of herbivores and microorganisms to the common chemical profile of the plant.<sup>27</sup> The presence of different forms of bisamides in the same plant species suggests close biogenetic relationships between them. Cycloaddition of the pyrrolidine bisamide odorine (**58**) to a flavonoid affords aglaines

**Table 3.** Aminopyrrolidine bisamides from plants of the genus *Aglaia* (Meliaceae).

A, B and C (66–68) as well as agloforbesines A and B (70 and 71).<sup>47</sup> Simultaneous presence of pyrrolidine bisamides and the corresponding linear analogues [e.g., odorine (58) and secoodorine (30),<sup>25</sup> pirifirine (61) and secopirifirine (29),<sup>25</sup> agleptine (63), isoagleptine (64), leptantine (65) and aglaithioduline (31) or aglaithioduline (32)],<sup>27</sup> in the same plant species prompts a conclusion that all alkaloids containing a 2-aminopyrrolidine fragment have a biogenetic linear putrescine bisamide precursor;<sup>25</sup> its cyclisation is effected by an enzymatic system of its own.<sup>21</sup>

## 2. Cyclic spermidine alkaloids

### a. 13-Membered cyclic spermidine alkaloids

Palustrine (76), the first alkaloid in this series, was isolated from marsh horsetail *Equisetum palustre* L. in 1936.<sup>50</sup> The asymmetry of spermidine structure enables the formation of two types of cyclic alkaloids, viz., type A (compounds 76–84) and type B (compounds 85–98).<sup>51</sup>

Both types of alkaloids occur in plants (Table 4). Mayfoline (98) belonging to the B-type alkaloid contains a hydroxy substituent at the secondary nitrogen atom of the spermidine chain; this feature has been observed for the first time in this type of a compound. Plants containing this kind of an alkaloid may contain its analogue the N-hydroxy group in which is replaced by the N-acetyl group.<sup>8</sup>

### b. Spermidine alkaloids isolated from various species of plants of the genera *Oncinotis*, *Lunaria* and *Codonocarpus*

Polyamine alkaloids present in plants of the genus *Oncinotis* (Apocynaceae) are classified into two groups, viz., linear and macrocyclic. All macrocyclic keto lactams contain a 16-membered hydrocarbon chain linked to the neighbouring nitrogen atoms of spermidine. Depending on the mode of attachment of the chain to spermidine, one can distinguish monocyclic inandenines (com-

Inandenines, inandeninols

pounds **99–102**, Table 5),<sup>58,59</sup> bicyclic oncinotines (compounds **103–107**, Table 5)<sup>59</sup> and linear tenuilobine (**19**).

Oncinotines

$R^1 = O, R^2 = H_2; R^1 = H_2, R^2 = O;$   
 $x = 1, y = 4; x = 2, y = 3.$

The specific content of an alkaloid in a plant depends on the species and the organ from which it was isolated. Thus the stem bark of the Nigerian species *O. nitida* Benth. predominantly contains oncinotine (**103**) and its isomers, viz., neooncinotine (**104**) and isooncinotine (**105**). Inandenines were found in this plant in only minor amounts and were isolated as a non-separable mixture of isomers. In contrast, leaves of *O. inandensis* Wood et Evans and *O. tenuiloba* are rich in inandenines. The concentration of inandeninols, i.e., the secondary alcohols formed upon reduction of the keto groups of inandenines, in these plant species is very small. However, in the leaves of *O. nigra* Pich. these compounds are present as major components.<sup>58,59</sup>

Lunarine (**108**) isolated from *Lunaria annua*<sup>60</sup> differs from lunaridine (**109**) which is present in *L. biennis* and *L. rediviva*<sup>8</sup>

108, 109

**108:** X = NH, Y = CH<sub>2</sub>;  
**109:** X = CH<sub>2</sub>, Y = NH.

110

simultaneously with lunarine, in the mode of attachment of spermidine. Codonocarpine (**110**) was isolated from the bark of *Codonocarpus attenuatus* (Phytolaccaceae).<sup>8</sup>

### 3. Cyclic spermine alkaloids

#### a. 17-Membered cyclic spermine alkaloids

Compounds containing spermine and carboxylic acids constitute a large group of cyclic polyamine alkaloids. 17-Membered cyclic spermine alkaloids form a special group. Depending on the nature of the carboxylic acid and the substituents at the nitrogen atoms of the 17-membered macrocycle, these alkaloids are divided into two groups, viz., alkaloids from *Verbascum* (Scrophulariaceae), *Incarvillea sinensis*, *Clerodendrum buchneri* (Verbenaceae) (group A, compounds **111–128**, Table 6)<sup>61–67</sup> and budmunchiamines from plants of the *Albizia* genus (group B, compounds **129–148**, Table 7).<sup>68–72</sup>

The 17-membered rings of the group A alkaloids contain fragments of dihydrocinnamic acid or its 4-methoxy derivative and spermine ( $R^3 = R^4 = H$ , compounds **111–121**) or its cyclic analogue ( $R^3 - R^4 = -CH_2-$ , compounds **122–128**). The structures of (-)-protoverbine (**111**) and (+)-protomethine (**122**) are typical basic structures.

111

122

The alkaloids protoverbine **111** and (+)-protomethine (**122**) are thought to be putative biogenetic precursors of a large class of spermine alkaloids. Thus, compound **111** is a hypothetical precursor of verbacine (**112**) and verballoicine (**113**), while compound **122** is a precursor of (+)-verbamethine (**123**) and (+)-isoverbamethine (**124**).<sup>61</sup> Compounds **112** and **113** are often considered as biogenetic precursors of their *N*-acetylated derivatives verbasce-nine (**118**) and verballosceneine (**119**). Simultaneous isolation of all the four compounds provides supporting evidence in favour of this hypothesis.<sup>66</sup>

Fragments of cinnamic, 4-methoxycinnamic, 3,4-dimethoxy-cinnamic (*E*- or *Z*-forms), acetic and formic acids are typical

the major components of *Verbascum pseudonobile* Stoj. et Stef. (Scrophulariaceae), while the (*E*)-verbacitrine/(*Z*)-isoverbactrine pair was isolated from this plant species in only minor amounts.<sup>65</sup> Incasines B and B′ isolated from *Incarvillea sinensis* were also found in *V. pseudonobile*. The (*E*)-verbamedine/(*Z*)-isoverbamedine pair was structurally identical to incasines A and A′, although in the authors' opinion<sup>65</sup> the structures of the latter were not established unambiguously.

The *E*:*Z* ratio of the isomeric pairs of alkaloids containing cinnamic acid fragments (**112**: **113** and **123**: **124**) is 5:4, that of the alkaloids containing a 3,4-dimethoxycinnamic substituent (**114**: **115** and **125**: **126**) is 1:9. Similar ratios were obtained after irradiation of these alkaloids with visible or UV light ( $\lambda = 365$  nm). It was thus concluded that *Z*-isomers represent photoisomerisation products of the corresponding *E*-isomers formed in intact plant tissues under the influence of solar irradiation.<sup>64</sup>

The 17-membered rings of the group B alkaloids, viz., budmunchiamines, isolated from plants of the genus *Albizia*, contain spermine and various fatty acid fragments (R<sup>1</sup>CH<sub>2</sub>COOH) [R<sup>1</sup> = C<sub>n</sub>H<sub>2n+1</sub>, where  $n \geq 9$ , or R<sup>1</sup> = C<sub>m</sub>H<sub>2m</sub>C(O)C<sub>p</sub>H<sub>2p+1</sub>, where  $m + p = 13$ ], the major part of the alkyl chains of the fatty acids (substituent R<sup>1</sup>) is not incorporated into the macrocycle. The classification of budmunchiamines (from A to L) is based on the length of the side alkyl chain (R<sup>1</sup>) and the degree of methylation of the nitrogen atoms in the macrocycle.

The lengths of the side alkyl chains of the alkaloids of the same series are constant; within the series, the differences reflect different degrees of methylation of the nitrogen atoms in the macrocycle or the presence of hydroxy groups in the side chain R as, e.g., in budmunchiamines C and K. Budmunchiamines L are an exception: all the four nitrogen atoms in the macrocycles in these alkaloids are non-methylated and differ from one another only in the length of the alkyl side chain.

Budmunchiamines are largely isolated from legumes (Leguminosae) and different species of mimosa (Mimosoidae): from seeds of *Albizia amara* Bolv. and an Indian plant (*Alb. lebbek* Benth.), from the stem skins of the Kenyan species *Alb. gummifera*

(J.F.Gmel.) C.A.Sm. and *Alb. schimperana* Oliv. and from the stem bark (budmunchiamines L4 and L5) and leaves (budmunchiamines L5) of the Panamanian plant *Alb. adinocephala* (J.D.Sm.) Britton et Rose ex Record.

#### b. Spermine bimacrocylic alkaloids of the aphelandrine type

Spermine alkaloids of the aphelandrine type were isolated from the roots of plants of three families, viz., Acanthaceae, Scrophulariaceae and Ephedraceae. These alkaloids contain two macrocycles one of which is identical to the 17-membered lactam ring of the aforementioned group A spermine alkaloids, whereas the other (13-membered) macrocycle contains a fragment of the highly substituted dihydrobenzofuran core. Aphelandrine type alkaloids can also be regarded as compounds the spermine component in which is acylated by two fragments of *p*-coumaric acid.

Alkaloids of the aphelandrine type

R<sup>1</sup> = H, OMe; R<sup>2</sup> = H, Me; R<sup>3</sup> = H, OMe; R<sup>4</sup> = H, OH, OAc.

Plants of the genus *Aphelandra* (Acanthaceae) occur on the territory extending from the south of Mexico to the north of Argentina and are represented by nearly 165 species. The roots of some representatives of this genus (*A. tetragona*, *A. squarrosa*, *A. sinclairiana*, *A. pepeparodii*, *A. aurantiaca*, *A. chamissoniana*, *A. fuscopunctata*) contain the bicyclic spermine alkaloid (+)-aphe-landrine (**149**) and its diastereoisomer (–)-oranthine (**150**) (syn. ephedradine A).

Aphelandrine was also isolated from *Encephalosphaera lasian-dra* also belonging to this family; oranthine was isolated from *Chaenorhinum minus*, *Schweinfurthia papilioacea* (Scrophulariaceae) and *Ephedra* (Ephedraceae). The alkaloid (–)-*O*-methylo-ranthine (**151**) was found in *C. minus* and *C. villosum* (Scrophulariaceae); (–)-epioranthine (**152**) was found in *S. papilioacea* (Scrophulariaceae). Representatives of yet another group of alkaloids structurally similar to aphelandrine, viz., (–)-ephe-dradines B, C and D (compounds **153–155**), were found in *Ephedra* (Ephedraceae).<sup>73, 74</sup>

- 151:**  $R^1 = R^2 = H, R^3 = Me$ ;  
**152:**  $R^1 = R^2 = R^3 = H$ ;  
**153:**  $R^1 = R^3 = H, R^2 = OMe$ ;  
**154:**  $R^1 = H, R^2 = OMe, R^3 = Me$ ;  
**155:**  $R^1 = OMe, R^2 = R^3 = H$ .

The isolation of (+)-*N*(6)-hydroxyaphelandrines (**156**) and (+)-*N*(6)-acetoxyaphelandrine (**157**) from the roots of *A. fusco-punctata* confirmed that macrocyclic spermine alkaloids are typical of the genus *Aphelandra*.<sup>73</sup> However, in the upper (super-terrestrial) parts and in cell cultures of *A. tetragona* and *A. sinclairiana*, this type of alkaloid was not found.<sup>74</sup>

Besides oranthine and ephedradines B and C, the roots of some plants of the family Scrophulariaceae contain a variety of other macrocyclic spermine alkaloids. Thus chaenorine (**158**) and chaenorpine (**159**) were isolated from the plant *C. minus*, while 18-*O*-methylchaenorpine (**160**) was isolated from *A. tetragona*. The alkaloids **158–160** are structurally similar to the aphelandrine alkaloids **149–157**.<sup>75, 76</sup>

- 158:**  $R^1 = H, R^2 = Ac, R^3 = H, R^4 = OMe$ ;  
**159:**  $R^1 = OH, R^2 = R^3 = R^4 = H$ ;  
**160:**  $R^1 = OMe, R^2 = R^3 = R^4 = H$ .

### c. Spermine alkaloids from *Homalium* plants

The group of homaline alkaloids comprises four spermine derivatives, viz., homaline (**161**), hopromine (**162**), hoprominol (**163**) and hopromalinol (**164**), isolated from the leaves of plants of the genus *Homalium* and *Homalium pronyense* Guillaum (Flacourtiaceae) growing in the rainforests of New Caledonia.<sup>77, 78</sup>

- 161:**  $R^1 = R^2 = (S)\text{-Ph}$ ;  
**162:**  $R^1 = n\text{-C}_5\text{H}_{11}, R^2 = n\text{-C}_7\text{H}_{15}$ ;  
**163:**  $R^1 = n\text{-C}_5\text{H}_{11}, R^2 = \text{CH}_2\text{CH}(\text{OH})\text{C}_5\text{H}_{11}\text{-n}$ ;  
**164:**  $R^1 = \text{Ph}, R^2 = \text{CH}_2\text{CH}(\text{OH})\text{C}_5\text{H}_{11}\text{-n}$ .

## 4. Biological activities of cyclic alkaloids

In the past decade, plants of the genus *Aglaia* (Meliaceae) attracted keen attention as a novel source of unique natural compounds, primarily because of unusually high insecticidal activities of their lipophilic extracts. Non-nitrogenous flavaglines with a cyclopenta[*b*]benzofuran backbone manifest especially high insecticidal and antiproliferative activities;<sup>49</sup> their hypothetical biosynthetic intermediates are polyamine-containing taspakines devoid of insecticidal activity.<sup>48</sup>

Some bisamide alkaloids isolated from plants of the genus *Aglaia*, e.g., dehydroodrine (**60**), manifest cytotoxic activity.<sup>46</sup> The spermidine alkaloid lunarine (**108**) causes time-dependent inhibition of trypanthione reductase (presumably, this reaction is accompanied by the binding of the enzyme to one of the double bonds in the lunarine macrocycle).<sup>79</sup>

The arboreal plant *Alb. gummifera* (J.F.Gmel.) C.A.Sm. is widely used in the folk medicine of Kenya. Its bark possesses pronounced antipyretic properties and is a popular remedy against cold, dermatosis, gonorrhea, malaria, gastric pains (as aqueous extract) and wound contamination (as powder).<sup>69</sup> Yet another Kenyan plant, *Alb. schimperana* Oliv., is used for the treatment of bacterial and parasite-borne infections (pneumonias, infected injuries, malaria) and as a component of antipyretic and analgesic drugs.<sup>70</sup> The species *Alb. julibrissin* is a component of a patented herbal mix for regulation of the level of female hormones. The therapeutic activity of budmunchiamines is usually associated with their physiological effect on the human nervous system.<sup>80</sup>

Wide application of plants of the genus *Albizia* in folk medicine has given strong impetus to their comprehensive studies. It was found that budmunchiamines isolated from these plants

manifest different types of biological activity. A mixture of budmunchiamines A–C (compounds **129–131**) (4 : 1 : 1) has non-specific cytotoxic and antibacterial (*Salmonella typhimurium* TM677) effects; besides, it prevents platelet aggregation and transformation of human lymphocytes and inhibits cyclooxygenase activity.<sup>81</sup>

Budmunchiamines L4 (**147**) and L5 (**148**) induce moderate inhibition of plasmepsin II,<sup>¶</sup> a specific enzyme of the malaria pathogen *Plasmodium falciparum* ( $IC_{50} = 14$  and  $15 \mu\text{mol litre}^{-1}$ , respectively).<sup>72</sup> The currently observed increase in the gravity of the disease and its abundance due to appearance of novel drug- and insecticide-resistant parasites and mosquitos makes the development of newer treatment strategies and novel antimalarial drugs with enhanced properties and new in principle mechanisms of action a central task. This situation is further aggravated by the lack of efficient vaccines and the ambiguity of results of some clinical trials of novel antimalarial drugs.

Budmunchiamines **129**, **132** and **139–144** isolated from the Kenyan plants *Alb. gummifera* and *Alb. schimperana* possess antibacterial and cytotoxic properties.<sup>69</sup> Their antibacterial activities were tested in experiments with two Gram-positive (*Bacillus subtilis* and *Staphylococcus aureus*) and two Gram-negative (*Escherichia coli* and *Pseudomonas aeruginosa*) bacteria; chloramphenicol was used as a standard. Cytotoxicity studies were carried out on sea shrimp larvae. It was found that the biological activities of budmunchiamines strongly depend on two factors, viz., the presence of hydroxy groups in the side alkyl chain R<sup>1</sup> and the degree of methylation of the nitrogen atoms in the macrocycle. A decrease in the degree of methylation of nitrogen atoms (from three to two groups) has no effect on the antibacterial activity, but causes significant reduction of the cytotoxic activity. Both antibacterial and cytotoxic activities decrease significantly, if the side alkyl chain R<sup>1</sup> contains hydroxy groups.<sup>69</sup> The decrease in antibacterial and cytotoxic activities of budmunchiamines A–I (**129–138**) in the presence of carbonyl groups in their side chains provide conclusive evidence in favour of this assumption.<sup>68</sup>

Budmunchiamine A (**129**) was examined for the ability to control the activity of calcium receptors, which are extremely sensitive to even minor changes in  $\text{Ca}^{2+}$  concentrations. It was found that compound **129** inhibits the effect of the extracellular  $\text{Ca}^{2+}$  ion on the cell containing the  $\text{Ca}^{2+}$  receptor. This finding led the authors to conclude<sup>82</sup> that budmunchiamine A is a helpful tool in structure–activity studies.

Ephedradines extracted from plant roots are used as essential components of the Oriental antiperspirant composition ‘mao-kon’. Pharmacological studies have shown that this preparation exhibits antitussive and antiallergic properties.<sup>83</sup> Intravenous injection of ephedradine dihydrochlorides or -bromides to mice produces a hypotensive effect.<sup>84</sup>

\* \* \*

The data presented in this review demonstrate the extreme structural diversity of plant polymethyleamine alkaloids. Many of them showed high activity in pharmacological tests (Table 8) and proved to be promising models in comprehensive structure–activity studies. The wealth of literature data on various biological activities of polymethyleamine alkaloids and the abundant experience in their synthesis open up broad opportunities for the development of novel, highly efficient drugs.

¶ Plasmepsin II is a representative of the plasmepsin family and plays a crucial role in the survival and proliferation of enzymes. It is extensively studied and readily available and is thereby used as a target of choice for screening a library of natural products.

**Table 8.** Biological activities of plant source alkaloids of the polymethyleamine series.

| Type of biological activity                                                 | Alkaloids                         |                     |
|-----------------------------------------------------------------------------|-----------------------------------|---------------------|

**Abstract.** The modern theoretical models of the active–passive transition and of the passive state of metals are surveyed. General regularities underlying the functioning mechanisms of passivating oxide layers as well as the adsorption and salt passivation are formulated. The bibliography includes 99 references.

## I. Introduction

Despite numerous studies of the passive state of metals conducted over the last few decades and extensive experimental data collected in this field, there is still no consensus on the mechanism of formation<sup>1–19</sup> and functioning<sup>20–25</sup> of passivating (oxide) layers (hereinafter, PL). Passivating systems are thermodynamically non-equilibrium, therefore it is the *in situ* techniques that are the most efficient in their studies. Probably, this is one of the reasons for the frequent succession violations of the theoretical concepts related to the passivity problem, *i.e.*, earlier prevailing concepts are rejected and replaced with new ones. This substantiates a thorough comparative analysis of different passivity models.

The current understanding of the mechanism of the formation of a PL has evolved through several steps. The original concept elaborated by representatives of the German school of electrochemists<sup>26–34</sup> postulated the existence of an equilibrium phase oxide (the so-called phase-film concept). This implied that the passivation is caused by the mechanical shielding of the metal surface (*S*) by a thermodynamically equilibrium oxide layer, the constant passive current being in this case due to the chemical dissolution of the oxide. Gradually, serious contradictions to experiments were found within this concept. In particular, it appeared that the critical potentials observed in polarisation curves, *i.e.*, the activation and passivation potentials, differed from the potentials of formation of the respective oxides. For instance, in the case of iron, the difference is as large as 0.63 V (relative to the standard hydrogen electrode).<sup>26</sup> The experimen-

tally established dependence of the passivation and activation potentials on the electrolyte composition, pretreatment of the metal surface and its properties also contradicted to the phase-film concept. The postulate on the constancy of the passive current, which is equivalent to the rate of the chemical dissolution of the passivating oxide, was disproved by the experimental results, which supported the electrochemical mechanism of transition of the passivated metal into a solution. However, despite the above contradictions, Vetter has proposed<sup>26</sup> an approach rationalising the stability and functioning of a PL. According to the experimental results,<sup>19, 25, 26</sup> the stability is due to the ion exchange between the PL and the electrolyte, which complies with the general conditions of the thermodynamical equilibrium between these two phases.

By the late 1970s, the self-contradictory, in general, phase-film model featured the correct idea that it is the oxide layer that plays a prominent role in the passivation mechanism. These concepts were further developed by other authors who considered the processes of ion transfer through the interfaces and the effects of ion vibrations in the nodes of a crystal lattice.<sup>35–46</sup> The processes of the cluster growth of oxide PL on iron, nickel, copper and other metals were investigated, and semiconducting properties of the PL and the mechanism of breakdown of the passive state were analysed. Popov and Sakha<sup>47</sup> formulated the following systematisation criteria for the models of the passive state.

1. Functioning of a passivating layer is stable provided that the equilibrium between the oxide and the electrolyte is achieved owing to the exchange of oxygen ions. Since the passivated metal undergoes anodic dissolution, the equilibrium with the electrolyte is incomplete and involves only the oxygen sublattice of the PL. Overall, the system oxide–electrolyte is non-equilibrium thermodynamically and thus it should be analysed taking into consideration kinetic factors.

2. The anion composition of a stationary PL remains constant; the anions drift gradually following the shift of the interface metal–oxide (M–O) due to the hopping diffusion. Meanwhile, the composition of the cation (metal) sublattice of the PL is continuously renewed due to transfer of the  $M_{ox}^{z+}$  ions into the electrolyte, which is accompanied by cleavage of their bonds with the  $O_{ox}^{2-}$  anions migrating in the bulk of the PL. A part of the  $M_{ox}^{z+}$  ions that diffuse through the PL from the interface M–O come into the electrolyte independently of the migration of the oxygen anions, which results in continuous disappearance of oxide cells within the PL.

3. In a stationary mode, new oxide cells are continuously formed at the interface M–O, which compensates for their dissolution in the electrolyte. This provides the stability of the PL. The  $O_{ox}^{2-}$  anions are incorporated into the metal phase so that the compensating process of metal conversion into passivating oxide occurs. The volume of the latter typically exceeds the initial volume of the metal.

4. The metal conversion process gives rise to the spatial balance problem due to the difference in the volumes of the initial metal and the derived oxide. The balance is kept due to non-equilibrium cation vacancies at the interface oxide–electrolyte (O–E), which diffuse through the PL towards the interface M–O, where they convert into oxide anion vacancies.<sup>19, 25</sup> This is the first role played by the non-equilibrium vacancies.

5. The passivity region has a finite dimension (length), which means that a passivity theory should describe the transpassive transition.<sup>19, 23, 25</sup> This necessitates accounting for the diffusion in the PL, which gives rise to a dependence of the concentration of non-equilibrium vacancies (*i.e.*, point defectiveness of the PL), which affects the PL length, on the anode potential  $\varphi$ . At low defect concentrations in the PL (*e.g.*, in the cases of Al, Ti, Ta and Zr), the transition potential can be appreciably high. This is the second role played by the non-equilibrium vacancies.

6. A passivity theory should explain from a unified standpoint the mechanisms of the processes that proceed at both interfaces, O–E and M–O, and the ion transfer between them.

The behaviour of metals in electrolyte solutions is characterised by a dependence of the current density of the anode dissolution  $i_a$  on the interface potential drop. A polarisation curve typical of such metals as Fe, Ni and Cr is shown schematically in Fig. 1.

The state of a metal surface in an electrolyte is determined by the value of  $\varphi$ . Four major states of a surface are known, *viz.*, active dissolution, active-passive transition, passive state and transpassive transition, to which correspond the following four ranges of the potential values:  $\varphi < \varphi_0$ ,  $\varphi_0 < \varphi < \varphi_a$ ,  $\varphi_a < \varphi < \varphi_p$  and  $\varphi > \varphi_p$  in Fig. 1. The characteristic points  $\varphi_0$ ,  $\varphi_a$  and  $\varphi_p$  depend on the metal and electrolyte properties and on their interaction.

The present review describes the existing theories of the mechanism and kinetics of processes occurring in two most important and complex states, *viz.*, the active-passive transition and the passive state itself.

The multitude of corrosion phenomena cannot be covered within a single theory. The knowledge of the specificity of a system is a prerequisite of any study. For instance, one should determine the statistical scatter in the interatomic distances and bond directions within a PL to account for its incomplete structural ordering (*i.e.*, when it is amorphous). A microscopic-level mechanism of the metal–electrolyte interactions can also be highly specific to the system, *etc.*

**Figure 1.** The experimental<sup>26</sup> (solid line) and theoretical<sup>19</sup> (dashed line) dependences of the current densities ( $i_a$ ) corresponding to dissolution of a metal in an electrolyte on the anode potential;  $i_A(\varphi)$  is the current density in the Tafel region,  $(\varphi_0 - \varphi_a)$  is the active-passive transition,  $(\varphi_a - \varphi_p)$  is the passivity region.

Meanwhile, shapes of the polarisation curves are essentially identical for many metals: they show the aforementioned regions of the active and passive dissolution as well as of the active-passive and transpassive transitions. This indicates that it is possible (and thus desirable) to develop a unified theoretical model to include maximally simplified processes that govern the shapes of the polarisation curves. These processes include migration of ions through the interfaces PL–metal and PL–electrolyte and within the PL structure itself, an increase in the defectiveness of a PL upon an increase in the potential and the PL crystallisation during the active-passive transition. The kinetics of these processes differ depending on the potential and therefore one process dominates at any specific potential value, which gives rise to the alteration of the four above regions with an increase in the potential. The unified elementary model serves as a base ('framework'), which can be extended or modified to take into account specific factors for consideration of real systems. The author believes that exactly this purpose is pursued by the theory described below, which is open for any extensions and modifications.

## II. Formation of a passivating oxide layer upon the active–passive transition ( $\varphi_0 < \varphi < \varphi_a$ )

According to numerous investigations, the compositions and structures of passivating layers on such metals as Fe, Cr, Ni, Mo and Cu correspond to those of metal oxides  $M_nO_m$  (*e.g.*,  $Fe_2O_3$  or  $Fe_3O_4$  in the case of iron). This is evident from both early studies of passivating layers using X-ray diffraction<sup>26</sup> and layer-by-layer etching and more recent methods of scanning tunnelling and optical microscopy.<sup>45, 46</sup> Ellipsometry is becoming increasingly popular in studies of PL.<sup>48–52</sup> Especially promising is the ellipsometric topography method,<sup>53, 54</sup> which exploits the dependence of the transmission coefficient of a PL on the radiation wavelength.

If an oxide PL possesses a disordered structure (*i.e.*, it is amorphous, as in the case of PL formed on Al, Ti, Ta, Zr and other metals), it can be described by statistical distributions of the interatomic distances and angular directions. However, the passive current density and other parameters can finally be expressed<sup>25</sup> through dispersions in the interatomic distances, angular directions and electric field strengths within the PL. The problem of the independent determination of these parameters is not solved as yet.

In agreement with the concepts formulated above and the general theory of heterogeneous nucleation,<sup>1–18</sup> it was suggested<sup>18–21</sup> that it is the two-dimensional nuclei of an oxide  $MO_{z/2}$  that are formed in the initial step of PL formation on the surface of anodically dissolving metal. The formation of nuclei starts at the point  $\varphi_0$  of the second region in the polarisation curve and is completed at  $\varphi_a$  in the end of this region (see Fig. 1).

In the steady-state mode, the probability  $I_e$  of nuclei generation (the number of nuclei per  $cm^2$  per s) is an increasing function of the anode potential  $\varphi$ . Respectively, the steady-state coverage  $\Theta_e$  of the surface  $S$  by nuclei also increases reaching the maximum value  $\Theta_e(\varphi_a) \sim 1$  at  $\varphi_a$ .

A further increase in the potential actuates the transition into the passive region in which the thickness of the passivating layer  $\delta(\varphi)$  increases with retention of the equilibrium between the oxide and the electrolyte. Indeed, an equilibrium potential  $\varphi_{pb}$  is settled in this range, whereas the surplus potential drop  $(\varphi - \varphi_{pb})$  is expended within the thickness  $\delta(\varphi)$  of the passivating layer.

This section considers modern models of the kinetics of formation of a PL, functional dependences of  $I_e$ ,  $\Theta_e$  and anodic current density  $i_a$  on the potential, the energy of the interparticle interactions, energetic heterogeneity of the metal surface and other parameters. These dependences reproduce a nearly vertical decrease (by 5–7 orders of magnitude) in the current upon the active-passive transition, *i.e.*, over a narrow range of potentials  $\varphi_0 < \varphi < \varphi_a$  with a width of only 50–70 mV.

### 1. Kinetics of crystallisation of a passivating layer

Simulations of crystallisation of passivating layers on metal surfaces are based on the molecular-kinetic theory of nucleation. This theory developed in the mid 1970s<sup>1–18</sup> retains its significance to date. According to this theory, nuclei of the passivating layer are generated due to the stepwise attachment of particles to faces of the existing two-dimensional crystals (*i.e.*, prenuclei).

The molecular-kinetic theory<sup>1–18</sup> differs from two other thermodynamical theories by Volmer and Gibbs, which consider generation of nuclei as a mere condensation process without any structure formation. In contrast, the molecular-kinetic theory describes the stepwise attachment of particles to a crystal taking into account its surface structure, influence of neighbours and possible ordering into a crystal lattice. The key steps of these processes can be established<sup>1–14</sup> using simple models that approximate a crystal structure with a lattice of points or array of cubes. These models are based on the nearest-neighbour-interaction approximation, which assumes that the interactions between the real particles rapidly attenuate with an increase in the interparticle distances.

Let the interatomic distance in the crystal be  $r_0$  and its size  $a = nr_0$  changes due to elementary processes of the type  $a \rightarrow a \pm r_0$ , *i.e.*, due to attachment or detachment of a peripheral atomic row, which gives rise to the transformation of the crystal with an edge  $a$  to that with an edge  $a \pm r_0$ . If  $P$  and  $V$  are, respectively, the probabilities and the rates of the following transitions

$$\begin{aligned} P_{a \rightarrow a \pm r_0}, \quad P_{a \pm r_0 \rightarrow a}, \\ V_{a \rightarrow a \pm r_0}, \quad V_{a \pm r_0 \rightarrow a} \end{aligned} \quad (1)$$

$n_a$  is the concentration of crystals with an edge  $a$ , then

$$\begin{aligned} V_{a \rightarrow a \pm r_0} &= n_a P_{a \rightarrow a \pm r_0}, \\ V_{a \pm r_0 \rightarrow a} &= n_{a \pm r_0} P_{a \pm r_0 \rightarrow a}. \end{aligned} \quad (2)$$

Provided that  $a \gg r_0$ , the following relations can be derived

$$\begin{aligned} P_{a+r_0 \rightarrow a} &\simeq P_{a \rightarrow a-r_0}, \\ P_{a \rightarrow a+r_0} &\simeq P_{a-r_0 \rightarrow a}. \end{aligned} \quad (3)$$

The resultant rates of the direct and reverse stationary transitions ( $I$ ) are given by

$$I = V_{a-r_0 \rightarrow a} - V_{a \rightarrow a-r_0} = V_{a \rightarrow a+r_0} - V_{a+r_0 \rightarrow a} \quad (4)$$

or further

$$\begin{aligned} I &= V_{a \rightarrow a+r_0} - V_{a+r_0 \rightarrow a} = \\ &= n_a (P_{a \rightarrow a+r_0} - P_{a \rightarrow a-r_0}) - P_{a \rightarrow a-r_0} (n_{a+r_0} - n_a). \end{aligned} \quad (5)$$

If  $a$  reaches the value  $a_2 = n_2 r_0$ , where  $n_2$  is the number of particles in the edge of the two-dimensional nucleus, then

$$P_{a_2 \rightarrow a_2+r_0} = P_{a_2 \rightarrow a_2-r_0}.$$

Furthermore, for sufficiently large  $a$

$$\begin{aligned} n_{a+r_0} - n_a &\simeq \left( \frac{dn_a}{da} \right) r_0, \\ a &\gg r_0. \end{aligned} \quad (6)$$

Taking into account the equation (5), we obtain

$$I_e = \left( P_{a \rightarrow a-r_0} \frac{dn_a}{da} \right)_{a=a_2}. \quad (7)$$

The first term in the right part of the equation can be expressed through the work of formation of the peripheral atomic row ( $W_{a_2}$ )

$$P_{a_2 \rightarrow a_2-r_0} = \text{const} \left[ a_2 \exp \left( -\frac{W_{a_2}}{kT} \right) \right]^2. \quad (8)$$

The exponent 2 means that a transition of a square nucleus with an edge  $a_2$  into that with an edge  $a_2 + r_0$  requires simultaneous attachment of two rows of particles to two adjoining edges;  $a_2^2$  is the area of the substrate where the nucleus is formed. The second term can be determined from (3) and (4) reformulated as

$$\begin{aligned} \frac{n_{a+r_0} - n_a}{n_a - n_{a-r_0}} &= \frac{P_{a \rightarrow a+r_0}}{P_{a \rightarrow a-r_0}}, \\ \frac{P_{a \rightarrow a+r_0}}{P_{a \rightarrow a-r_0}} &= \left[ \exp \left( -\frac{W_a - W_a^*}{kT} \right) \right]^2. \end{aligned} \quad (9)$$

Here,  $(W_a^* - W_a)$  is the difference between the energies of attachment and detachment of a peripheral row of particles.<sup>25</sup> The equations (6), (8) and (9) can be transformed into

$$\begin{aligned} \ln \left( \frac{dn_a}{da} \right)_{a+r_0} - \ln \left( \frac{dn_a}{da} \right)_a &= r_0 \frac{d}{da} \left( \ln \frac{dn_a}{da} \right), \\ r_0 \frac{d}{da} \left( \ln \frac{dn_a}{da} \right) &= \left[ \exp \left( -\frac{W_a - W_a^*}{kT} \right) \right]^2. \end{aligned} \quad (10)$$

This according to Stranski *et al.*<sup>2,5</sup> gives rise to

$$\left( \frac{dn_a}{da} \right)_{a=a_2} = \text{const} \exp \left( -\frac{W}{2kT} \right), \quad (11)$$

where  $a_2 = n_2 r_0$ ,  $W = 2n_2 \Psi$  ( $\Psi$  is the interaction energy of two particles arranged at a distance  $r_0$  from each other).

If  $n_2$  is the number of particles in the edge of a square two-dimensional nucleus and  $a_2 > a$ , then the work of its formation can be represented as a product of the perimeter ( $L$ ) and specific edge surface of the nucleus ( $\kappa$ )

$$W = L\kappa,$$

where  $L = 4a_2$ ,  $\kappa = \Psi/2r_0$ . With account of the equations (7), (8) and (11), this gives rise to

$$I_e = \text{const} \left[ a_2 \exp \left( -\frac{W_{a_2}}{kT} \right) \right]^2 \exp \left( -\frac{W}{2kT} \right), \quad (12)$$

$$a_2 = n_2 r_0,$$

$$W_{a_2} = \left( \Psi - \frac{\Psi}{n_2} \right),$$

$$W = 2n_2 \Psi.$$

The terms in the right part of the equation (12) account for structuring and condensation, respectively (through values of  $W_{a_2}$  and  $W$ ).

It has been shown<sup>19</sup> that the number of particles in the edge of a nucleus of passivating oxide upon formation of the PL on the surface of an anodically dissolving metal is expressed as

$$n_2(\varphi) = \frac{\Psi}{ze(\varphi - \varphi_{p1}) + \Psi_0 - \Psi},$$

where  $\varphi_{p1}$  is the potential of formation of the passivating oxide  $\text{MO}_{x/2}$ , and  $\Psi_0$  is the interaction energy of particles constituting the oxide nucleus with the metal substrate.

According to the equation (12), the rate of formation of the oxide is

$$I_e(\varphi) \simeq I_0 \exp \left[ -\frac{2\Psi^2/kT}{ze(\varphi - \varphi_{p1}) + \Psi_0 - \Psi} \right]. \quad (13)$$

This formula is in agreement with that derived by Pangarov.<sup>11</sup>

## 2. Coverage of the metal surface with a passivating oxide

The process of coverage of the metal surface with a passivating oxide has been investigated by several authors.<sup>19, 26</sup> The oxide nuclei are generated according to the reaction

Two different phases, *viz.*, the metal  $M$  and an aqueous electrolyte, serve as sources of ions. This is a feature of the PL formation. At the active-passive transition, the nuclei of  $MO_{z/2}$  are in equilibrium only with the metal phase. To realise the complete equilibrium, the interphase potential at the interface with the electrolyte should have a specific value, which is not yet reached at  $\varphi < \varphi_a$ . Therefore, the nuclei dissolve after certain (mean) lifetime.

Indeed, upon the active-passive transition, the transfer of the  $M^{z+}$  cations from  $MO_{z/2}$  into the electrolyte (*i.e.*, dissolution) is continuously compensated for by their transport from the metal substrate. This means that the cationic sublattice of the nucleus remains in a stationary state. From this viewpoint, the critical nucleus of  $MO_{z/2}$ , as has been said above, is in equilibrium with the metal  $M$ , and its size  $a_2$  is determined by the standard equation

$$\sum_i \mu_i v_i = ze\varphi,$$

where  $\mu_i$  and  $v_i$  are the chemical potential and stoichiometric coefficient of the  $i$ th reactant in the equation (14), respectively.

The oxygen sublattice of the nucleus of  $MO_{z/2}$  is not in a stationary state, since the transfer of the  $O^{2-}$  anions into the electrolyte is not compensated for by other processes. This is accompanied by the following reactions

The overall process can be formulated as

The current density induced by oxygen removal is

$$\begin{aligned} I_O(\varphi_b) &= \\ &= i_{ex} \left\{ \exp \left[ \alpha_O \frac{z_O F}{RT} (\varphi_b - \varphi_{pb}) \right] - \exp \left[ -\beta_O \frac{z_O F}{RT} (\varphi_b - \varphi_{pb}) \right] \right\}, \end{aligned} \quad (15)$$

where  $i_{ex}$  is the exchange current;  $\alpha_O$  and  $\beta_O$  are the transfer coefficients ( $\alpha_O + \beta_O = 1$ ,  $z_O = 2$ );  $F$  is the Faraday number;  $\varphi_b$  is the interface potential;  $\varphi_{pb}$  is the potential of the partial oxygen equilibrium. The equilibrium of the oxide with the electrolyte with respect to oxide ions is achieved only in the end of the transition, *i.e.*, at the potential  $\varphi \sim \varphi_a$  (see Fig. 1), the equilibrium being characterised by

$$\begin{aligned} \varphi_b(\varphi) &= \varphi_{pb}, \\ \varphi &= \varphi_a, \end{aligned} \quad (16)$$

where  $\varphi_{pb}$  is defined by the condition

$$I_O(\varphi_{pb}) = 0. \quad (17)$$

Therefore, in the end of the active-passive transition, the dissolution of passivating nuclei gradually ceases, the first oxide monolayer becomes continuous, the coverage reaches the value of  $\Theta_e(\varphi_a) = 1$ , and gradual transition to the passive region occurs.<sup>19, 20</sup>

However, this is still an incomplete physical description of the active-passive transition since the reaction (14) competes with the process of active anodic dissolution, which proceeds according to the scheme

$A^{z_A-}$  are activating anions from the electrolyte and  $\sigma$  is the fraction of the electron charge involved in the chemisorption bonding. The metal surface is covered not only with two-dimensional nuclei [the degree of coverage is  $\Theta_e(\varphi)$ ], but with surface complexes  $(MvA)^{-vz_A+\sigma}$  [the degree of coverage is  $\Theta_a(\varphi)$ ] as well. The stationary equations for  $\Theta_e(\varphi)$  and  $\Theta_a(\varphi)$  can be written as

$$(1 - \Theta_a - \Theta_e)K_a(\varphi) = \Theta_a K_i(\varphi), \quad (20)$$

$$(1 - \Theta_a - \Theta_e)I_e = \Theta_e I_O(\varphi),$$

where  $K_a(\varphi)$ ,  $K_i(\varphi)$  are the rates of adsorption of activating anions  $A^{z_A-}$  and ionisation of the intermediate complexes  $(MvA)^{-vz_A+\sigma}$ , respectively,

$$K_a(\varphi) = k_a C_a^v \exp \left[ \frac{\alpha_a (z_A - \sigma) F \varphi}{RT} \right],$$

$$K_i(\varphi) = k_i \exp \left[ \frac{\alpha_i (z_M - \sigma) F \varphi}{RT} \right].$$

$k_a$ ,  $C_a^v$  and  $k_i$  are preexponential factors;  $\alpha_a$  and  $\alpha_i$  are the transfer coefficients of anions and ions of the intermediate complexes, respectively.

Therefore,

$$\Theta_e = \frac{I_e}{I_O + (1 + \Theta'_a)I_e} (1 - \Theta'_a), \quad (21)$$

$$\Theta_a = (1 - \Theta_e)\Theta'_a,$$

$$\Theta'_a = \frac{K_a(\varphi)}{K_a(\varphi) + K_i(\varphi)}. \quad (21a)$$

The anodic currents (rates)  $I_e(\varphi)$  and  $i_a(\varphi)$  corresponding to the processes (14) and (19) differently depend on the potential  $\varphi_0$ . At low  $\varphi$ , the reactions (19) dominate and the coverage  $\Theta_e(\varphi)$  is small. With an increase in  $\varphi$ , the rate  $I_e(\varphi)$  increases and  $I_e(\varphi_0) \sim i_a(\varphi_0)$  at  $\varphi = \varphi_0$  (see Fig. 1). Starting from this moment, two-dimensional nuclei are predominantly generated owing to the strong dependence of  $I_e$  on  $\varphi$ , and the current density of anodic dissolution decreases by several orders of magnitude with a change in  $\varphi$  in a narrow range of the order of tens of mV. The total current density  $j(\varphi)$  caused by the transfer of the  $M^{z+}$  ions into the electrolyte is described by the equation

$$j(\varphi) = \Theta_a(\varphi)K_i(\varphi) + [I_O(\varphi_b) + i_O(\varphi_b)]\Theta_e(\varphi), \quad (22)$$

where

$$i_O(\varphi_b) = i_0 \exp \left( \frac{\alpha z_M F}{RT} \varphi_b \right),$$

$i_0$  is the preexponential factor and  $\alpha$  is the particle transfer coefficient.

The formula (22) takes into account all mechanisms contributing to the value of  $j(\varphi)$ . The first term corresponds to the active dissolution; the second one is due to dissolution of the nuclei at a rate  $I_O(\varphi_b)$ , which results in flaking away of the  $M_{ox}^{z+}$  ions; the third term accounts for the metal ion transfer through the nuclei into the solution and their migration through the two-dimensional passivating oxide layer; it predominates for the passive region at  $\varphi > \varphi_a$ .

## 3. The energetic inhomogeneity of a metal surface

The concepts described above underlie the modern theory of the PL formation. A further step in this approximation consists of consideration of the energetic inhomogeneity of a surface, which implies that different areas of a surface  $\Delta S_i$  interact with the electrolyte with different strengths and generate different current densities of anodic dissolution. A variable energy  $\Psi_{0i}$  can be

attributed to every sufficiently small area and the overall surface will thus be characterised by a sum

$$S = \sum_i \Delta S_i(\Psi_{0i})$$

or integral

$$S = \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} dS(\Psi_{0i}),$$

the integration limits  $\varepsilon_{\max}$  and  $\varepsilon_{\min}$  depend on the properties of the metal. The electrode processes can be described using the specially specified autonomous function  $f(\Psi_{0i})$  of statistical distribution of energies  $\Psi_{0i}$  over the surface, the local current density  $j(\varphi, \Psi_{0i})$  and the local coverage  $\Theta(\varphi, \Psi_{0i})$ . Their integral values are determined by the following equations

$$\begin{aligned} \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} f(\Psi_{0i}) d\Psi_{0i} &= 1, \\ i_a(\varphi) &= \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} d\Psi_{0i} f(\Psi_{0i}) j_i(\varphi, \Psi_{0i}), \\ \Theta_e(\varphi) &= \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} d\Psi_{0i} f(\Psi_{0i}) \Theta_{ei}(\varphi, \Psi_{0i}). \end{aligned} \quad (23)$$

The energy of interaction of particles constituting a nucleus with the metal  $\Psi_{0i}$  is contained in the probability (13) and, consequently, in all other parameters. The local coverages and current densities can be expressed as follows:

$$\Theta_{ei}(\varphi, \Psi_{0i}) = \frac{I_{ei}(\varphi, \Psi_{0i})[1 - \Theta'_a(\varphi)]}{I_O(\varphi_b) + [1 - \Theta'_a(\varphi)]I_{ei}(\varphi, \Psi_{0i})}, \quad (24)$$

$$\Theta_{ai}(\varphi, \Psi_{0i}) = [1 - \Theta_{ei}(\varphi, \Psi_{0i})] \Theta'_a(\varphi),$$

$$I_{ei}(\varphi, \Psi_{0i}) = I_0 \exp \left[ -\frac{2\Psi^2/kT}{ze(\varphi - \varphi_0) + \Psi_{0i} - \Psi} \right],$$

$$j_i(\varphi, \Psi_{0i}) = \Theta_{ai}(\varphi, \Psi_{0i})K_i(\varphi) + [I_O(\varphi_b) + i_O(\varphi_b)]\Theta_{ei}(\varphi, \Psi_{0i}).$$

The formulas (23) and (24) together determine the total coverage  $\Theta_e(\varphi)$  of the surface  $S$  with the two-dimensional passivating oxide layer and the total anodic current density  $i_a(\varphi)$  within the region of the active–passive transition. The system of equations (23), (24) and (21a) gives rise to

$$\Theta_e(\varphi) = \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} d\Psi_{0i} f(\Psi_{0i}) \Theta_{ei}(\varphi, \Psi_{0i}),$$

$$i_a(\varphi) = \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} d\Psi_{0i} f(\Psi_{0i}) j_i(\varphi, \Psi_{0i}),$$

$$i_A(\varphi) = \frac{K_a(\varphi)K_i(\varphi)}{K_a(\varphi) + K_i(\varphi)},$$

$$i_a(\varphi) = i_A(\varphi)[1 - \Theta_e(\varphi)] + [I_O(\varphi_b) + i_O(\varphi_b)]\Theta_e(\varphi),$$

where  $i_A(\varphi)$  corresponds to the current density of the active dissolution of those parts of the metal surface, which are not covered by passivating two-dimensional nuclei.

The latter expression represents the general formula for the calculation of the dissolution current  $i_a(\varphi)$  over the whole range of the potential. The calculations using this formula (see the dashed line in Fig. 1) agree with the experimental data.<sup>26</sup>

The functions  $i_A(\varphi)$  and  $\Theta_e(\varphi)$  play the key role in the prepassive region  $\varphi < \varphi_0$ . According to calculations, it is the active dissolution that makes the dominant contribution to the total anodic current  $i_a(\varphi)$  before the maximum of the polarisation curve (*i.e.*, at  $\varphi < \varphi_0$ ) because  $\Theta_e(\varphi)$  is small and  $i_A(\varphi)$  becomes more important. After the maximum, *i.e.*, in the region of the active–passive transition, the coverage  $\Theta_e(\varphi)$  rapidly increases and the active dissolution is gradually replaced by the formation of two-dimensional nuclei. A continuous monolayer with  $\Theta_e \approx 1$  is completed at  $\varphi = \varphi_a$  and the passivity region itself starts afterwards ( $\varphi > \varphi_a$ ).

### III. Processes in a steady-state passivating oxide layer at $\varphi_a < \varphi < \varphi_p$

The processes proceeding in a passivating layer have been analysed in numerous studies.<sup>19, 22–25, 37–47, 55–59</sup> According to the concepts developed in these works, the structure of a PL consists of two interpenetrating ionic sublattices (metallic and oxygen). The ions electrodiffuse *via* vacancies in the respective sublattices. Overall, the composition of PL formed on hard metals (Fe, Ni, Cr, Cu, *etc.*), as has been mentioned above, corresponds to oxides  $M_nO_m$ . The ions constituting these oxides are marked with the subscript index ‘ox’, *i.e.*,

Positions of the PL and interfaces M–O and O–E are shown in Fig. 2. To provide stability of the PL, the interphase (crystal–electrolyte) equilibrium conditions should be met at the external interface O–E for both the cation and anion sublattices.<sup>19, 26, 27</sup> For a general case of an ionic crystal  $N_nP_m$ , these conditions are derived from the expressions for the ion current densities  $i_N$  and  $i_P$ .

$$i_N = \vec{k}_N \exp \left( \alpha_N \frac{z_N F}{RT} \varphi_b \right) - \overleftarrow{k}_N C_N \exp \left( -\beta_N \frac{z_N F}{RT} \varphi_b \right), \quad (25)$$

$$i_P = \vec{k}_P C_P \exp \left( \alpha_P \frac{z_P F}{RT} \varphi_b \right) - \overleftarrow{k}_P \exp \left( -\beta_P \frac{z_P F}{RT} \varphi_b \right),$$

$$\alpha_P + \beta_P = 1,$$

$$\alpha_N + \beta_N = 1,$$

where  $\vec{k}$  and  $\overleftarrow{k}$  are the rate constants of the direct and reverse reactions of the ion transfer into the electrolyte solution;  $\alpha$  and  $\beta$  are the transfer coefficients;  $C_N$ ,  $C_P$ ,  $z_N$  and  $z_P$  are the concentration and charge numbers, respectively, of ions  $N^{z_N+}$  and  $P^{z_P-}$  that constitute  $N_nP_m$  crystal;  $\varphi_b$  is the interface O–E potential.

**Figure 2.** A scheme of ion concentration distributions  $N_M(x)$  (1) and  $N_O(x)$  (2) in a passivating layer.  $\delta(\varphi) = A_2 - A_1$ .

At the equilibrium, the currents  $i_N$  and  $i_P$  should be equal to zero, and the potential  $\varphi_b$  should have its equilibrium value  $\varphi_{pb}$ , *i.e.*,

$$\begin{aligned} i_N &= 0, \\ i_P &= 0, \\ \varphi_b &= \varphi_{pb}. \end{aligned}$$

This gives rise to the following two expressions for  $\varphi_{pb}$

$$\begin{aligned} \varphi_{pb} &= \frac{RT}{z_N F} \left( \ln \frac{\overleftarrow{k}_N C_N}{\overrightarrow{k}_N} \right), \\ \varphi_{pb} &= \frac{RT}{z_P F} \left( \ln \frac{\overleftarrow{k}_P}{\overrightarrow{k}_P C_P} \right). \end{aligned} \quad (26)$$

They are compatible provided that

$$\begin{aligned} C_N^n C_P^m &= \left( \frac{\overleftarrow{k}_N}{\overrightarrow{k}_N} \right)^n \left( \frac{\overleftarrow{k}_P}{\overrightarrow{k}_P} \right)^m, \\ z_N n &= z_P m. \end{aligned} \quad (27)$$

If these conditions are not met, no equilibrium is possible between the electrolyte and the ionic crystal and the latter disintegrates.

The situation is more complicated in the case of a PL. Indeed, since the anodic current is non-zero in the passivity region  $\varphi_a \leq \varphi \leq \varphi_p$ , which means that the passivated metal dissolves at a low rate, the metal sublattice of the PL appears non-equilibrium with respect to the electrode.

Notwithstanding, according to experiments, passivating layers are stable, and the anodic current does not depend on the potential in the range  $\varphi_a \leq \varphi \leq \varphi_p$  (see Fig. 1).

These experimentally established facts are only possible provided that two conditions are met. First, the oxygen sublattice should be in equilibrium with the electrolyte in a steady-state mode, *i.e.*, a partial equilibrium PL–electrolyte should be realised, which means that

$$\begin{aligned} i_O &= 0, \\ i_M &\equiv i_a \neq 0, \end{aligned} \quad (28)$$

where  $i_O$  and  $i_M$  are the current densities of the  $O_{ox}^{2-}$  and  $M_{ox}^{z+}$  ions, respectively. Second, the transfer of the  $M_{ox}^{z+}$  ions from the PL to the electrolyte should be compensated for by their continuous supply from the bulk of the PL to its border (that is the interface O–E). The interface M–O serves as a source of the  $M_{ox}^{z+}$  ions.

Therefore, all the processes proceeding at the interfaces and in the bulk of the PL are self-consistent. Three components can be distinguished in the mechanism of a PL functioning, *viz.*, the interaction of the interface O–E with the electrolyte, which initiates detachment of the  $M_{ox}^{z+}$  ions from the PL lattice and their transfer into the electrolyte; the ion transfer through the bulk of PL described above; the processes at the interface M–O where the  $O_{ox}^{2-}$  ions diffuse into the metal and form new cells  $M_n O_m$ . These three components and the self-consistency between them have been considered elsewhere.<sup>19, 23–25</sup>

### 1. The interaction between metal and electrolyte at the interface oxide–electrolyte

Activating anions  $A^{zA-}$  and water molecules are adsorbed at the metal surface  $S$  and form molecular complexes  $(MA \cdot v H_2O)^{z-zA+\sigma}$  with the  $M_{ox}^{z+}$  ions. This is accompanied by weakening of binding of the surface sites  $M_{ox}^{z+}$  with the surface itself, *i.e.*, the energy barrier to their transfer into the electrolyte is decreased. The molecular complexes are characterised by a mean lifetime  $\tau$  on the metal surface; the  $M^{z+}$  ions constituting the complexes detach from the surface and pass into the electrolyte. The mechanism of the surface disintegration (anodic dissolution) can be represented with a two-step scheme

The  $A^{zA-}$  species and  $H_2O$  molecules manifest catalytic activity, and the resultant current density  $i_a$  of the  $M^{z+}$  ions in the steps (29) (that is the number of the elementary acts of the particle detachment per s per  $cm^2$ , *i.e.*,  $i_a \sim 1/\tau$ ) is given by

$$i_a \simeq k N_M [A^{zA-}] \exp \left[ - \frac{\varepsilon - \alpha(z - \sigma) F \varphi_b}{RT} \right], \quad (30)$$

where  $k$  is the rate constant of the second step of the reaction (29);  $N_M \simeq 10^{16} \text{ cm}^{-2}$  is the concentration of the  $M_{ox}^{z+}$  ions on the surface  $S$ ;  $\varepsilon$  is the binding energy of the complexes, which depends on the existence of  $A^{zA-}$ ;  $\alpha$  is the transfer coefficient describing the asymmetry of the potential drop ( $\alpha < 1$ ). The involvement of the  $A^{zA-}$  anions from the electrolyte in the elementary acts of the anodic dissolution has been established experimentally.

The equilibrium exchange of the oxide ions between the PL and the electrolyte, which provides the stability of the PL, is the second stationary process proceeding on the metal surface<sup>26</sup>

This exchange realises a partial equilibrium between the electrolyte and the PL. It determines the equilibrium potential  $\varphi_{pb} = \varphi_b$  of the passive region, and, consequently, independence of the current corresponding to the anodic dissolution of the passivated metal of the anode potential. Water molecules dissociating upon adsorption on the metal surface serve as a source of ions in the process (31). A more detailed scheme of the oxide ion exchange is given below:

the overall process can be represented as

The current density corresponding to the reaction (33) is described by the equation

$$i_O = \overrightarrow{k} [H_2O] N_M \exp \left( \frac{\alpha_O z_O F \varphi_b}{RT} \right) - \overleftarrow{k} N_O [H^+]^2 \exp \left( - \frac{\beta_O z_O F \varphi_b}{RT} \right),$$

where  $N_M$  and  $N_O$  are the surface concentrations of the  $M_{ox}^{z+}$  and  $O_{ox}^{2-}$  ions, respectively, on the metal surface,  $\alpha_O + \beta_O = 1$ ,  $z_O = 2$ . If the equilibrium (33) is reached, then

$$\begin{aligned} i_O &= 0, \\ \varphi_b &= \varphi_{pb}. \end{aligned} \quad (34)$$

This gives rise to

$$\varphi_{pb} = \frac{RT}{z_O F} \ln \left( \frac{\overleftarrow{k}}{\overrightarrow{k}} \frac{N_O}{N_M} \frac{[H^+]^2}{[H_2O]} \right). \quad (35)$$

The value of  $\varphi_{pb}$  can be estimated using the following relations:<sup>19</sup>

$$\begin{aligned} \varphi &= \varphi_{pb} + \Delta\varphi, \\ \Delta\varphi &= E\delta(\varphi), \\ E &= \frac{\varphi_p - \varphi_{pb}}{\delta_p}, \end{aligned} \quad (35a)$$

where  $\Delta\varphi$  and  $E$  are the potential drop and decrease in the electric field strength within the PL;  $\delta_p$  is the thickness of the PL at  $\varphi = \varphi_p$  (see Fig. 1).

The equation (35a) gives rise to

$$\varphi_{pb} = \frac{\varphi_a \delta_p - \varphi_p \delta_a}{\delta_p - \delta_a}, \quad (35b)$$

where  $\delta_a$  is the thickness of the PL in the beginning of the passive region.

Since the equilibrium interphase potential (35) is constant in the passive region  $\varphi_a \leq \varphi \leq \varphi_p$ , the thickness of the PL depends on  $\varphi$ . It can be determined using the Güntersulz formula for the current density of the  $M^{z+}$  ions through the interface M–O,

$$i_b = i_{b0} \exp(\beta E), \quad (36)$$

where

$$E = \frac{\varphi - \varphi_{pb}}{\delta(\varphi)},$$

$$\beta = \alpha_b a_M \frac{zF}{RT},$$

$\alpha_b$  is the transfer coefficient at the interface PL–metal, and  $a_M$  is the sublattice constant of the PL. In a steady-state mode, flows of the metal ions through the interfaces M–O and O–E are the same, *i.e.*,

$$i_a = i_b. \quad (37)$$

The equations (30), (36) and (37) give rise to

$$\delta(\varphi) = \beta \frac{\varphi - \varphi_{pb}}{\ln(i_a/i_{b0})}. \quad (38)$$

A surplus potential drop  $\Delta\varphi = \varphi - \varphi_{pb}$  is realised on a thickness  $\delta(\varphi)$ .

## 2. Ion transfer in the bulk of the passivating layer

When an  $M_{ox}^{z+}$  metal ion passes from the PL lattice to the electrolyte, its original bonds to the neighbouring  $O_{ox}^{2-}$  counterions are broken, and thus the oxide unit cell is destroyed. This gives rise to a gradual drift of the interface O–E towards metal in a steady-state mode. Simultaneously, the dynamical equilibrium (31) is realised and consequently the anion composition of the PL remains constant.

At the inner interface M–O, the  $O_{ox}^{2-}$  ions constantly diffuse into the metal structure forming new PL cells and compensating for their disappearance from the outer interface O–E. The diffusion rate is determined by the formula for the current density  $i_b$  of the  $M^{z+}$  ions [see formula (36)]. The emerging oxide cells replace the metal M, which means that the metal is converted layer-by-layer into oxide. A part of the  $M^{z+}$  metal ions located near the interface M–O are transferred through it to the PL and converted into the  $M_{ox}^{z+}$  ions, which further migrate *via* vacancies of the metal sublattice towards the electrolyte. As a result, the near-interface area of the metal is enriched with vacancies, which are required for diffusion of the  $O_{ox}^{2-}$  ions into the metal lattice.

These processes result in a drift of the interface M–O towards the metal. If a metal layer with a thickness of  $\Delta x$  disappears for a time  $\Delta t$ , the interface M–O also drifts by  $\Delta x$  at a velocity of

$$v = \frac{\Delta x}{\Delta t} = \frac{i_b}{z_M F} \frac{\mu}{\rho_0}, \quad (39)$$

where  $\mu$  and  $\rho_0$  are the amount (in moles) and density of the metal, respectively. The whole anionic composition of the PL, *i.e.*, its oxygen sublattice, drifts together with the interface.

Thus the  $M_{ox}^{z+}$  and  $O_{ox}^{2-}$  ions move in the bulk of the PL in the opposite directions. This provides self-consistency in the kinetic and structural interrelations between the interfaces O–E and M–O.<sup>37–43</sup> The ratio of the electrodiffusion flows of these ions is determined by the strengths of their interactions with the electrolyte and the metal.

Thus, the mutually compensating processes of the PL formation and disintegration proceed at the interfaces O–E and M–O in the steady-state mode. The thickness of the PL remains constant at a level sufficient to make a surplus potential drop

$\Delta\varphi = \varphi - \varphi_{pb}$ , where  $\varphi_{pb}$  is the potential of the interface O–E, which remains constant over the whole passive region. As a result, the current density  $i_a$  corresponding to the transfer of the  $M_{ox}^{z+}$  ions into the electrolyte is independent of the anode potential. The ion transfer through the bulk of the PL proceeds by the mechanism of electrodiffusion in a strong electric field (in strong electric fields, the Ohm law is violated), this results in a specific concentration distribution of the  $M_{ox}^{z+}$  and  $O_{ox}^{2-}$  ions and non-equilibrium vacancies over the PL lattice. The ions move *via* vacancies of their own sublattices, their occurrence in foreign sublattices can be considered as fluctuations, since the own sublattices provide sufficient amount of free sites. In this context, the anion and cation sublattices can be regarded as closed subsystems.

### a. Electric field in the passivating layer

Let us introduce the following notations  $N_M(x)$ ,  $N_O(x)$ ,  $N_{Mv}(x)$  and  $N_{Ov}(x)$  for the concentrations of the  $M_{ox}^{z+}$  and  $O_{ox}^{2-}$  ions and the non-equilibrium vacancies of the metal  $V_M(x)$  and oxygen  $V_O(x)$  in the respective sublattices of the PL, respectively, *i.e.*,

$$N_M = [M_{ox}^{z+}], \quad (40)$$

$$N_O = [O_{ox}^{2-}],$$

$$C_M(x) = \frac{N_{Mv}}{N_{Mg}}, \quad (40a)$$

$$C_O(x) = \frac{N_{Ov}}{N_{Og}},$$

where  $N_{Mg}$  and  $N_{Og}$  are the densities of the total number of sites in the cation and anion sublattices

$$N_{Mg} = N_M(x) + N_{Mv}(x), \quad (41)$$

$$N_{Og} = N_O(x) + N_{Ov}(x).$$

The bulk charge density  $\rho(x)$  in the PL can be represented as a sum of the ion and electron terms<sup>55–57</sup>

$$\rho(x) = \rho_i(x) + \rho_e(x),$$

where

$$\rho_i(x) = e[z_M N_M(x) - z_O N_O(x)],$$

$$\rho_e(x) = -e C_e(x),$$

$C_e(x)$  is the electron concentration in the PL. The electric field potential in a layer  $\varphi_1(x)$  is given by the Poisson equation

$$\frac{d^2 \varphi_1(x)}{dx^2} = -\frac{4\pi}{\varepsilon_1} \rho(x),$$

$$\varphi_1(A_1) = \varphi_{pb},$$

$$\varphi_1(A_2) = \varphi,$$

$$A_1 \leq x \leq A_2(\varphi),$$

$\varepsilon_1$  is the dielectric constant of the PL,  $A_1$  and  $A_2$  are coordinates of the interfaces O–E and M–O, respectively (see Fig. 2). A solution of the Poisson equation can be written as

$$\varphi_1(Z) = \varphi_{pb} + (\varphi - \varphi_{pb})Z + \Phi_0 Q_0(Z), \quad (41a)$$

where

$$Z = \frac{x - A_1}{\delta(\varphi)},$$

$$\delta(\varphi) = A_2(\varphi) - A_1,$$

$$0 \leq Z \leq 1,$$

$$\Phi_0 = \frac{4\pi F z_M}{\varepsilon_1} \left( \frac{N_{Mg}}{N_A} \right) \delta^2(\varphi),$$

( $N_A$  is the Avogadro number),

$$Q_0(Z) = \int_0^Z d\eta \int_0^\eta d\xi \bar{\rho}(\xi) - Z \int_0^1 d\eta \int_0^\eta d\xi \bar{\rho}(\xi), \quad (41b)$$

$$\bar{\rho}(Z) = n_M(Z) - n_O(Z) - n_e(Z),$$

$$n_M(Z) = \frac{N_M(Z)}{N_{Mg}},$$

$$n_O(Z) = \frac{N_O(Z)}{N_{Og}},$$

$$n_e(Z) = \frac{C_e(Z)}{z_M N_{Mg}}.$$

The parameter  $\Phi_0 \sim \delta^2(\varphi)$  is small and thus the last term in the equation (41a) can be neglected. In the physical sense, this is due to the fact that the field of the bulk charge in the PL is small as compared to the field induced by the interphase potential drop. Taking this into account, the electric field strength in the PL can be rewritten as

$$\vec{E} = -k_0 \left[ -\frac{\partial \varphi_1(Z)}{\partial x} \right],$$

and

$$\frac{\partial \varphi_1(Z)}{\partial x} \simeq \frac{\varphi - \varphi_{pb}}{\delta(\varphi)},$$

which is in agreement with the expressions (36) and (38).

#### b. Electrodiffusion of ions of the passivating layer in a strong electric field

The ion transfer in a PL is determined<sup>37, 55–59</sup> by the kinetics of the  $M_{ox}^{+}$  ions transfer into the electrolyte and diffusion of the  $O_{ox}^{2-}$  ions into the metal. Owing to the transfer, specific concentration distributions of the  $N_M(x, t)$  and  $N_O(x, t)$  ions (see Fig. 2) and  $N_{Mv}(x, t)$  and  $N_{Ov}(x, t)$  vacancies are settled, which depend on the anode potential  $\varphi$ . They characterise the concentration of point defects in the PL, i.e.,  $C_M$  and  $C_O$  [see relations (40a)].

The defectiveness determines the stability of the PL structure. If the critical value  $C_c$  is exceeded, the structure disintegrates. This is achieved at a potential  $\varphi_p$ , which corresponds to the transpassive transition (see Fig. 1). Theoretical estimation of the values of  $\varphi_p$  and  $\varphi_a$  is one of the most important problems.<sup>60–72</sup>

The expressions for the electrodiffusion flows  $j_M$  and  $j_O$  of the  $M_{ox}^{+}$  and  $O_{ox}^{2-}$  ions through the PL lattice assume a strong electric field  $E$ . The ions move *via* vacancies of their own sublattices. The sum of flows of ions  $j_M(x)$  and  $j_O(x)$  and non-equilibrium vacancies  $j_{Mv}(x)$  and  $j_{Ov}(x)$  is equal to zero

$$j_M(x) + j_{Mv}(x) = 0, \quad (42)$$

$$j_O(x) + j_{Ov}(x) = 0.$$

A microscopic-level scheme of ion hopping between the neighbouring atomic planes separated by interatomic distances  $a_M$  and  $a_O$  can be applied<sup>19, 37</sup> to determine  $j_M(x)$  and  $j_O(x)$ . Typically, three consecutive atomic planes I, II and III with coordinates  $x$  and  $x \pm a$  (Fig. 3) are considered within a PL lattice. The probabilities of direct and reverse ion jumps between them are proportional to the concentrations  $N_M(x)$  or  $N_O(x)$ , to the number of unoccupied sites in the respective planes [i.e., concentrations  $C_M(x)$  and  $C_O(x)$ ] and to the activation energy of the jumps  $W_0$ . An electric field  $E$  decreases the activation energy  $W_0$  by  $\pm azFaeE$  (or, on the contrary, increases, if an ion moves against the field direction).<sup>37</sup> Taking this into account, the required flows of cations  $j_M(x)$  and anions  $j_O(x)$  can be represented as sums of the flows corresponding to direct and reverse jumps

$$j_M(x) = j_{II \rightarrow III}^M - j_{III \rightarrow II}^M, \quad (43)$$

$$j_O(x) = j_{I \rightarrow II}^O - j_{II \rightarrow I}^O.$$

The equations for  $j_M$  and  $j_O$  can be rewritten explicitly

$$j_M = a_M v \left[ N_M(x) C_M(x + a_M) \exp\left(-\frac{W_{M0} + \Delta W_M}{kT}\right) - N_M(x + a_M) C_M(x) \exp\left(-\frac{W_{M0} - \Delta W_M}{kT}\right) \right], \quad (44)$$

$$j_O = a_O v \left[ N_O(x - a_O) C_O(x) \exp\left(-\frac{W_{O0} + \Delta W_O}{kT}\right) - N_O(x) C_O(x - a_O) \exp\left(-\frac{W_{O0} - \Delta W_O}{kT}\right) \right], \quad (44a)$$

where  $v$  is the number of vibrational periods of ions in occupied sites;  $\Delta W_M$  and  $\Delta W_O$  are the changes in the energy barriers for ion hopping between the planes I–III (see Fig. 3) when the electric field with a strength  $E$  is applied.

**Figure 3.** An arrangement of the atomic planes I–III in a passivating layer;

$a_M$  is the interatomic distance within the metallic sublattice ( $a_O$  is the respective distance within the oxygen sublattice).

By expanding the functions  $N_M(x \pm a_M)$ ,  $C_M(x \pm a_M)$ ,  $N_O(x \pm a_O)$  and  $C_O(x \pm a_O)$  into series and taking only linear terms, the following final expressions for  $j_M$ ,  $j_O$ , diffusion coefficients ( $D_M$  and  $D_O$ ),  $\Delta W_M$  and  $\Delta W_O$  can be obtained

$$j_M \simeq -\frac{D_M}{a_M} C_M N_M - D_M C_M \frac{\partial N_M}{\partial x}, \quad \frac{\partial N_M}{\partial x} > 0, \quad (45)$$

$$j_O \simeq \frac{D_O}{a_O} C_O N_{MO} - D_O C_O \frac{\partial N_O}{\partial x}, \quad \frac{\partial N_O}{\partial x} < 0, \quad (45a)$$

$$D_M = a_M^2 v \exp\left(-\frac{W_{M0} - \Delta W_M}{kT}\right),$$

$$D_O = a_O^2 v \exp\left(-\frac{W_{O0} - \Delta W_O}{kT}\right),$$

$$\Delta W_M = \alpha_M z_M a_M e E,$$

$$\Delta W_O = \alpha_O z_O a_O e E,$$

$$z_O = 2.$$

The flows of non-equilibrium vacancies can be determined using these equations together with the condition (42).

The concentrations  $N_M(x, t)$  and  $N_O(x, t)$  of the  $M_{ox}^{+}$  and  $O_{ox}^{2-}$  ions contained in the formulas (45) are determined by equations of their hopping migration

$$\frac{\partial N_M}{\partial t} = -\frac{\partial j_M}{\partial x}, \quad (46)$$

$$\frac{\partial N_O}{\partial t} = -\frac{\partial j_O}{\partial x},$$

$$\Delta_1(t) \leq x \leq \Delta_2(t),$$

$$\Delta_2(t, \varphi) - \Delta_1(t) = \delta(t, \varphi).$$

The concentrations of the  $M_{ox}^{z+}$  and  $O_{ox}^{2-}$  ions at the interfaces M–O and O–E are equal to  $N_{M2} \equiv N_M(\delta)$  and  $N_{O1} \equiv N_O(0)$ , respectively, whereas the concentrations of their vacancies  $N_{Mv2}$  and  $N_{Ov1}$  at the same interfaces are interrelated through the following expressions

$$N_{M2} = N_{M0} - N_{Mv2},$$

$$N_{O1} = N_{O0} - N_{Ov1}.$$

The interface M–O serves as a source of the  $M_{ox}^{z+}$  ions and a sink of the cation vacancies. Similarly, the interface O–E serves as a source of the  $O_{ox}^{2-}$  ions and a sink of the anion vacancies. Therefore,

$$N_{Mv2} \ll N_{M2} \simeq N_{M0},$$

$$N_{Ov1} \ll N_{O1} \simeq N_{O0}.$$

For a steady-state mode, the system of equations (44)–(46) can be reduced to two equations for concentrations of non-equilibrium cation and anion vacancies  $C_M(x)$  and  $C_O(x)$  within the respective sublattices of the PL [ $0 \leq x \leq \delta(\varphi)$ ]<sup>19</sup>

$$\frac{D_M}{a_M} C_M(1 - C_M) - D_M C_M \frac{dC_M}{dx} + v(1 - C_M) = v \frac{N_{met}}{N_{M0}}, \quad (47)$$

$$-\frac{D_O}{a_O} C_O(1 - C_O) - D_O C_O \frac{dC_O}{dx} + v(1 - C_O) = 0,$$

$$C_M(0) \equiv C_{M1}, \quad C_M(\delta) \equiv C_{M2} \sim 0,$$

$$C_O(0) \equiv C_{O1} \simeq 0, \quad C_O(\delta) \equiv C_{O2},$$

where  $v$  is the velocity of the interface M–O drift,  $N_{met}$  is the concentration of occupied sites in the metal lattice.

These vacancies induce an electrical charge and strains in the PL structure and determine its point defectiveness, which in turn determines the dimension of the passive region, *i.e.*, the value of the anode potential  $\varphi = \varphi_p$ .

Actually, the point defectiveness of a PL cannot exceed a certain threshold depending on the strength of the PL ionic structure. Thus, there is a critical, *i.e.*, the maximum possible value  $C_c = (C_M)_{max}$  of the concentration  $C_M(x)$ . When the critical concentration is exceeded, the dependence of the thickness of the passivating layer on the anode potential [see equation (38)] is violated, which actuates the transpassive transition (transpassivation) observed at  $\varphi = \varphi_p$ . The theoretical prediction of  $\varphi_p$  as a function of the characteristic parameters of a passivating system is a key challenge to a passivation theory.

The critical defectiveness is reached at  $\varphi = \varphi_p$  at the interface O–E since it serves as a source of vacancies of the cation sublattice. In order to find  $\varphi_p$ , one can determine the functions  $C_M(x)$  and  $C_O(x)$  from the equation (47) and then set  $C_{M1} = C_M(0)$ . Additionally, it should be taken into account that  $C_M(x) \ll 1$ ,  $C_O(x) \ll 1$ . In this case,

$$\int_0^\delta C_M(x) dx + \frac{a_M}{2} C_{M1}^2 \simeq v \frac{a_M \delta}{D_M} \left( \frac{N_{met}}{N_{M0}} - 1 \right), \quad (48)$$

$$\int_0^\delta C_O(x) dx + \frac{a_O}{2} C_{O2}^2 \simeq v \frac{a_O \delta}{D_O}.$$

An approximate solution of the first equation gives

$$2 C_{M1} + C_{M1}^2 - 2q\delta = 0,$$

where

$$q = \frac{v}{D_M} \left( \frac{N_{met}}{N_{M0}} - 1 \right).$$

For instance, in the case of a system Fe in 1 M  $H_2SO_4$  (see Refs 73 and 74), which is characterised by the following parameters  $D_M \simeq 0.5 \times 10^{-16} \text{ cm}^2 \text{ s}^{-1}$ ,  $z_M \simeq 3$ ,  $\alpha_M \simeq 0.5$ ,  $i_b \simeq 10^{-6} \text{ A cm}^{-2} \text{ s}^{-1}$ ,  $\delta \sim 10^{-7} \text{ cm}$ , the equation is transformed into

$$C_{M1} = q\delta(\varphi). \quad (49)$$

### c. Transpassive transition

The equation (49) implies that the maximum possible defectiveness  $C_c$  corresponds to the ultimate thickness of the passivating layer  $\delta_p$  exactly at the potential of the transpassive transition  $\varphi_p$

$$\delta_p = \frac{C_c}{q}. \quad (50)$$

A study of the stability of a lattice with respect to its point defectiveness for the case of a cubic packing of black and white balls has established that  $C_c \simeq 0.2$ , since the long-range order disappears at  $C > 0.2$ .<sup>75</sup>

An expression for the required  $\varphi_p$  can be obtained from the equations (50), (36) and (38). Indeed, the value of the anode potential corresponding to the oxygen equilibrium  $\varphi_{pb}$ , which is contained in the equation (38), can be estimated using the equation (35b). This gives rise to

$$\varphi_p = \varphi_{pb} + \frac{\delta_p}{\beta} \ln \left( \frac{i_a}{i_{b0}} \right), \quad (51)$$

$$\beta = \alpha_b a_M \frac{zF}{RT},$$

$\delta_a$  is the thickness of the PL in the beginning of the passive region ( $\varphi = \varphi_a$ ), where the PL can be regarded as a monolayer.

Thus, the equations (51), (35b) and (50) comprise a system of three equations with three unknowns, *viz.*,  $\varphi_p$ ,  $\varphi_{pb}$  and  $\delta_p$ . Solving this system, for instance, for M = Fe, yields:  $\varphi_{pb} \simeq 0.4 \text{ V}$ ,  $\varphi_p \simeq 1.6 \text{ V}$ ,  $\delta_p \simeq 2 \times 10^{-7} \text{ cm}$ , which is in agreement with the experimental data.<sup>26</sup>

## 3. The interface metal–oxide

### a. Interphase reactions

As has been shown above, the incorporation of near-boundary  $O_{ox}^{2-}$  ions belonging to the anion sublattice of the PL into the metal is the main process proceeding at the interface M–O. The anions react with the  $M^{z+}$  cations forming new unit cells of the passivating oxide  $M_n O_m$  and giving rise to a drift of the interface M–O at a velocity  $v$  [see equation (39)].

To form a new cell, an  $O_{ox}^{2-}$  ion should pass an interatomic distance  $a_O$  typical of the anion sublattice structure and cross the interface M–O, so that a potential drop  $\Delta\varphi = a_O E$  is overcome. The electric field  $E$  decreases the transition barrier by  $\Delta U = \alpha_O z_O a_O e E$ .

The probability of oxygen incorporation is proportional to the number of unoccupied sites in the near-boundary layer of the metal  $\Delta M$ , which is equivalent to the concentration  $C_{met}$  of vacancies in the lattice  $\Delta M$ . The respective current density of incorporation  $i_{b0}$  is ( $m/n = z/2$ )

$$i_{b0} = i_{b0}^0 C_{met}^{z/2} \frac{N_{O2}}{N_{Og}} f(U) \exp(\beta_O E), \quad (52)$$

$$\beta_O = \alpha_O z_O a_O \frac{F}{RT},$$

$$E = \frac{\varphi - \varphi_{pb}}{\delta(\varphi)},$$

$$C_{\text{met}} = \frac{N_{\text{vmet}}}{N_{\text{g}}},$$

$$N_{\text{g}} = N_{\text{met}} + N_{\text{vmet}},$$

where, as before,  $N_{\text{O}_2^-}$  is the concentration of the  $\text{O}_{\text{ox}}^{2-}$  ions at the interface M–O;  $N_{\text{met}}$ ,  $N_{\text{vmet}}$  and  $N_{\text{g}}$  are the concentrations of metal atoms and vacant sites in the metal lattice and their sum, respectively. The transfer coefficient  $\alpha_{\text{O}}$  characterises the asymmetry of the energy barrier  $\Delta U$ ;  $f(U)$  is the term describing the ordering process within  $\Delta M$ .

Due to conversion of the metal into the oxide, an oxide layer with a thickness  $\Delta_{\text{ox}}$  and a number of the  $\text{M}_{\text{ox}}^{z+}$  cations  $\Delta N_1$  appears in place of the starting boundary layer  $\Delta M$  with a number of metal atoms  $\Delta N$ . In general, thicknesses of the layers  $\Delta M$  and  $\Delta_{\text{ox}}$  are different. As has been mentioned above, the spatial balance is kept due to the subsystem of vacancies.<sup>19</sup>

Evidently,  $\Delta N_1 < \Delta N$ . Consequently, only a part of ions from  $\Delta N$  is involved in the formation of oxide in the layer  $\Delta_{\text{ox}}$ . The remaining part  $\Delta N_2 = \Delta N - \Delta N_1$  is surplus and should move away through the interface M–O into the PL and further to the electrolyte. This is the only way to keep the spatial balance in the layer  $\Delta M$ . Meanwhile, the continuous transfer of the  $\text{M}_{\text{ox}}^{z+}$  ions should proceed in the PL by the mechanism of hopping migration in a strong electric field, as discussed above.

Consequently, the total current  $i_{\text{b}}$  of the metal disintegration (or anode dissolution) specified in the formula (36) can be subdivided into the current of the  $\text{M}_{\text{ox}}^{z+}$  ion transfer through the PL  $i_{\text{bM}}$  and the current  $i_{\omega}$  corresponding to the formation of oxide cells within the layer  $\Delta M$ . The latter is determined by the number of bonds between the  $\text{M}^{z+}$  ions and incorporated oxide ions formed per second in the layer  $\Delta M$ , which generate  $\omega$  new cells in each unit volume, *i.e.*,

$$\Delta N_1 + \Delta N_2 = \Delta N, \quad (53)$$

$$i_{\text{bM}} + i_{\omega} = i_{\text{b}},$$

for meaning of  $i_{\text{b}}$ , see the formula (36).

The formation mechanism of new cells  $\text{M}_n\text{O}_m$  based on the vacancy model of the interphase processes has been considered elsewhere.<sup>19,37</sup> To form a cell,  $m \text{O}_{\text{ox}}^{2-}$  ions should diffuse from the PL to the layer  $\Delta M$  leaving  $m$  anion vacancies in the PL layer. This requires availability of  $m$  vacant sites  $V_{\text{M}}$  within the lattice  $\Delta M$ , which can be generated only as a result of preceding transition of  $m$  out of  $\Delta N_2$  ions  $\text{M}^{z+}$  into the PL. These incoming ions occupy  $m$  cation vacancies within the cation sublattice of the PL (which are in turn transferred from the interface O–E by the flow of vacancies) and move towards the electrolyte. The flows of vacancies  $j_{\text{Mv}}$  and  $j_{\text{Ov}}$  are generated due to the hopping migration of the  $\text{M}_{\text{ox}}^{z+}$  and  $\text{O}_{\text{ox}}^{2-}$  ions in the opposite directions within the PL.

Thus, the formation of an oxide cell  $\text{M}_n\text{O}_m$  is described by a scheme involving several steps. In the first step,  $m \text{M}^{z+}$  ions pass from the metal lattice to the PL being converted into  $\text{M}_{\text{ox}}^{z+}$  ions and leaving  $m$  vacancies  $V_{\text{M}}$  in originally occupied sites, which can be written as

The vacancies  $V_{\text{M0}}$  appear at the interface M–O owing to their hopping migration from the source, *viz.*, the external interface O–E. New  $\text{M}_{\text{ox}}^{z+}$  ions migrate in the opposite directions, *i.e.*, towards the interface O–E, which serves as their sink.

In the second step,  $m \text{O}_{\text{ox}}^{2-}$  ions are incorporated into the metal, occupy vacancies  $V_{\text{M}}$  and are converted into the  $(\text{O}_{\text{ox}}^{2-})_{\text{M}}$  ions of the transition layer  $\Delta M$ , which can be represented as

Vacancies  $V_{\text{O0}}$  are generated in the formerly occupied sites and then migrate towards the interface O–E.

In the third step, the ions within  $\Delta M$  undergo structural ordering, which results in the formation of an oxide cell  $\text{M}_n\text{O}_m$ , *i.e.*,

This process is quantified by the term  $f(U)$  in the equation (52). The overall process including the steps (54) and (56) can be written as

The above scheme implies that the conversion of vacancies and of their flows occurs at the interface M–O (Fig. 4), *viz.*,

$$V_{\text{M0}} \longrightarrow V_{\text{M}} \longrightarrow V_{\text{O0}},$$

$$j_{\text{Mv}} \longrightarrow j_{\text{Ov}},$$

so that the vacancies  $V_{\text{M}}$  act as mediators combining the processes (54) and (56).

**Figure 4.** A scheme of concentration distributions of non-equilibrium vacancies in the cationic (1) and anionic (2) sublattices of a passivating layer.

## b. Current densities

According to the equation (52), the total current density of the metal anode dissolution can be represented as a sum of two terms. The first term is the current density  $i_{\text{bM}}$  corresponding to the transition of the  $\text{M}^{z+}$  ions from  $\Delta M$  to the PL, which gives rise to the generation of vacancies  $V_{\text{M}}$  within the layer  $\Delta M$  with the concentration  $C_{\text{met}}$ . The second term is the current density  $i_{\omega}$  corresponding to the formation of cells of  $\text{M}_n\text{O}_m$  in the layer  $\Delta M$  owing to the incorporation of the  $\text{O}_{\text{ox}}^{2-}$  ions at a velocity  $i_{\text{bO}}$ .

The parameters  $i_{\text{b}}$ ,  $i_{\text{bM}}$ ,  $i_{\text{bO}}$  and  $i_{\omega}$  are linked through a self-consistent relation<sup>19–25</sup> imposed by the reactions (54) and (55). Indeed, currents of these reactions are equal, since they represent currents of the formation of the vacancies  $V_{\text{M}}$  and simultaneously of their filling with the  $\text{O}_{\text{ox}}^{2-}$  ions, therefore, in a steady-state mode,

$$i_{\text{bM}} = i_{\text{bO}}. \quad (57)$$

If  $\omega$  oxide cells  $\text{M}_n\text{O}_m$  are formed in the unit volume of  $\Delta M$  per second, this consumes  $n\omega \text{M}^{z+}$  and  $m\omega \text{O}_{\text{ox}}^{2-}$  ions, which means that

$$i_{\omega} = n\omega ze, \quad (58)$$

$$z \equiv z_{\text{M}},$$

$$i_{\text{bO}} = m\omega 2e.$$

The required relation can now be derived from the equations (53), (57) and (58)

$$\begin{aligned}
i_w &= \frac{n}{\gamma m} i_{bO}, \\
i_{bO} &= i_{bM}, \\
i_b &= i_w + i_{bM} = \left( \frac{\gamma m + n}{\gamma m} \right) i_{bO}, \\
\gamma &= \frac{2}{z}, \\
i_{bO} &= i_{bO}^0 C_{\text{met}}^{z/2} \frac{N_{O_2}}{N_{O_0}} f(U) \exp(\beta_O E), \\
C_{\text{met}} &= \left\{ \frac{i_{bO} \exp[(\beta - \beta_O)E]}{i_{bO}^0 [(\gamma m + n)/\gamma m] (N_{O_2}/N_{O_0}) f(U)} \right\}^{2/z}.
\end{aligned}$$

This makes it possible to calculate the number of oxide cells  $M_nO_m$  appearing per second per  $\text{cm}^2$  of the interface  $M-O$

$$\omega = \frac{i_w}{n z e} = \frac{i_b}{(n + \gamma m) z e}.$$

For an oxide  $M_2O_3$ ,  $n = 2$  and  $m = 3$ .

The above mathematical approach is applicable to such metals as Fe, Ni, Cr, Mo, Cu, *etc.* Passivating layers on their surfaces are crystalline. In the case of the so-called valve metals (Ta, Ti, Al, Sn, Sb, *etc.*), the PL are characterised by amorphous structures. To allow for this, a statistical scatter in the interatomic distances and angular directions has to be taken into consideration. In such a case, coefficients in the transfer equations will be random quantities and the equations themselves will be stochastic.

The ion transfer also referred to as electrodiffusion, or hopping migration, plays an important role in the functioning mechanism of an oxide PL. It can be formulated as follows.

1. Ion flows provide kinetic and structural interrelations between the interfaces and enable occurrence of electrochemical reactions on them. This retains the ionic sublattices of the PL and ensures its stability.

2. Ion flows govern the growth of the layer  $\delta(\varphi)$  thickness. At any potential  $\varphi$ , a specific surplus potential  $\varphi - \varphi_{pb}$  is consumed so that the partial interphase equilibrium metal–electrolyte is maintained.

3. The concentration of vacancies increases with an increase in the thickness  $\delta(\varphi)$  and reaches its critical value  $C_c$  inducing the transpassive transition at  $\varphi = \varphi_p$ . Therefore, the ion transfer determines the extension of the passive region.

4. Ion transfer generates a subsystem of non-equilibrium vacancies, which maintains the spatial balance at the interface  $M-O$ .

In the case of metal alloys, which are the main engineering materials, the passivation process is more complicated. First, a border layer of the alloy appears, which is characterised by modified physical properties. Second, passivating oxide layer formed on the alloy surface contains at least three (in the case of a simple binary A–B alloy) rather than two components. An attempt to develop a theory for such a system has been undertaken<sup>19</sup> but the goal is still far from reach.

Unfortunately, outdated concepts are still employed in the studies devoted to the mechanisms of the electrode processes. The electrode surface is represented as an array of distributed microelectrodes forming galvanic pairs anode–cathode. Within this approach, fictitious electric circuits composed of a small group of atoms are considered and characterised with parameters applicable to macrocircuits, such as resistivity, current and so on.

#### IV. Other models of the passive state of metals

The mathematical model of passivating layers outlined above is based on the general thermodynamical principle stating that a stable passive state of a metal surface is only possible provided

that conditions of the interphase equilibrium between the passivating layer and the electrolyte are met. According to extensive investigations accomplished by the electrochemists of the German school,<sup>26–34</sup> this equilibrium is established due to the reaction

*i.e.*, due to the exchange of the oxide ions (that are formed upon dissociative adsorption of water) between water and the oxide sublattice of the PL. Transfer of the  $M_{ox}^{z+}$  ions from the metal sublattice is continuously compensated for by their supply from the metal substrate. The self-consistency of all the processes is determined by the value of the equilibrium interphase potential  $\varphi_{pb}$ . The following two equations

$$\begin{aligned}
\vec{k} [H_2O] \exp\left(\alpha_O z_{rmo} F \frac{\varphi_{pb}}{kT}\right) - \overleftarrow{k} [H^+]^2 \exp\left(-\beta_O z_O F \frac{\varphi_{pb}}{kT}\right) &= 0, \\
\alpha_O + \beta_O &= 1
\end{aligned}$$

express the equality of the total numbers of the direct and reverse reaction events (59) occurring at a unit surface for 1 s. The self-consistency of the processes can be explained by the stability of anodically dissolvable (*i.e.*, thermodynamically non-equilibrium, in overall) oxide.

Attempts have been undertaken<sup>60–67</sup> to rationalise functioning of a PL in a different way assuming no interphase equilibrium. A few of them are briefly considered below. A mathematical model referred to as ‘self-adjusting dissolution of a passivated metal’<sup>63</sup> assumes simultaneous consistent changes in the anode potential  $\varphi$ , dissolution current density  $i$  and thickness of the passivating layer  $\delta(\varphi)$ .

The model is supposed to explain the independence of the stationary current density of the anode potential. It postulates that a PL and a double electrical layer (DEL) can be considered as series capacitors. In that case, the potential drops in the layer and DEL are inversely proportional to their capacities  $C_f$  and  $C_d$ , respectively,

$$\frac{\varphi - \varphi_b - \varphi_{12}}{\varphi_b} = \frac{C_d}{C_f}. \quad (60)$$

Here,  $\varphi_b$  is the DEL potential and  $\varphi_{12}$  is a suggested potential drop at the interface with the metal. The postulated inverse proportionality substitutes the condition of Vetter’s partial oxygen equilibrium (59). Another assumption is that the PL is dissolved according to the equation

and is formed at the opposite interface

The rates of these reactions are described by the following expressions

$$i_1 = K_1 \exp\left[\frac{\alpha_1(n - z)F}{RT} \varphi_b\right], \quad (63)$$

$$i_2 = K_2 \exp\left(\frac{\alpha_O z_O F}{RT} aE\right),$$

where subscripts 1 and 2 denote the interfaces PL–electrolyte and PL–metal, respectively;  $a$  is the interatomic distance. It is also assumed that the reactions

are compatible provided that the exchange current of the first reaction exceeds substantially that of the second one.

This condition can be considered as unrealisable since the corrosion potential of a passivated metal sometimes manifests

sensitivity to the currents at levels comparable to the rate of corrosion and it is the equilibrium that adjusts itself to the potential  $\phi_b$  rather than *vice versa*.<sup>63</sup> It is also presumed that

$$C_f = \frac{\varepsilon_f}{\delta(\phi)},$$

$$C_d = \frac{\varepsilon_d}{\delta_d},$$

where  $\varepsilon_f$ ,  $\varepsilon_d$ ,  $\delta(\phi)$  and  $\delta_d$  are dielectric constants and thicknesses of the PL and DEL, respectively. Taking into account the above assumptions, the equation (60) is transformed into

$$\frac{\phi - \phi_b - \phi_{12}}{\phi_b} = \frac{\varepsilon_f}{\varepsilon_d} \frac{\delta(\phi)}{\delta_d}, \quad (64)$$

and the following equation is postulated for the film thickness

$$\delta(\phi) = \frac{\phi - \phi_{12} - \phi_b}{E}.$$

The system composed of the last two equations contains three unknowns, *viz.*,  $\delta(\phi)$ ,  $E$  and  $\phi_b$  at a fixed  $\phi_{12}$ . The equality of the steady-state rates of dissolution [see equation (63)] and formation of the passivating layer [see (61) and (62)] can be used as the third equation, *i.e.*,

$$i_1 = K_1 \exp\left[\frac{\alpha_1(n-z)F}{RT} \phi_b\right] = K_2 \exp\left(\frac{\alpha_O z_O F}{RT} aE\right) = i_2.$$

This gives rise to

$$\phi_b = \frac{RT}{\alpha_1(n-z)F} \ln\left(\frac{K_2}{K_1}\right) + \frac{\alpha_O z_O}{\alpha_1(n-z)} aE. \quad (65)$$

The system (60)–(65) is now closed with respect to the unknowns  $\phi_b$ ,  $E$  and  $\delta(\phi)$  provided that the value of  $\phi_{12}$  is known. After a few simplifying assumptions, these equations can be transformed into

$$\phi_b = \frac{RT}{F\alpha_O z_O} \ln\left(\frac{K_2}{K_1}\right) \left[ \frac{\varepsilon_d a}{\varepsilon_f \delta_d} - \frac{\alpha_2(n-z)}{\alpha_O z_O} \right]^{-1},$$

$$E = \frac{RT}{F\alpha_O z_O} \ln\left(\frac{K_2}{K_1}\right) \left\{ \frac{\varepsilon_d}{\varepsilon_f} \delta_d \left[ \frac{\varepsilon_d a}{\varepsilon_f \delta_d} - \frac{\alpha_2(n-z)}{\alpha_O z_O} \right]^{-1} \right\}.$$

The last two formulas are final since they are no more dependent on the potential drop  $\phi_{12}$ . Also note that the following expressions can be written instead of the equation (64)

$$\frac{\phi_p}{\phi_d} = \frac{Q_s}{Q_d} \frac{c_d}{c_p},$$

$$Q_s \neq Q_d,$$

$$Q_s + Q_d + Q_M = 0,$$

where  $\phi_d$  is the DEL potential,  $Q_s$  is the solution charge,  $Q_d$  is the DEL charge,  $c_d$  is the DEL capacity,  $c_p$  is the PL capacity,  $Q_M$  is the metal charge.

Other models do not require fulfilment of the condition of the interphase equilibrium between the passivated metal and water molecules of a solvent as regards oxygen ions. In the model proposed by Alekseev and Kolotykin,<sup>66</sup> no diffusion is considered and the current is assumed to be due to the migration of ions in a constant electric field. Respectively, the concentrations of ionic components in sublattices of the PL are independent of coordinates and identical at both interfaces. The neglect of diffusion decreases the order of the ion transfer equations; interfaces and the transpassive transition are described by the integration limits.

The above considerations support Vetter's suggestion<sup>26</sup> that the stability of a passivating layer is caused by the equilibrium exchange of oxygen ions between the PL anionic sublattice and the electrolyte. The existence of the metal sublattice of the PL is provided by a steady-state supply of the  $M^{z+}$  ions from the metal through the PL to the interface with the electrolyte. This compensates for continuous transfer of the  $M^{z+}$  ions into the electrolyte. Thus, the cation composition of a PL is continuously renewed, whereas the anion composition remains constant but constantly drifts following the dissolving metal surface. The oxygen equilibrium according to Vetter (32) coincides with the condition of the thermodynamical phase equilibrium.<sup>70–72</sup>

Admitting the fundamental character of studies performed by representatives of the German school of electrochemists, it however was noted that their suggestions on the chemical mechanism of dissolution of a passivated metal are erroneous. Actually, the mechanism is electrochemical in character, as has been demonstrated by Novakovsky and Likachev.<sup>68,69</sup> Therefore, it might be concluded that the experimental fundamentals of the passivity theory are laid by the combination of the two works cited above.<sup>26,68</sup>

## V. The adsorption and phase-film theories of passivity

The current understanding of the passive state of metals has been evolving over the entire time of its investigation. Originally, the adsorption and phase-film theories of passivity were widely adopted. Their experimental backgrounds have been summarised elsewhere.<sup>73–76</sup> The major postulates of the theories can be formulated as follows.

A general assumption that the passivation is caused by the interaction of the surface metal atoms with the oxygen of the adsorbed water molecules underlies the adsorption theory. This is based on the experimental data from polarisation measurements combined with dedicated studies of adsorption phenomena. It has been established that the current density of the anodic dissolution decreases manyfold when a small amount of oxygen ions forming only a fraction of an oxygen submonolayer is adsorbed.

The following adsorption schemes were considered in order to rationalise this experimental fact

$$(1 - \Theta)K_{ad} = \Theta K_i, \quad (66)$$

where

$$K_{ad} \sim \exp(\alpha_a \sigma \varepsilon),$$

$$K_i \sim [\beta_i(z_M - \sigma)\varepsilon],$$

$$\varepsilon = \frac{F\phi}{RT},$$

$$i_a = \Theta K_i,$$

$\Theta$  is the coverage of the metal surface with adsorption complexes formed as a result of the interaction between the surface metal atoms and the oxygen atoms of water molecules;  $K_{ad}$  is the rate of formation of these complexes;  $K_i$  is the rate of transfer of the complexes to the solution;  $\varepsilon$  is a dimensionless potential;  $\sigma$  is the fraction of partially transferred charge;  $i_a$  is the transition current density. The equation (66) gives rise to

$$i_a = \frac{K_{ad} K_i}{K_{ad} + K_i}. \quad (67)$$

This equation clearly shows that the equation (66) cannot reproduce the shape of the polarisation curve shown in Fig. 1 for any possible combination of  $K_{ad}$  and  $K_i$ . Indeed, only three cases are possible.

1.  $K_{ad} \sim K_i$ ; the rates of formation and dissolution of the complexes are similar; consequently,  $i_a \approx K_i$  or  $i_a \approx K_{ad}$ ; the dissolution current increases exponentially with an increase in

the potential so that no active – passive and passive transitions can be identified in the polarisation curve.

2.  $K_{ad} \gg K_i$ ; the dissolution step is rate-limiting. In this case, the dependence of the dissolution current on the potential is the same as above.

3.  $K_{ad} \ll K_i$ ; the adsorption step is rate-limiting and  $i_a \sim K_{ad}$ ; the situation remains the same: no passivity region can be identified.

The conclusion on the impossibility of identification of an extended passivity region in the polarisation curve based on the equation (66) directly follows from the equation (67). Since the passivity region is characterised by  $i_a = \text{const}$ , the equation (67) can be represented in an algebraic form with respect to the potential  $\varphi$

$$\frac{K_{ad}(\varphi)K_i(\varphi)}{K_{ad}(\varphi) + K_i(\varphi)} = \text{const}, \quad (68)$$

the equality condition is met only for one or a few values of  $\varphi$ , which correspond to the roots of the equation. In other words, no extended passivity region is possible.

Sukhotin suggested<sup>76</sup> a modification of the passivity theory by complicating the adsorption scheme through inclusion of several interaction steps of metal atoms with water molecules. Each step gives rise to its own coverage  $\Theta_k$  of the surface with oxygen-containing complexes, such as  $[\text{MOH}]_{ad}$ ,  $[\text{M}(\text{OH})_2]_{ad}$ ,  $[\text{M}(\text{OH})_3]_{ad}$  and  $[\text{MO}]_{ad}$ . Consequently, the partial currents corresponding to individual steps are  $i_k = \Theta_k K_{i,k}$ , the total coverage  $\Theta$  and the total dissolution current  $i_a$  can be represented as

$$\Theta = \sum_k \Theta_k,$$

$$i_a = \sum_k \Theta_k K_{i,k}.$$

The kinetics of each  $k$ th steps is determined by its parameters  $\alpha_k$ ,  $\beta_k$ ,  $K_{ad,k}$  and  $K_{i,k}$ . The total number of such steps is large. The theoretical results are to be reconciled with the experimental data by a proper selection of the steps. Nevertheless, despite the use of numerous free variables, discrepancies remain significant,<sup>76</sup> which indicates inadequacy of the adsorption model of passivity. Probably, the substantial deceleration of anodic dissolution by a small amount of preadsorbed oxygen relates to the repulsive interactions between the adsorbed ions. Their mutual influence impedes adsorption on the adjacent neighbouring sites giving rise to a specific dead zone around each adsorbed ion. Taking this into account,<sup>19</sup>

$$K_{ad} \sim \exp(-f_a \Theta) \exp(\alpha_a \sigma \varepsilon),$$

$$K_i \sim \exp(f_i \Theta) \exp[\beta_i (z_M - \sigma) \varepsilon],$$

where  $f_a$  and  $f_i$  are constants. These expressions also describe blockage of the active sites on an energetically heterogeneous metal surface, which is a reason for deceleration of the anodic dissolution.

No doubt, the adsorption from solution always represents the first step of formation of a passivating oxygen layer on a metal surface. However, as has been mentioned above, the presence of an oxygen ad-layer is not sufficient to explain all the regions observed in polarisation curves (in particular, the transpassive transition and a finite dimension of the passive region, which is characterised by the independence of the current of a passivated metal dissolution on the potential). Therefore, additional steps of the mechanism of formation of a passivating system have to be considered. The fact of formation of oxide layers with finite thicknesses, which corresponds to the equilibrium oxide – electrolyte, also support the above requirement.

The evolution of concepts concerning oxygen-induced passivation has resulted in the emergence of a phase-film theory of oxide passivity. This theory postulates<sup>26,76</sup> the existence of a

thermodynamically stable oxide layer (unlike that described above) on the surface of hard metals, which is observed at anode potentials  $\varphi > \varphi_a$ . This layer is referred to as a ‘film’. Its structure corresponds to stoichiometry  $M_nO_m$ . In the case of valve metals, the film is structurally disordered and can be substantially thicker. Within this theory, the passivation is explained by a mechanical shielding of the metal surface by the phase oxide. The independence of the passive current of the anode potential seems to be attributed to the chemical dissolution of the oxide layer. The potential corresponding to the beginning of the passive region  $\varphi_a$  (see Fig. 1) is interpreted as a potential of formation of the equilibrium oxide.

The postulate on the chemical mechanism of dissolution of the passivating oxide adopted in the phase-film theory is not supported by experimental data.<sup>68</sup> Typically, the potential of the beginning of the passive region  $\varphi_a$  differs from the potential of formation of the equilibrium oxide. For instance, this discrepancy is as large as 0.63 V in the case of iron.<sup>26,76</sup> Neither the experimentally observed dependences of  $\varphi_a$  on the surface properties of the metal (e.g., its cleanliness<sup>70</sup>), nor the solution composition and other factors can be explained within this theory.

The passivity theories that were developed later still relied on the assumption that the passivation was achieved due to the interaction of the metal surface with oxygen produced by dissociation of adsorbed water molecules. Presumably, the  $\text{O}^{2-}$  ions interact with the surface metal atoms forming the topmost ordered monolayer of oxide  $M_nO_m$ . This assumption is in agreement with the general theory of heterogeneous formation of a crystal phase through the generation of its two-dimensional nuclei or their stacks. Evidently, kinetics of such a process differs from that of a simple adsorption. In particular, the probability of generation of a two-dimensional nucleus manifests a stronger dependence on the interphase potential drop [see formula (13)].

In the course of growth, further oxide layers are formed atop the first structured monolayer. The increase in the thickness of the layer is caused, first, by too high an electrodiffusion current of the metal ions through the oxide layer to the interface O – E and, second, by too low a surplus potential expended for the current passage through the interface

$$\Delta\varphi = \varphi - \varphi_b.$$

Therefore, the dissociation of water molecules (the donor of the  $\text{O}^{2-}$  ions) is too intense. Due to an excess of the reactants, i.e.,  $\text{O}^{2-}$  and  $\text{M}^{z+}$  ions, new oxide cells are formed, the thickness of the layer increases and, respectively, the potential  $\varphi_b$  decreases.

This process ceases when the potential  $\varphi_b$  decreases to the level corresponding to the equilibrium between the PL and the electrolyte due to thickening of the PL. This means that a steady-state mode of the anodic dissolution of passivated metal is settled. Since then, new cells of oxide  $M_nO_m$  are formed only on the inner interface, where the oxide ions are incorporated into the metal. This process compensates for the disappearance of cells at the interface O – E. Only anionic sublattice of oxide  $M_nO_m$  is in equilibrium with the electrolyte. Between the two interfaces, oppositely directed electrodiffusion flows of the metal and oxide ions are established. Therefore, a stationary passivating layer, overall, is non-equilibrium. The interphase potential drop is

$$\Delta\varphi = \varphi - \varphi_{pb},$$

$$\varphi_b = \varphi_{pb},$$

$$\delta = \delta(\varphi),$$

where  $\varphi_{pb}$  corresponds to the Vetter potential<sup>26,27</sup> and  $\delta(\varphi)$  is the stationary thickness of the PL dependent on  $\varphi$ . Due to changes in  $\delta(\varphi)$ , the structure of the PL and processes proceeding in it adjust themselves to conditions of the thermodynamical equilibrium with the electrolyte at every value of  $\varphi$ . In contrast to this, the adsorption theory of oxygen passivation assumes that the oxide coverage remains monolayer at all values of  $\varphi$  and only the dependence of  $\varphi$  on the adsorption coverage of the metal surface

with oxide ions is considered. In other words, growth of the passivating layer is admitted only along this surface.

The oxygen-adsorption and phase-film theories can be considered as particular cases of the formation and functioning of an passivating oxide system (see Sections II and III of the present review).

It is known that a metal can be protected by inhibition of its surface with certain chemicals. The initial stage of this process also includes adsorption from solution, which plays the major role in the mechanism of formation of inhibiting coatings.<sup>77–79</sup> Several authors suggested<sup>80–84</sup> that the inhibition mechanism relates to a change in the rate of the electrode reactions involving organic compounds. This can be due to redistribution of charges over the double electric layer.

The development of mixtures of adsorption inhibitors that provide more efficient protection than any of their components becomes increasingly important. The non-additive action of such mixtures was attributed<sup>85–88</sup> to a change in the charge of the DEL due to the adsorption of anions, which adds a partial negative charge to the intrinsically positive metal surface. An analysis of possible reasons for the non-additive protective action of inhibitor mixtures and, particularly, their mutual intensification (*i.e.*, synergism) has been performed by Kuznetsov *et al.*<sup>89,90</sup>

Finally, it should be noted that not only the initial stage but further steps as well can be of significance in explaining the inhibition mechanism. These steps can either have the adsorption character (*i.e.*, polymolecular adsorption) or the mechanism involved is similar to that of salt passivation considered below.

## VI. The salt passivation theory

At a potential  $\varphi < \varphi_a$  preceeding the oxide passivation, salt layers (SL) also possessing protective properties can appear on a metal surface.<sup>76</sup> The formation of such layers is referred to as salt passivation (SP) (sometimes, primary salt passivation).

The SP is observed in aqueous solutions of  $H_2SO_4$ ,  $HClO_4$ ,  $HNO_3$  and other acids in the presence of metal ions capable of forming poorly soluble salts with the respective  $A^{n-}$  anions. Two different mechanisms of the SL formation can be envisaged, depending on the solution composition and the nature of the ions.

The first mechanism is realised if salt-forming metal ions are the components of the acidic solution and the SL emerges due to salt precipitation on the metal surface. The formation of an SL according to this mechanism is determined by the saturation of the solution with reactants, the surface solubility product and general regularities of the heterogeneous nucleation.

The second mechanism is realised if the salt-forming  $M^{z+}$  metal ions are not present in the starting solution but are produced due to the interaction of the metal surface with the  $A^{n-}$  anions yielding salt molecules, *i.e.*, the SP is accompanied by the metal ionisation

and the anions are involved in the elementary events of the anodic process.

In this mechanism, the strength of the interparticle binding between the SP molecules and between an SP molecule and the metal substrate are of primary importance. This strength depends on the metal nature and solution composition. On the other hand, it determines the coverage of the surface with the salt layer and the rate of SL dissolution in the electrolyte. There are two possible mechanisms of the formation of an SL structure involving the  $A^{n-}$  anions and  $M^{z+}$  surface ions in the elementary acts.

According to the first variant, the bonds are sufficiently strong and thus the entire metal surface is covered with the SL, which means that  $\Theta = 1$ . Thus, a continuous salt layer with a thickness  $\delta(\varphi)$  is formed as a result. Its protective properties are determined by the strength of the bonds at the interface with the electrolyte, which prevents transfer of the  $M^{z+}$  ions to the electrolyte. Such an SL can possess a crystalline or amorphous structure. An amor-

phous structure within this approach to the SP problem can be regarded as a lattice that is characterised by a statistical scatter in the interatomic distances and angular directions.

A continuous SL is analogous in properties to a passivating oxide layer with the only difference that both the interparticle  $M-O$  bonds in the oxide and binding of the oxide to the metal substrate are stronger. Therefore, the protective properties of an oxide PL surpass those of an SL by several orders of magnitude. This was the first possible mechanism of formation of an SL corresponding to the complete coverage of the metal with salt. The theory of its emergence is fully analogous to the theory of oxide PL outlined in Sections II and III.

The second variant implies that the bonds formed between the SL and the metal are less strong (probably, due to the influence of the energetical inhomogeneity of the metal surface, which gives rise to continuous variations in the activity of different surface areas in the course of dissolution). For this reason, only a part of the surface appears covered, *i.e.*,  $\Theta < 1$ , and the SL cannot be continuous. The value of  $\Theta$  is determined by a balance of the direct and reverse processes of surface coverage. This mechanism of functioning of an SL has been considered by Sidorenko *et al.*<sup>91,93,95</sup> and by Popov *et al.*<sup>92,94–96</sup>. Its basic aspects can be formulated as follows.

The structure of an SL cannot be static since it is discontinuous and contains the  $M^{z+}$  ions of a metal that is dissolved. This follows from the general regularities of nucleation (of the SL, in this case), which starts with the adsorption step and generation of two-dimensional salt nuclei on the metal surface (at a coordinate  $x = 0$ ). The process further continues to the region  $x > 0$ , where the nuclei grow on the related, *i.e.*, their own, substrate. This should lead to the formation of a system of pores filled with the electrolyte within the salt structure. The pores constitute a connected space  $\Omega$  with an interface  $\Sigma$ . The existence of pores is necessitated by the fact that metal undergoes anodic dissolution only from uncovered parts of its surface put in contact with the electrolyte that is a mandatory participant of elementary events. Furthermore, the electrolyte solution is an ion-conducting medium, which is required for the withdrawal of the dissolved  $M^{z+}$  ions.

Popov *et al.*<sup>95,96</sup> demonstrated that a solution cannot be either oversaturated or unsaturated or simply saturated in all pores simultaneously. In other words, none of the three following relations

$$C_M^n C_a^m > C_H,$$

$$C_M^n C_a^m < C_H,$$

$$C_M^n C_a^m = C_H,$$

where  $C_M = [M^{z+}]$  and  $C_a = [A^{n-}]$  are the concentrations of the  $M^{z+}$  cations and  $A^{n-}$  counteranions, respectively, and  $C_H$  is the solubility product of the passivating salt  $M_nA_m$ , can be valid for all pores simultaneously. Indeed, in the first case, the pores would disappear owing to constant precipitation (crystallisation) of the salt on the pore walls so that the surface  $S$  would appear completely shielded and the metal dissolution would stop. In the second case, the pore walls would dissolve and the SL would disappear. In the third case, the concentration gradients of ionic components would become zero. This means that all pores at any moment  $t$  can be subdivided into two classes. In the first type of pores, the solution is oversaturated and the salt crystallises on the pore walls filling them. In the second type of pores, the solution is unsaturated and the salt is dissolved. The pores are continuously redistributed over the two classes. In other words, any elementary volume of an SL at any moment  $t$  represents either a solution-filled pore or solid phase. The steady-state porosity  $g(x)$ , which provides stable functioning of the SL, depends on the mean ratio of times, for which an elementary volume exists in these two states. The interface  $\Sigma$  does not remain static but rather continuously fluctuates. The porosity  $g(x)$  is a function of coordinate due to the

non-zero concentration gradients  $c_M(x)$  and  $c_A(x)$ . The reported data<sup>91–96</sup> are fully consistent with the experimental results.<sup>26,97</sup> Froment *et al.*<sup>97</sup> filmed an SL *in situ* using an accelerated-motion camera at a high magnification ( $\sim 3500$  times) and discovered a phenomenon referred to as ‘crystal swarming’, which is consistent with the above theory.<sup>91–96</sup> The apparent current density of the metal dissolution passing through an SL is given by the formula

$$i = g_s f(\varphi),$$

$$g_s = g(x)|_{x=0} = 0,$$

$$f(\varphi) = zF \frac{K_{ad}(\varphi)}{1 + \beta},$$

$$\beta = \frac{K_{ad}(\varphi)}{K_i(\varphi)},$$

where  $f(\varphi)$  is the actual current density at an uncovered part of the metal surface;  $K_{ad}(\varphi)$  and  $K_i(\varphi)$  are the rates of anion adsorption and metal ionisation in the elementary events of anodic dissolution (transfer of the  $M^{z+}$  ions into the electrolyte), respectively. The ion transfer processes proceeding in the pore space of an SL including reactions at the pore walls (*i.e.*, precipitation of the salt on them or dissolution) have been considered elsewhere.<sup>25,96,98,99</sup>

## VII. Conclusion

The investigations into the regularities of the interphase phenomena in non-equilibrium systems metal–electrolyte and into the passivation mechanism, in particular, are interdisciplinary in their nature combining physics of metals, solutions and electrolytes and interface processes. Such studies should take into account numerous factors and parameters, which affect the corrosion kinetics and determine the complex shape of polarisation curves (see Fig. 1). With this respect, the present review capitalises on the unified model principle, which assumes that all the phenomena proceeding on the surface of a dissolving metal as well as a sequence of the surface states are governed by a few key processes. The kinetics of these processes differs depending on the anode potential  $\varphi$  and therefore one process dominates at any specific potential value, which gives rise to the alteration of the surface states (with an increase in the potential  $\varphi$ ) corresponding to kinks of the polarisation curve and characteristic potentials  $\varphi_0$ ,  $\varphi_a$  and  $\varphi_p$ . The dissolution mechanism is changed at these points.

Adherence to the above principle imposes restrictions upon arbitrary assumptions in theoretical speculations with plentiful unknown parameters. The validity of this approach is also justified by the fact that the shapes of polarisation curves are virtually identical for the majority of metals (*e.g.*, Fe, Cr, Ni, Mo, *etc.*).

In the case of an anodically dissolvable metal, the unified model only includes such processes as the  $M^{z+}$ ,  $M_{ox}^{z+}$  and  $O_{ox}^{2-}$  ion transfer through the interfaces  $M-O$  and  $O-E$ ; hopping migration of the ions within the PL lattice; PL crystallisation by the mechanism of two-dimensional nucleation. This model is sufficient to reproduce the entire polarisation curve.

Specific features of real systems can be addressed by including respective supplementary factors. The problems of the electrochemical metal passivation under applied voltage and of the elementary event of the anodic dissolution are of special interest. They also can be treated within the approach described.

**Abstract.** Data on the chemical vapour deposition of thin-film dielectrics based on silicon nitride, silicon oxynitride and silicon dioxide and on phosphorus- and boron-containing silicate glasses are generalised. The equipment and layer deposition procedures are described. Attention is focussed on the analysis and discussion of the deposition kinetics and on the kinetic models for film growth. The film growth processes are characterised and data on the key physicochemical properties of thin-film covalent dielectric materials are given. The bibliography includes 139 references.

## I. Introduction

Layered semiconductor, dielectric and metallic composite materials are used in high-precision technologies. Such structures are the basis of modern electronics (in particular, solid-state integrated circuits are fabricated from single-crystalline silicon on semiconductor wafers).

Fabrication and use of multilayer structures became possible after solving the complicated problems of semiconductor materials science concerned with the synthesis of defect-free dielectric films (*e.g.*, silicon dioxide, silicon nitride, boron nitride and tin, titanium, aluminum, *etc.*, oxide films). At present, such films are fabricated using various versions of the chemical vapour deposition (CVD) technique.<sup>1</sup>

CVD methods have been used to fabricate ‘wafer – thin film’ structures since the mid-1960s.<sup>2,3</sup> The growth of a thin film, in the course of a CVD process, on the surface of a wafer heated to the desired temperature is the result of irreversible reactions of initially gaseous compounds. Dielectric films are synthesised using both research and industrial CVD flow reactors operating at atmospheric, reduced and low pressures. Vapour-phase mixtures of the precursors, oxidants or ammonia, in the presence of various carrier gases, are supplied to the reactor by a pressure drop in the carrier gas stream or as a result of the evacuation of the

system with a vacuum pump. One of the most important features of CVD processes is the possibility to grow films of variable thickness (from a few hundredths of a micrometre to a few micrometres) at relatively low temperatures. For instance, silicon dioxide films can be CVD grown at temperatures below 373 K, whereas silicon monoxide is formed at a noticeable rate by the oxidation of monocrystalline silicon with O<sub>2</sub> at temperatures above 1173 K. The film synthesis temperature can also be reduced by an additional (non-thermal) activation of the vapour phase using a high-frequency discharge, photochemically or by using laser irradiation.

Wide use of CVD methods in basic research and large-scale production is due to the fact that they require relatively simple equipment, are safe and manufacturable and provide high quality thin-film coatings fabricated under the optimum synthesis conditions. At present, thin-film CVD processes are basic technological processes in electronics<sup>4–6</sup> and their proportion in the overall device fabrication cycle is continuously increasing as the devices and methods of fabrication of multilayer structures become more and more complicated.

Both research practice and applied use of CVD methods face the problem of describing the film growth processes, which involves the establishment of some functional dependences.

First, it is necessary to obtain quantitative relations between the film growth rate and the parameters of the CVD process, *e.g.*, temperature (*T*), pressure (*P*), linear rate of gas stream (*v*) and the ratio of the component concentrations in the vapour phase (taking into account the geometry of the CVD reactor), features of the spatial arrangement of wafers in the reactor and the thermal and gas-dynamic effects in the reactor. Usually, these are the key factors for the optimization of the film deposition process, which eventually involves achievement of a maximum film growth rate at a minimum possible film thickness mismatch (desired values lie within limits of a few percent) across the entire wafer surface.

There are a number of good examples of solving optimization problems in film growth processes for different reactor types and various dielectric materials. One of them is modelling the operation of a low-pressure flow tube reactor under isothermal conditions.<sup>7</sup> The authors<sup>7</sup> succeeded in determining the parameters and spatial arrangement of wafers corresponding to a minimum film thickness mismatch at maximum reactor charge (several tens or even hundreds of semiconductor wafers). This is, in particular, due to the fact that no detailed information on the chemical stages of the growth process was required; the model

Received 26 November 2003

*Uspekhi Khimii* 74 (5) 452–483 (2005); translated by A M Raevskiy

included only the rate constants for the reactions on the wafer surface or in the vapour-phase and the vapour-phase diffusion coefficients. However, in spite of the paramount importance of this solution, it is only a particular case for modelling of CVD process.

The second necessary functional dependence is a relation between the chemical composition and microcomposition of the film and the input parameters of the CVD process. For instance, the composition of silicon nitride films grown by ammonolysis of monosilane is usually described by the formula  $\text{Si}_3\text{N}_4$ . However, the microcomposition of such films should be described in terms of concentrations of the NH and SiH groups,<sup>8</sup> because the overall concentration of hydrogen in the silicon nitride films can vary between 4 at.% and 20 at.%, depending on the CVD method employed in each particular case. For many practical applications in electronics, the microcomposition plays the key role; therefore, this level of modelling of the CVD process requires knowledge of all stages of the growth process.

The third group of functional dependences includes correlations between the properties of the deposited films and the CVD conditions. It should be noted that most studies of the properties of dielectric materials were carried out using a particular deposition technique and a narrow range of parameters for the CVD processes.

Finally, searching for correlations between the electrophysical properties of deposited materials and the CVD parameters, including the reactor type, starting compounds, deposition conditions, *etc.*, is also an important task.

The considerable interest in the CVD processes is reflected in a continuous stream of publications, most of which describe the operation regimes, reactors and the properties of the films obtained. The properties of the films have been studied to different extents. Silicon-based films widely used in electronics have been best studied. The results of the investigations of silicon nitride films obtained up to 1980 have been comprehensively treated in a monograph.<sup>8</sup> Data on the deposition of silicon dioxide films, and especially binary and ternary silicate glass films, have almost not been summarised earlier. More complex thin-film materials, *e.g.*, silicate glasses, synthesised in four- and five-component chemical systems, have been poorly studied. This leads to an inadequate understanding of the physicochemical processes used in electronics. This conclusion can be drawn after close examination of the available monographs.<sup>2-6</sup> For instance, at present, the epitaxy, diffusion and thermal oxidation processes have been studied in detail and theoretically substantiated, whereas chemical vapour deposition of dielectric thin films is still descriptive in character.

This review is concerned with the analysis of the problems of CVD of dielectric thin films. We discuss the methodological problems of CVD and the fundamentals of the molecular theory of dielectric film growth. The key characteristics responsible for the growth processes and main physicochemical properties of thin-film covalent dielectric materials are also considered.

## II. Chemical vapour deposition of thin-film dielectric materials: general

### 1. Reactions

Basic to CVD processes are the following chemical reactions of carbon and silicon compounds: pyrolysis (cracking process), reduction, oxidation, hydrolysis, ammonolysis and dehydrogenation. Given below are some examples of these reactions.

#### *Pyrolysis*

#### *Reduction*

#### *Oxidation*

#### *Hydrolysis*

#### *Ammonolysis*

#### *Interaction with methane*

#### *Interaction with monosilane*

Among these, the hydrolysis and oxidation reactions are the fastest. A special position is occupied by the oxidation of silane, which proceeds as a branched-chain process; therefore,  $\text{SiO}_2$  films can be fabricated at low temperatures ( $\sim 343$  K). Note that in the case of CVD processes, the reaction schemes presented above can be used for descriptive purposes only, because the composition of the by-products depends on the particular conditions. For instance, the oxidation of hydrides under CVD conditions can result in both hydrogen and water.

Studies on the deposition of silicon nitride films in the course of the interaction between  $\text{SiCl}_4$  and  $\text{NH}_3$ , and of nickel films during pyrolysis of nickel carbonyls, were carried out more than four decades ago. Since then, some concepts of the character of these processes have been proposed and accepted.<sup>8,9</sup> The CVD approach can be employed to obtain (i) dielectric materials ( $\text{SiO}_2$ , binary and ternary glasses  $\text{SiO}_2\text{--B}_2\text{O}_3$ ,  $\text{SiO}_2\text{--P}_2\text{O}_5$ ,  $\text{SiO}_2\text{--B}_2\text{O}_3\text{--P}_2\text{O}_5$ ,  $\text{Si}_3\text{N}_4$ , silicon oxynitride  $\text{Si}_3\text{N}_4\text{--SiO}_2$  and  $\text{Al}_2\text{O}_3$ ,  $\text{AlN}$ ,  $\text{Ge}_3\text{N}_4$ ,  $\text{TiO}_2$ ,  $\text{TiC}$ ,  $\text{TiN}$ ), which are used as screening films, protective coatings, mirrors and waveguides; (ii) polycrystalline and amorphous semiconductor films (silicon,  $\text{SiC}$  and compounds of the types  $\text{A}^{\text{III}}\text{B}^{\text{V}}$  and  $\text{A}^{\text{II}}\text{B}^{\text{VI}}$ ) used for fabrication of transistor structures; (iii) metals and alloys ( $\text{Ni}$ ,  $\text{Al}$ ,  $\text{W}$ ,  $\text{Ta}$  and  $\text{Mo}$  and nickel, manganese, iron, titanium, cobalt, chromium, tungsten, tantalum, molybdenum, platinum and aluminum silicides) for production of conductors; (iv) superconductors  $\text{Nb}_3\text{Sn}$ ,  $\text{Nb}_3\text{Ge}$ ,  $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ,  $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_x$  ( $n = 1-3$ ); (v) ferroelectrics  $\text{Pb}(\text{Zr,Ti})\text{O}_3$  and  $(\text{Ba,Sr})\text{TiO}_3$ ; (vi) transparent conductors  $\text{SnO}_2(\text{In}_2\text{O}_3)$ , *etc.*

Thin film-wafer composites have found a variety of technological applications in electronics, mechanical engineering, power engineering, medicine, *etc.* The CVD method differs from other known thin film fabrication techniques (thermal, plasma or ion deposition) in the size of the deposited particles, which is of the order of a few tenths of a nanometre (*cf.* tens of nanometres for other methods). Molecular dispersion of the deposited particles makes possible the deposition of compact coatings on surfaces

with complex reliefs, with good adhesion and high mechanical properties for the coatings.

## 2. Thermodynamic aspects of CVD

The problem of growth of a dielectric film is part of the known problem with solid phase formation from particles present in gas or vapour phases. The thermodynamic aspect of this problem was first considered by Volmer.<sup>10</sup> The cases for complex multicomponent systems used for epitaxial crystal growth were generalised by Schäfer<sup>11</sup> and Kuznetsov *et al.*<sup>12</sup> However, it is impossible to analyse the film growth rate using thermodynamic description of chemical systems, because the vast majority of dielectric film fabrication processes proceed under conditions that are far from the thermodynamic equilibrium.

Concerning the possibility of using the crystal-growth theory methods to describe the growth of dielectric thin films, we can say the following.

The modern crystal-growth theory concerns three main problems:

- the mechanism of a new phase nucleation on the surface of a crystal or in the medium surrounding the growing crystal (*e.g.*, the gas or vapour phase);

- the nature of the processes that govern the nucleation kinetics (according to the layer-by-layer growth theory, these are the surface diffusion processes);

- the problem of retention of the growing plane in the crystal; solutions to this problem are best demonstrated in the Kossel model for an ideal crystal and in the model by Frank, Burton and Cabrera<sup>13</sup> for a real crystal (motion of the front of a screw dislocation).

In the theory of gas-phase nucleation, the critical radius,  $r_c$ , of a spherical nucleus is expressed through the surface energy  $\sigma$ ; the molecular volume,  $v_m$ , of the nucleus; the vapour pressure  $P_v$ ; and the equilibrium pressure  $P_e$  at the temperature  $T$

$$r_c = \frac{2\sigma v_m}{RT \ln(P_v/P_e)}. \quad (1)$$

Consider, as an example, formation of silicon dioxide films by the oxidation of monosilane with  $O_2$ , assuming that the gas–solid system is in thermodynamic equilibrium. Using the following dependence,<sup>†</sup>

$$P_e = 4.11 \times 10^{13} \exp\left(-\frac{336.4}{RT}\right)$$

we obtain  $P_e = 4 \times 10^{-8}$  Pa for  $T = 573$  K. Then, using the published data<sup>14,15</sup> for  $P_e = 133.3$  Pa ( $v_m = 22$  cm<sup>3</sup> and  $\sigma = 2 \times 10^{-5}$  J cm<sup>-2</sup>), we get  $r_c = 0.03$  nm. This means that the formation of silicon dioxide film does not begin with a homogeneous nucleation step. However, it is known that (i) reactions of monosilane with oxygen-containing oxidants ( $O_2$ ,  $N_2O$ ,  $CO$ ) result in  $SiO_2$  as the solid product and (ii) silicon dioxide molecules transferred to the vapour phase upon evaporation of this compound are present only above molten  $SiO_2$  (at  $T \sim 2273$  K).<sup>14</sup> Therefore, chemical vapour deposition of silicon dioxide films proceeds under conditions that are far from the thermodynamic equilibrium. Similar analysis of the growth of silicon nitride films in the course of monosilane ammonolysis leads to the same conclusion.

The analysis given above excludes the possibility of forming three-dimensional nuclei in the vapour phase; however, we can assume the appearance of a two-dimensional nucleus on the surface and consider the unique kinetic features of its growth. The melting temperatures,  $T_m$  (in K), of silicon and silicon compounds and the temperature intervals ( $\Delta T$ ) corresponding to typical conditions of synthesis for these compounds are listed below.

| Material        | $T_m$ | $(2/3)T_m$ | $\Delta T$ |
|-----------------|-------|------------|------------|
| Silicon         | 1693  | 1128       | 870–910    |
| Silicon dioxide | 1773  | 1182       | 470–970    |
| Silicon nitride | 2173  | 1448       | 970–1120   |

It is known that atom transfer processes, such as diffusion, viscous flow, recrystallisation, *etc.*, can be considered fast if they proceed at temperatures exceeding a value of  $(2/3)T_m$ . The data listed above show that in all cases silicon dioxide and silicon nitride films are formed at temperatures that are several hundreds of degrees lower than the corresponding  $(2/3)T_m$  value. This means that the mobility of the atoms of the growing film is hindered in the course of synthesis and the surface self-diffusion cannot be as intense as is assumed in layer-by-layer crystal growth theory.

Quantitative information about surface diffusion can be extracted from the results of experiments on the sintering of finely dispersed  $SiO_2$  powders obtained by hydrolysis of organosilicon compounds. The activation energy for the sintering of powders is known to be nearly 711 kJ mol<sup>-1</sup>; this process only proceeds at a measurable rate at 1273 K.<sup>16</sup>

Thus, thin-film dielectric materials are formed under CVD conditions as a result of complex heterogeneous chemical reactions involving vapour-phase processes and transformations on the growing surface of the dielectric material.

## 3. Kinetic aspects of CVD. Multipath and multistage film growth processes

Thin-film dielectric materials can be fabricated by deposition from vapour phases containing at least two reactive components using three main types of reactions. These are pyrolysis (thermal decomposition of organoelement compounds), oxidation and ammonolysis. For instance,  $SiO_2$  films can be obtained under CVD conditions and by pyrolysis, while  $Si_3N_4$  films can be prepared by ammonolysis of silicon compounds.

Let us illustrate specific features of the kinetics of the CVD reaction by taking silicon nitride films obtained in two reactions, (1)  $SiCl_4 + NH_3$  and (2)  $SiH_4 + NH_3$ , as examples. For the reaction involving  $SiCl_4$ , the formation of a product of direct interaction,  $Cl_3SiNH_2^+$ , in the vapour phase was detected by mass spectrometry,<sup>17</sup> the concentration of  $Cl_3SiNH_2^+$  being about 20% of the starting concentration of the  $SiCl_4^+$  ion. Considerable amounts of products of secondary collisions, containing one or two silicon atoms and  $NH_2$  groups were also detected; besides, these products always contain HCl. These results show that the first intermediate product of the vapour-phase reaction is  $Cl_3SiNH_2$  and further reactions result in the formation of  $Si(NH_2)_2Cl_2$  and  $Si_2NHCl_6$  particles. Detailed analysis of these reaction schemes and information on the rate constants for the different stages can be found in the literature (see, *e.g.*, Refs 8, 18, 19). Figure 1 presents a scheme of possible transformations of the starting reagents in the formation of  $Si_3N_4$  films.

**Figure 1.** A scheme illustrating the sequence of stages and routes of chemical transformations during the formation of silicon nitride layers in the  $SiCl_4$ – $NH_3$  system.<sup>18</sup>

<sup>†</sup> From this point on the activation energy is given in kJ mol<sup>-1</sup>.

In the  $\text{SiH}_4 + \text{NH}_3$  system, the sequence of reactions, resulting in the formation of silicon nitride films, can involve both pure vapour-phase reactions:

and surface reactions:

These reaction schemes serve as the basis for a generalised kinetic model of a complex CVD reaction, determining the growth of a film. For instance, the overall reaction of the precursors A and B (Fig. 2) results in the formation of structural units of a thin-film dielectric material (DM)

This reaction is generally a multistage and multipath process. Consider three main paths. Route I is the interaction between A and B in the adsorption layer by the Langmuir–Hinshelwood or by the Eley–Rideal mechanisms. Route II is the interaction between the intermediate product, I, and the surface, S, of the growing film, resulting in the formation of an intermediate product, F, which is eventually transformed in the reaction zone into structural units of the DM and thus causes regeneration of an element of the pristine surface. Route III is characterised by the formation of the intermediate product, I, in the vapour phase and the subsequent formation of a by-product (end product C).

**Figure 2.** Generalised kinetic scheme of formation of a dielectric layer during the CVD process.<sup>18</sup>

A and B are the starting reagents;  $\text{A}_s$  and  $\text{B}_s$  are the reagents in the adsorption stage; I and F are intermediate products in the vapour phase and in the adsorption layer, respectively; C is a side product (gas or powder); and DM is the end product (thin layer of dielectric material).

The aforementioned can be represented as the matrix of stoichiometric coefficients of CVD stages (Table 1). In this representation, the growth process is described as a complex reaction following three concurrent routes, each of them being a multistage process. In particular, route I involves stages 2, 3, 4 and 6; route II involves stages 1, 5 and 6 and route III involves stages 1 and 7. Thus, the growth of a dielectric thin film can be considered as a multipath and multistage chemical reaction. To describe the kinetics of this reaction, one must have a complete set of rate constants for each of the individual stages. This is an intricate experimental task, which importantly can be solved using the

**Table 1.** Matrix of stoichiometric coefficients of different stages of the CVD process.<sup>18</sup>

| No. | Stage                                | Route |    |     |
|-----|--------------------------------------|-------|----|-----|
|     |                                      | I     | II | III |
| 1   | A + B = I                            | 0     | 1  | 1   |
| 2   | A + S = $\text{A}_s$                 | 1     | 0  | 0   |
| 3   | B + S = $\text{B}_s$                 | 1     | 0  | 0   |
| 4   | $\text{A}_s + \text{B}_s = \text{F}$ | 1     | 0  | 0   |
| 5   | I + S = F                            | 0     | 1  | 0   |
| 6   | F = DM                               | 1     | 1  | 0   |
| 7   | I = C                                | 0     | 0  | 1   |

formal approaches developed in the theory of the kinetics of heterogeneous catalysis.

#### 4. Structural aspect of thin film synthesis under CVD conditions

Formation of thin-film dielectric materials under CVD conditions proceeds as a heterogeneous chemical reaction, *i.e.*, a sequence of elementary acts involving the embedding of structural units into the matrix of the growing film. An important feature of this class of compounds is the absence of long-range order in their structures. Short-range order in covalent dielectric materials can be described using the concept of structural units proposed by Myuller.<sup>20</sup> A structural unit is the smallest possible atomic group in the nearest coordination sphere of a given atom, which reflects its coordination and the unique features of its embedding into the matrix material. Examples of the main structural units are provided by  $\text{SiO}_{4/2}$  for silicon dioxide,  $\text{BO}_{3/2}$  and  $\text{BO}_{4/2}$  for boron oxide,  $\text{O}-\text{P}^+\text{O}_{3/2}$  for phosphorus oxide,  $\text{GeO}_{4/2}$  for germanium oxide and  $\text{SiN}_{4/3}$  for silicon nitride. The properties of a layer can strongly depend, not only on the main unit, but also on other structural units. For instance,  $\text{SiO}_2$  layers can contain inclusions with  $\equiv\text{Si}-\text{OH}$  or  $\equiv\text{Si}-\text{H}$  bonds, *i.e.*, structural units  $\text{SiO}_{3/2}\text{OH}$ ,  $\text{SiO}_{2/2}(\text{OH})_2$  or  $\text{HSiO}_{3/2}$ ,  $\text{H}_2\text{SiO}_{2/2}$ . This means that the layer compositions should be described as sets of structural units responsible for the short-range order in the layer of dielectric material. Another important feature is connected with the character of a given combination of structural units, which governs the nature of the medium-range order in the layer. It is known that the  $\text{SiO}_{4/2}$  tetrahedra in  $\text{SiO}_2$  layers can be combined in such a fashion that formations of four-, five-, six- and eight-membered rings, comprised of the  $\text{Si}-\text{O}-\text{Si}$  bridges, become possible. This results in the appearance of micropores and mesopores in the matrix.

Structural features of synthesised films are also related to the character of the long-range order in the structure. When synthesising semiconductor films, it is usually possible to obtain single-crystalline films. Metal films are, as a rule, polycrystalline, while the synthesis of dielectric materials leads to formation of glassy or amorphous films. Interrelations between these structures are illustrated in Fig. 3, which shows variations in the structure of a  $\text{SiO}_2$  film of various degrees of disorder.<sup>21</sup>

The key role in the formation of a film structure is played by the temperature of the wafer, but generally one must also take into account other starting parameters of the CVD processes. Note that the properties of the surface of a dielectric material are determined by the set of the surface structural units characterised by the different heats of adsorption of the reagents. In this connection, one can assume a non-uniform energy distribution across the surface of the growing dielectric material. In contrast to the crystal model by Kossel, in which non-uniform energy distribution is determined by structural features, the model of a growing dielectric film is governed by the discrete set of structural units with different chemical compositions. This can be exemplified by considering the data on the surface chemistry of silica gels and quartz glass.

**Figure 3.** Scheme illustrating interrelations between defects in the crystalline, glassy and amorphous silicon dioxide.<sup>21</sup>

A study of the surface of a cleaved  $\text{SiO}_2$  face revealed the presence of  $\text{O}_2\text{SiO}_{3/2}$  and  $\text{OSiO}_{3/2}$  sites (see Ref. 22). Investigations of the adsorption characteristics of silica gels<sup>23,24</sup> established the presence of the  $(\text{O}_{3/2}\text{Si})_2\text{O}$ ,  $\text{HOSiO}_{3/2}$  and  $(\text{HO})_2\text{SiO}_{2/2}$  surface sites. The results of studies of the growth of polycrystalline silicon films and the data on hydrogen adsorption on the surface of this material indicates the formation of the  $\text{HSiSi}_{3/4}$  and  $\text{H}_2\text{SiSi}_{2/4}$  surface sites. Thus, generally, the surface energy of the growing dielectric material can be different at different points of the surface, owing to the chemical inhomogeneity of the adsorption sites. However, it should be noted that this can manifest itself only at low coverages of the adsorption layer. If the growth occurs as a monolayer or ultrahigh coverage, the kinetics of the process should be described with allowance for uniform energy distribution across the surface.

In the theory of layer-by-layer crystal growth, an important role is played by screw dislocations, whose outcrops provide a kind of constant sink for adatoms to the monatomic step. A distinctive feature of the glassy state of a compound is the absence of regular dislocation-type defects. This means that structurally, a dielectric film has a highly ordered surface. Some problems can be due to crystallisation of films, *viz.*, if it does occur, structural defects appear on the surface of the dielectric film.

It is possible to analyse various growth processes of thin-film dielectric materials from a unified point of view by using the concept of a reaction zone (a concept traditionally used in solid state chemistry when considering topochemical reactions). In certain simple cases, the reaction zone can be as thin as the monolayer coating. Generally, the thickness of the reaction zone is in the order of a few atomic sizes.

### III. Characteristics of film growth processes

#### 1. CVD equipment and reagents

A number of simplified schemes of flow reactors most widely used for the deposition of dielectric films are shown in Fig. 4. In these reactors, wafers can be arranged on heated pedestals or inside a quartz tube with isothermal heating. In the former case, the temperature of the reactor walls is lower than the wafer temperature; these reactors being called 'cold-wall' reactors. In the latter

**Figure 4.** Main types of reactors (simplified schemes): atmospheric pressure reactor (a), reduced pressure reactor (b), low pressure reactor (c) and low pressure reactor with cross-vertical coaxial arrangement of wafers (d).

Gas inlet (1), exhaustion of used gas mixture or evacuation (2), heater (3), pyramidal heater (3a), wafer (4), gas distributor system (including the system with high-frequency power) (5).

case, wafers and reactor walls have the same temperature; these reactors being called 'hot-wall' reactors. The spatial arrangement of wafers in 'hot-wall' reactors can vary, namely, along or normal to the gas stream (see Fig. 4 c,d); respectively, one deals with flow and flow-diffusion reactors.

Depending on the reagent pressure, CVD reactors are conditionally divided into the atmospheric pressure reactors ( $P \geq 1 \times 10^5$  Pa), reduced pressure reactors ( $P < 1 \times 10^5$  Pa) and low pressure reactors ( $P \sim 10 - 2000$  Pa). The abbreviations of the corresponding CVD processes, derived from the reactor names, are APCVD, RPCVD and LPCVD, respectively. As the pressure under CVD conditions decreases, the reagent diffusion coefficients increase and the process is shifted to such an operation regime for which the mass transfer conditions become insignificant. This makes it possible to vary the spatial orientation of wafers, and hence improve the performance of CVD processes in the flow-diffusion LPCVD reactors (see Fig. 4 d).

The gas flow rate in the course of deposition can vary from a few (LPCVD reactors) to several hundreds (APCVD reactors) of  $\text{cm}^3 \text{ s}^{-1}$ , which approximately corresponds to a range of linear rates for the gas stream from a few  $\text{cm s}^{-1}$  (APCVD reactors) to tens of  $\text{m s}^{-1}$  (LPCVD reactors). Evacuation of LPCVD reactors is achieved using high-pressure vacuum pumps. If necessary, so-called Roots pumps are also used; their performance can be as high as several hundreds of  $\text{dm}^3 \text{ s}^{-1}$ , at pressures ranging between a few tens to hundreds of Pa.

A significant drawback of all flow reactors is their low performance due to incomplete consumption (often, less than 10%) of the starting reagents, which often does not meet environmental safety conditions. Studies on the possibility of using reactors with a closed gas cycle for the synthesis of thin films led to unsatisfactory results, owing to intense formation of by-products (microparticles) in the cold regions of reactors. However, it was found that silicon nitride films can be synthesised from  $\text{SiCl}_4$  and  $\text{NH}_3$  using a LPCVD reactor with a quasi-closed cycle. After evacuation of the reactor, the flow rates of the starting reagents, in the ratios corresponding to the stoichiometric equation, are specified. A stable low pressure in the reactor is self-maintained during the course of the growth process, because all products of this reaction are isolated as solids deposited on the cold walls of the reaction chamber.

Thin film deposition itself occurs when the vapour-gas mixture of a specified composition is supplied for a necessary

time interval into the reactor containing no atmospheric gases (this is achieved by blowing-in an inert gas or by evacuation); the wafer temperature must be pre-stabilised. Equipment and methods for the deposition of thin-film dielectric materials have been well documented (see, e.g., Refs 25–27).

Numerous combinations of various compounds were used in the studies of the CVD synthesis of dielectric films carried out over a long period of time. For instance, silicon dielectric films were deposited using monosilane, disilane, dichlorosilane, silicon tetrachloride, tetraethylorthosilicate (TEOS), dimethyldichlorosilane, hexamethyldisilazane and hexamethyldisiloxane. Nowadays, the starting combinations of silicon compounds for industrial use in electronics are well established.

Silicon nitride films are mainly synthesised by ammonolysis of dichlorosilane in LPCVD reactors and much more rarely by ammonolysis of silicon tetrachloride. The ammonolysis of monosilane is mainly used in the case of plasma-enhanced deposition.

Silicon dioxide films, as well as boron-containing and phosphorus-containing glass films are fabricated using two versions of the CVD method:

— hydride technique involving monosilane (if necessary, phosphine and diborane are also used) and oxygen in all types of reactors at a low temperature ( $\sim 673$  K); in some cases, boron trichloride and organic esters of boric, phosphorous or phosphoric acids are used instead of diborane and phosphine;

— pyrolysis of tetraethylorthosilicate at temperatures above 923 K or oxidation of mixtures of this compound with organic esters in all types of reactors at a low temperature ( $\sim 673$  K); here, possible oxidants are oxygen or oxygen–ozone mixtures (with ozone concentration of up to 13 mass%).

## 2. Characteristics of film deposition regimes in flow reactors

Gas flows under CVD conditions are characterised by the Reynolds number

$$Re = \frac{\rho_g v d}{\eta_g}$$

( $\rho_g$  is the density of the gas,  $\eta_g$  is the viscosity of the gas,  $v$  is the linear flow rate of the gas stream and  $d$  is the characteristic linear size of the reactor), which varies between 10 and 100. At such Re values, turbulence effects are insignificant. Depending on the total pressure in the reactor, the Knudsen numbers (ratio of the mean free path of molecules to the linear size of the reactor) vary from 1 (in RPCVD reactors) to  $10^{-4}$  (in APCVD reactors). If a process is carried out at a pressure in the range 133–1333 Pa, the diffusion coefficients of reagents increase by 1.9–2.9 orders of magnitude compared to their values under normal conditions. Because of this, the process becomes kinetically controlled. A quantitative characteristic of this regime is the ratio of the reaction rate to the diffusion rate — the Thiele criterion, which, for a first-order reaction, has the form

$$\Phi = \frac{k d}{D},$$

where  $k$  is the rate constant for the reaction and  $D$  is the diffusion coefficient. At  $\Phi \leq 0.1$ , the process is determined by the rate of the heterogeneous reaction, becoming diffusion controlled at  $\Phi \geq 1$ .

## 3. Experimental determination of film growth rate constants

Methodologically correct determination of the growth rate constants is of crucial importance for the qualitative description of film growth processes under CVD conditions. The growth rate depends on specific features of the heat and mass transfer processes, viz., the reactor and wafer heating mode, reactor geometry, shape of wafer pedestals, reactant gas supply technique, total pressure and linear flow rates of gas mixtures. In some particular cases, it is possible to perform quantitative heat and mass transfer calculations and determine the growth rate constants. These parameters can also be determined experimentally.

**Figure 5.** Growth rate distribution of silicon nitride layers along the axis of a horizontal isothermal reactor with isothermal zone 1123 K (shown by dashed line).<sup>8</sup>

Linear rate  $/\text{cm s}^{-1}$ : 494 (1), 395 (2), 328 (3) and 197 (4);  $P = 1995$  Pa,  $[\text{SiH}_4] = 2.76 \times 10^{-7}$  mol litre $^{-1}$ ,  $[\text{NH}_3]/[\text{SiH}_4] = 90$ .

Isothermal horizontal tube reactors of internal radius  $r_r = 20$ –60 mm (see Fig. 4 c,d) with a sufficiently extended isothermal zone in the central part of the reactor appear to be most convenient for carrying out such experiments. The length of the isothermal zone is usually at least one third of the total length of the reactor. The thickness of the film deposited on wafers (wafer radius,  $r_w$ , usually lies between 20 and 50 mm) varies along the length of the reactor, namely, it increases at the beginning of the isothermal zone, reaches a maximum value and decreases near the end of the isothermal zone. This is illustrated in Fig. 5. In the initial portions of curves, the deposition rate ( $W$ ) increases to its maximum value ( $W_{\text{max}}$ ), corresponding to the instant when the gas stream is heated in the whole volume. Subsequent decrease in the deposition rate is due to depletion of monosilane. Let a gas stream move along the reactor at the linear rate  $v$  and the gas mixture arrives at point  $x$  at time

$$\tau = \frac{x}{v},$$

which is called the residence time of the gas mixture in the reactor. Using this ratio, the dependence of the rate of the process on the coordinate (along the reactor) can be re-calculated to the corresponding dependence on  $\tau$ .

After this treatment, the family of dependences shown in Fig. 5, plotted in the new coordinates, looks as a single kinetic curve, passing through a maximum ( $\tau_{\text{max}}$ ). In this case, the process can be described by the model of a plug reactor, which is based on two assumptions: (1) constant reagent concentrations at a given reactor section and (2) the rate of convective transfer of a reagent is higher than the diffusion rate along the reactor axis. Analysis of the curves plotted in Fig. 6 a revealed yet another salient feature, namely, depletion of the gas mixture decreases exponentially (this is clearly seen in Fig. 6 b).

The rate of conversion of the  $i$ th component, of initial concentration  $c_{0i}$ , in the course of a first-order chemical reaction is expressed as follows:

$$-\frac{dc_i}{dt} = kc_i, \quad c_i = c_{0i} \exp(-kt).$$

From here, the rate constant for the reaction is given by:

$$k = \frac{\Delta \ln(c_i/c_{0i})}{\Delta t}.$$

The rate constant for the reaction can be determined by plotting the film growth rates,  $W_{\text{max}}$ , corresponding to maxima on the  $W(x)$  curves (see Fig. 5) vs. concentration  $c_{0i}$ :

$$W_{\max} = kc_{0i}^n.$$

In this case, it is possible to determine both the rate constant  $k$  and the reaction order  $n$ . Determination of the initial concentration  $c_{0i}$  can appear to be difficult. In the case in point, the stage described by the raising portion of the  $W(\tau)$  curve (see Fig. 6a) is characterised by partial depletion of the gas mixture from the  $i$ th component, and the  $c_{0i}$  value does not correspond to the real initial concentration. The depletion value,  $\Delta c_i$ , must be calculated by integrating the total mass of the layer formed on the reactor walls from the point corresponding to the beginning of registration of the film growth to the point  $x_{\max}$  (maximum position):

$$\Delta c_i = \xi \frac{\rho_f 2\pi r_f}{v_T M} \int_0^{x_{\max}} W_x dx.$$

Here  $\xi$  is the stoichiometric number, which shows how many moles of the  $i$ th reagent should be consumed in order to form 1 mole of product,  $\rho_f$  is the film density,  $v_T$  is the gas flow rate at the temperature  $T$  and  $M$  is the molecular mass of the film material. This expression for  $\Delta c_i$  is valid for a cylindrical reactor with horizontally arranged small wafers (see Fig. 4c). In other cases (e.g., vertically arranged wafers), calculations are more complicated.

**Figure 6.** Dependences presented in Fig. 5 plotted in the 'growth rate–residence time of the gas mixture in the reactor' coordinates (a) and in semilogarithmic coordinates (b).<sup>8</sup>

For notation (1–4), see the caption to Fig. 5.

If the change,  $\Delta h$ , in the thickness of the deposited film after time  $\Delta t$  in a flow reactor of the surface area  $S$  equals the deposition rate  $W_s$ , one can find the number,  $\Delta m$ , of moles of reaction product formed:

$$\Delta m = \frac{S\rho_f}{M} \frac{\Delta h}{\Delta t} \Delta t = \frac{S\rho_f}{M} W_s \Delta t.$$

For a static system or under plug reactor conditions one has

$$\Delta m = -\xi V \frac{\Delta c}{\Delta t} \Delta t = -\xi V W_v \Delta t,$$

where  $V$  is the volume of the reactor,  $c$  is the molar concentration of the reagent and  $W_v$  is the rate of the vapour-phase reaction. For a one-path process, one gets a simple relation between these rates:

$$\frac{dh}{dt} = \xi \frac{VM}{S\rho_f} \frac{dc}{dt}.$$

Generally (the case of multipath reactions),  $W_v > W_s$  and the ratio of these rates determines the contribution of a given path. When the reaction kinetics is studied experimentally, one must determine how the ratio of the surface area,  $S$ , of the reactor to its volume,  $V$ , affects the reaction rate. This criterion allows us to answer the question of which (gas-phase or heterogeneous) stage is the rate-determining step of the reaction. Assuming that a certain reaction is characterised by the dependence  $W = kc$ , if the overall rate is determined by the slow surface reaction, i.e.,

$$W_s = \frac{dh}{dt} = k_s c,$$

where  $k_s$  is the rate constant for the surface reaction, the rate of the reagent conversion is given by

$$-\frac{dc}{dt} = \frac{S\rho_f}{M\xi V} \frac{dh}{dt}$$

and

$$\frac{dc}{c} = \frac{S\rho_f}{M\xi V} k_s dt.$$

From here it is seen that:

$$W_s = k_s c_0 \exp\left(-\frac{S}{V} \frac{\rho_f}{M\xi} k_s t\right).$$

Having determined the rate constant at  $t = 0$  (this corresponds to the position in the plot shown in Fig. 6a), we obtain the  $k_s$  value, which is independent of the reactor geometry. Using the experimental data in the  $\ln W - t$  coordinates, one can find the effective rate constant

$$k = \frac{S}{V} \frac{\rho_f}{M\xi} k_s,$$

which depends on the  $S/V$  ratio. In particular, for cylindrical reactors one has  $S/V = 2/r_r$ . In this case it is convenient to compare the reaction development times  $\tau_1$  and  $\tau_2$ , corresponding to the same degree of reagent conversion in reactors of different cross-sectional areas (radii  $r_{r1}$  and  $r_{r2}$ ). As can be seen,  $\tau_1/\tau_2 = r_{r1}/r_{r2}$ . This can be illustrated by Fig. 7, where the growth rate of silicon nitride films in the reaction of monosilane with ammonia in different cylindrical reactors is plotted against time. Both cases are characterised by the same maximum rate, although the linear gas flow rates differ by nearly a factor of four. Assuming that the reactions are complete at, e.g., 70% conversion, one can obtain  $\tau_1 = 0.26$  and  $\tau_2 = 0.10$  s, the  $\tau_1/\tau_2$  ratio being in good agreement with the ratio  $r_{r1}/r_{r2} = 38/16 = 2.4$ .

**Figure 7.** Growth rate of silicon nitride layer plotted vs. the residence time of gas mixture in reactors of radii 38 (1) and 16 mm (2).<sup>8</sup>  $T = 1123$  K,  $P = 2000$  Pa,  $[\text{SiH}_4] = 3.64 \times 10^{-7}$  mol litre<sup>-1</sup>, gas flow rate  $70 \text{ cm}^3 \text{ s}^{-1}$  under normal conditions,  $[\text{NH}_3]/[\text{SiH}_4] = 90$ .

Let us consider a volume gas-phase reaction. Assuming that passage of the gas containing an active reagent with the concentration  $c$  along the reactor at the rate  $v_T$  results in the formation of a film of thickness  $\Delta h$  after time  $\Delta t$ :

$$\Delta h = \frac{M}{S\rho_F} v_T c \Delta t.$$

The rate constant for the deposition reaction is given by:

$$k = \frac{M\xi}{S\rho_F} v_T.$$

From here we get:

$$W = \frac{M}{S\rho_F} v_T c_0 \exp\left(-\frac{Mxi}{S\rho_F} v_T t\right).$$

This equation shows that, firstly, the deposition rate at  $t = 0$  is proportional to the linear gas flow rates. Secondly, a decrease in the reaction rate with time, in reactors of different cross-sections and experiments with constant linear gas flow rate, is independent of the reactor cross-section and inversely proportional to the reactor surface area (for a cylinder, to  $\sim r_r^{-1}$ ) at constant gas flow rate.

Mention may also be made that the rate constants for growth can be most reliably determined when using the dependences that follow the process to high degrees of reagent conversion. Usually, the progression of the reaction is accompanied by significant changes in the kinetics of the process and, as a consequence, by changes in the properties of the growing film. Processes in LPCVD reactors are conducted to low degrees of reagent conversion (usually, 5%–10%); therefore, such reactions are of limited use for determining rate constants.

#### 4. Comparative characteristics of industrial CVD processes

Practical implementation of CVD in high-precision technologies often involves the use of various reactors and various combinations of reagents (and hence chemical reactions) with significantly different deposition conditions. In addition, different CVD processes are described to different extents. In particular, the approach to the determination of the rate constants (see above) has only been practically implemented for silicon nitride. Numerous studies on the subject report mainly on the dependences of the deposition rates on some parameters of the CVD processes for particular types of reactors, while the geometric parameters of reactors are often not reported.

However, long-term investigations in the field of the synthesis of silicon-based dielectric materials showed that different film deposition processes can be compared, in order to determine the most efficient technology, by using simplified approaches that are consistent with the general method of analysis of the rate constants (see above). The good reasons are as follows.

Firstly, the kinetic dependences shown in Fig. 5, as an example, appeared to be valid for all dielectric thin film deposition processes involving two or more components. The dependences only differed in the positions of the maxima of curves (the exceptions are pyrolysis of monosilane and oxidative pyrolysis of TEOS). In addition, the reactors studied met the ideal displacement conditions.

Secondly, almost all dielectric film deposition processes studied are first order with respect to the silicon-containing compound and pseudo zero order with respect to oxidants or ammonia. Acceleration or retardation of the oxidation processes in the presence of phosphorus or boron compounds manifested themselves in corresponding changes in the film growth rates.

Thirdly, industrial CVD processes proceed under conditions of maximum reaction yield, which correspond to regions of maxima in the kinetic curves.

Fourthly, modern deposition processes are performed at similar  $S/V$  ratios because high-quality film deposition in reactors

requires elimination of the 'extra' volumes in which undesired gas-phase processes can proceed. For instance, the spacing between wafers in the most widely used industrial CVD reactors (see Fig. 4*b,d*) is  $\sim 5$  mm.

Fifthly, using the film growth laws, industrial CVD processes can be characterised by a simplified approach to multipath and multistage reactions. In the framework of the kinetic model discussed above, we chose a simplified model for a CVD process, which involves three possible paths: a heterogeneous route (I), a two-stage route involving stages of homogeneous formation and heterogeneous consumption of the intermediate product (II) or formation of side aerosol products (III).

To perform a generalised characterisation of CVD processes, the main parameter chosen was the so-called effective rate constant,  $k_{\text{ef}}$ , for the process, *i.e.*, the ratio of the deposition rate, corresponding to the maximum value ( $W_{\text{max}}$ ) in the  $W = f(\tau)$  curve, to the concentration of the silicon component [Si] in the vapour phase

$$k_{\text{ef}} = \chi \frac{W_{\text{max}}}{[\text{Si}]}, \quad (2)$$

where  $\chi$  is the coefficient of proportionality. Substantiation of this approach to the description of CVD processes and the determination of  $k_{\text{ef}}$  is available in the literature (see, *e.g.*, Refs 28–31). A comparison of different processes for the synthesis of polycrystalline silicon, silicon nitride and silicon dioxide thin films and glasses showed that the experimental  $k_{\text{ef}}$  value lies in the range  $\sim 0.3$ – $10$  cm s $^{-1}$ .

Based on the results obtained, a classification of CVD processes for silicon thin films was proposed,<sup>29–31</sup> which allows for the specific features of the thin film synthesis in various chemical systems (Table 2).

#### 5. Growth of thin film dielectrics on relief surfaces

Fabrication of high-precision microelectronic devices involves a transformation of an initially planar wafer surface into a relief surface. The width of gaps separating adjacent elements of devices and the relief height can vary from fractions of a micrometre to a few micrometres. Film deposition on relief surfaces occurs at different rates. This fact is allowed for by so-called layer conformity,<sup>4–6</sup> *i.e.*, the ratio of the film thickness on the lateral face of the step to the film thickness on the top of the step  $h_2/h_1$  (Fig. 8). It was established<sup>29,32,33</sup> that layer conformity (in %) in the dielectric silicon film deposition processes depends on the rate constant  $k_{\text{ef}}$ ; the approximate empirical relation being as follows:

$$\frac{h_2}{h_1} \approx 45.4 k_{\text{ef}}^{-0.51}.$$

Some experimentally determined conformity values and intervals for the deposition on relief steps of rectangular cross-section are listed in Table 2.

Thin film deposition on the relief steps of microelectronic devices comprising ultra-small gaps between elements faces the

**Figure 8.** Cross-section of steps with deposited layer and corresponding main parameters.<sup>33</sup> Wafer (1), relief step (2), deposited layer (3) and unfilled void (4).

**Table 2.** Classification of CVD processes of silicon-containing thin films.<sup>30–32</sup>

| Process characteristics                                                                               | Type of CVD process |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |                                                  |                                   |                                                                                                                                                                                                                                            |                                                                                                                                                      |

problem of high-quality (continuous) filling of the gaps with deposited film containing voids (see Fig. 8). This problem is known in the literature as the ‘Gap fill’ problem. A possible criterion for the filling of a certain gap is the parameter  $h_{st}/G^2$  (Refs 32 and 33). The quality of gap filling using CVD methods can be assessed using the approximate relationship:

$$\frac{h_{st}}{G^2} \approx 3.03k_{ef}^{-1.47}$$

( $h_{st}/G^2$  in  $\mu\text{m}^{-1}$ ).

## 6. Modern approaches to the optimisation of industrial CVD processes

The modern high-precision technologies used in microelectronics were designed to be implemented in so-called group production, *i.e.*, treatment of a particular number of wafers during one technological process. This approach implies a very high level (>95%) of reproducibility of the properties of the material and the sizes of device elements within the same semiconductor wafer, and for all wafers within the same group. This requires (i) determination of the most important parameters of the CVD processes under study, which can influence the device characteristics, and (ii) plotting their distributions schematically, shown in, *e.g.*, Fig. 9a. The desired reproducibility of the parameters of high-precision devices is achieved as a result of the optimisation of technological processes, which implies a search for an optimum ‘parameter window’ for the CVD process (see Fig. 9b), which can be realised in a reactor by using a particular combination of starting reagents. In the case of CVD processes, the number of such parameters is rather large, *viz.*, the temperature, reagent concentrations, pressure, reagent feed rate, *etc.*

**Figure 9.** Conditional CVD parameter distribution before and after optimisation of the deposition process (a) and the parameter window (b). Dashed lines correspond to parameters 1–n.

Optimisation leads to a narrowing of the parameter distribution (see Fig. 9a). A CVD process reproducibility in the chosen parameter window is confirmed by running the ‘marathon’ test (check of the equipment and technological processes for continuous operation, or the mean-time-between-failure evaluation). When running such tests, the total number of wafers treated in a 24 h day can be as high as a few thousands, all film parameters being checked for, *e.g.*, on every 25th wafer. The reproducibility control of the CVD process, and maintenance of the parameter

distribution within the specified intervals and within the limits of necessary deviations, is achieved using methods of mathematical statistics. Combining this approach with full automation of the film deposition equipment allows one to obtain reproducible film thickness parameters and the physicochemical and electrophysical properties of the films deposited.

## IV. Deposition of silicon nitride films

Silicon nitride and boron nitride thin film fabrication technology is based on the ammonolysis reactions at elevated temperatures in the vapour phase. Silicon nitride deposition reactions are conducted using silicon hydrides, silicon halides, ammonia and hydrazine.<sup>8</sup>

The results of kinetic studies of  $\text{SiH}_4$  and  $\text{SiCl}_4$  ammonolysis have been summarised.<sup>8,34</sup> Only a few publications concerned with the kinetics of dichlorosilane ammonolysis are available, and these data have not been reviewed so far. Below we present the most important data on the kinetics and growth mechanisms of the systems involving  $\text{SiH}_4$ ,  $\text{SiCl}_4$ ,  $\text{SiH}_2\text{Cl}_2$  and  $\text{NH}_3$ .

### 1. System $\text{SiH}_4$ – $\text{NH}_3$

The main kinetic characteristics of the process of silicon nitride film deposition in the temperature range 873–1123 K were determined using an isothermal reactor, operating in the ideal-displacement regime at linear gas flow rates ranging between 4 and 20  $\text{cm s}^{-1}$ . These characteristics depend on the monosilane concentration (in the range from  $1 \times 10^{-5}$  to  $7 \times 10^{-5}$   $\text{mol litre}^{-1}$ ) and ammonia concentration (in the range from  $2 \times 10^{-5}$  to  $2.5 \times 10^{-2}$   $\text{mol litre}^{-1}$ ). The film growth rate increases in proportion to the increase in the monosilane concentration; the activation energy for this reaction, equal to 160.6  $\text{kJ mol}^{-1}$ , was determined from the temperature dependence of the rate constant. The reaction rate is independent of the ammonia concentration in the range from  $1 \times 10^{-5}$  to  $1 \times 10^{-3}$   $\text{mol litre}^{-1}$  and then monotonically increases. Taken altogether, the kinetic data obtained were described by the following empirical equation:<sup>8</sup>

$$W = k_1[\text{SiH}_4] \left[ \frac{k_2[\text{NH}_3]}{1 + k_2[\text{NH}_3]} + (1.80 \pm 0.05) \right] \frac{1}{1 + k_3[\text{H}_2]}. \quad (3)$$

The coefficients of this equation are listed in Table 3. The  $k_1$  constants of the processes carried out at reduced pressures are five to ten times higher than those carried out at atmospheric pressure. The difference is more pronounced when comparing the data for processes performed at higher temperatures. One can assume that the more accurate  $k_1$  values were determined in the experiments at a reduced pressure. This permits the most accurate determination of the rates at low degrees of monosilane conversion (here, the content of such a reaction product as, *e.g.*, hydrogen in the vapour phase, can be neglected).

To analyse the reaction of monosilane with ammonia, let us return to Fig. 5, which presents the silicon nitride growth rate distribution along the isothermal zone of the reactor. The decrease in the monosilane concentration during the reaction corresponds

**Table 3.** Parameters of empirical equation (3) obtained for the low and atmospheric pressure CVD reactors ( $\text{\AA litre mol}^{-1} \text{ min}^{-1}$ ).<sup>8</sup>

| T / K | $k_1$                        | $k_2$              | $k_3$              |
|-------|------------------------------|--------------------|--------------------|
|       | LPCVD                        | APCVD              |                    |
| 873   | —                            | $0.58 \times 10^6$ | —                  |
| 973   | $(10.6 \pm 1.6) \times 10^7$ | $0.81 \times 10^7$ | $0.26 \times 10^4$ |
| 1023  | $(4.9 \pm 0.6) \times 10^8$  | —                  | —                  |
| 1073  | $(6.7 \pm 0.7) \times 10^8$  | $0.33 \times 10^8$ | $0.11 \times 10^4$ |
| 1123  | $(10.6 \pm 0.2) \times 10^8$ | —                  | —                  |

to 30%–50% monosilane conversion. At these degrees of conversion, the monosilane decomposition rate is given by:<sup>35</sup>

$$\frac{d[\text{H}_2]}{dt} = 10^{13.2} \exp\left(-\frac{214.0}{RT}\right) [\text{SiH}_4].$$

Unfortunately, this equation is valid for a relatively narrow temperature range. But the assumption of its validity at  $T = 973$  K is such that, if the overall reaction is limited by the rate of the homogeneous reaction, these degrees of conversion will be attained at a distance of a few millimetres from the beginning of the isothermal zone. These estimations suggest that thermal decomposition of monosilane, considered as a stage of the synthesis of silicon nitride, is a fast reaction. The reactions

result in the formation of the vapour-phase species  $\text{SiH}_2$  and  $\text{SiH}_3$ , involved in the interaction with the solid surface:

The composition of the particles forming the solid phase varies depending on the degree of monosilane conversion. Tetravalent silicon in  $\text{SiH}_{y(\text{sol})}$  is involved in Si–H bonding and in the bonds with the atoms of the solid phase (Si–Si or Si–N). At  $y = 2$ , the surface  $\text{SiH}_2$  group is not an adsorption site, but at  $y < 2$  it can form a chemisorption bond. Hydrogen desorption from silicon surfaces has been well studied<sup>36,37</sup> and it was shown that hydrogen atoms are strongly adsorbed on the silicon surface and that an exposure of 0.3 Langmuir leads to the formation of coatings similar to monolayers. Two adsorption forms can be clearly seen in the thermodesorption spectra. It is assumed that the first form corresponds to the surface complex  $\equiv\text{SiH}$ , characterised by a desorption energy of  $2.5 \pm 0.1$  eV; the second form being the structure  $=\text{SiH}_2$ , with a desorption energy of  $1.9 \pm 0.3$  eV.

Thermal decomposition of ammonia in the vapour phase at low pressures is proportional to the ammonia and inert gas concentrations, the rate constant (in  $\text{s}^{-1}$ ) being given by:<sup>38</sup>

$$k = 10^{14.4} \exp\left(-\frac{275.8}{RT}\right).$$

In studies of the thermal decomposition of ammonia in ammonia–argon mixtures at Ar concentrations in the range  $6 \times 10^{-4}$ – $3 \times 10^{-3}$  mol  $\text{cm}^{-3}$ , the first order rate constant (in  $\text{s}^{-1}$ ) is found from the equation:

$$k = 10^{12.82 \pm 0.54} \exp\left(-\frac{409.6 \pm 20.9}{RT}\right).$$

The reaction proceeding under these conditions involves breaking of the N–H bond, characterised by a dissociation energy of 427.3 kJ  $\text{mol}^{-1}$ .

Vapour-phase synthesis produces no stable intermediates ( $\text{SiH}_4$  and  $\text{NH}_3$ ). A laser IR heating study<sup>39</sup> of the pyrolysis of monosilane–ammonia mixtures revealed (i) almost no decrease in the ammonia concentration under conditions of fast monosilane decomposition and (ii) the absence of stable products of the reaction between monosilane and ammonia, in the vapour phase. However, in the presence of ammonia the activation energy for monosilane pyrolysis decreases from  $250.4 \pm 8.4$  to  $154.2 \pm 8.4$  kJ  $\text{mol}^{-1}$ . No simple explanation for this effect has been proposed as yet. One can assume that the reaction between ammonia and monosilane results in unstable products, which favours generation of radicals. One such product can be silylamine

$\text{H}_2\text{NSiH}_3$ . In contrast to similar phosphorus and arsenic compounds,  $\text{H}_2\text{PSiH}_3$  and  $\text{H}_2\text{AsSiH}_3$ , silylamine is unstable; attempts at detecting it in the vapour phase having failed.

Thus, vapour-phase decomposition of ammonia can occur only at temperatures that are much higher than the temperature interval under study, 873–1073 K. Therefore, the decomposition of ammonia mainly proceeds by a heterogeneous mechanism, described by the following reactions:

As can be seen, the surface of the growing silicon nitride film meets the conditions necessary for establishment of an adsorption equilibrium. For instance, conventional film growth rates lie in the range  $10^{-2}$ – $10^{-1}$  nm  $\text{s}^{-1}$  (*i.e.*,  $\sim 5 \times 10^{14}$  molecule  $\text{cm}^{-2}$   $\text{s}^{-1}$ ). The collision frequency of  $\text{NH}_3$  molecules with the surface is  $3 \times 10^{16}$  molecule  $\text{cm}^{-2}$   $\text{s}^{-1}$  at a partial pressure of 1330 Pa, being a few orders of magnitude higher than the growth rate. Therefore, reaction (4) results in the establishment of an equilibrium, which is followed by a concentration dependence of the process, according to the Langmuir equation. The effective heat of adsorption of ammonia on the silicon nitride surface is 95.3 kJ  $\text{mol}^{-1}$ .

Decomposition of monosilane and ammonia leads to the formation of groups containing Si–H or N–H bonds on the film surface. The presence of chemisorbed hydrogen atoms on the surface hampers further adsorption; because of this, reactions producing active sites (hydrogen desorption reactions) are needed:

The retarding effect of hydrogen in the temperature range 973–1073 K at  $[\text{SiH}_4] = 3.0 \times 10^{-5}$  and  $[\text{NH}_3] = 6.4 \times 10^{-3}$  mol litre $^{-1}$  manifests itself as a dramatic decrease in the deposition rate<sup>40</sup> upon changing the hydrogen concentration from 0 to  $3.5 \times 10^2$  mol litre $^{-1}$ . The effective heat of hydrogen adsorption on the silicon nitride surface, determined from the temperature dependence of the adsorption constant, is 67.3 kJ  $\text{mol}^{-1}$ . Yet another reason for the retardation of the synthesis of silicon nitride in the presence of hydrogen can be the reversibility of the vapour-phase reaction, *e.g.*,

In this case

$$[\text{SiH}_2] = \frac{[\text{SiH}_4]}{[\text{H}_2]} K,$$

where  $K$  is the equilibrium constant.

Based on the natural assumption that the reaction rate is proportional to the concentration of  $\text{SiH}_2$  particles, we summarise that the temperature dependence of the reaction rate must have the form  $\exp[-(E_a + \Delta H)/RT]$ , where  $E_a$  is the activation energy for the reaction proceeding in the absence of hydrogen in the vapour phase, and  $\Delta H$  is the enthalpy of the reaction of  $\text{SiH}_2$  production from monosilane. The enthalpies of formation of monosilane and silylene are 34.6 and 247.9 kJ  $\text{mol}^{-1}$ , respectively;<sup>41</sup> therefore, the effective activation energy for the reaction must increase by 213.3 kJ  $\text{mol}^{-1}$  in the presence of hydrogen. It was experimentally found that the activation energy for the deposition of silicon nitride films in the presence of hydrogen is 234 kJ  $\text{mol}^{-1}$ , *i.e.*, increases by  $\sim 66$ –75 kJ  $\text{mol}^{-1}$ . Hence, our assumption of shift of the equilibrium in a certain vapour-phase reaction in the presence of hydrogen contradicts the experimental data.

Thus, the growth rate of silicon nitride films in the reaction of monosilane with ammonia is determined by a transformation in the adsorption layer, hydrogen desorption being the slowest stage. The results of our qualitative considerations permit the derivation of an expression for the growth rate of dielectric films. Let us

assume that four types of adsorption site can be present on the surface of a growing silicon nitride film. These types are as follows: **I** —  $\text{>Si}$ , **II** —  $\text{>SiH}_2$ , **III** —  $\text{>Si(NH}_3\text{)}_{(\text{ads})}$  and **IV** —  $\text{>SiNH}$ .

Assume also that only one reaction, *e.g.*, reaction (5), can proceed in the vapour phase. Consider the following reactions involving the adsorption sites on the surface of the growing film:

The reaction proceeding in the interior of the growing film is:

In addition to the stages considered above, a side reaction of ammonia decomposition can probably proceed on the surface of the growing film:

As the gas stream moves along the axis of the isothermal reactor, this reaction provides an increasing concentration of hydrogen in the mixture, which results in a decrease in the silicon nitride growth rate.

Taking into account the scheme of consecutive and concurrent reactions taking place on the surface of the growing film (see above), the equation for the growth rate of the dielectric film can be written in the form:

$$W = k_1[\text{I}][\text{SiH}_4] + k_4[\text{III}] + k_5[\text{II}][\text{SiH}_2] + k_6[\text{IV}][\text{SiH}_2].$$

Note that in this expression, the growth rate of structural units containing Si–N bonds is determined by the terms containing the  $k_4$  and  $k_6$  constants. The terms containing the  $k_1$  and  $k_5$  constants are responsible for the growth rate of structural units containing Si–Si bonds. This means that the stoichiometry of the films synthesised will change, depending on the reaction conditions. The rates of the stages governed by the  $k_5$  and  $k_6$  constants explicitly depend on the concentrations of the intermediate products of monosilane decomposition in the vapour phase ( $\text{SiH}_2$  and  $\text{SiH}_3$ ); therefore, specific features of the vapour-phase reactions will manifest themselves in the kinetics of silicon nitride film growth.

## 2. System $\text{SiCl}_4$ – $\text{NH}_3$

Experimental data on silicon nitride deposition in the  $\text{SiCl}_4$ – $\text{NH}_3$  system have been summarised.<sup>8,18,34</sup> The silicon nitride film growth rate distribution profile along the length of the isothermal zone of a flow tube isothermal LPCVD reactor, in the temperature range 1023–1173 K, at  $\text{SiCl}_4$  and  $\text{NH}_3$  concentrations lying in the ranges  $1 \times 10^{-5}$ – $1 \times 10^{-4}$  and  $1 \times 10^{-4}$ – $2 \times 10^{-3}$  mol litre<sup>-1</sup>, respectively, has a characteristic curve shape with a maximum, similar to the curves shown in Fig. 5. An increase in the linear flow rate of the gas mixture leads to a shift of the maximum into the interior of the reactor. These data suggest that the criterion for plug reactors is met in this case.<sup>42</sup> The dependence of the maximum reaction rate on the ammonia concentration at various  $\text{SiCl}_4$  concentrations, and on the  $\text{SiCl}_4$  concentration at a constant  $\text{NH}_3$  concentration, show that initially the reaction rate is proportional to the  $\text{NH}_3$  and  $\text{SiCl}_4$  concentrations. At specified  $\text{SiCl}_4$  concentrations, the region of zero order reaction with respect to

$\text{NH}_3$  is clearly seen, starting from a certain concentration of  $\text{SiCl}_4$ . A change in the  $\text{SiCl}_4$  concentration at a specified  $\text{NH}_3$  concentration initially leads to a linear increase in the reaction rate, which is then replaced by a region corresponding to zero order with respect to  $\text{SiCl}_4$ . In mixtures with a large excess of ammonia, the reaction rate increases with the  $\text{SiCl}_4$  concentration, faster than does a linear function.

Taking into account the characteristic dependences of the silicon nitride film growth rate on the ammonia concentration, it was assumed that the growth mechanism corresponds to a heterogeneous reaction, similar to the Langmuir–Hinshelwood reaction. This means that the process is treated as a reaction in the adsorption layer, with the reaction rate governed by the coverage of the surface of the growing film by the adsorbed  $\text{SiCl}_4$  and  $\text{NH}_3$  molecules. However, the aforementioned observations show that this assumption can only be valid for a particular set of reaction parameters. For instance, if wafers are vertically arranged in the isothermal LPCVD reactor (see Fig. 4d), the deposition rate depends on the spacing between wafers.<sup>43</sup> Analysis of the results obtained show that these features correspond to retardation at the stage of surface transformation, with allowance for diffusion supply of reagents from the vapour phase.

A strong dependence of the reaction rate on the reactor geometry was also established for the APCVD reactor at high reagent concentrations. Figure 10 presents the results obtained in two series of experiments, carried out using reactors of 67 and 14 mm diameter. As can be seen, the maximum growth rate decreases as the diameter of the reactor decreases. The results obtained can be understood if we assume that the film formation is preceded by a volume vapour-phase chemical reaction in the reactor. Therefore, the overall process must be analysed from the standpoint, according to which the synthesis of silicon nitride in the reaction of  $\text{SiCl}_4$  with  $\text{NH}_3$  proceeds as a two-path multistage reaction, controlled by the contributions of both consecutive and concurrent transformations in the vapour phase and on the surface of the growing film. Here, it is important to take into account the specific features of the chemical interactions in the  $\text{SiCl}_4$ – $\text{NH}_3$  system.

**Figure 10.** Silicon nitride film growth rate plotted vs. residence time for reactors of diameter 67 (1) and 14 mm (2).<sup>42</sup>  
 $[\text{SiCl}_4] = 6.3 \times 10^{-5}$  mol litre<sup>-1</sup>,  $[\text{NH}_3] = 1 \times 10^{-3}$  mol litre<sup>-1</sup>,  $T = 1023$  K.

Lin has shown<sup>17</sup> that the first intermediate product of the vapour-phase reaction is  $\text{SiNH}_2\text{Cl}_3$  and that subsequent reactions result in the formation of  $\text{Si(NH}_2\text{)}_2\text{Cl}$  and  $\text{Si}_2\text{NHCl}_6$ . These features can be explained assuming a multi-stage character for the reactions

or

The variety of polymeric particles, containing several  $\text{NH}_2$  groups, shows that subsequent reactions proceed as a sequence of random collisions.

One can assume that the vapour-phase reaction results in  $\text{SiNH}_2\text{Cl}_3$ , and in the simplest case, the film growth mechanism can involve two consecutive stages with rate constants  $k_1$  and  $k_2$ :<sup>44</sup>

An expression for the maximum deposition rate in flow reactors, with inclusion of the rate constants for the reaction stages listed above, was derived for the operational regimes in the regions of zero-order reaction with respect to  $\text{NH}_3$ .<sup>44</sup> In its simplified form, it is as follows:

$$W_{\max} \approx k_2[\text{SiCl}_4]_0 \left( \frac{S}{V} \frac{k_2}{k_1} \right)^{[(V/S)(k_1/k_2)-1]^{-1}},$$

where  $[\text{SiCl}_4]_0$  is the concentration of  $\text{SiCl}_4$  at the beginning of the reaction zone and  $S/V$  is the surface-area-to-volume ratio of the reactor. The estimates of the rate constants are listed below:

$$k_1 = 1.3 \times 10^2 \exp\left(-\frac{25}{RT}\right),$$

$$k_2 = 1.5 \times 10^{25} \exp\left(-\frac{75.3}{RT}\right)$$

(here,  $k_1$  is given in  $\text{s}^{-1}$  and  $k_2$  is given in  $\text{molecule cm}^2 \text{s}^{-1}$ ).

### 3. System $\text{SiH}_2\text{Cl}_2 - \text{NH}_3$

The kinetics of interactions in the  $\text{SiH}_2\text{Cl}_2 - \text{NH}_3$  system in various types of reactors is much less studied, compared to other systems.<sup>45–53</sup> The most interesting results were obtained in the studies carried out using isothermal flow LPCVD reactors,<sup>48–50</sup> in which the kinetics of film growth from monosilane, dichlorosilane, dimethyldichlorosilane and silicon tetrachloride was compared directly under identical conditions.

The kinetics of silicon nitride film growth in the ammonolysis of dichlorosilane was investigated in the temperature range 1023–1123 K with variable reagent concentrations. The  $[\text{NH}_3]/[\text{SiH}_2\text{Cl}_2]$  reagent ratio was varied from 1 to 17, the pressure varied between 60 and 1200 Pa and the linear flow rate of the gas mixture was in the range 1450–2870  $\text{cm s}^{-1}$ . In this range of linear flow rates of the gas mixture along the reactor, the shape of the growth rate profiles and the absolute values of the reaction rates were constant, the deposition rate was first-order with respect to dichlorosilane and pseudo zero order with respect to ammonia at large excesses of  $\text{NH}_3$  with respect to  $\text{SiH}_2\text{Cl}_2$ . An empirical expression for the deposition rate (in  $\text{nm s}^{-1}$ ) takes the form:

$$W = 3.15 \times 10^{12} \exp\left(-\frac{152.3}{RT}\right) [\text{SiH}_2\text{Cl}_2].$$

Two possible mechanisms of ammonolysis of dichlorosilane have been proposed.<sup>51–53</sup> One of them is similar to the mechanism of the ammonolysis of  $\text{SiCl}_4$ , involving formation of intermediate products (e.g.,  $\text{SiH}_2\text{NH}_2\text{Cl}$ ) and the other mechanism involves a proton abstraction and the formation of  $\text{SiCl}_2$  as an intermediate. Analysis of the silicon nitride deposition rate profiles obtained for the ammonolysis of  $\text{SiH}_4$ ,  $\text{SiH}_2\text{Cl}_2$  and  $\text{SiCl}_4$  (see Fig. 11 a) reveals

**Figure 11.** Silicon nitride deposition rate profiles obtained for ammonolysis of monosilane (1), dichlorosilane (2) and silicon tetrachloride (3) in low-pressure flow CVD reactor (a) and the deposition rate profiles predicted by the theory of consecutive one-side reactions for  $k_2/k_1 = 5$  (1) and  $k_2/k_1 = 0.2$  (2) (b);<sup>49</sup>

(a): concentration of silicon-containing compound is  $1.86 \times 10^{-6} \text{ mol litre}^{-1}$ , 'ammonia-to-silicon-containing compound' concentration ratio is 17,  $r_r = 61 \text{ mm}$ ,  $T = 1098 \text{ K}$ ,  $P = 333 \text{ Pa}$ ,  $v = 650 \text{ cm s}^{-1}$ .

significant differences between the mechanisms of the ammonolysis of monosilane and its chlorinated derivatives, also giving an indication of the similar mechanisms of ammonolysis of other chlorinated derivatives. Moreover, the profiles for ammonolysis of dimethyldichlorosilane,  $\text{SiH}_2\text{Cl}_2$  and  $\text{SiCl}_4$  are nearly identical, which points to the possibility of forming intermediates similar to  $(\text{CH}_3)_2\text{SiNH}_2\text{Cl}$ . The ammonolyses of  $\text{SiH}_2\text{Cl}_2$  and  $\text{SiCl}_4$  are characterised by similar effective rate constants in the  $W_{\max}$  regions (0.74 and 0.46  $\text{cm s}^{-1}$ , respectively) and conversions (26.6% and 18%, respectively), which are much lower than for the ammonolysis of  $\text{SiH}_4$  (4.9  $\text{cm s}^{-1}$  and 46.5%).

Taking into account the aforementioned observation, the growth of silicon nitride films can be correctly described in terms of a two-step reaction of homogeneous formation and heterogeneous consumption of intermediate products. The dependences of the accumulation of the end product on the reaction time ( $d[F]/dt$ ) (see Fig. 11 b), obtained in the framework of the theory of consecutive one-side first-order reactions

(A is the starting substance, I is the intermediate product and F is the end product) for the different limiting stages, are similar in shape to the curves obtained for the deposition of silicon nitride films (see Fig. 11 a). The limiting stage of the ammonolysis of monosilane is the formation of the intermediate product, while the ammonolysis of chlorinated monosilane derivatives is limited by the stage of heterogeneous consumption of the intermediate product.

### 4. Industrial methods of deposition of silicon nitride films

Since the early 1980s, the most widely used (in electronics) industrial method involves the use of dichlorosilane in flow LPCVD reactors. Typical conditions for the deposition reaction are as follows:  $T \approx 973 \text{ K}$  at a pressure of less than 65 Pa. In this case, the deposition rates are of the order of a few hundredths of a

nanometre per second, and the thickness non-uniformity on wafers of diameters smaller than 200 mm is less than  $\pm 2\%$  at a foreign defect (microparticles of size exceeding  $0.2 \mu\text{m}$ ) level of less than  $0.1 \text{ defect cm}^{-2}$ . The concentration of hydrogen in the films is  $\sim 4 \text{ at.}\%$  and the refractive index varies in the range  $1.96\text{--}2.00$ . As old CVD equipment for electronics is replaced by single-wafer reactors (wafer diameter up to 300 mm) (see Fig. 4b), interest in the ammonolysis of monosilane is retained. This is due to low degree of chloride conversion and correspondingly to the extensive formation of by-products (silicoimides) that poison the vacuum systems of CVD reactors.

Low-temperature deposition of silicon nitride films from mixtures of monosilane, ammonia and/or nitrogen involves plasma activation [most often, the so-called diode systems (see Fig. 4b) are used]<sup>54</sup> and occurs at temperatures below 723 K. In this case, the film composition strongly depends on the temperature and on the ammonia/monosilane ratio. Unfortunately, low-temperature silicon nitride films contain hydrogen, bonded to silicon or nitrogen; the total concentration of hydrogen exceeding  $10^{21} \text{ atom cm}^{-3}$ . Concentration depends on the deposition temperature and, for the  $\text{SiH}_4\text{--NH}_3\text{--N}_2$  system, can be 20 at.%–30 at.% at 573 K and up to 5 at.%–10 at.% at 873 K. Removal of ammonia from monosilane–nitrogen mixtures on increasing in the high-frequency power supplied, allows a 25 at.%–30% reduction of the hydrogen concentration at the same deposition temperature.<sup>55</sup>

At lower temperatures (373–573 K) under plasma activation conditions, it is also possible to use plasma pyrolysis of organo-element compounds that simultaneously contain silicon and nitrogen (hexamethyldisilazane, hexamethylcyclotrisilazane and diethylaminotrimethylsilane). By varying the high-frequency power supplied, one can vary the concentration of  $\text{CH}_3$  groups in the end polymeric material, which is often called 'silicon nitride'. The molecules of the starting compounds contain no Si–H bonds, which are formed during the synthesis<sup>56</sup> due to abstraction of protons and  $\text{CH}_3$  groups from the molecules of the starting compounds, the formation of radicals adsorbed on the surface, followed by proton addition to broken silicon bonds. Thus, fabrication of hydrogen-free films by the plasma pyrolysis of organo-element compounds appears to be impossible.

## V. Deposition of silicon oxynitride films

A number of systems were proposed for the CVD synthesis of SiON films, e.g.,  $\text{SiH}_4\text{--NH}_3\text{--CO}_2$ ,  $\text{SiH}_4\text{--NH}_3\text{--NO}$  and  $\text{SiH}_4\text{--NH}_3\text{--N}_2\text{O}$ .<sup>18, 57</sup> Let us consider the first system in more detail.

In deriving an expression for the deposition rate of films of various chemical compositions, one must use the mole-based units, e.g.,  $\text{mol min}^{-1} \text{ cm}^{-1}$ . Using ellipsometric measurements of the film thickness and the refractive index, one can determine the chemical composition by a linear approximation, assuming that the refractive index,  $RI_{\text{SiON}}$ , of the silicon oxynitride film is defined through the mole fractions of silicon nitride ( $z_1$ ) and silicon dioxide ( $z_2$ ) (the refractive indices of silicon nitride and silicon dioxide are  $RI_n = 2.025$  and  $RI_{\text{ox}} = 1.45$ , respectively):

$$RI_{\text{SiON}} = z_1 RI_n + z_2 RI_{\text{ox}}.$$

The growth rate,  $W_M$  ( $\text{mol min}^{-1}$ ), of silicon oxynitride film can be found from the equation:

$$W_M = \frac{\rho_f S W}{M} 1.67 \times 10^{-11}.$$

Here  $\rho_f$  and  $M$  are the density and the molecular mass (they can be determined with ease using the data listed in Table 4),  $S$  is the surface area of the hot wafer and  $W$  is the growth rate ( $\text{nm s}^{-1}$ ).

Experiments were carried out in a vertical non-isothermal reactor of surface area  $1058 \text{ cm}^2$ , at a gas flow rate of  $1.83 \text{ dm}^3 \text{ s}^{-1}$ , under conditions where the reaction was not

**Table 4.** Characteristics of silicon oxynitride film.<sup>18</sup>

| Refractive index | Molecular mass | Molar refraction | Density / $\text{g cm}^{-3}$ |
|------------------|----------------|------------------|------------------------------|
| 2.025            | 140.0          | 23.03            | 3.09                         |
| 1.9              | 121.6          | 19.46            | 2.91                         |
| 1.8              | 106.4          | 16.51            | 2.75                         |
| 1.7              | 92.0           | 13.71            | 2.59                         |
| 1.6              | 78.4           | 11.07            | 2.42                         |
| 1.5              | 66.4           | 8.74             | 2.23                         |
| 1.45             | 60.0           | 7.50             | 2.15                         |

limited by the mass supply rate. The reaction is first order with respect to monosilane and the deposition rate is independent of the  $\text{NH}_3$  and  $\text{CO}_2$  concentrations in the range from  $10^{-3}$  to  $5 \times 10^2 \text{ M}$ . The empirical dependences of the formation of  $\text{SiO}_2$ ,  $\text{Si}_3\text{N}_4$  and silicon oxynitride SiON at 1123–1323 K are as follows:

$$k_{\text{SiO}_2} = 2.4 \times 10^5 \exp\left(-\frac{100.3}{RT}\right) [\text{SiH}_4], \quad (6)$$

$$k_{\text{Si}_3\text{N}_4} = 22.3 \times 10^5 \exp\left(-\frac{121.2}{RT}\right) [\text{SiH}_4], \quad (7)$$

$$k_{\text{SiON}} = 3.5 \times 10^5 \exp\left(-\frac{98.2}{RT}\right) [\text{SiH}_4].$$

Considering the oxynitride film growth as a reaction following two concurrent paths, viz., ammonolysis of monosilane ( $W_n$ ) and oxidation of monosilane ( $W_{\text{ox}}$ ), the expression for  $W_{\text{SiON}}$  can be written as:

$$W_{\text{SiON}} = W_n + W_{\text{ox}}.$$

Then, assuming that the rate of formation of the structural units  $\text{SiN}_{4/3}$  and  $\text{SiO}_{4/2}$  is proportional to the surface coverage of the  $\text{NH}_3$  and  $\text{CO}_2$  molecules ( $\theta_{\text{NH}_3}$  and  $\theta_{\text{CO}_2}$ , respectively), and taking into account Eqns (6) and (7), one can write

$$W_n = k_{\text{Si}_3\text{N}_4} [\text{SiH}_4] \theta_{\text{NH}_3}^{l_1},$$

$$W_{\text{ox}} = k_{\text{SiO}_2} [\text{SiH}_4] \theta_{\text{CO}_2}^{l_2},$$

where  $l_1$  and  $l_2$  are the reaction orders with respect to their corresponding components. Assuming that  $\text{NH}_3$  and  $\text{CO}_2$  are the most intensely adsorbed species, we get

$$\theta_{\text{NH}_3} = \frac{p_{\text{NH}_3}}{(\alpha_{\text{CO}_2}/\alpha_{\text{NH}_3})p_{\text{CO}_2} + p_{\text{NH}_3}},$$

$$\theta_{\text{CO}_2} = \frac{p_{\text{CO}_2}}{(\alpha_{\text{CO}_2}/\alpha_{\text{NH}_3})p_{\text{NH}_3} + p_{\text{CO}_2}},$$

where  $\alpha_{\text{CO}_2}$  and  $\alpha_{\text{NH}_3}$  are respectively the constants of adsorption equilibrium between  $\text{CO}_2$  and  $\text{NH}_3$ .

Treatment of experimental data using this approach gave the characteristic dependence of the partial rates of formation of structural units of silicon nitride and silicon dioxide, which were used to determine the coefficients  $l_1$  and  $l_2$  ( $l_1 = 0.6$  and  $l_2 = 0.5$ ). Generally, the rates of formation of the corresponding structural units, in the course of silicon oxynitride film growth, differ from the growth rates of the silicon nitride and silicon dioxide films. In particular, the rate of formation of  $\text{SiN}_{4/3}$  in silicon oxynitride is lower than in silicon nitride, while the rate of formation of  $\text{SiO}_{4/2}$  in silicon oxynitride is higher than that in silicon dioxide. However, it should also be noted that these differences are small, being only slightly larger than the scatter of experimental data.

Recently, oxynitride films used as anti-reflecting coatings in electronics have been fabricated from  $\text{SiH}_4\text{--NH}_3\text{--N}_2\text{O--N}_2$  mixtures using low-temperature plasma synthesis. Such methods

allow films of a wide range of compositions to be fabricated by varying the component ratio in the gas mixture.<sup>54</sup>

## VI. Deposition of silicon dioxide films

Silicon dioxide films can be fabricated in the temperature range from a few hundreds of degrees to 1300 K (and higher) by oxidation, pyrolysis, hydrolysis and plasma-enhanced reactions. Below we consider the results of investigations of some most important processes in the CVD synthesis of oxide films.

### 1. Oxidation

Among the practically used CVD reactions, oxidation reactions are the best studied. They are conducted using monosilane, silicon, chlorides and the alkyl and alkoxy derivatives of monosilane as sources of silicon and oxygen, nitrogen oxides, CO<sub>2</sub>, ozone–oxygen mixtures and hydrogen peroxide as oxidants. Low-temperature film deposition (at temperatures below 850 K) is performed using a plasma of the starting components.

#### a. System SiH<sub>4</sub>–O<sub>2</sub>

At present, the SiH<sub>4</sub>–O<sub>2</sub> system is the best studied and most widely used in the synthesis of silicon dioxide films. This system has been the subject of long-term studies in different types of reactors as the method for synthesising of silicon dioxide films at temperatures below 720 K and as the basic system for the synthesis of complex silicate glasses.

The combustion of monosilane was first studied by Shantarovich,<sup>58</sup> who established a chain-radical character for this process. The ‘combustion peninsula’, which determines the range of the temperature and pressure values suitable for reaction in the SiH<sub>4</sub>–O<sub>2</sub> system, is shown in Fig. 12. If the parameters of a system lie outside the ‘combustion peninsula’, the gas mixture is inert and can be kept with no apparent changes as long time as required. Thus, in any case, the reaction products (aerosil, silicon dioxide thin film or both) in the SiH<sub>4</sub>–O<sub>2</sub> system are formed as a result of a branched chain process (BCP). Experimentally, the motion from the outside towards the interior of the ‘combustion peninsula’ (on, *e.g.*, raising the temperature with constant values for the other parameters) will give a stepwise shape to the reaction rate curve. In connection to this, attempts to explain the experimentally observed stepwise temperature dependence of silicon dioxide film deposition rate by invoking the mechanism of a reaction between the adsorbed SiH<sub>4</sub> and O<sub>2</sub> molecules on the silicon or silicon dioxide surface<sup>59,60</sup> (*e.g.*, the Langmuir–Hinshelwood mechanism), seem to be unsubstantiated.

The character of the monosilane oxidation reaction, which proceeds as an SiH<sub>4</sub>–O<sub>2</sub> gas mixture moving along the horizontal tube reactor, is as follows: the reaction rate increases until a maximum thickness of silicon dioxide thin film is achieved,<sup>61</sup> and

**Figure 12.** ‘Ignition peninsula’ for combustion of monosilane. [SiH<sub>4</sub>] (vol. %): 49 (1), 39 (2), 30 (3) and 14 (4).<sup>58</sup>

**Figure 13.** Silicon dioxide growth rate profiles along the reactor axis for different temperature profiles. (a) [O<sub>2</sub>]/[SiH<sub>4</sub>] = 10 (1), 30 (2), 50 (3), 100 (4), 300 (5); (b) [O<sub>2</sub>]/[SiH<sub>4</sub>] = 10 (1), 70 (2), 120 (3), 180 (4); [SiH<sub>4</sub>] =  $2.9 \times 10^{-2}$  mol.%, linear flow rate 19 cm s<sup>-1</sup>. Curves 6 (a) and 5 (b) denote the temperature profiles in the reactor.<sup>61</sup>

then rapidly decreases (Fig. 13a,b). A comparison of these dependences with the temperature profile in the reactor showed that the reaction is accelerated as the temperature increases. Also of note is that the initial portions of the curves are shifted towards the inside of the reactor as the [O<sub>2</sub>]/[SiH<sub>4</sub>] ratio increases, *i.e.*, corresponding to the points characterised by higher temperatures.

Note that in this case, the reaction rate at the maximum of the curve is not a characteristic parameter of the process. In particular, Fig. 13a shows that for the reactor with a steep temperature profile, the  $W_{\max}$  value increases as the oxygen concentration in the gas mixture increases. However, in the case of a flattened temperature profile in the reactor (see Fig. 13b), the maximum in the  $W(x)$  dependences initially increases and then decreases as the [O<sub>2</sub>]/[SiH<sub>4</sub>] ratio increases; as a result, we contain a dome-shaped character for the deposition rate dependences, plotted in the  $W_{\max}$ –[O<sub>2</sub>]/[SiH<sub>4</sub>] coordinates.

Using these dependences, we can compare the ignition limits of gas mixtures with the critical parameters determining the formation of silicon dioxide thin films. Data on the degree of monosilane combustion are presented in Fig. 14, and in Fig. 15 we compare the regions of SiO<sub>2</sub> film growth and monosilane combustion. These results show that film growth occurs only under conditions corresponding to monosilane ignition (in this case, the upper ignition limit). The film growth conditions correspond to O<sub>2</sub> and SiH<sub>4</sub> concentrations that are below the corresponding straight lines. Here, we have

**Figure 14.** Degree of monosilane combustion,  $[\text{SiH}_4]_j/[\text{SiH}_4]_0$ , plotted vs.  $\text{O}_2$  concentration.<sup>18</sup>  
 $T = 573$  (1),  $623$  (2),  $673$  (3),  $693$  (4),  $723$  K (5);  $[\text{SiH}_4] = 8.7 \times 10^{-2}$  mol. %.

$$[\text{O}_2]/[\text{SiH}_4] = A \exp\left(\frac{-33.4}{RT}\right),$$

where  $A$  is the pre-exponent.

By studying the film growth rate distribution along the isothermal reactor zone<sup>62,63</sup> (Fig. 16), it is possible to establish the laws of silicon dioxide film growth under the conditions corresponding to the lower ignition limit. Particular attention should be paid to the regular increase in the growth rate towards the end of the isothermal zone. It becomes more pronounced as the partial pressure of monosilane increases and reflects the acceleration of the reaction due to the development of the branched chain process.

The limiting character of the phenomenon is illustrated in Fig. 17. We can determine the pressure ( $P_1$ ), corresponding to the lower ignition limit of the gas mixture. The expression for  $P_1$  contains the rate constants for the branching ( $k_b$ ) and heterogeneous loss ( $k_d$ ) of the reaction chains

$$P_1 = \frac{k_d}{2k_b f},$$

where  $f$  is the mole fraction of the component involved in the act of branching.<sup>64</sup>

**Figure 15.**  $\text{SiO}_2$  film growth regions (solid lines) and monosilane ignition regions (dashed lines).<sup>18</sup>  
 $T = 573$  (1),  $623$  (2),  $673$  (3),  $693$  K (4).

**Figure 16.**  $\text{SiO}_2$  growth rate distribution in a horizontal isothermal reactor.<sup>63</sup>  
 $T = 413$  K, diameter of the reactor is 1.3 cm, the partial pressure of monosilane, Pa: 25.3 (1), 26.7 (2), 32.0 (3), 36.0 (4) and 40.0 (5); gas flow rate is  $0.83 \text{ cm}^3 \text{ s}^{-1}$ ,  $[\text{O}_2]/[\text{SiH}_4] = 2$ .

**Figure 17.**  $\text{SiO}_2$  growth rate plotted vs. monosilane pressure in reactors of different diameters.<sup>64</sup>  
Diameter of the reactor/cm: 2 (1), 1.6 (2) and 1.3 (3);  $T = 373$  K;  $[\text{O}_2]/[\text{SiH}_4] = 1$ , gas flow rate is  $0.56 \text{ cm}^3 \text{ s}^{-1}$ .

In practice, the BCP studies usually involve observing the ignition of the reacting gas mixture. A number of unexpected features were disclosed in determining the lower ignition limit from the chemiluminescence of the  $\text{SiH}_4 - \text{O}_2$  mixtures.

Firstly, the position of the lower ignition limit is 'sensitive' to the state of the reactor walls. This manifests itself, in particular, in different  $P_1$  values determined by approaching the limit using a mixture at a pressure lower than  $P_1$  (approach from below), and by approaching the limit using higher pressures (approach from above).

Secondly, a peculiar feature of the combustion of the  $\text{SiH}_4 + \text{O}_2$  mixture is a double ignition under static conditions.<sup>65-67</sup> Using emission spectra, the formation of excited  $\text{OH}^*$  radicals (band at 306.4 nm) in the flame was detected.<sup>66</sup> An EPR study<sup>67</sup> revealed the presence in the flame of hydroxyl groups and oxygen atoms in concentrations of  $10^{13} - 10^{14} \text{ particle cm}^{-3}$ . The active role of oxygen atoms in chain branching processes was proved in the experiments using inhibitors. It is known that the loss rate of oxygen atoms increases in the presence of propylene. For instance, the addition of  $\text{C}_3\text{H}_6$  (1%) increases the lower ignition limit by 40% at 623 K.<sup>62</sup>

Figure 18 shows that the concentrations of oxygen atoms and hydroxyl groups increase as the  $[\text{O}_2]/[\text{SiH}_4]$  ratio increases.<sup>67</sup> The following reactions in the flame are most probable:

**Figure 18.** Concentration of oxygen atoms (1) and hydroxyl groups (2) plotted vs.  $[O_2]/[SiH_4]$  ratio in the initial mixture in  $SiH_4$  flame.<sup>67</sup> Total pressure is 400 Pa,  $T = 723$  K.

Radicals  $\cdot SiH_3$ , present in the vapour phase, were detected by laser magnetic resonance. The concentration of  $\cdot SiH_3$  radicals in the monosilane flame<sup>68</sup> was  $4 \times 10^{13}$  particle  $cm^{-3}$ . Analysis of the luminescence spectrum showed that the  $\cdot OH$  radicals are in an electronic excited state and the energy of the emission quantum is  $388 \text{ kJ mol}^{-1}$ . This suggests the occurrence of the following reaction

where L is the molecule involved in ternary collision. Indirect measurements showed that  $[O][H] \approx 10^{26} \text{ particle}^2 \text{ cm}^{-6} \text{ s}^{-2}$ . In addition to the particles mentioned above, electronically excited  $SiO^*$  molecules (band  $A'\Pi-X'\Sigma^+$ , emission quantum energy  $504 \text{ kJ mol}^{-1}$ ) were identified using the luminescence spectra. No more reliable data on the composition of the gas phase in the monosilane flame are available at the moment. At the same time it must be remembered that Shantarovich<sup>58</sup> assumed the presence of an intermediate, silanone  $H_2SiO$  ('silicon aldehyde'). Products containing silicon–oxygen double bonds [silanone  $H_2SiO$ , silanoic acid  $HSiOH$  and silicic acid  $(HO)_2SiO$ ] were detected only in an argon matrix at 17 K.<sup>69</sup>

When analysing the data on the kinetics of monosilane oxidation, the possibility of the formation of short-lived products must be taken into account. The inclusion of their properties allows one to establish the mechanism of the formation of finely dispersed aerosil ( $SiO_2$ ) powder, which usually accompanies the growth of  $SiO_2$  films.

Calculations<sup>70</sup> of the following dimerisation reaction

showed that the formation of the four-membered ring occurs barrierlessly and that the enthalpy of reaction is  $\Delta H_{298}^\circ = -441.8 \text{ kJ mol}^{-1}$ . The formation of trimers and tetramers is also characterised by a large exothermic effect. Silanone decomposition by the reaction

was shown<sup>71</sup> to be hampered because its activation energy is  $358.6 \text{ kJ mol}^{-1}$ . Dimerisation of  $SiO$  proceeds barrierlessly.<sup>72</sup> Two more end products,  $H_2$  and  $H_2O$ , were identified in the vapour phase. In relation to this, two possible routes of monosilane combustion are discussed:

**Figure 19.** Degree of silane combustion  $[SiH_4]_j/[SiH_4]_0$  (1) and yields of the end gaseous products  $H_2$  (2) and  $H_2O$  (3) (rel. u.) plotted vs. the  $P_0/P_1$  ratio for a 9.4%  $SiH_4$  + 64%  $O_2$  + 26.6% He mixture at 423 K and  $P_1 = 203.9$  Pa.<sup>73</sup>

Quite reliable data are available, showing that the formation of water in the vapour phase is not due to subsequent combustion of hydrogen.<sup>73</sup> Analysis of the dependence (see Fig. 19) of the degree of monosilane combustion on the  $P_0/P_1$  ratio ( $P_0$  is the initial pressure in the mixture) shows that the hydrogen/water concentration ratio also varies with the  $P_0/P_1$  parameter. Water molecules can be formed as a result of the vapour-phase reaction and as a product of desorption from the surface of solid  $SiO_2$  particles. For this reason, no exact reaction equation for monosilane combustion has been derived to date.

Atoms and radicals produced in the combustion of monosilane in oxygen in the vapour phase are highly reactive species; their recombination on the surface results in the formation of silicon dioxide structural units. Some types of interactions can be established using the bond dissociation energy values. For instance, the reaction

produces a surface silicon atom bonded to two hydrogen atoms and to the oxide matrix through two bridging oxygen atoms. The reaction requires an energy expenditure for the breaking of two  $Si-H$  bonds; the formation of products will be accompanied by the release of the energy of two  $Si-O$  bonds and the energy of formation of the  $H_2$  molecule. This approach was used for the evaluation of thermal effects for different types of structural units (Table 5).

In analysing these data, considerable attention must be paid to the high thermal effect of forming the main structural unit, the

**Table 5.** Enthalpies of formation of structural units in the  $Si-H-O$  system.<sup>18</sup>

$\text{SiO}_{4/2}$  tetrahedron, and the structural unit  $\text{H}_2\text{SiO}_{2/2}$ , a building block with a two-dimensional chain structure. Account must also be taken of the fact that breaking of single chemical bonds with oxygen atoms is, as a rule, characterised by low activation energies<sup>74</sup> (usually, at most  $16.7 \text{ kJ mol}^{-1}$ ). This suggests that the main direction of reactions is determined by the stages involving oxygen atoms rather than molecules.

The most practically valuable problems in the synthesis of silicon dioxide thin films by the oxidation of monosilane with oxygen are the formation of aerosil, non-stationarity in the deposition process and the porosity of silicon dioxide films.

The essence of the first problem is that the sizes of aerosil microparticles are comparable with or larger than the size of elements of microelectronic devices. Therefore, it is highly probable that a microparticle arriving at the wafer surface during the film synthesis will be a reason for improper operation of the device. In relation to this, the level of microdefects in thin films is one of the most important characteristics of industrial CVD reactors. For instance, at the end of the twentieth century in semiconductor electronics, the level of extra film defects for CVD processes was less than  $0.1 \text{ defect cm}^{-2}$  for the wafer surface at microparticle sizes exceeding  $0.2 \mu\text{m}$ . Using microprobe analysis on the vapour phase in the film synthesis zone, it was established that aerosil microparticles are formed in the oxidation of monosilane by oxygen in all types of reactors.<sup>75–77</sup>

Various studies<sup>63, 78–82</sup> are of interest from the standpoint of determining the conditions for the growth of defect layers. They were carried out at relatively low deposition temperatures ( $373–673 \text{ K}$ ) and reagent pressures ( $< 133 \text{ Pa}$ ) in reactors of different sizes. A qualitative picture of the arrangement of the silicon dioxide film growth and aerosil formation regions, at constant values of other parameters, is shown in Fig. 20. The  $AB$  line in Fig. 20a corresponds to the limiting pressure  $P_1$  (no reaction occurs below  $P_1$ ). At  $P > P_1$ , silicon dioxide films are formed in the region above the portion of the  $AB$  curve (solid line) and below the pressure limiting line (dashed line). Above the dashed line lies the region of aerosil formation. As the temperature decreases, the range of pressures ( $\Delta P = P - P_1$ ) suitable for the fabrication of dioxide films regularly narrows. Below a certain temperature at  $P > P_1$  (where the curve of the limiting pressure is shown as a dashed line) the exclusive reaction product is aerosil.

**Figure 20.** Regions of  $\text{SiO}_2$  thin-film growth and aerosil formation in the  $\text{SiH}_4\text{--O}_2$  system (a) and influence of the reactor surface-to-volume ratio on positions of these regions,  $(S/V)_1 < (S/V)_2 < (S/V)_3$  (b). For details, see text.<sup>78</sup>

Analysis of the dependences shown in Fig. 20b reveals a general trend, namely, the growth regions are shifted as the ratio of the inner surface area,  $S$ , to the volume,  $V$ , of the reactor, in the deposition zone, changes. As can be seen, the  $S/V$  parameter increases as the number of the curve increases. The effect of the  $S/V$  ratio on the film growth conditions in reactors of different sizes has been studied in detail.<sup>63</sup> The deposition was performed in quartz tube reactors with horizontally arranged wafers. It was found that at a specified temperature, pressure and  $[\text{O}_2]/[\text{SiH}_4]$  ratio, the  $P_1$  values are inversely proportional to the diameter of the reactor (*i.e.*, they increase with an increase in the  $S/V$  ratio, which is characteristic of the BCP). It is important to note that an increase in the  $S/V$  ratio (decrease in the diameter of the reactor) is accompanied by (i) an increase in the limiting pressure  $P_1$  and (ii) a simultaneous regular shift of the region of formation of silicon dioxide thin films towards low temperatures; moreover, the aerosil formation boundary is also shifted. This is an indication of improved conditions for the synthesis of defect-free thin films.

Thus, only by varying the reactor geometry, is it possible to carry out the reaction in any of the three regions shown in Fig. 20a. By varying the  $S/V$  ratio within certain limits in the film growth region, one can also change the film growth rate (this parameter will decrease with an increase in the  $S/V$  ratio). In practical implementations of the BCP for the fabrication of defect-free silicon dioxide thin films, the  $S/V$  ratio must be increased by exclusion of the 'extra volumes' in reactors by, *e.g.*, filling the gaps on both sides of wafers in the tube reactor (see Fig. 4d) with hollow vessels of the same external diameter as the wafers in order to retain the gas-dynamic parameters of the reactor.

The second and third problems are characteristic of very low-temperature ( $373–473 \text{ K}$ ) conditions for film deposition in the  $\text{SiH}_4\text{--O}_2$  system. When  $\text{SiO}_2$  is deposited at such temperatures, the kinetics of film growth is strongly dependent on the state of the inner surface of the reactor.<sup>78, 79</sup> The state of the surface (first of all, the composition and structure) governs its adsorption capacity and chain loss efficiency. Changes in these properties cause changes in the rates of the heterogeneous stages, branched chain reactions and  $\text{SiO}_2$  film deposition at constant pressure, temperature and concentration of starting reagents. Even if the parameters of the deposition process can be preset and maintained at constant levels, the chemical state of the reactor surface still cannot be controlled, but it is this factor that affects the kinetics of the chain process and leads to non-stationarity of the growth rate in the initial stages. This kind of non-stationarity will be observed until the coverage of the whole reactor surface with a new  $\text{SiO}_2$  film is complete. When the surface of the growing film is covered by the adsorption layer of a specified composition, which is reproduced in the course of further deposition, the growth rate takes a constant value. If deposition begins in a reactor whose surface was preliminarily covered with a silicon dioxide film (so-called 'modified reactor'), theoretically no transient processes would occur. This is not the case however, because the chemical properties of the surface are determined by the composition of the reacting gas mixture, from which the material is formed. Therefore, the surface properties of the newly formed silicon dioxide film will, as a rule, be different from those of the starting oxide, *i.e.*, the transient process will also occur in the modified reactor.

The kinetics of the initial stages of silicon dioxide film growth, until a thickness of  $10–20 \text{ nm}$ , was studied *in situ* using a fast automated ellipsometer.<sup>79</sup> The results obtained were summarised in the form of a diagram plotted in 'pressure of the starting gas mixture ( $P$ )–chain loss efficiency' ( $\beta$ ) coordinates and shown in Fig. 21. The  $\beta$  value characterises the change in the chemical state of the surface in the course of deposition. The  $ab$  curve drawn conditionally (the particular shape of this dependence cannot be obtained from experimental data, but it is known that  $P_1$  increases with increasing  $\beta$ ) shows the change in the limiting pressure  $P_1$  upon an increase in  $\beta$ . Below this curve lies the region corresponding to no reaction. The shaded region meets the quasi-stationary growth conditions. Experiments showed that the process always

**Figure 21.** Regions with different kinetics of the initial stages of  $\text{SiO}_2$  thin film growth.<sup>78</sup>

For details, see text.  $P_1$  is the limiting pressure.

develops towards quasi-stationary growth. Depending on which direction we move along the curve (to the right or to the left), the  $\beta$  and, correspondingly,  $P_1$  values can decrease or increase.

The shape of the kinetic curves is governed by the initial conditions, *viz.*, the pressure and the chemical state of the surface. In the regions *A*, *B* and *C* (see Fig. 21) we schematically show the kinetic curves which are observed in the initial stages of growth, plotted in the 'film thickness – film growth time' coordinates. Film growth in region *A* occurs with acceleration and in the regions *B* and *C* with retardation. No stationary film growth occurs in region *B* because the growth rate decreases down to zero. Thus, all the experimentally observed shapes of the kinetic curves, which characterise the non-stationarity of the process in its initial stages, are explained by a concept of a transient process of new surface formation on the reactor walls and wafer. The properties of this surface are determined by the deposition conditions.

In studies of the kinetics of film growth until the thickness 100–1000 nm, using a quartz crystal microbalance, it was found that at temperatures below 523 K, the quasi-stationary growth, which follows the dramatic change in the growth rate in the initial stages, is retained until a thickness of 20 to 30 nm. Further increase in the film thickness leads to a monotonic (much slower compared to the changes in the initial stage) decrease in the growth rate.<sup>78</sup> The lower the synthesis temperature and the higher the pressure of the gas mixture, the more pronounced the decrease in the growth rate; in long-term experiments, the growth rate can decrease to zero.

In these experiments, the deposition rate decreases after completion of the initial transient period, in which a  $\text{SiO}_2$  layer is grown in the reactor. This means that retardation of the BCP in the course of film growth is due to other reasons, not associated with the change in the chemical state of the surface. A qualitative explanation for the decrease in the growth rate observed in this thickness range is as follows. Growth of a film is accompanied by the formation of its macro- and microstructure, which are to a great extent determined by the deposition conditions. An adsorption porosimetry study<sup>80</sup> showed that a large number of mesopores of diameter 3 to 10 nm, connected to the surface, were formed in the film under the experimental conditions. The appearance of open pores increases the real surface area of the growing film and the permeability of the film to the diffusion of the sorbed particles towards the near-surface region of the film. Taken altogether, this favours the extension of the heterogeneous reaction zone, leads to more efficient chain loss per unit surface area and, correspondingly, to a decrease in the BCP rate.

This explanation is substantiated by the following experimental results. It was found<sup>80</sup> that the porosity of thin films synthesised at temperatures below 523 K dramatically decreases upon introduction of small amounts of ammonia into the monosilane–oxygen gas mixture. Deposition of these films must not cause

a marked increase in the real surface area. If the deposition rate decreases due to the formation of the porous structure, the growth rate of such films must be independent of time. Indeed, a qualitative difference between the kinetics of thin film growth in the presence and in the absence of ammonia additives was found.<sup>81</sup> In the presence of ammonia the growth rate was independent of time until a thickness of at least 1000 nm was achieved. A constant growth rate of thin films was also observed at temperatures above 523 K because the porosity of the deposited thin film dramatically decreases with increasing synthesis temperature.

Non-stationarity of the growth of silicon dioxide thin films at low temperatures (below 573 K) and low pressures can be explained by the superposition of two processes with different dynamics, a fast process of maximum duration 120 s and a slow one. The fast process is due to the change in chemical state of the surface in the course of deposition. The slow rate decrease process is associated with changes in the real film surface owing to the formation of mesopores connected to the surface in the course of deposition. In addition to the effect of temperature on the porosity of silicon dioxide films, it is also affected by the total pressure in the course of deposition. This fact is illustrated by the dependence of the minimum pore size on the total pressure, obtained at temperatures below 473 K (Fig. 22).

The problem of aerosol formation (see above) gave an impetus to search for methods of control (in fact, inhibition) of the BCP, including the problem of improving the conformality of film deposition on stepwise reliefs. As a possible variant, the effect of such inhibitors as  $\text{C}_2\text{H}_4$ ,  $\text{C}_2\text{H}_6$ ,  $\text{C}_2\text{H}_2$ ,  $\text{NH}_3$ ,  $\text{NO}$  and  $\text{NO}_2$  on the oxidation of monosilane by oxygen was studied.<sup>83,84</sup> As can be seen from Fig. 23,  $\text{C}_2\text{H}_2$  and  $\text{NO}$  have no effect on the reaction,

**Figure 22.** Minimum pore radius plotted vs. total pressure during the formation of  $\text{SiO}_2$  layer in the  $\text{SiH}_4$ – $\text{O}_2$  system.<sup>82</sup>

**Figure 23.** Illustration of the effect of the increase in the concentration of inhibitors (large vertical arrow) in the  $\text{SiH}_4$ – $\text{O}_2$  gas mixture on the rate of monosilane consumption.

Dashed line and dashed arrow denote the dynamics and the time of complete consumption of monosilane under inhibitor-free conditions, solid arrow denotes the time corresponding to wafer position in the reactor.<sup>83</sup>

while other compounds inhibit the oxidation of monosilane. In this case the situation on a wafer, whose arrangement in the reactor was characterised by a particular reaction time, is as follows. The silicon dioxide film growth rate correspondingly decreases and the conformality of deposition on the lateral surfaces of gaps in complex-shape reliefs is significantly improved. Nevertheless, it is now impossible to fundamentally improve the quality of deposited silicon dioxide films by the known methods of control of the BCP of monosilane oxidation by oxygen. Consequently, other chemical systems have been the subject of intensive research since the late 1970s.

### b. System $\text{SiH}_4\text{--N}_2\text{O}$

In the  $\text{SiH}_4\text{--N}_2\text{O}$  system,  $\text{SiO}_2$  can be fabricated at temperatures above 773 K (higher than in the case of the  $\text{SiH}_4\text{--O}_2$  system). By varying the  $[\text{N}_2\text{O}]/[\text{SiH}_4]$  ratio it is possible to vary the film composition continuously from amorphous/polycrystalline silicon at  $[\text{N}_2\text{O}] = 0$  to oxygen-doped polycrystalline silicon of composition  $\text{SiO}_y$  ( $y < 2$ ) at  $0.2 < [\text{N}_2\text{O}]/[\text{SiH}_4] < 10$  and further for silicon dioxide at  $[\text{N}_2\text{O}]/[\text{SiH}_4] > 50$ . Strictly speaking, in the first two cases, we are concerned with semiconductor or semi-insulating films rather than dielectric ones; therefore, they are of specific interest.<sup>‡</sup>

In flow LPCVD reactors amorphous silicon films are fabricated at a deposition temperature of  $\sim 823$  K, and polycrystalline silicon films at temperatures above 893 K. The growth rate of polycrystalline silicon depends on the reaction development time (it rapidly decreases starting at 0.05 s). In the initial stages, the deposition rate of polycrystalline silicon films depends strongly on the wafer material. Until a film thickness of  $\sim 22$  nm, the deposition rates are relatively low and therefore we can talk of an induction period in the film growth. This period is determined by the duration of the growth stages of individual nuclei, their outgrowth and their closure into a continuous layer. After completion of the induction period, the growth continues on the surface of polycrystalline silicon film, the growth rate being independent of the characteristics of the wafer material. In a particular range of pressures, the deposition rate is governed by first-order processes with respect to  $\text{SiH}_4$ . The temperature dependence of the growth rate is characterised by an activation energy of  $148.8 \text{ kJ mol}^{-1}$  for low degrees of monosilane conversion and of  $218.2 \text{ kJ mol}^{-1}$  for high conversions. The activation energy at low conversions depends on the wafer material. Pyrolysis of  $\text{SiH}_4$  follows two concurrent paths and results in the formation of reactive silylene ( $\text{SiH}_2$ ) molecules and silyl radicals  $\text{SiH}_3$ . The intermediate products involved are  $\text{Si}_2\text{H}_6$  and  $\text{Si}_3\text{H}_8$ . The presence of  $\text{SiH}_2$  and  $\text{SiH}_3$  in the vapour phase will lead to a more intense adsorption of these species on the growing surface, while the presence of polysilane molecules in the vapour phase favours the formation of silicon clusters in the vapour phase.

At a preset  $\text{SiH}_4$  concentration, the overall growth rate of oxygen-doped polycrystalline silicon ( $\text{SiO}_y$ ) films changes in a complex manner<sup>86</sup> (Fig. 24a). As can be seen, until  $[\text{N}_2\text{O}]/[\text{SiH}_4] = 10$  the growth rate decreases as follows

$$W = \frac{W_{\text{Si}}}{1 + g_{\text{N}_2\text{O}} p_{\text{N}_2\text{O}}},$$

where  $W_{\text{Si}}$  is the growth rate of the polycrystalline silicon film,  $g_{\text{N}_2\text{O}}$  is a constant and  $p_{\text{N}_2\text{O}}$  is the partial pressure of  $\text{N}_2\text{O}$ . At  $[\text{N}_2\text{O}]/[\text{SiH}_4] > 10$ , the growth rate monotonically increases, and at  $0.05 < [\text{N}_2\text{O}]/[\text{SiH}_4] < 0.6$ , the  $y$  value changes almost linearly between 0 and 1.25 (Fig. 24b).<sup>87,88</sup> The film growth rate distribution along the length of the reactor at reaction times no longer than 0.01 s exhibits a characteristic rate maximum; this feature

**Figure 24.** Growth rate (a) and oxygen content (b) in silicon-doped  $\text{SiO}_2$  thin films plotted vs.  $[\text{N}_2\text{O}]/[\text{SiH}_4]$  ratio.<sup>86</sup> (a):  $T = 913$  K,  $[\text{SiH}_4] = 8.0 \times 10^{-7} \text{ mol litre}^{-1}$ ; (b):  $T = 923$  K.

permits a quantitative description of the process. The temperature dependence of the deposition rate is characterised by an activation energy of  $140.8 \pm 4.0 \text{ kJ mol}^{-1}$ .

The growth of oxygen-doped polycrystalline silicon films is governed by the laws of the reactions taking place in the adsorption layer. In connection with this mention may be made that a direct experimental proof of the adsorption of  $\text{N}_2\text{O}$  molecules on the silicon dioxide surface was obtained. It is noteworthy that the constants of the adsorption equilibria on the  $\text{SiO}_2$  surface for  $\text{SiH}_4$  and  $\text{N}_2\text{O}$  ( $g_{\text{N}_2\text{O}}$  and  $g_{\text{SiH}_4}$ , respectively) are comparable.<sup>86</sup> The dependence shown in Fig. 24a can be treated as follows: the film growth rate decreases as the pressure of  $\text{N}_2\text{O}$  increases due to the competitive adsorption of  $\text{SiH}_4$  and  $\text{N}_2\text{O}$  onto the same active sites.

The growth of  $\text{SiO}_2$  films in the system under study occurs at  $[\text{N}_2\text{O}]/[\text{SiH}_4] > 50$ .<sup>89–91</sup> The process can conveniently be observed in the temperature range 833–1073 K. The deposition rate profiles along the reactor axis are presented in Fig. 25. Maxima in the deposition rate profiles correspond to the inner part of the reactor; the higher the monosilane concentration in the mixture, the larger the shift of the maximum. The initial portions of the

**Figure 25.** Growth rate distribution of  $\text{SiO}_2$  thin films in an atmospheric pressure isothermal reactor.<sup>90</sup> The partial pressure of  $\text{SiH}_4$  is 10.6 Pa; the partial pressure of  $\text{N}_2\text{O}$  /kPa: 2.0 (1), 5.1 (2), 8.1 (3), 15.2 (4) and 30.7 (5). Dashed line denotes the isothermal zone for  $T = 833$  K.

<sup>‡</sup> The readers who are interested in this problem are directed to Refs 18 and 85–88, which present a comprehensive treatment of the growth kinetics of such films.

curves are linear, their slopes being proportional to the pressure of  $N_2O$ . In the temperature range 1023–1073 K the growth rate maxima correspond to the beginning of the isothermal zone; in the inner part of the reactor the growth rates dramatically decrease. From these plots it follows that below 973 K, the rate of the process is described by the expression

$$W = k_1 p_{N_2O(0)} + k_2 (p_{N_2O(0)} - p_{N_2O(x)}),$$

where  $k_1$  and  $k_2$  are the rate constants and  $p_{N_2O(0)}$  and  $p_{N_2O(x)}$  are the partial pressures of  $N_2O$  at the beginning of the isothermal zone and at a point  $x$  on the axis of the reactor, respectively.

This equation reflects the fact that the reaction follows two paths. One of them, with the rate constant  $k_1$ , is responsible for the adsorption mechanism of  $SiO_2$  formation. The other path, characterised by the rate constant  $k_2$ , determines the effect of the vapour-phase reactions on the growth of  $SiO_2$  films. Involvement of the vapour-phase stages of the reaction is directly observed upon introduction of small concentrations of radical inhibitors into the vapour phase. For instance, the addition of less than 1% of ethylene or propylene into the gas mixture causes the growth rate at 873 K to decrease several-fold. The same additives introduced at 1073 K cause only a 20%–25% decrease in the growth rate. The temperature dependence of  $k_1$  is characterised by an activation energy of 196 kJ mol<sup>-1</sup>, the pre-exponent being equal to  $1.7 \times 10^{11}$  Å min<sup>-1</sup> (mm Hg)<sup>-1</sup>.

Thus, the two-path process of  $SiO_2$  film growth involves two concurrent reactions. These are the heterogeneous reaction between adsorbed  $SiH_4$  and  $N_2O$  molecules and the vapour-phase autocatalytic or chain reaction, involving the products of  $N_2O$  decomposition. Most probably, the chain reaction of monosilane oxidation with oxygen, produced in the heterogeneous decomposition of  $N_2O$ , accelerates the overall reaction.

The empirical relationships for evaluating the deposition rates (at  $T = 923$  and 1023 K) in isothermal reactors with a dense cross-vertical arrangement of wafers (with  $\sim 15$  mm spacings) (the deposition rate of  $SiO_2$  is given in nm s<sup>-1</sup>) are as follows:<sup>91</sup>

$$W_{923} = 1.67 \times 10^{-5} p_{SiH_4}^{0.5} p_{N_2O},$$

$$W_{1023} = 5.0 \times 10^{-7} \left( 320 - \frac{p_{N_2O}}{p_{SiH_4}} \right) p_{SiH_4}^{0.5} p_{N_2O}.$$

The assumption of a branched chain component of the oxidation of monosilane by  $N_2O$  (this unambiguously indicates the possibility of formation of the aerosol phase under CVD conditions) was experimentally proved by studies of the conditions for intense nucleation in the vapour phase, using gas mixtures of preset composition.<sup>91</sup> The film surfaces were checked for the presence of microparticles using an optical microscope and by scattering with photons produced by a He-Ne laser (laser light was introduced through transparent windows parallel to the axis of a flow isothermal hot-wall reactor); the light intensity was measured using a photodiode. For a known composition of gas mixture, light scattering began after a specific total pressure in the reactor had been exceeded. Once determined, the pressure values for the mixture compositions under study can be used to calculate the corresponding critical partial pressures of  $N_2O$  and  $SiH_4$ .

A generalised diagram, presented in Fig. 26, shows the regions of formation of reaction products in the form of thin films and aerosol for the deposition temperature 923 K. A correlation between the defects in the deposited film and the growth rate is apparent. Namely, defect-free silicon dioxide films grow in region *I* at rather low rates; region *II* corresponds to the appearance of microparticles on the surface of the silicon dioxide film, growing at a higher rate (the microparticles can be seen in the optical microscope); region *III* corresponds to intense nucleation in the vapour phase, where both the reactor walls and wafers become covered with a powder. The limiting growth rates of 'defect-free' silicon dioxide films in region *I* at the deposition temperatures 923, 1023 and 1123 K were estimated at  $\sim 0.08$ ,  $\sim 0.17$  and  $\sim 0.12$  nm s<sup>-1</sup>, respectively.

**Figure 26.** Regions of formation of the products of oxidation reaction: defect-free thin film (*I*), defect thin film (*II*) and aerosol (*III*) for the CVD process in the  $SiH_4$ – $N_2O$  system at 923 K.<sup>91</sup>

Growth rate /nm s<sup>-1</sup>: 0.033 (*I*), 0.066 (*II*) and 0.099 (*III*). Dashed line denotes the boundary between the regions *I* and *II* and curve 4 is the boundary of the region of aerosol formation (shaded).

### c. Systems $SiH_4$ – $NO$ and $SiH_4$ – $NO_2$

Depending on the concentration ratio of  $SiH_4$  and  $NO$  in the  $SiH_4$ – $NO$  system, both silicon dioxide (at  $[SiH_4]/[NO] < 0.25$ ) and silicon oxynitride (at  $[SiH_4]/[NO] = 0.5$ – $1.0$ ) films can be fabricated. The reaction

was studied at low degrees of conversion.<sup>92</sup>

The activation energy for this process is 125.4 kJ mol<sup>-1</sup>. Studies on the character of the adsorption processes on the surface of silicon at room temperature and an exposure of 10 Langmuir revealed<sup>93,94</sup> dissociative adsorption of  $NO$  and a monolayer coverage of the surface with the same coverages, equal to 0.5, for both oxygen and nitrogen atoms.

At a temperature of  $\sim 723$  K and a pressure of  $\sim 133$  Pa, the reaction proceeds slowly and obeys the laws of heterogeneous kinetics. As the pressure increases, the reaction is dramatically accelerated and intense chemiluminescence in the vapour phase is observed.<sup>92</sup>

### d. System $SiH_4$ – $CO_2$

The deposition of silicon dioxide films in the  $SiH_4$ – $CO_2$  system was studied in the temperature range 973–1373 K at  $[CO_2]/[SiH_4] = 100$ .<sup>95,96</sup> The deposition rate increases as the concentrations of both components increase, being higher in argon than in hydrogen. The two possible reaction routes are as follows:

The presence of excess silicon in the  $SiO_2$  films also indicates the occurrence of a concurrent reaction, viz., the thermal decomposition of monosilane.

### e. System $SiH_4$ – $H_2O_2$

The  $SiH_4$ – $H_2O_2$  system, at a deposition temperature similar to room temperature and a reduced pressure, was proposed in order to solve a topical problem of the high-quality filling of gaps between elements with complex reliefs in microelectronic devices.<sup>97</sup> The kinetics of film growth have not been reported as yet, but it was established that the main factor affecting the deposition rate is pressure. It is assumed that the oxidation reaction

is followed by polymerisation and the formation of a silicon dioxide film:

#### f. Oxidation of chlorinated and organic derivatives of monosilane

The  $\text{SiH}_2\text{Cl}_2\text{--N}_2\text{O}$ ,  $(\text{CH}_3)_2\text{SiCl}_2\text{--N}_2\text{O}$ ,  $\text{SiH}_2\text{Cl}_2\text{--O}_2$  and  $(\text{CH}_3)_2\text{SiCl}_2\text{--O}_2$  systems were studied in LPCVD reactors at temperatures 1023–1123 K.<sup>30, 45, 46, 98</sup> However, almost no kinetic data were reported. The first three systems are characterised by very low deposition rates (at most  $0.016\text{ nm s}^{-1}$ ) and a high sensitivity of the deposition processes on the total pressure in the reactor; a feature of the  $\text{SiH}_2\text{Cl}_2\text{--O}_2$  system is an intense aerosol formation. In all of these systems, the film thickness uniformity across the wafer is very low, but only the  $\text{SiH}_2\text{Cl}_2\text{--N}_2\text{O}$  system is used in high-precision technologies. The reaction for this system has the form:

The  $(\text{CH}_3)_2\text{SiCl}_2\text{--O}_2$  system appeared to be the most promising for the fabrication of silicate glass films at admissibly high temperatures, because the deposition rates under identical conditions were nearly an order of magnitude higher.<sup>30, 98</sup> The experiments were carried out using isothermal LPCVD reactors (see Fig. 4 *c, d*) at pressures 260–775 Pa in the temperature range 1023–1123 K. The deposition rate profiles in the reactors exhibited portions characterised by low deposition rate constants (a plateau), after which the growth rates increased. The plateau region became smaller as the pressure and temperature increased. The reaction is nearly first-order with respect to  $(\text{CH}_3)_2\text{SiCl}_2$ , while with respect to  $\text{O}_2$ , the reaction changes from a first-order process to a higher-order one.

$\text{SiCl}_4$  and  $\text{O}_2$  interact at temperatures  $> 1430\text{ K}$ <sup>99, 100</sup> following the reaction:

Reactions at temperatures 1073–1173 K result in thin films of two oxychlorides,  $\text{Si}_2\text{OCl}_6$  and cyclic oxychloride,  $\text{Si}_4\text{O}_4\text{Cl}_8$ . The oxidation of tin and titanium tetrahalides by oxygen at temperatures below 1073 K were also studied in order to obtain tin and titanium oxide films, respectively.<sup>18</sup>

#### g. Systems $\text{C}_2\text{H}_3\text{Cl}_2\text{CH}_3\text{SiH}_2\text{--O}_2$ and $(\text{CH}_3\text{CO}_2)_2(\text{C}_4\text{H}_9\text{O})_2\text{Si--O}_2$

Reactions in the  $\text{C}_2\text{H}_3\text{Cl}_2\text{CH}_3\text{SiH}_2\text{--O}_2$  and  $(\text{CH}_3\text{CO}_2)_2(\text{C}_4\text{H}_9\text{O})_2\text{Si--O}_2$  systems were assumed to be alternatives to the BCP in the low-temperature oxidation of monosilane, but they have found no practical applications because of low deposition rates. A typical deposition rate profile obtained<sup>101</sup> for the former system, at a deposition temperature of  $\sim 673\text{ K}$ , in a flow APCVD reactor, at a  $\text{C}_2\text{H}_3\text{Cl}_2\text{CH}_3\text{SiH}_2$  consumption of  $1.7 \times 10^{-3}\text{ cm}^3\text{ s}^{-1}$ , an oxygen consumption of  $25\text{ cm}^3\text{ s}^{-1}$  and a gas mixture flow rate of  $13\text{ cm}^3\text{ s}^{-1}$ , was similar to the profile shown in Fig. 11 *a*; with a deposition rate in the order of  $0.08\text{ nm s}^{-1}$ , this is two orders of magnitude lower than that for the oxidation of monosilane. The second system<sup>102</sup> exhibited a lowest practically admissible deposition rate of  $\sim 0.17\text{ nm s}^{-1}$ , only at temperatures above 823 K.

#### h. System $(\text{C}_2\text{H}_5\text{O})_4\text{Si--O}_3/\text{O}_2$

The  $(\text{C}_2\text{H}_5\text{O})_4\text{Si--O}_3/\text{O}_2$  system has been widely used in electronic technologies since the mid-1990s. At relatively low deposition temperatures, the growth rate of silicon dioxide films is high, with a low level of side aerosol phenomena. In addition, the system exhibits a unique ‘smoothed’ character in its film growth on stepwise reliefs, which has found practical applications. Unfortunately, there is lack of comprehensive experimental studies of the kinetics of thin film growth in this system, in spite of the availability of much practically useful technological data.

Tetraethoxysilane has long been used as the starting compound in the deposition of silicon dioxide thin films; however, the

information available mainly concerns the pyrolysis of TEOS.<sup>102–106</sup> This reaction proceeds at a noticeable rate at temperatures above 923 K (practically useful temperatures exceed 973 K); detailed consideration of the process being given below. It was also found<sup>104</sup> that in the presence of oxygen, the oxide thin films also grow at lower temperatures, and the maximum deposition rate is achieved at  $\sim 673\text{ K}$  (Fig. 27 *a*). It was assumed that this reaction results in the formation of polymeric structures.

**Figure 27.** Thin-film deposition rate in the TEOS– $\text{O}_2$  (1), TEOS– $\text{H}_2$  (2) and TEOS–Ar (3) systems plotted vs. temperature (*a*) and the  $\text{SiO}_2$  film deposition rate plotted vs. ozone concentration in the gas mixture for the silicon (1) and  $\text{SiO}_2$  thermally grown on silicon (2) wafers (*b*).<sup>107, 108</sup>

Studies<sup>107, 108</sup> on the possibility of a substantial increase in the thin film deposition rate, using ozone–oxygen mixtures containing  $\sim 1$  mass% of ozone as oxidants, for the low-temperature oxidation of TEOS (Fig. 27 *b*) were of great practical interest in the early 1990s. At higher absolute values of growth rate, the temperature dependence of the deposition rate in the presence of ozone retains its shape, shown in Fig. 27 *a* for the TEOS– $\text{O}_2$  system. However, in this case, a practically valuable increase in the growth rate is accompanied by non-stationarity of the film growth in the initial stage of the deposition reaction and by selectivity of thin film growth on the silicon, silicon dioxide and silicon nitride surfaces, which increases as the ozone concentration in the gas mixture increases. An increase in the deposition selectivity is accompanied by improved conformality of deposition and, as a consequence, by the appearance of a smoothed profile for deposited thin films on stepwise reliefs.<sup>108</sup>

The deposition of thin films in the TEOS– $\text{O}_3/\text{O}_2$  system can be considered as a new avenue in the CVD of oxide thin films, and of considerable research interest. However, most studies reported so far have been concerned with the practical aspects of CVD using a few types of industrial reactors. Not only the properties of silicon dioxide thin films, but also the film growth rate,<sup>108–110</sup> deposition selectivity, methods of controlling of this parameter using modified surfaces gas additives<sup>111, 112</sup> and the conformality of thin film deposition on stepwise reliefs, are the main parameters under study.<sup>108–110, 113, 114</sup>

In summarising the data on the growth rates for industrial processes of silicon dioxide thin film deposition at  $\sim 670\text{ K}$  and pressures of 25–100 kPa, with allowance for the fact that the

deposition rate is nearly first order with respect to TEOS and a pseudozero order with respect to  $O_3$ , the effective rate constant for the reaction was found to lie in the range  $0.1\text{--}0.2\text{ cm s}^{-1}$ .

## 2. Pyrolysis reactions

Silicon dioxide, as well as  $Al_2O_3$ ,  $SnO_2$ ,  $TiO_2$ ,  $ZrO_2$ , *etc.*, thin films can be grown by the pyrolysis of vapours of organoelement compounds.<sup>9</sup>  $SiO_2$  deposition is mainly performed by pyrolysis of TEOS.<sup>103–106</sup> Industrial deposition processes of silicon dioxide thin films for electronics in isothermal flow LPCVD reactors<sup>106</sup> make it possible to fabricate films characterised by very low thickness uniformity ( $\sim \pm 2\%$ ), simultaneously on a total of 150 silicon wafers with diameters of up to 300 mm, arranged at a distance of  $\sim 5$  mm from one another. At temperatures above 973 K, the rates of pyrolysis in the presence and absence of oxygen are nearly equal. Nevertheless, oxygen additives are usually used in order to minimise the concentrations of carbon-containing impurities in the deposited silicon dioxide thin film.

The kinetic data characterise the pyrolysis of TEOS as a heterogeneous reaction involving dissociative adsorption of TEOS in the initial stages. It was assumed that monomolecular decomposition can proceed at temperatures above 773 K. The stoichiometry of the pyrolysis reaction remains unknown, because the composition of the side reaction products ( $CO_2$ ,  $CO$ ,  $H_2$ ,  $H_2O$ ,  $C_2H_4$ , *etc.*) has not been exactly determined. The thin film growth rate at 998 K and a total pressure of 46.6 Pa, expressed through the partial pressure of TEOS ( $p_{TEOS}$ ), is described by the equation:

$$W = \frac{k_1 p_{TEOS}^{0.5}}{1 + k_2 p_{TEOS}^{0.5}}.$$

The effective activation energy for the reaction is  $\sim 194.4\text{ kJ mol}^{-1}$  at a total pressure of 33.3 Pa. The equation for the rate constant of pyrolysis (in  $s^{-1}$ ) in an APCVD reactor at 1023–1148 K with  $N_2$  as the medium takes the form:

$$k = 6.38 \times 10^{12} \exp \left( -\frac{238.2}{RT} \right).$$

## 3. Hydrolysis reactions

Vapour-phase hydrolysis of silicon, tin and titanium halides can be used to grow thin films of their corresponding dioxides at relatively low temperatures.<sup>115–117</sup> For instance, the interaction of  $SiF_4$  with  $H_2O$  was studied at 753–858 K and gas mixture pressures lying in the range 11.9–93.3 kPa.<sup>115</sup> The growth kinetics of  $SnO_2$  thin films was studied in the temperature range 753–981 K at linear flow rates exceeding  $6\text{ cm s}^{-1}$  (in this case, mass transfer phenomena do not influence the reaction rate).<sup>116</sup> Fluorine-containing silicon dioxide thin films, which have a more complex composition, are fabricated by the hydrolysis of alkoxy halides  $FSi(OAlk)_3$  at room temperature

followed by polymerisation.<sup>118</sup>

The limited use of low-temperature hydrolysis reactions in high-precision technologies for the fabrication of silicon dioxide thin films is mainly due to the low quality of the films produced.

Hydrolysis of  $AlCl_3$  and  $SiCl_4$ – $AlCl_3$  mixtures at temperatures above  $\sim 1123$  K in mixtures with  $CO_2$  and  $H_2$  is described by the following reactions:<sup>119, 120</sup>

which eventually result in  $Al_2O_3$  and  $SiO_2$  or in aluminosilicates (of general formula  $Al_2SiO_5$ ) in co-hydrolysis of halides.

The formation of  $Al_2O_3$  thin films was studied at a pressure of 13.3 kPa in the temperature range 1173–1423 K. The composi-

tion of the vapour phase (in mole fractions) was as follows: hydrogen, 0.05–0.95;  $AlCl_3$ , 0.005–0.03;  $CO_2$ , up to 100%.<sup>119</sup> Under these conditions, supersaturation with water vapours varied from 1.01 to 1.20 and supersaturation with  $AlCl_3$  varied from  $10^7$  to  $7.0 \times 10^{11}$ . The kinetic data were obtained under the conditions where the thin film growth rate was independent of the gas flow rate. The reaction rate at 1300 K increased as the partial pressure of  $AlCl_3$  increased, reached a maximum value at  $\sim 133.3$  Pa and then decreased on further increase in the partial pressure of  $AlCl_3$ . The dependence of the growth rate on the partial pressure of  $H_2$  obeyed an identical pattern, with the maximum value reached at  $\sim 7.33$  kPa. The temperature dependence of the process was characterised by an activation energy of  $146.3\text{ kJ mol}^{-1}$ . Most probably, the results obtained correspond to a heterogeneous reaction.

Co-hydrolysis of  $SiCl_4$  and  $AlCl_3$  was studied at temperatures 1123–1373 K, a pressure of 13.3 kPa, gas flow rates in the range  $3.67\text{--}16.7\text{ cm}^3\text{ s}^{-1}$  and mole fractions of 0.006–0.05 for  $SiCl_4$ , 0–0.015 for  $AlCl_3$  and 0.035–0.25 for  $CO_2$ .<sup>120</sup> The deposition rate of the films obtained at deposition temperatures above  $\sim 1273$  K under nearly optimum conditions was higher than  $\sim 1.6 \times 10^{-4}\text{ mg cm}^{-2}\text{ s}^{-1}$ . The activation energy for the deposition of  $SiO_2$ ,  $Al_2O_3$  and aluminosilicates at deposition temperatures above 1273 K was  $\sim 83.6\text{ kJ mol}^{-1}$  and increased to  $\sim 290\text{ kJ mol}^{-1}$  at lower temperatures for hydrolysis of  $SiO_2$ . The most interesting result obtained is a clearly seen linear dependence of the aluminosilicate deposition rate on the mole fraction of  $AlCl_3$  in the mixture, which considerably increases as the reaction temperature decreases; no dependence on the mole fraction of  $SiCl_4$  in the studied range of the experimental conditions was observed.

## 4. Plasma-enhanced oxidation reactions

Fabrication of oxide thin films in the oxidation reactions carried out at low temperatures ( $\sim 670$  K) and pressures of several hundreds of Pa using plasma-enhanced gas mixtures is of paramount practical interest, being in fact a specific field of CVD research. Considerable literature on the subject is available (see, *e.g.*, Refs 4–6, 54–56, 121–124).

The first system used for plasma-enhanced deposition at  $\sim 670$  K was  $SiH_4$ – $N_2O$ . Since the early 1990s the TEOS– $O_2$  system has been used. In principle, low-temperature plasma-enhanced synthesis of oxide films can also be performed using plasma-enhanced pyrolysis of organosilicon compounds (*e.g.*, TEOS, hexamethyldisiloxane, trimethoxychloromethylsilane, *etc.*) in an oxygen-free medium, because these molecules contain Si–O bonds.<sup>54</sup> However, the oxide films obtained contain a considerable amount of carbon, which is undesirable for micro-electronic devices. In this connection a necessary condition for plasma-enhanced synthesis of oxide films of desired quality is the presence of oxidants. In this case, in accord with the equation

even at 12-fold excess of an oxidant with respect to TEOS, the content of carbon in the films obtained can be high (up to  $\sim 3 \times 10^{20}\text{ atom cm}^{-3}$ ) and detectable by secondary ion mass spectrometry (SIMS). It was established that minimisation of the carbon content in the deposited films down to an admissible level of  $\sim 0.3 \times 10^{20}\text{ atom cm}^{-3}$  requires a 30–40-fold excess of oxygen with respect to TEOS.<sup>125</sup>

The deposition rate in the systems under study can be characterised as being first-order with respect to the source of silicon and a pseudozero order with respect to oxidant. The plot of the dependence of the deposition rate on the supplied high-frequency power is a curve with a linear portion followed by a plateau corresponding to the deposition. This permits variation of mechanical strain in the deposited film by varying the high-frequency power. (Optimisation of mechanical strain is of great importance for practical use of dielectric silicon dioxide thin films as passivators of metallisation of electronic devices). The activa-

tion energies for the plasma-enhanced oxidation reactions are  $\sim 10 \text{ kJ mol}^{-1}$ , which suggests that the temperature has little effect on the film growth kinetics.

The effective rate constant for plasma oxidation CVD processes was estimated at  $k_{\text{ef}} > 1$ . By and large, plasma enhanced deposition processes of silicon-containing films are consistent with the classification of CVD processes given in Table 2 and obey the laws of film growth on stepwise reliefs.

### 5. Industrial methods of silicon dioxide film deposition

Depending on the deposition temperature, silicon dioxide films used in electronics are divided into medium-temperature films (920–1000 K) and low-temperature ones ( $\sim 670 \text{ K}$ ); the latter being used for production of wafers containing metallic conductors. A commonly accepted medium-temperature method is oxidative pyrolysis of TEOS in isothermal LPCVD reactors. This industrial process has the best performance and parameters of deposited  $\text{SiO}_2$  films including the conformality of film growth on complex-shape reliefs.

At present, the most widely used industrial low-temperature CVD methods are oxidation of monosilane by oxygen at an atmospheric or low pressure, plasma-enhanced oxidation of TEOS by oxygen and of monosilane by  $\text{N}_2\text{O}$  and oxidation of TEOS by an ozone–oxygen mixture at an atmospheric or reduced pressure. The last-mentioned method is of limited use because of the drawback of the low density of silicon dioxide films, which depends on the properties of the material subjected to deposition. Fast methods of silicon dioxide deposition including plasma-enhanced techniques are mainly used in order to grow films on plane wafers; films on wafers with a complex relief are fabricated using oxidation by ozone–oxygen mixtures.

Recently, very dense silicon dioxide thin films with the high-quality (continuous) filling of narrow ( $< 0.2 \mu\text{m}$ ) gaps of a stepwise relief in microelectronic devices have been fabricated using the so-called ‘high-density plasma’ CVD (HDP-CVD) technique, where film deposition in the  $\text{SiH}_4\text{--O}_2$  system at pressures below 1 Pa is combined with sputtering of the material deposited by argon ions.<sup>126</sup> These processes have been comprehensively covered in Refs 32 and 33.

## VII. Deposition of multicomponent silicate glass thin films

Multicomponent dielectric thin films based on glass-forming oxides  $\text{SiO}_2$ ,  $\text{P}_2\text{O}_5$ ,  $\text{B}_2\text{O}_3$  and  $\text{GeO}_2$ , and belonging to silicate glasses, are prepared by CVD techniques and widely used in high-precision technologies as insulators.<sup>3–6, 127, 128</sup> Silicate glasses also possess specific properties, *e.g.*, the ability to help alkali metal ions, undergo a viscous flow at elevated temperatures, *etc.* Such glass films have long been used, but only a few kinetic studies of their growth characteristics are available. The reason for the lack of detailed kinetic studies is that such films were fabricated in industrial reactors only. To some extent this can be explained by the fact that the major component of practically interesting (valuable) compositions of silicate glasses is  $\text{SiO}_2$  (the overall concentration of other oxides is, as a rule, at most 30 mass %). Because of this, the processes of chemical vapour deposition of glasses are usually studied by analysing the changes upon the introduction of the second, third, *etc.*, components in the gas mixtures constituting the source of silicon and oxidant.

Binary phosphosilicate glass (PSG) and ternary borophosphosilicate glass (BPSG) films are best studied and most widely used in electronics.<sup>28, 30, 31, 127–137</sup> A necessary feature of glass film fabrication under the CVD conditions is the use of a strong oxidant. In the absence of the strong oxidant or when using a weak oxidant (*e.g.*,  $\text{N}_2\text{O}$ ), it is impossible to fabricate glass films without the use of excess silicon and carbon and the phosphorus content in the films is at most 1 mass%. It is commonly accepted that the glass-forming oxides ( $\text{SiO}_2$ ,  $\text{B}_2\text{O}_3$  and  $\text{P}_2\text{O}_5$ ) are formed as a result of independent oxidation reactions of hydrides  $\text{SiH}_4$ ,  $\text{PH}_3$

and  $\text{B}_2\text{H}_6$ , esters of silicic, boric, phosphorous and phosphoric acids and boron and phosphorus chlorides under the CVD conditions according to the schemes

However, exact equations of the oxidation reactions are unknown because the compositions of the side products depend on particular CVD conditions and have not been studied in detail (see above).

There are two main methods of fabrication of phosphorus- and boron-containing glass thin films, which are basic to industrial deposition techniques. One of them involves a combination of monosilane and hydrides, chlorides or organic esters at deposition temperatures in the range 620–720 K at atmospheric pressure or at low pressure of reagents. The other uses a combination of TEOS with phosphine or organic esters of boric, phosphorous or phosphoric acids and can be practically implemented in three versions, *viz.*, at 920–100 K and low pressure, at  $\sim 673 \text{ K}$  under PE-CVD conditions and at 670–770 K and atmospheric or reduced pressure of  $\text{O}_3/\text{O}_2$  mixtures (ozone concentration varies from 4 mass % to 12 mass %). The characteristics of five main industrial CVD processes are listed in Table 6. All these methods can be used for fabrication of not only BPSG thin films with boron and phosphorus concentrations of up to  $\sim 6 \text{ mass \%}$ – $8 \text{ mass \%}$  with respect to each element but also silicon dioxide and binary glass films by appropriately combining the starting reagents.

By and large, the glass film deposition processes are similar. They are nearly first order reactions with respect to the silicon-containing compounds and proceed in the presence of a large excess of oxidants, which corresponds to a pseudozero order with respect to the oxidants. The activation energies for the CVD oxidation processes (except for plasma-enhanced processes) reported by different authors lie in the range 62–209  $\text{kJ mol}^{-1}$ , those of the PE processes being an order of magnitude lower.

The influence of phosphorus- and boron-containing compounds on the parameters of the CVD processes of glass films is illustrated in Fig. 28*a*. Here, the ratios of the deposition rates ( $W$ ) of PSG and borosilicate glass (BSG) films to the deposition rate of silicon dioxide ( $W_{\text{SiO}_2}$ ) are plotted *vs.* the change in the mole ratio of the boron or phosphorus compounds to the mole ratio of the silicon compound in the vapour phase.

In the presence of phosphorus-containing compounds the oxidation reactions of silicon compounds are accelerated and their activation energies appreciably decrease (by a factor of 1.3–3). Acceleration of the reactions is favoured by a proportional increase in the phosphorus content in the deposited PSG and BPSG films, by a decrease in the film thickness uniformity and by enhanced formation of aerosol side products. The greatest acceleration of the CVD of silicate glass films (from 3 to 7 times) is achieved when using a mixture of TEOS with  $\text{PH}_3$  while the minimum acceleration is attained for the oxidation of monosilane mixed with any phosphorus compound mentioned above.

The oxidation reactions of monosilane, phosphine and other phosphorus compounds by dioxygen are known to proceed by a branched chain mechanism (see above). Taking into account this fact and the retardation of the oxidation reactions in the order  $\text{PH}_3\text{--PCl}_3\text{--organic esters}$ , the acceleration of the oxidation CVD processes studied clearly indicates their branched chain mechanism. However, boron compounds cause the CVD processes involving monosilane and phosphine to slow down, *i.e.*, inhibit the BCP. This is indicated by a decrease in the glass film deposition rate in the course of the oxidation processes involving monosilane and by a decrease in the phosphorus content in the glass films upon introduction of boron compounds into the starting gas mixtures. On the contrary, relatively slow TEOS oxidation reactions are accelerated upon introduction of boron compounds into the gas mixtures. The effect of the interaction

**Table 6.** Main characteristics of industrial glass film deposition processes.<sup>30–32</sup>

| Characteristic or parameter                                        | CVD technology                                           |                                             |                                               |                |                  |

between the boron and phosphorus compounds in the course of CVD processes on the final parameters of the deposited BPSG thin films can be characterised as follows: phosphorus compounds favour incorporation of boron into the film deposited while boron compounds inhibit the incorporation of phosphorus into the glass thin film.

A good illustration of the influence of acceleration and retardation of CVD processes is provided by Fig. 28 b. A model

**Figure 28.** Effect of phosphorus- and boron-containing compounds on the parameters of CVD processes (a) and the influence of acceleration (1) and retardation (2) of the oxidation reaction on the shape of the deposition rate profile in a flow reactor (3) (b).<sup>28, 30</sup> For details, see text.

flow reactor is characterised by a generalised SiO<sub>2</sub> deposition rate profile (curve 3) obtained by recalculating the experimental data to the corresponding coordinates. Analysis of the experimental profiles showed that the glass film deposition kinetics is governed by the phosphorus compounds. The presence of phosphorus compounds causes acceleration of the reactions and a shift of the deposition rate profiles to the left (towards shorter residence times) and favours the formation of aerosol reaction products. At the same time the presence of boron compounds causes retardation of the oxidation reactions and a shift of the deposition rate profile to the right; no aerosol particles are observed in this case (see Fig. 28 b). The limiting BPSG growth rates achieved in different deposition processes can be ~1.5–2 times higher than the growth rates listed in Table 6, which favours incorporation of microparticles into the glass films. The directions in which undesired aerosol effects in the deposition of BPSG thin films increase are shown by arrows in Fig. 28 b.

A comparison of various oxidation processes used for glass film deposition showed that in the case of PSG and BPSG the k<sub>ef</sub> value can lie in the range 1.1–2.5 cm s<sup>−1</sup>. Thus, in spite of considerable differences between the deposition of SiO<sub>2</sub> films involving monosilane and TEOS, the kinetic characteristics of these processes are quite similar to those of the deposition processes of glass films of similar compositions.

The problem of the quality of the surfaces of films deposited is topical when one deals with the CVD of glass films involving BCP. The surface roughness of a glass film is characterised (naked-eye observation) using such terms as ‘mirror’, ‘with inclusions’, ‘haze’, etc. The kinetic data on the CVD of glasses can be checked by studying the surface roughness of the BPSG films obtained by different methods using atomic force microscopy.<sup>138</sup> This method has been used in the thin-film surface roughness measurements since the mid-1990s. Comparative studies of the surfaces of glass films of different compositions have revealed some trends.<sup>138</sup> For instance, acceleration of the oxidation reactions by phosphorus compounds makes the glass surfaces rougher while retardation of the same oxidation reactions by boron compounds reduces the surface roughness. The surface roughness of thin films fabricated from TEOS by the methods 3 and 4 (see Table 6) lies in the range

0.8–2 nm. This is on average nearly 2.5 (6) times lower than surface roughness of thin films fabricated from monosilane by the method 1 at atmospheric (low) pressure. This confirms the occurrence of intense vapour-phase processes in the course of CVD involving monosilane. The large difference between the surface roughness of the thin films prepared at low and atmospheric pressures can be explained by substantially different growth rates.

The surface roughness of BSG thin films is about twice lower than those of the PSG and BPSG thin films fabricated under similar conditions. This result clearly indicates a decrease in the intensity of vapour-phase reactions in the presence of boron-containing compounds in the gas mixture. The maximum surface roughness of silicon dioxide films prepared by the oxidation of TEOS by a  $O_3/O_2$  mixture is  $\sim 6$  nm. This value decreases by more than an order of magnitude upon introduction of esters of boric and phosphoric acids to the gas mixture; apparently, in this case the mechanism of the CVD process changes.

Acceleration and retardation of oxidation processes by phosphorus and boron compounds suggests that the oxidation of the gas mixture components involves formation of common intermediates rather than intermediate products of individual reactions. Although the mechanisms of the oxidation reactions proceeding in the course of BPSG fabrication have not been studied so far, the totality of kinetic data on the influence of phosphorus compounds unambiguously points to the similarity of the mechanisms of the PSG and BPSG film deposition reactions involving radicals formed in the interaction between phosphorus-containing compounds and oxidants. This was included in a generalised scheme of the synthesis of oxide films,<sup>28,30</sup> which is based on the concept of multistage and multipath processes of the growth of dielectric films under CVD conditions (see above).

A scheme of the deposition of silicon dioxide and glass films is presented in Fig. 29 (shown is an example of a multicomponent chemical reaction involving TEOS, for which the acceleration effect is most pronounced). Heterogeneous formation of silicon dioxide (route I) proceeds either as pyrolysis of TEOS on the surface at high temperatures or, in the presence of ozone, as a reaction of adsorbed TEOS and ozone at low temperatures. In the latter case the structure of the film deposited is rougher and more porous than the structure of silicon dioxide films fabricated using oxygen as oxidant. This indicates that the silicon dioxide films are more structurally ordered. If boron and phosphorus compounds are introduced in the gas mixture, the process follows a two-stage scheme (route II), which implies homogeneous formation of intermediate products  $I_X$  and  $I_Y$  involving phosphorus-containing radicals (asterisked) followed by heterogeneous transformation of  $I_X$  and  $I_Y$  into the film deposited on the wafer. In the case of PSG

and BPSG, the film growth processes are limited by the stage of homogeneous formation of intermediate products  $I_X$ , whereas the growth of borosilicate glass films following the second route is limited by the heterogeneous stage of consumption of intermediate products  $I_Y$ . Aerosols are formed following route III involving formation of clusters (including those containing boron and phosphorus oxides) in the vapour phase.

A characteristic feature of glassy materials obtained from organic esters is the presence of carbon impurities in the films deposited. For instance, SIMS studies of phosphorus-enriched films prepared by the method 3 (7 mass % of phosphorus and 3 mass % of boron) revealed a uniform distribution of carbon along the film thickness and showed that its content is nearly three times lower than in the films with a similar content of phosphorus (4 mass %) and boron (4.5 mass %), being  $\sim 1.05 \times 10^{19}$  and  $\sim 3.19 \times 10^{19}$  atom  $cm^{-3}$ , respectively. Hydrogen impurities are present in glasses obtained by all deposition techniques. Generally, the content of hydrogen increases if the CVD temperature is below 670 K. The PSG and BPSG thin films freshly deposited by the method 3 and containing 4 mass % of boron and phosphorus are characterised by uniform distribution of hydrogen, its initial content being equal to  $\sim 3 \times 10^{20}$  atom  $cm^{-3}$ . The content of hydrogen in the glass films prepared by the methods 4 and 5 is  $\sim 6 \times 10^{20}$  and  $\sim 4 \times 10^{20}$  atom  $cm^{-3}$ , respectively.

Because of multicomponent composition of silicate glasses, many factors must be controlled. Among them, the most important is the behaviour of the phosphorus and boron components of the glass. Their concentrations and uniformity of distribution across the surfaces of wafers are determined either using destructive methods of spectral analysis, dissolution, *etc.*, or by pre-calibrated non-destructive methods (IR spectroscopy and X-ray fluorescence).

The compositions of the glass thin films prepared by CVD in the presence of a large excess of oxidants are similar to the compositions of stoichiometric glasses, *i.e.*, the films contain silicon, boron and phosphorus oxides  $SiO_2$ ,  $B_2O_3$  and  $P_2O_5$ , respectively. The absence of excess silicon is indicated by the refractive index values of these thin films (from 1.44 to 1.48) measured by ellipsometry. Phosphorus-containing compounds are oxidised to  $P_2O_5$ ; however, in some cases ion chromatography of glasses reveals the presence (less than  $\sim 1$  mass %) of phosphorus in the oxidation state +3, which corresponds to the phosphorus oxide  $P_2O_3$ . This is characteristic of the low-temperature processes of PSG and BPSG deposition from hydrides at low pressure and of the plasma-enhanced deposition techniques involving phosphines under oxidant-deficient conditions (or in the presence of a weak oxidant) at considerable high-frequency power supplied. For the plasma-enhanced glass deposition techniques, it was also reported that the ESCA spectra revealed the formation of not only the P–O (134 eV) but also the Si–P (130 eV) bond. Only phosphorus in the oxidation state +5 is detected in the thin films prepared using the oxidation systems involving organic esters at large excesses of oxidants. No phosphorus in other oxidation states was detected in the PSG thin films deposited in high-density plasma involving hydrides.<sup>139</sup> The use of appropriate synthetic strategy leads to uniform distribution of boron and phosphorus along the thickness of different BPSG thin films; this was confirmed by the results of layer-by-layer SIMS analysis.

Silicate glass thin films possess different properties. First of all, such films differ in degree of structural imperfection (defectness). One must distinguish between two components of this parameter. One component characterises the deposition technique itself (*i.e.*, the state of the equipment and the extent of optimisation of the deposition conditions) and is measured immediately after the deposition. The second component characterises the degree of defect of glasses as a specific property of the glassy material (*e.g.*, BPSG) and manifests itself when the glass film is exposed to atmospheric air. Depending on the glass composition, the value of this component can increase by several orders of

**Figure 29.** Three-path scheme of chemical vapour deposition of  $SiO_2$  and glass films in a chemical system containing organic esters of silicic, boric and phosphoric acids.<sup>28, 132</sup>

magnitude over short time intervals.<sup>134</sup> Problems concerned with the defectness of glass films are summarised in Refs 31 and 133–135.

Different properties of the glass thin films were explained by their different compositions and structures due to the use of a variety of deposition methods. The structure of the BPSG thin films is first of all determined by the boron-to-phosphorus oxide ratio in the glass. The dependence of the reactivity of the BPSG thin films towards, *e.g.*, absorbed water vapours  $\text{H}_2\text{O}_{(\text{abs})}$  present in the air on the film composition can be explained by the presence of boron atoms coordinated to three oxygen atoms ( $\text{BO}_3$ ) in the glass network, in which the silicon and phosphorus oxides are present in the form of tetrahedral  $\text{SiO}_4$  and  $\text{PO}_4$  units. The glass structural fragments ( $\equiv\text{Si}-\text{O}-$ )<sub>3</sub>OP and ( $\equiv\text{Si}-\text{O}-$ )<sub>3</sub>B react with water vapour as follows:

Prolonged interaction between the glass and water vapour and replacement of  $\equiv\text{Si}-\text{O}-$  groups by  $-\text{OH}$  groups lead to gradual leaching of boron and phosphorus from the glass film and formation of droplets containing phosphoric and boric acids on the glass surface. It was shown that the content of boron atoms coordinated to three oxygen atoms decreases with an increase in the concentration of phosphorus oxide in the glass film and that the content of boron atoms coordinated to four oxygen atoms increases. As a result, an increase in the phosphorus-to-boron content ratio in the glass makes the material less reactive towards water vapour in air.

Interrelation between the properties of glasses and specific features of deposition processes can be explained as follows. The most important physical property of glass thin films is their effective density (or its reciprocal, porosity). Unfortunately, no data on the density of the BPSG thin films, measured by direct methods are available in the literature as yet. Based on the totality of data on, in particular, the shrinkage and etch rates of samples in aqueous solutions of hydrofluoric acid, the highest porosity was ascribed to silicon dioxide, PSG, BSG and BPSG thin films fabricated by low-temperature oxidation of organic esters by  $\text{O}_3/\text{O}_2$  following the method 3 (see Table 6). The lowest porosity was ascribed to the thin films of the same glasses, fabricated by the PE-CVD (method 4) and especially the HDP-CVD (method 5) techniques. The highest porosity of the  $\text{SiO}_2$  and BSG thin films fabricated using the method 3 is associated with low  $k_{\text{ef}}$  value. This process was described in the framework of the two-stage scheme of sequential reactions with the heterogeneous limiting stage involving consumption of intermediate products, which is responsible for the formation of disordered glass structures in the course of the CVD process. On the contrary, fast deposition processes described in the framework of the two-stage scheme of sequential reactions with the homogeneous limiting stage involving formation of intermediate products make it possible to grow much more ordered (*i.e.*, dense) thin films.

## VIII. Conclusion

The authors of this review presented the key information on the chemical vapour deposition of layered dielectric materials and on the properties of covalent dielectrics used in electronics. Layered dielectric composites can be used not only in high-precision technologies but also in mechanical engineering, power engineering, medicine, *etc.*, the CVD methods are considered to be quite promising because they provide unique possibilities of deposition of thin and ultrathin coatings with preset properties and high mechanical and adhesive characteristics on surfaces with complex-shape reliefs.

Chemical transformations of reagents on the surface of a growing layer in the course of the CVD process occur within a layer that is somewhat thicker than a monolayer. This is basic to

the definition of the reaction zone concept. For different CVD processes, the thickness of the reaction zone can vary between a few and several tens of Ångströms. Because of the lack of reliable information on the structure of the reaction zone, researchers are forced to employ a traditionally used description of heterogeneous processes, which is based on the concept of an ideal adsorption layer (Langmuir–Hinshelwood or Ealey–Rideal kinetics), which uses physically incorrect models. Further progress in the CVD methods is closely related to the studies on the structure and dynamics of the reaction zone, which govern not only the dynamics and kinetics of the processes but also the main characteristics of the growing layer. Advances in solving the problems considered above are to a great extent due to the use of modern experimental equipment and especially the *in situ* recording techniques used in the course of the CVD processes. These are, *e.g.*, automatic ellipsometry and piezoquartz microbalance methods, which allow the dynamics and (under steady-state conditions) the kinetics of the process to be investigated. The laser heating technique (chemical thermometer) permits separation of the contribution of pure vapour-phase stages while the IR and Raman spectroscopies provide the possibility of monitoring the composition and temperature of the reacting gas flow. Modern methods of investigation of the aerosol phase make it possible to study nucleation in the vapour phase and to control the structural homogeneity of the deposited coatings.

**Abstract.** Data on the isolation of transactinide elements and their homologues and investigation of their chemical properties in solutions, which were obtained by chromatographic extraction and other methods, are generalised for the first time. Particular attention is given to model experiments on the prediction of the chemical properties and investigation of the relativistic effects of these elements on the basis of the behaviour of homologous elements in solutions containing various complexing ligands. The results and prospects for future research are discussed. The bibliography includes 105 references.

## I. Introduction

In recent years, considerable progress has been made in the synthesis of new transactinide elements (TAEs) or, as they are also called, superheavy elements (SHEs). The elements with atomic numbers  $Z = 114, 115, 116$  and  $118$  and the longest-lived (of the presently known) isotopes of element  $106$  ( $^{265}\text{Sg}$  and  $^{266}\text{Sg}$ ) have been synthesised for the first time in the Flerov Laboratory of Nuclear Reactions of the Joint Institute for Nuclear Research (FLNR JINR, Dubna, Moscow region, Russian Federation).<sup>1–4</sup> The element with  $Z = 113$  was observed in the decay chain of element  $115$ .<sup>2</sup> High stability to various types of nuclear radioactive decay in the vicinity of deformed ( $Z \approx 108, N = 162$ ) and spherical ( $Z = 114, N = 184$ ) nuclear shells was observed experimentally and established by calculations. This fact is indicative of the occurrence of the so-called ‘islands of stability’ among superheavy elements, which has been predicted as early as in the mid-1960s.

During production of new elements, their nuclear physical characteristics ( $T_{1/2}$ , the radioactive decay mode, *etc.*) are generally determined by measuring  $\alpha$  decay or spontaneous fission of the nucleus that formed and the correlations between the decay of parent and daughter radionuclides. However, the exact position of a new element in the Periodic Table should be confirmed by its chemical identification. Investigations of the chemical properties of superheavy elements provide deeper insight into their electronic structures.

Fourteen transactinide elements and  $\sim 70$  their isotopes have been produced. In 1997, IUPAC approved the names and chemical symbols of TAEs with  $Z = 104–109$ . In 2003–2004, the names and chemical symbols of elements  $110$  and  $111$  (Table 1) were approved. Other TAEs have no names. The chemical properties of only two TAEs, *viz.*, rutherfordium and dubnium, were studied in solution. Two experiments on the isolation and chemistry of seaborgium and one investigation of the chemistry of hassium have been carried out. Table 2 lists the isotopes of TAEs, which were studied by chemical methods in solution. The longest-lived  $^{261}\text{Rf}$  isotope ( $T_{1/2} = 78$  s) was discovered in 1970. However, detailed investigations of the chemical properties of rutherfordium in solution were started only in the early 1990s, which was associated with the development of new approaches to the isolation of TAEs. Investigation of the chemistry of transactinide elements and, particularly, of elements with  $Z \geq 106$ , is a complicated and laborious process. The difficulties are associated with very short lifetimes and low production cross-sections of TAEs in reactions with multicharged ions. These experiments are carried out only in a few research centres in the world (see Table 2).

**Table 1.** Names and symbols of transactinide elements.

| Atomic number ( $Z$ ) | Name          | Symbol |
|-----------------------|---------------|--------|
| 104                   | Rutherfordium | Rf     |
| 105                   | Dubnium       | Db     |
| 106                   | Seaborgium    | Sg     |
| 107                   | Bohrium       | Bh     |
| 108                   | Hassium       | Hs     |
| 109                   | Meitnerium    | Mt     |
| 110                   | Darmstadtium  | Ds     |
| 111                   | Roentgenium   | Rg     |

To find the optimum conditions for the isolation and investigation of the chemical properties of these elements, it is necessary to perform preliminary experiments with homologous elements in various systems. In addition, these experiments are required because the relativistic effects in the chemical behaviour of heavy elements can lead to considerable deviations from the general regularities.

The chemical properties of TAEs are studied both in the gas and liquid phases. Studies in the gas phase have the advantage that

TAEs with very short lifetimes can be investigated. Pioneering experiments on the chemistry of TAEs have been carried out by gas chromatography.<sup>33</sup> However, investigations in the gas phase are limited to volatile compounds. Besides, the electronic structures of the valence shells of elements in the gas phase can differ from those in the liquid state, which is reflected in their chemical behaviour.

Model experiments on the isolation and investigation of TAEs in solutions by ion-exchange chromatography in the on-line mode demonstrated the possibility of studying the physicochemical properties of radionuclides with half-lives of  $\sim 5\text{--}10\text{ s}$ .<sup>34, 35</sup> Short-lived radionuclides with half-lives of  $\leq 1\text{ s}$  were isolated and detected using the super fast SISAK III (Short-lived Isotopes Studied by the AKUFVE Technique) extraction system.<sup>36</sup>

In the last decade, investigations of the chemical properties of TAEs have attracted considerable interest. In 2000–2001, studies on the synthesis of TAEs were started in the world-famous Orsay (France) and JAERI (Japan) nuclear research centres, in particular, with the use of ion-exchange chromatography. The number of publications, including relativistic quantum-chemical calculations of the atom states of TAEs in different systems, sharply increased.<sup>37</sup>

In several reviews, experiments on the isolation and the chemical behaviour of TAEs in the gas and liquid phases were analysed (in solutions, the behaviour of only Rf, Db and Sg and their homologues was considered).<sup>38–41</sup> Data on model experiments aimed at studying TAEs in solutions containing various complexing ligands<sup>42–54</sup> are virtually lacking, although these experiments are required to search for the optimum conditions of isolation, prediction of the chemical properties of TAEs and elucidation of the relativistic effects.

The present review provides an overview of the general approaches to the development of procedures for isolation and investigation of the chemical properties of trace amounts of short-lived TAEs in solutions. The possibility of studying the chemical properties of TAEs (speciation of elements in solution, hydrolysis, complexation, valence states, *etc.*), including elements with  $Z \geq 106$ , was demonstrated by investigations of the homologous elements in various systems. The results of the isolation of short-lived isotopes of Hf, Ta, W, Re, Os, Hg, Pb as homologues of Rf, Db, Sg, Bh, Hs and elements 112 and 114, respectively, and studies of their chemical behaviour are considered. Experimental data on the isolation and the chemical properties of Rf, Db and Sg in solution obtained by chromatographic, extraction and other methods are summarised. In the review, it was shown that the relativistic effects can be revealed by performing comparative studies of the behaviour of TAEs and their homologues in solutions containing various complexing ligands. The results of studies and prospects for the use of different methods for the isolation and investigation of the chemical properties of TAEs in solution are discussed.

## II. Principles of production and isolation of transactinide superheavy elements

### 1. Production of heavy and superheavy elements

The first artificial actinide elements were produced primarily by successive neutron capture in high-flux nuclear reactors or underground nuclear explosions in high neutron fluxes. The last element prepared by this method was  $^{257}\text{Fm}$  ( $T_{1/2} \approx 100\text{ days}$ ,  $Z = 100$ ). Heavier nuclei are impossible to produce by this method because of short lifetimes. Transfermium elements have been synthesised

by reactions with multicharged ions at accelerators.<sup>‡</sup> The elements with  $Z = 101–105$  were prepared by so-called ‘hot-fusion’ reactions using bombardment of targets containing heavy isotopes of transuranium elements (from U to Es) with the accelerated  $^{11}\text{B}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ,  $^{15}\text{N}$ ,  $^{16}\text{O}$ ,  $^{18}\text{O}$ ,  $^{20}\text{Ne}$ ,  $^{22}\text{Ne}$  and  $^{24}\text{Mg}$  ions. The elements with  $Z = 106–112$  were produced by the ‘cold fusion’ reactions of the  $^{208}\text{Pb}$  and  $^{209}\text{Bi}$  nuclei with the ions varying from  $^{54}\text{Cr}$  to  $^{70}\text{Zn}$ . Longer-lived isotopes of Sg, Bh and Hs were synthesised by the reactions  $^{248}\text{Cm}(^{22}\text{Ne}, 4.5\text{n})$ ,  $^{249}\text{Bk}(^{22}\text{Ne}, 4\text{n})$  and  $^{248}\text{Cm}(^{24}\text{Mg}, \text{xn})$ , respectively. The elements with  $Z = 114, 115, 116$  and  $118$  were prepared using heavy isotopes of actinides ( $^{242}\text{Pu}$ ,  $^{244}\text{Pu}$ ,  $^{243}\text{Am}$ ,  $^{248}\text{Cm}$  and  $^{249}\text{Cf}$ ) as the targets and nuclei of the rare  $^{48}\text{Ca}$  isotope as the bombarding particles.

In model experiments, the behaviour of carrier-free short-lived homologous elements is generally studied. These isotopes are also produced by nuclear reactions with multicharged ions at a cyclotron or by uranium fission. With the aim of studying the chemical properties of element 114 using its homologue (lead), a radioisotope generator was constructed to produce the short-lived  $^{211}\text{Pb}$  isotope.<sup>54</sup>

## 2. Specificity of operations with short-lived elements at the tracer scale

Experiments with trace amounts of TAEs bring up the question about the reliability of the results obtained by studying the behaviour of several or even single atoms. The question arises as to whether the behaviour of trace amounts of elements is analogous to their behaviour in macroamounts. The classical law of mass action, which is used for the description of equilibria in chemical reactions, cannot be applied to reactions with single atoms, because one and the same atom cannot exist simultaneously in different species. To solve this problem, an expression equivalent to the law of mass action was proposed.<sup>55,56</sup> In this expression, the concentration (activity, partial pressure) is replaced by the probability of the existence of the species of the element in the corresponding phase (solid, liquid, gas). Therefore, the equilibrium constant (distribution coefficient) between two phases is determined by the probability of the existence of an atom (ion) of the element in a particular phase. Evidently, chromatographic systems, in which transitions of the substance from one phase to another are repeated many times, can be reliably used to study the chemical behaviour of elements at the tracer scale. The classical example supporting this fact is the use of chromatography in experiments on the isolation of 17  $^{256}\text{Md}$  atoms ( $T_{1/2} = 75$  min). The chemical identification of mendelevium was carried out from the peak position on the elution curve from a cation-exchange column with a solution of ammonium  $\alpha$ -hydroxyisobutyrate. The peak of mendelevium exactly coincides with the peak of thulium, which is its chemical analogue.<sup>57</sup> The behaviour of the element in trace amounts was demonstrated<sup>58</sup> to be identical to its behaviour in macroamounts in the absence of additional factors, for example, the influence of loading the resin with a macrocomponent in the chromatographic separation of elements. In my opinion, studies of the chemistry at the microamount level provide the most reliable insights into the chemical properties of elements, because in this case no side processes (polymerisation, disproportionation, *etc.*), which are often observed in experiments with macroamounts, occur.

## 3. Techniques for isolation and determination of short-lived radionuclides formed in reactions with multicharged ions

The techniques for isolation and determination of TAEs and short-lived isotopes of homologous elements, which are produced by nuclear reactions with multicharged ions at accelerators, have been described in detail in the literature.<sup>38–41</sup> The transport of nuclear reaction products from the irradiated target to the corresponding chemical apparatus is generally performed through

a thin capillary using an aerosol gas jet ( $\text{KCl}/\text{H}_2$ , *etc.*). Transactinide elements are isolated and their chemical properties are studied using both the cyclic and continuous (on-line) modes. The former mode involves repeated cycles of isolation, separation and determination of TAEs by correlating the  $\alpha$ – $\alpha$  decays of the parent and daughter radionuclides. The second mode is based on the on-line isolation of short-lived TAEs and separation from radionuclides, which hinder the detection, during their production followed by the long-lived decay product determination.

When isolating TAEs and investigating their behaviour by liquid extraction in the cyclic mode, all chemical operations are carried out manually. The optimum time for one experiment is several minutes. The extraction method was used to isolate  $^{261}\text{Rf}$  and study its chemical properties.<sup>14–17</sup> The process involving chromatographic methods was automated. The Automated Rapid Chemistry Apparatus (ARCA), which includes microcolumns and microprocessor computers, was used to isolate and study Rf,<sup>8–10</sup> Db (see Refs 22, 23, 25 and 26) and Sg.<sup>30,31</sup> This high-precision and expensive apparatus was described in detail in the studies.<sup>38,39,59</sup> The central part of the apparatus consists of an aerosol collector and two magazines each containing twenty  $1.6 \times 8$  mm microcolumns. The columns are packed with the necessary sorbent (ion-exchange resin, extractant on an inert support, *etc.*). A solution in which aerosol is dissolved is delivered to the collector. The resulting solution containing radionuclides (sorbate) is fed to one of the moving microcolumns. The column moves further and another solution (eluate, desorbate) is fed. Then the second column takes the place of the first column, and a new portion of the sorbate containing radionuclides is delivered, *etc.* Solutions eluted from each column are collected on individual supports, dried and directed to  $\alpha$ -spectrometric measurements. The minimum time for each cycle (dissolution of the aerosol, adsorption, elution, desorption and preparation of a source for radiometric measurements) is 45–90 s; 2/3 of this time is spent on the preparation of the source. The automated system makes it possible to perform repeated cycles of isolation of short-lived radionuclides; the number of cycles can be several thousand. However, the possibilities to use the ARCA apparatus for studying the chemistry of SHEs are limited due to very low yields of radionuclides in a unit time and the unreliability of the studies.

The isolation and determination of short-lived isotopes of TAEs in the continuous (on-line) mode holds the most promise. This approach involving ion-exchange chromatography was developed in FLNR JINR.<sup>6,60</sup> The scheme of the apparatus is shown in Fig. 1. The nuclear reaction products are directed to an absorber using an aerosol gas jet. The aerosol is dissolved in the

**Figure 1.** Scheme of the continuous radiochemical isolation of TAEs.<sup>6,60</sup> (1) An irradiated target, (2) a heavy ion beam, (3) an aerosol generator ( $\text{KCl}$ ), (4) an absorber, (5) a degasser, (6) a filter, (7) the solution under study, (8) peristaltic pumps, (9) the first cation-exchange column, (10) an anion-exchange column, (11) the second cation-exchange column, (12) an eluate.

<sup>‡</sup> The  $^{254}–^{258}\text{Md}$  isotopes were produced in the reactions  $^{253,254}\text{Es}(\alpha, \text{xn})$ .

solution under study, which is continuously fed to the absorber. Then the solvent containing TAEs and other radionuclides is passed through three ion-exchange columns connected in series. The first (cation-exchange column) is used to separate transactinide elements from actinide (primarily transplutonium) elements (TPEs), which are strongly retained on the cation-exchange resin, whereas TAEs remain in the solution and are sorbed on the second (anion-exchange) column. The decay products of TAEs, *viz.*, late TPEs (No, Fm, Es), are sorbed on the third (cation-exchange) column. Transactinide elements are identified by long-lived decay products after their desorption from the third column and preparation of one sample (source) for  $\alpha$ -spectrometric measurements. Therefore, this method allows one to perform continuous isolation and separation of short-lived TAEs from TPEs produced in nuclear side reactions followed by their detection by long-lived decay products, which are accumulated throughout the experiment. The latter fact is of considerable importance for the isolation of trace amounts of radionuclides (single atoms) with a low production cross-section in nuclear reactions. The method of continuous isolation of TAEs was successfully used to isolate and investigate  $^{261}\text{Rf}$  (see Refs 6, 7, and 60; in the cited studies, the element is called Kurchatovium, Ku) and  $^{262}\text{Db}$  (see Ref. 27) in dilute solutions of hydrofluoric acid. This approach was also used in model experiments on the isolation and investigation of the behaviour of short-lived isotopes of transition d elements (homologues of TAEs). These radionuclides were also determined in the on-line mode using high-resolution HPGe detectors connected to a computer.<sup>34, 35, 43, 44, 46, 48, 52, 61–64</sup>

The super fast SISAK III system, which includes mixers, minicentrifuges and a liquid scintillation detector, was designed for isolation of TAE by extraction and its determination in the on-line mode. Radionuclides are determined in a flowing organic phase. The system was successfully used to separate short-lived radionuclides, including homologues of TAEs.<sup>36, 50, 65–67</sup> The short-lived  $^{257}\text{Rf}$  isotope ( $T_{1/2} \approx 4$  s) was isolated for the first time (in 2001) and chemically identified with the use of the SISAK system.<sup>20</sup>

### III. Isolation and chemical properties of transactinide elements with $Z = 104–118$ and their homologues

#### 1. Rutherfordium

##### a. Theoretical prerequisites

Rutherfordium is the first element in the series of d-transition elements in the seventh period of the Periodic table.<sup>8</sup> Relativistic calculations by the Dirac–Fock method demonstrated<sup>68</sup> that the electronic configuration of an isolated atom of element 104 in the ground state is  $[\text{Rn}]5f^{14}6d^27s^2$ . Therefore, Rf belongs to Group IVB and its chemical properties would be analogous to the properties of Hf and Zr. It was also hypothesised<sup>38</sup> that the electronic configurations  $5f^{14}6d^7s^27p^1$  or  $5f^{14}7s^27p^2$  (after the filled radon shell) can exist. In this cases, rutherfordium can exhibit chemical properties similar to those of p elements (for example, of Pb). However, the lead atom has a completely filled d shell:  $[\text{Xe}]4f^{14}5d^{10}6s^26p^2$ . If only the outer electron shells are taken into account, thorium is also an electronic analogue of rutherfordium:  $[\text{Rn}]f^06d^27s^2$ . Hence, thorium can be considered as a pseudohomologue of rutherfordium. Plutonium is also considered as a pseudohomologue, because Pu(IV) involved in certain systems behaves analogously to Group IVB elements.

§ Hereinafter, the groups of elements are denoted by Roman numerals (I–VIII), which are used in the ‘short-period’ form of the Periodic table. In the ‘long-period’ form of the Periodic table, the groups of elements are denoted by Arabic numerals (1–18).

#### b. Behaviour of Group IVB elements in solution

To isolate rutherfordium and study its chemical properties by ion-exchange chromatography, the behaviour of its homologues and pseudohomologues, *viz.*, Hf, Zr, Th and Pu, was investigated in solutions containing inorganic and organic complexing ligands (upon their sorption on cation- and anion-exchange resins).<sup>6, 8, 42–45, 47, 60, 62, 69</sup>

**Use of cation-exchange resins.** Figure 2 illustrates the influence of the nature and concentration of an acid on the distribution coefficients ( $K_d$ ) of hafnium, thorium, some TPEs, rare-earth elements and strontium upon sorption on Dowex-50  $\times$  8 cation-exchange resin. In these experiments, strontium was studied as a homologue of element 102 (No) produced in the decay chain

(e.c. is electron capture).

A knowledge of the behaviour of No, as well as trivalent TPEs (REEs), which are produced in substantial amounts in the synthesis of TAEs, is of particular importance if the latter are identified from daughter decay products.

Hafnium is virtually not sorbed by the cation-exchange resin from HF,  $\text{H}_3\text{PO}_4$  and  $\text{H}_2\text{C}_2\text{O}_4$  solutions but exhibits high adsorbability in  $\text{H}_2\text{SO}_4$  solutions at a concentration of  $\leq 0.1$  mol litre<sup>-1</sup>. Thorium is much more strongly (compared to Hf) sorbed on the cation-exchange resin, this difference being most pronounced in dilute HF and  $\text{H}_3\text{PO}_4$  solutions. Transplutonium elements, REEs and strontium have large distribution coefficients ( $\geq 10^4–10^6$ ) in acids at concentrations of  $\leq 0.1–0.5$  mol litre<sup>-1</sup>. The degree of sorption of the elements sharply decreases with increasing concentration of the acid due to competitive sorption of  $\text{H}^+$  on the cation-exchange resin.

**Figure 2.** Plots of the distribution coefficients of elements *vs.* the acid concentration in solutions for sorption on Dowex-50  $\times$  8 cation-exchange resin.<sup>43, 45, 47</sup>

Acid: (a) HF, (b)  $\text{H}_3\text{PO}_4$ , (c)  $\text{H}_2\text{SO}_4$ , (d)  $\text{H}_2\text{C}_2\text{O}_4$ .

The order of elution of the elements from the cation-exchange resin reflects their tendency to form complexes in solution. The low adsorbability of Hf on the cation-exchange resin is attributable to the fact that transition d elements are more prone to form neutral and negatively charged complexes with  $F^-$ ,  $H_2PO_4^-$  and  $C_2O_4^{2-}$  than with the  $HSO_4^-$  ions. The presence of  $F^-$  anions in  $H_2SO_4$  solutions leads to a sharp decrease in the distribution coefficients of hafnium already at the HF concentration higher than  $5 \times 10^{-4}$  mol litre $^{-1}$ , whereas the distribution coefficients of strontium and TPEs (REEs) remain virtually unchanged (Fig. 3).<sup>45</sup> An analogous behaviour of hafnium and zirconium is observed upon their sorption on the cation-exchange resin from mixed  $HNO_3$ /HF solutions. An increase in the HF concentration from  $5 \times 10^{-4}$  to  $5 \times 10^{-2}$  mol litre $^{-1}$  in 0.1 M  $HNO_3$  solution leads to a decrease in the distribution coefficients of zirconium and hafnium by approximately three orders of magnitude.<sup>8</sup> These data are indicative of the formation of stable neutral and negatively charged complexes of these elements with  $F^-$  ions in solutions containing HF at concentrations of  $\geq 10^{-3}$  mol litre $^{-1}$ . At lower HF concentrations, cationic complexes and various hydrolysed forms adsorbed on the cation-exchange resin can exist. Therefore, the ability of inorganic ligands to form complexes with Hf and Zr increases in the following series  $OH^- > F^- > H_2PO_4^- > HSO_4^-$ .

**Figure 3.** Plots of the distribution coefficients of elements vs. the HF concentration in a 0.05 M  $H_2SO_4$  solution for sorption on Dowex-50  $\times$  8 cation-exchange resin.<sup>45, 47</sup>

The difference in the distribution coefficients of Hf, Zr, TPEs (REEs) and Sr is responsible for the high separation factors of these elements on the cation-exchange resin in dilute HF,  $H_3PO_4$ ,  $H_2C_2O_4$  and  $H_2SO_4$ /HF solutions. Hence, these systems can be used to separate Hf and Zr (Rf) from TPEs from large volumes of solutions with purification factors of  $\geq 10^5$ – $10^6$  on small cation-exchange columns in the on-line mode.<sup>6, 42–45, 47</sup> In this case, weakly adsorbed elements (Hf, Zr, Rf) are continuously washed out, whereas TPEs, REEs and Sr (No) remain on the column.

**Use of anion-exchange resins.** The plots of the distribution coefficients of Hf, Sr and TPE (REEs) vs. the concentration of acids upon their adsorption on Dowex-1  $\times$  8 anion-exchange resin from HF,  $H_2SO_4$ ,  $H_3PO_4$  and  $H_2C_2O_4$  solutions are shown in Fig. 4. The distribution coefficients of hafnium and zirconium are rather high ( $> 10^2$ – $10^4$ ), whereas TPEs (REEs) and strontium are virtually not sorbed on the anion-exchange resin from HF,  $H_3PO_4$  and  $H_2SO_4$  solutions but have high adsorbability in dilute  $H_2C_2O_4$  solutions. Sorption of TPEs (REEs) and Sr in  $H_2C_2O_4$  solutions sharply decreases in the presence of small amounts of HCl (Fig. 5). Therefore, anion-exchange columns can be used both to concentrate Rf, Hf and Zr and separate these elements from the daughter radionuclides (TPEs, REEs) in dilute HF,  $H_2SO_4$ ,  $H_3PO_4$ ,  $H_2C_2O_4$ /HCl and  $H_2SO_4$ /HF solutions.<sup>5, 43–47</sup>

Acid: (a) HF, (b)  $H_3PO_4$ , (c)  $H_2SO_4$ , (d)  $H_2C_2O_4$ .

**Figure 5.** Plots of the distribution coefficients of elements vs. the HF concentration in a 0.05 M  $H_2C_2O_4$  solution for sorption on Dowex-1  $\times$  8 anion-exchange resin.<sup>44</sup>

### c. Model experiments

The possibility of using various systems for the isolation of TAEs in the on-line mode was examined in model experiments on the isolation of short-lived hafnium isotopes and investigation of their chemical behaviour under conditions simulating isolation of Rf.<sup>34, 43, 44, 46, 61, 62, 70</sup> The hafnium isotopes were produced by the nuclear reactions  $^{144}\text{Sm}(^{20}\text{Ne}, xn)\text{Hf}$  and  $\text{Gd}(^{18}\text{O}, xn)\text{Hf}$  at the U-400 cyclotron (FLNR JINR). The scheme of isolation was analogous to that presented in Fig. 1. The solution under study containing nuclear reaction products was continuously passed (at a flow rate of  $\sim 2$  ml min $^{-1}$ ) through three  $0.4 \times 4$  cm columns, which were connected in series and filled with Dowex-50  $\times$  8 cation-exchange resin, Dowex-1  $\times$  8 anion-exchange resin and Dowex-50  $\times$  8 cation-exchange resin, respectively.  $\gamma$ -Spectrometric measurements of the columns were carried out in turn both in

**Table 3.** Sorption (from 0.5 M H<sub>3</sub>PO<sub>4</sub> solutions) of hafnium isotopes produced in the reactions Gd(<sup>18</sup>O, xn) and radioactive decay products of hafnium on ion-exchange columns.<sup>43</sup>

|                            |                       |              | <sup>170</sup> Hf          | 960                   | 100          |                            |                       |              |

the on-line mode (the solution containing radionuclides was passed through the columns) and in the off-line mode (the flow of the solution was discontinued). Radionuclides of hafnium and its daughter decay products, which were detected on three ion-exchange columns by passing a 0.5 M H<sub>3</sub>PO<sub>4</sub> solution containing the radionuclides, are given in Table 3.<sup>43</sup> The hafnium radionuclides were completely sorbed on the anion-exchange column, whereas its radioactive decay products, REEs (Lu, Yb), were detected primarily on the last column (> 90%), and substantially smaller amounts of the latter products were detected on the first column. Rare-earth elements, which are the daughter radionuclides of Hf, were sorbed on the first cation-exchange column; these radionuclides were produced in the system before the solution was passed through this column. The second cation-exchange (third in order) column sorbed radionuclides produced by the decay of Hf isotopes, which were retained on the anion-exchange column, for example,

Analogous results were obtained in model experiments on the isolation of short-lived Hf isotopes from 0.2 M HF and 0.05 M H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>/0.1 M HCl solutions.<sup>44,46</sup> These experiments demonstrated that the above-mentioned systems can be used for the continuous, on-line, isolation of <sup>261</sup>Rf and its determination by the long-lived decay products, viz., <sup>253</sup>Fm and <sup>253</sup>Es.

A procedure was developed for the determination of the distribution coefficients of Rf between anion-exchange resins and HNO<sub>3</sub>/HF solutions in the on-line mode in the study of short-lived Hf isotopes.<sup>62</sup> The conditions of sorption (the amount and the nature of the anion-exchange resin, the elution rate) were chosen so that the retention time of Hf (Rf) on the column corresponds to the half-life of the radionuclide. Hafnium was found to be sorbed on the anion-exchange resin as the negatively charged HfF<sub>6</sub><sup>2-</sup> complex.

#### d. Isolation of rutherfordium and investigation of its chemical properties

**Chromatographic methods.** As mentioned above, pioneering experiments on the isolation of <sup>261</sup>Rf and investigation of its chemical behaviour in solution were carried out by ion-exchange chromatography, which had been used earlier for the identification of TPEs (LBL, Berkley, USA, 1970).<sup>5</sup> Like zirconium and hafnium, rutherfordium was eluted from a cation-exchange column with a solution of  $\alpha$ -hydroxyisobutyric acid ( $\alpha$ -HIBA) much more rapidly than TPEs. In the experiment, 17  $\alpha$ -decays of <sup>261</sup>Rf (T<sub>1/2</sub> = 65 s) and its daughter radionuclide <sup>257</sup>No (T<sub>1/2</sub> = 25 s) were observed. The second investigation of Rf in solution was published 10 years later, when the first automated apparatus for rapid isolation of short-lived TAEs was constructed.<sup>12</sup>

The behaviour of rutherfordium in HCl solution was studied by the extraction-chromatographic method using columns filled with Aliquat-336 (methyltricapryl ammonium chloride) on an inert support. A 12 M HCl solution containing Rf and Hf radionuclides and trivalent TPEs was passed through a column, which was then washed with a 6 M HCl solution. Transplutonium elements were eluted from the column with a 12 M HCl solution.

The main amounts of Rf and Hf were found in the 6 M HCl fraction. In the experiment, only six  $\alpha$ -decays of <sup>261</sup>Rf and its daughter element (<sup>257</sup>No) were observed. However, the authors of the study<sup>5</sup> concluded that Rf, like Hf and Zr, forms negatively charged complexes in concentrated HCl solution. More recently, the ability of Rf to form negatively charged chloride complexes in concentrated HCl solution was confirmed by the ion-exchange method (JAERI, Japan).<sup>9</sup> The experiments were carried out on an AIDA apparatus (Automated Ion Exchange Separation Apparatus Coupled with the Detection System for Alpha Spectroscopy), which is an improved modification of the above-described ARCA apparatus. It was demonstrated that sorption of Rf, Hf and Zr on CA08Y anion-exchange resin increases with increasing concentration of HCl from 7.0 to 11.5 mol litre<sup>-1</sup> (K<sub>d</sub> may be as large as ~ 10<sup>3</sup>), whereas Th is not sorbed on the anion-exchange resin. The adsorbability of the elements decreases in the series Rf > Zr > Hf, which indicates that Rf is more prone to form negatively charged chloride complexes (compared to Hf and Zr) in concentrated HCl solutions.

The chemical properties of Rf in dilute HF solutions were studied by the above-described method for the continuous isolation of short-lived radionuclides followed by their identification by long-lived decay products (FLNR JINR).<sup>6,60</sup> The <sup>261</sup>Rf isotope was produced using a combined target consisting of <sup>248</sup>Cm and <sup>157</sup>Gd, which was bombarded at the U-400 cyclotron with <sup>18</sup>O ions with an energy of 97–102 MeV and a beam intensity of 4 × 10<sup>12</sup> pps. The scheme of isolation of radionuclides from the irradiated target was analogous to that presented in Fig. 1. A 0.2 M HF solution containing radionuclides was continuously passed at a flow rate of 1.5–2.0 ml min<sup>-1</sup> through three columns (0.4 × 4 cm), which were connected in series and filled with Dowex-50 × 8 cation-exchange resin, Dowex-1 × 8 anion-exchange resin and Dowex-50 × 8 cation-exchange resin, respectively. The first cation-exchange column was replaced from time to time with a new column (after 300 ml of the solution was passed). The time of aerosol transport to the absorber was 5 s. The time during which the solution was passed through the absorber and three ion-exchange columns was no longer than 30 s. Throughout the experiment, radionuclides that appeared in different parts of the system were monitored by radiometry using Ge/Li detectors. The Hf isotopes, which were produced in the Gd(<sup>18</sup>O, xn) reactions, and isotopes of REEs, which were produced by the decay of hafnium, were detected on the anion- and cation-exchange columns, respectively. The total time of irradiation was 24 h. After completion of irradiation, the cation-exchange columns were washed with 6 M HNO<sub>3</sub> solutions, which were analysed for  $\alpha$  and  $\gamma$  activities. The  $\alpha$  spectra of radionuclides desorbed from the first and second cation-exchange columns are shown in Fig. 6. It can be seen that curium isotopes were present in large amounts on the first column (see Fig. 6a). This is accounted for by the fact that the target substance appeared in the system. In addition, the peaks characteristic (in energy of  $\alpha$  particles) of the Cf isotopes, <sup>253</sup>Es, <sup>254</sup>Fm and <sup>255</sup>Fm are clearly seen. The spectrum of the desorbate from the second cation-exchange column (see Fig. 6b) shows only a small amount of Cm isotopes, whereas Cf isotopes are absent, which is indicative

**Figure 6.**  $\alpha$ -Spectra of radionuclides, which were produced in the synthesis of  $^{261}\text{Rf}$ .<sup>6,60</sup> The desorbates from the first (a) and second (b) cation-exchange (Dowex-50  $\times$  8) columns.

of a high degree of purification ( $K_p \approx 10^5$ ) from these radionuclides on the first column. There is a peak in the region of  $^{253}\text{Es}$  (6.63 MeV), whereas  $\alpha$  particles belonging to the  $^{254}\text{Fm}$  and  $^{255}\text{Fm}$  isotopes are not observed. In the time measurements of the  $\alpha$  activity of the desorbate from the second cation-exchange column, the activity first increased and then decreased with  $T_{1/2} = 20$  days, which corresponds to  $T_{1/2}$  for  $^{253}\text{Es}$ . The initial increase is associated with accumulation of  $^{253}\text{Es}$ , which was produced by the  $\beta$  decay of  $^{253}\text{Fm}$  that formed in the chain

The absence of the  $^{254}\text{Fm}$  and  $^{255}\text{Fm}$  isotopes and the presence of the  $^{253}\text{Fm}$  and  $^{253}\text{Es}$  isotopes on the second cation-exchange column unambiguously indicate that the latter isotopes are produced by the decay of  $^{261}\text{Rf}$ , which is retained on the anion-exchange column. Evidently, Rf, like Group IVB elements (Hf and Zr), forms negatively charged complexes in dilute HF solutions. These complexes are not sorbed on the cation-exchange resin but are strongly retained on the anion-exchange resin. A total of  $\sim 500$   $\alpha$  particles belonging to  $^{253}\text{Es}$ , which was produced by the decay of  $^{261}\text{Rf}$ , were detected, which is larger by an order of magnitude than the amount of  $^{261}\text{Rf}$  isolated in other experiments. This is evidence that the method under consideration has advantages in isolating TAEs at the tracer scale and providing reliability of their identification.

The anion-exchange behaviour of Rf, Zr and Hf in 1.9–13.9 M HF solutions was studied using an automated AIDA chemical apparatus.<sup>10</sup> Sorption of Zr and Hf was found to decrease sharply at HF concentrations higher than 8 mol  $\cdot$  litre $^{-1}$ , whereas sorption of Rf decreases gradually already at HF concentrations higher than 4 mol  $\cdot$  litre $^{-1}$ . This difference was accounted for by the formation of less stable fluoride complexes of rutherfordium due to the possible influence of the relativistic effects.<sup>19</sup>

The determination of the distribution coefficients of  $^{261}\text{Rf}$  between Wofatit HS 36 anion-exchange resin and mixed  $\text{HNO}_3/\text{HF}$  solutions in the on-line mode demonstrated that the coefficients for Rf and Hf in 0.1 M  $\text{HNO}_3/0.27$  M HF and 0.2 M  $\text{HNO}_3/0.27$  M HF solutions are of the same order of

magnitude ( $\sim 50$  and  $\sim 15$ , respectively).<sup>7</sup> However, the investigation of sorption of  $^{261}\text{Rf}$  and Hf on Bio-Rad AG1X8 anion-exchange resin (with an ARCA apparatus) showed<sup>8</sup> that the distribution coefficients of Rf and Hf in 0.1 M  $\text{HNO}_3$  solutions containing HF at a concentration of  $1 \times 10^{-2}$ –1.0 mol  $\cdot$  litre $^{-1}$  differ by more than two orders of magnitude. In this case, the degree of sorption of Rf on the anion-exchange resin was very low ( $K_d < 8$ ). Hence, the authors of the study<sup>8</sup> have cast doubt on the results obtained in the study.<sup>7</sup> Moreover, the behaviour of Rf in  $\text{HNO}_3/\text{HF}$  solutions was demonstrated to be analogous to the behaviour of its pseudohomologue Th both on the anion- and cation-exchange resins. However, it is not quite correct to compare the results of the cited studies,<sup>7,8</sup> because anion-exchange resins with different functional groups were used. The low distribution coefficients  $K_d$  (see Ref. 8) of Rf on the anion-exchange resin cannot serve as an evidence for the absence of anionic fluoride complexes of Rf. The presence of  $\text{NO}_3^-$  ions, which are strongly sorbed on the anion-exchange resin, leads to a substantial decrease in radionuclide sorption. The decrease in the  $\text{HNO}_3$  concentration from 0.1 to 0.01 mol  $\cdot$  litre $^{-1}$  was demonstrated<sup>8</sup> to cause an increase in the distribution coefficient of rutherfordium by more than an order of magnitude ( $\geq 10^2$ ) and it becomes similar to  $K_d$  for Hf within the experimental error. Later on, it was found that the presence of  $\text{HNO}_3$  in HF solutions has a much stronger effect on the sorption of Rf on the anion-exchange resin compared to the sorption of Hf or Zr.<sup>11</sup>

The anion-exchange behaviour of rutherfordium in concentrated  $\text{HNO}_3$  solution was studied with the use of an AIDA apparatus.<sup>9</sup> Irradiation of the combined  $^{248}\text{Cm} + \text{natGe} + \text{natGd}$  target (nat is natural) with  $^{18}\text{O}$  ions produced  $^{261}\text{Rf}$  along with the  $^{85}\text{Zr}$  and  $^{169}\text{Hf}$  isotopes. It was found that Rf, like Zr and Hf, is virtually not sorbed on CA08Y anion-exchange resin from 8 M  $\text{HNO}_3$  solution. Preliminary experiments showed that Th and Pu have high adsorbability ( $K_d \geq 10^2$ – $10^3$ ) under the same conditions.

**Extraction methods.** *Extraction with triisooctylamine (TIOA).* Upon isolation of Rf by extraction from 0.5, 4.0 and 8.0 M HF solutions using a 0.25 M TIOA solution in xylene as the extractant<sup>17</sup> (383 experiments), 14  $\alpha$ – $\alpha$  correlations of the  $^{261}\text{Rf}$ – $^{257}\text{No}$  were observed in the organic fraction (only upon extraction from 0.5 M HF solutions). Group IV elements were extracted with TIOA from HF solutions in the series  $\text{Ti} > \text{Zr} \approx \text{Hf} > \text{Rf}$ , i.e., the order varies inversely with their ionic radii ( $\text{Rf} > \text{Hf} \geq \text{Zr} > \text{Ti}$ ), which is indicative of the formation of inner-sphere complexes.

The  $^{261}\text{Rf}$  isotope was extracted from 12 M HCl solutions with 0.1 M and 1.0 M TIOA solutions in benzene.<sup>14</sup> In the organic phase, 20 events with energies of  $\alpha$  particles belonging to  $^{261}\text{Rf}$  and  $^{257}\text{No}$  were observed (only upon extraction with 0.1 M TIOA). Under analogous conditions,  $^{95}\text{Zr}$  and  $^{95}\text{Nb}$  were extracted with  $K_d \geq 10^2$ , whereas  $^{152}\text{Eu}$  and  $^{228}\text{Th}$  were virtually not extracted. Hence, the data on the extraction confirm the results of chromatographic experiments on the formation of negatively charged Rf complexes in concentrated HCl solutions.<sup>9,12</sup>

*Extraction with tributyl phosphate (TBP).* With the aim of studying neutral rutherfordium chloride complexes, extraction of  $^{261}\text{Rf}$ ,  $^{95}\text{Zr}$ ,  $^{169}\text{Hf}$ ,  $^{228}\text{Th}$  and  $^{238}\text{Pu}$  was examined with the use of a TBP solution in benzene as the extractant depending on the concentrations of HCl and the  $\text{Cl}^-$  and  $\text{H}^+$  ions.<sup>15</sup> The Group IVB elements were extracted from 8–12 M HCl solutions with TBP (0.25 mol  $\cdot$  litre $^{-1}$ ) in the following order:  $\text{Zr} > \text{Rf} > \text{Hf}$ . In the case of extraction of  $^{261}\text{Rf}$ ,  $^{95}\text{Zr}$ ,  $^{175}\text{Hf}$ ,  $^{181}\text{Hf}$  and Ti with a 0.35 M TBP solution in benzene from concentrated HCl solutions, the elements were extracted in another order:<sup>16</sup>  $\text{Zr} > \text{Hf} > \text{Rf} > \text{Ti}$ . The distribution coefficients of Rf, Hf and Zr in the TBP/HCl system were determined by extraction chromatography (using an automated ARCA apparatus).<sup>13</sup> In 8 M HCl solutions, the distribution coefficients of Rf, Hf and Zr are 150, 53 and 1180, respectively. Therefore, the extractability of Group IV elements and their tendency to form neutral chloride

complexes decrease in the series  $Zr > Rf > Hf$ , which was observed experimentally<sup>15</sup> and predicted theoretically.<sup>71</sup>

Rutherfordium was not extracted from 7.75–12 M HBr solutions with the use of a 0.35 M TBP solution in benzene as the extractant.<sup>16</sup> However, the degree of isolation by extraction in the presence of LiBr was  $\sim 90\%$ . Extraction of Group IV elements from HBr solutions decreases in the series  $Zr > Hf > Rf \approx Ti$ , which was also observed for extraction from HCl solutions.<sup>16</sup>

**Extraction with dibutylphosphoric acid (DBPA).** The extraction method in the on-line mode with the use of the SISAK system was employed for the first time for the isolation of the short-lived  $^{257}Rf$  isotope ( $T_{1/2} \approx 4$  s) produced in the nuclear reaction  $^{208}Pb(^{50}Ti, n)^{257}Rf$ . Before chemical determinations, Rf was separated from other radionuclides in a gas-filled separator.<sup>20</sup> This made it possible to decrease the amounts of fission products and radionuclides, which were produced in multinucleon transfer reactions, by more than three orders of magnitude and optimize the on-line isolation and determination of  $^{257}Rf$ . The  $^{257}Rf$  isotope was extracted with a 0.25 M DBPA solution in toluene from 6 M  $HNO_3$ . The experiment time was  $\sim 18$  h, and 5  $\alpha$ - $\alpha$  correlations assigned to the  $^{257}Rf$ – $^{253}No$  pair were observed in the organic phase. Under these conditions, the behaviour of Rf is analogous to the behaviour of its light homologues, *viz.*, Zr and Hf.

**Adsorption methods.** The adsorption method combined with extraction by thenoyltrifluoroacetone (TTA) was developed for studying chelate Rf complexes in the investigation of the adsorption of Hf and Zr on a hydrophobised glass surface from 0.01 M and 1 M HCl solutions saturated with TTA.<sup>72</sup> Short-lived Rf and Hf isotopes were synthesised in the reactions  $^{248}Cm/^{152}Gd(^{18}O, 5n)$  and  $^{261}Rf/^{165}Hf^{19}$  at the U-400 cyclotron (FLNR JINR). The experiment was carried out for 16 h, during which 600 sorption cycles of radionuclide isolation were carried out and five  $\alpha$  decays of  $^{261}Rf$  were observed. All events were observed only for adsorption from 0.01 M HCl solutions with thenoyltrifluoroacetone. The short-lived  $^{168}Hf$  isotope was virtually equally sorbed from 0.01 M and 1.0 M HCl solutions (87% and 82%, respectively). It appeared that the behaviour of  $Rf^{4+}$  in the HCl–TTA system differs from the behaviour of its homologues and resembles the behaviour of  $Po^{4+}$ ,  $Sn^{4+}$  and  $Ti^{4+}$ , which form neutral complexes with TTA only in weakly acidic solutions.<sup>19</sup>

To study the hydrolysis of Rf, the ability of Group IVB elements to be adsorbed on glasses treated with transition metal ferrocyanides was investigated.<sup>18</sup> Cobalt ferrocyanides show high selectivity to the tetravalent  $Zr^{4+}$ ,  $Hf^{4+}$  and  $Th^{4+}$  cations and low selectivity to their hydrolysed  $M(OH)_3^+$  or  $M(OH)_2^{2+}$  forms. A substantial decrease in the sorption of Rf on cobalt ferrocyanide was observed already at HCl concentrations lower than 3 mol litre<sup>-1</sup>, whereas sorption of Zr and Hf decreased only at HCl concentrations lower than 1 and 0.5 mol litre<sup>-1</sup>, respectively. Consequently, hydrolysis increases in the series  $Hf < Zr < Rf$ . This behaviour of Rf was accounted for by the influence of the relativistic effect due to which the  $Rf^{4+}$  ion in aqueous solution has a coordination number of 6, whereas the coordination number of Zr and Hf is 8. However, this conclusion is inconsistent with theoretical and experimental data,<sup>73</sup> according to which the tendency of Group IVB elements to be hydrolysed increases in the reverse order,  $Rf < Hf < Zr$ , *i.e.*, in accordance with the change in the ionic radii of the elements.

## 2. Dubnium

### a. Theoretical prerequisites

The electronic configuration of an isolated atom of element 105 in the ground state should be  $[Rn]5f^{14}6d^37s^2$ . The Group VB elements Nb and Ta are chemical homologues of dubnium, and Pa is a pseudohomologue. Relativistic calculations by the Dirac–Fock method demonstrated that 7p electrons are absent in the ground state of the atom.<sup>74</sup> Therefore, no substantial deviations in the chemical behaviour of element 105 associated with relativistic effects are expected. In solution, the main oxida-

tion state of Db would be +5, although Db can also exist in lower oxidation states in the presence of strong reducing agents.<sup>75</sup>

### b. Isolation of dubnium and investigation of its chemical properties

Pioneering experiments on the isolation of element 105 and investigation of its chemical properties (earlier, this element was called hanium, Ha) in solution were carried out with the  $^{262}Db$  isotope ( $T_{1/2} = 34$  s), which was produced by the nuclear reaction  $^{249}Bk(^{18}O, 5n)$  (LBL).<sup>21</sup> When studying the chemistry of dubnium, sorption on the glass surface from fuming  $HNO_3$  solutions characteristic of Group VB elements and extraction with methyl isobutyl ketone (MIBK) from mixed  $HNO_3/HF$  solutions were investigated. Both series of experiments were carried out manually. Dubnium was adsorbed from a 15 M  $HNO_3$  solution. In 800 experiments on glass, 24  $\alpha$ - $\alpha$  decays of  $^{262}Db$  and its daughter element  $^{258}Lr$  ( $T_{1/2} = 4.3$  s) were observed. Under identical conditions, the degree of sorption of Nb and Ta was 42% and 80%, respectively. By contrast, Group IVB elements (Zr, Hf) were not sorbed. However, upon extraction of dubnium with MIBK from 3.8 M  $HNO_3/1.1$  M HF solutions (335 experiments), no events of  $\alpha$  decay or spontaneous fission of  $^{262}Db$  or  $^{258}Lr$  in the organic fraction were observed. In the authors' opinion, this behaviour of Db could be associated with the formation of unextractable doubly charged complexes  $DbF_2^{2-}$  or mixed oxyfluoride complexes. Under analogous conditions, tantalum forms singly charged  $TaF_6^-$  complexes, which are well extracted by MIBK. The possibility of relativistic stabilisation of 7s orbitals and, as a consequence, the formation of  $Db^{3+}$ , which is not extracted by MIBK, is also not ruled out.

**Extraction chromatography methods.** Extraction of dubnium with TIOA from HCl solution in the presence of small amounts of HF was studied using an ARCA apparatus.<sup>22,23</sup> The  $^{262}Db$  isotope was sorbed on a column containing TIOA on an inert support from a 12 M HCl/0.02 M HF solution. Then the column was successively washed with 4 M HCl/0.02 M HF (Pa–Nb fraction) and 6 M  $HNO_3/0.015$  M HF (Ta fraction). The  $\alpha$  activity of the  $^{262}Db$ – $^{258}Lr$  pair was found primarily in the Pa–Nb fraction. Therefore, the Group V elements are extracted with TIOA in the series  $Ta > Nb > Db > Pa$ . In the studies,<sup>22,23</sup> the 'non-tantalum' behaviour of dubnium was attributed to the fact that this element, like Nb and Pa, forms the oxyhalide or hydroxy halide complexes  $[NbOCl_4]^-$  and  $[PaOCl_4]^-$  or  $[Pa(OH)_2Cl_4]^-$ , whereas tantalum forms the purely halide complex  $[TaCl_6]^-$  under these conditions. However, this explanation is not fully explicit because the fact that HCl solutions contain the strong complexing ligand ( $F^-$  ions) is ignored.

With the aim of examining the similarity between the chemical properties of Db and Pa, a series of experiments on the extraction of Db, Pa and Nb with diisobutylcarbinol, which is a selective extractant for Pa, was carried out.<sup>24</sup> Radionuclides were sorbed on a column with diisobutylcarbinol from a 7 M HBr solution, and the column was then successively washed with a 6 M HCl/0.02 M HF solution (Nb fraction) and a 0.5 M HCl solution (Pa fraction). The investigation revealed the following series:  $Pa > Nb > Db$ . This series does not confirm the similarity in the behaviour of Db and Pa observed upon their extraction with TIOA.

The extraction behaviour of Group VB elements on a column with Aliquat-336 from pure HCl, HF and HBr solutions using an ARCA apparatus was studied in detail.<sup>25</sup> It was found that the elements were extracted from 6 M HCl solutions in the series  $Pa \gg Nb \geq Db > Ta$ . In a 4 M HF solution, dubnium was sorbed on an anion-exchange column with the distribution coefficients  $K_d > 570$ . These coefficients are similar to those for Nb and Ta ( $\geq 10^3$ ). By contrast, Pa is sorbed only to a small extent ( $K_d \approx 19$ ) under these conditions. Therefore, the Group V elements were extracted from 4 M HF solutions with Aliquat in the following series:  $Ta \geq Nb > Db > Pa$ . The degree of extraction of the Group V elements from solutions of hydrohalic acids decreases in the series  $HF > HCl > HBr$ .<sup>25</sup> These characteristic

features are consistent with the results of relativistic calculations on the stability of negatively charged halide complexes of Group V elements.<sup>71, 76</sup>

**Ion-exchange method.** The ion-exchange method in the on-line mode was used to isolate dubnium and study its behaviour in dilute HF solutions.<sup>27</sup> The <sup>262</sup>Db isotope was produced by the nuclear reaction (<sup>248</sup>Cm, xn <sup>19</sup>F) at the accelerator at the Institute of Nuclear Physics (Orsay, France). A 0.2 M HF solution containing nuclear reaction products was gradually passed through three ion-exchange columns filled with a cation-exchange resin (Bio Rad AG 50W × 8), a macroporous anion-exchange resin (Bio Rad AG MP1) and a cation-exchange resin (AG50W × 8), respectively. A high degree of purification of Db from actinide elements was achieved on the first column, Db was adsorbed on the second column, and its decay products were retained on the third column. The <sup>262</sup>Db isotope was identified by the long-lived decay product <sup>254</sup>Fm (*T*<sub>1/2</sub> = 3.24 h) after its desorption from the third cation-exchange column. It was demonstrated that <sup>262</sup>Db, which could be produced by the reaction <sup>248</sup>Cm + <sup>19</sup>F, was virtually completely (67 atoms) sorbed on the second (anion-exchange) column. A preliminary investigation of the behaviour of Group V elements on AG MP1 anion-exchange resin in HF solutions demonstrated that the elements in the HF concentration range of 0.01–0.3 mol litre<sup>−1</sup> are sorbed in the series Ta ≫ Pa > Nb with the distribution coefficients of ≥10<sup>4</sup>. The authors of the study<sup>27</sup> believed that Db, like its homologues Ta and Nb and pseudohomologue Pa, forms negatively charged complexes in dilute HF solutions, and these complexes are strongly sorbed on the anion-exchange resin.

**Anion-exchange method.** The anion-exchange behaviour of Db and its homologues and also of Pa in concentrated HF solutions was studied<sup>29</sup> with the use of an AIDA apparatus. In 14 M HF solutions, *K*<sub>d</sub> values are 35 for Db, 150 for Nb, 175 for Ta and 18 for Pa. Therefore, the order of sorption is the same as that observed for extraction with Aliquat (reagents containing identical functional groups) from 4 M HF solutions.<sup>25</sup> However, the distribution coefficients for Db on the anion-exchange resin in 14 M HF solutions are closer to those for Pa, whereas the distribution coefficients of Db for extraction from 4 M HF solutions are close to those of Nb and Ta (see above).

**Cation-exchange method.** The <sup>263</sup>Db (*T*<sub>1/2</sub> = 27 s) isotope, which was produced in the reaction <sup>249</sup>Bk (<sup>18</sup>O, 4n), was isolated and chemically identified with the use of α-hydroxyisobutyric acid as the eluent. The experiments were carried out on an ARCA apparatus. During elution of radionuclides, dubnium was washed out together with Nb, Ta and Pa from a cation-exchange column with a solution of α-HIBA within the first four seconds, unlike tri- and tetravalent radionuclides. In the authors' opinion,<sup>26</sup> the pentavalent state of dubnium is the most stable in solution.

The cation-exchange method combined with extraction was used to prove a new decay branch of <sup>263</sup>Db through electron capture and to identify <sup>263</sup>Rf.<sup>28</sup> After elution of <sup>263</sup>Db from the cation-exchange column with α-HIBA, the eluate was transferred into a 9 M HCl solution, from which radionuclides were extracted with a TBP–cyclohexane mixture. In the extractant, spontaneous fission of <sup>263</sup>Rf (*T*<sub>1/2</sub> = 20 min) was observed; the latter isotope could be produced only by the decay <sup>263</sup>Db(e.c.) → <sup>263</sup>Rf(s.f.).<sup>†</sup>

Model experiments demonstrated that dubnium can be isolated by extraction with trioctylamine (TOA) from solutions of α-hydroxyisobutyric and lactic acids in the on-line mode using the SISAK system.<sup>67</sup>

### 3. Seaborgium

#### a. Theoretical prerequisites

Calculations by the Dirac–Fock method predicted<sup>68</sup> the 5f<sup>14</sup>6d<sup>4</sup>7s<sup>2</sup> electronic configuration for a free neutral atom of element 106 in the ground state, *i.e.*, this element belongs to Group VIB. Tungsten and molybdenum are homologues of seaborgium

and U is its pseudohomologue. In aqueous solutions, Sg<sup>6+</sup> would be expected to be the most stable oxidation state of seaborgium, although the possibility of the existence of the tetravalent state in the absence of complexing ligands cannot be ruled out.<sup>77</sup> The characteristic feature of elements belonging to this group is that they form oxygen-containing compounds in aqueous solutions through strong M–O covalent bonds.

#### b. Behaviour of Group VIB elements in solutions

To identify seaborgium by chemical methods, it is necessary to separate it from daughter radionuclides, which can be produced both by nuclear reactions in the synthesis and the radioactive decay

With the aim of finding the optimum conditions for the isolation and identification of seaborgium based on its daughter decay products, the ion-exchange behaviour of its homologues, *viz.*, W and Mo, and homologues of rutherfordium and nobelium, *viz.*, Hf and Sr, respectively, the pseudohomologue U and some TPEs (Cm) and REEs (Eu) in dilute H<sub>2</sub>SO<sub>4</sub> and H<sub>2</sub>SO<sub>4</sub>/HF solutions was studied.<sup>51</sup> The effect of the H<sub>2</sub>SO<sub>4</sub> concentration on the distribution coefficients of the elements upon their sorption on cation- and anion-exchange resins is illustrated in Fig. 7. Tungsten is sorbed only to a small extent on cation-exchange resins from solutions containing H<sub>2</sub>SO<sub>4</sub> at concentrations lower than 0.1 mol litre<sup>−1</sup>, whereas the distribution coefficients of U, Hf, Sr, Cm and Eu are ≥10<sup>3</sup>–10<sup>4</sup> (see Fig. 7a). Tungsten, hafnium and uranium are sorbed on anion-exchange resins with distribution coefficients larger than 10<sup>2</sup>–10<sup>3</sup>, whereas Sr, Cf and Eu are virtually not sorbed from these solutions (see Fig. 7b). Therefore, cation-exchange columns can be used to separate W (Sg) from daughter elements, *viz.*, Hf (Rf), Sr (No) and REEs (TPEs), and from U in the on-line mode. Anion-exchange columns can be used to concentrate Group IV–VI elements and separate them from di- and trivalent elements. Since the presence of small amounts of HF in dilute H<sub>2</sub>SO<sub>4</sub> solutions has only a slight effect on the sorption of W, Hf, Sr, TPEs and U,<sup>51</sup> these solutions can also be used to isolate and study seaborgium.

Sorption of Group IV–VI elements on Dowex-50 × 8 cation-exchange resin and Dowex-1 × 8 anion-exchange resin from mixed HCl/HF solutions has been studied in detail.<sup>69</sup> It was demonstrated that Group VI and V elements can be separated from Group IV elements in the on-line mode with the use of 0.05–0.1 M HCl solutions containing 1 × 10<sup>−3</sup> mol litre<sup>−1</sup> HF.

**Figure 7.** Plots of the distribution coefficients of elements vs. the H<sub>2</sub>SO<sub>4</sub> concentration for sorption on Dowex-50 × 8 cation-exchange resin (a) and Dowex-1 × 8 anion-exchange resin (b).<sup>51</sup>

<sup>†</sup> s.f. is spontaneous fission.

The possibility of determining the distribution coefficients of Sg and the compositions of complexes in HCl/HF and HNO<sub>3</sub>/HF solutions was examined by studying the sorption of W and Mo on anion-exchange resins containing various functional groups.<sup>63, 78</sup> The sorption selectivity and the separation factor of W and Mo were demonstrated to depend strongly on the composition of the solution and the nature of the functional groups of the ion-exchange resin. The optimum conditions for the separation of the W–Mo pair in the on-line mode were found.

To isolate seaborgium with the use of the SISAK extraction system, extraction of <sup>176</sup>W, <sup>177</sup>W, <sup>99</sup>Mo, U, Th, Am, Cm, La, Ce, Tb, Lu and Hf from HNO<sub>3</sub>, H<sub>3</sub>PO<sub>4</sub> and H<sub>2</sub>SO<sub>4</sub> solutions was studied<sup>79, 80</sup> using Aliquat-336 and TOA. The optimum conditions for the separation of Group VI elements and U from TPEs, REEs and Hf were found. The extraction of elements in different oxidation states decreases in the series  $M^{4+} > MO^{2+} > M^{3+}$ .

### c. Model experiments

**Ion-exchange methods.** Short-lived tungsten isotopes, which were produced in the nuclear reactions Sm (<sup>24</sup>Mg, xn) at a cyclotron, and Mo, Zr, Ba and REE radionuclides produced by fission of <sup>235</sup>U were isolated in model experiments and their chemical behaviour in dilute H<sub>2</sub>SO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>/HF,<sup>52</sup> HF (see Refs 34, 46 and 48) and HCl/HF solutions<sup>61</sup> was studied. The radionuclides were isolated and determined in the on-line mode using two–three ion-exchange columns. Table 4 lists the tungsten isotopes and products of their radioactive decay, which were determined on columns during elution with a 0.05 M H<sub>2</sub>SO<sub>4</sub> solution containing the radionuclides. The Hf and REE isotopes, which were produced by the decay of tungsten before the solution was fed into the column, were sorbed on the first (cation-exchange) column. The tungsten isotopes and products of their radioactive decay, viz., the ‘daughter’ (tantalum) and ‘granddaughter’ (hafnium) isotopes, adsorbed on the second (anion-exchange) column. The ‘great-granddaughter’ isotopes (Lu and Yb, respectively) were retained on the third (cation-exchange) column. The <sup>168</sup>W, <sup>169</sup>W and <sup>172</sup>W isotopes were found on the anion-exchange resin, but the shorter-lived <sup>167</sup>W isotope ( $T_{1/2} = 19.3$  s) was not detected because of the lack (at that instant) of data on the  $\gamma$ -radiation energies of this radionuclide. However, the presence of the <sup>167</sup>Ta, <sup>167</sup>Hf, <sup>167</sup>Lu and <sup>167</sup>Yb radionuclides, which could be produced only by successive  $\beta^+$ -decays of <sup>167</sup>W, on the anion-exchange column and the second cation-exchange column, provides evidence that this isotope was also present on the anion-exchange column.

Therefore, the short-lived parent radionuclide was chemically identified based on the genetic relationship to longer-lived decay products. The results of model experiments suggest that <sup>265</sup>Sg ( $T_{1/2} = 7 \pm 3.3$  s) can be isolated and its chemical properties can be studied in the on-line mode followed by the identification with

the longer-lived decay products <sup>261</sup>Rf, <sup>253</sup>Fm and <sup>253</sup>Es, which can be accumulated on anion-exchange or cation-exchange columns.

**Extraction method.** Tungsten and molybdenum as homologues of Sg were isolated by on-line extraction using the SISAK system.<sup>67</sup> It was demonstrated that the degree of extraction of Group VI and V elements with TOA from solutions of  $\alpha$ -hydroxyisobutyric or lactic acids is 80% (or higher), whereas Group IV elements (Hf) and REEs remain in the aqueous phase. The best separation was achieved by extraction from 1 M  $\alpha$ -HIBA solutions at pH 1–2 with the use of 0.046 M TOA as the extractant.

### d. Isolation of seaborgium and investigation of its chemical properties

The first experiments on the isolation of seaborgium and investigation of its behaviour in solution were carried out after the ‘long-lived’ <sup>265</sup>Sg ( $T_{1/2} = 7 \pm 3$  s) and <sup>266</sup>Sg ( $T_{1/2} = 20 \pm 16$  s) isotopes had been synthesised in FLNR JINR,<sup>4</sup> although the <sup>263</sup>106 isotope ( $T_{1/2} = 0.9$  s) was discovered as early as 1974. The <sup>265</sup>Sg and <sup>266</sup>Sg isotopes were produced in the nuclear reaction <sup>248</sup>Cm + <sup>22</sup>Ne at the Unilac Accelerator Facility (Darmstadt, Germany).<sup>30</sup> Seaborgium was separated from other radionuclides on the ARCA apparatus using chromatographic columns (1.6 × 8 mm) filled with Aminex A-6 cation-exchange resin (17  $\mu$ m). A 0.1 M HNO<sub>3</sub>/5 × 10<sup>−4</sup> M HF solution was used as the eluent. The seaborgium fractions were collected during the first ten seconds. Preliminary experiments showed that, under these conditions, the degree of elution of tungsten from the column was 85%, whereas trivalent actinides, Group IV elements and uranium remained on the column; 4000 cycles of isolation and determination of seaborgium were carried out. Three pairs of  $\alpha$ – $\alpha$  correlated decays for <sup>261</sup>Rf and <sup>257</sup>No, which are the daughter decay products of <sup>265</sup>Sg, were observed. The <sup>265</sup>Sg isotope ( $T_{1/2} \approx 7$  s) was not detected directly because the total time consumed for the chemical operations was 38–45 s. These results suggest that seaborgium exists in solution in the stable hexavalent state and, like its light homologues, viz., tungsten and molybdenum, forms neutral (SgO<sub>2</sub>F<sub>2</sub>) or anionic (SgO<sub>2</sub>F<sub>3</sub><sup>−</sup>) oxyhalide complexes. The existence of ‘seaborgates’ SgO<sub>4</sub><sup>−</sup>, by analogy with molybdates and tungstates, cannot be ruled out as well.<sup>30</sup>

Another series of experiments on the isolation of seaborgium was carried out with the use of HF-free 0.1 M HNO<sub>3</sub> solutions as the eluent.<sup>31</sup> The <sup>265</sup>Sg and <sup>169</sup>W isotopes were produced simultaneously by bombardment of the combined <sup>248</sup>Cm + Gd target with <sup>22</sup>Ne ions. All other experimental conditions were identical to those used in the earlier experiment.<sup>30</sup> The first portions of the eluate (0.1 M HNO<sub>3</sub>) contained ~60% of <sup>169</sup>W; only one  $\alpha$ – $\alpha$  decay pair corresponding to <sup>261</sup>Rf–<sup>257</sup>No was observed. However, according to the estimates,<sup>31</sup> five  $\alpha$ – $\alpha$  correlated events were expected. Based on this fact, the authors hypothesised that in dilute HNO<sub>3</sub> solution, seaborgium gives the positively charged hydrolysed Sg(OH)<sub>4</sub>(H<sub>2</sub>O)<sub>2</sub><sup>+</sup> or Sg(OH)<sub>5</sub>(H<sub>2</sub>O)<sup>+</sup> species, which are sorbed on cation-exchange resins. In such solutions, the behaviour of seaborgium is similar to that of uranium. Tungsten forms primarily the neutral WO<sub>2</sub>(OH)<sub>2</sub> compounds, which remain in solution.<sup>31</sup>

**Table 4.** Distribution of tungsten isotopes produced in the nuclear reactions Sm(<sup>24</sup>Mg, xn) and radioactive decay products of tungsten on ion-exchange columns (from 0.05 M H<sub>2</sub>SO<sub>4</sub> solutions); the measurements were carried out in the on-line mode.<sup>48, 52</sup>

| <sup>167</sup> Yb                                       | 17.5 min  | <sup>170</sup> Ta                                      | 6.8 min   |                                                         |           |
|                                                         |           | <sup>172</sup> Ta                                      | 38.8 min  |                                                         |           |
|                                                         |           | <sup>167</sup> Hf                                      | —         |                                                         |           |

## 4. Bohrium and hassium

### a. Theoretical prerequisites

It was predicted<sup>68</sup> that the configurations of the outer electron shells of elements 107 and 108 are 6d<sup>5</sup>7s<sup>2</sup> and 6d<sup>6</sup>7s<sup>2</sup>, respectively. Therefore, Bh and Hs belong to Groups VIIB and VIIIB, respectively. Rhenium and technetium are the chemical homologues of Bh. Osmium and ruthenium are the chemical analogues of Hs. The characteristic feature of elements of these groups is that they can exist in various oxidation states. In particular, the stable states +7, +5 and +3 were predicted for Bh.<sup>77</sup> Since the highest oxidation state within the group is stabilised on going to heavier elements, bohrium, by analogy with rhenium, would be expected to occur in aqueous solution in the heptavalent oxidation state as the BhO<sub>4</sub><sup>−</sup> oxy anion. Evidently, hassium, by analogy with

osmium, can exhibit the maximum oxidation state of +8 (volatile tetroxide  $\text{OsO}_4$ ) and a lower valence state in aqueous solution.

### b. Model experiments

**Ion-exchange methods.** Model experiments on the isolation of the short-lived osmium and rhenium isotopes under conditions simulating isolation of Hs and Bh, respectively, were carried out at the U-400 cyclotron in FLNR JINR. Osmium radionuclides were produced in the nuclear reactions  $^{nat}\text{Dy}(^{20}\text{Ne}, xn)^{172-178}\text{Os}$ . Rhenium and tungsten isotopes were present in the system as decay products of osmium, for example,

The isolation was carried out from 0.05 M  $\text{H}_2\text{SO}_4$  and 0.05 M  $\text{HCl}$  solutions in the on-line mode with the use of ion-exchange columns connected in series (cation-exchange resin – anion-exchange resin – cation-exchange resin).<sup>53, 64</sup> In both systems, Os and Re were not sorbed on the cation-exchange resin, but were strongly retained on the anion-exchange column, which is indicative of the presence of neutral or negatively charged forms of the elements in these solutions. Table 5 lists the nuclear physical characteristics of the radionuclides detected on the anion-exchange column (the on-line mode) when passing a 0.05 M  $\text{HCl}$  solution through the column.<sup>64</sup> Short-lived osmium isotopes with  $T_{1/2} = 16\text{--}55 \text{ s}$  were isolated. There is a genetic relationship between the osmium isotopes and the daughter decay products of rhenium and tungsten. Hence, these systems can be used to isolate Hs and Bh in the on-line mode.

The possibility of identifying the valence states and speciation of Hs and Bh in dilute  $\text{HCl}$  solutions was demonstrated in the study of the sorption of Os and Re on various sorbents (in the on-line mode).<sup>64</sup> Dowex-50  $\times 8$  cation-exchange resin, Dowex-1  $\times 8$  anion-exchange resin, mixed  $\text{K}_2\text{Ni}[\text{Fe}(\text{CN})_6]$  ferrocyanide and tri-*n*-octylphosphine oxide (TOPO) containing a sorbent on an inert support were used in the study. During the experiment, the order in which the columns containing various sorbents were connected was varied. Figure 8 shows the  $\gamma$  spectra of three columns connected in series: the cation-exchange resin, ferrocyanide and the anion-exchange resin. The spectra were measured when a solution of radionuclides in 0.05 M  $\text{HCl}$  was passed through these columns. Osmium, rhenium and tungsten radionuclides were sorbed only on the anion-exchange column. These radionuclides were not observed on the columns with the cation-exchange resin and ferrocyanide. The radionuclides were also absent in the solutions after they have been passed through the anion-exchange column.<sup>64</sup> Since only the  $\text{Os}^{3+}$  and  $(\text{OsO}_2)^{2+}$  cations are sorbed on the cation-exchange resin and ferrocyanide from dilute  $\text{HCl}$  solutions,<sup>81</sup>  $\text{Os}^{4+}$  were, evidently, present in the model experiment as the major form, that sorbed on the anion-exchange resin as  $(\text{OsCl}_6)^{2-}$ . When the columns were connected in the cation-

**Figure 8.**  $\gamma$ -Spectra of three columns connected in series and filled with Dowex-50 (a),  $\text{K}_2\text{Ni}[\text{Fe}(\text{CN})_6]$  (b) and Dowex-1 (c), which were measured when passing a 0.05 M  $\text{HCl}$  solution containing radionuclides (in model experiments with osmium and rhenium isotopes).<sup>64</sup>

exchange resin – TOPO – anion-exchange resin series, the osmium isotopes were also found only on the anion-exchange column, whereas Re was detected primarily on the anion-exchange column and, partially, on the TOPO-containing column.<sup>64</sup> In weakly acidic solutions, Re exists in the stable anionic  $\text{ReO}_4^-$  form, which is not sorbed on the cation-exchange resin, but is strongly retained both on the anion-exchange resin and the TOPO-containing sorbent to form the  $3(\text{TOPO})\text{H}_3\text{O}^+ + \text{ReO}_4^-$  or  $(\text{TOPO})\text{H}^+ + \text{ReO}_4^-$  solvates.

In the study, it was shown that Re and Tc (homologues of Bh) can be separated from Nb and Ta on a cation-exchange column with the use of mixed  $\text{HNO}_3/\text{HF}$  solutions (at 75 °C) as the eluent.<sup>49</sup>

**Extraction method.** The extraction method for the separation of Re and Tc in  $\text{HNO}_3$  solution from Nb, Ta, actinides and other elements using a 0.05 M TOA solution in toluene was developed with the aim of isolating Bh in the SISAK system.<sup>50</sup> In the study of Re and Tc, a selective method was developed for the isolation of Bh by extraction with TOA from solutions of  $\alpha$ -hydroxyisobutyric acid in the presence of an oxidising agent ( $\text{NaBrO}_3$ ).<sup>82</sup>

No experiments on the isolation of Bh from solution were carried out. The  $^{267}\text{Bh}$  isotope ( $T_{1/2} \approx 17$  s), which was produced by the reaction  $^{249}\text{Bk}(^{22}\text{Ne}, 4n)$  as the volatile oxychloride  $\text{BhO}_3\text{Cl}$ , was isolated by gas chromatography.<sup>83</sup> The long-lived  $^{269}\text{Hs}$  ( $T_{1/2} \approx 10$  s) and  $^{270}\text{Hs}$  ( $T_{1/2} = 2-7$  s) isotopes were isolated for the first time as the volatile tetroxide  $\text{HsO}_4$ .<sup>84</sup>

In the CALLISTO project, hassium was studied in the liquid phase using a new procedure for the isolation and transport of volatile nuclear reaction products in an aerosol-free gas flow.<sup>32, 85</sup> The  $^{269}\text{Hs}$  isotope produced in the nuclear reaction  $^{248}\text{Cm}(^{26}\text{Mg}, 5n)$  was oxidised to a volatile oxide (apparently,  $\text{HsO}_4$ ) in the gas flow ( $\text{O}_2 + \text{He}$ ) and transferred to a special device, in which  $\text{HsO}_4$  was trapped and Hs was detected. The device contained a stainless steel plate, which was coated with a thin NaOH film and located a distance of 1 mm from 16 silicon detectors. In the experiment, six  $6\alpha-\alpha$  correlations were observed in the decay chain of  $^{269}\text{Hs}$ . It was hypothesised<sup>32</sup> that octavalent hassium was isolated as sodium hassate  $\text{Na}_2[\text{HsO}_4(\text{OH})_2]$ , by analogy with  $\text{OsO}_4$ , whose dissolution in NaOH affords osmate  $\text{Na}_2[\text{OsO}_4(\text{OH})_2]$ .

## 5. Meitnerium and darmstadtium

Relativistic calculations for elements 109 and 110<sup>68</sup> predicted the  $5f^{14}6d^77s^2$  and  $5f^{14}6d^97s^1$  electronic configurations, respectively, for their neutral atoms in the free state. Therefore, Mt and Ds belong to Group VIII platinum elements. Iridium and platinum are the chemical homologues of meitnerium and darmstadtium, respectively. In recent years, the ‘long-period’ form of the Periodic table has gained increasing acceptance. In my opinion, this form reflects the chemical similarity, in particular, between the platinum-group elements, to a lesser extent compared to the ‘short-period’ form. In the ‘long-period’ form, elements 109 and 110 are placed in the ninth and tenth groups, respectively.

The characteristic feature of platinum elements is that they can form complexes with various ligands in solution.

No attempts to study the chemical properties of Mt and Ds in the liquid and gas phases have been reported. Apparently, this is associated with the very short lifetimes of the  $^{266}\text{Mt}$  ( $T_{1/2} = 5$  ms) and  $^{269}\text{Ds}$  ( $T_{1/2} = 393$   $\mu\text{s}$ ) isotopes, which were produced by the nuclear reactions  $^{209}\text{Bi}(^{58}\text{Fe}, n)$  and  $^{208}\text{Pb}(^{62}\text{Ni}, n)$ , respectively.

## 6. Roentgenium and element 112

### Theoretical prerequisites

According to the general regularities, elements 111 and 112 can be assigned, respectively, to Groups IB and IIB (or Groups 11 and 12 in the ‘long-period form’) of the seventh period. Gold and mercury are the chemical homologues of elements 111 and 112, respectively. Group IB and IIB elements have a completely filled  $d^{10}$  electron shell. Hence, these elements are characterised by a lower diversity of valence states compared to other groups of transition d elements. The presence of the  $d^{10}$  shell is responsible for the chemical inertness of metals and their tendency to form intermetallic compounds. Another specific feature of these elements is the formation of compounds with covalent bonds. Relativistic calculations predicted that the most stable oxidation states of elements 111 and 112 are +3 and +2, respectively. In the metallic state, element 112 may be highly volatile by analogy with noble gases.<sup>86, 87</sup>

Data on the chemical properties of element 111 are lacking.

### b. Model experiments

Model experiments on the isolation of element 112 from solution were carried out with the use of short-lived Hg isotopes in the on-line mode.<sup>88</sup> It was demonstrated that Hg is strongly adsorbed from 0.05 M  $\text{H}_2\text{SO}_4$  solution on a column, which is filled with glass granules treated with silver.

### c. Isolation of element 112

Element 112 has only been isolated in the gas phase (FLNR JINR).<sup>89, 90</sup> The  $^{283}112$  isotope (s.f.,  $T_{1/2} = 3$  min.) was produced simultaneously with the short-lived  $^{185}\text{Hg}$  isotope ( $\alpha$ ,  $T_{1/2} = 49$  s) in the reactions  $^{238}\text{U} + \text{Nd}(^{48}\text{Ca}, xn)$  at the U-400 cyclotron. The nuclear reaction products in the gas flow (He) were passed to a counting apparatus consisting of a system of semiconducting detectors with a gold coating and an ionisation chamber, which recorded  $\alpha$  decay and spontaneous fission. Compared to Hg, element 112 interacts much more weakly with gold, and its chemical behaviour is more similar to that of Rn under the conditions used.<sup>90</sup>

It was predicted<sup>91</sup> that the  $\alpha$  decay of element 112 can occur to form the following chain:

In experiments on the synthesis of element 112 by the reaction  $^{238}\text{U}(^{48}\text{Ca}, xn)$  (FLNR JINR, in 2004), a chain of four successive  $\alpha$  decays was observed. The chain was terminated to give spontaneously fissionable  $^{267}\text{Rf}$  isotope ( $T_{1/2} \approx 3$  h) as the final product.<sup>92</sup> The occurrence of such decay chains offers possibilities of isolating element 112, studying its chemistry in solution in the on-line mode and determining it based on long-lived decay products.

## 7. Elements 113 and 114

### a. Synthesis and theoretical prerequisites

Data on the synthesis of element 113 are lacking. However,  $\alpha$  activity with  $T_{1/2} = 0.5$  s was observed in the decay chain of element 115, and this activity was assigned to element 113.<sup>2</sup>

Element 114 has attracted particular interest because of the theoretical predictions of ‘islands of stability’ for  $Z = 114$  and  $N = 184$ . Considerable attention has been given to a search for this element in nature, because calculations predicted that the lifetime of this radionuclide may be comparable with the age of the Earth. However, numerous investigations did not give positive results, and studies in this field were terminated. According to the modern concept,<sup>91</sup> even-even isotopes of elements 108 and 110 with a closed spherical shell ( $N = 180-184$ ) should be even more stable. Hence, studies aimed at searching for SHEs in nature will be continued.

In 1998–1999, element 114 was synthesised in the reactions  $^{244}\text{Pu}(^{48}\text{Ca}, 3-4n)$  and  $^{242}\text{Pu}(^{48}\text{Ca}, 3n)$  at the U-400 cyclotron (FLNR JINR).<sup>1</sup> The  $\alpha$  decay chain

and two identical decay chains of the  $^{288}114$  isotope were observed. These chains afforded finally the spontaneously fissioning  $^{280}110$  isotope. Therefore, the effect of stabilisation of the neutron-excessive nuclei with  $Z = 114$  ( $N = 175, 174, 173$ ) in the vicinity of the closed neutron shell  $N = 184$  was established experimentally (earlier, this effect was predicted theoretically).

After filling the d shell of transition elements 111 and 112, the p shell of the subsequent elements begins to be filled. Hence, elements 113 and 114 belong to the so-called ‘post-transition’ or p elements. The valence electrons of these elements occupy the ns and np sublevels. Thallium and lead are homologues of elements 113 and 114, respectively. It was predicted<sup>93</sup> that  $113^{+1}$  and  $114^{+2}$  are the most stable oxidation states. In addition, due to relativistic effects, element  $114^{+2}$  should exhibit stronger complexing properties than  $\text{Pb}^{+2}$  and, under particular conditions, would be similar to  $\text{Hg}^{+2}$ .

No experiments on the isolation of element 113 and investigation of its chemical properties have been carried out.

### b. Model experiments

Model experiments on the isolation of element 114 and investigation of its chemical properties were carried out using its homologue, viz., Pb.<sup>54,94,95</sup> To produce the short-lived carrier-free <sup>211</sup>Pb isotope ( $T_{1/2} = 36.1$  min) a simple and efficient procedure was developed for the on-line isolation of this element from parent radionuclides (based on the same principle as a radioisotope generator).

**Construction of the generator.** The <sup>211</sup>Pb isotope belongs to the main branch of the decay chain of the actinide family

The repeated isolation of the <sup>211</sup>Pb isotope was carried out with the use of a small cation-exchange column on which <sup>227</sup>Ac or <sup>223</sup>Ra was sorbed, while the short-lived <sup>211</sup>Pb isotope was washed out with a solution of an appropriate composition. The scheme of the generator and the elution curves of <sup>211</sup>Pb using solutions of various compositions are shown in Fig. 9.

**Figure 9.** The generator of <sup>211</sup>Pb; 0.4 × 5 cm cation-exchange column (a) and the elution curves of <sup>211</sup>Pb with 1 M and 0.5 M HCl solutions (solid and dashed lines, respectively) containing CH<sub>3</sub>OH (b).<sup>94</sup> [CH<sub>3</sub>OH] (%): (1, 1') 0, (2, 2') 80, (3, 3') 90.

**Investigation of the ion-exchange behaviour of Pb. Cation-exchange resin.** With the aim of finding the optimum conditions for elution of <sup>211</sup>Pb and stronger retention of the parent radionuclides sorbed on a cation-exchange column, the static and

dynamic characteristics of sorption of elements were examined depending on the composition of the solution, the concentration of the acid (HCl, HBr) and the nature of the solvent (alcohols, ketones, etc.). The distribution coefficients of actinide elements and Ra were demonstrated to be higher in the presence of an organic solvent, whereas the distribution coefficients of Pb, on the contrary, decrease due to strong complexation in aqueous-organic solutions. In HBr solutions, the distribution coefficients of Pb are lower than those in HCl solutions due to the formation of more stable bromide complexes. The distribution coefficients of actinide elements in aqueous-organic solutions of HCl and HBr are larger than  $K_d$  for lead by four orders of magnitude, which allows the repeated elution of <sup>211</sup>Pb from a generator over a long period of time. The purification factors of <sup>211</sup>Pb from actinides are  $> 10^5 - 10^6$ .<sup>54,94,95</sup>

**Anion-exchange resin.** Lead is characterised by low adsorbability on anion-exchange resins from 1–2 M HCl solutions ( $K_d \approx 30$ ) and high adsorbability from HBr solutions ( $K_d \geq 10^3$ ) (Fig. 10). These facts support the conclusion that anionic bromide complexes of lead are more stable than the corresponding chloride complexes. In the presence of organic solvents, the sorption of lead on anion-exchange resins from HCl solutions sharply increases.<sup>54,95</sup> Due to the high distribution coefficients of Pb in dilute HBr solutions and aqueous-methanolic HCl solutions, lead can be concentrated on small anion-exchange columns with simultaneous separation from Hf and actinides, which are not sorbed on anion-exchange resins under these conditions.

**Figure 10.** Plots of the distribution coefficients of Hf (1, 2, 3) and Pb (1', 2', 3') vs. the concentration and nature of acid for sorption on Dowex-50 × 8 cation-exchange resin (a) and Dowex-1 × 8 anion-exchange resin (b). (1, 1') HF, (2, 2') HCl, (3, 3') HBr.

Experiments on the isolation of the short-lived <sup>211</sup>Pb isotope from a generator and investigation of its chemical behaviour by repeated elution from a cation-exchange column with solutions of various compositions are, in fact, model experiments on the isolation of element 114 and investigation of its chemistry in the on-line mode. In experiments performed in FLNR JINR (in 2004), two chains were observed in the synthesis of element 114 in the reaction <sup>242</sup>Pu(<sup>48</sup>Ca, 3n).<sup>92</sup> These chains consist of four and five successive  $\alpha$  decays and are completed by the spontaneous fission of <sup>271</sup>Sg ( $T_{1/2} = 2.4^{+4}_{-1}$  min) and <sup>267</sup>Rf ( $T_{1/2} = 3.3$  h), respectively. Evidently, on-line isolation followed by identification of longer-lived decay products can be used for element 114.

## 8. Elements 115 and 116

Element 115 was synthesised in the nuclear reaction <sup>243</sup>Am(<sup>48</sup>Ca, xn)<sup>291-xn</sup>115 at the U-400 cyclotron (FLNR JINR, in

2003).<sup>2</sup> For the  $^{288}115$  isotope ( $T_{1/2} \approx 87$  ms), which was produced in channels with evaporation of three neutrons, three identical chains of five successive  $\alpha$  decays giving finally  $^{268}\text{Db}$  (s.f.,  $T_{1/2} = 16^{+19}_{-6}$  h) were observed. For the  $^{287}115$  isotope ( $T_{1/2} \approx 32$  ms), which was produced in the reaction upon evaporation of four neutrons, a chain of four successive  $\alpha$  decays completed by the spontaneous fission of  $^{267}\text{Db}$  (s.f., 73 min) was observed.

Element 116 was synthesised in the same laboratory (in 2000–2001) by the nuclear reaction  $^{248}\text{Cm}(^{48}\text{Ca}, 4n)$ .<sup>3</sup> Three identical decay chains corresponding to the isotope were observed:

Therefore, in addition to the discovery of new element 116, the discovery of element 114, which has been synthesised earlier by the reaction  $^{244}\text{Pu}(^{48}\text{Ca}, 4n)$ ,<sup>1</sup> was confirmed. More recently (in 2004), three more isotopes of element 116 with masses 290–293 were produced by the reactions  $^{245}\text{Cm}$ ,  $^{248}\text{Cm} + ^{48}\text{Ca}$ .<sup>92</sup>

According to the general regularities of the filling of electron shells, elements 115 and 116 can be assigned to p elements, and Bi and Po are, respectively, their chemical homologues. Relativistic calculations demonstrated that element 115 is rather stable in the oxidation state of +1 and the chemical properties of element 115 are to a certain extent similar to the properties of  $\text{Tl}^+$ . The most stable oxidation state of element 116 is +2.<sup>96</sup>

In the studies,<sup>97,98</sup>  $^{268}\text{Db}$  was isolated as the terminal decay product of element 115, which was produced in the reaction  $^{243}\text{Am}(^{48}\text{Ca}, 3n)$  at the U-400 cyclotron (FLNR JINR). The products of the nuclear reactions were collected in the surface layer of a copper catcher block. Radionuclides were separated from macroamounts of copper by precipitation of  $\text{La}(\text{OH})_3$  with ammonia. Group V elements were separated from actinides and lanthanides on a cation-exchange column filled with Dowex-50  $\times$  8 with the use of a 1 M HF solution as the eluent. The eluent was evaporated on a polyethylene film (0.4  $\mu\text{m}$  thick), which was placed between a pair of semiconducting detectors surrounded by  $^3\text{He}$  counters for measuring  $\alpha$  particles, fission fragments and neutrons. Fifteen events of spontaneous fission with  $T_{1/2} = 32^{+11}_{-7}$  h were observed, and they were assigned to the  $^{268}\text{Db}$  isotope. These results are in good agreement with the results of physical experiments on the synthesis of element 115, where the  $^{268}\text{Db}$  isotope was observed for the first time after five successive  $\alpha$  decays of the parent nucleus of the  $^{288}115$  isotope.<sup>2,92</sup> Therefore, the formation of element 115 in the reaction  $^{243}\text{Am} + ^{48}\text{Ca}$  and the formation of element 113 in the decay chain of element 115 were confirmed.

The chemical identification of element 116 has not been described.

## 9. Elements 117 and 118

Data on the synthesis of element 117 are lacking. Element 118 was produced by the reaction  $^{208}\text{Pb} + ^{83}\text{Kr}$  (LBL)<sup>99</sup> (more recently, these data were not confirmed). In the Laboratory of Nuclear Reactions of the Joint Institutes of Nuclear Research, element 118 was synthesised in the reaction  $^{249}\text{Cf} + ^{48}\text{Ca}$ .<sup>92,100</sup>

According to the general regularities, element 117 can be assigned to the halides with pronounced metallic properties, and At is a chemical homologue of this element. It was predicted that element 117 is more stable in the oxidation state of +3 than in the oxidation state of +1 due to relativistic effects. In certain solutions, the behaviour of element 117 may be similar to that of  $\text{Au}^{+3}$ .<sup>77</sup> Element 118 has a completed outer electron shell and should belong to the noble gases. In going from light to heavier analogues, the inertness of noble gases decreases. Hence, the reactivity of element 118 would be expected to be higher. In particular, its solubility in water would be expected to be higher compared to other inert gases.

## IV. Conclusion

In the last 10–15 years, considerable progress has been made in isolating TAEs and investigating their chemical properties in solution. A high-precision automated apparatus has been constructed and is being improved. This apparatus allows one to perform repeated isolation, separation and determination of transactinide elements. An efficient method has been developed for the on-line isolation of TAEs and investigation of their chemical properties during the production in nuclear reactions followed by their identification with long-lived decay products. New approaches to the isolation of short-lived isotopes of TAEs ( $^{257}\text{Rf}$ ,  $^{269}\text{Hs}$ , elements 112 and 115) on the tracer scale have been devised. These approaches are based on the use of separators, transport of radionuclides from the irradiated target in an aerosol-free gas flow, *etc.*

The behaviour of Rf and Db in solutions of hydrohalic acids has been thoroughly studied by chromatographic and extraction methods. It has been established with a high degree of assurance that Rf and Db form negatively charged complexes in dilute HF solutions and concentrated HCl solutions. It has been demonstrated that the stability of Rf and Db complexes with halide ions increases in the series  $\text{Br}^- < \text{Cl}^- < \text{F}^-$ , *i.e.*, in the order characteristic of Group IVB and VB elements. However, the results of comparative investigations of the stabilities of halide complexes of elements belonging to the same group by determining the distribution coefficients or the elution (extraction) order of elements are ambiguous and sometimes contradictory. The discrepancies can be attributed to various factors, primarily, to the low statistics and the possible losses of trace amounts of elements in the different steps of their isolation. Hence, conclusions about the behaviour of seaborgium in  $\text{HNO}_3$  solutions, which have been made on the basis of the detection of one atom, are unjustified. Short-lived radionuclides are generally determined only in one phase and at one concentration. When operating with a limited number of atoms, errors, for example, in the determination of the distribution coefficients may be larger than 100%.

In studies of the behaviour of homologous elements, the optimum conditions were found for isolation of TAEs with  $Z = 104$ –108, 112 and 114 and investigation of their chemical properties in solutions containing various inorganic and organic complexing ligands ( $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{H}_2\text{PO}_4^-$ ,  $\text{HSO}_4^-$ ,  $\text{C}_2\text{O}_4^{2-}$ , TOA, TBP, TOPO, *etc.*) in the on-line mode by chromatographic and extraction methods. The ability of inorganic ligands to form complexes with Group IVB and VB elements increases in the following series  $\text{OH}^- > \text{F}^- > \text{H}_2\text{PO}_4^- > \text{HSO}_4^- > \text{Cl}^- > \text{Br}^-$ . Investigations of the behaviour of short-lived rhenium and osmium isotopes in dilute HCl solutions using various sorbents demonstrated that the species and oxidation states of Bh and Hs can be determined. Homologous elements are widely used to test and construct new systems for the isolation and investigation of the chemical properties of TAE in solution. Model experiments on the extraction of short-lived zirconium and hafnium isotopes (homologues of rutherfordium) with macrocyclic ligands from solutions of mineral acids were carried out.<sup>101</sup> Zirconium and hafnium were separated by extraction with TOA in  $\text{H}_2\text{SO}_4$  solutions using the SISAK system.<sup>102</sup> A new method for the isolation and identification of superheavy elements by electrochemical deposition in systems containing several working electrodes made of different materials is in the development stage.<sup>103</sup>

An investigation of the relativistic effects in heavy element chemistry is a fundamental problem of modern radiochemistry. The influence of the relativistic effect of the electron shells of heavy atoms on the chemical properties of TAEs remains an open question. First experimental results, in which 'deviations' in the extraction and ion-exchange behaviour of dubnium and rutherfordium compared to the behaviour of their light homologues have been observed and assigned to the influence of the relativistic effects, have been revised and call for further study. The absence of unambiguous evidence for the influence of these effects is asso-

ciated with the difficulty of revealing substantial differences in the behaviour of elements belonging to the same group due to the similarity of their chemical properties and unreliable statistics. Moreover, regularities in the behaviour of elements observed in studies of extraction and ion exchange, *i.e.*, the distribution coefficients, do not always reflect the order in which the stability of the complexes changes. Depending on the nature and concentration of the ligand, the character of the resulting complex (inner- or outer-sphere complexes) and the nature of the sorbent (an extractant, a solvent) and, consequently, the adsorption (extraction) mechanism, an inversion in the behaviour of elements with similar chemical properties can be observed.

In my opinion, investigations of systems in which heavy elements can exhibit substantially different chemical properties (for example, in solutions containing various complexing ligands) have the most promise for revealing relativistic effects. As mentioned above, relativistic calculations predicted that the Rf atom can have the  $5f^{14}6d7s^27p^1$  or  $5f^{14}7s^27p^2$  electronic configuration along with the  $[Rn]5f^{14}6d^27s^2$  configuration. Evidently, under particular conditions (for example, in the presence of stabilising ligands), Rf can exhibit properties typical of p elements (Pb, Bi). In solutions of hydrohalic acids, Group IVB d elements form complexes whose stability increases from Br to F. For p elements, inverse dependence is observed, *i.e.*, the stability of halide complexes increases in the series  $F < Cl < Br$ .<sup>104, 105</sup> Actually, comparative studies of the ion-exchange behaviour of Hf and Pb in dilute solutions of hydrohalic acids demonstrated that Hf is strongly sorbed on cation-exchange resins from HCl and HBr solutions and is not sorbed from HF solutions. In contrast, Pb is more strongly sorbed on cation-exchange resins from HF solutions and is sorbed to a lesser extent from HCl and HBr solutions (see Fig. 10a). An inverse situation is observed for sorption on anion-exchange resins (see Fig. 10b). The results presented in Fig. 10 correlate well with the stability constants of halide complexes of hafnium and lead. As demonstrated above, Rf is not sorbed on cation-exchange resins from solutions containing HF at concentrations higher than  $0.1 \text{ mol litre}^{-1}$ , but it is strongly retained on anion-exchange resins (*i.e.*, its behaviour is analogous to that of Group IVB d elements). Evidently, investigations of the ion-exchange behaviour of Rf in dilute HBr solutions can reveal the extent to which this element exhibits the properties characteristic of p elements.

Studies of the behaviour of TAEs in different oxidation states in the presence of oxidising (or reducing) agents or by electrochemical oxidation (reduction) in the course of their isolation also hold promise for elucidating the relativistic effects. In this case, the distribution coefficients should be substantially different, due to which the experiments can be performed in the on-line mode.

The relatively long half-lives of some TAEs with  $Z \geq 106$  allow one to study the chemical properties of these elements in solution. However, the main problem is that SHEs are produced in very low yields in a unit of time (for example,  $1 \text{ atom h}^{-1}$  for Sg), and the yields sharply decrease with increasing  $Z$  ( $1 \text{ atom day}^{-1}$  for element 112). In this connection, methods based on the on-line isolation of TAEs during their synthesis hold the most promise. In the near future, one would expect that new longer-lived isotopes of SHEs in the vicinity of the 'islands of stability' will be discovered. Hence, the development of efficient procedures for the isolation and investigation of such isotopes on the basis of studies of the behaviour of their homologues is of primary importance.

I thank Academician B F Myasoedov for valuable advice and helpful discussion.

**Abstract.** Data on the synthesis and properties of aza- and diazacrown compounds containing a phenyl group at a nitrogen atom or an *o*-phenylene fragment annelated to the macrocycle are generalised. The functional derivatives of these compounds and their heteroanalogues with O, S and N atoms are considered. The bibliography includes 217 references.

## I. Introduction

Crown compounds bind metal cations, organic cations and neutral molecules through multidentate coordination to heteroatoms incorporated in the macrocycle. Due to this feature, they are used successfully as selective ligands,<sup>1,2</sup> for extraction and separation of metal cations,<sup>3,4</sup> for ion transport through membranes, in ion selective electrodes,<sup>5</sup> as phase transfer catalysts and as synzymes that simulate enzymic activity,<sup>6</sup> in photosensitive systems,<sup>7–12</sup> etc.

Crown ethers in which one or two oxygen atoms have been replaced by nitrogen atoms are referred to as azacrown ethers or azacrown compounds; if the number of nitrogen atoms in the macrocycle is greater than two, the latter name is used most often. In addition to the IUPAC names, two special nomenclatures are used to designate azacrown compounds. According to one of them, developed by Pedersen in 1967,<sup>13</sup> the total number of macrocycle units (the size) is indicated ahead of the word 'crown' and the total number of heteroatoms is indicated after this word. In the case of nitrogen analogues, the positions of nitrogen atoms are numbered separately, precede the whole compound name and are accompanied by the prefix '(di-, tri-, etc.) aza' (for example, 1,10-diaza-18-crown-6 ether). The second nomenclature was proposed by Busch in 1972.<sup>14</sup> In this case, the macrocycle size is given

in square brackets, this is followed by an indication of the type of heteroatoms, with their number given as the subscript (e.g., [15]N<sub>4</sub>O or [14]N<sub>4</sub>; the last macrocycle is called cyclam).

The interest in azacrown derivatives persists, first of all, due to their extensive practical use. In particular, diazacrown compounds are important intermediates in the synthesis of cryptands. Azacrown compounds attract the attention of researchers in many fields due to their unusual complexing properties, intermediate between the properties of crown ethers, which firmly bind alkali and alkaline earth metal ions, and the properties of cyclams, which form stable complexes with heavy and transition metal ions.

Apart from the traditional applications of azacrown compounds, of special interest is the use of those fragments, in which the nitrogen atom is conjugated with the chromophore, as parts of photosensitive, chromogenic, fluorescent and photochromic ligands. These compounds can form the heart of optical sensors for metal and ammonium ions, optical information recording systems, photoswitched molecular devices and machines for molecular electronics, transporting agents for the photocontrolled membrane transport of metal cations, etc. For this reason, we summarise here the data on the synthesis of several classes of azacrown compounds in which the macrocycle nitrogen atom is conjugated with the benzene ring.

A number of reviews on the methods of synthesis of azacrown compounds have been published. Two of these consider crown ether analogues containing only nitrogen atoms as heteroatoms and cover a period from 1967 to 1987.<sup>15,16</sup> The most comprehensive data on the synthesis of azacrown compounds with different sets of heteroatoms were reported by Bradshaw *et al.* in a monograph<sup>17</sup> published in 1993. Among the latest studies, noteworthy is the review<sup>18</sup> devoted to the synthesis of fused aza- and thiaazacrown compounds. However, none of the published reviews consider specially the synthesis of azacrown compounds in which at least one nitrogen atom of the macrocycle is conjugated with a benzene ring; no systematic data are currently available on this topic.

This review is devoted to the synthesis and chemical properties of azacrown compounds based on macrocycles of various sizes (starting with the smallest, nine-membered one) containing three or more heteroatoms. A special feature of the molecules of these compounds is the presence of not more than two phenyl or annelated *o*-phenylene fragments linked to the macrocycle

through nitrogen; the other heteroatoms may be represented by O, S and N atoms. The azacrown compounds having heteroaromatic substituents, organoelement (P-, As- and Se-containing) and organometallic derivatives or polymers containing phenylaza or benzoazacrown compounds are beyond the scope of this review. Several examples are related to the synthesis and modification of benzoannulated cryptands. The review covers the publications from the late 1960s to 2003 and includes some studies published in 2004.

## II. *N*-Phenylazacrown compounds

There are three main approaches to the synthesis of phenylazacrown compounds differing by the type of reaction used, which include the condensation of two fragments, aromatic nucleophilic substitution and cross-coupling.

### 1. Methods based on the condensation of two fragments

The base-induced condensation of *N*-aryldiethanolamines or their derivatives with oligoethylene glycols or their aza or thia analogues is a widely used method for the synthesis of *N*-phenylazacrown compounds. Using this method, Vögtle and Dix performed the first synthesis<sup>19,20</sup> of *N*-phenylaza-15(18)-crown-5(6) ethers. With dichlorides as the electrophilic component, NaOH is used most often as the base, while in the case of ditoluenesulfonate this is NaH.<sup>19–21</sup>

Phenylazacrown ethers **1c–i** containing Me, MeO, Cl or NO<sub>2</sub> groups in the *ortho*- or *para*-position of the benzene ring were prepared by condensation of *N*-aryldiethanolamine with oligoethylene glycol dimethanesulfonates (or ditoluenesulfonates) in the presence of sodium hydride<sup>22–26</sup> or with dichlorides in the presence of sodium hydroxide,<sup>27–29</sup> while 3-nitrophenylaza-15-crown-5 ether **1j** was synthesised using sodium *tert*-butoxide as the base.<sup>30</sup> The use of derivatives with hard oxygen-containing leaving groups (ditoluenesulfonates, dimethanesulfonates) and strong bases (sodium hydride and *tert*-butoxide) allows one to synthesise *N*-arylazacrown ether derivatives **1** in higher yields than the use of dichlorides in the presence of alkali.

Ms is MeSO<sub>2</sub>, Ts is 4-MeC<sub>6</sub>H<sub>4</sub>SO<sub>2</sub>.

The same method was utilised to obtain azacrown ether **3** with a long alkyl chain from *N*-phenyldiethanolamine and ditoluenesulfonate **2** under the action of potassium *tert*-butoxide.<sup>31</sup>

Using a similar procedure, a series of benzophenylazacrown ethers **4** have been prepared (with NaH as the base).<sup>32</sup> Interestingly, the methoxy derivative **4** (R<sup>1</sup> = H, R<sup>2</sup> = OMe) was also prepared using an alternative method of synthesis, namely, from *N*-aryldiethanolamine ditoluenesulfonate and the corresponding diol. The yields of products **4** were moderate in all cases.

R<sup>1</sup> = H, Me; R<sup>2</sup> = H, OMe, Me, Bu<sup>t</sup>.

*N*-Phenyltetraazacrown compound **5** was obtained by the reaction of ditoluenesulfonate **6** with the disodium salt of tritosylamide **7**. The tosyl groups were removed by refluxing with sodium metal in *n*-butanol.<sup>33</sup>

The condensation of *N*-phenyldiethanolamide dichlorides, ditoluenesulfonates or dimethanesulfonates with dithiols under the action of sodium hydroxide or potassium carbonate gave *N*-phenyldithiaazacrown compounds **8** (for the derivative with X = OMs, *n* = 1, the yield was 40%).<sup>34–37</sup>

$n = 1, 2$ ;  $X = \text{Cl, OTs, OMs}$ ;

(a)  $\text{NaOH}$ , dioxane– $\text{Bu}^t\text{OH}$ ; (b)  $\text{K}_2\text{CO}_3$ ,  $\text{MeCN}$ .

Compounds **9**, containing oxygen and sulfur atoms in various combinations in the macrocycle, have been prepared.<sup>32</sup> The starting compounds used for this purpose were *N*-(4-methoxyphenyl)diethanolamine ditoluenesulfonate and diols or dithiols.

$X, Y = \text{O, S}$ .

*N*-Phenylpolythiaazacrown compounds with two, three or four sulfur atoms in the macrocycle have been obtained by the reactions of dithiols with  $\alpha,\omega$ -dihalides in the presence of caesium carbonate in DMF.<sup>38–40</sup> In the synthesis of dithiaaza-9-crown-3 compound **10**, the product of [2 + 2]-condensation of both reactants, compound **11**, was also isolated, although the reaction was carried out under high dilution conditions in order to avoid the condensation.<sup>38</sup> Higher yields of trithiaaza-12-crown-4 and tetra-thiaaza-15-crown-5 compounds **12** compared to those of macrocycle **10** were attributed to the greater steric strain in the latter compound.

Yet another version of the condensation of two fragments is the cyclodialkylation of anilines.<sup>22, 24, 41–53</sup> This approach is usually employed to prepare *N*-phenylazacrown ethers with small rings. An early study<sup>41</sup> describes the synthesis (without indication of the yields) of *N*-(2-hydroxyphenyl)aza-12-crown-4

ether by the reaction of *o*-aminophenol with the dichloride prepared from tetraethylene glycol on refluxing in water.

The reaction of aniline and its derivatives with the diiodides prepared from tri-, tetra- or pentaethylene glycols in the presence of sodium carbonate in acetonitrile resulted in the synthesis of arylazacrown ethers **13**.<sup>22, 24, 42–50</sup>

| R <sup>1</sup> | R <sup>2</sup> | R <sup>3</sup> | n   | Yield (%) |
|----------------|----------------|----------------|-----|-----------|

| H              | NHAc           | NHAc           | 2   | 42        |

*N*-Phenylaza-14-crown-4 ether **14**, which contains two hydroxyl groups in the macroheterocycle, is formed upon the reaction of aniline with diethylene glycol diglycidyl ether in methanol at room temperature.<sup>51, 52</sup>

The synthesis of *N*-phenyl-3-oxoaza-15(18)-crown-5(6) ethers **15** by the two-step condensation of *N*-(polyoxyethylene)anilines with bromoacetic acid has been described;<sup>53</sup> first, the reaction is induced by sodium or potassium carbonate and then by the carbonate and benzenesulfonyl chloride in dioxane. However, the yields were low.

$n = 2$  (9%), 3 (16%);  $M = \text{K, Na}$ .

Unsubstituted *N*-phenylazacrown compounds have been used to prepare various chromo- and fluoroionophores,<sup>54–57</sup> in particular, azo dyes<sup>20, 25, 26, 37</sup> and squaric acid derivatives).<sup>58</sup>

## 2. The introduction of a macrocyclic fragment by aromatic nucleophilic substitution

Many derivatives of *N*-phenylazacrown compounds have been obtained by arylation of the nitrogen atom in the macrocycle. Halobenzenes containing electron-withdrawing substituents are employed most often for this purpose.

Arylazacrown ethers **16a–e** have been prepared by the reaction of aza-15-crown-5 ether with various fluoro- and

chloro-substituted benzenes (Table 1). The process conditions (heating of a reactant mixture in a polar solvent or in a neutral solvent under the action of a base) depend on the nature of the arylating reagent. Dinitrophenyl derivatives **16f** (see Table 1) with various macrocycle sizes are formed in high yields in the reaction of 2,4-dinitrochlorobenzene with *N*-unsubstituted azacrown ethers in the presence of tetrabutylammonium acetate in diethyl ether.<sup>62, 63</sup>

The synthesis of (4-cyanophenyl)cyclam **17** from cyclam and 4-fluorobenzonitrile has been reported;<sup>64</sup> however, the product yield is not indicated in the publication.

2',4'-Dinitrophenylcyclen **18** was prepared in two stages and characterised as the trihydrochloride. The reaction of 1-fluoro-2,4-dinitrobenzene with cyclen **19** was carried out in the presence of sodium hydrogen carbonate and was followed by treatment of compound **20** with hydrochloric acid in methanol.<sup>65</sup>

Boc is *tert*-butoxycarbonyl.

Bis(azacrown) compounds can be synthesised from dihalobenzenes. For example, the reaction of 1,5-difluoro-2,4-dinitrobenzene with two equivalents of cyclen **19** yields mainly bis(cyclen) **21**. A small amount of cyclen **22** was also isolated (Scheme 1).<sup>66</sup>

The *meta*- and *para*-chloro derivatives of phenyldiazacrown ethers were synthesised by the reaction of the dichlorobenzene complex with cyclopentadienyliron hexafluorophosphate and diazacrown ether. The subsequent demetallation of the compounds formed was attained by irradiation with a halogen quartz lamp (100 W).<sup>67</sup>

Scheme 1

The refluxing of a mixture of aza-15(18)-crown-5(6) ethers (or diaza-15-crown-5 ether) with phloroglucinol with azeotropic removal of water gave rise to *N*-(3,5-dihydroxyphenyl)azacrown ethers **23**.<sup>68–70</sup>

X = O:  $n = 1$  (16%), 2; X = NCH<sub>2</sub>C<sub>6</sub>H<sub>4</sub>OMe-2,  $n = 1$ .

Compounds **23** condense with squaric acid to give squarelium dyes.<sup>68, 70</sup>

### 3. Cross-coupling reactions

In recent years, a new approach to the preparation of the compounds in question, based on palladium-catalysed *N*-arylation of azacrown ethers, has been developed.<sup>66, 71–73</sup> The reaction is normally carried out in toluene in the presence of sodium *tert*-butoxide. The advantage of this method is the possibility of using non-activated or sterically hindered aryl halides.

The cross-coupling of azacrown ethers catalysed by systems including a palladium complex ([Pd]) and a phosphine ligand (L) was first carried out for 4-nitro- and 4-cyanobromobenzenes. Aza-18(15,12)-crown-6(5,4) ethers were used to give arylazacrown compounds **24** (Table 2, method A).<sup>71</sup> The highest product yields (57%–88%) were observed when a mixture of Pd(OAc)<sub>2</sub> and PPh<sub>3</sub> was used as the catalyst.

A large series of *N*-phenylaza-15-crown-5 ethers **24** with various substituents in the benzene ring have been synthesised from aza-15-crown-5 ether and aryl bromides *via* the palladium-catalysed Buchwald–Hartwig amination (see Table 2, method B).<sup>72</sup> It was demonstrated that a combination of Pd<sub>2</sub>(dba)<sub>3</sub> and electron-excessive sterically hindered biphenyl-based phosphine is an efficient system for the catalysed coupling of aza-15-crown-5 ether with both electron-deficient and electron-excessive aryl bromides. The reaction occurs under mild conditions, the product yields being 75%–91%. Compounds **24** containing a substituent in the *ortho*-position were also prepared using this catalyst system, although the yields were lower (~40%).

The cross-coupling of cyclen **19** with mono- and dihalobenzenes resulted in the isolation of *N*-aryl-substituted (**25**) and phenylene-bridged cyclens **26** in moderate yields.<sup>66</sup> In the former case, toluene, THF, bromobenzene and a toluene–18-crown-6 mixture were used as solvents.

**Table 2.** Preparation of *N*-arylazacrown ethers by cross-coupling.

| Method | [Pd]                                           | L                                                                                    | R <sup>1</sup> –R <sup>5</sup>                                                                                                                                                                              | <i>n</i> |

X = I, Br; R = H, NO<sub>2</sub>, CH(OCH<sub>2</sub>CH<sub>2</sub>O), CHO; [Pd] = Pd<sub>2</sub>(dba)<sub>3</sub>, Pd(OAc)<sub>2</sub>; L = 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl (BINAP), 1,1'-bis(diphenylphosphino)ferrocene (DPPF), PPh<sub>3</sub>, 2-(di-*tert*-butylphosphino)biphenyl.

(4-Cyanophenyl)cyclam **17** (see Section II.2) is also formed upon arylation of cyclam with 4-bromobenzonitrile in the presence of the Pd(dba)<sub>2</sub>–1-(*R*)-(1-methoxyethyl)-2-(*S*)-diphenylphosphinoferrocene (PPF-OMe) catalyst system and sodium *tert*-butoxide (yield 22%).<sup>73</sup>

### III. Functional derivatives of *N*-phenylazacrown compounds

Many functional derivatives of *N*-phenylazacrown compounds are formed during the construction of the macrocycle (see Section II). An alternative way is to introduce functional groups into the benzene ring of pre-formed *N*-phenylazacrown compounds *via* electrophilic substitution or to modify the existing substituents. Reactions of this type are presented below.

#### 1. Nitro, nitroso and amino derivatives of *N*-phenylazacrown compounds

Direct nitration of *N*-phenylaza-15-crown-5 ether **1a** with nitric acid at low temperature resulted in the 2,4-dinitrophenyl derivative **27**.<sup>63</sup>

When *N*-(*o*-methoxyphenyl)aza-15(18)-crown-5(6) ethers **1c,e** were made to react with sodium nitrite in aqueous AcOH, nitration products **28** were isolated in high yields instead of the expected nitroso compounds.<sup>74</sup> The direction of substitution is determined by the aniline nitrogen atom — the nitro group enters the *para*-position with respect to this atom. The researchers suggested that nitration gives a radical cation as an intermediate. It is of interest that the use of traditional nitrating agents (HNO<sub>3</sub>, HNO<sub>3</sub>–H<sub>2</sub>SO<sub>4</sub> or NO<sub>2</sub>BF<sub>4</sub>) results in very low yields of nitration products in this reaction.

4'-Nitroso-*N*-phenylaza-15-crown 5-ethers **29** were prepared by nitrosation of *N*-phenylaza-15-crown-5 ethers with sodium nitrite in hydrochloric acid.<sup>20, 69</sup>

*N*-(4'-Nitrosophenyl)azacrown ethers condense with malononitrile and dicyanovinyl derivatives to give chromoionophoric compounds.<sup>69, 75</sup>

The reduction of nitroso derivative **29a** with lithium trihydridoaluminate gives azo compound **30** and its *N*-oxide (in a 1 : 3 ratio) in a total yield of 65%.<sup>20</sup>

A major route of modification of the nitroso group in *N*-phenylazacrown ethers is reduction to the amino group. The nitroso group in **29a** was reduced with tin(II) chloride in HCl with heating (yield 87%)<sup>20</sup> or with hydrogen in the presence of Raney nickel (Ni-Ra) at room temperature and atmospheric pressure (the yield was not reported).<sup>76</sup>

Amino derivatives of *N*-phenylazacrown ethers can also be prepared by palladium-catalysed reduction of nitro compounds with hydrogen<sup>30, 61, 74</sup> or by reduction with tin(II) chloride.<sup>24</sup>

| Position of NO <sub>2</sub> | R                 | <i>n</i> | Reaction conditions | Yield (%) | Ref. |
|-----------------------------|-------------------|----------|---------------------|-----------|------|
| 4                           | H                 | 0        | <i>b</i>            | 89        | 24   |
| 4                           | H                 | 1        | <i>b</i>            | 85        | 24   |
| 4                           | CO <sub>2</sub> H | 1        | <i>a</i>            | 94        | 61   |
| 4                           | OMe               | 1        | <i>a</i>            | 98        | 74   |
| 4                           | OMe               | 2        | <i>a</i>            | 68        | 74   |
| 3                           | H                 | 1        | <i>a</i>            | 85        | 30   |

A number of *para*- or *ortho*-substituted *N*-(aminophenyl)aza- and -diazacrown ethers were synthesised by nucleophilic aromatic substitution of chlorine in complexes **31**, followed by demetallation on exposure to UV light.<sup>67, 77</sup> The total yields of amino derivatives in relation to the starting dichlorobenzene complex with [CpM]<sup>+</sup>PF<sub>6</sub><sup>−</sup> were 26%–37% (for M = Ru) and 50%–96% (for M = Fe).

M = Ru: *n* = 1, 2; X = O; Y = CH<sub>2</sub>; M = Fe: *n* = 1, 2; X = O, NH, NAc, NBz, NBn; Y = CH<sub>2</sub>, CHOH, NH.

The obtained 4-amino- and 3,4-diamino derivatives of *N*-phenylazacrown ethers were used in condensations with various

substituted benzaldehydes, giving rise to chromoionophoric Schiff's bases.<sup>21, 50</sup>

$n = 1$ :  $R^1 = \text{OH}$ ,  $R^2 = R^3 = R^4 = R^5 = \text{H}$  (84%);  $R^1 = \text{OH}$ ,

$R^2 = R^3 = \text{H}$ ,  $R^4 = \text{H}_2\text{N}$ ,  $R^5 = \text{N}=\text{CH}-\text{C}_6\text{H}_4-\text{OH}$  (80%);

$n = 2$ :  $R^1 = \text{H}$ ,  $\text{OH}$ ;  $R^2 = \text{H}$ ,  $\text{OMe}$ ;  $R^3 = \text{H}$ ,  $\text{OMe}$ ,  $\text{NO}_2$ ,  $\text{NMe}_2$ ;  $R^4 = R^5 = \text{H}$  (20%–84%).

Acylation of *m*-amino-*N*-phenylaza-15-crown-5 ether **32** with acyl chlorides or acid anhydrides provided the synthesis of a series of amphiphilic azacrown ethers able to form bilayer membranes.<sup>30, 78</sup>

$R = \text{Me}$ ,  $\text{Et}$ ,  $\text{Pr}^n$ ,  $\text{Pr}^i$ ,  $n\text{-C}_n\text{H}_{2n+1}$  ( $n = 5, 11, 13, 15, 17$ );

(a)  $\text{RCOCl}$ ,  $\text{KOH}$ ,  $\text{PhH}$ ; (b)  $\text{Ac}_2\text{O}$ ; (c)  $(\text{EtCO})_2\text{O}$ .

*N*-(4'-Aminophenyl)azacrown ethers can add to naphthoquinones<sup>54</sup> and dicyanovinyl-containing heterocycles<sup>79</sup> to afford chromoionophoric compounds.

## 2. Halogen derivatives of *N*-phenylazacrown compounds

Examples of the synthesis of bromo derivatives of *N*-phenylazacrown compounds *via* electrophilic substitution are documented. Different brominating agents were used and the product yields were often high.

For example, bromination of *N*-phenylaza-15(18)-crown-5(6) ethers with tetrabutylammonium tribromide in dichloromethane<sup>80</sup> or with *N*-bromosuccinimide (NBS) in tetrachloromethane<sup>81</sup> furnishes the corresponding 4-bromophenyl derivatives **33**.

(a)  $\text{Bu}_4\text{NBr}_3$ ,  $\text{CH}_2\text{Cl}_2$ ; (b)  $\text{NBS}$ ,  $\text{CCl}_4$ .

| $n$ | Reaction conditions | Yield (%) |
|-----|---------------------|-----------|
| 1   | <i>b</i>            | —         |
| 1   | <i>a</i>            | 82        |
| 2   | <i>a</i>            | 76        |

The *o*-bromo derivative of *N*-(formylphenyl)aza-15-crown-5 ether **34** was prepared from aldehyde **35** using tetrabromocyclohexadienone as the brominating agent.<sup>82</sup>

Cyclen **36**, prepared by reductive methylation of compound **5**, reacts with bromine in dioxane to give the product in a high yield.<sup>33</sup> In this case, bromination occurs at the *para*-position of the *N*-phenyl group.

## 3. Formyl derivatives of *N*-phenylazacrown compounds

Numerous publications have been devoted to the introduction of a formyl group into *N*-phenylazacrown compounds. The formylation of *N*-phenylazacrown ethers<sup>19, 20, 27–29, 49</sup> and *N*-phenylpolythiaazacrown compounds<sup>83, 84</sup> has been accomplished by the Vilsmeier reaction.

The formyl derivatives of mixed oxathiaazacrown compounds have been synthesised in a similar way.<sup>34</sup>

$n = 1, 2$ .

Hydrogenolysis of benzyl ether **37a** at room temperature and a pressure of 1 atm resulted in salicylaldehyde derivative **38a**.

Treatment of dimethoxy derivative **37b** with aluminium chloride in dichloromethane induces the selective demethylation of the methoxy group located in the *ortho*-position relative to the formyl group to give compound **38b**.<sup>49</sup> Hydroxyaldehydes **38** were used to prepare fluorophores, in particular, azacrown-containing coumarins.<sup>49</sup>

$R^1 = \text{H}, R^2 = \text{OBn}$  (a);  $R^1 = R^2 = \text{OMe}$  (b).

The introduction of the reactive formyl group in the molecule opens the way for the preparation of other derivatives of azacrown compounds. Indeed, the reaction of aldehyde **37c** with hydroxylamine in aqueous ethanol affords oxime **39**, which is reduced by zinc in acetic acid to yield aminomethylated *N*-phenylaza-15-crown-5 ether **40**.<sup>28, 29</sup>

By the reaction of 2,4-dinitro-6-trifluoromethylphenylhydrazine with the formyl derivatives **35** ( $X = \text{O}, n = 3$ ) and **41** ( $X = \text{S}, n = 1, 3$ ), the corresponding hydrazones have been obtained.<sup>83, 85</sup> These were used for the extraction of heavy and transition metal ions<sup>83, 85, 86</sup> and for  $\text{Ag}^+$  transport through liquid membranes.<sup>87</sup>

$X = \text{O}; n = 3$  (49%);  $X = \text{S}; n = 1$  (39%), 3 (52%).

The condensation of aldehyde **35** with *para*-substituted anilines provided the route to chromoionophoric Schiff's bases.<sup>21</sup>

$R = \text{H}, \text{OMe}, \text{OEt}, \text{NMe}_2, \text{F}, \text{Cl}, \text{Br}$ .

The aldehyde functional group in azacrown compounds can also be modified *via* reactions with C-nucleophiles. 4'-Formyl-*N*-phenylaza-15-crown-5 ether **35** reacts with acetone in an alkaline medium to give bis(crown ether) dibenzylideneacetone, which exhibits fluoroionophoric properties.<sup>88</sup>

Compounds containing an active methylene group can undergo Knoevenagel condensation with the formyl derivatives of *N*-phenylazacrown ethers. Under these conditions, 4'-formyl-*N*-phenylaza-18(15)-crown-6(5) ethers react with malononitrile to yield crown-containing benzylidenemalononitriles.<sup>75</sup>

The nitroethylene derivative **42** has been prepared by the reaction of aldehyde **37c** with nitromethane in an acetic acid–ammonium acetate mixture. The reduction of this product gives azacrown ether **43**,<sup>28, 29</sup> which has found application as an intermediate *en route* to fluorescent indicators of sodium ions.

The reduction<sup>76</sup> of the formyl group in *N*-phenylaza-15-crown-5 ether **35** on treatment with sodium borohydride affords the corresponding alcohol, while the oxidation of this group<sup>89</sup> with sodium permanganate in acetone affords crown-containing benzoic acid **44**.

Cinnamaldehydes based on *N*-phenylazacrown ethers were prepared by two routes. One employs the Wittig reaction of aldehyde **35** with phosphonium salt **45**.<sup>82</sup> In the alternative procedure,<sup>90</sup> the modified Vilsmeier reaction of *N*-phenylazacrown ethers with *N*-methyl-*N*-phenyl-3-aminoacrolein is used; the products are formed under mild conditions in 35% ( $n = 1$ ) and 37% ( $n = 2$ ) yields.

The formyl derivatives of *N*-phenylazacrown ethers are widely used in the synthesis of crown-containing stilbenes,<sup>20, 82, 91</sup> diphenylbutadienes,<sup>82</sup> hetarylphenylethylenes<sup>92–95</sup> and styryl,<sup>20, 92, 93, 96–101</sup> merocyanine<sup>20, 93, 102–104</sup> and butadienyl dyes.<sup>90</sup> These compounds have chromo- and fluoroionophore properties and are distinguished by high sensitivity and selectivity with respect to alkali and alkaline earth metal cations.<sup>20, 82, 90–117</sup>

#### 4. Azacrown-containing benzoic acids

The preparation and chemical properties of azacrown compounds containing an *N*-(4-carboxy)phenyl group are considered only in two papers.<sup>81, 89</sup>

The synthesis of azacrown-containing benzoic acid **44** from the formyl derivative<sup>89</sup> has been described above (see Section III.3). The same compound is produced when carbon dioxide is passed into a tetrahydrofuran solution of the lithium derivative of *N*-(*p*-bromophenyl)aza-15-crown-5 ether.<sup>81</sup>

Acid **44** has been converted to give diverse derivatives, namely, the methyl ester (by the reaction with dimethyl sulfate in the presence of potassium carbonate in acetone),<sup>81</sup> the chloride (on treatment with SOCl<sub>2</sub> in a DMF–toluene mixture) and the amide (by the reaction of the chloride with 4-aminopyridine) (Scheme 2).<sup>89</sup>

#### IV. *N,N'*-Diphenyldiazacrown compounds

Generally, the routes to *N,N'*-diphenyldiazacrown compounds differ little from the above methods used to prepare their analogues with one nitrogen atom in the macrocycle. Diphenyldiaza derivatives are obtained most often by condensation of two fragments and by *N*-arylation of diazacrown ethers.

#### 1. Routes based on the condensation of two fragments

The two versions of this type of condensation (the reactions of toluenesulfonates with alcohols under the action of bases) are presented below. The reaction of *N*-phenyldiethanolamine ditoluenesulfonates with *N*-phenyldiethanolamine or *N*-phenylazatetraethylene glycol derivatives in the presence of sodium hydride resulted in *para*-substituted *N,N'*-diphenyldiaza-12(18)-crown-4(6) ethers **46**.<sup>118</sup>

X = H, Y = Ts; *n* = 0, 1; R = H, Me, OMe, Cl;

X = Ts, Y = H; *n* = 1; R = H (18%);

(a) NaH; (b) Bu<sup>t</sup>OK.

In a similar method, *N*-phenylazatetraethylene glycol ditoluenesulfonate reacts with *N*-phenyldiethanolamine, which also gives *N,N'*-diphenyldiaza-18-crown-6 ether **46** (*n* = 1).<sup>38</sup> In this case, potassium *tert*-butoxide was used as the base.

The condensation of dihalide **47** with various dithiols<sup>34, 38</sup> affords *N,N'*-diphenyltetraethiadiaza-18-crown-6 ether **48** and *N,N'*-diphenyldiaza-15-crown-5 compound **49** containing two S atoms and one O atom in the macrocycle.

Hal = Br, X = S(CH<sub>2</sub>)<sub>2</sub>S (**48**, 11%); X = O (**49**).

As noted above (see Section II.1), the *N,N'*-diphenyltetraethiadiaza-18-crown-6 compound **11**, in which the nitrogen atoms in the macrocycle are separated by three ethylene units, has been isolated as a side product in 2% yield in the synthesis of *N*-phenyldithiaaza-9-crown-3 compound **10** (see Section II.1).<sup>38</sup>

The condensation of diphenyldiamines **50a–g** and **51** (prepared from the corresponding anilines) (Scheme 3) with the dichlorides of dibasic carboxylic acids<sup>74, 119–125</sup> followed by the reduction of the obtained diamides is another method for the

Scheme 2

Scheme 3

Scheme 4

X =  $\text{CMe}_2\text{CMe}_2$ ;  $n = 6, 10, 12, 14$  (61%–85%); X =  $\text{CH}_2\text{CMe}_2\text{CH}_2$ ;  $n = 10$  (62%), 12 (58%).

synthesis of *N,N'*-diphenyldiazacrown derivatives. The reactions of compounds **50a–g** were carried out in the presence of pyridine in benzene or toluene under high dilution conditions (Table 3). The reducing agents used included boron compounds ( $\text{B}_2\text{H}_6$ ,  $\text{BH}_3$  complexes with  $\text{Me}_2\text{S}$  or THF,  $\text{NaBH}_4$ ) and lithium tetrahydroaluminate. *N,N'*-Diphenyldiaza-24-crown-8 ethers **52d** ( $n = 2$ ,  $m = 2$ ) and **52g** ( $\text{R}^1 = \text{H}$ ;  $\text{R}^2 = \text{Me}$ ,  $\text{MeO}$ ,  $\text{Br}$ ;  $n = 2$ ;  $m = 2$ ) were prepared in 18%–33% total yields relative to the starting 4-substituted aniline.<sup>124</sup>

A similar reaction of dianiline **51** was carried out in benzene under the action of triethylamine.<sup>123</sup>

The removal of the tosyl protective groups from the nitrogen atoms in diazacrown compound **52c** was induced by sodium naphthalenide in tetrahydrofuran under mild conditions (yield 70%).<sup>120</sup> Diaza-15(18)-crown-5(6) ethers **52e,f** were used to prepare azo dyes.<sup>126</sup>

A series of macrocyclic *N,N'*-diaryldiaza(oligomethylene)diamides **53** has been obtained by condensation of diaryldiamines containing different numbers of methylene groups with dicarboxylic acid dichlorides on treatment with triethylamine in benzene under high dilution conditions (Scheme 4).<sup>127,128</sup> Compounds **53**, when introduced into polyvinyl chloride membranes, have shown high selectivity for  $\text{Li}^+$  ions.

## 2. Aromatic nucleophilic substitution reactions

Like azacrown ethers, diaza derivatives can be prepared by aromatic nucleophilic substitution in which the amino group of the crown compound attacks the carbon atom bonded to a halogen in an activated aryl halide.

*N,N'*-Diphenyldiazacrown compounds **54a–j**, containing electron-withdrawing substituents in the *para*- and *ortho*-positions of the benzene ring, have been synthesised by *N,N'*-diarylated diazacrown ethers.<sup>60,61,122,129–131</sup> The conditions of this reaction (the type of base and solvent) were mainly determined by the nature of the arylating agent. For example, the reaction of diaza-18-crown-6 ether with 2-chloro-3,5-dinitrobenzophenone

Table 3. Diphenyldiazacrown ether derivatives **52**.

<sup>a</sup> The yield is given in relation to the starting 4-substituted aniline.

or with methyl 4-chloro-3,5-dinitrobenzoate in the presence of triethylamine in benzene gives compounds **54a,b** in high yields.<sup>60</sup> Compounds **54c,d** were prepared in a similar way.<sup>60</sup>

*N,N'*-Diphenyldiazacrown ethers **54e,f**, containing *ortho*-nitro- and *para*-trifluoromethyl groups, were prepared by the reaction of diazacrown ethers with the corresponding aryl chloride in the presence of triethylamine in THF under rigorous conditions (8 kbar pressure).<sup>129, 130</sup> Diaza-15-crown-5 ether reacts with 2-fluoro-5-nitroanisole<sup>61</sup> and diaza-18-crown-6 ether reacts with 4-fluoronitrobenzene<sup>131</sup> in pyridine, giving rise to *N,N'*-bis(nitrophenyl)diazacrown ethers **54g,h**. The diacyl derivatives **54i,j** were produced upon condensation of diaza-18(15)-crown-6(5) ethers with 4-fluoropropiophenone in the presence of tetra-butylammonium fluoride at 150 °C.<sup>122</sup>

### 3. Cross-coupling reactions

The preparation of *N,N'*-diphenyldiazacrown compounds *via* cross-coupling has been reported.<sup>132</sup> The arylation of diaza-18-crown-6 ether with *p*-bromobenzotrifluoride catalysed by Pd<sub>2</sub>(dba)<sub>3</sub>–Xantphos in the presence of the Carboxypack C graphite without a solvent resulted in compound **55**.

### 4. The substitution of hydrogen by diazacrown compounds

This method for the synthesis of *N,N'*-diphenyldiazacrown ethers, which is seldom encountered in the literature, is based on the addition of diazacrown ethers to an activated double bond followed by oxidation of the resulting adduct with excess reagent.

*N,N'*-Diphenyldiazacrown ethers **56a,b**, containing *ortho*- and *meta*-methoxy groups in the benzene rings have been prepared by hydrogenation of crown-containing *p*-benzoquinones **57a,b**. The reaction takes place in MeOH under atmospheric pressure at room temperature in the presence of palladium.<sup>61, 133, 134</sup> Macrocycles **57** were synthesised by the reaction of *p*-benzoquinone with diazacrown ethers. Apparently, benzoquinone itself, which is used in a large excess with respect to the crown ether, acts as the oxidant in this reaction.

*n* = 1 (**a**), 2 (**b**).

## V. Functional derivatives of *N,N'*-diphenyldiazacrown compounds

The transition from unsubstituted *N,N'*-diphenyldiazacrown compounds to their functional derivatives is similar to the reactions of *N*-phenylazacrown compounds.

### 1. Nitro and amino derivatives of *N,N'*-diphenyldiazacrown compounds

*N,N'*-Bis(nitrophenyl)diazacrown compounds can be prepared by the nitration of the aromatic ring. Treatment of *N,N'*-diaryl-diaza-15-crown-5 ether **56a** with an HNO<sub>3</sub>–AcOH mixture results in 4,4'-dinitro derivative **58**.<sup>131</sup>

*N,N'*-Bis(*o*-methoxyphenyl)diaza-15(18)-crown-5(6) ethers **52e,f** react with sodium nitrite in aqueous AcOH (see also Section III.1) to give compounds **59** containing one or two nitro groups, whose ratio depends on the macrocycle size.<sup>74</sup> The researchers noted that the use of traditional nitrating agents (HNO<sub>3</sub>, HNO<sub>3</sub>–H<sub>2</sub>SO<sub>4</sub> or NO<sub>2</sub><sup>+</sup>BF<sub>4</sub><sup>–</sup>) results in a total yield of both mono- and dinitration products of only 5%–10%.

$n = 1$ : R = H (48%), NO<sub>2</sub> (17%);  $n = 2$ : R = H (43%), NO<sub>2</sub> (36%).

Amines **60a–d** have been prepared by the reduction of nitro derivatives of *N,N'*-diaryldiazacrown ethers with hydrogen in the presence of a palladium catalyst in dimethylformamide or ethanol.<sup>74, 131</sup> Conducting the reaction in acetic anhydride gave 4,4'-diacetamide derivative **60e**.<sup>61</sup>

| Compound <b>60</b> | R <sup>1</sup>  | R <sup>2</sup> | R <sup>3</sup> | R <sup>4</sup>  | R <sup>5</sup> | $n$ | Yield (%) |
|--------------------|-----------------|----------------|----------------|-----------------|----------------|-----|-----------|
| <b>a</b>           | NO <sub>2</sub> | H              | H              | NH <sub>2</sub> | H              | 2   | —         |
| <b>b</b>           | NO <sub>2</sub> | OMe            | OMe            | NH <sub>2</sub> | H              | 1   | > 95      |
| <b>c</b>           | H               | H              | OMe            | H               | H              | 1   | 59        |
| <b>d</b>           | H               | H              | OMe            | H               | H              | 2   | 75        |
| <b>e</b>           | NO <sub>2</sub> | H              | H              | NHAc            | Ac             | 1   | 82        |

The bromine atom in compound **52g** is easily replaced by the morpholine residue in the presence of a palladium catalyst.<sup>124</sup>

The acylation of diamine **61** with succinic anhydride in pyridine gave the corresponding disuccinic acid.<sup>120</sup>

R = CH<sub>2</sub>CH<sub>2</sub>CO<sub>2</sub>H.

Chloroacetamides **62** were synthesised in 62% yield by the reaction of amines **60c,d** with chloroacetic anhydride under the action of sodium carbonate in 1,4-dioxane.<sup>135</sup>

## 2. Formyl derivatives of *N,N'*-diphenyldiazacrown compounds

The formyl derivatives of *N,N'*-diphenyldiazacrown ethers **63a–e**<sup>61, 83, 125, 133, 134</sup> and *N,N'*-diphenylthiadiazacrown compounds **64**<sup>83</sup> and **65**<sup>34</sup> were obtained by the Vilsmeier reaction.

| Compound <b>63</b> | R <sup>1</sup> | R <sup>2</sup> | $m$ | $n$ | Yield (%) |
|--------------------|----------------|----------------|-----|-----|-----------|
| <b>a</b>           | H              | CHO            | 1   | 1   | 68        |
| <b>b</b>           | OMe            | CHO            | 0   | 1   | 75        |
| <b>c</b>           | OMe            | CHO            | 1   | 1   | 68        |
| <b>d</b>           | H              | H              | 3   | 3   | 47        |
| <b>e</b>           | H              | CHO            | 3   | 3   | 41        |

X = S(CH<sub>2</sub>)<sub>2</sub>S (**64**), O (**65**).

On treatment with boron trichloride, compounds **63b,c** undergo selective demethylation of the methoxy groups that occupy the *ortho* positions with respect to the formyl functions. Dialdehyde **66** thus formed was used to prepare fluorescent reagents for  $\text{Na}^+$  and  $\text{K}^+$  ions.<sup>61, 133, 134</sup>

$n = 1$  (78%),  $2$  (45%).

The condensation of diformyl derivatives of *N,N'*-diphenyldiaza-18-crown-6 ether **63c** and *N,N'*-diphenyltetraethiadiaza-18-crown-6 compound **64** with dinitrotrifluoromethylphenylhydrazine affords hydrazones **67** and **68** in 68% and 52% yields, respectively.<sup>83</sup>

### 3. Acyl derivatives of *N,N'*-diphenyldiazacrown compounds

Diazacrown-containing  $\alpha,\beta$ -unsaturated ketones **69a,b** were prepared by converting the methyl groups of the propionyl substituent of compounds **54a,b** into methylene groups (see Section IV.2).<sup>122</sup> The reaction took place *via* selenium derivatives **70a,b**. The enolates, obtained by deprotonation of ketones **54** under the action of lithium diisopropylamide, reacted with phenylselenenyl chloride under mild conditions. The oxidation of diselenides **70** with sodium periodate was accompanied by elimination of organoselenium residues. Compounds **69a,b** thus formed react with arylhydrazines to give pyrazolines that are used as fluorescent indicators for the  $\text{Na}^+$  and  $\text{K}^+$  ions.

**69a** (72%); **69b** (75%)

$n = 1$  (**a**),  $2$  (**b**).

## VI. Benzoazacrown compounds

Benzoazacrown compounds that contain one or two nitrogen atoms conjugated with the benzene ring are obtained most often by [1 + 1]-condensation. In some cases, intramolecular cyclisation of podands (open-chain analogues of crown ethers) is used.

### 1. Condensation of two fragments

One method of synthesis of benzoaza- and benzodiazacrown compounds is the reaction of 2-aminophenols or *o*-phenylenediamines with oligoethylene glycol derivatives.<sup>41, 136–143</sup>

Thus by condensation of 2-aminophenols and *o*-phenylenediamine with the dichlorides, obtained from oligoethylene glycols, in DMF or water, Lockhart *et al.*<sup>41, 136, 137</sup> performed the first synthesis of azacrown compounds **71** with different macrocycle sizes (the yields were not reported). More recently, the same researchers described the synthesis<sup>138</sup> of benzodiazacrown compounds **71** by the condensation of *o*-phenylenediamine with tetraethylene glycol ditoluenesulfonate under the action of potassium carbonate in dimethylformamide on heating; however, the product yield was low.

(a) DMF; (b)  $\text{H}_2\text{O}$ ; (c)  $\text{K}_2\text{CO}_3$ , DMF.

| Y   | X  | $n$  | R  |
|-----|----|------|----|
| Cl  | O  | 0–5  | H  |
| Cl  | NH | 0, 1 | H  |
| Cl  | NH | 1    | Me |
| OTs | NH | 1    | H  |

By the reaction of 2-aminophenol with the dichlorides prepared from tri- and tetraethylene glycol in aqueous butanol in the presence of sodium hydroxide, Pedersen and Bromels<sup>139</sup> have synthesised benzoaza-15(18)-crown-5(6) ethers **71** in moderate yields (25% and 16%, respectively). The same method<sup>140</sup> resulted in isolation of benzoaza-15-crown-5-ether in only 8% yield.

$n = 1$  (25%),  $2$  (16%).

Benzodiazacrown compounds **72a–d** have been prepared by condensation of *N,N'*-disubstituted *o*-phenylenediamines with chlorex.<sup>141, 142</sup> The tosyl groups in compound **72c** are removed by heating in concentrated  $\text{H}_2\text{SO}_4$  (yield 48%).

R = Me (**a**), Et (**b**), Ts (**c**), Ac (**d**).

Mesyl protection has also been used for the synthesis of nitrogen-containing benzocrown compounds **73**.<sup>143</sup> Mesylamides form crown compounds in higher yields than the corresponding tosylamides; however, it is difficult to prepare *N*-unsubstituted products from them. No data on the successful removal of mesyl groups from compounds **73** can be found in the literature.

X = O (32%), NMs (5%).

The acylation of *o*-phenylenediamine with dicarboxylic acid dichlorides<sup>142, 144</sup> or tetracarboxylic acid dianhydrides<sup>145</sup> yielded macrocyclic diamides **74** and **75**. The reduction of compound **74** with lithium tetrahydroaluminate resulted in benzodiazacrown-3 compound **76**,<sup>142</sup> whose acylation with acetic anhydride afforded the corresponding *N,N'*-diacyl derivative in 25% yield.

R = CH<sub>2</sub>CH<sub>2</sub> (95%), CH<sub>2</sub>(CH<sub>2</sub>OCH<sub>2</sub>)<sub>2</sub>CH<sub>2</sub> (77%);  
(a) Na<sub>2</sub>CO<sub>3</sub>, xylene (62%); (b) Et<sub>3</sub>N, MeCN (30%).

Bis(chloroacetamide) **77** reacts with primary amines to give macrocyclic amides **78**. The mechanism includes an intramolecular rearrangement of the intermediate adduct **79**.<sup>146</sup>

R = Bn, 4-MeC<sub>6</sub>H<sub>4</sub>, 2,4-Me<sub>2</sub>C<sub>6</sub>H<sub>4</sub>, 4-EtOC<sub>6</sub>H<sub>4</sub>,  
3-Br-2,4,6-Me<sub>3</sub>C<sub>6</sub>H<sub>3</sub>NHCOCH<sub>2</sub>.

Several examples of the synthesis of benzoazacrown compounds based on their linear analogues have been reported. Thus podands **80** and **81**, containing two terminal NH or SH groups, have been converted into benzopolyaza- and benzopolythiaza-crown compounds **82** and **83**.<sup>147, 148</sup> The removal of the tosyl groups in compound **82** was accomplished under acidic conditions as for sulfonamide **72c**, namely, by heating the compound in concentrated H<sub>2</sub>SO<sub>4</sub> (yield 94%).

R = H (31%), OMe (17%).

The condensation of podand **84** with diethanolamine tritoluenesulfonate induced by potassium *tert*-butoxide in *tert*-butyl alcohol furnished the tosyl derivative of benzodiazacrown-6 ether **85**.<sup>149</sup> In this case, the *N*-tosyl group was removed by treatment with lithium tetrahydroaluminate.

Acylation of benzodiazacrown-6 ether **86** with *O,O'*-ethylenediglycolic acid dichloride in THF in the presence of pyridine, followed by the reduction of the resulting diamide **87** with the borane complex with THF, afforded the corresponding benzocryptand **88**.<sup>149</sup>

## 2. Arylation of $\alpha,\omega$ -diamino compounds with 1,2-dihalobenzenes

The reactions of *o*-dihalobenzenes with diamines deserve a separate section. In these cases, the bonds between the nitrogen atoms and the benzene ring are formed as a result of nucleophilic aromatic replacement of halogen atoms in activated aryl halides or as a result of C–N cross-coupling.

The benzodithiadiazacrown compound **89**, containing two nitrile groups on the benzene ring, has been prepared by the reaction of 4,5-dichlorophthalonitrile with an acyclic dithioamide under the action of potassium carbonate in DMF.<sup>150</sup>

Benzocyclam **90** and benzopolyazacrown compounds **91a–e** with different macrocycle sizes were prepared by amination of 1,2-di- or 1,2,3-trihalobenzenes with linear polyamines in the presence of the Pd(dba)<sub>3</sub>–BINAP catalyst system.<sup>151</sup> In addition to the macrocycles, linear products were also isolated in these reactions. The attempts to prepare benzodiazacrown-15-crown-5 ether derivatives from 2,6-dichlorobromobenzene and the corresponding trioxadiazacrown-15-crown-5 ether derivatives with the same catalyst system have not met with success. Only the linear product was isolated in this case.

| Compound 91 | X                               | Y                               | n | Yield (%) |
|-------------|---------------------------------|---------------------------------|---|-----------|
| a           | CH <sub>2</sub> CH <sub>2</sub> | CH <sub>2</sub>                 | 1 | 47        |
| b           | CH <sub>2</sub>                 | CH <sub>2</sub>                 | 1 | 27        |
| c           | CH <sub>2</sub>                 | CH <sub>2</sub> CH <sub>2</sub> | 1 | 17        |
| d           | CH <sub>2</sub>                 | CH <sub>2</sub>                 | 2 | 12        |
| e           | CH <sub>2</sub>                 | CH <sub>2</sub>                 | 3 | 10        |

## 3. Intramolecular cyclisation of podands

This method of synthesis is based on the transformation of a linear molecule into a macrocycle with an annulated benzene ring. Urethane-type benzoazacrown compounds **92** are obtained from betaines **93**.<sup>152</sup> Under drastic conditions, these products rearrange into intermediate, readily cyclisable *N*-aryl isocyanates. The addition of template salts (NaBF<sub>4</sub>, KBF<sub>4</sub>) was found to affect only slightly the yields of these crown compounds.

Hydrogenation of nitrobenzenes containing an aldehyde function in the peripheral substituent, over a platinum or a palladium catalyst in ethanol, furnished a large series of benzoazacrown compounds **94a–g**.<sup>153</sup> Apart from compounds **94**, the reaction mixture contained in some cases dibenzodiazacrown compounds **95b,e–g** and polymerisation products. It was shown that the formation of nine- or ten-membered macrocycles is less favourable than the formation of dimers **95** with a macrocycle comprising 18–20 units (see below, Section VIII.2.a, synthesis of compounds **95h–o**). After the introduction of an *N*-benzoyl group into the nitroaldehyde molecule, this reaction gives only the nine-membered compound **94a**. Monomers **94f,g** with a macrocycle size of 15 and 16 units are formed more readily than the corresponding dimers **95f,g** (30- and 32-membered rings). In these cases, the **94**:**95** ratio in the products varies from 1.5:1 to 3:1. It is noteworthy that 11-, 13- and 14-membered benzoazacrown compounds **94c–e** were synthesised in high yields without dimer formation (except for slight amounts of **95e**).

| Compounds 94, 95 | X                                                                                     | Catalyst | Yield (%) |    |
|------------------|---------------------------------------------------------------------------------------|----------|-----------|----|

## 4. Synthesis of benzoazacrown ethers by the transformation of the benzocrown macrocycle

We proposed a new methodology for the synthesis of benzoazacrown ethers based on a stepwise ring transformation of benzocrown ethers. A distinctive feature of this method is macrocycle opening upon cleavage of the Ar–O bond followed by ring closure to give the corresponding aza analogues. The starting compounds used were benzocrown ethers whose benzene ring contained an electron-withdrawing group (nitro or formyl group), which activated the regioselective macrocycle opening induced by amines.<sup>155–158</sup> For successful recyclisation, the hydroxyl group present in the nitrogen-containing podands thus formed was

Scheme 5

$X = \text{CHO}, \text{NO}_2$ ;  $n = 0-2$ .

replaced by a better leaving group such as a chlorine or an iodine atom.<sup>159–164</sup> The general pattern of the stepwise ring transformation in benzocrown ethers can be represented by Scheme 5.

The key step of this reaction sequence is ring closure in the podands to give the azamacrocyclic. Several procedures differing in the reaction conditions were developed. Ring closure in the halogen derivatives of azapodands can take place both under the action of bases and without bases. Most often, iodine derivatives of azapodands are used to prepare benzoazacrown ethers.

Heating of formyl-containing iodides **96a** in the presence of alkali metal carbonates affords *N*-methylbenzoazacrown ethers **97a**<sup>159–161</sup> together with *N*-demethylated benzoazacrown ethers **98a** as side products (yields 11%–18%). However, in the absence of bases, the reaction gives mainly (in some cases, only) *N*-demethylated benzoazacrown ethers. A drawback of the two methods of ring closure is the very long duration: the reaction does not go to completion even after 150 h. An increase in the time of heating results in a pronounced decrease in the yield of products **97a** (especially in the case of a 18-membered macrocycle) due to substantial resinification of the reaction mixture. Nitro-substituted iodopodand **96b** was converted into *N*-methylbenzoaza-15-crown-5 ether **97b**, whose yields in the presence and in the absence of potassium carbonate were 54% and 22%, respectively.<sup>165</sup>

$X = \text{CHO}, n = 0-2$  (**a**);  $X = \text{NO}_2, n = 1$  (**b**);  
 $Y = \text{I}, \text{Cl}$ ; B is a base.

The use of alkali metal hydroxides or NaH, which are stronger bases than alkali metal carbonates, allows selective preparation of *N*-methylated benzoazacrown ethers **97** over much shorter periods of time.<sup>162–166</sup> Indeed, sodium hydride-induced ring closure in iodopodands **96** takes place on heating for 0.5–2 h. The yields of the products are much higher with NaH than with hydroxides; in some cases, not only iodo but also less reactive chloro derivatives can be used. Table 4 summarises all the preparative procedures for ring closure in halopodands **96**.

Heating of iodide **99** in the presence of  $\text{K}_2\text{CO}_3$  resulted in *N*-methylbenzoaza-9-crown-3 ether in 57% yield in relation to the converted iodide (the degree of conversion was only 23%).<sup>166</sup>

**Table 4.** Methods for the preparation of azacrown ethers **97** from halopodands.

|                                | 2        | I  | NaH, THF                                                         | 71                        | 162–165  |

As an example of another application of podands in the synthesis of benzoazacrown ethers, one can consider the synthesis of compound **100**, which contains an ester group in the macrocycle. This azacrown ether was prepared in two ways: by intramolecular esterification of acid **101** under the action of *N,N'*-dicyclohexylcarbodiimide (DCC) and by transesterification of podand **102** in the presence of *p*-toluenesulfonic acid as the catalyst (Scheme 6).<sup>167</sup>

The resulting *N*-methylated benzoazacrown ethers form complexes with metal cations characterised by high stability constants, due to the specific features of their conformations. The complexing properties of these compounds substantially exceed those of widely used *N*-phenylazacrown ethers (and in many cases, benzocrown ethers, too) with the same macrocycle size.<sup>161, 165, 168</sup> Owing to the presence of a nitro or a formyl group in the products obtained, it is possible to convert them into diverse derivatives containing benzoazacrown ether fragments. These can be used as selective ligands for metal cations, for the extraction of metal ions

Scheme 6

**B** is 4-pyrrolidinopyridine.

from water and for membrane transport of metal ions, as ion selective dyes and fluoroionophores, in ion selective electrodes, and as parts of polymer films and Langmuir–Blodgett films.

## VII. Functional derivatives of benzoazacrown compounds

### 1. Synthesis of benzoazacrown compounds with substituents in the benzene ring

Only a few examples of the synthesis of benzoazacrown derivatives by electrophilic substitution in the benzene ring have been reported.

On treatment with sodium nitrite in hydrochloric acid under mild conditions, benzoaza-15-crown-5 ether **71** is converted into *N*-nitroso derivative **103**, which isomerises in the presence of cold concentrated  $\text{HCl}$  to give 3'-nitrosobenzo derivative **104**.<sup>139</sup>

Azo coupling of benzoaza-12-crown-4 with *p*-nitrophenyldiazonium chloride leads to crown-containing azobenzene in which the substituent is in the *para*-position relative to the macrocycle nitrogen atom.<sup>169</sup>

Compound **105** undergoes selective nitration, under mild conditions, of the 5-position of the benzene ring annelated to the macrocycle.<sup>147</sup>

4'-Nitrobenzotriazacrown compound **106** (see below, Section VII.2) is reduced with hydrogen in the presence of a palladium catalyst to form aniline derivative **107**.<sup>147</sup> This product reacts with picryl chloride in the presence of potassium carbonate to afford benzotriazacrown compound **105**.<sup>147</sup>

(a)  $\text{H}_2$ ,  $\text{Pd/C}$ ,  $\text{TsOH}$ , aq.  $\text{EtOH}$ ; (b)  $\text{PicCl}$ ,  $\text{K}_2\text{CO}_3$ ,  $\text{MeOH}$ .

The formylation of benzocryptand **88** has been carried out by the Vilsmeier reaction.<sup>149</sup>

## 2. Benzoazacrown derivatives at the macrocycle nitrogen atom

The examples of synthesis of functional derivatives at the nitrogen atom refer to benzoaza-15-crown-5 ether **71**. This compound reacts with acyl chlorides with acylation of the secondary nitrogen atom.<sup>136</sup>

X = Br (**a**, 95%), CO<sub>2</sub>H (**b**, 59%).

The amide bond in compound **108a** was reduced with various reagents. This gave *N*-alkylbenzoaza-15-crown-5 ethers in good yields.<sup>136</sup>

Attempts at alkylation of benzotriazacrown compounds **109** with ClCH<sub>2</sub>CO<sub>2</sub>H have failed. However, this reaction readily proceeds when ethyl bromoacetate is used as the alkylating agent.<sup>147</sup>

## VIII. Dibenzoazacrown compounds

### 1. Dibenzoazacrown derivatives

The dibenzomonoazacrown ethers described in the literature, in which the nitrogen atom of the macrocycle is conjugated with two benzene rings, have been synthesised by two routes.<sup>170, 171</sup>

The first route involves the condensation of bisphenol **110** with oligoethylene glycol derivatives under the action of bases. The reactions with oligoethylene glycol ditoluenesulfonates (*n* = 2, 4) were performed in the presence of caesium carbonate in acetonitrile,<sup>170</sup> while the reactions with dihalides and ditoluenesulfonate (*n* = 3) were performed in the presence of potassium carbonate (with addition of catalytic amounts of KI in the case of dichlorides) in various solvents. The highest product yields were attained in cyclohexanone.<sup>171</sup> The addition of LiBr as the template salt in the synthesis of dibenzomonoaza-12-crown-4 ether increased the yield from 8% to 30%. The cyclisation of compound

**110** (*R*<sup>1</sup> = CHO, Ac) is accompanied by deacylation giving rise to macrocycles **111**, which contain a secondary amino group. Subsequently, compound **111** (*n* = 3, *R*<sup>2</sup> = Cl, *R*<sup>3</sup> = H) was acylated. The reaction of **111** with formic acid and acetic anhydride furnished *N*-formylated and *N*-acetylated dibenzoazacrown ethers in 60% and 76% yields, respectively.

*R*<sup>1</sup> = *R*<sup>2</sup> = *R*<sup>3</sup> = H, X = OTs, *n* = 2–4 (22%–68%);

*R*<sup>1</sup> = H, CHO, Ac; *R*<sup>2</sup> = Cl; *R*<sup>3</sup> = H, Cl;

X = Cl, Br; *n* = 1–4 (24%–51%).

The second route to dibenzomonoazacrown ethers consists of the intramolecular cyclisation of podand **112** in the presence of potassium carbonate and copper(I) bromide under drastic conditions (Dowtherm, 220 °C).<sup>171</sup> Two products were isolated — compounds **113** and **114**. The latter can also be synthesised from the NH-unsubstituted derivative **113** by treatment with formic acid.

In some cases, podands containing two phenylene substituents are used as substrates in the synthesis of dibenzomonoazacrown ethers. Thus hydrogenation of nitroaldehyde **115** over a platinum or a palladium catalyst gives dibenzoazacrown ether **116** in 47% and 65% yield, respectively.<sup>153</sup>

Examples of dibenzodiazacrown compounds in which one nitrogen atom is conjugated with the benzene ring, while the second nitrogen atom is separated from the aromatic ring by a methylene bridge are reasonably assigned to the same Section. Compound **117** was prepared by condensation of *N,N'*-ditosylamide **118** with dibromomethane, induced by sodium *n*-butoxide in DMF.<sup>172</sup> Attempts at detosylation by treatment with concentrated H<sub>2</sub>SO<sub>4</sub> failed.

The reaction of diamine **119** with carbon disulfide in pyridine using iodine as the catalyst resulted in the synthesis of dibenzoazacrown compound **120**, which is a thiourea derivative.<sup>173</sup>

## 2. Dibenzodiazacrown and dibenzotetraazacrown compounds

The construction of the macrocycle in the dibenzoazacrown compounds containing two or four nitrogen atoms conjugated with benzene rings is based most often on the condensation of two fragments. Only a few examples of the synthesis of dibenzotetraazacrown compounds from four fragments have been reported.

### a. Syntheses based on the condensation of two fragments

The alkylation of diamines or  $N,N'$ -disubstituted analogues under the action of bases is a widely used method for the synthesis of dibenzodiazacrown compounds. The alkylating agents used include  $\alpha,\omega$ -dihaloalkanes and derivatives of oligoethylene glycols and their aza analogues.<sup>143, 174–179</sup>

Dibenzodiazacrown compounds **121a–c** have been prepared in good yields by the reaction of  $N,N'$ -derivatives of diamines **122a–c** with dibromoethane in the presence of sodium *n*-butoxide.<sup>174</sup> The tosyl groups present in compound **121c** were removed by heating in concentrated  $\text{H}_2\text{SO}_4$  (yield 89%).

$\text{R} = \text{Me}$  (a),  $\text{Bz}$  (b),  $\text{Ts}$  (c).

Under the same conditions, dibenzyl ether **123** was converted to **124** using dibromomethane and 1,2-dibromoethane as well as analogous  $O,O'$ -ditoluenesulfonates with longer alkylene chains as the alkylating agents.<sup>175</sup>

(a)  $\text{Br}(\text{CH}_2)_n\text{Br}$  ( $n = 1, 2$ ); (b)  $\text{TsO}(\text{CH}_2)_m\text{OTs}$  ( $m = 3, 4$ );  $p = 1–4$ .

Dibenzodiazacrown compounds **125** (Table 5) have been prepared in moderate yields by the alkylation of either the diamine as dihydrochloride (**126a**) or the  $N,N'$ -ditosyl derivative **126b** with the corresponding dihalides under the action of alkali metal carbonates.<sup>176</sup> In the latter case, the tosyl groups were removed after the reaction by treatment with sodium naphthalenide in dimethoxyethane.

Dibenzodiazacrown compounds **127** were prepared by the reaction of the  $N,N'$ -ditosyl derivative of diamine **128** with ditoluenesulfonates of propylene or butylene glycols on heating in  $\text{DMF}$ .<sup>177</sup> Detosylation with concentrated  $\text{H}_2\text{SO}_4$  was successful only for compound **127** ( $n = 1, m = 4$ ).

$n = 0, 1; m = 3, 4$ .

The sodium hydride-induced condensation of diamine **129**, containing  $N$ -acetyl protective groups, with the dichloride prepared from diethylene glycol affords dibenzodiazacrown-18-crown-6 compound **130**.<sup>178</sup>

Dinitrodibenzodiazacrown-30-crown-10 ether **131**, with  $N$ -methyl substituents, has been obtained under similar conditions using appropriate reagents.<sup>179</sup>

In an early study,<sup>143</sup> dibenzodiazacrown, triaza- and tetraaza-18-crown-6 compounds **132** were synthesised by condensation of  $N$ -tosyl- or  $N$ -mesyldiamines with appropriate ditoluenesulfonates. The reaction proceeds in the presence of potassium *tert*-butoxide in *tert*-butyl alcohol. The removal of the sulfonyl groups from the macrocycle nitrogen atoms is best accomplished by the heating of compounds **132** with an  $\text{AcOH}$  (glacial)– $\text{HBr}$ – $\text{PhOH}$  mixture (the yields of the  $\text{NH}$  derivatives were 30%–82%). Minor amounts of benzene ring bromination products were also isolated;

**Table 5.** Synthesis of dibenzodiazacrown compounds **125**.

| Compound <b>126</b> | X                    | Y                                                                                                                                   | Z                                                                                | Hal | Reaction conditions                                                                                 | Yield (%) |

the bromine atoms were removed by treatment with hydrazine on a Pd catalyst.

R = Ms: X = Y = O (40%);

R = Ts: X = NTs; Y = O (54%), NTs (20%).

Yet another method used rather widely to prepare dibenzodiazacrown compounds is acylation of the corresponding bridged bis(anilines) with dicarboxylic acid derivatives. Most often, this process is induced by bases and is carried out under high dilution conditions.<sup>136, 144, 169, 178, 180–194</sup> The diamides formed are subsequently reduced by lithium tetrahydroaluminate or diborane.<sup>136, 169, 180–183, 185–193</sup>

Dibenzodiazacrown compounds with different macrocycle sizes **133** have been obtained by the acylation of diamines **134** with oxalic and di- or triglycolic acid dichlorides (Scheme 7, Table 6).<sup>136, 169, 180–183</sup> Compounds **133** with *m* = 1 were used in Pb<sup>2+</sup> extraction experiments and that with R<sup>2</sup> = Bu<sup>t</sup> was also employed to study Pb<sup>2+</sup> ion transport through plasticised cellulose triacetate membranes.<sup>181</sup>

Dibenzodiazacrown compounds **133a,b** were employed in the preparation of benzoannelated cryptands **135a,b**.<sup>180, 182</sup> The substrates **133a,b** were acylated with triglycolic acid dichloride under high dilution conditions, and the subsequent reduction of the resulting amides **136a,b** was carried out with a solution of diborane in THF. The yields were reported only for R<sup>1</sup> = H, R<sup>2</sup> = OBn: **136b**, 43%; **135b**, 88%.<sup>182</sup>

135a,b

$R^1 = \text{Me}$ ,  $R^2 = \text{H}$  (a);  $R^1 = \text{H}$ ,  $R^2 = \text{OBn}$  (b).

*N,N'*-Dicarboxymethyldibenzotetraazacrown compounds **137** have been obtained from diamines and ethylenediaminetetraacetic acid dianhydride in dioxane.<sup>184</sup>

$n = 1$  (55%),  $2$  (42%).

Macrocyclic 18–24-membered dibenzotetraaza- (**138a**) and dibenzopolyazatetralactams (**138b**) are formed in the reaction of diamines with derivatives of dicarboxylic acids under the action of triethylamine. The reaction occurs in highly diluted solution in the case of oxygen-containing compounds **138a** ( $X = Y = \text{O}$ ) and without dilution in the case of polyazacrown compounds **138b** ( $X = \text{NBoc}$ ,  $\text{NCbz}$ ;  $Y = \text{NBoc}$ ).<sup>144</sup>

138a (63%–72%); 138b (30%–35%)

$n = m = 1, 2$ ;  $X = Y = \text{O}$ ;  $R = \text{Cl}$  (a);  
 $n = 2$ ;  $m = 1, 2$ ;  $X = \text{NBoc}$ ;  $Y = \text{NBoc}$ ,  $\text{NCbz}$ ;  $R = \text{PivO}$  (b);  
 Boc is *tert*-butoxycarbonyl, Cbz is benzyloxycarbonyl,  
 Piv is *tert*-butylcarbonyl

A series of 15- and 18-membered dibenzodiazacrown (**139a,b**) and dibenzodithiadiazacrown compounds (**139c–e**) (Table 7), containing one or two O, S or N atoms in the macroheterocycle in addition to the two N atoms, have been synthesised from diamines **140a–e** and dichlorides of dibasic acids (glutaric, diglycolic, thiodiglycolic and *N*-tosyliminodiacetic). Pyridine was used as the base and the condensation was carried out in a highly diluted benzene solution. The subsequent reduction of the carbonyl groups in the resulting diamides **141a–e** was performed by treatment with a solution of borane in THF or dimethoxyethane.<sup>185–193</sup>

Amides **141e** were prepared by condensation in dichloromethane in the presence of KF and catalytic amounts of  $\text{Bu}_4\text{NHSO}_4$ .<sup>194</sup> An attempt to reduce amides **141a–c** with lithium tetrahydroaluminate was successful only for **141a** with  $Y = \text{CH}_2$  (yield 77%).<sup>185</sup> The tosyl group in compounds **139b** ( $Z = \text{NTs}$ ;  $Y = \text{CH}_2$ , O, NTs) was removed by treatment with an  $\text{AcOH}-\text{HBr}-\text{PhOH}$  mixture (yields up to 60%), whereas in compound **139b** ( $Z = \text{O}$ ,  $Y = \text{NTs}$ ), the removal took place only on treatment with sodium in boiling *n*-butanol (yield 67%).<sup>186</sup>

(a) Py, PhH; (b) KF,  $\text{Bu}_4\text{N}^+\text{HSO}_4^-$ ,  $\text{CH}_2\text{Cl}_2$ .

A number of 16–18-membered dibenzodiazacrown compounds **139f**, containing polymethylene chains (3 to 5 units) and additional donor atoms (O, S and N) in the macrocycles, have been synthesised by acylation of the corresponding diamines with

**Table 7.** Synthesis of dibenzodithiadiazacrown compounds **139**.

<sup>a</sup> For compound **139g**,  $X = \text{OCH}_2\text{CH}(\text{OH})\text{CH}_2\text{O}$ .

dicarboxylic acid dichlorides under similar conditions (see Table 7).<sup>186, 195</sup> The tosyl group from **139f** ( $n = 5$ ;  $Y = \text{NTs}$ ) was removed by treatment with an  $\text{AcOH-HBr-PhOH}$  mixture (yield 71%).

The macrocyclic 15-membered compounds **139a,c** and 16–20-membered compounds **139b** ( $Z = \text{O}$ , NTs;  $Y = \text{CH}_2$ , O, NTs), **139f** ( $n = 3-5$ ;  $Y = \text{S}$ ;  $n = 5$ ;  $Y = \text{CH}_2$ , O, NTs) and **139e** were used in experiments on extraction and membrane transport of heavy and transition metal ions.<sup>192–194, 197–199</sup>

The acylation of acetoxy-substituted aromatic diamine **140g** with glutaric, diglycolic, thiodiglycolic and *N*-tosyliminodiacetic acid dichlorides in the presence of pyridine in benzene gave 16-membered acetoxy-substituted crown lactams (see Table 7). The reduction of these products with diborane in dimethoxyethane to give macrocyclic diamines **139g** is accompanied by elimination of the acetyl group.<sup>196</sup> On attempted reduction in THF, only extremely stable complexes of compounds **139g** with the solvent and, perhaps, with boron hydride were isolated.

Macrocyclic diamides **142**, containing trifluoromethyl groups, have been prepared by acylation of diamines **143** with oxalyl chlorides.<sup>200</sup>

$X = \text{CH}_2\text{CH}_2$  (50%),  $(\text{CH}_2)_2\text{S}(\text{CH}_2)_2$  (79%).

In the synthesis of compounds **144**, diimidazolides **145** were used as acylating agents.<sup>178</sup> The reaction takes place on heating of the reactants in pyridine, but the product yields are relatively low.

$X = (\text{CH}_2)_3$ ,  $\text{CH}_2(\text{CH}_2\text{OCH}_2)_n\text{CH}_2$  ( $n = 1, 2$ );  $Y = \text{O}$ , S, NMe.

*o*-Phenylenediamine diamide **146** has been prepared by condensation of *o*-phenylenediamine with dichloride **147** at room temperature.<sup>201</sup>

Macrocyclic derivatives of *N,N'*-diphenylthiourea **148** were obtained by the reaction of bis(anilines) **149** with carbon disulfide in pyridine in the presence of iodine as the catalyst.<sup>173</sup>

Dibenzodiazia-18-crown-6 ether **150** and its chloro derivative **151** are formed upon intramolecular alkylation of aromatic amines **152** and **153** in the presence of sodium carbonate.<sup>202</sup> Amines **152**, **153** were formed in a 10:1 ratio upon the reduction of nitro compound **154**. Due to their low stability, they were not separated but used in the condensation as a mixture. The yields of products **150** and **151** are given in relation to the starting nitro compound **154**.

Dibenzodithiadiazacrown dioximes **155a,b** were synthesised from diamines **156a,b** and oxalylidihydroxymoyl chloride in an aqueous solution of sodium carbonate at low temperature.<sup>203, 204</sup> Dibenzodithiadiazia-12-crown-4 tetraoxime **155c** was prepared from dioxime **156c** in ethanol in the presence of sodium hydrogen carbonate.<sup>205</sup>

$X = \text{CH}_2\text{CH}_2$  (**a**, 27%),  $\text{CH}_2(\text{CH}_2\text{OCH}_2)_3\text{CH}_2$  (**b**, 63%);  
 $\text{C}(=\text{NOH})\text{C}(=\text{NOH})$  (**c**, 65%);  
 (a)  $\text{Na}_2\text{CO}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{CH}_2\text{Cl}_2$ ; (b)  $\text{NaHCO}_3$ ,  $\text{EtOH}$ .

The macrocyclic diimines obtained by condensation of aliphatic diamines with the corresponding dialdehydes are important precursors of dibenzotetraazacrown compounds.<sup>206, 207</sup>

The reduction of diimines **157** yields dibenzotetraazacrown compounds **158** (Table 8).<sup>207–209</sup> Schiff's bases **157** ( $Y = \text{O}$ , S, NH) were synthesised in the presence of *p*-toluenesulfonic acid, which served as the catalyst.<sup>207</sup>

The reactions of diimines **157** ( $n = 2$ ;  $m = 1, 2$ ; Y is none or  $\text{CH}_2$ ) with Grignard reagents have produced tetraazacrown compounds with alkyl substituents in the macrocycle **159**.<sup>208, 210</sup>

$n = 2-5$ , R = Et (87%–94%);  $n = 3$ , R = Pr<sup>n</sup> (80%), Bu<sup>n</sup> (71%).

An unusual procedure has been developed for the synthesis of symmetric dibenzotetraazacrown compounds **160**.<sup>211</sup> Dihydrofuran was used as the reagent; first, it was ozonised and then reduced with sodium cyanoborohydride to dialdehyde. The product was used, without isolation, in the reductive alkylation of *N,N'*-dimethyl-*o*-phenylenediamine. The resulting diamine **161** was converted into dibenzotetraazacrown compound **160** using a similar reaction sequence. The yield of product **160** is given in relation to *N,N'*-dimethyl-*o*-phenylenediamine.

Dibenzodiaza- and tetraazacrown compounds **162** were prepared from diamines **163** and 2-alkyl-3-ethoxyacroleins.<sup>208, 212, 213</sup> The condensation products **164** thus formed, which contain C=C and C=N double bonds, were reduced with hydrogen over a Pd catalyst.<sup>208, 212</sup>

| X  | R  | Yield (%) |     |
|----|----|-----------|-----|
|    |    | 164       | 162 |
| O  | H  | 37        | 86  |
| O  | Me | 26–41     | 84  |
| NH | Me | 40        | 57  |

Hydrogenation of aldehydes **165** containing an *o*-nitrophenylene substituent has yielded a series of 16-, 18- and 20-membered dibenzodiazaacrown compounds **95h–o**.<sup>153</sup> It is noteworthy that no formation of monomers (benzoazacrown compounds) was observed in the synthesis of 18- and 20-membered macrocycles **95h,j–m,o** (see Section VI.3, the synthesis of compounds **94a–g**).

#### b. Condensation of four fragments

Macrocyclic dibenzotetramides **138a** are formed as side products (yields < 5%) in the reaction of *o*-phenylenediamine with di- and triglycolic acid chlorides in the presence of triethylamine under high dilution conditions in MeCN.<sup>144</sup> The reaction gave benzodi-

lactam monomers (yield 30% for benzodilactam **74** with  $n = 1$ , see Section VI.1) or oligomers as the major products.

$n = 1, 2$ .

Tetraaza[14]annulene **167** has been prepared by the condensation of *o*-phenylenediamine with propionaldehyde; the catalytic reduction of this product with hydrogen in the presence of Raney nickel gives dibenzocyclam **168**.<sup>215</sup>

Dibenzodithiatetraazacrown compounds **169** were obtained in high yields by treatment of *N,N'*-diallyl-*N,N'*-ditosyl-*o*-phenylenediamines **170** with sulfur(II) chloride.<sup>216</sup> In the case of substituted *o*-phenylenediamine **170** ( $R^1 = \text{Me}$ ), this reaction gives a mixture of isomers.

$R^1 = R^2 = \text{H}$ ;  $R^1 = \text{Me}$ ;  $R^2 = 4\text{-Me}, 5\text{-Me}$ .

## IX. Functional derivatives of dibenzoazacrown compounds

### 1. Dibenzoazacrown derivatives at the benzene ring

The number of functional derivatives of dibenzoazacrown compounds at the benzene ring reported in the literature is relatively small. These compounds were mainly prepared during the dibenzoazacrown ring construction by condensation of reactants already containing the required substituents (see Section VIII.2). Some examples of the synthesis of functional derivatives of dibenzoazacrown compounds by electrophilic aromatic substitution have been reported.

For example, formylation of dibenzodiazacrown compound **171** by the Vilsmeier reagent gave dialdehyde **172** (yield 77%). The

removal of the benzyl protective groups in the aryl substituents by hydrogenolysis gave rise to the desired product **173** (yield 97%).<sup>182</sup>

$R = \text{CH}_2\text{CO}_2\text{Me}$  (**171**, **172**, **173**);

$R-R = \text{CH}_2(\text{CH}_2\text{OCH}_2)_2\text{CH}_2$  (**135b**, **174**, **175**).

A similar formylation of benzoannulated cryptand **135b**, followed by reductive elimination of the benzyl groups in compound **174**, resulted in the formation of compound **175** in an overall yield of 71%.<sup>182</sup> Macrocycles **173** and **175** were used to prepare crown-containing coumarins, which are fluorescent reagents for alkali and alkaline earth metal ions.

Dibenzodiazacrown compounds easily enter into azo coupling with *p*-nitrophenyldiazonium chloride.<sup>169</sup>

Reduction of the dinitro derivative of *N,N'*-dimethyldibenzo-diaza-30-crown-10 compound **131** with hydrogen over a palladium catalyst gave diamine **176**. This product reacts with methyl isothiocyanate to give a crown-containing thiourea derivative (yield 40% in relation to the starting compound **131**).<sup>179</sup>

### 2. Derivatives of dibenzoazacrown compounds at the macrocycle nitrogen atom

*N*-Substituted dibenzoazacrown compounds are often formed upon cyclisation or condensation of fragments (see Section

VIII.2). In addition, these compounds can be obtained by direct alkylation of pre-formed macrocycles; however, only a few such examples are known.

The reaction of compound **177** with dialkyl sulfate in methanol gave *N,N'*-dialkyl derivatives **121**.<sup>175</sup>

R = Me (56%), Et (62%).

Derivatives **178** have been prepared in a similar way.<sup>181–183</sup> Alkylation of dibenzodiazacrown compounds **133** with ethyl or methyl bromoacetate proceeds in the presence of potassium carbonate or 1,8-bis(dimethylamino)naphthalene (BDN). Compound **178** ( $n = m = 1$ ) has been used as an extractant for  $\text{Pb}^{2+}$  ions and in  $\text{Pb}^{2+}$  transport through plasticised membranes based on cellulose triacetate.<sup>181</sup>

| R <sup>1</sup> | R <sup>2</sup> | R <sup>3</sup> | m | n | Yield (%) |
|----------------|----------------|----------------|---|---|-----------|
| H              | H              | Et             | 1 | 1 | 71        |
| H              | F              | Et             | 0 | 2 | 54        |
| OBn            | H              | Me             | 0 | 2 | 91        |

The reductive alkylation of dibenzocyclam **168** with an aqueous solution of formaldehyde and sodium cyanoborohydride in acetonitrile yielded the tetramethyl derivative of dibenzocyclam **179**.<sup>217</sup>

## X. Conclusion

The data presented in the review were classified according to the chemical type of the synthesised structures. To sum up, it is pertinent to present a brief systematisation of the data in terms of the synthetic methods used, as shown in Table 9. It can be seen that, despite the diversity of approaches, [1 + 1]-condensation of two acyclic fragments still remains the key route to azacrown compounds. Nucleophilic aromatic substitution is widely used to prepare *N*-phenylaza- and *N,N'*-diphenyldiazacrown compounds, which is attributable to the ready availability of the starting compounds. The other methods for the synthesis of azacrown compounds are encountered much more rarely in relevant publications. Meanwhile, more and more publications deal with the synthesis of such compounds by C–N cross-coupling. Of the most recent publications on this topic, of special interest in our opinion are the studies on the synthesis of benzo-diazacrown compounds started not long ago.<sup>151</sup>

It should also be noted that the synthesis of functional derivatives of *N*-phenylaza- and *N,N'*-diphenyldiazacrown compounds is documented rather extensively. The number of known derivatives of annelated azacrown ethers is much smaller. The chemistry of benzoazacrown compounds has been poorly developed until recently because the synthesis of these compounds by condensation of two fragments is complicated and the podands needed for intramolecular condensation are difficult to obtain. We proposed a new methodology for the synthesis of functional derivatives of benzoazacrown ethers by the stepwise

**Table 9.** Brief characteristics of the main methods of synthesis of azacrown compounds (as presented in this review).

| Reaction type                                   | Desired products                          | Features of the method                               | Range of yields (%) | Number of references |

**Abstract.** The key methods for the preparation of magnetic nanoparticles are described systematically. The experimental data on their properties are analysed and generalised. The main theoretical views on the magnetism of nanoparticles are considered. The bibliography includes 416 references.

## I. Introduction

In the last two decades, new terms with the prefix ‘nano’ have rushed into the scientific vocabulary — nanoparticle, nanostructure, nanotechnology, nanomaterial, nanocluster, nanochemistry, nanocolloids, nanoreactor and so on. A series of new journals are devoted particularly to this subject, monographs with the corresponding names have appeared, ‘nano’-specialised institutes, chairs and laboratories have been founded; and numerous conferences are held. In most cases, new names were applied to long known objects or phenomena; however, new objects inaccessible for researchers some 20 years ago have also appeared. These include fullerenes, quantum dots, nanotubes, nanofilms and nanowires, *i.e.*, the objects with at least one nanometer ( $10^{-7}$ – $10^{-9}$  m) dimension.

The enhanced interest of the researchers in nanoobjects is due to the discovery of unusual physical and chemical properties of these objects, which is related to manifestation of so-called ‘quantum size effects.’ These arise in the case where the size of

the system is commensurable with the de-Broglie wavelengths of the electrons, phonons or excitons propagating in them.

A key reason for the change in the physical and chemical properties of small particles as their size decreases is the increased fraction of the ‘surface’ atoms, which occur under conditions (coordination number, symmetry of the local environment, *etc.*) differing from those of the bulk atoms. From the energy standpoint, a decrease in the particle size results in an increase in the fraction of the surface energy in its chemical potential.

Currently, unique physical properties of nanoparticles are under intensive research.<sup>†</sup> A special place belongs to the magnetic properties in which the difference between a massive (bulk) material and a nanomaterial is especially pronounced. In particular, it was shown that magnetisation (per atom) and the magnetic anisotropy of nanoparticles can be much greater than those of a bulk specimen, while differences in the Curie ( $T_C$ ) or Neel ( $T_N$ ) temperatures, *i.e.*, the temperatures of spontaneous parallel or antiparallel orientation of spins, between nanoparticle and the corresponding microscopic phases reach hundreds of degrees. In addition, magnetic nanomaterials were found to possess a number of unusual properties — giant magnetoresistance, abnormally high magnetocaloric effect, and so on.

The magnetic properties of nanoparticles are determined by many factors, the key of these including the chemical composition, the type and the degree of defectiveness of the crystal lattice, the particle size and shape, the morphology (for structurally inhomogeneous particles<sup>†</sup>), the interaction of the particle with the surrounding matrix and the neighbouring particles. By changing the nanoparticle size, shape, composition and structure, one can control to an extent the magnetic characteristics of the material based on them. However, these factors cannot always be controlled during the synthesis of nanoparticles nearly equal in size and chemical composition; therefore, the properties of nanomaterials of the same type can be markedly different.

<sup>†</sup>Almost all particles are inhomogeneous because the properties of the surface and the interior of the particle are inevitably dissimilar. It can be stated with confidence that any nanoparticle has a ‘shell’ but not all of them have a clear-cut ‘core’.

The last years have seen changes in the development of magnetic nanomaterials, which can be called revolutionary, to say the least. This is related both to the development of efficient methods for the preparation and stabilisation of nano-sized magnetic particles and to the progress in the physical methods for the investigation of such particles. For example, it became possible to prepare nanometre metal or oxide particles as not only ferromagnetic fluids (the preparation process was developed back in the 1960s)<sup>2,3</sup> but also as particles included into 'rigid' matrices (polymers, zeolites, *etc.*).

The magnetic characteristics of a material consisting of a non-magnetic solid dielectric matrix with magnetic nanoparticles (3–10 nm) distributed in the matrix were described in 1980.<sup>4</sup> The presence of nanoparticles<sup>‡</sup> in these materials and their composition were established by small-angle X-ray scattering and Mössbauer spectroscopy.<sup>5</sup> More recently, these samples were investigated once again by modern methods, which largely confirmed the earlier results.<sup>6</sup>

Magnetic nanoparticles are abundant in nature and are found in many biological objects.<sup>7</sup> Magnetic nanomaterials are used in information recording and storage systems, in new permanent magnets, in magnetic cooling systems, as magnetic sensors, *etc.* All this accounts for the interest of various specialists in these systems.

Extensive literature is devoted to the applied aspects of the state-of-the-art technology of magnetic recording and its prospects.<sup>8</sup> Currently, powders with micron-size  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, Co- $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, Fe or Fe-Co grains are used most often in magnetic tapes or discs as media for magnetic recording. In this case, recording of one bit requires about 10<sup>9</sup> atoms,<sup>9</sup> whereas with the use of nanomaterials (particles 10 nm in diameter), not more than 10<sup>5</sup> atoms. Thus, transition to magnetic nanomaterials increases the information recording density by a factor of 10<sup>3</sup>–10<sup>4</sup>.

Among the magnetic materials that have found broad practical application in technology, ferromagnets deserve attention. An important characteristic of a ferromagnet is the coercive force ( $H_c$ ), *i.e.*, the magnetic field strength  $H$  corresponding to the point with  $B = 0$  on the symmetric hysteresis loop  $B(H)$  of the ferromagnet. Here  $B$  is the magnetic field induction in a ferromagnetic sample with zero demagnetising factor (for example, in a long cylinder whose axis is directed along the field). One more characteristic, apart from  $H_c$ , is the intrinsic coercive force ( $H_{ci}$ ), defined as the magnetic field strength at the point  $M = 0$  on the symmetric  $M(H)$  hysteresis loop of the ferromagnet, where  $M$  is the magnetisation of a ferromagnetic sample with zero demagnetising factor. The coercive force and the intrinsic coercive force normally do not differ much in magnitude, but these are different physical quantities. When designing new magnetic materials, it is often a goal to attain the highest  $H_c$ . Modern magnetic materials have  $H_c = 2$ –3 kOe (see Section IX).

In terms of the coercive force, ferromagnets are subdivided into soft magnetic ( $H_c < 12.6$  Oe) and hard magnetic ( $H_c > 126$  Oe) ones. The magnets with intermediate coercive force values are referred to as semi-hard. Table 1 presents data on the dependence of the magnetic properties of ferromagnets on the dimensions of the constituent particles. Apart from the dimensions, the magnetic properties of particles depend on the external conditions: temperature, pressure and, in some cases, the local environment, *i.e.*, the medium in which the particle occurs, in particular, the crystalline or amorphous bulk matrix (for a particle), the local crystal environment (for a single atom) or the substrate (for a film).

In addition to ferromagnets in which the magnetic moments of the atoms are ordered, magnetic spin glasses — systems in which the competition of random magnetic interactions between magnetic moments results in a magnetic disordered state — also find application in technology.

The purpose of this review is to survey the state-of-the-art views on the physics, the chemistry and the methods of preparation and stabilisation of magnetic nanoparticles used in nanotechnology for the design of new instruments and devices.

## II. Nanoparticles and materials based on them (classification, definitions)

First of all, it is necessary to consider the general concepts related to the nano-sized objects.

A nano-object is a physical object differing appreciably in properties from the corresponding bulk material and having at least one nanometre dimension (not more than 100 nm).

Nanotechnology is the technology dealing with both single nano-objects and materials and devices based on them and with processes that take place in the nanometre range.

Nanomaterials are those materials whose key physical characteristics are dictated by the nano-objects they contain. Nanomaterials are classified into compact materials and nanodispersions. The first type includes so-called 'nanostructured' materials,<sup>10</sup> *i.e.*, materials isotropic in the macroscopic composition and consisting of contacting nanometre-sized units as repeating structural elements.<sup>11</sup> Unlike nanostructured materials, nanodispersions include a homogeneous dispersion medium (vacuum, gas, liquid or solid) and nano-sized inclusions dispersed in this medium and isolated from each other. The distance between the nano-objects in these dispersions can vary over broad limits from tens of nanometres to fractions of a nanometre. In the latter case, we are dealing with nanopowders whose grains are separated by thin (often monoatomic) layers of light atoms, which prevent them from agglomeration.

A nanoparticle is a quasi-zero-dimensional (0D) nano-object in which all characteristic linear dimensions are of the same order of magnitude (not more than 100 nm). Nanoparticles can basically differ in their properties from larger particles, for example, from long- and well-known ultradispersed powders<sup>12</sup> with a grain size above 0.5  $\mu$ m. As a rule, nanoparticles are shaped like spheroids. Nanoparticles with a clearly ordered arrangement of atoms (or ions) are called nanocrystallites. Nanoparticles with a clear-cut discontinuity of the system of electronic energy levels are often referred to as 'quantum dots' or 'artificial atoms' (most often, they have compositions of typical semiconductor materials).<sup>13,14</sup>

The term 'cluster', which has been widely used in chemical literature in former years, is currently used to designate small nanoparticles with sizes less than 1 nm. Thus, the term 'nanoclusters'<sup>15</sup> is excessive, because all known clusters have nanometre dimensions.

Nanorods and nanowires are quasi-one-dimensional (1D) nano-objects. In these systems, one dimension exceeds by an order of magnitude the other two dimensions, which are in the nano-range. This class includes, in particular, interesting nanostructures such as 'quantum wires'.<sup>16</sup>

The group of two-dimensional objects (2D) includes planar structures — nanodiscs, thin-film magnetic structures, magnetic nanoparticle layers, *etc.*, in which two dimensions are an order of magnitude greater than the third dimension, which is in the nanometre range.

In this review we use the molecular approach outlined in a previous publication,<sup>17</sup> namely nanoparticles are considered as giant pseudomolecules having a core and a shell and often also external functional groups. The unique magnetic properties are usually inherent in the particles with a core size of 2–30 nm. For magnetic nanoparticles, this value coincides in the order of magnitude with the theoretical estimate for the smallest dimensions of a magnetic domain in most magnetic materials (see Table 1).

‡ In those years, the term 'nanoparticle' did not yet exist and these objects were called 'ligand-free metal clusters' or just 'clusters.'

**Table 1.** Type of the change of the magnetic properties of a ferromagnet with a decrease in the substance dimensions from macroscopic to atomic.

| Object                                                                              | Characteristic size   | Specific magnetic properties                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|-------------------------------------------------------------------------------------|-----------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Macroscopic (bulk) sample                                                           | $\geq 1 \mu\text{m}$  | spontaneous magnetisation below $T_C$ . The appearance of a nonzero magnetic moment is suppressed by the formation of a domain structure                                                                                                                                                                                                                                                                                                                                                |
| Microscopic sample                                                                  | 50–1000 nm            | magnetic characteristics strongly depend on the sample pre-history, preparation and processing method                                                                                                                                                                                                                                                                                                                                                                                   |
| Single-domain magnetic particles (small magnetic particles) in a diamagnetic matrix | 1–30 nm               | the presence of a blocking temperature <sup>a</sup> $T_b < T_C$ below which the magnetic moment of the particle retains orientation in space, while the particle ensemble demonstrates a magnetic hysteresis. At a temperature higher than $T_b$ , the particle transfers into the superparamagnetic state. In the $T_b < T < T_C$ region, the particle has a spontaneous magnetisation and a nonzero total magnetic moment, which easily changes the orientation in the external field |
| Single atom (ion)                                                                   | $\sim 0.2 \text{ nm}$ | usual paramagnetic properties                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

<sup>a</sup> For isolated nanoparticles with sizes 1–30 nm, the temperature scale has one more characteristic point apart from the Curie and Neel temperatures, namely, the ‘blocking’ point  $T_b < T_C(T_N)$ .

### III. Methods for the preparation of magnetic nanoparticles and nanomaterials

If the methods used to prepare nanoparticles are classified in terms of the type of the precursor and the features of its processing, the following key approaches to the formation of nanoparticles can be distinguished:

- preparation from macroscopic materials by dispersion;
- chemical synthesis, *i.e.*, targeted change in the substance composition with termination (in some way) of the nascent phase growth at the nano-size stage;
- transformations of nanoparticles with the change in the composition.

The last-mentioned route has found only a limited use as yet and is represented by a few examples.

A series of general methods for the nanoparticle synthesis have now been developed.<sup>18</sup> Most of them can also be used for the preparation of magnetic particles. An essential feature of their synthesis is the preparation of particles of specified size and shape (at least, the scatter of sizes should be small, 5%–10%, and controllable). The shape control and the possibility of synthesis of anisotropic magnetic structures are especially important. In order to eliminate (or substantially decrease) the interparticle interactions, magnetic nanoparticles often need to be isolated from one another by immobilisation on a substrate surface or in the bulk of a stabilising inert matrix. It is important that the distance between the particles in the matrix should be controllable. Finally, the synthetic procedure should be relatively simple, inexpensive and reproducible.

The development of magnetic materials is often faced with the necessity of preparing nanoparticles of a complex composition, namely, ferrites, complex NdFeB or SmCo<sub>5</sub> alloys, *etc.* In these cases, the range of synthetic approaches substantially narrows down. For example, the thermal evaporation of compounds with a complex elemental composition is often accompanied by a violation of the stoichiometry in the vapour phase, resulting in the formation of other substances, while the atomic beam synthesis does not yield a homogeneous distribution of elements on the substrate. The mechanochemical methods of powder dispersion also violate (in some cases, substantially) the phase composition: in particular, ferrites do not retain the oxygen stoichiometry. Finally, the preparation of a target phase from heteroelement precursors may be associated with the difficulty of synthesis of the precursors. For example, no volatile compounds with a Sm atom bonded to five Co atoms are known; the maximum chemically attainable element ratio in Sm[Co(CO)<sub>4</sub>]<sub>3</sub> is 1 : 3. It is even more difficult to propose a volatile stoichiometric precursor for the synthesis of NdFeB nanoparticles.

The physical characteristics of nanoparticles are known to be substantially dependent on their dimensions. Unfortunately, most of the currently known methods of synthesis afford nanoparticles with rather broad size distributions (dispersion  $\sigma > 10\%$ ). The thorough control of reaction parameters (time, temperature, stirring velocity and concentrations of reactants and stabilising additives) does not always allow one to narrow down this distribution to the required range. Therefore, together with the development of methods for synthesis of nanoparticles with a narrow size distribution, the techniques of separation of nanoparticles into rather monodisperse fractions are perfected. This is done using controlled precipitation of particles from surfactant-stabilised solutions followed by centrifugation (the coarsest fraction is the first to be precipitated). After decantation, the precipitate can again be dissolved and subjected to precipitation/centrifugation. The process is repeated until nanoparticle fractions with specified sizes and dispersion degrees are obtained.

The methods of nanoparticle preparation cannot be detached from stabilisation methods. For 1–10 nm particles with a high surface energy, it is difficult to select a really inert medium,<sup>17</sup> because the surface of each nanoparticle bears the products of its chemical modification, which affect appreciably the nanomaterial properties. This is especially important for magnetic nanoparticles in which the modified surface layer may possess magnetic characteristics markedly differing from those of the particle core. Nevertheless, the general methods for nanoparticle synthesis not related directly to the stabilisation and the methods where the nanoparticle formation is accompanied by stabilisation (in matrices, by encapsulation, *etc.*) will be considered separately.

The methods of generation of magnetic nanoparticles in the gas or solid phase using high-energy treatment of the material are usually called physical, while the nanoparticle syntheses, which are often carried out in solutions at moderate temperatures are chemical methods. The chemical methods for the preparation of magnetic nanoparticles have developed most intensively in recent years; however, physical methods should not yet be considered as outworn.

#### 1. Physical methods for the preparation of magnetic nanoparticles

##### a. Condensation methods

The method of nanoparticle synthesis from supersaturated metal vapours is based on the classical nucleation theory in which the nascent phase clusters are described by the spherical liquid drop model. Nanoparticles (clusters) are prepared using various ways of metal evaporation: laser vaporisation,<sup>19, 20</sup> thermal vaporisation,<sup>21, 22</sup> arc discharge, plasma vaporisation,<sup>23</sup> and solar energy-induced evaporation.<sup>24</sup> In each method, special installations are employed differing in engineering solutions of particular units.<sup>25</sup>

All the methods for metal evaporation listed above allow one to study both the physicochemical characteristics of nanoparticles in the gas phase (before the metal vapour deposition on the substrate) and the properties of films and powders obtained upon deposition. Since recently, the cryogenic method has been used to prepare nanoparticles. In this case, the condensation of metal atoms and metal compounds occurs at low temperatures in a cryogenic matrix, most often, in a liquid inert gas. This method allows the preparation of chemically highly pure nanoparticles uniform in composition and structure and having no pores or other morphological inhomogeneities.

In the classical thermal vaporisation method, a metal or alloy sample is heated in a tungsten boat in an argon or helium stream. The atoms of the vaporised metal lose kinetic energy upon collisions with inert gas atoms, gather in clusters and condense on a cooled substrate as a nanodispersed powder. By varying the evaporation rate, the substrate temperature and gas pressure and composition, one can control the particle size in the 3–100 nm range. Most often, prior to opening the installation and taking out the sample, nanoparticles are passivated by passing an inert gas/oxygen mixture for several minutes. In particular, this method was used to prepare heterometallic nanoparticles (~30 nm) with the composition Fe–M (M = Ni, Mn, Pt, Cr).<sup>21</sup> For the Fe–Cr system, it was shown that for a Cr content of 47.7 at.%, the metastable  $\sigma$ -phase with a tetragonal lattice detected in the 440–830 °C temperature range in the state diagram of the Fe–Cr alloy predominates in nanoparticles.<sup>21,22</sup>

Individual magnetic nanoparticles were first obtained by the molecular beam method.<sup>26,27</sup> In this case, metal evaporation takes place in vacuum in a diaphragm chamber. The evaporated particles pass through the diaphragm and form the molecular beam. The beam intensity determines the rate of condensation of the particles on the substrate. This method produces largely free (*i.e.*, ligand-free) clusters (nanoparticles); therefore, it can be used to determine the intrinsic magnetic properties of these particles without the distorting influence of the environment and to understand the fundamental grounds of the physics of magnetic clusters. Although unsurpassed in this respect, the molecular beam method has not found practical use for the preparation of magnetic nanomaterials.

The synthesis of nanoparticles by a hydrogen plasma metal reaction (HPMR) has been reported;<sup>28,29</sup> therefore, we do not consider this method here.

The preparation of nanoparticles by metal vapour spraying is a rather well-developed method in both practical and theoretical aspects. With thermal or laser vaporisation, this method allows the synthesis of gram amounts of nanoparticle powders. This method can be used for dispersing metals, alloys or oxides; however, the cost of nanomaterials obtained in this way remains rather high.

The low-energy cluster beam deposition (LECBD) method includes deposition of non-charged particles with a very low kinetic energy on a substrate.<sup>30</sup> In this case, the particles are not destroyed on getting on the substrate and can be inserted into various type of matrices, which are formed simultaneously by vaporisation of their components from another source. The size and composition of the deposited nanoparticles are controlled in the gas phase prior to deposition on the substrate using mass-analysing systems of various types.

#### b. Methods of nanodispersion of a compact material

The mechanochemical dispersion of a compact material in mills of various designs appears an attractive way to produce disperse systems. However, there exists a mechanical dispersion limit for solids,<sup>31,32</sup> which prevents in some cases the preparation of nanosized particles with a narrow dispersion. In addition, high energy impact on the material being ground result in intensive interaction of the nanoparticles formed with the dispersion medium. Some examples of successful use of mechanochemical dispersion for the

preparation of magnetic nanoparticles are given in the following Sections.

Electrolytic erosion can also be used to disperse metals and alloys. In this case, spraying takes place inside a dielectric liquid and the liquid transformation products coat the surface of the nanoparticles formed. Depending on the process conditions, the metal nature, and the dispersion medium, the diameter of the nanoparticles formed is usually in the 2.5–20 nm range, but some particles can be as large as 100 nm.<sup>33</sup> Presumably, small particles are formed on quenching the metal vapour, while large ones are produced from molten drops. Using electrolytic erosion, nanoparticles with a complex composition for permanent magnets have been obtained.<sup>34</sup> However, in this case, too, the nanoparticles formed interact to a noticeable extent with the medium. For example, when organic solvents are used as the dielectric medium, product carbonisation takes place, while in the case of molten sulfur, sulfides are formed.<sup>35</sup>

Electrochemical generation is used as a method for the synthesis of substantial amounts of rather small (1–2 nm) nanoparticles with a narrow dispersion.<sup>36</sup> A standard electrochemical cell containing an alcohol solution of tetraalkylammonium halide was used to obtain cobalt particles. On passing the current, the cobalt anode dissolved to give Co nanoparticles near the cathode (glass carbon). The influence of electrolysis conditions on the magnetic characteristics of the resulting nanoparticles was studied using several examples.

The average size of a particle formed upon electrochemical dispersion is inversely proportional to the current density. The colloid solution of nanoparticles formed upon electrolysis can be stored under argon for several months. Evaporation of the solvent yields crystallites, which can be readily converted again into a colloid suspension.

The electrochemical process was used to obtain  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles (3–8 nm), stable in organic solvents due to adsorption of cationic surfactants.<sup>37</sup>

## 2. Chemical synthesis of magnetic nanoparticles

Chemical methods for the synthesis of nanoparticles have been surveyed in a recent review;<sup>38</sup> therefore, we will mention only the latest publications illustrating the trends in the development of this approach.

Diverse metal-containing compounds (MCC) including metal carbonyls, organometallic compounds, metal carboxylates, *etc.*, are used as the precursors in the synthesis of magnetic nanoparticles. Most often, precursors decompose on heating or UV irradiation; other types of treatment of MCC, resulting in nanoparticles, have also been developed.

#### a. Thermolysis of metal-containing compounds

Thermal decomposition of metal-containing compounds has been studied in detail in relation to the development of the scientific grounds of the metal organic chemical vapour deposition (MOCVD) technique, which is used successfully to obtain nanoparticles. In a one-step CVD synthesis of nanodispersed Fe oxides, [Fe(OBu<sup>t</sup>)<sub>3</sub>]<sub>2</sub> has been proposed as the MCC.<sup>39</sup> When the reaction is carried out in a liquid medium in the presence of surfactants or polymers, it is possible to stabilise the resulting amorphous nanoparticles with diameters of up to 10 nm. An interesting example of two-stage thermolysis of Fe(CO)<sub>5</sub> has been reported.<sup>40</sup> First, an iron oleate complex is formed from Fe(CO)<sub>5</sub> and oleic acid at 100 °C; at 300 °C, the complex decomposes to give primary 'loose' nanoparticles (4–11 nm). After maintaining at 500 °C, these are converted, as shown by powder X-ray diffraction, into crystalline  $\alpha$ -Fe nanoparticles. Laser photolysis of volatile MCC (most often, metal carbonyls) is also suitable for this purpose.<sup>41</sup>

#### b. Decomposition of metal-containing compounds on ultrasonic treatment

In this method, metal carbonyls and their derivatives are used as metal-containing compounds, although cases of successful use of

other organometallic compounds are also known. For example, Co nanoparticles were synthesised by ultrasound-induced decomposition of a solution of  $\text{Co}_2(\text{CO})_8$  in toluene.<sup>42</sup> In order to retain the monodispersity and prevent aggregation of the particles formed, sodium bis(2-ethylhexyl)sulfosuccinate was added to the solution. 'Amorphous' Co-containing nanoparticles were also obtained by ultrasonic treatment of a solution of  $\text{Co}(\text{CO})_3(\text{NO})$  in decane in the presence of oleic acid.

For the synthesis of Fe-containing magnetic nanoparticles,  $\text{Fe}(\text{CO})_5$  is used most often.<sup>43</sup> Ultrasonic decomposition of iron pentacarbonyl in polyvinylpyrrolidone resulted in amorphous  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles. Their dimensions were determined by the nature and concentration of the surfactants present in the solution.<sup>44</sup> It was shown experimentally that ultrasonic treatment of labile MCC is a convenient way of producing nanoparticles under mild conditions, which is important for the preparation of metastable aggregates. However, there are no methods for controlling their dimensions.

### c. The reduction of metal-containing compounds

Magnetic metallic nanoparticles can be prepared from metal salts using strong reducing agents, namely, alkali metal dispersions in ethers or hydrocarbons, alkali metal complexes with organic electron acceptors (e.g., naphthalene),  $\text{NaBH}_4$  and other complex hydrides. By using  $\text{NaBH}_4$  in aqueous solutions at room temperature, both homo- (Fe, Co, Ni) and heterometallic (Fe–Co, Fe–Cu, Co–Cu) nanoparticles were obtained as amorphous powders containing substantial amounts of boron (20 mass % or more). The reduction of  $\text{CoCl}_2$  with  $\text{LiBH}_4$  in the presence of trialkylphosphines yields nanoparticles of pure cobalt  $\epsilon$ -phase with 2–11 nm size (depending on the alkyl chain length in trialkylphosphine).<sup>45</sup>

The general method for the preparation of metallic nanoparticles by reducing metal salts in aprotic solvents is documented.<sup>46</sup> High-boiling alcohols are often used as reducing agents. The reduction of cobalt acetate with dodecane-1,2-diol at 250 °C in oleic acid in the presence of trioctylphosphine gives 3–8 nm metal particles.<sup>47</sup> nickel-containing nanoparticles have been prepared in a similar way.<sup>48</sup>

Yet another method of synthesis is represented by radiation chemical reduction of metal ions in aqueous solutions. In particular,  $\gamma$ -irradiation of deaerated solutions of  $\text{Co}^{2+}$  and  $\text{Ni}^{2+}$  perchlorates in the presence of sodium formate and a stabiliser (surfactant) affords spherical nanoparticles (2–4 nm) of these metals with a narrow pore size distribution.<sup>49</sup>

### d. Synthesis in reverse micelles

Recent years were marked by intensive development and wide use of the synthesis nanoparticles in nano-sized 'reactors' as the size of 'nanoreactors' can be controlled within certain limits. A micelle is an example of these nanoreactors. Reverse micelles are tiny drops of water stabilised in a hydrophobic liquid phase due to the formation of a surfactant monolayer on their surface. Owing to the exactly measured amount of MCC in each micelle (as the nanoparticle formation occurs without substance supply from the outside), it is possible not only to control the composition and the average size of the particles but also to obtain monodisperse samples with a narrow particle size distribution. Thus Co nanoparticles were synthesised by mixing two colloid solutions of reverse micelles with the same diameter (3 nm), one containing  $\text{CoCl}_2$  and the other containing sodium tetrahydroborate of the same concentration.<sup>50</sup> Magnetic nanoparticles with an average diameter of 5.8 nm and a polydispersity of 11% were obtained in hexane as a colloid dispersion stable against aggregation and oxidation during a week. Syntheses of cobalt nanoparticles in reverse micelles are described in detail in the literature.<sup>51–53</sup>

### e. Sol–gel method

The sol–gel method is widely used in a number of technologies.<sup>54</sup> In nanotechnology, it is used most often to obtain metal oxides

but is also applicable to the synthesis of nanosized metals and fused bimetallic and heteroelement particles. For example, reduction of  $\text{Ni}^{2+}$  and  $\text{Fe}^{2+}$  ions inserted in silica gel in 3 : 1 ratio with hydrogen at 733–923 K resulted in  $\text{Ni}_3\text{Fe}$  nanoparticles (4–19 nm) within the  $\text{SiO}_2$  matrix.<sup>55</sup>

### e. Synthesis of magnetic nanoparticles at a gas–liquid interface

Nanoparticles can also be synthesised in the absence of solid substrates or matrices by redox reactions at an interface between two phases, one containing a metal compound (precursor) and the other, the reducing agent. This method was first implemented by Faraday back in 1857 to prepare a stable colloid solution of gold nanoparticles.<sup>56</sup> A new approach to the synthesis and self-assembly of nano-sized structures including magnetic ones in a fully anisotropic two-dimensional reaction system has been reported.<sup>57–64</sup> Nanoparticles were synthesised in a Langmuir monolayer of amphiphilic molecules,<sup>§</sup> incorporating the precursor molecules at a gas–liquid interface. Decomposition of metal compounds in such a monolayer initiates the appearance and nucleation of active intermediates and the two-dimensional growth of nanoparticles on the liquid surface. The surfactant molecules of the monolayer can react with the nanoparticles formed and affect the growth processes, thus opening the way for effective control of the size and morphology of the structures formed. The growth and self-organisation of nanoparticles can also be affected by changing the chemical composition of the liquid or gas phase, *i.e.*, by adding compounds that react with nanoparticles on the liquid surface, by varying the temperature, by exposing the monolayer to electric or magnetic fields or various types of radiation (including light).

Two-dimensional diffusion and growth of nanoparticles depend on the thermodynamic state of the Langmuir monolayer. This can exist as so-called two-dimensional gas, two-dimensional liquid or a condensed two-dimensional phase (when the molecules are located close to one another). When the monolayer passes into the condensed state, the diffusion controlled processes stop and the system state settles down. This allows one to stop the nanoparticle growth and organisation at the specified moment and then to transfer the monolayer with the resulting nanoparticles and nanostructures on solid substrates and to study the resulting planar nanostructures by various methods.

The decomposition of the precursor molecule at the interface can be induced by electromagnetic radiation (in particular, light). This photochemical decomposition of iron pentacarbonyl in the Langmuir monolayer under contact with air gives nanoparticles and nanostructures of iron oxides, mainly  $\gamma\text{-Fe}_2\text{O}_3$ .<sup>59</sup> An external magnetic field has a substantial influence on the shape of the resulting anisotropic magnetic nanoparticles, their shape and orientation being dependent on the orientation of the applied field with respect to the interface.<sup>59, 60, 62</sup>

The influence of the applied fields on the two-dimensional growth of amorphous iron-containing magnetic nanoparticles by decomposition of iron pentacarbonyl on exposure to UV radiation in a mixed Langmuir monolayer at a gas–water interface with stearic acid as the surfactant has been studied.<sup>57, 58, 60, 62</sup> During the nanoparticle formation, the monolayer existed in the 'gas-like' state (the surface pressure was equal to zero).

The magnetic properties of multilayer Langmuir–Blodgett films containing nanoparticles were studied by EPR, which revealed ferromagnetic resonance signals and superparamagnetism.<sup>60</sup> Studies by scanning tunnelling microscopy (STM), atomic force microscopy (AFM) and transmission (tunnelling) electron microscopy (TEM) have shown that the size and shape of nanoparticles may change substantially during the growth from disc-like to oriented oblong under the action of an external magnetic field directed parallel to the monolayer plane.<sup>59</sup> When the mag-

§ Stearic or arachidic acid or other surfactants are normally used as amphiphilic molecules.

**Figure 1.** TEM (a) and ACM (b) micrographs of iron-containing nanoparticles synthesised in a Langmuir monolayer.<sup>59</sup>

netic field is perpendicular to the monolayer plane, the nanoparticles acquire an anisotropic shape symmetric relative to the axis that passes through the nanoparticle centre at right angle to the interface (Figs 1–3).

Figure 1 shows iron oxide nanoparticles synthesised in a Langmuir monolayer with the initial ratio  $\text{Fe}(\text{CO})_3 : \text{C}_{17}\text{H}_{35}\text{CO}_2\text{H} = 10 : 1$  under UV irradiation (4 min) at 21 °C and pH 5.6 in the absence of an external magnetic field. The resulting nanoparticles were planar and radially symmetric. Figure 2 shows the nanoparticles synthesised under analogous conditions but with an external magnetic field applied parallel to the monolayer plane. This gave anisotropic oblong nanoparticles whose longer axis coincided with the field direction.<sup>59</sup>

If the energy of the magnetic dipole–dipole interaction of nanoparticles exceeds the energy of thermal (Brownian) motion  $k_B T$  ( $k_B$  is the Boltzmann constant), the magnetic particles can be combined into chain structures. The formation of chain aggregates of magnetic particles is typical, in particular, of magnetic liquids. Figure 3 shows an organised chain ensembles of iron-containing magnetic nanoparticles synthesised in a Langmuir monolayer with an external magnetic field applied and with a short-term UV irradiation.<sup>60</sup>

Highly organised lamellar molecular structures obtained by the Langmuir–Blodgett method have been used as ordered matrices in the synthesis of various nanoparticles, including semiconductor particles, doped with magnetic metal ions (DMS).<sup>65,66</sup> Thus CdS (3 nm) particles doped by  $\text{Mn}^{2+}$  ions were prepared by treatment with  $\text{H}_2\text{S}$  of a Langmuir–Blodgett film consisting of a mixture of cadmium and manganese salts of arachidic acid.

**Figure 2.** TEM (a) and ACM (b) micrographs of iron-containing nanoparticles synthesised in a Langmuir monolayer with application of a 2 kG external magnetic field directed parallel to the monolayer plane.<sup>59</sup>

Multilayer ordered structures have also been obtained by the Langmuir–Blodgett method *via* the formation of stable iron stearate monolayers on the aqueous phase surface.<sup>67,68</sup>

**Figure 3.** ACM micrographs of iron-containing nanoparticles synthesised in a Langmuir monolayer on a short-term (6 s) UV irradiation followed by dark incubation (4 min) with application of an external 2 kG magnetic field directed parallel to the monolayer plane.<sup>60</sup>

### 3. Specific methods for the preparation of particular types of magnetic nanoparticles

#### a. Heterometallic nanoparticles

As a rule, these particles are prepared by simultaneous thermal decomposition of two MCC of different compositions (hydrogen is used most often as the reducing agent). This method was used to prepare heterometallic nanoparticles,  $\text{Fe}_{48}\text{Pt}_{52}$  and  $\text{Fe}_{70}\text{Pt}_{30}$ , from  $\text{Pt}(\text{acac})_2$  and  $\text{Fe}(\text{CO})_5$ .<sup>69</sup> In the synthesis of Co–Pt particles, either  $\text{Pt}(\text{acac})_2$ , or  $\text{Pt}_2(\text{dba})_3$  (dba is dibenzylideneacetone) was used as the source of Pt, while sources of Co included  $\text{Co}_2(\text{CO})_8$ ,  $\text{Co}(\text{CO})_3(\text{NO})$ <sup>70</sup> and  $\text{Co}(\eta^3\text{-C}_8\text{H}_{13})(\eta^4\text{-C}_8\text{H}_{12})$ .<sup>71</sup>

Using the synthesis of  $\text{CoPt}_3$  nanoparticles as an example, the mechanism of homogeneous nucleation has been studied. This allowed researchers<sup>72</sup> to deliberately and reproducibly obtain nanoparticles of the specified composition with a narrow size distribution in the 3–18 nm range. The synthesis of so-called ‘shell’ CoPt nanoparticles has been described.<sup>73</sup> The researchers first obtained Pt nanoparticles of diameter 2.5 nm and then coated them with a controlled amount of Co layers. This resulted in Co–Pt nanoparticles with a diameter of 7.6 nm.

In some cases, heterometallic particles are called ‘alloys,’ in our opinion, this is not always appropriate. For example, using the same initial compounds,  $\text{Co}_2(\text{CO})_8$  and  $\text{Pt}(\text{hfac})_2$ , two types of Co–Pt nanoparticles with the same composition and different structures have been obtained,<sup>74</sup> namely, particles with a uniform distribution of Co and Pt atoms and particles with a cobalt core and a platinum shell, Pt@C. In the latter type of particles, mixing of the atoms of two metals is possible only at the interface.

It is also pertinent to consider the procedure for the synthesis of cobalt ferrite  $\text{CoFe}_2\text{O}_4$  nanoparticles,<sup>75</sup> in which the first stage includes the preparation of the Fe–Co heterometallic particles and the second stage, their oxidation to  $\text{CoFe}_2\text{O}_4$ . Another route to analogous particle implies the use the heterometallic  $(\eta^5\text{-C}_5\text{H}_5)\text{CoFe}_2(\text{CO})_9$  cluster as the starting compound. The cobalt ferrite nanoparticles were also prepared by the micro-emulsion method<sup>76</sup> from a mixture of Co and Fe dodecylsulfates treated with an aqueous solution of methylamine.<sup>77, 78</sup>

#### b. Ferrites

Microcrystalline ferrites form the basis of materials currently used for magnetic information recording and storage. To increase the recorded information density, it seems reasonable to obtain nanocrystalline ferrites and to prepare magnetic carriers based on them. Grinding of microcrystalline ferrite powders to reach the nanosize of grains is inefficient, as this gives particles with a broad size distribution, the content of the fraction with the optimal particle size (30–50 nm) being relatively low.

The key method for the preparation of powders of magnetic hexagonal ferrites with a grain size of more than 1  $\mu\text{m}$  includes heating of a mixture of the starting compounds at temperature above 1000 °C (so-called ceramic method). An attempt has been made<sup>79</sup> to use this method for the synthesis of barium ferrite nanoparticles. The initial components (barium carbonate and iron oxide) were ground for 48 h in a ball mill and the resulting powder was mixed for 1 h at a temperature somewhat below 1000 °C. This gave rather large particles (200 nm and greater) with a broad size distribution. Similar results have been obtained in the mechanochemical synthesis of barium ferrite from  $\text{BaCl}_2$ ,  $\text{FeCl}_3$  and alkali with subsequent oxidative annealing.<sup>80</sup>

Nanocrystalline ferrites are often prepared by the co-precipitation method. The  $\text{MnFe}_2\text{O}_4$  spinel nanoparticles with a diameter of 40 nm are formed upon the addition of an aqueous solution of stoichiometric amounts of  $\text{Mn}^{2+}$  and  $\text{Fe}^{3+}$ -chlorides to a vigorously stirred solution of alkali.<sup>81</sup> The  $\text{MgFe}_2\text{O}_4$  (6–18 nm),<sup>82</sup>  $\text{Co}_{0.2}\text{Zn}_{0.8}\text{Fe}_2\text{O}_4$  (2–45 nm)<sup>83</sup> and  $\text{BaFe}_{12-2x}.\text{Sn}_x\text{Zn}_x\text{O}_{19}$  ( $\sim 45$  nm)<sup>84</sup> nanoparticles were obtained in a similar way. The  $\text{SrFe}_{12}\text{O}_{19}$  nanoparticles (30–80 nm) were synthesised by co-precipitation of Sr and Fe citrates followed by annealing of the resulting precipitate.<sup>85</sup> Co-precipitation upon decomposition of a mixture of  $\text{Fe}(\text{CO})_5$  and  $\text{Ba}(\text{O}_2\text{C}_7\text{H}_{15})_2$  under ultrasonic

treatment has been successfully used<sup>86</sup> for the synthesis of barium ferrite nanoparticles ( $\sim 50$  nm).

Methods for the preparation of ferrite nanoparticles of different compositions in solutions at moderate temperatures have been developed. First, worth mentioning is the sol–gel method resulting in highly dispersed powders with required purity and homogeneity. Low annealing temperatures allow one to control crystallisation and to obtain single-domain magnetic ferrite nanoparticles with narrow size distributions and to easily dope the resulting particles with metal ions. This procedure was used to obtain Co- and Ti-doped barium ferrite nanoparticles (smaller than 100 nm)<sup>87</sup> and, Zn-, Ti- and Ir-doped strontium ferrite particles with a similar size.<sup>88</sup>

Smaller nanoparticles (15–25 nm) of cobalt ferrite were obtained in a hydrogel containing lecithin as the major component. Judging by the good magnetic characteristics, these particles possessed a substantial degree of crystallinity without any annealing.<sup>89</sup> The sol–gel method was successfully used to synthesise a Co ferrite nanowire 40 nm in diameter with a length of up to a micrometre.<sup>90</sup> This wire can also be obtained within carbon nanotubes.<sup>91</sup> For the synthesis of ferrite nanoparticles, oil-in-water type micelles<sup>92</sup> and reverse (water-in-oil) micelles<sup>93</sup> are also widely used.

The homogeneity of metal ion distribution in final products can be enhanced and the required stoichiometry can be attained by using pre-synthesis of heterometallic complexes of various composition. The thermal decomposition and annealing of the pre-synthesised  $[\text{GdFe}(\text{OPr})_6(\text{HOPr})]_2$  complex give  $\text{GdFeO}_3$  nanoparticles ( $\sim 60$  nm).<sup>94</sup> Virtually monodisperse nanoparticles (9 nm) of cobalt ferrite are formed<sup>75</sup> from  $(\eta^5\text{-C}_5\text{H}_5)\text{CoFe}_2(\text{CO})_9$ . First, the Co–Fe nanoparticles are prepared and then they are oxidised during annealing.

#### c. Nanoparticles of rare earth elements

Six of the nine rare earth elements (REE) are ferromagnetic.<sup>¶</sup> The magnetic nanomaterials based on these REE occupy a special place, as they can be used in magnetic cooling systems.<sup>95</sup> However, REE nanoparticles (of both metals and oxides) are still represented by only a few examples, most of all, due to the high chemical activity of highly dispersed REE. A synthesis of coarse ( $95 \times 280$  nm) spindle-shaped ferromagnetic  $\text{EuO}$  nanocrystals suitable for the design of optomagnetic materials has been reported.<sup>96</sup> The  $\text{EuS}$  nanocrystals were prepared by passing  $\text{H}_2\text{S}$  through a solution of europium in liquid ammonia.<sup>97</sup> The size of the  $\text{EuS}$  magnetic nanoparticles formed can be controlled (to within 20–36 nm) by varying the amount of pyridine added to the reaction medium.<sup>97</sup>

Gadolinium nanoparticles (12 nm) were prepared by reduction of gadolinium chloride by Na metal in THF. They proved to be extremely reactive and pyrophoric, which, however, did not prevent characterisation of these particles and measuring their magnetic parameters.<sup>98</sup> The Gd, Dy and Tb nanoparticles with an average size of 1.5–2.1 nm and an about 20% degree of dispersion were obtained in a titanium matrix by ion beam sputtering.<sup>99, 100</sup> At 4.5 K, the coercive forces for  $\sim 10$  nm Tb and Gd nanoparticles were 22 and 1 kOe, respectively. As the particle size decreases ( $< 10$  nm), the  $H_c$  value rapidly diminished to zero, which is related, in the researchers’ opinion,<sup>100</sup> to the decrease in the Curie temperature for small nanoparticles.

#### d. Magnetic nanoparticles of anisotropic shapes

The nanoparticles anisotropic in shape (non-spherical) are of special interest for magnetic recording purposes. A material containing oblong (needle-shaped) or flat (disc-shaped) particles is more easily susceptible to magnetic texturing, *i.e.*, ordering of the directions of the magnetic axes of the particles. This has long

¶ The atomic magnetic moments of rare earth elements are greater than that of Fe.

been used, for example, in audio recording tapes.<sup>101</sup> In addition, non-spherical particles possess an additional source of magnetic anisotropy, *i.e.*, the shape anisotropy. It was shown experimentally and substantiated theoretically<sup>102</sup> that planar ultrathin particles should be single-domain, irrespective of their in-plane dimensions. For these planar particles, the shape anisotropy is comparable in magnitude with the magnetic crystal anisotropy. The magnetic interaction between thin nanoparticles in plane is much lower than that between spherical nanoparticles in the bulk.

No theory of the synthesis of anisotropic particles has been developed due to the lack of methods of deliberate change of the nanoparticle shape in solutions. Although papers devoted to the synthesis of Co,<sup>103</sup> Fe<sup>104</sup> and Ni<sup>105</sup> anisotropic magnetic nanoparticles have been published, this still does not imply that the shape of magnetic nanoparticles is subject to reproducible control. Recently,<sup>106</sup> conditions for the preparation of highly anisotropic cobalt nanoparticles by the reduction of  $\text{Co}(\eta^3\text{-C}_8\text{H}_{13})(\eta^4\text{-C}_8\text{H}_{12})$  with hydrogen have been found. By varying conditions of synthesis and the oleylamine to oleic acid ratio, the researchers selectively obtained spherical nanoparticles (4–10 nm), nanoneedles (40 nm long and 9 nm in diameter) and even nanowires.

Experimental data and theoretical calculations show that the interparticle anisotropic magnetic dipole–dipole interactions and kinetic factors can play a significant role in the magnetic nanoparticle growth induced by external fields. If at the moment of synthesis of iron oxide magnetic nanoparticles, the reaction medium is exposed to a magnetic field, the process yields anisotropic (oblong) particles. Apparently, this synthesis opens up the way for effective control of the morphology of magnetic nanomaterials.

Using the preparation of magnetic nanoparticles by ultrasound-induced decomposition of  $\text{Fe}(\text{CO})_5$  in a decalin solution as an example,<sup>107</sup> the effect of an external magnetic field on the growth processes has been studied. In an external magnetic field (7 kG), amorphous  $\text{Fe}_2\text{O}_3$  nanoparticles were formed, of which 20%–30% had an anisotropic shape (50 nm long and 5 nm in diameter). In the absence of a magnetic field only quasi-isotropic nanoparticles with an average size of 25 nm were obtained. The electric arc decomposition of  $\text{Fe}(\text{CO})_5$  resulted in thread-like (10 to 100 nm in diameter) compounds also consisting of  $\alpha\text{-Fe}$  and  $\text{Fe}_3\text{C}$  nanoparticles.<sup>108</sup>

The standard way of synthesis of nanothreads and nanowires composed of anisotropic Fe and Co nanoparticles includes the electrolysis of solutions of the metals at an aluminium cathode, which is pre-coated by an  $\text{Al}_2\text{O}_3$  layer containing channels with a diameter of 18–35 nm and a depth of up to 500 nm.<sup>109</sup> During the electrolysis, these channels are filled by the reduced metal. After completion of the process, the matrix is dissolved in a mixture of acids to separate the nanoparticles. According to TEM, the nanoparticles have a length of up to 500 nm and an average diameter of 16 nm. Magnetic measurements have shown that the samples obtained have a coercive force of 2.7 kG for Fe (the highest value for pure  $\alpha\text{-Fe}$  particles) and 1.4 kG for Co. By using an upgraded procedure, it is possible to prepare Fe nanowires ( $d = 5$  nm) with a coercive force of 4.19 kG at 5 K.<sup>110</sup> Subsequently, column Co–Pt structures with a high magnetic anisotropy, promising for magnetic recording, have been obtained by this method.<sup>111</sup> An attempt has been made to control the magnetic anisotropy of Co–Pt nanoparticles.<sup>112</sup>

A peculiar procedure of thermal decomposition of carbonyls has been employed to prepare Fe and Co nanowires.<sup>113</sup> The particles were grown on the poles of a permanent magnet in the reaction area. This procedure allowed the preparation of 8–10 nm thick whiskers several millimetres long. The synthesis of monoatomic chains consisting of Co atoms has been reported.<sup>114</sup>

A simple method for the synthesis of heterometallic nanowires ( $d \approx 30$  nm, more than 10  $\mu\text{m}$  long) by heating a solution of platinum acetylacetonate and cobalt carbonyl in ethylenediamine

at 200 °C for several days has been described.<sup>115</sup> The Fe–Pt, Ni–Pt and Cr–Pt nanowires were obtained in a similar way.

#### 4. Methods for the synthesis of stoichiometrically inhomogeneous magnetic nanoparticles

The surface anisotropy markedly contributes to the total magnetic anisotropy of a nanoparticle; therefore, by controlling the surface composition, it is possible to control the magnetic properties of nanoparticles.

##### a. Oxidation of nanoparticles

No targeted research into the reactivity of oxidised nanoparticles or its comparison with the reactivity of the corresponding compact materials has been carried out; only a few publications considered the magnetic properties of the oxidised nanoparticles. For example, the magnetic properties of cobalt nanoparticles,<sup>†</sup> which were obtained by vacuum evaporation on the LiF substrate and then oxidised by exposure to air for a week, have been studied.<sup>116</sup> According to electron diffraction for two samples differing in the particle size (2.3 and 3.0 nm), the intensity of the HCP-Co reflections decreased after oxidation to become  $\sim 1/3$  of the CoO-HCP line intensity. Hence, the researchers concluded that a small stable core of unoxidised cobalt atoms remains in all particles after oxidation. Comparative X-ray diffraction studies of the samples consisting of Co nanoparticles distributed in polyvinylpyridine stored under Ar and in air (the storage time was not indicated)<sup>117</sup> revealed no significant differences. Therefore, the authors considered a low degree of oxidation for cobalt.

In a more comprehensive study,<sup>118</sup>  $^{57}\text{Co}$ -enriched cobalt nanoparticles were subjected to oxidation directly in a Mössbauer spectrometer. For this purpose, argon containing  $\sim 80$  ppm of  $\text{O}_2$  was passed through the sample at 300 K for 18 h. Analysis of the emission Mössbauer spectra showed that oxidation results in a fairly well-organised CoO layer on the surface of Co particles. Passing a pure oxygen stream through this gently oxidised sample for 1 h at 300 K did not induce any spectral changes. In the opinion of the researchers cited,<sup>118</sup> this is indicative of complete passivation of Co particles at the first oxidation stage.

It should be noted that the oxidation of magnetic metal nanoparticles during their synthesis cannot be avoided completely. Thorough mass-spectroscopic analysis of Fe nanoparticles obtained by laser vaporisation of the metal in a pure He medium showed that at least 5% of particles contain at least one oxygen atom.<sup>20</sup> If the deposition of oxygen present in the gas phase in trace amounts on the nanoparticle surface cannot be avoided even under these 'exceptional' conditions, it is evident that under 'usual' conditions, the nanoparticles of magnetic metals would always contain some amounts of oxides or suboxides of the elements on the surface. It can be plainly seen in the HRTEM micrograph (HRTEM is high-resolution tunnelling electron microscopy) of  $\alpha\text{-Fe}$  nanoparticles (20 nm) synthesised by laser pyrolysis of  $\text{Fe}(\text{CO})_5$  under inert atmosphere that the particles are coated with a (3.5 nm) layer of iron oxide (the content of the chemically bound oxygen is 14.4 mass %).<sup>119</sup>

The data on the reactivity of Fe nanoparticles with respect to oxidation reported in the literature are contradictory. Thus rather large ( $\sim 40$  nm) nanoparticles of pure Fe obtained by thermal vaporisation contained less than 8 mass % of the oxide after exposure to air for three months.<sup>120</sup>

In some studies, the preparation of metal nanoparticles (especially Fe) was followed by their passivation, for example, by keeping for several hours in an atmosphere of oxygen-diluted argon.<sup>121</sup> This procedure prevented further spontaneous particle aggregation. The structure and the magnetic characteristics of such passivated nanoparticles (15–40 nm) have been described in detail.<sup>122</sup> The continuous oxide layers that coat the metallic

<sup>†</sup> Non-oxidised particles had a hexagonal close packing (HCP), while the oxidised ones, a face-centred cubic (FCC) lattice.

nanoparticle can be clearly seen in TEM images reported in this study. The interaction of the ferromagnetic core and the oxide shell, which resembles in the magnetic characteristics the interaction of magnetic moments in spin glass, was studied.

The oxidation of amorphous  $\text{Fe}_{1-x}\text{C}_x$  nanoparticles obtained by thermal decomposition of  $\text{Fe}(\text{CO})_5$  in decalin in the presence of oleic acid for several weeks in air<sup>123</sup> has shown that the particles (6.9 nm) having a spherical shape and a very narrow size distribution consist of  $\alpha$ - and  $\gamma$ - $\text{Fe}_2\text{O}_3$ . However, passivation of nanocrystalline ( $\sim 25$  nm) Fe particles obtained by metal evaporation in a helium stream results in only a thin (1–2 nm) film of an antiferromagnetic oxide (apparently,  $\text{FeO}$ ) forming on the surface.<sup>124</sup>

#### b. Chemisorption of small molecules on a nanoparticle surface

The interaction of  $\alpha$ -Fe nanoparticles (2.4 nm) with small  $\text{CO}$ ,  $\text{H}_2$  and  $\text{O}_2$  molecules has been studied.<sup>125</sup> It was noted that chemisorption of these molecules on a nanoparticle surface induces only minor changes in the parameters of the Mössbauer spectra. The reaction of  $\alpha$ -Fe nanoparticles (2.3 nm) with nitrogen was studied *in situ* by Mössbauer spectroscopy.<sup>126</sup> It was shown that only the Fe atoms of the surface layer participate in the chemical binding of nitrogen (the process starts at 300 K). Note that the effect of the bound oxygen on the state of the metal surface atoms differs appreciably from that found for  $\text{O}_2$  (see Ref. 127) and  $\text{CO}$  chemisorption.

#### c. Targeted modification of the surface of magnetic nanoparticles

The immobilisation of biological molecules (amino acids, DNA, simple peptides, polysaccharides, lipids) on the surface of magnetic nanoparticles is of certain interest for the design of magnetic markers used in biological and medical experiments. Physical sorption is often sufficient for such immobilisation; however, in some cases, chemical binding of the nanoparticle to the biomolecule is required. A seven-stage synthesis of  $\gamma$ - $\text{Fe}_2\text{O}_3$  nanoparticles ( $\sim 20$  nm) containing on the surface fragments of long organic molecules ending with reactive aldehyde groups has been described.<sup>128</sup> By the reaction of these aldehyde groups with enzyme amino groups, stable enzyme complexes with the magnetic  $\gamma$ - $\text{Fe}_2\text{O}_3$  nanoparticle were obtained. The heterogeneous catalytic activity of the enzyme immobilised in this way was found to be retained much longer than the activity of the same enzyme sorbed on a support surface.

### IV. The most widely encountered magnetic nanoparticles

The fundamental characteristics of any nanoparticles, including magnetic ones, are the stoichiometry and the phase state. This Section considers the main types of magnetic nanoparticles and examples of their synthesis.

**Fe.** The preparation of nanoparticles consisting of pure iron is a complicated task, because they always contain oxides, carbides and other impurities.

**BCC-Fe ( $\alpha$ -Fe).** The  $\alpha$ -Fe nanoparticles with a body-centred cubic (BCC) lattice and an average size of  $\sim 10$  nm were prepared by grinding a high-purity (99.999%) Fe powder for 32 h.<sup>129</sup>

A sample containing pure iron as nanoparticles ( $d_{\text{aver}} = 10.5$  nm) can also be obtained by evaporation of the metal in an Ar atmosphere followed by deposition on a substrate.<sup>121</sup> When evaporation took place in a helium atmosphere, the particle size varied in the range of 10–20 nm.<sup>130</sup> Relatively small (100–500 atoms) Fe nanoparticles are formed in the gas phase on laser vaporisation of pure iron.<sup>20</sup>

**FCC-Fe ( $\gamma$ -Fe).** In the phase diagram of a bulk Fe sample, this phase exists at the ambient pressure in the temperature range of 1183–1663 K, *i.e.*, above the Curie point (1096 K). In some special alloys, this phase, which exhibits antiferromagnetic properties (the Neel temperature is in the 40–67 K range), was observed at room temperature.<sup>131–133</sup> However, a Mössbauer

spectroscopy study<sup>134</sup> has shown that the FCC-Fe nanoparticles (40 nm) remain paramagnetic down to 4.2 K.

Some publications dealing with the synthesis of Fe nanoparticles present fairly weighty reasons indicating that these nanoparticles had an FCC structure. Apparently, the nanoparticles containing  $\gamma$ -Fe were first obtained by Majima *et al.*<sup>135</sup> These particles contained substantial amounts of carbon (up to 14 mass %) and had an austenite FCC structure analogous to  $\gamma$ -Fe. The researchers believed that the laser they used made it possible to reach a temperature of 1173–1423 K (the region of existence of  $\gamma$ -Fe in the phase diagram) in the reaction medium at the pulse instant, while the presence of reactive atomic carbon formed upon decomposition of  $\text{CO}$  and the short time of the laser pulse (100 nm) created the necessary conditions for fixing of the metastable structure. However, later, evidence for the existence of the  $\gamma$ -phase in the Fe nanoparticles that do not contain substantial amounts of carbon have been obtained. Nanoparticles ( $\sim 8$  nm) consisting, according to powder X-ray diffraction and Mössbauer spectroscopy, of  $\gamma$ -Fe (30 at. %),  $\alpha$ -Fe (25 at. %) and iron oxides (45 at. %), were synthesised<sup>136</sup> by treatment of  $\text{Fe}(\text{CO})_5$  with a  $\text{CO}_2$  laser radiation. The content of the  $\gamma$ -phase in the nanoparticles did not change for several years; the particles remain non-magnetic down to helium temperatures.

**'Amorphous' Fe (metallic glass).** The ultrasonic treatment of  $\text{Fe}(\text{CO})_5$  in the gas phase or of a solution of  $\text{Fe}(\text{CO})_5$  in decane at 0 °C under an inert atmosphere gave an X-ray amorphous powder as rather coarse ( $\sim 30$  nm) nanoparticles. The nanoparticles consisted of  $>96$  mass % of Fe,  $<3$  mass % of C and 1 mass % of O.<sup>137</sup> Differential thermal analysis (DTA) of the powder showed an exothermal transition around 585 K, which corresponded, in the authors' opinion, to crystallisation of the amorphous iron. Smaller Fe particles (8.5 nm) were obtained by thermal decomposition of  $\text{Fe}(\text{CO})_5$  in decalin (460 K) in the presence of surfactants.<sup>138</sup> The X-ray diffraction pattern of the powder formed did not display any sharp maxima, indicating the absence of a crystalline phase. It was assumed that amorphisation was due to the high content of carbon ( $>11$  mass %) in the nanoparticles studied.

**$\text{Fe}_2\text{O}_3$ .** Among several crystalline modifications of  $\text{Fe}_2\text{O}_3$ , there are two magnetic phases, namely, rhombohedral  $\alpha$ - $\text{Fe}_2\text{O}_3$  (hematite) and cubic  $\gamma$ - $\text{Fe}_2\text{O}_3$  (maghemite) phases. In the  $\alpha$ - $\text{Fe}_2\text{O}_3$  structure, all  $\text{Fe}^{3+}$  ions have an octahedral coordination, whereas in  $\gamma$ - $\text{Fe}_2\text{O}_3$  having the structure of a cation-deficient  $\text{AB}_2\text{O}_4$  spinel, the metal atoms A and B occur in tetrahedral and octahedral environments, respectively.

The oxide  $\alpha$ - $\text{Fe}_2\text{O}_3$  is antiferromagnetic at temperatures below 950 K, while above the Morin point (260 K) it exhibits so-called 'weak' ferromagnetism.

The  $\alpha$ - $\text{Fe}_2\text{O}_3$  and  $\text{FeOOH}$  (goethite) nanoparticles are obtained by controlled hydrolysis of  $\text{Fe}^{3+}$  salts.<sup>139</sup> In order to avoid the formation of other phases, a solution of ammonia is added to a boiling aqueous solution of  $\text{Fe}(\text{NO}_3)_3$  with intensive stirring. Boiling for 2.5 h and treatment of the precipitate with ammonium oxalate (to remove the impurities of other oxides) affords a red powder containing  $\alpha$ - $\text{Fe}_2\text{O}_3$  nanoparticles (20 nm).<sup>140</sup> These nanoparticles are also formed on treatment of solutions of iron salts ( $\text{Fe}^{2+}:\text{Fe}^{3+} = 1:2$ ) with an aqueous solution of ammonium hydroxide in air.<sup>141</sup> The synthesis of regularly arranged  $\alpha$ - $\text{Fe}_2\text{O}_3$  nanowires with a diameter of 20–40 nm and a length of 2–5  $\mu\text{m}$  has been described.<sup>142</sup>

A bulk  $\gamma$ - $\text{Fe}_2\text{O}_3$  sample is a ferrimagnet below 620 °C. The  $\gamma$ - $\text{Fe}_2\text{O}_3$  nanoparticles (4–16 nm) with a relatively narrow size distribution have been obtained<sup>40</sup> by mild oxidation (on treatment with  $\text{Me}_3\text{NO}$ ) of pre-formed metallic nanoparticles. The same result can be attained by direct introduction of  $\text{Fe}(\text{CO})_5$  into a heated solution of  $\text{Me}_3\text{NO}$ . The oxidation with air oxygen is also used to prepare  $\gamma$ - $\text{Fe}_2\text{O}_3$  nanoparticles. For this purpose, the  $\text{Fe}_3\text{O}_4$  nanoparticles (9 nm) are boiled in water at pH 12–13.<sup>143</sup> The kinetics of this process was studied.

The most popular route to  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles is thermal decomposition of Fe<sup>3+</sup> salts in various media. Rather exotic groups are used in some cases as anions. For example, good results have been obtained by using iron complexes with cupferron.<sup>144</sup> Special-purity  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> is formed upon vaporisation of iron(III) oxide in a solar furnace with subsequent condensation.<sup>145, 146</sup> A mechanochemical synthesis of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> has been described.<sup>147</sup> An iron powder was milled in a planetary mill with water. During milling, the Fe atoms displace hydrogen from water and are converted into  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>. The researchers consider that this is a convenient one-stage synthesis of maghemite nanoparticles (15 nm).

**Fe<sub>3</sub>O<sub>4</sub> (magnetite).** The cubic spinel Fe<sub>3</sub>O<sub>4</sub> is ferrimagnetic at temperatures below 858 K. The route to these particles used most often involves treatment of a solution of a mixture of iron salts (Fe<sup>2+</sup> and Fe<sup>3+</sup>) with a base under an inert atmosphere. For example, the addition of an aqueous solution of ammonia to a solution of FeCl<sub>2</sub> and FeCl<sub>3</sub> (1 : 2) yields nanoparticles, which are transferred into a hexane solution by treatment with oleic acid.<sup>148</sup> The repeated selective precipitation gives Fe<sub>3</sub>O<sub>4</sub> nanoparticles with a rather narrow size distribution. The synthesis can be performed starting only from FeCl<sub>2</sub>, but in this case, a specified amount of an oxidant (NaNO<sub>2</sub>) should be added to the aqueous solution apart from alkali. This method allows one to vary both the particle size (6.5–38 nm) and (to a certain extent) the particle shape.<sup>149</sup>

In some cases, thermal decomposition of compounds containing Fe<sup>3+</sup> ions under oxygen-deficient conditions is accompanied by partial reduction of Fe<sup>3+</sup> to Fe<sup>2+</sup>. Thus thermolysis of Fe(acac)<sub>3</sub> in diphenyl ether in the presence of small amounts of hexadecane-1,2-diol (probable reducer of a part of Fe<sup>3+</sup> ions to Fe<sup>2+</sup>) gives very fine Fe<sub>3</sub>O<sub>4</sub> nanoparticles (about 1 nm), which can be enlarged by adding excess Fe(acac)<sub>3</sub> into the reaction mixture.<sup>150</sup> For partial reduction of Fe<sup>3+</sup> ions, hydrazine has been recommended.<sup>151</sup> The reaction of Fe(acac)<sub>3</sub> with hydrazine is carried out in the presence of a surfactant. This procedure resulted in superparamagnetic magnetite nanoparticles with controlled sizes, 8 and 11 nm.

Previously, Fe<sub>3</sub>O<sub>4</sub> nanoparticles with an average size of 3.5 nm have been prepared by thermal decomposition of Fe<sub>2</sub>(C<sub>2</sub>O<sub>4</sub>)<sub>3</sub> · 5 H<sub>2</sub>O at  $T > 400$  °C.<sup>152</sup> The controlled reduction of ultradispersed  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> in a hydrogen stream at 723 K (15 min) is a more reliable method of synthesis of Fe<sub>3</sub>O<sub>4</sub> nanoparticles. Particles with ~13 nm size were prepared in this way.<sup>153</sup>

**FeO (wustite).** Cubic Fe<sup>2+</sup> oxide is antiferromagnetic ( $T_C = 185$  K) in the bulk state. Joint milling of Fe and Fe<sub>2</sub>O<sub>3</sub> powders taken in a definite ratio gave nanoparticles (5–10 nm) consisting of FeO and Fe.<sup>154</sup> On heating of these particles at temperatures of 250–400 °C, the metastable FeO phase disproportionates to Fe<sub>3</sub>O<sub>4</sub> and Fe, while above 550 °C it is again converted into nanocrystalline FeO.<sup>155, 156</sup>

**$\alpha$ -FeOOH (goethite).** Among the known oxide hydroxides Fe<sub>2</sub>O<sub>3</sub> · H<sub>2</sub>O, the orthorhombic  $\alpha$ -FeOOH (goethite) is antiferromagnetic in the bulk state and has  $T_C = 393$  K,<sup>157</sup>  $\beta$ -FeOOH (akagenite) is paramagnetic at 300 K,<sup>158</sup>  $\gamma$ -FeOOH (lipidocrokit) is paramagnetic at 300 K and  $\delta$ -FeOOH (ferroxhyte) is ferrimagnetic.<sup>159</sup> Although the bulk  $\alpha$ -FeOOH is antiferromagnetic, in the form of nanoparticles it has a nonzero magnetic moment due to the incomplete compensation of the magnetic moments of the sublattices. Goethite nanoparticles have been studied by Mössbauer spectroscopy.<sup>160, 161</sup> As a rule,  $\alpha$ -FeOOH is present in iron nanoparticles as an admixture phase.

**Fe<sub>x</sub>C<sub>y</sub>.** Iron carbide is often present in Fe-containing nanoparticles. It is formed either upon decomposition of organic ligands present in the starting MCC or upon the reaction of Fe with the organic medium in which the synthesis is carried out. Data on the preparation of nanoparticles wholly consisting of iron carbide of one or another composition are few. It has been shown by Mössbauer spectroscopy<sup>162</sup> that thermal decomposition of

Fe(CO)<sub>5</sub> (353 K) on a carbon support forms Fe<sub>78</sub>C<sub>22</sub> nanoparticles (3.9 nm).

**Ferrofluids** or so-called magnetic liquids are suspensions of colloid magnetic particles stabilised by surfactants in liquid media.<sup>2, 3</sup> The magnetic phase in ferrofluids can be represented by magnetite,<sup>163</sup> ferrites<sup>164</sup> and Fe<sub>x</sub>C<sub>y</sub> particles resulting from the thermal decomposition of Fe(CO)<sub>5</sub>.<sup>165</sup> Decalin or silicone oil are the usual liquid phases. The dimensions of magnetic particles are 5–10 nm. The commercial magnetic liquids most often contain magnetite.<sup>2, 166, 167</sup> Description of magnetic liquids with a Curie point below the boiling point has been reported.<sup>164, 168, 169</sup> The use of these composites is considered in a review.<sup>170</sup>

Apart from the 'classical' ferrofluids, ferrofluid emulsions in which oil drops containing a magnetic phase are dispersed in water by means of surfactants are also known.<sup>171</sup> The preparation of lyotropic ferromagnetics stable for several months with a high content (up to 1 vol.%) of the magnetic component,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles (~6 nm), based on a ferrofluid has been reported.<sup>172</sup>

**Fe–Co alloys.** The saturation magnetisation of Fe–Co alloys reaches a maximum at a Co content of 35 at.%; other magnetic characteristics of these metals also increase when they are mixed. Therefore, Fe<sub>x</sub>Co<sub>y</sub> nanoparticles attract considerable attention. Thus Fe, Co and Fe–Co (20 at.%, 40 at.%, 60 at.%, 80 at.%) nanoparticles (40–51 nm)<sup>173</sup> with a structure similar to the corresponding bulk phases have been prepared in a stream of hydrogen plasma. The Fe–Co particles reach a maximum saturation magnetisation (61 cm<sup>3</sup> g<sup>−1</sup>) at 40 at.% of Co and a maximum coercive force (860 Oe) is attained at 80 at.% of Co.

**Fe–Ni.** The bulk samples of the iron–nickel alloys are either nonmagnetic or are magnetically soft ferromagnets (for example, permalloys containing >30% of Ni and various doping additives). When the content of nickel is ~30%, their magnetic properties approach the properties of invar (36% of Ni, 64% of Fe, about 0.05% of C). The Fe–Ni nanoparticles have a much lower saturation magnetisation than the corresponding bulk samples over the whole concentration range.<sup>174</sup> An alloy containing 37% of Ni has a low  $T_C$  and a FCC structure. It consists of nanoparticles (12–80 nm) superparamagnetic over a broad temperature range.<sup>175</sup> Theoretical calculations predict a complex magnetic structure for these Fe–Ni particles (clusters).<sup>176</sup>

**Fe–Pt.** Nanoparticles of this composition have received much attention in recent years due to the prospects for a substantial increase in the information recording density for materials based on them.<sup>69</sup> The Fe–Pt nanoparticles (6 nm) with a narrow size distribution were prepared by joint thermolysis of Fe(CO)<sub>5</sub> and Pt(acac)<sub>2</sub> in the presence of oleic acid and oleylamine. Hexadecane-1,2-diol served as the reducing agent for Pt<sup>2+</sup>. Further heating resulted in the formation of a protective film from the products of thermal decomposition of the surfactant on the nanoparticle surface, which does not change significantly the particle size. These particles can be arranged to form regular films and so-called 'colloid crystals'.<sup>177</sup> The reaction of FePt nanoparticles with Fe<sub>3</sub>O<sub>4</sub> followed by heating of the samples at 650 °C in an Ar + 5% H<sub>2</sub> stream resulted in the FePt–Fe<sub>3</sub>Pt nanocomposite with unusual magnetic characteristics.<sup>178</sup>

**Co.** Methods for the synthesis and magnetic properties of cobalt nanoparticles have been described in detail in a review;<sup>18</sup> therefore, we do not consider them here.

**CoO.** Cubic cobalt oxide is antiferromagnetic and has  $T_N = 291$  K. Cobalt monoxide has played an important role in the discovery of the 'exchange shift' of the hysteresis curve,<sup>179, 180</sup> first found for samples consisting of oxidised Co nanoparticles.<sup>181</sup> Data on the dependence of  $T_N$  on the particle size were obtained in a study of CoO nanoparticles dispersed in a LiF matrix.<sup>116</sup> The particles obtained by vacuum deposition contained a small metal core, according to powder X-ray diffraction. As the particle size decreased from 3 to 2 nm,  $T_N$  decreased from 170 to 55 K, which can be explained satisfactorily in terms of the mean-field theory.<sup>122</sup> Apparently, the presence of an oxide layer on cobalt

nanoparticles can markedly increase the coercive force. For example, the coercive forces (at 5 K) of monodisperse 6 and 13 nm oxidised Co particles obtained by plasma gas condensation in an installation for the investigation of molecular beams were  $\sim 5$  and 2.4 kOe, respectively.<sup>182</sup> Unfortunately, the blocking temperature for 6 nm nanoparticles was lower than room temperature ( $\sim 200$  K); therefore, under normal conditions, their coercive force was equal to zero.

**Co<sub>3</sub>O<sub>4</sub>.** The Co<sub>3</sub>O<sub>4</sub> nanoparticles (cubic spinel) with sizes of 15 to 19 nm dispersed in an amorphous silicon matrix exhibited ferrimagnetic<sup>‡</sup> properties at temperatures below 33 K (for bulk samples,  $T_N = 30$  K).<sup>183</sup> A method for controlled synthesis of Co<sub>3</sub>O<sub>4</sub> cubic nanocrystallites (10–100 nm) has been developed.<sup>184</sup>

**Ni.** The number of publications devoted to the preparation of Ni nanoparticles is small, unlike Co and, the more so, Fe nanoparticles. In addition to the conventional metal evaporation methods,<sup>150</sup> thermal decomposition of organonickel compounds [Ni(CO)<sub>4</sub>, Ni(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub> (see Ref. 185) and Ni(COD)<sub>2</sub> (COD is cyclo-octadiene)<sup>186</sup>] and the reduction of NiBr<sub>2</sub> in the presence of PPh<sub>3</sub> by treatment with potassium metal deserve attention.<sup>187</sup> In the latter case, Ni nanoparticles ( $\sim 3$  nm) coated by a thin oxide film are formed.

**Materials for magnetic information recording.** The following compositions are usually considered in the literature as media for magnetic information recording:  $\alpha$ -Fe,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>–Fe<sub>3</sub>O<sub>4</sub>, Co– $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, CrO<sub>2</sub>, BaFe<sub>12</sub>O<sub>19</sub>. The compositions used in reality are much more complex, because they are doped by various additives that influence particular characteristics of the material. In recent years, nanocrystalline (5–10 nm) CoPr, FePt, CoPt, CoSm, SmFeSiC and SmFeAlC films are regarded as most promising.<sup>188</sup>

## V. Methods of nanoparticle stabilisation

### 1. Encapsulation of nanoparticles and the preparation of magnetic nanoparticles in a shell

Nanoparticles of some metals are known to be pyrophoric, *i.e.*, they spontaneously ignite in air at room temperature; therefore, the creation of a protective shell on such nanoparticles (encapsulation) is a widely used protection and stabilisation method. Carbon is often used as the protective coating. The carbon layers formed on the metal surface are usually graphite-like and, hence, conductive. In those cases where an electrically insulating coating is required, boron nitride layers are used.<sup>189</sup>

Encapsulation of magnetic nanoparticles makes them stable against oxidation, corrosion and spontaneous aggregation, which allows them to retain the single-domain structure. The magnetic particles coated by a protective shell can find application as the information recording media, for example, as magnetic toners in xerography, magnetic ink, contrasting agents for magnetic resonance images, ferrofluids and so on. If the nano-sized magnetic particles are retained after compaction, the materials based on them can serve as excellent initial components for the preparation of permanent magnets.

The coating of metal particles by carbon (carbonisation) was first observed in the research of heterogeneous catalysis almost 50 years ago. Subsequently, this process (deleterious to oil refining and other industries) was comprehensively studied and, in recent years, it has been used deliberately to stabilise nanoparticles. The first structurally characterised carbon-encapsulated nanoparticles were obtained as side products in the electric arc synthesis of fullerenes. Subsequently, special studies have been carried out to identify the possibilities of using this method for the targeted

synthesis of encapsulated nanoparticles, especially magnetic ones. These investigations have been surveyed.<sup>190</sup>

The original version of the arc method allowed one to prepare reliably only encapsulated nanoparticles of REE carbides. Subsequently, the yield of encapsulated nanoparticles has been increased due to a decrease in the amount of fullerenes formed. In this variant, the method became applicable for the synthesis of reasonable amounts of encapsulated magnetic nanoparticles (Fe–Co, Mn–Al). The encapsulated Fe and Co nanoparticles with a saturation magnetisation reaching  $200 \text{ cm}^3 \text{ g}^{-1}$  were synthesised in this way. The perfection of the experimental technique allowed the researchers to eliminate completely the formation of pure carbon-containing products. This procedure was used to obtain Fe, Co and Ni nanoparticles (56, 40 and 37 nm, respectively) coated by 3 or 4 layers of graphitised carbon.<sup>191</sup> The authors emphasise that in none of the cases were metal carbide phases detected. However, the attempts to prepare encapsulated nanoparticles of hard magnetic materials, NdFeB or SmCo<sub>5</sub>, proved unsuccessful — each element formed separate encapsulated particles.

Other methods for the synthesis of encapsulated magnetic nanoparticles are based on the use of high-temperature plasma, laser pyrolysis and thermal vaporisation. Thus the cobalt and carbon vapours formed upon an arc discharge in a helium atmosphere were condensed in the gas phase prior to deposition onto a cooled substrate.<sup>192</sup> This gave spherical particles with a radius of 10 to 100 nm consisting of a metallic core and a carbon shell, which contains up to 30 graphite-like carbon layers. Such a shell is considered to prevent oxidation of the metallic core.<sup>193</sup> Other compounds can also be used to form the protective shell. Thus treatment of a mixture of boron and cobalt powders with H<sub>2</sub> and NH<sub>3</sub> at 800 °C for 3 h furnished Co nanoparticles (20–60 nm) coated by a  $\sim 5$ -nm thick BN coating.<sup>189</sup> A CVD process for one-stage synthesis of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles (20–30 nm) coated by a SiO<sub>2</sub> layer with the same thickness has been developed.<sup>194</sup>

Due to the high temperature of carbon evaporation, the synthesis in radiofrequency plasma burners is considered to be most promising for obtaining large-scale amounts of encapsulated magnetic nanoparticles. Nanoparticles of metals, alloys, carbides and oxides can be prepared by this method. A drawback of this method is inhomogeneity of nanoparticles and differences in their composition.

Chemical methods are also used successfully for encapsulating magnetic nanoparticles. Thus stirring of a solution of tetraethoxysilane in alcohol with an aqueous suspension of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles (24 h, 50 °C) gives Fe<sub>2</sub>O<sub>3</sub> nanoparticles (4–5 nm) coated by amorphous SiO<sub>2</sub>. The particles were found to retain the composition, the size and the shape after heating at 250 °C in an O<sub>2</sub> atmosphere.

Hydrolysis of Si, Ti and Zr alkoxides in the presence of metal nanoparticles is a general method for forming shells of the oxides of these elements on the particle surface. In some cases, the synthesis of oxides takes place simultaneously with the synthesis of the nanoparticles. This method was used to prepare<sup>195</sup> Co magnetic nanoparticles coated by SiO<sub>2</sub> layers. The starting compounds used were Fe(acac)<sub>3</sub> and Si(OEt)<sub>4</sub>, the oxidative thermal decomposition of which in a flow reactor at 1000 °C gave the corresponding particles.

The coating of magnetic nanoparticles by a thin layer of a non-magnetic metal is considered to be a promising method for their stabilisation. For example, the synthesis of Fe<sub>3</sub>O<sub>4</sub> nanoparticles (5 nm) coated by metallic gold has been reported.<sup>196</sup> When determining the composition and the structure of these objects, the researchers faced serious difficulties. Much attention has been devoted in recent years to the methods for the formation of thin polymeric coatings (especially those based on biocompatible and readily biodegradable polymers) on the surface of magnetic nanoparticles.<sup>197</sup>

<sup>‡</sup> Ferrimagnetism below  $T_N$  is typical of nanoparticles of all antiferromagnetic phases, because, unlike bulk samples, the magnetic moments of sublattices are not fully compensated. In particular, the arrangement of magnetic moments in the near-surface layer of nanoparticles differs appreciably from that in the bulk, which is specified by the type of crystal lattice and the type of exchange interactions.

## 2. Self-assembled monolayers on the nanoparticle surface

Self-assembled monolayers (SAM) on the nanoparticle surfaces are represented by monomolecular layers of amphiphilic molecules, which protect the particles from aggregation and simultaneously stabilise their suspensions (solutions) in certain solvents. In a typical example of the self-assembly of a monolayer of amphiphilic molecules of fatty acids on the  $\text{Fe}_3\text{O}_4$  nanoparticle surface,<sup>198</sup> the freshly prepared nanoparticles (obtained by the standard procedure by treatment of a mixture of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  chlorides with aqueous  $\text{NH}_3$ ) were washed, separated into fractions by centrifuging and treated with an excess of lauric or decanoic acid, whose molecules were adsorbed on the surface of each particle. The protective role of amphiphilic molecules was manifested most clearly in the targeted synthesis of Co–Pt<sub>3</sub> nanoparticles of a strictly specified size (1.5–7.2 nm).<sup>199</sup> In the researchers' opinion, the success of the synthesis is related first of all to the use of a new stabilising agent, 1-adamantanecarboxylic acid.

The effect of cationoid (cetyltrimethylammonium bromide, CTAB) and anionoid (sodium dodecylbenzenesulfonate, DBS) surfactants on the stabilisation of  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles (4–5 nm) has been studied.<sup>200</sup> A nanoparticle having a large number of defects and dangling bonds on the surface is considered to interact with the surfactant rather strongly. This interaction has a pronounced influence on the electronic structure of the particle surface.<sup>201</sup>

Self-assembled monolayers are needed to create aqueous dispersions of magnetic nanoparticles.<sup>202</sup> Diverse magnetic colloid isotropic (magnetic emulsions<sup>203</sup> and vesicles<sup>204–206</sup>), anisotropic (steric and electrostatic ferrosmections<sup>207, 208</sup>) and lyotropic ferronematics have been obtained on the basis of nanoparticles coated by a surfactant monolayer (see Section IV).<sup>172</sup>

## VI. Types of materials containing magnetic nanoparticles

We discussed above 'free' nanoparticles as powders or suspensions (in the gas or liquid media). In practice, magnetic nanoparticles are normally used as films (2D systems) or compact materials (3D systems). The mere compacting of magnetic nanoparticles even those having a protective coating on the surface often results in the loss or substantial change in their unique physical characteristics. An optimal material should be a non-magnetic dielectric matrix with single-domain magnetic nanoparticles with a narrow size distribution regularly arranged in the matrix.

### 1. Nanoparticles on a substrate surface

The methods for the preparation of magnetic nanoparticles on substrates have been described in detail in a review.<sup>209</sup> The same review presents comparison of the properties of these systems with the properties of free clusters.

The crystalline surface of the substrate exerts an 'organising' influence on the magnetic nanoparticles, thus promoting the growth of well-crystallised particles (replication effect), even when their dimensions do not exceed 3 nm. This was confirmed by the data of high-resolution tunnelling electron microscopy, which allows one to examine the atomic structure. The Co nanoparticles with dimensions not exceeding 3 nm were obtained by the LECBD method (see Section III) on a niobium foil; the structure of these particles was modelled by a truncated multi-wall octahedron containing 1289 metal atoms.<sup>30</sup> Scanning tunneling microscopy<sup>210</sup> has been used to study the formation of bimetallic Co–Pd nanoparticles by metal vapour deposition on an  $\text{Al}_2\text{O}_3$  surface. Due to the substantial difference between the crystal structures of the two metals, their joint crystallisation and growth on the same substrate proceed according to different patterns, either the growth of a Pd layer on the Co base or the growth of a Co nanoparticle on the Pd base.

The influence of the nanoparticle size and the distance between them in the matrix on their magnetic characteristics has been studied by the LECBD technique.<sup>211</sup> Iron and cobalt nanoparticles containing about 300 atoms ( $d \approx 1.5$  nm) have been prepared by laser vaporisation. Before getting on the substrate, the particle beam passes through a time-of-flight mass spectrometer. Magnetic, structural and electric studies of these films demonstrated that the effect of the matrix on the properties of nanoparticles is slight. The obtained dependences of the magnetic properties of the material on the particle concentration in the beam allowed the researchers to trace the system evolution from the superparamagnetic to ferromagnetic state following the enhancement of the interaction between the particles.

It was shown by powder X-ray diffraction and TEM that the  $\text{ZrO}_2$  surface influences the morphology of the nanocrystallites of, for example,  $\alpha\text{-Fe}$  and  $\text{Fe}_3\text{O}_4$  formed thereon.<sup>212</sup> To prepare these, Fe was applied by the ion implantation process on a polished (100) face of cubic  $\text{ZrO}_2$  stabilised by yttrium. The subsequent heat treatment of the samples on the surface gave (depending on the conditions) either  $\alpha\text{-Fe}$  nanoparticles (10–20 nm) (1100 °C, Ar + 4%  $\text{H}_2$ ) or  $\text{Fe}_3\text{O}_4$  nanoparticles (3–9 nm) (milder conditions). To our knowledge, the formation of  $\gamma\text{-Fe}$  nanocrystallites (FCC phase) on the  $\text{ZrO}_2$  surface was detected for the first time in the same study.

In another study,<sup>213</sup> an ordered ensemble of nanoparticles was formed using a hydroxide substrate (the composition of which was not indicated) pre-modified by a polyvinylpyrrolidone or polyethyleneimine monolayer. The modified substrate was immersed for a short period (30 s) into a solution of Fe–Pt nanoparticles stabilised by oleic acid and oleylamine. The molecules of the stabilising agents weakly linked to the nanoparticle surface were displaced by the polymer functional groups, which resulted in attachment of the particle to the substrate. Repeating this process many times gave regular three-dimensional structures of magnetic nanoparticles.

### 2. Nanoparticles in matrices

It has already been noted that stabilisation of nanoparticles is a necessary condition for the production of materials with reproducible properties. A highly promising method of stabilisation is the introduction of nanoparticles in different types of matrices.

#### a. Inorganic matrices

**Zeolites and molecular sieves.** The rigid matrices (zeolites) with fixed cavities and channels have long been used to prepare and stabilise nanoparticles. A frequently used matrix is faujasite, a NaX type zeolite with cavities having a diameter of 1.3 nm and connected by channels with a diameter of 0.8 nm. Before preparing nanoparticles in zeolite channels, water is removed from the channels at 673 K. The subsequent adsorption of  $\text{Fe}(\text{CO})_5$  on the faujasite surface at 77 K and its decomposition at 453 K in vacuum result in  $\alpha\text{-Fe}$  nanoparticles (4 mass %) formed in the zeolite channels.<sup>214</sup> The X-ray diffraction data and the results of magnetic measurements do not rule out completely the possibility of formation of  $\alpha\text{-Fe}$  nanoparticles also on the external surfaces of the zeolite grains. When the NaY zeolite is used as the matrix, the standard procedure for the preparation of nanomaterials includes dehydration (2 h, 500 °C) in an inert gas flow, filling of the cavities that have become vacant with  $\text{Co}_2(\text{CO})_8$ , controlled thermal decomposition of the carbonyl inside the zeolite cavities at 200 °C and the removal of CO ligands with a hydrogen flow.<sup>215</sup> The  $^{59}\text{Co}$  NMR data (spin echo method) led the researchers to the conclusion that the NaY cavities in the resulting material contained unoxidised cobalt particles with a 0.6–1.0 nm size.

The method for nanoparticle introduction into the LTA zeolite  $\text{Na}_{12}\text{Si}_{12}\text{Al}_{12}\text{O}_{48} \cdot 27\text{H}_2\text{O}$  is basically different.<sup>216</sup> The method includes the introduction of 7.72 mass % of  $\text{Fe}^{3+}$  into ion channels by conventional ion exchange, zeolite dehydration in vacuum at 673 K and the reduction of iron ions with sodium metal vapour. The material thus obtained contained  $\alpha\text{-Fe}$  nanoparticles

(1.1 nm) in the matrix cavities. In the synthesis<sup>217</sup> of Fe nanoparticles (4–6 nm) in X- and Y-zeolites,  $\text{NaN}_3$ , which gives highly reactive Na metal upon thermal decomposition, was used as the reducing agent.

Apart from zeolites, other porous matrices, for example, molecular sieves are also used to stabilise nanoparticles. A method for the introduction of  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles (5.6 nm) into porous aluminosilicates synthesised simultaneously with nanoparticles has been developed.<sup>218</sup> The presence of nanometre-sized regular channels in the molecular sieves can be used to prepare magnetic nanostructures with anisotropic shapes inside the channels. In particular, the introduction of an aqueous solution of iron nitrate into a silicate molecular sieve (SBA-15) sample impregnated with a toluene solution of [(2-aminoethyl)amino]propyltrimethoxysilane (to modify the internal surface of the matrix) and the subsequent annealing of the sample at 600 °C in air gives  $\alpha\text{-Fe}_2\text{O}_3$  nanowire 6 nm in diameter in the matrix channels.<sup>219</sup> To take out the nanowire, the matrix was dissolved in alkali. The impregnation of a silicate molecular sieve powder of a different composition (MCM-41) with an aqueous solution of  $\text{CoCl}_2$  followed by matrix annealing for 3 h in an oxygen flow at 750 °C gave<sup>220</sup> an antiferromagnetic material containing 6 mol.% of  $\text{Co}_3\text{O}_4$  as nanoparticles (1.6 nm).

**Glass.** The conventional glass and its porous modifications are convenient matrices for nanoparticle stabilisation. A powder consisting of sodium glass ground to a grain size of several microns can exchange some  $\text{Na}^+$  ions for  $\text{Fe}^{3+}$  ions in an aqueous solution. The subsequent reduction of  $\text{Fe}^{3+}$  with hydrogen at 823–923 K affords nanoparticles (5.5–8.5 nm) consisting of  $\alpha\text{-Fe}$  and small amounts of  $\text{FeO}$ .<sup>221</sup> In another method, the  $\text{Fe}(\text{CO})_5$  vapour adsorbed by a porous glass (Porous Vycor Glass) with an average pore diameter of 10 nm was subjected to photolysis. The decomposition products filling the pores were 65% iron metal (in the researchers' opinion the rest were oxides).<sup>222</sup>

**Xerogel and silica gel.** The xerogel formed after drying (< 100 °C) of a silicic acid gel possesses good mechanical properties and a transparency comparable to that of glass. This makes this material an appropriate matrix for nanoparticle stabilisation. For example,  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles (~10 nm) were prepared in a xerogel.<sup>223</sup> The shortest distances between the particles in the matrix were shown to be 50 nm, which may imply that they are magnetically isolated. The bulk samples containing magnetically oriented superparamagnetic maghemite  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles introduced in the silica gel matrix exhibited an optical anisotropy in an external magnetic field induced by magneto-optical effects.<sup>224</sup>

**Highly dispersed  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$ .** The methods of synthesis of highly dispersed metallic catalysts supported on the  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  oxides are also applicable for the preparation of magnetic nanoparticles.<sup>225</sup> Thus ultrasonic treatment of solutions of  $\text{Fe}(\text{CO})_5$  and  $\text{Co}(\text{CO})_3\text{NO}$  in decane containing ultradisperse silica gel has given silica gel particles whose pores contained (TEM data) magnetic nanoparticles, Fe, Co or Fe–Co alloy [when both  $\text{Fe}(\text{CO})_5$  and  $\text{Co}(\text{CO})_3\text{NO}$  were used simultaneously].<sup>226</sup> A high catalytic activity of these particles for the reforming of hydrocarbons or catalytic hydrogenation of CO was demonstrated. The difficulties faced by identification of Co nanoparticles on the  $\text{Al}_2\text{O}_3$  surface obtained by the reduction of Co aluminates have been discussed.<sup>227</sup>

**Magnetic nanoparticles in non-magnetic metals.** Magnetic metals can be dispersed in non-magnetic metals forming no alloys; this gives magnetic nanoparticles in a non-magnetic metal matrix. The mutual diffusion of the metal atoms in these samples is very limited. The non-magnetic matrices used most often are copper,<sup>228</sup> chromium and silver.<sup>211</sup> To prepare Co–Ag samples, a version of the LECBD method was used: a silver matrix was formed on a substrate simultaneously with deposition of Co nanoparticles (3–4 nm). A similar outcome can be attained by joint evaporation of Ag and Fe (or Co).<sup>229</sup> Cobalt nanoparticles (~3 nm) in a platinum matrix were synthesised in a similar way.<sup>230</sup>

To prepare samples containing Fe nanoparticles in mercury, 2 mass % of Na was first dissolved in mercury and the amalgam thus obtained was placed in an aqueous solution of an iron salt. After some period, iron reduced to the metallic state passed into mercury to give  $\alpha\text{-Fe}$  nanoparticles (about 4000 atoms per particle).<sup>231</sup>

An interesting series of studies is devoted to the reaction of nanodispersed non-mixing metals. The joint condensation of Fe and Li vapours onto a liquid nitrogen-cooled substrate (pentane) gives  $\alpha\text{-Fe}$  nanoparticles (3 nm) coated by a lithium metal layer.<sup>232</sup> The oxidation of these particles in air gave a powder of  $\alpha\text{-Fe}$  nanoparticles coated by a  $\text{Li}_2\text{CO}_3$  layer stable for several months. Iron nanoparticles coated by a Mg or  $\text{MgF}_2$  layer were synthesised in a similar way.<sup>233</sup>

**Dispersed carbon.** The impregnation of dispersed carbon with an aqueous solution of cobalt nitrate containing  $^{57}\text{Co}$  (10  $\mu\text{Cu}$ ), subsequent drying (1 mass % Co) and reduction in an  $\text{H}_2$  flow (573 K, 20 h) directly in the cell of a Mössbauer spectrometer resulted in the formation of Co particles with a size from 2 to 5 nm.<sup>118, 234</sup>

## b. Organic polymer matrices

The stabilisation of nanoparticles in polymer matrices is the first method for the production of magnetic nanomaterials.<sup>235, 236</sup> The monograph<sup>41</sup> devoted to the synthesis of metal nanoparticles in polymers includes a small chapter describing the preparation of magnetic materials. In recent years, a number of new interesting publications on this topic have appeared.

**Ion exchange resins.** A widely used method for the production of nanoparticles is based on the ability of ion exchange resins to absorb substantial amounts of metal ions. Further reduction or, more rarely, oxidation gave nanoparticles of the required composition inside the matrix.<sup>237</sup> Thus treatment of a resin preliminarily saturated with  $\text{Co}^{2+}$  ions with excess  $\text{NaBH}_4$  yielded Co–B-containing nanoparticles with a broad size distribution (3–30 nm).<sup>238</sup> The resin saturation with  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions and the subsequent treatment with alkali at 65 °C afforded  $\text{Fe}_3\text{O}_4$  nanoparticles with sizes of 4–15 nm.<sup>239</sup> In the case of resin impregnation with only iron(II) ions, these were partially oxidised by heating the resin at 70 °C in an aqueous solution containing a mixture of potassium nitrate and hydroxide. The magnetite nanoparticles formed inside the resin had an average diameter of 17 nm.<sup>240</sup> Using the standard Dowex resin, well characterised  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles (8.5 nm) with a narrow size distribution were obtained.<sup>241</sup>

**Soluble polymers.** If a MCC is decomposed in a polymer-containing solution, the new phase nuclei formed, after having reached a size of several nanometres, would be built into the polymer matrix due to the high surface energy. When the polymer contains heteroatoms or functional groups capable of coordination, the process is more efficient. For example, a sol of  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles is easily incorporated into polyvinyl alcohol to give a dispersion with an average particle size of 6.4 nm.<sup>242</sup> A method for the preparation of Co nanoparticles in polyvinylpyrrolidone has been reported.<sup>117, 243</sup> In this case, decomposition of  $\text{Co}(\eta^3\text{-C}_8\text{H}_{13})(\eta^4\text{-C}_8\text{H}_{12})$  is carried out in the presence of a polymer in a THF solution at 60 °C in a hydrogen flow (10 h). The black powder thus formed is purified by reprecipitation from THF or  $\text{CH}_2\text{Cl}_2$ . A similar procedure starting from the corresponding organometallic compounds<sup>244</sup> gave small (2 nm) heterometallic nanoparticles, Co–Rh and Co–Ru, in polyvinylpyrrolidone. The use of a simpler method (treatment of the polyvinylpyridine– $\text{Co}^{2+}$  complex with alkali)<sup>245</sup> gives large nanoparticles (50 nm) containing both CoO and  $\text{CoCl}_2$ .

For the synthesis of Fe containing particles,  $\text{Fe}(\text{CO})_5$  is used most often. A large series of polymers containing Fe nanoparticles (7–16 nm)<sup>246</sup> have been obtained by heating solutions of polymers and  $\text{Fe}(\text{CO})_5$  in decalin under argon (130–160 °C, 16 h). The polymers used included polybutadiene, polystyrene and styrene copolymers with butadiene, 4-vinylpyridine, *N*-vinylpyr-

rolidone, phenylvinylketoxime. The magnetic properties of the samples, which contained, according to the researchers' statement,<sup>247</sup> Co nanoparticles in polystyrene, were described.

**Carbochain polymers without heteroatoms and functional groups.** The possibility of using polymers containing no functional groups or heteroatoms as matrices for stabilisation of magnetic nanoparticles seems quite attractive, as these polymers (e.g., polyethylene and polypropylene) are good dielectrics; they are stable, inexpensive and easily processable into articles of any shape. The advantages of magnetic materials obtained using these polymers are low specific gravity, high homogeneity of nanoparticle distribution and, what is the most important, isolated arrangement of the nanoparticles at distances much greater than their dimensions. However, the lack of solubility (or poor solubility) of most polymers of this type in organic solvents appreciably restricts the possibilities of introduction and homogeneous distribution of magnetic nanoparticles with a narrow size distribution in these polymers.

The mechanochemical dispersion process, i.e., long-term grinding (up to 200 h) of an iron powder with polyethylene grains under Ar, proved to be inefficient for the preparation of a Fe–polyethylene nanocomposite.<sup>248</sup> The minimum size of the obtained particles was 10 nm (based on X-ray reflection broadening), the size distribution was broad and the distribution of particles in the matrix was nonuniform. The well developed method for forming nanoparticles (2–8 nm) in a solution (melt) of polymers in mineral oil is more promising. This method is versatile as regards both the composition of the resulting magnetic nanoparticles (Fe, Co, Ni, Fe–Co, Fe–Mo, Fe–Pt, Fe–Nd, Fe–Sm, Fe<sub>2</sub>O<sub>3</sub>, Fe<sub>3</sub>O<sub>4</sub>, ferrites) and type of polymer (low- and high-density polyethylene, polypropylene, polyamides). The content of nanoparticles in the sample can reach 60 mass %. The synthesis of magnetic nanomaterials as washers (25 × 5 mm) and thick (3 mm) films possessing good magnetic characteristics has been reported.<sup>5, 6, 249</sup>

The introduction of nanoparticles into a practically versatile carbochain polymer, namely, polytetrafluoroethylene, has been a difficult task until recently. However, recently<sup>250, 251</sup> a method for immobilisation of magnetic (Fe, Co, Ni) nanoparticles (6–12 nm) on the surface of ultradisperse polytetrafluoroethylene nanograins (150–200 nm) has been developed. Using this method, a readily magnetised sample was obtained.

**Polymers containing heteroatoms.** The polymers containing coordinating atoms can act as macromolecular ligands with respect to both metal ions and nanoparticles. In particular, they are able to replace other ligands. The introduction of Co, Fe, Fe–Pt and Co–Pt nanoparticles stabilised by oleic acid and oleylamine into a solution of polyvinylpyrrolidone or polyethyleneimine in CH<sub>2</sub>Cl<sub>2</sub> resulted in a soluble polymer containing the above-listed nanoparticles. This method was used to create polymer films with a regular arrangement of nanoparticles.

Polyvinylpyrrolidone was used<sup>252</sup> to stabilise Ni nanoparticles (3–4 nm) synthesised by the reduction of Ni(COD)<sub>2</sub> with hydrogen at room temperature, while polyacrylamide was used to produce Ni nanoparticles on  $\gamma$ -irradiation.<sup>253</sup>

**Polyimines.** An original method for the introduction of nanoparticles into polyimines<sup>254</sup> that present interest from the applied standpoint consists of saturation of the polymer by magnetic metal ions (Fe<sup>2+</sup>, Co<sup>2+</sup>) followed by air exposure of the material. The spontaneous hydrolysis of the Fe<sup>2+</sup> and Co<sup>2+</sup> salts in the polymer after the removal of water from it (during drying of the sample) yields Fe<sub>2</sub>O<sub>3</sub> and CoO nanoparticles, respectively.

Implantation of high-energy Fe<sup>+</sup> ions (40 keV) into ~1  $\mu$ m-thick polymer films has been used<sup>255</sup> to prepare Fe nanoparticles (mainly,  $\alpha$ -Fe).

**Block copolymers.** Block copolymers contain regular cavities with a lamellar, cylindrical or spherical shape, which can serve as nanoreactors for the synthesis of nanoparticles.<sup>256</sup> The synthesis of films of the [NORCOOH]<sub>30</sub>[MTD]<sub>300</sub> block copolymers (NORCOOH is 2-norbornerne-5,6-dicarboxylic acid, MTD is

methyltracyclododecene) containing  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles (5 nm) has been described.<sup>257</sup>

## VII. Magnetic nanoparticles in biological objects

Long before the first magnetic nanoparticles have been synthesised, they were detected in natural biological complexes. It was found that magnetic nanoparticles play an important role in the metabolism and functioning of living organism. The magnetic nanoparticles found most often in living organisms are magnetite and ferrihydrite (the mineral core of ferritin).

Magnetite-containing magnetosomes are rather abundant and have been repeatedly observed by TEM.<sup>258</sup> Highly ordered quasi-one-dimensional chain ensembles of magnetic nanoparticles of iron oxides (Fe<sub>3</sub>O<sub>4</sub> with a  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> impurity) are present in the magnetic bacteria *Magnetotactic spirillum* and play an important functional role by ensuring the orientation of bacteria in the Earth's magnetic field.<sup>7</sup> The formation of inorganic nanostructures in biological systems occurs spontaneously on contact with a highly organised molecular matrix; it is highly reproducible as regards the particle shape and composition and takes place at nearly ambient temperatures (much below 100 °C) and in the aqueous phase. These processes include a set of complex and not fully understandable reactions that substantially depend on the supramolecular organisation of particles and the structure of the organic matrix, which influences the nanoparticle nucleation and growth. For example, the bacterial protein *Listeria innocua*, having an inner cavity with a diameter of 5 nm, has been used to prepare the  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles with a narrow size distribution ( $9.3 \pm 0.2$  nm).<sup>259</sup> Elucidation of the mechanism of biomineralisation and their use for the development of new methods for the synthesis of nanoparticles and the effective control of their composition, structure, size and morphology can form a rather promising approach in nanobiotechnology and in the development of new nanomaterials.

The magnetic nanoparticles are found not only in bacteria but also in the cells of higher living organisms. It is considered that the anisotropic magnetite nanoparticles present in cells can interact with the Earth's magnetic pole and transfer information to other bioreceptors of the organism. Presumably, the stable space sense of many higher living organisms (for example, in the seasonal migration of birds and fishes) is related to their ability to locate themselves with respect to the Earth's magnetic field at each particular instant.

Ferritin is the most abundant form of non-haem iron in living organisms and plants.<sup>260</sup> Its major role is to preserve the biological reserve of iron.<sup>261</sup> This water-soluble protein consists of an inorganic core with a diameter of ~7 nm and a protein shell with ~6 nm thickness. The core contains ~4500 Fe<sup>3+</sup> ions<sup>262</sup> as a hydrated oxide close in composition to FeOOH<sup>263</sup> and has H<sub>2</sub>PO<sub>3</sub> groups on the external surface.<sup>264, 265</sup> In terms of the type of magnetic structure, ferritin is an antiferromagnet; however, due to the incomplete compensation of magnetic moments of the two sublattices, the ferritin core has a nonzero magnetic moment, like other magnetic nanoparticles of similar sizes. Ferritin itself exhibits superparamagnetic properties. Horse spleen ferritin is commercially available and has been comprehensively studied.<sup>266</sup>

Since natural ferritin mainly contains antiferromagnetic ferrihydrite with a relatively low magnetic moment as the core, modified magnetoferritin in which the ferrihydrite core has been replaced by a magnetite or maghemite core with a higher magnetisation is used more often for applied purposes (Fig. 4).<sup>267, 268</sup> The protein shell ensures the biocompatibility of ferritin and magnetoferritin particles.

The synthetic polymer colloids containing magnetic nanoparticles were first obtained in the mid-1970s. They have found application in biochemical experiments on the targeted interaction with cells and biologically active compounds, gene transfer and DNA extraction.<sup>269</sup> Of considerable interest is the synthesis of inorganic magnetic nanoparticles using organised molecular

Figure 4. Scheme of the change in the magnetic core of ferritin.

structures analogous to biological systems. In particular, inclusion of magnetic nanoparticles into multilayer polyelectrolyte shells of latex particles containing glucose oxidase allowed the efficiency of these particles as nanobioreactors to be markedly increased due to the effective stirring of their colloid solution in the alternating magnetic field.<sup>270</sup>

Organised polymer systems and even single macromolecules are now widely used in nanotechnology for the formation of ordered ensembles of nanoparticles and nanostructures. The preparation of new organised planar complexes of amphiphilic polycations with DNA formed in a monolayer on the aqueous surface has been described.<sup>271</sup> In addition to individual quasi-linear DNA molecules, DNA complexes with a toroidal structure and complexes with planar, extended, and net-like structures were found on the monolayer surface. The monolayer and multilayer films formed on the basis of these complexes were used as nanoreactors for the synthesis of inorganic nanostructures. First, binding of  $\text{Fe}^{3+}$  cations from the aqueous phase took place followed by the formation of the inorganic phase in the presence of a reducing agent ( $\text{NaBH}_4$  or ascorbic acid) at pH 9–10 in air. This gave superthin stable polymeric nanocomposite films incorporating DNA molecules and assembled quasilinear ensembles of 2–4 nm iron oxide nanoparticles (magnetite and maghemite) as structural units.<sup>272–274</sup>

The introduction of iron oxide nanoparticles into DNA complexes can be used to elucidate the role of iron ions in the change in the composition and magnetic properties of nucleoprotein DNA complexes at certain stages of the cell cycle. It has been reported<sup>275</sup> that the magnetite nanoparticles formed upon mixing of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions in the presence of DNA practically did not react with DNA. The corresponding DNA complexes with magnetite nanoparticles have been prepared by reduction (increase in the pH) of pre-synthesised DNA complexes with  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions.

Magnetic nanoparticles can be used in the systems of targeted transfer of biologically active compounds and drugs (in particular, for the cancer therapy using the hyperthermic effect caused by magnetic heating<sup>269, 276, 277</sup>), in the detection, isolation, immobilisation and modification of biologically active compounds, cells and cell organelles, and as contrasting materials in magnetic resonance tomography.<sup>258</sup> Of particular interest is the synthesis of so-called biocompatible magnetic nanoparticles, which is attained by modification and structuring of their surface.<sup>278</sup> A serious problem that can restrict the application of magnetic nanoparticles is their potential toxicity.<sup>279</sup>

## VIII. Physical methods for determination of the composition and dimensions of nanoparticles

Nanomaterials represent a relatively new object for studies by physical methods. There is no unique method for determination of the nanoparticle composition and dimensions; as a rule, a set of methods including powder X-ray diffraction, TEM, EXAFS, *etc.*, are used. Detailed analysis of the potential of these methods is beyond the scope of our review. We only outline, using a number of examples, the problems faced by researchers in determination of the nanomaterial structures and the ways for solving these problems.

X-Ray diffraction analysis of nanomaterials seldom produces diffraction patterns with a set of narrow reflections adequate for identification of the composition of the particles they contain. Some X-ray diffraction patterns exhibit only two or three broadened peaks of the whole set of reflections typical of the given phase. First of all, this is the case for freshly prepared samples containing nanoparticles with dimensions of several nanometres. To obtain more reliable information on the composition of these samples, they are 'hardened' on heating, which makes the X-ray diffraction pattern more informative.

In the case of larger particles (provided that high-quality X-ray diffraction patterns can be obtained), it is often possible not only to determine the phase composition but also to estimate, based on the reflection width, the size of coherent X-ray scattering areas, corresponding to the average crystallite (nanoparticle) size. This is usually done by the Scherrer formula

$$d = \frac{0.9\lambda(54.7)}{b \cos \theta},$$

where  $\lambda$  is the X-ray wavelength,  $b$  is the width at half-height of the reflection after correction for the instrumental broadening, deg, and  $2\theta$  is the diffraction angle.

In some cases, it is possible to identify fine structural effects, for example, phase transitions in Co metal particles. In most cases, the synthesis of cobalt nanoparticles at moderate temperatures gives the high-temperature FCC  $\beta$ -Co phase<sup>116</sup> whose heating and cooling (down to 28 K) do not result in phase transformations. In a special study<sup>280</sup> devoted to the preparation of nanoparticles of the Co metal with a hexagonal close packing, the possible reasons for the stability of Co nanoparticles as the  $\beta$ -phase and the driving forces and the mechanism of the  $\beta \rightarrow \alpha$  transition are discussed. It was found that long-term (for more than a week) keeping of samples containing  $\beta$ -Co nanoparticles in air did not cause any significant changes in their X-ray diffraction patterns. It was shown that even in thin Co films alternating with thicker Cu layers, the FCC structure of the  $\beta$ -phase is retained.

The modern possibilities of the use of synchrotron radiation for determination of the structures of magnetic materials have been discussed.<sup>281</sup>

The nanoparticle dimensions are determined most often using TEM, which directly shows the presence of nanoparticles in the material under examination and their arrangement relative to one another (Fig. 5). The phase composition of nanoparticles can be derived from electron diffraction patterns recorded for the same sample during the investigation. Note that in some cases, TEM investigations of dynamic processes are also possible. For example, the development of dislocations and disclinations in the

Figure 5. Micrograph of a sample containing Co nanoparticles in a polyethylene matrix.

**Figure 6.** Typical HRTEM micrograph of a cobalt nanoparticle in a LDPE matrix.

nanocrystalline BCC-Fe during the mechanochemical treatment has been observed.<sup>282</sup>

More comprehensive information is provided by high-resolution transmission electron microscopy, which allows one to study the structure of both the core and the shell of a nanoparticle with atomic resolution, and in some cases, even to determine their stoichiometric composition. Figure 6 shows a typical HRTEM image of a cobalt nanoparticle in a polyethylene matrix, which allows one to determine the particle shape and dimensions, the type of crystal lattice, the distance between the layers and the presence of a shell.

The structures of non-crystalline samples are often studied by EXAFS spectroscopy. An important advantage of this method is its selectivity, because it provides the radial distribution (RDA) curve for the atoms of the local environment of the chosen chemical element in the sample. The interatomic distances ( $R$ ) and coordination numbers ( $N$ ) obtained by EXAFS are then compared with the known values for the particular phase. Thus using this method, two types of cobalt atoms were detected in the Co nanoparticles formed on laser vaporisation, namely, the internal atoms with a shortest Co–Co distance of 2.50 Å (comparable with that observed in the Co metal) and the surface atoms with a Co–Co distance of 2.80 Å.<sup>211</sup> The total number of Co–Co bonds for a Co atom, *i.e.*, its coordination number  $N$ , was equal to 11 according to EXAFS (for the bulk FCC-Co,  $N = 12$ ). The decrease in the coordination number was attributed to the presence of a large portion of surface atoms with low coordination numbers. This was used to estimate the average Co particle size (3–4 nm). These data are in good agreement with the results obtained by TEM and small-angle X-ray scattering (SAXS) for these samples.

Mössbauer spectroscopy provides data on the phase composition of nanoparticles, especially, magnetic phases. The method is widely used to determine the structure of Fe-containing nanoparticles.<sup>283–285</sup> For example, Mössbauer spectroscopy has been used to establish the composition of magnetic particles formed upon thermal decomposition of  $\text{Fe}(\text{CO})_5$  in a polyethylene matrix.<sup>6</sup> It was shown that the particles consist of  $\alpha$ -Fe,  $\gamma$ - $\text{Fe}_2\text{O}_3$  and iron carbides in ratios depending on the nanoparticle concentration in the matrix.

Other physical methods are used more rarely to study the nanoparticle structures. Integrated research makes it possible to determine rather reliably the structures of simple nanoparticles; however, determination of the structures of nanoparticles com-

posed of a core and a shell of different compositions are often faced with difficulties.

The structural studies of nanoparticles should result ultimately in the construction of structural models. Unfortunately, this is not always done. Meanwhile, the results obtained by EXAFS are difficult to interpret without model construction. For example, the construction of models for the spherical Co nanoparticles ( $d = 1.6$ – $2.6$  nm) with HCP, FCC, BCC and mixed types of packing and comparison of the RDA curves calculated for them with experimental curves indicate that the inner and surface areas of the particle have different structures.<sup>117</sup> The arrangement of atoms in the core corresponded to a BCC lattice with short Co–Co distances, while on the particle surface the arrangement of the cobalt atoms was less ordered, the relationship of distances rather resembling the HCP structure. However, the Co–Co distances inside the particle and on the surface determined experimentally differed from each other by a greater value than the corresponding postulated distances, which was not quite consistent with the model proposed.

The nanoparticle shell always contains light atoms (O, C, B, *etc.*). The problem of identification of these atoms, determination of their number and the mode of interaction with the core metal remain most challenging. The ‘cluster’ model of a nanoparticle accounts for a number of structural features of its surface layer in which the metal crystal lattice is ‘diluted’ with light atoms (O, C) according to a pattern well-known in the cluster chemistry.<sup>286</sup> According to this model, the surface layer of a particle has three types of binding between light atoms and metal polyhedra (*i.e.*, with fragments of the metal packing), namely, terminal, bridging and intrapolyhedral.

A typical example of the construction of models of these nanoparticles has been reported.<sup>50</sup> The reduction of  $\text{CoCl}_2$  with  $\text{NaBH}_4$  is accompanied by insertion of the boron atoms into the Co particle, especially, the surface layers. The comparison of the calculated dependences of the electron density for a number of model nanoparticles (neat Co;  $\text{B}_2\text{O}_3$ -coated cobalt or cobalt boride) with the experimental dependences obtained by SAXS showed that none of these models corresponds to the experimental data. It was suggested that the Co nanoparticles formed are either devoid of the ligand shell or are surrounded by a monoatomic layer, which cannot be detected by SAXS.

A number of models of the structure of nanoparticles with complex compositions are discussed in the literature. A study of iron-containing nanoparticles in the ethylene–tetrafluoroethylene (FT-40) copolymer matrix by Mössbauer and X-ray emission spectroscopy has shown<sup>287</sup> that the particle is composed of  $\alpha$ -Fe and iron carbide and fluoride (the fluoride results from defluorination of the matrix). For interpreting the results, the researchers proposed so-called ‘onion’ model for the structure of the nanoparticle with an  $\alpha$ -Fe core coated by iron fluoride and carbide shells. Figure 7 shows a version of this model describing the

**Figure 7.** Model of the structure of a metallic nanoparticle stabilised by a PTFE grain.

structure of a nanoparticle located on the surface of a super-dispersed polytetrafluoroethylene (PTFE) nanograin.

## IX. Characteristic features of the nanoparticle magnetism (theory)

It will not be an exaggeration to say that the intensive studies of nanoparticles as a special class of objects started from the discovery of unusual magnetic properties. In 1930, Frenkel and Dorfman showed on the basis of energy considerations that particles of a sufficiently small size should be single-domain. In the mid-20th century, the theory of single-domain particles started to be actively developed<sup>288–299</sup> and the related phenomena were studied experimentally.<sup>300–309</sup> These studies identified a substantial increase in the coercive force of a ferromagnet on passing from a multidomain to the single-domain structure, which is important for the creation of permanent magnets. The results of calculation of the characteristic particle size (for different magnetic materials) where the particle becomes single-domain are presented in Table 2.

**Table 2.** Critical diameter (for room temperature) of a single-domain spherical particle with the axial magnetic anisotropy.

| Material                           | Critical diameter /nm  |                  |                  |

<sup>a</sup> A similar value (26 nm) is reported in another publication.<sup>313</sup>

The critical diameter values corresponding to particle transition from the multidomain to the single-domain state presented in the Table were calculated for spherical particles with an axial magnetic anisotropy. For other types of anisotropy (cubic, hexagonal, *etc.*) and other particle shapes, the numerical estimation of the critical diameter for the single-domain character changes. In particular, the particle can be transferred into the single-domain state without decreasing the volume if it has a shape other than a sphere, for example, an oblong ellipsoid. Experimental determination of the critical diameter above which a single-domain particle becomes multidomain is a complicated task, although now it has become possible to observe this transition directly through a magnetic force microscope<sup>314,315</sup> or a quantum magnetic interferometer (μ-SQUID).<sup>316–318</sup> For a 20 nm-thick disc-like cobalt particle, a study by a magnetic force microscope gave a critical diameter for the single-domain state of 200 nm. Elliptical particles with the same thickness became single-domain at sizes less than 150 × 450 nm. These values are markedly greater than the calculated ones (see Table 2).

To put it more exactly, the term ‘single-domain’ does not require a necessary uniform magnetisation throughout the whole particle bulk but only implies the absence of domain walls. In addition, a single-domain particle is not necessarily a ‘small’ particle (as opposed to a ‘bulk’ particle) as regards specific magnetic characteristics. Data of a publication<sup>319</sup> and their analysis<sup>320</sup> demonstrate that a rather large particle can be single-domain but still possessing the physical properties of a bulk material. Thus, the specific properties of nanoparticles start to be manifested at sizes much smaller than the ‘single-domain limit’.

It is considered that significant changes in the main physical characteristics of a bulk material appear when the dimensions of its particles decrease to an extent where the ratio of the number of surface atoms  $N_s$  to the total number  $N$  of atoms in the particle approaches 0.5.<sup>17</sup> An interesting formulation of this criterion as applied to magnetic nanoparticles has been proposed. Assuming that in a surface layer of thickness  $\Delta r$  (defectiveness parameter), the number of exchange bonds is twice as low as that in the particle bulk and that the Curie temperature is directly proportional to the bulk density of exchange bonds, Nikolaev and Shipilin<sup>320</sup> have analysed the dependence of  $T_C$  on the magnetite particle size obtained earlier.<sup>319</sup> The defectiveness parameter  $\Delta r$  was found to depend on the particle radius  $r$ . In particular, for magnetite  $\Delta r \rightarrow 0$  for  $r \geq 20$  nm (the radius for the single-domain state of magnetite is  $\sim 70$  nm, see Table 2). As the particle radius decreases, the parameter  $\Delta r$  substantially increases and for  $r = 2.5$  nm, it amounts to 0.5 nm. Thus, the smaller the magnetic particle size, the greater the effective depth to which the violation of the regular structure extends.

One more remarkable property of the nanoparticles, which allowed their experimental discovery in the mid-20th century, is the superparamagnetism. The higher the particle magnetic moment, the lower the magnetic field  $H_s$  that is required to observe the magnetisation saturation phenomenon. In a rough approximation, the  $H_s$  value (saturation field) can be estimated from the formula

$$\mu_{\text{ef}} H_s \approx k_B T,$$

where  $\mu_{\text{ef}}$  is the effective magnetic moment of the particle. For paramagnetic Gd(SO<sub>4</sub>)<sub>3</sub> · H<sub>2</sub>O, the effective magnetic moment of the Gd<sup>3+</sup> ion is 7  $\mu_B$ . Thus, the  $H_s$  value for this paramagnet at room temperature would be  $H_s \approx 300 k_B / 7 \approx 10^6$  Oe. For a particle with an effective magnetic moment of 10<sup>4</sup>  $\mu_B$ , the saturation field would decrease to 10<sup>3</sup> Oe. The phenomenon of saturation of the magnetisation curve in low (for a usual laboratory) fields of  $\sim 1$  kOe has been called ‘superparamagnetism,’ while a material exhibiting such properties is called a ‘superparamagnetic’.<sup>§</sup>

The model of an ideal superparamagnetic was mainly worked out by the early 1960s,<sup>321</sup> but now it continues to develop.<sup>312,322</sup> The simplest variant of this model considers a system of  $N$  non-interacting identical particles with the magnetic moment  $\mu_{\text{ef}}$ . Since the magnetic moment of the particle is assumed to be large, its interaction with the magnetic field  $H$  is calculated without taking the quantum effects into account. In the case of isotropic particles, the equilibrium magnetisation of the  $\langle M \rangle$  system is described by the Langevin equation

$$\langle M \rangle = N \mu_{\text{ef}} \left[ \text{cth} \left( \frac{\mu_{\text{ef}} H}{k_B T} \right) - \frac{k_B T}{\mu_{\text{ef}} H} \right]. \quad (1)$$

Equation (1) has been derived with the assumption that single particles are magnetically isotropic, *i.e.*, all directions for their magnetic moments are energetically equivalent, but this condition is hardly ever fulfilled. If the particles are magnetically anisotropic, the calculation of the equilibrium magnetisation becomes more complicated. According to the nature of factors giving rise to the non-equivalence of the directions of magnetic moments, one can distinguish the magnetically crystalline anisotropy; the shape anisotropy; anisotropy associated with the internal stress and external impact; exchange anisotropy, and so on.<sup>323</sup>

For nanoparticles, the surface magnetic anisotropy plays a special role. Unlike other kinds of magnetic anisotropy, the surface anisotropy is proportional to the surface area of the particle  $S$  rather than to its volume  $V$ . The surface anisotropy

§ Typical features of a superparamagnetic include also the absence of a magnetic hysteresis and the presence of thermal fluctuations of the magnetic moment of a nanoparticle (similar to the thermal fluctuations in a conventional paramagnetic).

appears due to the violation of the symmetry of the local environment and the change in the crystal field, which acts on magnetic ions located on the surface. Uniaxial anisotropy is the simplest type of magnetic anisotropy as regards the symmetry properties.<sup>¶</sup> In the general case, the equation for the energy of the uniaxial magnetic anisotropy is written as the sum of two contributions:

$$E(\theta) = (K_V V + K_S S) \sin^2 \theta, \quad (2)$$

where  $K_V$  is the volume anisotropy constant,  $V$  is the particle volume,  $K_S$  is the surface anisotropy constant,  $\theta$  is the angle between the vector of the particle magnetic moment  $\mathbf{m}$  and the anisotropy axis.

When the surface makes no contribution to the anisotropy, the angular dependence of the particle energy has the form

$$E(\theta) = K_V V \sin^2 \theta.$$

If no external magnetic field or surface anisotropy are present, the minimum energy of the particle is attained at the orientation of the magnetic moment  $\mathbf{m}$  along the anisotropy axis. In this case, two neighbouring minima are separated by a barrier with height  $K_V V$ . In an external magnetic field  $H$  applied at the angle  $\psi$  to the anisotropy axis, the particle energy is equal to

$$E(\theta) = K_V V \sin^2 \theta - M_s V H \cos(\theta - \psi). \quad (3)$$

(The particle is assumed to be uniformly magnetised to saturation, its magnetic moment being  $m = M_s V$ .) The dependence of the particle energy on the angle  $\theta$  for different angles  $\psi$  is shown in Fig. 8 for  $K_V = 4.5 \times 10^5 \text{ J m}^{-3}$ ,  $V = 10^3 \text{ nm}^3$ ,  $M_s = 1.4 \times 10^6 \text{ A m}^{-1}$ ,  $H = 10^5 \text{ A m}^{-1}$ . It can be seen that in the vicinity of  $\theta = 0, \pi$  and  $2\pi$ , there are three energy minima separated by non-equivalent barriers [in the case of  $\psi = 0$  and  $\pi$  (curves 1 and 5), the barriers are equivalent].

In the general case, in the presence of an external magnetic field, rotation of the magnetic moment of the particle to reach the orientation corresponding to an energy minimum requires overcoming an energy barrier,  $\Delta E \approx K_V V$ . The relation for the characteristic time of thermal fluctuations of the magnetic moment of a single-domain particle with a uniaxial anisotropy provided that  $\Delta E/k_B T \geq 1$  was obtained by Neel<sup>295</sup>

$$\tau = \tau_0 \exp\left(\frac{\Delta E}{k_B T}\right). \quad (4)$$

Later, relation (4) was extended by Brown<sup>296–299</sup> to the cubic anisotropy case.<sup>†</sup>

The pre-exponential factor  $\tau_0$  depends on many parameters including temperature, gyromagnetic ratios, saturation magnetisation, anisotropy constants, the height of energy barrier, and so on.<sup>324, 325</sup> However, for the sake of simplicity  $\tau_0$  is often considered to be a constant in the range of  $10^{-9} - 10^{-13} \text{ s}$ .<sup>311</sup>

Relation (4) determines the characteristic time needed for the thermal equilibrium in a system of non-interacting single-domain magnetic particles to establish. At higher temperatures,  $\Delta E/k_B T \ll 1$ ; the time required for system transition into a state with the minimum energy is short compared to the characteristic time of measurements  $\tau_{\text{meas}}$ , and the system is not expected to show a magnetic hysteresis. In the case where  $\Delta E/k_B T \gg 1$ , the system transition into an equilibrium state may take a very long time depending appreciably on the particle. For  $\tau_0 = 10^{-9} \text{ s}$ ,  $K_V = 10^5 \text{ J m}^{-3}$  and  $T = 300 \text{ K}$  for a magnetically anisotropic

**Figure 8.** Angular dependence of the energy of a uniaxial magnetic particle  $E(\theta)$  at different orientations of the external magnetic field  $H$ .  $\psi = 180$  (1),  $135$  (2),  $90$  (3),  $35$  (4),  $0$  (5).

spherical particle  $11.4 \text{ nm}$  in diameter, we get  $\tau = 10^{-1} \text{ s}$  and for a particle with a diameter of  $14.6 \text{ nm}$ ,  $\tau = 10^8 \text{ s}$ .<sup>311</sup>

If  $\tau_{\text{meas}} \gg \tau$ , the system occurs in the superparamagnetic state and rapidly reaches an equilibrium magnetisation on changing the temperature or the external field. Otherwise ( $\tau_{\text{meas}} \ll \tau$ ), after a change in the external magnetic field, the system does not arrive to a new equilibrium state over the time  $\tau_{\text{meas}}$  and its magnetisation does not change. The case  $\tau = \tau_{\text{meas}}$  in relation (4) corresponds to the blocking temperature  $T_b$ . If  $\tau_{\text{meas}} = 100 \text{ s}$  (characteristic time for the static magnetic measurements) and  $\tau_0 = 10^{-9} \text{ s}$ , the condition  $\tau_{\text{meas}} = \tau$  in relation (4) gives  $K_V V \approx 25.3 k_B T$ . Hence,

$$T_b = \frac{K_V V}{25 k_B}. \quad (5)$$

It is noteworthy that relation (5) specifies the blocking temperature for a zero magnetic field. As the external magnetic field is enhanced, the blocking temperature decreases by a power law

$$T_b(H) = T_b(0) \left(1 - \frac{H}{H_c}\right)^\kappa, \quad (6)$$

where  $\kappa = 2$  (for low fields<sup>326</sup>) and  $2/3$  (for high fields<sup>327</sup>),  $H_c = 2 K/M_s$ .

The experimental data obtained for magnetite nanoparticles show that upon an increase in the field from zero to  $700 \text{ Oe}$ , the blocking temperature decreases from  $140$  to  $75 \text{ K}$ , relation (6) being fulfilled rather accurately below  $50 \text{ Oe}$  with  $\kappa = 2$ , and for fields from  $50$  to  $700 \text{ Oe}$ , with  $\kappa = 2/3$ .<sup>328</sup>

When investigating the magnetic properties of the samples containing nanoparticles, the magnetisation curve is usually measured up to saturation magnetisation (Fig. 9).<sup>329</sup> To deter-

**Figure 9.** Magnetisation vs. magnetic field value (at  $295 \text{ K}$ ) for a sample containing  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles in a polyethylene matrix.<sup>329</sup>

<sup>¶</sup> The anisotropy is called uniaxial if the magnet has only one axis of easy magnetisation. The easy magnetisation axis in a magnetically anisotropic medium corresponds to a direction of the magnetisation vector relative to the crystal lattice of the magnet such that the energy of the magnetically anisotropic medium is minimum.

<sup>†</sup> In the case of cubic anisotropy, there are three mutually perpendicular easy magnetisation axes.

mine the temperature dependence of the magnetic moment  $m$ , two types of measurements are carried out, namely, zero-field cooling (ZFC) and field cooling (FC). According to the ZFC procedure, the sample is cooled (usually down to the liquid helium temperature) in the absence of a magnetic field and then a moderate measuring field is applied (1–100 Oe) and the temperature is gradually raised, the magnetic moment  $m_{\text{ZFC}}(T)$  values being recorded. The FC procedure differs from ZFC only by the fact that the sample is cooled in a nonzero magnetic field. For magnetic nanoparticles, the  $m_{\text{FC}}(T)$  and  $m_{\text{ZFC}}(T)$  curves usually coincide at relatively high temperatures but start to differ below a certain temperature  $T_{\text{ir}}$  (irreversibility temperature). The  $m_{\text{ZFC}}(T)$  curve has a maximum at some temperature  $T_{\text{max}}$ , and the  $m_{\text{FC}}(T)$  curve, most often, ascends monotonically to very low temperatures (Fig. 10). The dependence of magnetisation on the applied field at various temperatures is often additionally measured (Fig. 11).<sup>330</sup> Electron magnetic resonance and Mössbauer spectroscopy data are also used for analysis of the magnetic properties.

For an idealised system containing identical nanoparticles with uniaxial anisotropy and a random orientation of easy magnetisation axes, the difference between the temperature dependences of  $m_{\text{FC}}$  and  $m_{\text{ZFC}}$  at a qualitative level follows from Eqn (3) and Fig. 8. In the case of a zero field, on cooling below the blocking temperature, the magnetic moments of particles are oriented along their easy magnetisation axes [ $\theta = \psi = 0$  in Eqn (3)], the total magnetic moment of the system being equal to zero both at the beginning and at the end of cooling. After the

external field  $H$  has been switched on, the magnetic moments for which  $\theta - \psi < 90^\circ$  [see Eqn (3)] do not need to overcome an energy barrier and they rotate to the minimum-energy position, thus creating a non-zero magnetisation. For example, for the curve  $\psi = 35^\circ$  in Fig. 8, the rotation angle will be  $29^\circ$ . Conversely, the magnetic moments for which  $\theta - \psi > 90^\circ$  on switching on the magnetic field are separated from the energy minimum by a potential barrier which they can overcome only over a long period of time [see Eqn (4)]. Therefore, in the case of ZFC measurements for  $T < T_b$ , the system gets into a metastable state with a relatively low total magnetic moment  $M_s^2 H / 3K_V$ , which does not depend on the temperature.<sup>331</sup> When  $T = T_b$ , the system passes *via* a jump<sup>‡</sup> into a stable superparamagnetic state with the magnetic moment

$$m_{\text{ZFC}} = \frac{M_s^2 V H}{3k_B T}. \quad (7)$$

For  $M_s V H / k_B T$  and a random orientation of the axes of easy magnetisation of particles, relation (7) holds also for  $T > T_b$ .<sup>310</sup>

In the FC measurements, cooling of the sample takes place in a nonzero magnetic field; at any temperature above  $T_b$ , magnetisation is determined by Eqn (7). When  $T < T_b$ , the system magnetisation can no longer change over the time of measurements. Therefore, the magnetic moment in the FC procedure at  $T < T_b$  is equal to

$$m_{\text{FC}} \approx \frac{M_s^2 V H}{3k_B T} = \text{const.}$$

For a system consisting of single-domain nanoparticles with a size, shape, *etc.* dispersions, the  $m_{\text{ZFC}}(T)$  and  $m_{\text{FC}}(T)$  curves are not separated at  $T = T_b$ , but are separated at a higher temperature  $T_{\text{ir}} > T_b$ , which is called the irreversibility point.<sup>332</sup> Another characteristic point in the  $m_{\text{ZFC}}(T)$  curve is the temperature  $T_{\text{max}}$ , which is often identified as the average temperature of system blocking ( $T_b$ ). For a temperature below  $\langle T_b \rangle$ , an increase in  $m_{\text{FC}}(T)$  is observed, which is then replaced by a ‘saturation’ section and in some cases, by a maximum.<sup>310</sup> The  $T_{\text{ir}}$  value can be identified with the blocking temperature for the largest particles, and  $T_{\text{max}}$ , with the blocking temperature for the smallest particles. However, it should be borne in mind that all these characteristic temperatures (and their relationship with the volume distribution of particles) can depend on the rate of sample cooling and subsequent heating<sup>333</sup> and on the intensity of the interparticle interactions. If the rate of sample heating is much lower than the cooling rate, the  $m_{\text{FC}}(T)$  may have a maximum at  $T < \langle T_b \rangle$ .<sup>310</sup> In the case of strong interparticle interactions, the energy distribution of particles  $\Delta E$  [see Eqn (2)] may narrow down (in relative units  $\sigma/\mu$ , where  $\sigma$  is the dispersion,  $\mu$  is the average value) with respect to the volume distribution.<sup>310</sup> In this case, a more accurate calculation of the local magnetic field acting on a single particle is required.

‡ In experimental studies at  $T = T_b$ , sharp changes in magnetisation are never observed, because a size spread (and, generally, other types of spread) always exists for the particles. Small particles pass into the superparamagnetic state at a lower temperature than large particles and the magnetisation jump is smeared. The temperature corresponding to the maximum in the  $m_{\text{ZFC}}(T)$  curve roughly coincides with the average temperature of particle transition into the superparamagnetic state, which corresponds to the maximum distribution of all particles over the volume  $V$ . In addition, even for absolutely identical particles, the relaxation time increases smoothly rather than by a jump, although rapidly. It follows from relation (4) that

$$\frac{d\tau}{\tau} = - \left( \frac{dT}{T} \right) \left( \frac{\Delta E}{k_B T} \right) \approx -25 \left( \frac{dT}{T} \right),$$

*i.e.*, near  $T_b$  the relative change in the relaxation time is 25 times as fast as the relative change in the temperature.

**Figure 10.** Temperature dependences of the magnetic moment (ZFC and FC measurements) for a sample containing  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles in a polyethylene matrix.

**Figure 11.** Magnetisation vs. the magnetic field at 295 (1), 77 (2) and 4.2 K (3) for a sample containing Co nanoparticles (4 mass %) in a polyethylene matrix.<sup>330</sup>

Note that the  $m_{ZFC}(T)$  and  $m_{FC}(T)$  curves differ not only for the systems of magnetic nanoparticles but also for macroscopic magnets with disorder elements (exchange coupling frustration, topological disorder, structural defects) and even in ordered ferromagnets with a substantial magnetic anisotropy.<sup>334</sup>

The difficulty of the theoretical investigation of the magnetic hysteresis in nanoparticles lies in the fact that this non-linear, non-equilibrium and non-local phenomenon caused by the existence of energy minima (resulting from the magnetic anisotropy) and the barriers separating them depends, in a complex manner, on the external magnetic field. The results of theoretical studies using relatively simple models seldom provide a plausible description for real magnetic nanomaterials as they do not take into account their microstructure, in particular, the effect of boundaries and defects on the local magnetisation.<sup>317</sup>

An important role of the microstructure in the formation of magnetic characteristics is indicated by the studies of nanocomposite materials (for example, Nd–Fe–B/ $\alpha$ -Fe<sup>335</sup> and FePt–Fe<sub>3</sub>Pt<sup>178</sup> systems), which represent a magnetically soft medium with nano-sized grains distributed therein ( $< 100$  nm).<sup>336</sup> In these materials, the magnetically hard phase ensures a high coercive force, while the magnetically soft phase provides a high saturation magnetisation. In addition, the substantial exchange interaction between the grains ensures a relative residual magnetisation higher than 0.7.<sup>335, 336</sup> Therefore, materials of this type are called exchange-coupled magnets.

In recent years attempts have been undertaken to study the effect of the internal structure (microstructure) of a nanoparticle on the magnetic characteristics of real nanomaterials.<sup>312</sup> Most successful was the use of numerical calculations within the framework of the micromagnetism theory (so-called ‘computer micromagnetism’).<sup>337–340</sup> Even when a nanoparticle has a defect-free crystal structure, the different local environments of atoms at the particle boundary and inside the particle result in a nonuniform magnetisation in the particle and distortion of the perfect collinear magnetic structure.<sup>341, 342</sup> The calculations show that at the final temperature, magnetisation decreases along the direction from the particle centre toward the boundary,<sup>343</sup> and the magnetic moment of each particular surface atom can be greater than that of the bulk atoms.<sup>344</sup> The decrease in the magnetisation on the particle surface compared to that in the bulk is due a lower energy of the surface spin wave excitations,<sup>322</sup> in other words, more pronounced action of the thermal fluctuations on the surface. The increase in the magnetic moment of surface atoms can be attributed, within the framework of the band theory, to the decrease in the coordination number, and, as a consequence, to narrowing the corresponding energy band and an increase in the density of states. Apparently, this also accounts for the rare cases of magnetic order appearing in metal nanoparticles whose bulk analogues are non-magnetic.<sup>345–348</sup>

The qualitative isothermal dependence of the coercive force  $H_c$  on the characteristic size of magnetic particles is shown in Fig. 12a. The increase in  $H_c$  upon a decrease in the particle size follows from the Stoner–Wohlfarth theory according to which the spins of atoms forming a nanoparticle rotate coherently, *i.e.*, concertedly. It is known from experiments that the coercive force in real magnetic materials (including nanomaterials) is much lower<sup>8</sup> than the limiting values predicted by the theory even at very low temperatures. One reason is that under the action of an external magnetic field, the spins of the atoms forming the nanoparticle can rotate not only coherently but also in a more complex manner to form spin modes: ‘swirls’ (Fig. 13), ‘fans’, *etc.*<sup>312</sup> The appearance of non-coherent spin modes is facilitated if nanoparticles form agglomerates (for example, chains). The coherent

**Figure 12.** Qualitative (a) and quantitative (b) dependences of the coercive force  $H_c$  on the particle diameter.<sup>318</sup>

(a) Qualitative dependence that follows from the simple model of single-domain particle; (b) experimental (dots) and calculated (curves 1–3) dependences for iron nanoparticles. The experimental values were obtained for iron particles in oxide  $\text{Al}_2\text{O}_3$  (light dots) and  $\text{SiO}_2$  (dark dots) matrices. The calculation was carried out with the assumption that  $K_s = 4 \times 10^{-4} \text{ J m}^{-2}$  and  $K_v = 5 \times 10^4 \text{ J m}^{-3}$ ; (1) cubic bulk anisotropy, (2) axial surface anisotropy, (3) simultaneous account for the axial surface anisotropy and bulk anisotropy.

**Figure 13.** Simplest spin modes formed upon magnetisation reversal in a single-domain particle: (a) coherent rotation, (b) eddy mode.<sup>312</sup>

rotation can, apparently, take place only in absolutely defect-free uniform particles with a zero surface anisotropy.

It is evident by intuition that the coercive force should be the lower the greater the number of options (mechanisms) for spin rotation in the direction opposite to the initial one. In a multidomain particle, this rotation can be additionally associated with the displacement of domain boundaries.<sup>349</sup> As the particle size decreases, the number of domains decreases, and the role of interdomain boundaries in magnetisation reversal becomes less pronounced. Therefore, up to the critical particle size ( $d_{cr}$ , see Fig. 12a), the coercive force increases with a decrease in  $d$ . However, further decrease in the particle size and transition to

§ According to the Stoner–Wohlfarth model, the anisotropy field  $H_A = 2K_v/M_s$  is the upper limit for  $H_c$ . According to a publication,<sup>312</sup> the  $H_c$  value in real materials varies in the range of  $(0.2–0.4)H_A$ .

single-domain particles entails an increase in the role of thermal fluctuations. This explains a decrease in  $H_c$  at  $d < d_{cr}$  (see Fig. 12 a, b).

Important information on the magnetic properties of nanoparticles and material based on them can be derived from measurements of slow relaxation processes.<sup>310, 322, 328, 350</sup> In the simplest cases, for a system of identical magnetic nanoparticles, the equilibrium magnetisation upon the change in the magnetic field (for example, quick switching off) is described by the equation

$$M(t) = M_0 \exp\left(-\frac{t}{\tau}\right), \quad (8)$$

where the relaxation time  $\tau$  is determined by relation (4).

For low-temperature measurements of the residual magnetisation of systems containing magnetic nanoparticles which can exist in the blocked state, three types of experimental procedures are used<sup>¶</sup> (see Ref. 351). During the measurements of isothermal residual magnetisation (IRM), the sample is cooled in a zero magnetic field; after that, the field  $H$  is first applied and then switched off at a constant temperature  $T$ . In this case, the residual magnetisation of  $M_{IRM}$  depends on the  $H$  and  $T$  values. In the measurements of the thermal residual magnetisation  $M_{TRM}$ , the sample is placed in a constant magnetic field  $H$  at a high temperature (when all particles are superparamagnetic) and then cooled to low temperature and the field is switched off. Finally, the DC demagnetisation is measured in the same way as  $M_{IRM}$ , but the sample is first magnetised to saturation at low temperature, then the field  $H$  is switched on in the opposite direction and then switched off. In the absence of interparticle interactions<sup>328</sup>

$$M_{DCD}(H) = M_{IRM}(\infty) - 2M_{IRM}(H). \quad (9)$$

The non-observance of this rule is considered to indicate the presence of interaction between the particles,<sup>352</sup> although for a particle with mixed anisotropy (for example, uniaxial + cubic), this conclusion should be used with caution.<sup>353</sup>

For real systems, the function  $f(E)$  of particle distribution over the heights of the energy barrier always has a finite width, which is associated with the size, shape, morphology and composition differences between the particles. In this case, the relaxation properties of a system cannot be described using one parameter. For a rectangular distribution  $f(E)$ , the simple equation (8) should be replaced by the following relation<sup>311</sup>

$$M(t) = M_0 - S \ln\left(\frac{t}{\tau_0}\right), \quad (10)$$

where  $S$  is the magnetic viscosity coefficient.

If the applied external magnetic field  $H$  varies at a constant temperature, the maximum magnetic viscosity coefficient is attained at  $H = H_c$ . The logarithmic law (10) is usually confirmed experimentally only for relatively short observation periods.<sup>310</sup> The deviations from the logarithmic law can provide information on the symmetry of magnetic anisotropy, size distribution of particles, and so on.

Taking account of magnetic interactions between nanoparticles is a complicated theoretical task. In a recent discussion<sup>310, 354, 355</sup> dealing with the effect of interparticle interactions on the blocking temperature, two models were proposed, one predicting an increase in  $T_b$ ,<sup>345</sup> whereas the other, conversely, a decrease in  $T_b$ <sup>310</sup> following an enhancement of the interparticle interactions. The interactions change the height of the energy barrier separating two states of a particle with the opposite directions of the magnetic moment. If the barrier grows,  $T_b$  increases and *vice versa*. The influence of the change in the distances between the maghemite nanoparticles with a diameter

of 6–7 nm on the blocking temperature has been studied experimentally.<sup>356</sup> The distances between the particles were changed by compacting the sample. The maximum increase in the sample density was 55%; simultaneously,  $T_b$  [corresponding to the maximum in the curve  $m_{ZFC}(T)$ ] increased from 50 to 80 K. Assuming that for noncharged nanoparticles, the predominant magnetic dipole–dipole interactions are inversely proportional to the cubed distance between the particles, one can expect a linear dependence of  $T_b$  on the sample density. This is in good agreement with a publication.<sup>356</sup>

In the presence of interparticle interactions, the qualitative picture of the behaviour of a system of magnetic nanoparticles following a decrease in temperature may become more complicated than the mere transition to the blocked state.<sup>357</sup> The possible transitions are shown in Fig. 14.<sup>310</sup> If the particles are arranged irregularly in space, the interparticle interactions should transfer the system into the ‘spin glass’ type state at some temperature  $T_g$ .<sup>357</sup> Which of the temperatures, either  $T_g$  or the average blocking temperature  $\langle T_b \rangle$  would be higher for the given type of particles depends on the particle size and on the average distance between them. Since the temperature dependences of the magnetic moment (ZFC–FC) for a system of non-interacting particles and for a ‘spin glass’ are similar,<sup>358</sup> determination of the nature of the transition is a non-trivial task.

**Figure 14.** Scheme of the possible transitions in a system of magnetic nanoparticles arranged randomly in space taking into account interparticle interactions.<sup>310</sup>

(1) Transition from the paramagnetic to superparamagnetic state within single particles; (2) transition from the superparamagnetic into ‘blocked’ state; (3) transition from the ‘blocked’ state into a ‘spin glass’ type state; (4) transition from the superparamagnetic state to a ‘spin glass’ type state.

To choose theoretically between these states, one first has to know the way of estimating the interacting force in the nanoparticle system. Often, it is assumed that the interparticle interactions can be neglected if the particle concentration in the matrix is low and, hence, the average distance between them is rather high (1.5 times higher than the average particle diameter).<sup>351</sup> This assumption can be proved by verifying experimentally the fulfillment of relation (9).

Recently,<sup>359</sup> an interesting approach to taking account of the effect of interparticle interactions on the magnetisation curves of nanoparticles has been proposed. On the basis of the monotonic decrease in  $\mu_{ef}$  with a decrease in temperature observed experimentally, the researchers cited introduced phenomenological corrections into relation (1). It was assumed<sup>359</sup> that the magnetic dipole–dipole interactions, which predominate in the systems under consideration, act as a random factor and prevent magnetisation (ordering) of the system, *i.e.*, function in the same way as the temperature. It is worth noting that, although the proposed

<sup>¶</sup> These measurements are carried out at relatively low temperatures so that the particles (or their substantial portion) passed into the blocked state.

approach<sup>359</sup> is strictly applicable only to equilibrium systems, it describes satisfactorily the magnetisation curves at any temperatures, including those below the blocking temperature  $T_b$  [in this case, the average value over two branches of the hysteresis loop should be taken as  $M(H)$ ]. The applicability of this model for  $T < T_b$  is apparently due to the predominance of interparticle interactions over one-particle effects for all the samples studied.<sup>359</sup>

## X. Magnetic characteristics of nanoparticles (experimental data)

The first experimental data on the properties of magnetic nanoparticles were obtained in experiments with cluster beams.<sup>26,27</sup> Despite the difficulty of interpretation, these experiments provided the unique possibility of determining the dependence of magnetic parameters on the number of atoms in the nanoparticle. Thus isothermal dependences of the average atomic magnetic moment  $\langle\mu_{\text{ef}}\rangle$  on the number of atoms  $n$  in Fe, Co, Ni nanoparticles demonstrated for the first time that the specific magnetic moment of a nanoparticle increases with a decrease in the particle size. This trend is the most pronounced for Ni, which may be due to a higher density of the valence electrons.<sup>26</sup> The Co nanoparticles with a number of atoms  $n$  of 56 to 215 are superparamagnetic at 97 K having  $\langle\mu_{\text{ef}}\rangle = 2.24 \mu_B$ . This value is greater than the  $\mu$  values for macroscopic samples of cobalt.<sup>26,27</sup>

Thus, the experimental data imply that the effective magnetic moment of atoms in 3d-metal nanoparticles can be greater than its magnetic moment in a bulk metal. This may be attributed to the fact that the magnetic moment of an atom on the cluster surface should be regarded as localised, while in the bulk metal with band magnetism, as a delocalised (this delocalisation results in a decrease in the average magnetic moment of the atom in the bulk metal). It is noteworthy that for the smallest Ni nanoparticles, the magnetic moment barely changes with temperature over the whole temperature range studied, due to the large number of surface atoms.<sup>26</sup> For larger clusters, a non-zero contribution of surface atoms into the magnetic moment is retained even at temperatures above 631 K (the Curie temperature of the bulk phase). For Ni<sub>550–600</sub> nanoparticles, the magnetic moment at 631 K amounts to 25% of the low-temperature value  $0.6 \mu_B$ .

Thus, it follows from experiments with molecular beams that the magnetic order is retained in nanoparticles at higher temperatures than in the bulk samples,<sup>26,27</sup> which is manifested as an increase in the Curie temperature with respect to bulk phases. For cobalt ( $T_C \approx 1400$  K), the atomic magnetic moment in nanoparticles with the numbers of atoms  $n = 50–600$  changes only slightly with an increase in the temperature to  $\sim 1000$  K and always remains greater than the bulk value. The temperature dependences of the average magnetic moment for iron nanoparticles follow a more complex pattern. A possible reason is in the specific features of the iron phase diagram and structural transitions, which complicate the pattern of magnetic behaviour. No transitions to the conventional paramagnetic state were detected up to the highest temperatures ( $\sim 1000$  K).

The properties of REE clusters, namely, Gd<sup>26</sup> and Tb<sup>360</sup> clusters, are even more peculiar. Whereas 3d-metal nanoparticles behave in molecular beam experiments as either superparamagnetic particles or particles with a ‘frozen’ magnetic moment, Gd<sub>*n*</sub> clusters exhibit a dual behaviour.<sup>27</sup> Two types of clusters with the same mass but different properties have always been observed in experiments,<sup>361</sup> namely, those having properties of superparamagnetic particles and those with the properties of ‘frozen’ moment particles. It is yet unclear whether this is related to the existence of structural or magnetic isomers of the same Gd<sub>*n*</sub> cluster.

Among the gadolinium clusters studied with numbers of atoms from 11 to 92, superparamagnetic properties were found for Gd<sub>22</sub>, Gd<sub>30</sub> and Gd<sub>33</sub> (even at low temperatures).<sup>26,27,361</sup> Conversely, the Gd<sub>11–16</sub>, Gd<sub>19–21</sub>, Gd<sub>23–26</sub>, Gd<sub>53</sub>, Gd<sub>54</sub> and

some other clusters clearly exhibit ‘frozen’ magnetic moments at 100 K. As the temperature increases to room temperature, some of these clusters become superparamagnetic (for example, Gd<sub>17</sub>), whereas some other (Gd<sub>12–16</sub>, Gd<sub>19–21</sub>, Gd<sub>23</sub>, Gd<sub>26</sub>, Gd<sub>55</sub>) remain ‘frozen’. At  $800 \pm 200$  K, all the gadolinium clusters studied become superparamagnetic, the atom magnetic moments in the clusters remaining ordered, *i.e.*, the Curie temperature for gadolinium clusters is much higher than for the bulk phase (293 K). It should be noted that the effective magnetic moment per atom in all Gd<sub>*n*</sub> clusters is at least twice lower than the bulk value equal to  $7 \mu_B$ .

Terbium clusters behave similarly to gadolinium clusters.<sup>360</sup> At room temperature, the vast majority of terbium clusters are superparamagnetic. At low temperatures, many of them pass to a state characterised by a ‘frozen’ magnetic moment but some remain superparamagnetic. Using the Tb<sub>*n*</sub> clusters as examples, the influence of the addition of oxygen to a metal cluster was studied. It was found that the addition of oxygen to Tb<sub>*n*</sub> clusters, except for Tb<sub>22</sub>, does not change their magnetic properties. The magnetic moment of the superparamagnetic Tb<sub>22</sub> cluster ‘freezes’ at  $\sim 250$  K upon the addition of oxygen.

Clusters of some other elements: chromium ( $n = 9 \pm 31$ ), palladium ( $n = 100 \pm 120$ ) and vanadium ( $n = 8 \pm 99$ ) have also been studied using cluster beams.<sup>26</sup> They all proved to be paramagnetic.<sup>†</sup>

The interest in magnetic nanoparticles inserted into various matrices is due, first of all, to their potential practical use. In addition to traditional catalysis,<sup>363</sup> magnetic nanoparticles can be used for superhigh-density information recording,<sup>364–366</sup> for solving some medical problems (for example, as drug carriers)<sup>367,368</sup> and for creation of heavy-duty magnets,<sup>335,369,370</sup> ‘spin’ electronics elements<sup>281,371–374</sup> and various sensors,<sup>371,375</sup> including biomolecular ones.<sup>376</sup>

The last 10 years were marked by impressive progress in the development of materials for high-density magnetic recording. In 1992, the highest density of magnetic recording in commercial hard discs was about 10 Mbit in<sup>–2</sup>. With this recording density, the dimensions of one bit in the plane of a round-shaped magnetic medium equals  $800 \times 64 \text{ nm}^2$ . This corresponds to 40 000 bpi along the track and 25 000 tpi (see<sup>‡</sup>) in the radial direction.

In 2001, a magnetic recording density of 100 Gbit in<sup>–2</sup> was attained,<sup>366</sup> which corresponds to a bit dimensions of  $300 \times 15 \text{ nm}^2$ . In view of the fact that one storage bit now forms up to 1000 separate grains (this is due to the need to maintain the signal-to-noise ratio at a plausible level), to reach a recording density of 100 Gbit in<sup>–2</sup>, the size of one particle in the radial direction should be about 0.3 nm, *i.e.*, 2–4 atoms. Further increase in the density suggests both a decrease in the particle size and modification of the record format.

Owing to the magnetic nanomaterials, the amount of the stored information has been increased by 4 orders of magnitude during the last 20 years. The size of the hard discs of home personal computers has increased from 10 Mbyte (in the mid-1980s) to 300–500 Gbyte (currently). These achievements in the magnetic recording became possible, first of all, due to the decrease in the size of the transition region<sup>§</sup> between the neighbouring bits and a decrease in the distance between the recording head and the surface of the magnetic medium.<sup>377</sup>

† The magnetism of the nanoparticles of non-magnetic metals is beyond the scope of this review; therefore, we refer only to the most significant publications.<sup>345,346,362</sup>

‡ The plane of the round-shaped magnetic medium is divided into concentric tracks.

§ The width of the transition region for a continuous magnetic medium equals the minimum distance between the regions with opposite directions of magnetisation. For a discrete medium containing magnetic particles in a non-magnetic matrix, the width of the transition layer is equal to the average distance between the particles.

The existence of the transition region between the neighbouring 'bits' with a parallel orientation of magnetic moments (lying in the plane of the magnetic layer) is due to their 'demagnetising' fields and also the scattered field of the recording head. The width of the transition region  $a$  can be estimated from the formula

$$a \approx \frac{dM_R D}{H_c}, \quad (11)$$

where  $d$  is the distance between the recording head and the magnetic medium surface,  $M_R$  is the residual magnetisation,  $D$  is the magnetic layer thickness.<sup>377</sup> It can be seen from relation (11) that the greater the coercive force and the smaller the  $M_R D$  product, the thinner the transition layer. Thus, these two parameters are the most important characteristics of a material for magnetic recording.

Although an increase in  $H_c$  results in a higher recording density, the coercive force should not be too high, because in this case, the recording head would require creation of strong magnetic fields for magnetisation reversal.<sup>¶</sup> The characteristic  $H_c$  values for modern materials used in magnetic recording amount to  $\sim 2500$  Oe (for floppy discs)<sup>365</sup> and  $\sim 3500$  Oe (for hard discs).<sup>378, 379</sup> The recording heads with a higher coercive force should be fabricated from materials with a high saturation magnetisation, for example,  $\text{Fe}_{65}\text{Co}_{35}$ .<sup>366</sup> According to forecasts, the use of these heads would make it possible to reach a 500 Gbit in<sup>-2</sup> density of the vertical recording for a medium containing 5 nm nanoparticles with  $H_c \approx 16000$  Oe.<sup>366</sup> Among the known magnets, this coercive force is demonstrated only by Nd–Fe–B (14000 Oe) and  $\text{Sm}_2\text{Co}_{17}$ – $\text{SmCo}_5$  (9000 Oe) produced by sintering.<sup>312, 380</sup>

For  $\alpha$ -Fe, the record-breaking  $H_c$  value at room temperature ( $\sim 2700$  Oe) was observed for large cylindrical nanoparticles with a length of 250–500 nm and a diameter of 16 nm obtained in a porous aluminium matrix.<sup>109</sup> At low temperatures ( $\sim 10$  K), the values  $H_c \approx 2400$ – $2600$  Oe were found for much smaller particles (3–5 nm).<sup>121</sup> The particles formed were virtually unoxidised on the surface and their forced oxidation resulted in lowering of  $H_c$  to 2100 Oe. The coating of  $\alpha$ -Fe nanoparticles by rare earth oxides resulted in a decrease of  $H_c$  to 1750–1950 Oe.<sup>381</sup> In the researchers' opinion,<sup>382</sup> the reversal of magnetisation of these nanoparticles is a coherent rotation, *i.e.*, it corresponds to the classical Stoner–Wohlfarth model.

The coercive force of a ferromagnetic material is generally described by the formula<sup>381</sup>

$$H_c = \frac{2\alpha K_V}{M_s} - N_{\text{ef}} M_s, \quad (12)$$

where  $\alpha$  and  $N_{\text{ef}}$  are the 'microstructure defectiveness' parameter of the material.<sup>†</sup> The first term in Eqn (12) corresponds to the contribution of the crystalline magnetic anisotropy and the second one is due to the shape anisotropy. For an isolated particle,  $N_{\text{ef}}$  means the demagnetising factor; in this case,  $\alpha = 1$ . The theoretical limit for the coercive force is often estimated from the formula  $(H_c)_{\text{max}} = 2 K_V/M_s$ , which corresponds to a single-domain spherical particle with coherent magnetisation rotation. For iron, nickel and cobalt nanoparticles, the calculated  $(H_c)_{\text{max}}$  values are  $\sim 600$ ,  $\sim 200$  and  $\sim 7500$  Oe, respectively.<sup>312</sup> Note that owing to the shape anisotropy [the second term in relation (12)], coercive force values of  $\sim 14$ ,  $\sim 11$  and  $\sim 4$  kOe can be obtained for single-domain iron, cobalt and nickel particles,<sup>383</sup> which is markedly greater than  $(H_c)_{\text{max}}$ . Unfortunately, the experimental values of  $H_c$  for magnetic materials (including those containing nanocryst-

allites, nanoparticles or nanograins) rarely exceed 25%–30% of  $(H_c)_{\text{max}}$  (so-called Brown paradox).<sup>382, 384</sup>

The up-to-date permanent magnets can be assigned to nanocrystalline materials, as they consist of separate magnetic grains usually compacted by either of two methods, by sintering or from a melt. The former method yields multidomain grains with characteristic sizes of 1–20  $\mu\text{m}$  and the latter one furnishes single-domain grains with a size of 10–200 nm.<sup>381</sup> The materials for magnetic recording are also granulated. The use of a single grain as an information bit can be taken as a natural limit to the increase in the magnetic recording density.<sup>378</sup>

For reliable information storage, the magnetic moment of a particle should not change under the action of thermal fluctuations for a long period of time. To this end, the particle size should satisfy the 'superparamagnetic limit' condition according to which the particle should be in the blocked state at room temperature. At  $K_V V/300k_B = 40$ , the lifetime of a one-particle information bit is  $\sim 10$  years, while at  $K_V V/300k_B = 60$ , it is  $10^9$  years.<sup>378</sup> Thus, a decrease in the particle size requires an increase in their magnetic anisotropy.

It has already been noted that the magnetic anisotropy of nanoparticles includes a number of constituents: crystalline magnetic anisotropy, shape anisotropy, surface anisotropy and other (see Section IX).<sup>310</sup> The crystalline magnetic anisotropy, which makes the major contribution to the magnetic anisotropy, depends on the chemical composition and the crystal structure of the compound. Now the record values for the crystalline magnetic anisotropy<sup>‡</sup> (in  $\text{J m}^{-3}$ ) were found for  $\text{SmCo}_5$  ( $17.0 \times 10^6$ ),  $\text{Sm}_2\text{Fe}_4\text{B}$  ( $12.0 \times 10^6$ ),  $\text{Sm}_2\text{Fe}_{17}\text{N}_3$  ( $8.9 \times 10^6$ ),  $\text{PtFe}$  ( $6.6 \times 10^6$ ),  $\text{Pr}_2\text{Fe}_{14}\text{B}$  ( $5.6 \times 10^6$ ),  $\text{YCo}_5$  ( $5.2 \times 10^6$ ),  $\text{Nd}_2\text{Fe}_{14}\text{B}$  ( $5.0 \times 10^6$ ),  $\text{CoPt}$  ( $4.9 \times 10^6$ ),  $\text{Sm}(\text{Fe}_{11}\text{Ti})$  ( $4.9 \times 10^6$ ) and  $\text{Sm}_2\text{Co}_{17}$  ( $3.3 \times 10^6$ ).<sup>312</sup>

In the modern hard discs, the CoPt alloy with Cr, Ta, B, Mn additives needed to reduce the interaction between single grains, are used as the magnetic layer. This decreases the length of the transition region, and, as a consequence, leads to a higher recording density. The possibility of using compounds with a higher anisotropy, in particular, compounds of magnetic 3d metals with rare earth metals for magnetic recording is currently under investigation.<sup>335</sup>

Figure 12b shows the dependences of the coercive force of iron nanoparticles on their diameter  $d$  at room temperature.<sup>313</sup> Nanoparticles were obtained by radiofrequency sputtering of iron under argon (at a low pressure) followed by annealing in a vacuum. It can be seen that  $H_c$  reaches a maximum at  $d = 18$  nm, which approximately corresponds to the single-domain structure limit for  $\alpha$ -Fe. For  $d > 18$  nm, the coercive force decreases according to the law  $\sim 1/d$ . To interpret the obtained dependence, Chen *et al.*<sup>313</sup> had to assume the presence of the effective surface magnetic anisotropy  $K_{\text{ef}}$  in a particle

$$K_{\text{ef}} = \frac{6K_S}{d}. \quad (13)$$

The parameter  $K_S$  found in the study cited<sup>313</sup> was  $4 \times 10^{-4} \text{ J m}^{-2}$ . In an earlier work<sup>127</sup> in which relation (13) was first proposed, the value  $K_S \approx 10^4 \text{ J m}^{-2}$  was found to explain the presence of giant magnetic resonance in  $\alpha$ -Fe nanoparticles on a carbon (soot) surface. From the symmetry considerations, the parameter  $K_S$  for perfect spherical nanoparticles should be equal to zero;<sup>322</sup> therefore, it can apparently be used to estimate the deviation of the nanoparticle shape from spherical.<sup>127</sup>

Note that the surface anisotropy can serve as a resource for increasing the coercive force of the nanoparticle. Calculation of the influence of the surface anisotropy on  $H_c$  for the ellipsoidal maghemite nanoparticles with a longer axis of  $\sim 300$  nm has shown that for  $K_S \approx 2 \times 10^{-2} \text{ J m}^{-2}$  the coercive force ( $\sim 2$  kOe) is twice as great as that for  $K_S = 0$ .<sup>385</sup> The reasons for the difference between the magnetic properties of nanoparticles

¶ This can be avoided by heating the writable region by a laser beam, which would induce a temporary decrease in the coercive force.

† The microstructure defectiveness means any deviation from the perfect crystal structure inherent in single crystals.<sup>382</sup>

‡ All anisotropy values refer to room temperature.

formed by this class of compound with similar sizes and chemical composition have been discussed.<sup>386</sup>

The temperature dependence of the saturation magnetisation of the  $\alpha$ -Fe nanoparticles<sup>§</sup> coated by a Mg or MgF<sub>2</sub> shell has been studied.<sup>223</sup> Particles with a size of 3–18 nm were prepared by condensation in pentane at 77 K in evacuated quartz tubes. The magnetic moment was measured at a field strength of up to 55 kOe. The saturation magnetisation for iron nanoparticles with sizes of <7 nm was much lower than that for the bulk iron ( $\sim 220$  s cm<sup>3</sup> g<sup>-1</sup>).<sup>¶</sup> The temperature dependence of the magnetisation for all the particles studied corresponded approximately to the law

$$M_s(T) = M_0[1 - BT^b], \quad (14)$$

where  $B$  and  $b$  are a constant and the Bloch factor, respectively. For the bulk ferromagnets,  $b = 1.5$ , *i.e.*, the '3/2 law' holds. However, in the study cited,<sup>223</sup> this rule is valid only for particles with the characteristic size  $d > 7$  nm, whereas for smaller particles, the parameter  $b$  is much lower (thus for the Fe@MgF<sub>2</sub> nanoparticles with  $d = 3$  nm,  $b = 0.37$ ). However, for 2–3 nm iron nanoparticles in a SiO<sub>2</sub> matrix, the parameter  $b$  was 3/2,<sup>387</sup> while for MnFe<sub>2</sub>O<sub>4</sub> particles (5–15 nm),  $b = 1.5$ –1.9 were found.<sup>388</sup> A similar value ( $b = 1.9$ ) was found for the Fe<sub>x</sub>C<sub>y</sub> nanoparticles ( $d = 3.1$  nm).<sup>389</sup> The Bloch constant  $B$  for both types of nanoparticles is several orders of magnitude higher than the value for the bulk material. For the Fe@MgF<sub>2</sub> particle with  $d < 4$  nm, the  $B$  value is an order of magnitude greater than for Fe@Mg. Thus, the magnetic properties of nanoparticles (magnetisation and its temperature variation) depend more crucially on the state of the particle surface than on the particle volume.

A similar conclusion can be drawn from the results of another publication<sup>390</sup> in which three types of samples containing iron nanoparticles were studied. The average diameter of particles obtained by the reduction of oxides was about 20 nm in all samples, but the thickness of the oxide shell surrounding the metallic core was different in different samples. The saturation magnetisation  $M_s$  was  $\sim 970$ –1300 kA m<sup>-1</sup> at  $T = 1.5$  K and decreased as the oxide shell became thicker. Since the magnetisation of iron oxides is lower than that of  $\alpha$ -Fe, the decrease in  $M_s$  can be attributed to an increase in the proportion of the oxide phase in the particle volume. The different magnetisation levels can also be observed for the same phase with different levels of defectiveness.<sup>386</sup>

The smaller the particles, the more pronounced the effect of the surface layer on the magnetic properties. Figure 15 shows the temperature dependences of the coercive force of iron nanoparticles in the amorphous matrix of aluminium oxide obtained by laser vaporisation in a high vacuum.<sup>391</sup> It can be seen in HRTEM images that the particles are well isolated: the distance between separate elliptical nanoparticles is about 2.5–3.7 nm. The blocking temperatures [determined from the maximum in the  $m_{ZFC}(T)$  curve] and the coercive force (at 10 K) depend on the particle diameter.

§ The crystal structure of the particles and almost complete absence of oxide phase were proved by powder X-ray diffraction.

¶ The decrease in the saturation magnetisation of ferro-, ferri- and antiferromagnetic nanoparticles with respect to bulk samples, which is observed in experiments almost in all cases, is usually attributed to off-orientation of the atomic magnetic moments in the particle.<sup>121, 386</sup> For iron nanoparticles, the decrease in magnetisation is often correlated with an increase in their oxidation state. The magnetisation of  $\alpha$ -Fe nanoparticles was found<sup>119</sup> to be 95 S cm<sup>3</sup> g<sup>-1</sup> and the magnetisation of Fe<sub>3</sub>C nanoparticles obtained in the same way (thermal decomposition of OMC) was 132 S cm<sup>3</sup> g<sup>-1</sup>. For bulk samples, an opposite relationship between the magnetisations is observed (220 for  $\alpha$ -iron and 14 S cm<sup>3</sup> g<sup>-1</sup> for iron carbide). This inversion was attributed<sup>119</sup> to different susceptibilities of these two types of nanoparticles to oxidation (the  $\alpha$ -Fe particles are more oxidised at the surface).

| $d$ / nm | $T_b$ / K | $H_c$ / Oe |
|----------|-----------|------------|
| 4.5–4.7  | 60        | 150        |
| 7.0–7.8  | 280       | 350        |

For the largest particles, the dependence  $H_c(T)$  is described by the relation

$$H_c(T) = H_c(0) \left(1 - \frac{T}{T_b}\right)^{0.5}, \quad (15)$$

derived<sup>321</sup> with the assumption of uniform magnetisation of the nanoparticle (this cannot be the case when a substantial surface layer is present). For smaller particles, the role of the surface is more pronounced and the temperature dependence of the coercive force has a more complicated pattern (see Fig. 15). Similar changes in the course of the  $H_c(T)$  curve were observed for nanoparticles (6–8 nm) depending on the oxidation state of the surface.<sup>392</sup>

The estimate of the particle size from the  $T_b$  values using the magnetic anisotropy parameter  $K_V = 4.8 \times 10^4$  J m<sup>-3</sup> for the 'bulk'  $\alpha$ -Fe almost coincided with the TEM data. The magnetic anisotropy values of  $\alpha$ -Fe particles ranged from  $8.4 \times 10^4$  to  $1.6 \times 10^5$  J m<sup>-3</sup>, the  $K_V$  value decreased with an increase in the shell thickness. Approximately the same values of magnetic anisotropy for iron nanoparticles were reported in other publications.<sup>121, 221, 392</sup>

The dependence of the coercive force on the temperature provides one more way for the determination of the blocking temperature.<sup>248, 330, 393</sup> Figure 16 shows the temperature dependences of the saturation magnetisation  $M_s$  and the coercive force  $H_c$  for iron nanoparticles with a diameter of 5–10 nm in a silicon nitride matrix.<sup>393</sup> It can be seen that at low temperatures, the coercive force is well described by relation (15), whereas near  $T_b$  (at 100 K), determined by extrapolating  $H_c(T^{0.5})$  to zero, the experimental  $H_c$  values markedly deviate from those calculated using relation (15). This may be due to the size spread of the particles or with strong interparticle interactions.<sup>248</sup> Note that the dependence of the saturation magnetisation  $M_s$  of these particles on temperature is well described by relation (14)<sup>393</sup> over the whole temperature range because inside a nanoparticle, the magnetic order is retained even at  $T \gg T_b$ . This method for determination of the blocking temperature from the  $H_c(T)$  dependence is especially convenient in the case where  $T_b$  is much higher than room temperature. This was demonstrated<sup>330</sup> using a cobalt nanoparticle in the polyethylene matrix.

The influence of modification of nanoparticles on their magnetic properties was also studied for 'layered' particles obtained by the reverse micelle method.<sup>394</sup> In the Fe–Au particles consisting of a ferromagnetic iron core (8–10 nm) and an Au shell, a shell thickness of 2–3 nm did not influence the blocking temperature ( $\sim 50$  K) or coercive force ( $\sim 400$  Oe) to within the

**Figure 15.** Coercive force  $H_c$  vs. temperature  $T$  for the iron nanoparticles in the Al<sub>2</sub>O<sub>3</sub> matrix.<sup>391</sup> Average particle size /nm: 4.5 (1), 7.0 (2), 9.0 (3).

**Figure 16.** Temperature dependences of the saturation magnetisation  $M_s$  (a) and coercive force  $H_c$  (b) for iron nanoparticles (with a diameter of  $\sim 5-10$  nm) in the silicon nitride matrix.<sup>393</sup>

The dots show the experimental data and the lines correspond to calculations in terms of the simple spin wave model; dots 1 and 2 correspond to two samples obtained under roughly the same conditions (given for evaluation of reproducibility of the results).

error of measurements. Approximately equal values of  $T_b$  and  $H_c$  were observed for nano-sized ‘onion’ particles consisting of an Au core and a Fe shell, which is in turn coated by gold<sup>394</sup> (Fig. 17). On the basis of these data, it was concluded that the contact with gold does not have any noticeable influence on the magnetic properties of Fe nanoparticles.<sup>394</sup> Note that nickel particles ( $\sim 700$  nm) coated by palladium ( $\sim 10$  nm) demonstrate, conversely, a marked (approximately twofold) growth of the coercive force compared to that of Ni particle devoid of this shell.<sup>395</sup> This

**Figure 17.** Micrograph of nanoparticles having the ‘onion’ nanostructure.<sup>394</sup>

might be due to the polarising magnetic effect of palladium atoms with respect to the ferromagnetic matrix.<sup>349</sup>

## XI. Further prospects for the study of magnetic nanoparticles

The fields considered above do not exhaust all possible aspects for the use of magnetic nanoparticles and nanomaterials. In particular, further development of electronics will be largely related to the use of magnetic nanoparticles. This is indicated by numerous works on spintronics — a new field of electronics dealing with charges and spins.<sup>371, 372, 396</sup> In recent years, considerable attention has been devoted to nanostructures based on magnetic semiconductors.<sup>397</sup> This is due to the prospects opened by the use of not only the charge of the current carriers (electrons and holes) in electronic semiconductor materials but also the magnetic moments directly related to the spin. Spin–orbit coupling may become an important tool for the control of magnetic characteristics in nanostructures.<sup>398</sup> It is expected that the use of the magnetic moment of the charge carrier would markedly extend the scope of the design of new electronic devices,<sup>399</sup> in particular, this would help to solve the problem of non-volatile superdense magnetic memory (MRAM — Magnetic Random Access Memory) which is not subject to wear on recording and reading operations.<sup>400, 401</sup>

Several groups of currently studied physical phenomena that may find application in spintronics can be distinguished:

- dependence of the electrical conductivity of a uniform material on an external magnetic field: anisotropic magnetoresistance (AMR) in thin ferromagnetic films (for example, in permalloy), giant magnetoresistance (CMR) in manganites;
- giant magnetoresistance (GMR) in structures with alternating layers of ferromagnetic and paramagnetic (or antiferromagnetic) metals and granulated structures;
- tunnelling magnetoresistance (Spin Depending Tunneling) in layered structures containing a paramagnetic (or antiferromagnetic) dielectric between layers of the ferromagnetic metal;
- injection of spin-polarised current carriers from a ferromagnetic material into a non-magnetic one;
- mutual influence of the magnetism and the density of various charge carriers in ferromagnetic semiconductors.

Many magnetoelectronic effects can be interpreted using the Mott–Campbell–Fert model according to which electrons with opposite spins are not mixed in scattering processes in a ferromagnet (two-current model). Since the density of the electron states depends appreciably on the spin, the probability of transition of a conduction electron between regions in a ferromagnet can be varied by changing their magnetisation. Thus the probability of transition between regions with a parallel orientation of the magnetisation vectors is higher (the electrical resistance is, correspondingly, lower) than that for the antiparallel orientation.

Study of the mutual influence of the magnetism and the electrical conductivity in ferromagnetic semiconductors (for example, ZnO–Mn) is a more complicated task. In these systems, the charge carriers are simultaneously mediators of the magnetic interaction between the localised magnetic moments of transition metal ions. By changing the concentration of the charge carriers (for example, by injection), one can control the strength of the magnetic interactions and, hence, the magnetic properties of the material, for example, magnetisation, which can affect the conductor resistivity.

Although the calculations show that the p-type magnetic semiconductors based on ZnO or GaN with 5% Mn and a charge carrier density of  $3.5 \times 10^{20} \text{ cm}^{-3}$  can form the basis of a material with  $T_C > 300 \text{ K}$ ,<sup>397</sup> no ferromagnetic semiconductors with a Curie temperature higher than room temperature have been obtained as yet.<sup>402</sup> Numerous accounts concerning overcoming this barrier for various compounds have not been reliably substantiated. The recognised record in this field now belongs to the

GaMnAs semiconductor with  $T_C = 110$  K.<sup>403</sup> Ferromagnetism above room temperature was discovered in the Co–ZnO, Fe, Cu–ZnO, V–ZnO and Co–TiO<sub>2</sub> samples (films or bulk samples); however, the obtained data are not perfectly reproducible.<sup>402</sup> The GaMnN, ZnO–Mn and Co–TiO<sub>2</sub> systems and other oxide semiconductors have also been mentioned as promising materials.<sup>403, 404</sup> For nanoparticles of this class, optical studies have been mainly carried out,<sup>405, 406</sup> while their magnetic properties have not been adequately studied.

Yet another problem of spintronics is the appearance of barriers at the boundaries between the layers with different magnetic or electric properties, which prevent realisation of spin–polarisation effects.

Some of the phenomena listed above have already been implemented in the GMR sensors (used, in particular, in the read heads of hard discs)<sup>371</sup> and in the first MRAM chips.<sup>407</sup> However, most of the enormous number of the proposed magnetoelectronic devices (spin filters, diodes, transistors) have not been implemented even on a laboratory scale (for example, Datta–Das spin-field-effect transistor). Some other (for example, the SPICE transistor) have been implemented as laboratory specimens, but not brought to a level of practical application as yet.<sup>408</sup>

The magnetic properties of nanoparticles can also prove quite useful for the design of quantum computers.<sup>409, 410</sup>

A revolutionary achievement is the design of MRAM chips.<sup>401</sup> This type of memory appears to be universal, because it surpasses the existing types of memory (SRAM, DRAM, FLASH, FRAM) in all important characteristics. The MRAM devices are able to compete successfully with hard discs, because at a comparable (in the future) recording density they do not contain moving parts. An especially attractive feature of the MRAM is non-volatility and wear resistance (infinite number of recording and reading events). Currently existing MRAM specimens with a 4 Mbit capacity are based on 0.18  $\mu\text{m}$  CMOS technology with a recording and reading time of 25 ns<sup>411</sup> and magnetic cells based on a magnetic tunnelling transition (MTJ).

To increase the recording density and decrease the current, it is most expedient to use ring magnetic cells.<sup>412, 413</sup> Their advantage over particles of other shapes is in the higher stability of the magnetic eddy configuration due to the absence of boundary distortions of the magnetic structure. This, in particular, can result in a decrease in the superparamagnetic limit, which would allow the use of particles of the minimum possible size. A method for the formation of ring cells on the silicon surface by means of electron lithography and subsequent molecular-beam epitaxy has been proposed.<sup>413</sup> The minimum inner diameter of particles obtained by this technique was 100 nm. A decrease in the particle size to 10 nm can increase the recording density to 400 Gbyte in<sup>–2</sup>, which is comparable with the recording density limit predicted for hard discs.<sup>412</sup>

Thus, by changing the morphology of nanoparticles (size, shape, composition, core–shell relationship, particle arrangement in the matrix), one can influence their magnetic characteristics. The crystal structure of the core and shell of the particle can be changed by heat treatment (annealing) or other methods of targeted change of nanoparticle properties. Complex particles have been obtained with regions responsible for different properties (for example, the magnetic nucleus and the biologically active shell) clearly separated in space and particles with extremal spatial characteristics (hyperplanar and ultrafine particles — nanowires). In some cases, valuable characteristics appear due to the lucky combination of the properties of particles and the matrix containing them (elastic exchange magnets, see Section IX).<sup>381, 414</sup>

However, the science of magnetic nanoparticles still has a broad spectrum of unsolved theoretical and practical problems. We would like to mention some of them.

A quantitative theory for the internal magnetic structure of nanoparticles is still lacking. The experience of using the simple theory of single-domain particles developed in the main in the mid-20 century by Neel and Brown shows that the model of

uniform (collinear) magnetisation of a nanoparticle without splitting into domains does not necessarily correspond to the real situation.<sup>312</sup> Since the solution of the static problem of distribution of magnetic moments in a nanoparticle is rather complicated, it is not surprising that a more complex dynamic task on nanoparticle magnetisation reversal is far from being solved.

One more practical problem which remains unsolved and thus holds up approaching the natural limit of the magnetic memory density is the insufficiently large (much lower than the theoretical value) coercive force of the nanoparticles suitable for the use in hard discs for technological reasons. Apparently, this is due to the complex internal magnetic structure of real nanoparticles.

The design of new highly ordered functional nanostructured composite materials with enhanced properties requires the development of effective methods for nanoparticle organisation. The future research will be aimed at development of the approaches to the synthesis of composite nanoparticles characterised by a set of practically valuable properties (magnetic, electrical, optical). Undoubtedly, magnetic nanoparticles would also find application in other fields, of which nanobiotechnology is expected to become most important. The possible use in biology and medicine, for example, as magnetic biomarkers, anticancer drugs, etc.<sup>269, 276, 277</sup>

## XII. Conclusion

Magnetic nanoparticles play an important role in the rapidly developing branches of science specialising in the study of objects (existing in nature or, more often, artificially produced) with nano-sized structural blocks. Despite the fact that the extensive use of magnetic nanoparticles (especially for biological applications<sup>415</sup>) and nanomaterials containing them is delayed by the difficulty of producing materials with a narrow size distribution of particles and stable reproducible characteristics and the high cost of their large-scale production,<sup>416</sup> such nanoparticles are used more and more often in the everyday practice. Some companies have already arranged the manufacture of the first samples of nanomaterials. In our opinion, it is time for extensive search for the ways of practical use magnetic nanoparticle.

**Abstract.** Studies devoted to simulations of crystal lattice effects on the electronic and spatial structures of organic molecules in molecular crystals with inclusion of the external potential created by the crystal environment into the Hamiltonian of the isolated molecule are surveyed. Various methods for the representation of the charge distribution in a molecule by atomic point charges or multipoles are compared and the necessity of the empirical correction of the molecular electrostatic potential obtained using the Hartree–Fock and semiempirical calculations is substantiated. The procedures for the modification of the Hamiltonian are analysed. The limits of applicability of this approach to simulations of specific intermolecular interactions (hydrogen bonds) are discussed. Examples of the use of methods based on the application of the electrostatic potential in the calculation of the crystal lattice energy, simulations of the molecular conformations in crystals and electronic excitations are presented. The importance of the results of computation of the electronic structures of molecules in crystals for systematisation of the crystal structures and, in particular, for comparative analysis of the structures of polymorph modifications is demonstrated. The bibliography includes 117 references.

## I. Introduction

Nowadays, various quantum chemistry methods are widely applied to simulate the spatial and electronic structures of molecules. *Ab initio* calculations of molecules comprising 15–25 second-row elements using extended basis sets and taking into account the electron correlations by the Müller–Plesset method have become routine.<sup>1</sup> Calculations within Density Functional Theory (DFT) require less computational resources but are not applicable to specific problems.<sup>2</sup> Semiempirical methods are utilised in calculations of systems composed of a few hundred atoms.<sup>3,4</sup> Since researchers are interested in predicting properties of not only isolated molecules but of molecules in condensed phases (*i.e.*, in solutions, crystals, amorphous films, *etc.*) as well,

the last 15 years have witnessed the intensive development of methods that account for the medium effects in quantum-chemical calculations.

Especially tremendous progress has been achieved in the simulations of interactions between solute and solvent molecules in solutions. Such investigations exploit two approaches that make it possible to reduce the duration of calculations to an acceptable level. The first approach uses a hybrid description of the system under consideration, *i.e.*, the central molecule is represented at the quantum-mechanical level, whereas solvent molecules are treated using molecular mechanics.<sup>5</sup> Within the second approach, the solvate environment of the central molecule is represented as a dielectric continuum.<sup>6,7</sup> It is remarkable that the energy of solvation of a number of molecular ions can be predicted quite precisely and, for instance, the fact of the existence of glycine molecules as zwitter-ions in aqueous solutions can be rationalised even within a simple continuum model without taking into account specific interactions between the solute molecule and its first solvate shell.<sup>8</sup> The continuum models are also used to calculate solvatochromic effects.<sup>9–11</sup>

Taking into account that crystals are characterised by long-range ordering, one can suggest that the long-range electrostatic interactions therein play an even more important role than in solutions. Numerous theoretical and methodical procedures developed for solvation models can also be adapted to simulations of the crystalline state.

The strict quantum-chemical approach implies the calculation of the band structure of the crystal under periodic boundary conditions.<sup>12,13</sup> A number of software codes suitable for the solution of this problem are available based on the Hartree–Fock (HF),<sup>14</sup> DFT<sup>15</sup> or semiempirical<sup>16</sup> methods. In organic crystallography, however, this approach is rarely applied, probably, for two reasons: first, the band structure calculations require significantly larger computational resources than respective calculations of isolated molecules; second, direct comparison of the results of the crystal band structure and isolated molecules calculations are difficult. Still, in the majority of cases, the electronic structures of molecules in crystals do not differ, in principle, from those of isolated molecule, and thus the effects of the intermolecular interactions can be taken into account by including the external electrostatic potential (EP) into the effective Hamiltonian. Definitely, this is not valid for crystals of charge-transfer molecular complexes and for homomolecular stacking structures of organic photoconductors. But even in these cases, a one-dimensional representation<sup>17</sup> usually appears sufficient, and

the interactions between the stacks can be described in terms of the external potential.

The present review is devoted to methods for the calculation of the electrostatic interactions in organic molecular crystals and to the application of these methods to the prediction of the crystal lattice energy and simulations of the spatial and electronic structures of molecules in crystals, including the dependence of the colour of crystals on the molecular packing therein.<sup>18</sup>

## II. Two definitions of the crystal electrostatic potential

The crystal electrostatic potential can be defined as an effective potential that is experienced by an infinitely small point charge placed in the crystal lattice. For any point in space with coordinates  $r$ , it can be represented by a scalar function  $\varphi(r)$ , which depends on the charge density distribution  $\sigma(r)$

$$\varphi(r) = \int_V \frac{\sigma(r')}{|r - r'|} dr', \quad (1)$$

where the integration is performed over the entire crystal volume  $V$ .

The charge density  $\sigma(r)$  contains the nuclear and electronic terms

$$\sigma(r) = \left[ \sum_i Z_i \delta(r - R_i) \right] - \rho(r), \quad (2)$$

where  $Z_i$  and  $R_i$  are the charge and coordinates of the  $i$ -th atomic nucleus, respectively,  $\delta$  is the delta-function, and  $\rho(r)$  is the electron density.<sup>19</sup> If a crystal has a finite size, the expression for  $\varphi(r)$  should also include the potential  $\varphi_0$  dependent on the shape and structure of the crystal surface.<sup>20</sup> The distribution  $\varphi(r)$  in a crystal can be derived experimentally, for instance, using X-ray diffraction.<sup>21</sup>

A different definition of the electrostatic potential can be formulated from the standpoint of energy. The total energy of a molecular crystal can be represented within the atom–atom approximation as

$$E = E_{r-d} + E_e, \quad (3)$$

where  $E_{r-d}$  is the sum of the energies of repulsion of complete electronic shells and the dispersion attraction of atoms for all molecules in the crystal,  $E_e$  is the total energy of the intermolecular Coulomb interactions.<sup>22</sup>

The first term in formula (3) is determined using the empirical pairwise potentials 6–12 or 6–exp, the second term is calculated from the charge density distribution in the crystal given by formula (2):

$$E_e = - \sum_i \sum_j \int_V \int_V \frac{\sigma_i(r_1) \sigma_j(r_2)}{|r_1 - r_2|} dr_1 dr_2, \quad (4)$$

the integration is performed over the entire crystal volume  $V$  and the summation is performed over all pairs of molecules ( $i < j$ ) in the crystal. The expression for  $E_e$  can be reformulated as

$$E_e = -N \int_V U(r) \sigma_A(r) dr, \quad (5)$$

where  $N$  is the number of molecules in the crystal and  $U(r)$  is the electrostatic potential experienced by the molecule A, which is created by other  $N-1$  molecules in the crystal. Sometimes, the potential  $U(r)$  is referred to as the Madelung potential to differentiate it from  $\varphi(r)$  (see Ref. 23).

Analysis of topological features of the electrostatic potential distribution  $\varphi(r)$  in different crystals gives important information on the electric field inside the crystal,<sup>24,25</sup> and, in particular, on specific features of the intermolecular interactions. However, in

the present review we are concerned only with the potential  $U(r)$  and focus on the methods for its calculation and inclusion into the computational schemes of quantum chemistry.

## III. Calculation of the electrostatic potential and modification of the molecular Hamiltonian

Direct inclusion of a set of point charges (from several tens to several hundreds) around a molecule into the molecular Hamiltonian is the simplest way to model the electrostatic interactions of the molecule within its crystal environment. This does not result in any significant increase in the computational time since only the number of one-electron integrals increases. Such a procedure was used for the first time more than 30 years ago<sup>26</sup> for simulations of distortions of the structure of  $\text{H}_3\text{O}^+$  ions in crystals of  $\text{HCl} \cdot \text{H}_2\text{O}$  and  $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$  using the HF method. The account of the effects of the environment was realised by specifying 50 point charges located at the van der Waals surface of the molecular ion. A similar approach was used in a study of crystals of cyanofornamide:<sup>27</sup> all atoms of 8 molecules from the closest environment were represented by 84 point charges, which were updated in every cycle of the self-consistent field (SCF) procedure. At present, options on the use of point charges are included in several common software codes for non-empirical calculations, such as Gaussian, Gamess and ADF.

Since the series (4) converges very slowly, the Ewald method is normally applied in crystallography for the calculation of the lattice sums.<sup>28</sup> The Ewald method was adapted to HF calculations in such a way that the calculated ‘pairwise Madelung constants’ are used for the modification of Coulomb integrals without recourse to redetermine the lattice sums in every SCF cycle.<sup>29,30</sup>

It is of note that calculation of the electrostatic contribution to the crystal lattice energy requires accurate determination of the EP, whereas changes in the structure of a molecule in the crystal are caused primarily by the potential gradients within its boundaries. The series in the expression for the potential gradient converges much faster than series (4), the rate of convergence being dependent on the space group of the crystal. Thus, in some cases, consideration of only closest neighbours (typically, within a sphere of 10–20 Å) gives quite accurate results, which are virtually not improved upon inclusion of more distant molecules into the calculation.<sup>31</sup> However, the error due to the series truncation increases for crystals composed of molecules with large dipole moments and for non-centrosymmetric space groups. In those cases, the summation has to be performed over a sphere of 100–200 Å to achieve satisfactory accuracy.<sup>32</sup>

In early studies,<sup>26,27,33</sup> the EPs of crystals were estimated from the point atomic charges calculated using the Mulliken prescription. Presently, it is widely accepted that the Mulliken charges are inappropriate for calculation of the molecular electrostatic potential (MEP)<sup>34,35</sup> and do not reproduce the dipole moments of molecules.<sup>36</sup> Therefore, alternative schemes for the representation of charge densities in molecules have been developed. Charges obtained by fitting to the MEP calculated from the charge density distribution<sup>37,38</sup> are common in molecular mechanics, however this charge retrieval procedure is an ill-posed problem and cannot be efficiently accomplished for large molecules. A procedure of empirical correction for the Mulliken charges obtained in semi-empirical [Austin Model 1 (AM1),<sup>39</sup> Parametrisation 3 (PM3),<sup>40</sup> Intermediate Neglect of Differential Overlap-Spectroscopic Parametrization (INDO/S)<sup>41</sup>] and *ab initio* calculations parametrised versus the experimental dipole moments of small organic molecules has been proposed by Truhlar *et al.*<sup>42,43</sup> These authors hoped not only to overcome the drawbacks resulting from the definition of the Mulliken charge itself but also to largely compensate for the systematic errors intrinsic to the semiempirical and HF calculations as well as for the errors of DFT calculations due to the restricted basis sets. Indeed, the above procedure reproduces the experimental values of the dipole moments with root-mean-square errors of 0.25–0.17 D (depending on the

quantum-chemical method used) for the original sample of 198 small molecules, which is 1.5–2 times smaller than those achieved in the direct calculations of the dipole moments from the charge densities. However the efficiency of the correction procedure decreases for compounds beyond the sample used for the parametrisation. For example, since nitro-compounds were not represented in the sample, the procedure not only fails to compensate for the overestimated dipole moments of compounds with an NO<sub>2</sub> group typically predicted by the AM1 and PM3 methods but gives even increased theoretical dipole moments.<sup>44</sup>

We note that the AM1 and PM3 methods provide nearly the same accuracy of calculation of the dipole moments for molecules composed of only first- and second-row elements as do the *ab initio* methods, which require significantly larger computational resources. Nitriles and nitro-compounds are the exception to this: the semiempirical methods underestimate the dipole moments of nitriles by 0.7–0.9 D and overestimate those of nitro-compounds by 0.6–0.8 D. The dipole moments calculated using the semiempirical methods better correlate with the results of the *ab initio* calculations with account for correlation effects<sup>†</sup> than those from the HF calculations.<sup>44</sup> Therefore, the semiempirical wave functions with empirical corrections for nitriles and nitro-compounds can indeed be used in the calculations of the MEPs of organic compounds without loss of accuracy.<sup>32</sup> On the other hand, the dipole moments of molecules containing sulfur, phosphorus or chlorine atoms are predicted by the semiempirical methods with significantly lower accuracy than by the *ab initio* methods with polarised basis sets.<sup>42</sup>

Among methods for the determination of atomic charges, the Hirshfeld method<sup>45</sup> is worth a special note, which assumes that the electron density at every point of the molecule should be divided over all constituent atoms proportional to their contributions to the electron density of the ‘protomolecule’, *viz.*, the respective set of atoms that do not interact chemically. Despite this unusual formulation, this method yields atomic charges that often reproduce the energy of the intermolecular interactions better than the Mulliken charges.

An extensive verification of different models based on point atomic charges has demonstrated that none of them is capable of reproducing the MEP with high accuracy.<sup>35</sup> An explicit consideration of the character of the electron density distribution in atoms, in particular its extension and asphericity (*e.g.*, lone pairs), is necessary in order to achieve the desirable level of accuracy. For this purpose, Stone proposed<sup>46,47</sup> a model of distributed multipoles, which enables determination of mono-, di-, quadrupole, *etc.* moments of atoms from the molecular wave function. Within the semiempirical methods based on the sp-basis, the quadrupole moment is the highest moment characterising a second-row element.<sup>48</sup> The original version of a common continuum model COSMO (Conductor-like Solvation Model) utilised only monopole and dipole moments of atoms, which gave satisfactory numerical results.<sup>8</sup> Later on,<sup>49</sup> the quadrupole moments were also included in the model.

According to the multi-centre model of point charges<sup>50</sup> also proposed for the semiempirical methods, an atom is represented by an atom core charge placed in the position of the atom nucleus surrounded by four pairs of charges, which mimic the native atomic orbitals.<sup>51</sup> The values of the charges are calculated based on the populations of the respective orbitals, and their distances from the atom nucleus depend on the contribution of the s-orbital into the respective sp<sup>n</sup>-hybrid orbital. The main idea behind this model is similar to that of the model of distributed multipoles, and the accuracy of the MEP calculated based on this model is higher

than those calculated within any scheme utilising point atomic charges (including those that use fitting to the MEP calculated directly from the electron density distribution). The contribution of higher electrical moments of atoms into the EP rapidly decreases with an increase in the distance; the contribution of quadrupole moments is as low as 1%–2% of the total EP at a distance of ~3.4 Å (which is the typical intermolecular distance in stacks of planar organic molecules). The contributions of quadrupole electrical moments become nevertheless substantial in crystals with short intermolecular contacts. However, the model cannot be applied to such systems, since the basic assumption of negligibly small intermolecular overlap of orbitals, which enables consideration of the intermolecular interactions within the classical theory, is then violated.<sup>52</sup>

Since the hydrogen atoms within the semiempirical calculations are assumed to possess only a 1s-orbital, they are represented in the multipole model as point charges. This representation is insufficient to correctly reproduce the MEP along the C–H direction; in order to reconcile the semiempirical results with the *ab initio* calculations [MP2/6–311+G\*\*, where 6–311+G\*\* is the Pople basis set extended with d- and p-polarisation functions with 1s-atomic orbitals approximated with six Gaussians and 2s- and 2p-orbitals approximated with five Gaussians grouped as (3,1,1)], additional point dipoles of 0.22 D<sup>52</sup> directed along the C–H bonds should be placed at the positions of all hydrogen atoms. As will be shown below, the contribution of the electrostatic interactions C–H...C into the total crystal lattice energy is small, but it has to be considered in simulations of crystal packing of aromatic hydrocarbons.<sup>53</sup>

Within a strict quantum-mechanical representation of a fragment of a crystal lattice by a cluster of *N* identical molecules composed of *M* atoms (the exchange interactions between the molecules are neglected), the following modification of the Fock matrix of a single molecule is necessary:<sup>23</sup>

$$F_{\mu\nu} = F_{\mu\nu}^0 + \left( \mu \left| \sum_{j=1}^M \sum_{i=2}^N -\frac{Z_j}{|r - R_j^i|} \right| \nu \right) + \frac{1}{2} \sum_{\lambda\sigma} P_{\lambda\sigma} \sum_{i=2}^N \left[ \left( \mu\nu | \lambda^i \sigma^i \right) + \left( \lambda\sigma | \mu^i \nu^i \right) \right], \quad (6)$$

where  $\mu$ ,  $\nu$ ,  $\lambda$  and  $\sigma$  are atomic orbitals, the superscript index *i* relates to the *i*th molecule in the cluster (*i* varies from 2 to *N*);  $Z_j$  is the nuclear charge of the *j*th atom;  $R_j^i$  is its radius-vector; *P* is the matrix of orders of the intramolecular bonds. The numerical solution of Eqn (6) represents a time-consuming task which requires calculation of numerous two-electron Coulomb integrals. The Coulomb integrals at long distances can be approximated with sufficient accuracy by two interacting multipoles, but overlapping charge distributions have to be taken into account at short distances.

Instead of Eqn (6), an approximate expression is often used, which is analogous to that used in many continuum models, *i.e.*,

$$F_{\mu\nu} = F_{\mu\nu}^0 + (\mu | U(r) | \nu), \quad (7)$$

where  $U(r)$  is the EP [see formula (5)].

The non-diagonal two-atom terms of the Hamiltonian are calculated within the semiempirical methods using empirical parameters; these terms remain constant upon modification of the Hamiltonian. Thus, the matrix element  $F_{\mu\nu}$  changes in the course of the iteration calculation only if both orbitals  $\varphi_\mu$  and  $\varphi_\nu$  belong to the same atom A.<sup>54</sup> The extension of  $U(r)$  in Eqn (7) into the Taylor series in the proximity of atom A indicates that  $U(A)$  contributes to  $F_{\mu\mu}$ ,  $U'(A)$  contributes to  $F_{\mu\nu}$  (where one of the atomic orbitals  $\mu$  or  $\nu$  is the s-orbital),  $U''(A)$  contributes to  $F_{\mu\mu}$  and  $F_{\mu\nu}$  (where both are the p-orbitals), *etc.* Higher-order derivatives can be neglected in the calculations, even neglect of the second derivative does not result in substantial errors.<sup>32,55</sup>

<sup>†</sup> DFT/TZVP and MP2/DZVP, where TZVP and DZVP are the basis sets with triply and doubly split valence atomic orbitals extended with d- and p-polarisation functions, MP2 is a method to account for the electron correlations within the approximation of the Müller–Plesset second-order perturbation theory.

Finally, we point to one fact that is almost ignored in the literature. Representation of the electrostatic contribution to the energy of the intermolecular interactions in the Coulomb form [see Eqn (4)] gives satisfactory results at large interatomic distances, but if the molecules are close to each other, the mutual repulsion of the electrons will be weaker than that predicted by the Coulomb law due to exchange and correlation interactions. It is well known from the practical use of semiempirical methods that the theoretical calculation of two-centre Coulomb integrals yields unsatisfactory results.<sup>56</sup> Thus, such integrals are determined using empirical equations which predict values much smaller than the theoretical ones at short distances. In particular, the Dewar–Sabelli–Klopman formula<sup>57,58</sup> is used for the calculation of two-centre integrals in the MNDO (Modified Neglect of Diatomic Overlap) family of methods

$$\gamma_{AB} = \left[ R_{AB}^2 + 0.25 \left( \gamma_{AA}^{-1} + \gamma_{BB}^{-1} \right)^2 \right]^{-1/2}, \quad (8)$$

where  $R_{AB}$  is the distance between atoms A and B. Thus, the modified potential determined according to the equation analogous to (8) rather than the Coulomb potential should be used for the calculation of the energy of interaction between the charge densities of molecules [see Eqn (4)]. Various types of potentials have been tested in calculations of the electronic structures of dimers of organic molecules.<sup>52</sup> In the case of the Coulomb potential, the intermolecular interactions appeared overestimated, whereas the modified potential well reproduced the results of the direct calculation of the electronic structure of molecular dimers, including ones with moderately strong H-bonds ( $O \cdots H$  and  $N \cdots H > 1.80$  Å).

#### IV. Polarisation of molecules in crystals and the crystal lattice energy

As a rule, the intramolecular charge transfer and the dipole moment of a molecule increase on going from the gas phase to the crystal. In principle, the dipole moments of molecules in crystals can be determined experimentally by an analysis of the electron density distribution from X-ray diffraction data.<sup>59,60</sup> For simple molecules, this procedure yields results in quite good agreement with the HF calculations of crystals under periodic boundary conditions (taking into account that the Hartree–Fock dipole moments are typically overestimated by 12%–15%). Several examples are given in Table 1.

Nevertheless, in the case of large molecules, the results strongly depend on the method used for the analysis of X-ray diffraction data. For instance, high-precision diffraction data were collected<sup>67</sup> for *p*-nitroaniline and 4-amino-4'-nitrobiphenyl (**1**), which were further processed using the multipole model developed by Coppens.<sup>68</sup> Depending on the constraints imposed on the parameters  $\kappa$  and  $\kappa'$  of the multipole model (which define the degree of compression of the valence shell) during fitting, a large scatter in the values of dipole moments was observed for *p*-nitroaniline, whereas an unrealistically large value was obtained for compound **1** irrespective of the procedure applied. Probably, this poor reproducibility of the results is due to correlation between the parameters  $\kappa$  and  $\kappa'$  of neighbouring atoms, which results in incorrect assignment of the electron density in the proximity of one atom to another atom. Therefore, the results obtained using the EP can be compared with the experimental data and higher-level calculations only for simple molecules.

The molecular geometry of acetamide in crystal was calculated using the HF/4–21G method.<sup>69</sup> The potential  $U(r)$  was approximated by point Mulliken charges of 102 neighbouring molecules within a sphere of 10 Å, which were updated every SCF cycle. The account of  $U(r)$  lead to an increase in the charge transfer from the amino group to the carbonyl group, which was accompanied by shortening of the C–N bond (by 0.021 Å) and lengthening of the C=O bond (by 0.022 Å). According to the experimental data, the C=O bond length increases by 0.03 Å and the C–N bond length

**Table 1.** The dipole moments (D) of molecules in crystals according to X-ray diffraction measurements and quantum-chemical calculations under periodic boundary conditions (the CRYSTAL<sup>14</sup> code) and those based on the electrostatic potential.

<sup>a</sup> The *ab initio* Hartree-Fock method with the 6–31G\*\* basis set. <sup>b</sup> The acronym stands for Self-Consistent Madelung Potential with Neglect of Diatomic Differential Overlap. <sup>c</sup> The *ab initio* DFT method with the Becke functional coupled with the Lee-Yang-Parr correlation functional (B3LYP) and the 6–311G\*\* basis set. <sup>d</sup> The *ab initio* Hartree-Fock method with the 6–21G\*\* basis set.

decreases by 0.043 Å on going from the gas phase<sup>70</sup> to the crystal.<sup>71</sup> Apparently, the effects of the crystal environment on the molecular geometry were underestimated in the aforementioned calculation. Probably, this is due to the fact that the model approximating the charge density by point charges is unable to correctly reproduce the effects of the intermolecular hydrogen bonds  $N-H \cdots O=C$ , which are present in the crystals of acetamide. It is of note that the maximum discrepancy between the theoretical and experimental data relates to the amino group. This indicates that, first, the neglect of the lone pairs of the oxygen atoms gives rise to underestimation of the strength of the H-bonds and, second, the representation of the hydrogen atoms of neighbouring molecules by point charges is an adequate approximation.

The SCMP-NDDO method, which features the AM1 parametrisation, accounts for the intermolecular van der Waals interactions based on the atom–atom potentials 6-exp and the Hamiltonian modified according to Eqn (6), was applied to 11 crystal structures formed by small polar organic molecules, including 8 compounds with intermolecular hydrogen bonds.<sup>63</sup> The results of crystal calculations for urea and formamide using this method and the HF method agree well both in terms of the absolute values and increases in the dipole moments due to crystal packing effects (see Table 1). For all 11 compounds, it was found that the increase in molecular dipole moments in the crystals was larger than in simulations of solvation in a polar solvent by the method of the self-consistent reaction field using an ellipsoidal cavity, *i.e.*, it appeared that the crystal lattice effects are stronger than the expected solvent influence.

The AM1 calculations for a sample of 79 organic crystal structures showed the mean increase in the molecular dipole moments in the respective crystals was 37%, but it varied significantly (from 14% to 100%) depending on the crystal packing motif.<sup>52</sup> A comparison of the EP effects with the solvent influence simulated by the COSMO method<sup>8</sup> demonstrated that the effect of the EP consideration exceeded the maximum possible solvent effect for 20% of the structures (half of which contained molecular ions), in an other 20% of cases, the EP effect was equivalent to that of a solvent with a dielectric permeability  $\epsilon > 10$ . The influence exerted by the crystal environment on the

packing motif can be traced for *p*-nitroaniline and *o*-methyl-*p*-nitroaniline as examples: both molecules in the isolated state are characterised by nearly identical dipole moments, but the EP induces a significant increase in the dipole moment for the former compound (see Table 1) and a decrease in the dipole moment by 1.1 D for the latter compound. For crystals containing two or more symmetrically independent molecules within the unit cell, the EP-based calculations make it possible to quantify the non-equivalency of the molecules. According to calculations performed for the crystal structures of 4-phenylazo-1-naphthylamine (**2**)<sup>72</sup> and 4-[(2-nitrophenyl)azo]phenol (**3**),<sup>73</sup> the dipole moments of molecules experiencing different crystal environments are also substantially different.

The crystal lattice effects on the electronic structures of azo dye molecules existing in the crystals in the quinonehydrazone form, 4-[(2-nitrophenyl)hydrazone]-4*H*-naphthalen-1-one (**4**)<sup>74</sup> and 1-[(2-nitrophenyl)hydrazone]-1*H*-naphthalen-2-one (**5**), were simulated using the EP.<sup>75</sup>

These molecules are characterised by rather large dipole moments (5.6 D and 6.8 D for compounds **4** and **5**, respectively) in the isolated state and form intermolecular hydrogen bonds C—H...O in the crystals. However the molecular dipole moments increase in the crystals by only 24% (**4**) and 22% (**5**).

The intermolecular interactions lead to changes in the molecular polarisability. In a calculation performed for urea crystals, it was assumed that the potential is created only by molecules connected to the central molecule by hydrogen bonds.<sup>33</sup> Under this assumption, one of the components of the molecular quadratic hyperpolarisability tensor ( $\beta_{zzz}$ ) doubled nearly (from  $-44$  to  $-74$  a.u.). The EP approach was also utilised in an HF calculation for triaminotrinitrobenzene crystals.<sup>30</sup> This compound is of interest since its centrosymmetrical crystal can generate the second harmonics of laser light.<sup>76</sup> The calculations predicted a 3–4-fold enhancement of the components of the molecular tensor in the crystal; the non-linear optical properties of the crystal can be explained by violations of ordering in terms of the alternation of molecular layers in the crystal along the crystallographic direction *z*.

Applications of the atom–atom potentials method to the calculation of the crystal lattice energies was considered in detail elsewhere.<sup>77,78</sup> Here, we confine ourselves only to discussion of the role played by the electrostatic interactions. Since the empirical parameters of the potentials 6–12 and 6-exp are often determined by fitting to the experimental crystallographic and thermodynamical data, they implicitly include the mean effects of the electrostatic interactions. Some authors suggest (see, for example, Ref. 79) that it is unnecessary to additionally consider electrostatic interactions when these potentials are used. Indeed, the intermolecular interactions in crystals formed by low-polar molecules are quite successfully described based on such potentials. However, simulation of the crystal structures containing moderately strong intermolecular hydrogen bonds within this model required the introduction of six additional pairwise poten-

tials for the systems A...H—B.<sup>80</sup> It is quite possible that further extension of the range of H-bonded systems would require introduction of new types of pairwise interactions.

The explicit consideration of the electrostatic interactions seems more reasonable from the methodological viewpoint. For this purpose, the empirical parameters contained in the expression for the potential should be separated from the Coulomb contribution during their fitting to the experimental data<sup>81</sup> or determined using quantum-chemical calculations.<sup>82</sup> In order to calculate the electrostatic component, either the lone pairs have to be represented by supplementary point charges<sup>81</sup> or the multipole representation of the atomic charge densities should be used.<sup>83</sup> According to the calculations performed within the multipole model,<sup>84</sup> the ratio of the electrostatic and the van der Waals terms strongly depends on the nature of the intermolecular interactions in the crystal. In particular, in the crystal structure of benzene, the electrostatic contribution is as low as 14% of the total crystal lattice energy, whereas it amounts to 43% and 83% in the crystal structures of benzoquinone and uracil, respectively. In those calculations, the multipole moments of atoms were the same as in the isolated molecules, *i.e.*, their polarisation in the crystals was neglected.

This drawback was corrected in the aforementioned SCMP-NDDO method, which used no special parametrisation for the hydrogen bonds.<sup>63</sup> This method was applied to calculate the crystal lattice energies of 11 polar organic compounds forming intermolecular H-bonds; the mean relative error of the determined values was 7%, which is somewhat smaller than that obtained using the empirical potentials without explicit account for the electrostatic interactions ( $\sim 10\%$ , see Refs 79, 80). The SCMP-NDDO method was also used in a calculation of relative energies of conformational polymorphs of famotidine (**6**).<sup>85</sup>

The energy of an isolated molecule in the stable polymorph was higher than that of the metastable polymorph by 17.9 kJ mol<sup>-1</sup> due to sterical hindrance. However, the total energy of the molecule in the stable polymorph appears only 1.9 kJ mol<sup>-1</sup> higher than that in the metastable polymorph owing to the more efficient electrostatic interactions therein. These calculations agree with high accuracy with the fact that it is the metastable form of **6** that starts to crystallise first despite being unstable thermodynamically.<sup>86</sup>

## V. Conformations of molecules in crystals

Conformations adopted by molecules of organic compounds often change upon transition from the gas phase or a solution into a crystal. Numerous examples of polymorphs formed by different conformers of a compound (so-called conformational polymorphism)<sup>87</sup> as well as the co-existence of several conformers in one crystal structure are known. Obviously, deviation of the molecular geometry in a crystal from the equilibrium geometry of the isolated molecule is caused by intermolecular interactions, including electrostatic ones.

An EP-based approach to the simulation of molecular conformations in crystals was applied for the first time to biphenyl. This example illustrates the importance of consideration of electrostatic interactions even for crystals formed by non-polar molecules. The biphenyl molecule is non-planar in the gas phase: the torsion angle between the planes of the phenyl rings  $\psi$  is 44(1)° according to electron diffraction data,<sup>88</sup> the energy barrier to planarisation is 8(2) kJ mol<sup>-1</sup>. In contrast, the molecule is planar in the crystal and occupies a special position on an inversion centre.<sup>89</sup> However a conformational analysis of the biphenyl

**Table 2.** Examples of calculations of molecular conformations in crystals based on the electrostatic potential.

| Compound                                                                              | Method                               | Comment                                                                                        | Ref.     |

|  11 | HF/6–31G, supermolecule <sup>b</sup> | three polymorphs, one of them contains two crystallographically independent molecules          | 101, 102 |

<sup>a</sup> APC means atomic point charges determined according to the Mulliken or Hirshfeld prescription. <sup>b</sup> Supermolecule is a cluster composed of 15 molecules surrounded by atomic point charges.

moiety in 68 crystal structures revealed<sup>90</sup> that, despite the majority of molecules is grouped at around  $\psi = 40^\circ$ , the planar or nearly planar geometry occurs much more frequently than it being allowed by the Boltzmann distribution with the torsion potential of the isolated molecule. A study of the phonon spectrum of crystals of biphenyl showed that the observed planar geometry is a result of dynamical disorder,<sup>91</sup> the energy minimum corresponds to  $\psi = \pm 20^\circ$ , and the height of the energy barrier to planarisation is 3.4 kJ mol<sup>−1</sup>.

The quantum-chemical calculation of a crystal of biphenyl was performed using the HF/4–21G method; the coordination shell included 36 neighbouring molecules, their atoms were represented by point Mulliken charges.<sup>92</sup> We note that in this case (the absence of the lone pairs and short intermolecular contacts and the zero dipole moment of the molecule), this approximation is satisfactory. The calculation yielded  $\psi = 45.7^\circ$  and a planarisation barrier of 7.9 kJ mol<sup>−1</sup> for the isolated molecule, which is in good agreement with the experimental data. The barrier height and the torsion angle decreased to 3 kJ mol<sup>−1</sup> and 27°, respectively, following the introduction of the crystal EP into the calculations.

The biphenyl molecules in the crystal structure are packed in a herring-bone arrangement: the C–H bonds are approximately perpendicular to the planes of the phenyl groups of neighbouring molecules. The C–H··· $\pi$  interactions in the crystal structures of aromatic hydrocarbons are sometimes considered as a particular case of very weak hydrogen bonds,<sup>93</sup> which decrease the energy of the  $\pi$ -orbitals and, consequently, promote stronger  $\pi$ -delocalisation over the molecule. Similar packing motifs are observed in a number of other crystal structures containing the biphenyl fragment; the angle  $\psi$  exceeds 25° in none of these structures (see

Ref. 90). Thus, the simulation of the EP effects on the conformation of the biphenyl molecules established the reason for the planarisation of the biphenyl fragment for the whole class of similar compounds.

Other examples of application of the EP to simulations of molecular conformations in crystals are listed in Table 2.

Optimisation of the molecular geometry based on the atomic point charges led in some cases to results contradictory to the experimental crystallographic data. In particular, abnormally short intermolecular contacts were revealed in one out of four polymorphs of **8** and in two out of four polymorphs of **9**. The results were more accurate when a molecular cluster surrounded by point charges was used in the calculation. For instance, both methods were applied to polymorphs of glycine, and the deviations of the calculated torsion angles from the experimental values were 3–5 times larger in the calculation of a single molecule in the field of point charges than in the calculation of a molecular cluster. On the one hand, failures in the use of the model of atomic point charges can be due to the inadequacy of the model for the calculation of the EP in these systems, since all of them contain intermolecular hydrogen bonds. On the other hand, the use of a molecular cluster implicitly takes into account the effects of the van der Waals interactions on the molecular geometry, since too short distances between atoms of neighbouring molecules are avoided in the cluster calculations.

## VI. Crystal packing effects on the energy of electronic transitions

The first examples of the existence of organic compounds as crystalline forms with different colours were described in the

beginning of the 20th century.<sup>103</sup> At present, the Cambridge Structural Database<sup>104</sup> stores information on more than 50 families of differently coloured polymorphs and pseudopolymorphs, although solid-state spectral data have been reported for only a few representatives. Various reasons can be responsible for the differences in colours of molecular crystals. Firstly, the molecules in the crystals can adopt different conformations or exist as tautomeric forms which differ substantially in the degree of intramolecular conjugation. For instance, one of the aforementioned polymorphs of **11** is yellow, the second one is pale yellow, whereas the third one is colourless. The molecules in the yellow polymorph are nearly planar; the CO<sub>2</sub>Me and OH groups are turned by 68–83° and 32–51°, respectively, in the colourless polymorph due to intermolecular hydrogen bonds and they occupy intermediate positions in the pale yellow polymorph. Secondly, changes in the colour can be due to excitonic effects or intermolecular charge transfer.<sup>105</sup> Finally, by analogy with solvatochromic effects, the absorption bands in a crystal can shift due to polarisation of the molecule in the crystal environment. We consider this phenomenon in more detail below.

#### Compound 12

exists as orange and pale yellow polymorphs, in which the difference in the conformations of the molecules is not sufficiently large to explain the difference in colours. The effects of the EP on the electronic structure of the molecule were simulated using the SCMP-NDDO method. Only configurations produced upon

transfer of an electron from the highest occupied to the lowest unoccupied molecular orbitals were taken into account to calculate the excitation energy. According to the calculation,<sup>106</sup> crystals of the orange form of **12** are characterised by an excitation energy 1700 cm<sup>-1</sup> lower than that of the yellow form, which is the reason for the different colours of the polymorphs.

The INDO/S method has specially been optimised for calculations of spectra of organic molecules but it is less suitable to calculations of the ground states of molecules and the electron density distribution, in particular, than other semiempirical methods. In this respect, an alternative procedure was proposed,<sup>32</sup> in which the AM1 or PM3 method is used for the calculation of the EP, and the resultant potential is included in the INDO/S type Hamiltonian. The excitation energies for 16 groups of polymorphs and pseudopolymorphs were calculated within this approach.<sup>52</sup> For six groups, it was the EP effects that were shown to be responsible for the experimentally observed difference in colours, and a fair agreement between the calculated changes in the excitation energies and shifts of the absorption bands was observed for those compounds, the solid-state reflection spectra of which were available from the literature (Table 3). For four other compounds, the differences in the molecular geometries and the potential effects considered separately appeared small, but the difference in colours could be attributed to their joint influence. Finally, for the remaining six compounds, the calculations yielded identical excitation energies for different polymorphs. Apparently, the difference in colours in those cases should be attributed to another reason. We note however that the results of computation evidently contradicted the experimental data in none of the 16 cases. Within this approach,<sup>52</sup> bathochromic shifts of the absorption bands of quinacridone<sup>112, 113</sup> and indigo<sup>114, 115</sup> on going from solutions to the crystals can also be rationalised.

**Table 3.** Examples of compounds forming differently coloured polymorphs for which the excitation energies (cm<sup>-1</sup>) were calculated using the INDO/S method with the electrostatic potential.

| Compound                                                                                         | Colour of the polymorph | Experiment                                 | Calculation                                          |                                                      | Ref.     |

<sup>a</sup> Position of the long-wavelength edge of the absorption band. <sup>b</sup> Position of the maximum of the fluorescence spectrum. <sup>c</sup> The crystal structure of the yellow polymorph contains two independent molecules.

The INDO/S method with included crystal EP was also applied to simulate the changes in dipole moments of the electronic transitions for crystals of certain amides, purines and pyrimidines with respect to the isolated molecules.<sup>55,116,117</sup> According to the calculations, a crystal-field-induced mixing of the  $n\pi^*$  and  $\pi\pi^*$  type excited states occurs, which gives rise to changes in the direction of the transition moments by  $10^\circ$  and even more. The calculations using the  $U(r)$  potential agree much better with the experimental spectra of the crystals than the respective calculations for the isolated molecules.

\* \* \*

Thus, the use of the crystal electrostatic potential in quantum-chemical calculations enables quite reliable determination of the crystal lattice energies and simulation of the geometry and electronic structure of molecules providing explanations of their changes on going from the isolated molecules to the crystals. The crystal lattice effects vary over a wide range depending on the packing motif and the character of the intermolecular interactions. This determines the difference in the properties of polymorph forms as well as variation of characteristics of crystallographically independent molecules experiencing different crystal environments. The systematic application of the EP-based calculations significantly extends the analytical potential of chemical crystallography as applied to molecular structures and makes it possible to step beyond a mere geometrical description.

**Abstract.** The review summarises data on transition metal complexes with the so-called non-innocent ligands. The specific feature of these complexes is that the oxidation state of the central metal atom and the electronic structure of the ligands are impossible to determine *a priori* and unambiguously. The results of experimental studies (spectroscopic, electrochemical, X-ray diffraction) of complexes with various non-innocent ligands are analysed. Particular attention is given to their structures and redox properties. The bibliography includes 208 references.

## I. Introduction

Transition metal complexes with the so-called non-innocent ligands have been known in coordination chemistry since the 1960s, when square-planar dithiolene (enedithiol) compounds were synthesised.<sup>1</sup> However, the term ‘non-innocent’ gained wide acceptance only in the 1990s, when such complexes attracted considerable attention.

The term ‘non-innocent’ is generally used in jurisprudence to distinguish the verdicts ‘non-innocent’ and ‘innocent’. This term was introduced in chemistry by Jørgensen in 1966. According to the definition by Jørgensen, a ligand is innocent if it allows the unambiguous determination of the oxidation state of the central metal atom. This definition refers only to the ligand, but, in actuality, the innocent or non-innocent behaviour is related to the complex as a whole.<sup>2</sup>

An example of complexes with a non-innocent ligand is the neutral nickel complex with glyoxalbis(2-mercaptoanil) Ni(gma)<sub>2</sub> (**1**) characterised by the presence of an extensive system of conjugated  $\pi$  bonds. This complex can be considered as a 16-electron Ni<sup>II</sup> complex with diiminodithiolate (**1a**) or di(iminothiosemiquinonate) (**1b**), as a 14-electron Ni<sup>IV</sup> complex (**1c**) or, alternatively, as an 18-electron Ni<sup>0</sup> complex (**1d**).

Consequently, neither the oxidation state of the central metal atom nor the charges on the donor atoms of the ligand can be *a priori* precisely defined, and these structures are often described by formulae with delocalised bonds (**1e**), which means that complex **1** is non-innocent.<sup>3</sup>

A ligand (or ligands) in non-innocent complexes cannot be unambiguously described by the formula acceptable to the free ligand [in the above example, this is the formula of the doubly-charged glyoxalbis(2-thiolatoanil) anion]. The introduction of metal changes the ligand (for example, the free ligand is irreversibly reduced or oxidised, whereas these transformations in the complex are reversible). Earlier,<sup>3</sup> we proposed the term ‘non-indifferent ligand’, which, in our opinion, correctly reflects the heart of the problem. The characteristic feature of complexes with non-indifferent (non-innocent) ligands is the involvement of both the ligand and metal in many chemical and physical processes, which were earlier assigned (on the basis of the theoretical formalism) to only either the metal or ligand.

To bring the metal in the above-mentioned structures to one oxidation state (Ni<sup>2+</sup>), it is necessary to add two electrons to structure **1c** and abstract two electrons from structure **1d**. Consequently, ligand **1c** should exist as the doubly-charged anion, whereas ligand **1d** should occur as the doubly-charged cation of complex **1** provided that divalent nickel is retained in the structure. Therefore, if the ligand rather than the metal is reduced (oxidised), the ligand can have different structures in different states of the complex. These ligands are called ‘redox-non-innocent’.

Scheme 1

For example, two one-electron oxidation processes and two one-electron reduction processes in diiminodithiolate complexes occur, apparently, with the involvement of the ligand, whereas the divalent state of the metal remains unchanged (Scheme 1).<sup>3</sup>

In dithiolene complexes (and many other analogous complexes), the oxidation states of the metal and the ligand also could not be unambiguously determined, which results in confusion in the interpretation of electrochemical data (elucidation of whether the metal or ligand is subjected to oxidation and reduction) and UV-Vis spectroscopic data. The true nature of metals and ligands has been debated for decades.

After the synthesis and characterisation of first dithiolenes and metal dithiolenes, numerous other complexes exhibiting non-innocent behaviour were found. Pyrocatechol derivatives (catecholates) and other *ortho*-disubstituted benzene derivatives (*o*-phenylenediamines, *o*-aminophenols, *o*-aminothiophenols, *etc.*) belonging to the same structural type have received the most attention.

A reasonable question arises concerning the meaning of the term 'non-innocent'. Presently, this term is sometimes (incorrectly) used in the sense that a ligand in a complex is redox-active. Hence it follows that the term 'non-innocent ligand' is applicable, for example, to dithiolenes.

It should be noted that it is rather easy to determine which fragment of the molecule is involved in oxidation or reduction for complexes in which the frontier orbitals of the metal and the ligand differ substantially in energy. For example, the metal atom in  $[\text{Ru}(\text{bipy})_3]^{2+}$  (bipy is 2,2'-bipyridyl) is oxidised at the potential of +1.26 V, whereas a series of reduction steps involve the ligand, because the metal  $d(\pi)$  orbital (HOMO) and the ligand  $\pi^*$  orbital (LUMO) differ substantially in energy.<sup>4</sup> In contrast,  $[\text{Cr}(\text{bipy})_3]^{3+}$  is involved in a series of reduction reactions,<sup>5</sup> which are much more difficult to interpret, because the metal- and ligand-centred orbitals involved in redox processes are comparable in energy. In actuality, the metal atom of  $[\text{Cr}(\text{bipy})_3]^{3+}$  is reduced in the first step to form  $[\text{Cr}^{\text{II}}(\text{bipy})_3]^{2+}$ , and the successive two-electron reduction occurs at the  $\pi^*$  orbital of the ligand to give a species described as  $[\text{Cr}^{\text{II}}(\text{bipy})_2(\text{bipy}^{\cdot-})]^+$  {or as  $[\text{Cr}^{\text{III}}(\text{bipy})_2(\text{bipy}^{\cdot-})_2]^+$ . Therefore, the ligand is redox-active both in  $[\text{Ru}(\text{bipy})_3]^{2+}$  and  $[\text{Cr}^{\text{II}}(\text{bipy})_3]^{2+}$ , but the term 'non-innocent' is applicable only to the latter complex. Moreover, the difficulties of description of dithiolene complexes arise from strong mixing of the frontier orbitals of the ligand and metal rather than from the fact that the ligand is redox-active. Hence, it is difficult to draw conclusions about the oxidation states of the metal and the ligand in complexes. In some cases, the metal- and ligand-centred frontier orbitals can be so close in energy that so-called 'redox-isomeric' complexes appear. For example, Pierpont and Lange described<sup>6</sup> the cobalt dioxolene complex, which exists in either form **2a** or form **2b** depending on the temperature of the sample.

Consequently, the term 'non-innocent' refers to a combination of the metal and the ligand, *i.e.*, to the complex as a whole

rather than to the redox-active ligand by itself. Lever and co-authors<sup>7</sup> noted that the electron distribution in coordination compounds depends on the degree of mixing of the metal and ligand orbitals, which, in turn, is a function of energy, symmetry and overlap of the valence orbitals of the metal and ligand. This brings up questions about the true oxidation state of the central metal atom in these complexes and the electronic structures which correctly describe the complexes. These questions have been debated in the literature for more than four decades.<sup>6,8</sup>

When considering transition metal complexes with non-innocent ligands, the concept of the oxidation state of a metal in complexes should also be refined. It was suggested<sup>9</sup> that the formal oxidation state of a metal in mononuclear coordination compounds should be distinguished from the physical oxidation state. The former is generally determined as a charge remaining on the metal after removal of all ligands in the electronic configurations with complete shells, *i.e.*, with lone pairs, whereas the physical oxidation state is determined by the true electronic state of the metal atom. For example, iron in  $\text{Fe}^{\text{III}}$  complexes can exist in the high-, medium- or low-spin state. The electronic configuration of a metal in complexes can be determined by spectroscopy. Hence, Jørgensen<sup>10</sup> suggested the term 'spectroscopic oxidation state' to describe this situation.

In many cases, the formal and physical oxidation states are identical {for example, the physical and formal oxidation states of low-spin Co ( $d^6$ ) in the  $[\text{Co}(\text{NH}_3)_6]^{3+}$  complex ion is +3}. However, this is not always the case. The physical oxidation state differs from the formal oxidation state, for example, if an open-shell organic radical is coordinated to a transition metal ion. For instance, the formal oxidation state of iron in the O-coordinated iron complex with the phenoxyl radical is +4. However, Mössbauer and Raman spectroscopy demonstrated that the iron ion in this complex with the radical ligand is in the physical oxidation state of +3 and has the  $d^5$  configuration  $(\text{Ph}-\text{O}^{\cdot})\cdots\text{Fe}^{\text{III}}$ .<sup>9</sup> Evidently, the complex containing the  $\text{Ph}-\text{O}-\text{Fe}^{\text{IV}}$  fragment differs in its electronic structure from the complex with the  $(\text{Ph}-\text{O}^{\cdot})\cdots\text{Fe}^{\text{III}}$  fragment.<sup>†</sup>

The term 'physical oxidation state' is not commonly accepted. Moreover, the terms 'physical and formal oxidation states' are often used as synonyms. However, it is necessary to distinguish these terms in certain areas of coordination chemistry. In particular, it is worthwhile using the terms 'innocent' and 'non-innocent' as referring to the ligand only in combination with the term 'physical oxidation state', thus underlining that the ligands do not necessarily have closed shells.

Clear criteria for the assignment of ligands in non-innocent complexes to a particular oxidation state are presently available. Oxidation and reduction can be easily followed from structural changes in the ligand, in particular, from the changes in the bond lengths. For example, the length of the C–N single bond in *o*-phenylenediamine ligands<sup>12</sup> is  $\sim 1.46$  Å. In *o*-diiminoquinones, both C=N bond lengths are  $\sim 1.31$  Å, whereas these bond lengths in the *o*-diiminobenzosemiquinonate radical have an

<sup>†</sup> Mononuclear copper complexes with phenoxy radicals were found in the active sites of galactose oxidases.<sup>11</sup>

intermediate value of  $\sim 1.36 \text{ \AA}$  (these ligands are considered in more detail in Section II.2).

An analogous regularity was found for pyrocatechol and *o*-aminophenol complexes<sup>13,14</sup> and for *o*-aminothiophenol complexes.<sup>12</sup> Besides, the structures of the above-mentioned compounds are always characterised by the following feature: in aromatic ligands, which contain an even number of electrons and can exist as neutral molecules, singly-charged anions or doubly-charged anions depending on the degree of protonation, all six C–C bonds in the benzene ring are identical in length, whereas there are three alternating ‘short–long–short’ bonds and three adjacent long bonds in the six-membered rings of semiquinone and quinone.

To determine the electron density distribution in complexes with non-innocent ligands, various spectroscopic methods (UV-Vis, IR, Mössbauer, X-ray electron spectroscopy and ESR), electrochemical and spectroelectrochemical methods are widely used along with the structural criteria. The spectroscopic methods allow one to reveal the presence of radical species and spin-density localisation.

As mentioned above, oxidation or reduction of ligands rather than metals is very typical of complexes with non-innocent ligands (for details, see below). In redox reactions, such ligands can serve as an ‘electronic buffer’,<sup>15</sup> which reversibly accepts and donates electrons, whereas the oxidation state of the central metal atom remains unchanged.

Below we consider complexes with various non-innocent ligands. Some widely known complexes with radical ligands, for example, complexes with a verdazyl radical, are beyond the scope of the present review. In such complexes, the ligand is unambiguously described as a radical (though delocalised) and the electronic structure and oxidation state of the metal are beyond doubt.

Several reviews have been devoted to various classes of non-innocent metal complexes: with oxygen-containing ligands based on pyrocatechols,<sup>1,16,17</sup> with dithiolene ligands,<sup>18</sup> with ligands based on aromatic diamines,<sup>19,20</sup> *p*-quinones,<sup>21</sup> corroles,<sup>22</sup> *etc.*<sup>23–25</sup> The present review summarises the results of investigations of complexes with non-innocent ligands carried out in the last decade, when the term ‘non-innocent’ has received wide recognition. Only the most important earlier studies are cited.

## II. Complexes with 1,2-disubstituted benzenes and ethylenes as ligands

Dithiolenes, pyrocatechols, *o*-phenylenediamines, *o*-aminophenols and other analogous compounds belong to a well-known class of non-innocent ligands. The doubly deprotonated form of such ligands can be considered as a prototype of non-innocent ligands.

As early as the 1960s, Holm and co-authors (see, for example, Refs 26 and 27) noted that complexes belonging to the structural type

X, Y = O, NH, S; M = Ni, Pd, Pt.

are readily subjected to chemical and electrochemical reversible one-electron oxidation and reduction. In early studies, the precise structures of most intermediates formed upon oxidation and reduction were not established. However, isoelectronic series of five compounds were proposed for their description, the *o*-quinoid structure being assigned to the ligand in the highest oxidised state based on ESR spectroscopic data.

### 1. Complexes with pyrocatechol-based ligands

Complexes containing the deprotonated pyrocatechol fragment  $\sigma$ -bonded to a transition metal can exist as various electronic tautomers<sup>28–30</sup> due to the ease of electron transfer between the metal and the ligand.

It was found<sup>12</sup> that *o*-catecholates in complexes can exist as aromatic closed-shell singly- or doubly-charged anions, even-electron neutral *o*-quinones or open-shell *o*-benzosemiquinone radicals ( $S = 1/2$ ).

Correspondingly, a variable-valence transition metal atom can give a series of complexes with different forms of these ligands, which are described by the same empirical formula, but differ in the ligand structure and oxidation state of the central metal atom.

Pyrocatechol is the simplest representative of this class of ligands. Nickel,<sup>28,29</sup> palladium and platinum<sup>30</sup> complexes with ligands containing unsubstituted and 3,5- and 3,6-di-*tert*-butyl-substituted aromatic rings have square-planar structures and are diamagnetic. X-Ray diffraction study demonstrated that the structures of the above-mentioned three *tert*-butyl-substituted complexes correspond to the following formulae.

The non-innocent nature of the catecholate ligand allows the isolation of iron dioxolene complexes containing the ligand and metal atom in different oxidation states.<sup>31</sup>

L is a tetraazamacrocyclic ligand.

Iron complex **3** can serve as a structural model of the iron-containing enzyme nitrile hydratase.<sup>32</sup>

Free pyrocatechol is irreversibly oxidised by electrochemical methods at 0.3–0.6 V to give *o*-benzoquinone. The formation of the complex is accompanied by a substantial change in the redox characteristics. For example, oxidation of ruthenium complex **4** becomes reversible, occurs by a one-electron mechanism (at –0.6 to –0.5 V)<sup>33</sup> with the involvement of only the ligand and affords the semiquinone complex, *i.e.*, the addition of metal to the oxygen atoms of the ligand leads to a radical change in the nature of the ligand.

R = H, 4-CO<sub>2</sub>H, 3,5-(SO<sub>3</sub><sup>–</sup>)<sub>2</sub>.

The Ru<sup>III</sup> complexes with L-DOPA, [Ru(edta)(L-DOPA)]Na<sub>3</sub> · 3 H<sub>2</sub>O and [Ru(edta)(L-DOPA)]Na<sub>4</sub> · 3 H<sub>2</sub>O behave analogously. Upon the complex formation, oxidation and reduction processes become reversible.<sup>34</sup>

Electrochemical oxidation of ruthenium(II) complex **5** with doubly deprotonated alizarine (1,2-dihydroxy-9,10-anthraquinone) containing the 2,2'-bipyridyl fragment involves successive one-electron oxidation of the metal atom and the ligand, both oxidation products (as salts) being isolated preparatively.<sup>35</sup>

The structures of these complexes were confirmed by ZINDO calculations.

In a series of pentadentate ligands containing the terpyridyl fragment linked to the pyrocatechol fragment, which were synthesised in the study,<sup>36</sup> and their complexes with cobalt **6a–c**, the pyrocatechol fragment of the ligand also exists as the aromatic doubly-charged anion. Two of these complexes (**6a,b**) were characterised by X-ray diffraction. The authors hypothesised that two one-electron reduction steps in electrochemical redox reactions occur successively with the involvement of the terpyridyl fragment and the cobalt ion, whereas the pyrocatechol fragment of the ligand is oxidised.

*n* = 4 (**a**), 5 (**b**), 6 (**c**).

For copper catecholate complexes, Abakumov *et al.*<sup>37</sup> demonstrated that reversible intramolecular electron transfer between the metal and the ligand can occur and it is induced by the replacement of the neutral ligand.

Cat is catecholate and SQ is semiquinone.

This reversible intramolecular metal–ligand electron transfer can occur also without changes in the composition of the coordination sphere about metal. For example, the reversible electron transfer in copper complexes with *N,N'*-disubstituted 1,4-diazabutadiene (DAD) is accompanied by a change in the geometry from square-planar (in the Cu<sup>II</sup> catecholate complex) to tetrahedral (in the Cu<sup>I</sup> semiquinone complex).<sup>38</sup>

Abakumov and Eremenko with co-workers<sup>39</sup> studied a copper complex containing simultaneously the di-*tert*-butyl-substituted catecholate and 1,4-diazabutadiene fragments. In solution, this neutral complex exists as an equilibrium mixture of two isomers, *viz.*, copper(I) semiquinonate **7a** and copper(II) catecholate **7b**.

The addition of a neutral ligand (CO or ArNC) to a solution induces electron transfer from the catecholate fragment to Cu<sup>II</sup> giving rise to a complex containing an additional neutral ligand. In the case of carbon monoxide, this transformation is reversible, and the position of equilibrium strongly depends on the temperature. At 300 K, an equilibrium mixture of derivatives of molecules **7a** and **7** is present in solution, whereas almost exclusively the (SQ)Cu<sup>I</sup>(η<sup>1</sup>-DAD)CO complex exists at 200 K.

The electronic structures of the Cr<sup>III</sup> semiquinone complex [Cr(tren)(3,6-DTBSQ)]<sup>2+</sup> [tren is tris(2-aminoethyl)amine, and 3,6-DTBSQ is 3,6-di-*tert*-butylthiosemiquinone] and its catecholate analogue [Cr(tren)(3,6-DTBCat)]<sup>+</sup> containing the doubly-charged anionic 3,6-di-*tert*-butylthiocatecholate ligand 3,6-DTBCat<sup>40</sup> were studied by the DFT method. The calculations demonstrated that the Cr ion (*S* = 3/2) is antiferromagnetically coupled to the semiquinone radical (*S* = 1/2), so that the spin state *S* = 1 is the major one. Both complexes were also characterised by X-ray diffraction, and there is a good agreement between the structural data and the results of calculations. A calculation method proposed<sup>41</sup> for chromium complexes, in which chromium is bound only to electron-donating oxygen atoms, allows one to determine the oxidation state of the metal atom based on the sum of the Cr–O bond lengths.

The ligands can include two *o*-semiquinone fragments (for example, in zinc complexes **8**).<sup>42</sup> All three known complexes were studied by X-ray diffraction, and the semiquinone structure of the ligand was confirmed by the characteristic C–C and C–O bond lengths.

X = NMe<sub>2</sub>, Bu<sup>t</sup>, NO<sub>2</sub>;

Tp is hydrotris(3-methyl-5-isopropylphenylpyrazolyl)borate.

Ligand **9** containing both the potential semiquinone and nitronyl-nitroxide radical centres was synthesised.<sup>43</sup> In the ground state, Ni, Mn, Co, Cu and Zn complexes **10** with this ligand exist as singlet biradicals.

In complexes **11** and **12**, the oxygen-containing ligand (according to the results of the study<sup>44</sup>) exists as *o*-quinone, and the Mn(CO)<sub>3</sub> fragment serves as a 'reservoir' accepting electrons during oxidation of the ligand, thus being responsible for the electron density distribution between the metal and ligand.

However, the structural study<sup>45</sup> demonstrated that the C–O bonds in complexes **11** and **12** (~1.29 Å) are longer than those in *o*-quinones (1.26–1.27 Å), *i.e.*, it cannot be stated that the structure of the ligand in these complexes precisely corresponds to *o*-quinone.

A comprehensive analysis of the literature data on polynuclear Ru<sup>II</sup> complexes with bridging dioxolene ligands and binuclear tris(pyrazolylborato)Mo(V) or Mo(VI) complexes with bridging bis-phenolate or bis-pyridyl ligands was presented in the review,<sup>1</sup> where the results of spectroscopic and spectroelectrochemical investigations of such complexes were discussed in detail, and the conclusion was drawn that there is a strong electron interaction between the metal ion and the bridging ligand. Complex **13** containing three coordinating catechol-type fragments in different oxidation states (one semiquinone fragment and two carbonyloxide fragments) in one ligand molecule is an interesting example cited in the review.<sup>1</sup>

## 2. Complexes with *o*-phenylenediamine-type ligands and their deprotonated and oxidised forms

Nickel *o*-phenylenediamine complex **14** is among the first synthesised and structurally characterised complexes with non-innocent ligands. Once the oxidation state of the central metal atom higher than +2 has been rejected, two different descriptions of the electronic structure of this complex were proposed. Gray and co-authors<sup>46</sup> suggested that this compound is the Ni<sup>II</sup> d<sup>8</sup> complex with a singlet biradical (**14a**), whereas Holm and co-authors<sup>8,47</sup> described this compound by two resonance hybrids **14b**. Evidently, molecules **14a** and **14b** should differ in energy, and the question is which formula gives a more adequate description.

More recently, Abakumov *et al.*<sup>28</sup> and Pierpont with co-authors<sup>29,30</sup> have assigned the electronic structures of compound **14** and its palladium and platinum analogues to type **14a**, *i.e.*, to complexes with two intramolecular antiferromagnetically coupled iminosemiquinonate ligands, taking into account the available structural data.

Generally speaking, *o*-phenylenediamines form complexes of different structural types with transition metals (Fe, Ni, Pd, Pt, Co) depending on the oxidation state and protonation of the ligand. Complexes in which the ligands belong to the forms listed below were synthesised and characterised by X-ray diffraction and electrochemical methods.<sup>47–52</sup>

The structural changes observed in these complexes were analysed in the review.<sup>19</sup>

Eremenko and co-workers<sup>53–60</sup> described complexes of platinum-group metals (Pd and Pt) and Ni with ligands of the *o*-phenylenediamine series. The reactions of *o*-phenylenediamine<sup>53,54</sup> and its *N*-methyl<sup>55</sup> and *N*-phenyl derivatives<sup>53</sup> with alkaline solutions of K<sub>2</sub>MX<sub>4</sub> (M = Pt, Pd; X = Cl, NO<sub>3</sub>) initially

produce the tetraamine doubly-charged cationic complexes  $M(o\text{-NH}_2\text{C}_6\text{H}_4\text{NHR})\text{X}_2$ , which are transformed in the presence of atmospheric oxygen into mononuclear  $\text{Pt}^{\text{II}}$  or  $\text{Pd}^{\text{II}}$  bis(semiquinonedimine) complexes **15a**.

$M = \text{Pt}, \text{Pd}; R = \text{H}, \text{Me}, \text{Ph}$ .

In earlier studies,<sup>53, 54</sup> these compounds were considered as the  $M(o\text{-NC}_6\text{H}_4\text{NR})$  ( $R = \text{H}, \text{Me}, \text{Ph}$ ) complexes (**15b**) with anionic quinoneimine ligands.

$M = \text{Pt}, \text{Pd}; R = \text{H}, \text{Me}, \text{Ph}$ .

The bidentate ligand, *viz.*, a *o*-phenylenediamine derivative, is described in terms of the nitrene-imide resonance.<sup>53</sup>

However, X-ray diffraction data<sup>53, 55</sup> are in better agreement with the semiquinone structure of the ligand [the C(ring)-N bond lengths are 1.335 and 1.352 Å, see above].

The reactions of the *o*-semiquinonedimine complexes  $M(o\text{-HNC}_6\text{H}_4\text{NPh})$  ( $M = \text{Ni}$  or  $\text{Pt}$ ) with carbonyl-containing iron and rhenium compounds are accompanied by reduction of the ligand to give Fe or Re phenylenediamide complexes.<sup>57</sup>

In the presence of silver triflate, the reaction yields heterobimetallic complex **16** containing an *o*-quinoneiminoimide-type ligand.<sup>57, 58</sup>

This deprotonated phenylenedimine ligand, but as a bridge, is present in the palladium complex generated in the reaction of the trinuclear complex  $\text{Pd}_3(\mu\text{-O}_2\text{CBu}^t)_6$  with *N*-Ph-*o*-phenylenediamine.<sup>58</sup>

Oxidation of  $\text{Pt}^{53, 59, 60}$  and  $\text{Pd}^{60}$  bis(semiquinonedimine) complexes with  $\text{AgOTf}$  affords binuclear  $\text{Pt}^{\text{III}}$  and  $\text{Pd}^{\text{III}}$  complexes **17**.

$M = \text{Pt}, \text{Pd}; R = \text{H}, \text{Ph}$ .

The structures of the binuclear complexes were established by spectroscopic and electrochemical methods and X-ray diffraction.

The reactions of  $\text{Ru}^{\text{III}}$  salts with *o*-phenylenediamine in the presence of an oxidant ( $\text{O}_2$  or  $\text{Hal}_2$ ) produced a series of  $\text{Ru}^{\text{II}}$  complexes with the *o*-benzoquinonedimine-type ligand, and the complexes were characterised by X-ray diffraction, electrochemical and spectroscopic methods.<sup>61</sup> In such complexes, the ligands are reduced in two one-electron steps to form ruthenium *o*-phenylenediamide complexes.

Ligands of the 1,2-bis(pyridine-2-carboxamido)benzene (bpb) series similar in electronic structure to *o*-phenylenediamine ligands also belong to the category of non-innocent ligands and can be involved in coordination compounds as doubly-charged anions ( $L$ ), one-electron oxidised radicals ( $L^{\text{ox1}}$ ) or two-electron oxidised diamagnetic iminoquinone species ( $L^{\text{ox2}}$ ).<sup>62, 63</sup>

$R = \text{H}$  (bpb),  $\text{Cl}$  (bpc).

The anion L is coordinated to Fe<sup>III</sup> as a non-innocent ligand, because in a complex it can be oxidised to the paramagnetic  $\pi$ -radical cation and then to the diamagnetic neutral benzoquinone species.

Mononuclear iron and cobalt complexes with the bpb and bpc ligands were synthesised and characterised.<sup>62</sup> It was demonstrated that these ligands in coordination compounds can exist in radical one-electron and diamagnetic two-electron oxidised forms, L<sup>ox1</sup> and L<sup>ox2</sup>. These complexes were studied by X-ray diffraction, ESR and UV-Vis spectroscopy and electrochemical methods. Photolysis of the high-spin (Bu<sub>4</sub>N)[Fe<sup>III</sup>(bpb)(N<sub>3</sub>)<sub>2</sub>] complex and its (bpc)<sup>2-</sup> analogue in acetone at room temperature afforded the diamagnetic binuclear complex (Bu<sub>4</sub>N)[Fe<sup>IV</sup>( $\mu$ -N)(bpb)<sub>2</sub>(N<sub>3</sub>)<sub>2</sub>] analogous to the complex with (bpc)<sup>2-</sup>. However, photolysis in frozen acetonitrile produced a low-spin complex, whose structure was described as [Fe<sup>III</sup>(bpb<sup>ox2</sup>)(N)(N<sub>3</sub>)<sub>2</sub>]. The mononuclear complexes (Bu<sub>4</sub>N)[Fe<sup>III</sup>(bpb)(CN)<sub>2</sub>], (Et<sub>4</sub>N)[Co<sup>III</sup>(bpb)(CN)<sub>2</sub>] and Na[Co<sup>III</sup>(bpc)(CN)<sub>2</sub>] · 3 MeOH are chemically and electrochemically oxidised to the corresponding complexes L<sup>ox1</sup>. The oxidised form of the complex with the radical-anionic ligand can be isolated after preparative electrolysis. An analogous reaction was carried out by a chemical method.

The binuclear Co<sup>III</sup> and Fe<sup>III</sup> complexes with the non-innocent 1,2,4,5-tetrakis(2-pyridinecarboxamido)benzene ligands were documented.<sup>62–64</sup>

The general formula of the CN-containing complexes with an L-type ligand is as follows:

X = Na, NBu<sub>4</sub>.

For iron complexes, the existence of the following five forms containing the central ligand and metal in different oxidation states was established: (1) doubly-charged anionic [Fe<sup>II</sup>L(CN)<sub>4</sub>]<sup>2-</sup>; (2) one-electron reduced mixed-valence [Fe<sup>III</sup>Fe<sup>II</sup>L(CN)<sub>4</sub>]<sup>3-</sup> with the diamagnetic L<sup>4-</sup> bridge; (3) completely reduced [Fe<sup>II</sup>L(CN)<sub>4</sub>]<sup>4-</sup>; (4) one-electron oxidised

[Fe<sup>III</sup>L<sup>ox1</sup>(CN)<sub>4</sub>]<sup>-</sup>; (5) completely oxidised [Fe<sup>IV</sup>L<sup>ox2</sup>(CN)<sub>4</sub>]. All forms were characterised by spectroscopic and electrochemical methods. The first and third forms were also studied by X-ray diffraction.<sup>64</sup> For cobalt complexes, three forms with different oxidation states of the ligand, [Co<sup>II</sup>L(CN)<sub>4</sub>]<sup>2-</sup> (*S* = 0), [Co<sup>II</sup>L<sup>ox1</sup>(CN)<sub>4</sub>]<sup>-</sup> (*S* = 1/2) and [Co<sup>II</sup>L<sup>ox2</sup>(CN)<sub>4</sub>] (*S* = 0), were investigated by X-ray diffraction.<sup>64</sup> It was concluded that the central 1,2,4,5-tetraaminobenzene fragment in the above-mentioned complexes can be oxidised in two reversible one-electron steps to paramagnetic (L<sup>ox1</sup>)<sup>3-</sup> and diamagnetic (L<sup>ox2</sup>)<sup>2-</sup> species.

### 3. Complexes of *o*-benzenedithiols and their deprotonated and oxidised forms

As early as the 1960s, it was found<sup>26,27</sup> that *o*-benzenedithiol complexes are readily involved in one-electron transfer reactions, the *o*-quinoid-type structure being assigned to the ligand in the highest oxidation state. However, although the existence of complexes with ligands in three oxidation levels has been rather easily established for *o*-catecholates, the situation for the corresponding *ortho*-dithio derivatives has remained unclear for a long time. For example, the existence of S,S-coordinated *o*-dithiobenzenesemiquinonate radical anions (rather than aromatic doubly-charged dithiolate anions) has been proposed for many complexes,<sup>65,66</sup> but this fact has not been supported by experimental evidence. Later on, the presence of such radicals was confirmed for the paramagnetic square-planar [Pd(bipy)(L<sup>Bu</sup>)]<sup>+</sup> complex (where L<sup>Bu</sup> is 3,5-di-*tert*-butylbenzene-1,2-dithiol)<sup>67</sup> by UV-Vis and ESR spectroscopy.

The nickel complex in which the metal is coordinated by two ligands with the molecular formula C<sub>14</sub>H<sub>20</sub>S<sub>2</sub>,<sup>68</sup> exists in three different forms, anionic, neutral and cationic, and the ligand exists as the dithiolate anion, the dithiosemiquinone radical and dithioquinone, respectively.

Recently, DFT calculations have convincingly demonstrated<sup>69</sup> that the spectroscopic oxidation state of the nickel atom in the diamagnetic square-planar NiL<sub>2</sub> complex (L is unsubstituted *o*-benzenedithiol) is +2 (d<sup>8</sup>), and both ligands are present as *o*-dithiobenzenesemiquinonates(1<sup>-</sup>). The Fe<sup>III</sup> and Fe<sup>IV</sup> complexes containing the *o*-benzenedithiolate ligands as doubly-charged anions were also studied by X-ray diffraction.<sup>70</sup> These results and the data published in the literature<sup>71</sup> have made it possible to propose structural criteria for assigning such ligands in complexes to a particular oxidation state.

The synthesis of a series of azo-coupled metal dithiolenes **18–20** containing Ni<sup>II</sup>, Pd<sup>II</sup> and Pt<sup>II</sup> and bis(diphenylphosphino)ethane (dppe) as an additional ligand and the synthesis of anionic nickel complex **21** were documented.<sup>72</sup>

M = Ni, Pd, Pt; R = H, Me, Cl, OMe.

All these complexes were studied by X-ray diffraction.<sup>65, 73, 74</sup> These complexes were electrochemically reduced. In the study,<sup>72</sup> it was hypothesised that the metal atom in the nickel complexes undergoes reversible one-electron reduction, whereas reduction of the platinum and palladium complexes is a reversible two-electron process, though it also involves the metal atom.

The electronic structures of the bis(*o*-benzenedithiolato)Au(III) anion and its neutral one-electron oxidised form were determined.<sup>65</sup> Earlier, the latter was described (based on poor-quality X-ray diffraction data) as an Au<sup>IV</sup> complex containing the central gold atom in the *d*<sup>7</sup> configuration.<sup>72</sup> Poor-quality X-ray diffraction data were also obtained for compounds containing the [AuL<sub>2</sub>]<sup>−</sup> anion (L is deprotonated *o*-benzenedithiol),<sup>75–79</sup> but these data did not provide unambiguous evidence for the true structure of the ligand in the complexes. More recently,<sup>74</sup> the neutral [AuL<sub>2</sub>] complex was demonstrated to be diamagnetic, and DFT calculations for the isolated molecule of this complex confirmed that the HOMO and LUMO are virtually purely bonding and antibonding combinations of the HOMO of the ligands, respectively.<sup>80</sup> This is possible only in the presence of the diamagnetic Au<sup>III</sup> ion in the *d*<sup>8</sup> electronic configuration, but this fact was not confirmed experimentally.

The square-planar diamagnetic Au<sup>III</sup> complexes with 3,6-di-*tert*-butylbenzene-1,2-dithiolate are oxidised with iodine in acetone to form neutral paramagnetic complexes of the corresponding *o*-dithiobenzosemiquinonate radical (the facts that the ligand

is oxidised and the reaction does not afford an Au<sup>IV</sup> complex were unambiguously established by Mössbauer, UV-Vis and ESR spectroscopy).<sup>65</sup> Analogous complexes containing the unsubstituted ligand (H<sub>2</sub>L is *o*-benzenedithiol), (NBu<sub>3</sub>H)[AuL<sub>2</sub>] and AuL<sub>2</sub>, were synthesised and characterised by X-ray diffraction. Taking into account the electronic structures of the paramagnetic neutral Au(L<sup>Bu</sup>)<sub>2</sub> and AuL<sub>2</sub> complexes, it was demonstrated<sup>65</sup> that these complexes contain the Au<sup>III</sup> ion (*d*<sup>8</sup>, *S* = 0) coordinated by two sulfur atoms of the *o*-dithiolate anion and the *o*-dithiobenzosemiquinonate(1<sup>−</sup>)  $\pi$ -radical, resulting in the ground state with *S* = 1/2. This fact was confirmed by the results of UV-Vis, IR and ESR spectroscopy.

#### 4. Dithiolene complexes

Quantum-chemical calculations demonstrated that the HOMO of dithiolene complexes is localised virtually completely on the ligand; consequently, the ligand should be oxidised in these reactions.<sup>81</sup> Transition metal dithiolene complexes, like the above-described *o*-benzenedithiol complexes, are characterised by the existence of a series of forms related to each other by reversible one-electron oxidation and reduction steps (M = Ni, Pd or Pt).<sup>82–84</sup>

The end members of the series are diamagnetic, whereas the singly-charged anion is a radical. The existence of singly- and doubly-charged cations was also assumed, the latter cation containing M<sup>II</sup> coordinated by two 1,2-dithione-type ligands. However, these cations have not been detected. The oxidation states of the metals and ligands are presented in Scheme 2.<sup>85</sup>

The non-innocent nature of the dithiolene ligands has been studied in considerable detail.<sup>86–90</sup> The structural changes in nickel complexes resulting from the transformation from one oxidation state to another were discussed in the study.<sup>85</sup> Both the reduced (anionic dithiolate) and oxidised (neutral dithiolene) forms of this ligand give stable complexes with transition metals. The latter form is more adequately described as a complex containing two radical-anionic ligands rather than by two resonance structures.

Scheme 2

Different members of the redox series under consideration (primarily for  $M = \text{Ni}$ ) were either isolated or generated in solution by chemical or electrochemical reactions. For example, the  $[\text{Ni}\{\text{S}_2\text{C}_2(\text{CN})_2\}]^{2-}$  and  $[\text{Ni}\{\text{S}_2\text{C}_2(\text{CN})_2\}]^-$  complexes were characterised in early studies.<sup>91,92</sup> More recently,  $[\text{Ni}(\text{S}_2\text{C}_2\text{Et}_2)]^-$  ( $z = 0, 1-$ ),  $[\text{Ni}\{\text{S}_2\text{C}_2(\text{CF}_3)_2\}]^-$  ( $z = 0, 1-, 2-$ ) and  $[\text{Ni}(\text{S}_2\text{C}_2\text{Ph}_2)]^-$  ( $z = 0, 1-, 2-$ ) were isolated in individual form (see Ref. 85 and references cited therein).

Calculated data on the electronic structures of the complexes were confirmed by the results of ESR spectroscopy for molybdenum-containing compounds **22** and **23** and the results of electrochemical investigations on molybdenum and tungsten complexes.<sup>93,94</sup>

$M = \text{Mo}, \text{W}$ .

Neutral organoantimony dithiolene complex **24**<sup>81</sup> was synthesised by adding  $\text{PhSbCl}_2$  to  $\text{Na}_2(\text{dmit})$  (dmit is 4,5-dithiolato-1,3-dithiole-2-thione).

The complex was characterised by spectroscopy (NMR and IR) and X-ray diffraction.

The dithione–dithiolate resonance cannot occur in nickel, palladium and platinum bis(*S*-benzyl-1,2-diphenylethylene-1,2-dithiolate) complexes **25**, and these compounds are ‘classical’ planar  $M^{\text{II}}$ -containing complexes.<sup>95</sup> However, irradiation of these complexes with visible light leads to successive elimination of both benzyl radicals from the ligand. Elimination of the first  $\text{CH}_2\text{Ph}^\bullet$  radical gives rise to radical complex **26**, in which 77%–94% of spin density is delocalised on the ligand depending on the nature of the metal. The latter radical complex decomposes in the dark to give the corresponding dithiolene complex **27** within approximately  $10^3$  s.

$M = \text{Ni}, \text{Pd}, \text{Pt}$ .

The spectroscopic [ESR, ENDOR, X-ray absorption spectroscopy, electron spin echo (ESE)] and calculated (DFT) data on nickel dithiolene complexes and their anionic species were summarised in the study.<sup>96</sup> According to these data, all nickel bis(dithiolene) complexes are characterised by back bonding, e.g., the energy of the valence orbitals of the ligands is higher than that of the d orbitals of the metal. A high energy of  $\pi$  orbitals of the ligand and good overlap of these orbitals with the Ni 3d

orbitals are responsible for the efficient ligand  $\rightarrow$  metal electron transfer.

The lowest bonding molecular orbital of nickel complexes in all three oxidation states has more than 50% s-character; in the doubly-charged anionic complex, the LUMO is an antibonding combination of the Ni 3d<sub>xy</sub> orbital (~25%) and the b<sub>1g</sub>-symmetry S 3p<sub>x+y</sub> orbital (~75%). The singly-occupied molecular orbital (SOMO) of the singly-charged anionic complex is an antibonding combination of the Ni 3d<sub>xz</sub> orbital (~25%) and the b<sub>2g</sub>-symmetry S 3p<sub>z</sub> orbital (59%), whereas the LUMO is analogous to the corresponding orbital of the doubly-charged anionic complex. In the neutral complex, both the in-plane (b<sub>1g</sub>) and out-of-plane (b<sub>2g</sub>) orbitals are unoccupied and include ~20% of the Ni 3d orbital. On the whole, the singly-charged anionic complex is characterised by localisation of the unpaired electron predominantly on the sulfur atom.

## 5. Magnetic properties of radical-ionic cyclopentadienyldithiolene complexes in the solid state

The ability of many non-innocent dithiolene square-planar  $[\text{M}^{\text{II}}(\text{S}_2\text{C}_2\text{R}_2)_2]^{2-}$  complexes to be reversibly oxidised in two steps, i.e., to exist in distinct oxidation states, allows the isolation of open-shell radical-anionic compounds (for example,  $[\text{Ni}\{\text{S}_2\text{C}_2(\text{CN})_2\}]^-$ ). In these compounds, efficient spin delocalisation over ligands is favourable for interactions in the solid state with a singlet–triplet, ferromagnetic or antiferromagnetic ground state. These complexes are of interest in materials science as potential solid materials with unique electronic properties, such as molecular metals, superconducting materials and magnetic crystals.<sup>18</sup>

In 1986, Cassoux *et al.*<sup>97</sup> discovered superconductivity of mixed-valence salts containing  $[\text{Ni}(\text{dmit})_2]^-$ , which gave rise to an outburst of activity in the field of synthesis of square-planar dithiolene complexes (with various new dithiolate ligands, different metals, two different dithiolene ligands or tetrathiafulvalene-based dithiolenes), nonplanar  $\text{CpCo}(\text{mnt})$  (mnt is maleonitrile-2,3-dithiolate),  $\text{Cp}_2\text{Ti}(\text{bdt})$  (bdt is benzene-1,2-dithiolate) complexes and the wedge-shaped sandwich complex  $\text{Cp}_2\text{Nb}(\text{dmit})$ .<sup>18</sup>

Dithiolene complexes have attracted widespread attention due to their analogy with the so-called molybdo- and tungstoenzymes (cofactors of oxomolybdoenzymes).<sup>98</sup> Different steps of the catalytic cycle during redox reactions of these enzymes involve conformational changes, in which non-innocent dithiolene complexes play a key role. Examples of such compounds are the structures of W- and Mo-containing (fragment) cofactors of aldehyde oxidoreductases from bacteria *Picrococcus furiosus* and *Desulfovibrio gigas* with one and two dithiolene fragments, respectively.

Based on the results of investigations of mixed complexes containing the dithiolene and Cp ligands, these complexes were classified into three groups.<sup>18</sup> The first group includes complexes generating radicals, in which the spin is completely or almost completely localised on the ligand. Examples are the trivalent cobalt complexes  $\text{CpCo(dmit)}$  and  $\text{Cp}^*\text{Co(dmit)}$ , where  $\text{Cp}^*$  is the pentamethylcyclopentadienyl anion. Oxidation of these diamagnetic complexes with bromine results in the formation of the bromide ion that is involved in the metal coordination sphere.

Studies by ESR demonstrated that the spin is localised predominantly on the dmit ligand and the paramagnetic  $\text{Cp}^*\text{Co(dmit)Br}$  complexes interact with the adjacent molecules *via*  $\text{S}\cdots\text{S}$  contacts to form homogeneous chains, which are adequately described by the Heisenberg antiferromagnetic chain model with large negative coupling between the radicals along the chain ( $J/k = -46.3 \text{ K}$  or  $32 \text{ cm}^{-1}$ ).

Upon oxidation of  $\text{Cp}^*\text{Co(dddt)}$  (dddt is 5,6-dihydro-1,4-dithiine-2,3-dithiolate) with  $\text{AgBF}_4$ , the  $\text{BF}_4^-$  anion is not coordinated, and the  $[\text{Cp}^*\text{Co(dddt)}]^+$  radical cation is unstable and is dimerised to the diamagnetic doubly-charged  $[\text{Cp}^*\text{Co(dddt)}]_2^{2+}$  cation. The sulfur atoms of the six-membered ring are involved in the coordination sphere of the adjacent cation to form a two-electron bond, *i.e.*, complete spin localisation on the dddt ligand leads to its coupling in the antibonding combination of two singly-occupied MOs.<sup>99</sup>

In both examples, intermolecular coupling occurs due to overlap of orbitals of different dithiolene fragments, and, if a covalent bond between the radicals is absent or this bonding can be precluded, the molecules possess properties of considerable interest in applied studies.

The second group includes complexes which form compounds containing an open-shell metal atom. Examples are the  $d^1$ -complexes  $\text{Cp}_2\text{V(dt)}$  and  $\text{Cp}_2\text{Nb(dt)}$  (dt is dithiolene). The  $d^0$ -complexes  $\text{Cp}_2\text{Ti(dt)}$  do not form stable radical ions. They are reduced at strongly negative potentials and are reversibly oxidised.<sup>100</sup> However, uranium can be transformed into the oxidation state  $\text{U}^V$ , and, although the neutral  $\text{Cp}_2\text{U(dddt)}$  complex does not form stable radical species, oxidation of  $[\text{U}^V(\text{cot})(\text{dddt})]$  (cot is cyclo-octatetraene) with  $\text{AgBF}_4$  affords the  $[\text{U}^V(\text{cot})(\text{dddt})]^-$  radical anion [salt with  $\text{Na(18-crown-6)(THF)}$ ]. The bond lengths in the dddt ligand of the radical anion are only slightly different from those in the starting doubly-charged anionic complex or in  $\text{Cp}_2\text{Ti(dddt)}$ , *i.e.*, the metal is subjected to oxidation to  $\text{U}^V$ . In the solid state, the spins are uncoupled.

Complexes of the third group, in which the unpaired electron is shared by the metal and the ligand, are intermediate between complexes of the first and second groups (an unpaired electron is

completely localised on either the ligand or the metal). Examples are molybdenum and tungsten  $d^1$ -complexes of the  $[\text{Cp}_2\text{M(dt)}_2]^+$  type. The  $\text{Cp}_2\text{Mo(dt)}$  ( $\text{Mo}^{\text{IV}}$ ,  $d^2$ ) complexes give reversible oxidation waves.<sup>101,102</sup> The  $\text{Cp}_2\text{Mo(dddt)}$  complex is oxidised by 7,7,8,8-tetracyanoquinodimethane (TCNQ), while  $\text{Cp}_2\text{Mo(dmit)}$  is oxidised by the strong acceptor,  $\text{TCNQF}_4$ , to form the corresponding radical-ionic salts  $\text{Cp}_2\text{Mo(dddt)}^+\text{TCNQ}^-$  and  $\text{Cp}_2\text{Mo(dmit)}^+\text{TCNQF}_4^-$ . Electrocrystallisation<sup>103</sup> afforded the  $\text{Cp}_2\text{Mo(dmit)}^+$  salts with different anions: monoatomic ( $\text{Br}^-$ ), tetrahedral ( $\text{BF}_4^-$ ,  $\text{ClO}_4^-$ ), octahedral ( $\text{PF}_6^-$ ,  $\text{AsF}_6^-$ ,  $\text{SbF}_6^-$ ) and more complex ( $\text{ReO(dmit)}_2^-$ ) anions. The most interesting result obtained in these investigations is the variability in the geometry of the  $d^1$ -radical cation and, particularly, in the puckering angle ( $\theta$ ) of the five-membered metallacycle with respect to the  $-\text{S}\cdots\text{S}-$  'hinge'.

The puckering angle varies from 0 to  $30^\circ$  depending on the nature of the ligand as exemplified by the  $\text{Cp}_2\text{Mo(dmit)}^+$  cation in Table 1 (see Ref. 18 and references cited therein).

**Table 1.** The puckering angle ( $\theta$ ) of the  $\text{MoS}_2\text{C}_2$  metallacycle and the C—S and C=C bond lengths in selected molybdenum and titanium complexes.

| Compound                                                                                | $\theta/\text{deg}$ | C—S / Å | C=C / Å |
|-----------------------------------------------------------------------------------------|---------------------|---------|---------|
| $\text{Cp}_2\text{Mo(dmit)}$                                                            | 4.2                 | 1.745   | 1.357   |
| $[\text{Cp}_2\text{Mo(dmit)}^+]\text{PF}_6^-$ (or $\text{AsF}_6^-$ , $\text{SbF}_6^-$ ) | 0.0                 | 1.691   | 1.41    |
| $[\text{Cp}_2\text{Mo(dmit)}^+][\text{ReO(dmit)}_2^-]$                                  | 5.6                 | 1.688   | 1.383   |
| $[\text{Cp}_2\text{Mo(dmit)}^+]\text{TCNQF}_4^-$                                        | 10.2                | 1.684   | 1.43    |
| $[\text{Cp}_2\text{Mo(dmit)}^+]\text{BF}_4^-$                                           | 23.21               | 1.718   | 1.360   |
| $[\text{Cp}_2\text{Mo(dmit)}^+]\text{Br}^-$                                             | 30.45               | 1.712   | 1.385   |
| $\text{Cp}_2\text{Ti(dt)}$                                                              | 43–51               |         |         |

Similar puckering (even to a larger extent) was observed for the titanium  $d^0$ -dithiolene complexes (see Table 1). The reason is that puckering allows the free  $d^0$  orbital of the  $\text{Cp}_2\text{Ti}$  fragment to be mixed with the HOMO of dithiolene, resulting in stabilisation of the  $d^0$  system. This mixing is impossible at  $\theta = 0^\circ$  due to symmetry mismatch between the  $d^0$  orbital and the HOMO in this conformation. According to this theory, puckering for the  $d^2$  complexes  $\text{CpMo(dt)}$  is absent, which was confirmed experimentally.<sup>18</sup>

Great puckering was observed for 'heavier' complexes,<sup>18</sup> for example, upon the replacement of Mo with W, S with Se in the ligand or both elements simultaneously. This fact is consistent with the results of DFT calculations.<sup>104</sup> For example, electrocrystallisation of  $\text{Cp}_2\text{Mo(dsit)}$  and  $\text{Cp}_2\text{W(dmit)}$  (dsit is 1,3-dithiole-2-thione-4,5-diselenolate, a selenium analogue of dmit) in the presence of  $\text{AsF}_6^-$  affords isostructural salts with  $\theta = 0^\circ$ , whereas heavier  $\text{Cp}_2\text{W(dsit)}$  gives a radically different structure with  $\theta = 30.1^\circ$ .<sup>104</sup>

A strongly puckered conformation cannot exist in structurally rigid *ansa*-metallocene dithiolene complexes, and, hence, oxidation of the unpuckered  $d^2$  complexes  $\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)_2\text{Mo(dmit)}$  and  $\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)_2\text{W(dmit)}$  ( $\theta_{\text{Mo}} = 0.68^\circ$ ,  $\theta_{\text{W}} = 0.29^\circ$ ) in  $\text{TCNQF}_4$  salts results in weak puckering ( $\theta_{\text{Mo}} = 7.35^\circ$ ,  $\theta_{\text{W}} = 6.99^\circ$ ).<sup>105</sup>

An increase in the puckering angle is indicative of enhancement of interactions between the frontier orbitals of the metal-locene and dithiolate fragments, with the result that the unpaired electron is shared by the ligand and the metal (more precisely, by the  $\text{Cp}_2\text{M}$  fragment). Therefore, the non-innocent character is not an indication of only a redox-active ligand. If there is strong mixing of the ligand and metal orbitals, the non-innocent behaviour characterises the complex as a whole (oxidation states of the metal or the ligand are difficult to determine).

The formation of crystals of radical-cationic  $d^1$  complexes in the presence of various anions involves a fine balance between the degree of intramolecular puckering, intermolecular spin-spin coupling and the counterion size aimed at decreasing the crystal free energy. Variations in the spin density on the dithiolene fragment and the crystal structure of the  $\text{Cp}_2\text{M}(\text{dt})^+\text{X}^-$  salts would be expected to change the magnetic properties of the substance in the solid state, because the latter are controlled by the strength of the  $\text{dt}\cdots\text{dt}$  and  $\text{dt}\cdots\text{Cp}$  intermolecular interactions. For the complexes under consideration, the following two main structural motifs were suggested: diads, which are associated with each other to a greater or lesser degree, or extended three-dimensional structures. Below are shown the possible models of interactions between the diads: uniform ( $\alpha = 1$ ) and alternate ( $0 < \alpha < 1$ ) chains and the so-called 'spin ladders'.<sup>18</sup>

Each circle indicates a spin carrier, and each line corresponds to interactions;  $J$  and  $\alpha J$  characterise interactions between the radicals along the chain. For example, the radical cations in the isostructural  $[\text{Cp}_2\text{Mo}(\text{dddt})][\text{TCNQ}]$  and  $[\text{Cp}_2\text{W}(\text{dddt})][\text{TCNQ}]$  complexes are actually arranged as diads with short  $\text{S}\cdots\text{S}$  contacts. These diads are not isolated from each other, but form alternate chains ( $0 < \alpha < 1$ ). The alternate chains are characterised by the following parameters:  $J_{\text{Mo}}/k = -26 \text{ K}$  ( $18 \text{ cm}^{-1}$ ),  $\alpha_{\text{Mo}} = 0.0\text{--}0.2$ ,  $J_{\text{W}}/k = -16 \text{ K}$  ( $11 \text{ cm}^{-1}$ ),  $\alpha_{\text{W}} = 0.5\text{--}0.6$ . Interactions between the molybdenum diads are stronger than those between the tungsten diads, which is attributed to a greater localisation of the spin on the metal in the tungsten complex. The interaction is antiferromagnetic ( $J < 0$ ) due to direct exchange interaction between SOMOs.

The model of a uniform chain ( $\alpha = 1$ ) is better applicable to  $[\text{Cp}_2\text{Mo}(\text{dsit})][\text{TCNQF}_4]$ , whereas  $[\text{Cp}_2\text{W}(\text{dsit})][\text{TCNQF}_4]$  is more adequately described by an alternate chain with  $\alpha = 0.5$ . Examples of molecular spin ladders are  $[\text{Cp}_2\text{Mo}(\text{dmid})][\text{TCNQF}_4]$  (dmid is 1,3-dithiol-2-one-4,5-dithiolate)<sup>106</sup> and  $[\text{Cp}_2\text{W}(\text{dsit})]\text{AsF}_6$ .<sup>104</sup> In these salts, the diads formed by two organometallic cations are arranged one above another to form a ladder-like system ( $|J_{\perp}| > |J_{\parallel}|$ ). In this case, stronger intermolecular interactions also occur in the molybdenum compounds, because the SOMO in molybdenum salts is localised to a larger degree on the dithiolene fragment compared to the tungsten complexes.

## 6. Non-innocent behaviour of thiolate ions

The results of experimental and calculated studies suggest that the HOMO of many metal thiolates is centred on the sulfur atom and has the character of its  $p$  orbital (see Ref. 107 and references cited therein). Hence, many reactions of transition metal thiolates, including redox reactions, would be expected to occur at the

sulfur atom. Oxidation of thiolate complexes gives rise to thiolate radicals.

The oxidation states of the Ni cofactor  $\text{F}_{430}$  in methyl coenzyme M reductase were studied<sup>108</sup> by magnetic circular dichroism, X-ray absorption spectroscopy and DFT calculations, and it was hypothesised that the oxidised state of the enzyme containing the Ni-SR bond can formally be described as a  $\text{Ni}^{\text{II}}$  complex with the thiyl radical ( $^{\bullet}\text{SCoM}$ , CoM is the coenzyme M).

This state can alternatively be described as  $\text{Ni}^{\text{III}}$  thiolate, but this description is less probable. Earlier, an analogous non-innocent behaviour of sulfur-containing ligands (S-centred radical, thiolate) was assumed in biochemistry.<sup>109</sup>

## 7. Complexes of *o*-aminophenols

Like other compounds belonging to the  $o\text{-XC}_6\text{H}_4\text{Y}$  structural type (X, Y = O, S or NH), *o*-aminothiophenols are classical non-innocent ligands. Ligands in complexes with V, Cr, Fe and Co and the corresponding catecholate, *o*-phenylenediamine and *o*-benzenedithiolate complexes can be assigned to a particular oxidation state on the basis of the structural criteria proposed in the study.<sup>110</sup> Complexes of *o*-aminophenol and its substituted analogues  $\text{H}_2\text{L}^1$  (see Refs 9 and 110) and  $\text{L}^2$  (see Refs 111 and 112) with  $\text{Fe}^{\text{III}}$ ,  $\text{Ni}^{\text{II}}$ ,  $\text{Co}^{\text{III}}$ ,  $\text{Pd}^{\text{II}}$  and  $\text{Cu}^{\text{II}}$  were documented. In these complexes, the ligand is present as the singly-charged anionic *o*-iminosemiquinone radical.

The  $\text{Co}^{\text{III}}(\text{L}^{\text{ISQ}1})_3$  (**28**),  $[\text{Cu}(\text{dmtacn})\text{L}^{\text{ISQ}1}]\text{PF}_6$  (**29**),  $\text{Cu}(\text{L}^{\text{ISQ}1})_2$  (**30**),  $\text{Ni}(\text{L}^{\text{ISQ}1})_2$ ,  $\text{Ni}(\text{ClL}^{\text{ISQ}1})_2$  and  $\text{Pd}(\text{L}^{\text{ISQ}1})_2$  compounds ( $\text{L}^{\text{ISQ}1}$  and  $\text{ClL}^{\text{ISQ}1}$  are  $\text{L}^1$  and  $\text{ClL}^1$ , respectively, in the semiquinone form, dmtacn is 1,4-dimethyl-1,4,7-triazacyclononane) were studied by X-ray diffraction.<sup>9</sup> The central metal atoms in copper complex **30** and divalent nickel and palladium complexes are in a square-planar environment. The ground state of complex **29** is  $S = 1$ , which is associated with the strong antiferromagnetic coupling between the  $\text{Cu}^{\text{II}} d_{x^2-y^2}$  orbital and the  $\pi$  orbital of the radical ligand. Complex **28** contains three virtually orthogonal semiquinone ligands  $\text{L}^{\text{ISQ}1}$ , and its ground spin state is  $S = 3/2$ . Other complexes are singlet biradicals, the central divalent metal atoms in these complexes have the  $d^8$  configuration, and the complexes are diamagnetic. A detailed study of electrochemical oxidation and reduction of all five complexes revealed a series of reversible one-electron steps, all processes occurring at the ligand.

For the HL<sup>1</sup> ligand (Ar = Ph)<sup>110</sup>

complexes with  $\text{Cr}^{\text{III}}(\text{L}^{\text{ISQ1}})_3$  (**31**),  $\text{Co}^{\text{III}}(\text{L}^{\text{ISQ1}})_3$  (**32**) and  $\text{Fe}^{\text{III}}(\text{L}^{\text{ISQ1}})_3$  (**33**) and a series of vanadium complexes, including  $\text{V}^{\text{V}}\text{L}^{\text{ISQ1}}(\text{L}^{\text{API}})_2$  (**34**) and  $\text{V}^{\text{V}}(\text{L}^{\text{API}})_2(\text{HL}^{\text{API}})$  (**35**), were described. All five compounds **31**–**35** were characterised by X-ray diffraction.

The electrochemical behaviour of the above-mentioned complexes was accounted for by redox processes involving both the metal and the ligand depending on the nature of the metal in the complex. For example, all redox processes in chromium complex **31** involve exclusively the ligand.

By contrast, the metal atom in vanadium complex **34** is reduced in the second and third steps, and, in addition, highly oxidised members of the redox series are electrochemically inaccessible.

The diamagnetic  $\text{LRu}^{\text{II}}(\text{acac})_2$  complexes (**36a,b**) [**L** is *o*-iminoquinone (**36a**) or *o*-iminothiosemiquinone (**36b**); compound **36a** was characterised by X-ray diffraction<sup>113</sup>] are irreversibly oxidised or reduced by electrochemical methods to form paramagnetic singly-charged cations and anions. Electrochemical, calculated and spectroscopic data demonstrated that the ligand is subjected to oxidation and reduction (below the acac ligands are omitted for simplicity; possible alternative formulae of the compounds are given in parentheses).

$$X = O(\mathbf{a}), S(\mathbf{b}).$$

*N,N'*-Bis[2-(4,6-di-*tert*-butyl)hydroxyphenyl]diethylenetriamine **37** was studied in complexation reactions with first-row transition metals (vanadium, chromium, iron and cobalt).<sup>110</sup> The resulting

complexes containing ligands in the above-mentioned three forms were studied in detail by electrochemical and spectroelectrochemical methods. The vanadium complex  $V^{VO}[(HL^{AP})NH(L^{AP})]$  with the triply-charged anion **37b** as the ligand was studied by X-ray diffraction.

## 8. Complexes of *o*-aminothiophenols and their selenium- and tellurium-containing analogues

Neutral square-planar  $\text{Ni}^{\text{II}}$ ,  $\text{Pd}^{\text{II}}$  and  $\text{Pt}^{\text{II}}$  bis(*o*-iminothioseminquinonate) complexes were synthesised and characterised. Being singlet biradicals, these complexes are diamagnetic. The reaction of *o*-aminothiophenols with  $\text{M}^{2+}$  salts in ethanol or acetonitrile in air produced both complexes with ligands containing the unsubstituted benzene ring<sup>46, 114–116</sup> and black-blue complexes based on 6-amino-2,4-di-*tert*-butylthiophenol.<sup>12, 117</sup> The structures of all the complexes synthesised were confirmed by NMR, UV-Vis and ESR spectroscopy and, in most cases, by X-ray diffraction analysis. The NMR spectra suggest that the *cis* and *trans* forms **A** and **B** of the complexes with di-*tert*-butyl-substituted ligands are in rapid equilibrium in solution.

$$\text{M} = \text{Ni}^{\text{II}}, \text{Pd}^{\text{II}}, \text{Pt}^{\text{II}} (\text{A}, \text{B}); \text{M} = \text{Ni}^{\text{II}}, \text{Pd}^{\text{II}} (\text{C}).$$

Both the *cis* and *trans* forms of the complexes were isolated and studied by X-ray diffraction analysis. The *cis*–*trans* transformation is fast in the case of Ni and slow in the case of Pt, whereas the rate of this transformation in the case of Pd is intermediate. It should be noted that the beige-yellow ‘classical’ complex **C** is derived from *o*-aminothiophenols and  $M^{2+}$  salts under inert atmosphere.

Spectroelectrochemical and electrochemical studies of the complexes **A** and **B** revealed a usual electron-transfer series, in which a singly-charged cation, a neutral species and singly- or doubly-charged anions were identified.<sup>13</sup> The ESR spectra of singly-charged cations of the nickel and platinum complexes confirmed that only the ligand is oxidised to form  $[\text{M}^{\text{II}}(\text{L}^{\text{ISQ}})(\text{L}^{\text{IBQ}})]^+$ , where  $\text{L}^{\text{IBQ}}$  is *o*-iminothioquinone. In contrast, the structures of the complexes for the corresponding singly-charged anions are most adequately described by the  $[\text{M}^{\text{II}}(\text{L}^{\text{ISQ}})$ .

$(L^{AP})^-$  and  $[M^I(L^{ISQ})_2]^-$  resonance structures, the contribution of the latter being considerable ( $L^{AP}$  is the doubly-charged *o*-imidothiophenolate anion).

The *o*-iminothiosemiquinonate radical is characterised by two intense  $\pi-\pi^*$ -charge transfer bands in the visible region of the UV-Vis spectra at  $\sim 640$  and  $560$  nm and by an intense ligand–ligand charge transfer band at the boundary between the visible and near-IR regions at  $730-840$  nm in the IR spectra.<sup>12</sup>

Analysis of the literature data on the geometric features of 120 complexes containing *o*-aminothiophenolate-type ligands<sup>12</sup> made it possible to propose criteria for the determination of the degree of protonation and oxidation of the ligands in these complexes. As in the *o*-phenylenediamine and *o*-catecholate complexes, the C–N and C–S bond lengths and the C=C bond lengths in the benzene ring are very characteristic. The bond lengths in the ligand are virtually independent of the nature of the coordinated metal. The radical form ( $L^{ISQ}$ ) of non-innocent *o*-aminothiophenolates is the major one in coordination compounds.

In 1997, a series of complexes **38** containing five-coordinate iron atoms and *o*-amidothiophenolate ligands were synthesised and characterised by X-ray diffraction and spectroscopic methods.<sup>118</sup>

R = Me, Et, Pr<sup>n</sup>, Bu<sup>n</sup>, Ph, cyclo-C<sub>6</sub>H<sub>11</sub>, OMe, OPh.

In the study,<sup>118</sup> the ligand was considered as the redox-innocent quadruply-charged 1,2-ethanediamido-*N,N'*-bis(2-benzenethiolate)<sup>4-</sup> anion, and the complex as a whole was described as an Fe<sup>IV</sup> complex ( $S = 1$ ) (**A**). This structure is consistent with the magnetic moment of  $2.76 \mu_B$  observed for this complex at room temperature and the data from cyclic voltammetry (reversible reduction of the complex at  $+0.04$  and  $-0.86$  V, which were assigned to the Fe<sup>IV</sup>/Fe<sup>III</sup> (**A/B**) and Fe<sup>III</sup>/Fe<sup>II</sup> (**B/C**) transitions, respectively) and Mössbauer spectroscopy, although a complete analysis of the latter spectrum was lacking.

However, the studies<sup>12, 119</sup> cast doubt on this description of the structures. In the study,<sup>119</sup> it was demonstrated that the bond lengths in this class of complexes determined by X-ray diffraction analysis are typical of complexes of the *o*-iminothiosemiquinonate radical, the physical oxidation state of iron in the complex is  $+2$  (structure **C**), and the spin  $S = 1$  observed for the ground state of the complex is attributed to strong intramolecular antiferromagnetic coupling between two organic radicals and the low-spin iron ion. Analysis of the spin-Hamiltonian<sup>12</sup> confirmed this assumption. Ghosh *et al.*<sup>119</sup> reproduced the experiment performed earlier by Sellmann *et al.*<sup>118</sup> and demonstrated that only the freshly prepared complex had the magnetic moment of  $2.76 \mu_B$ , whereas this value decreased to  $0.6 \mu_B$  after two crystallisations.

Analogous iron complexes containing the di-*tert*-butyl-substituted *o*-iminothiosemiquinonate fragments were described in the study.<sup>119</sup> The binuclear  $(\mu-NH, NH)[Fe^{III}L^{IP}L^{ISQ}]_2$  (**39**) and  $(\mu-S, S)[Fe^{III}L^{IP}L^{ISQ}]_2$  complexes (**40** and **41**) and the mononuclear  $Fe^{III}(L^{ISQ})_2[P(OPh)_3]$  complex (**42**) were synthesised and characterised by X-ray diffraction analysis.

The oxidation state of the ligands was established by X-ray diffraction and ESR, UV-Vis and Mössbauer spectroscopy.

Dimeric complexes **43–46** were synthesised under inert atmosphere in a neutral medium, *i.e.*, under conditions precluding deprotonation.<sup>120</sup>

Complexes **43–45** are sensitive to atmospheric oxygen and moisture and are transformed into the  $[\text{Fe}(\text{L}^{\text{ABT}})_2\text{L}^{\text{ISQ}}]$  complex ( $\text{L}^{\text{ABT}}$  is the *o*-aminobenzothiolate anion) in the presence of traces of oxygen. The latter complex is characterised by the ground spin state  $S = 3/2$ . Dimers **47a,b** are produced in the presence of  $\text{Et}_3\text{N}$  and traces of  $\text{O}_2$ .

The structures of compounds **44**, **46** and **47a** were determined by X-ray diffraction. Mössbauer spectra of compounds **43–45** unambiguously established the presence of the high-spin iron ion, whereas both medium-spin Fe ions ( $S_{\text{Fe}} = 3/2$ ) in dimers **47a,b** are antiferromagnetically coupled, resulting in the ground state  $S = 0$ .

Di- and trivalent cobalt complexes with the same ligands as in complexes **31–35** and **39–47** were documented.<sup>121</sup> In all the complexes synthesised, the ligands are redox-non-innocent, but oxidation and reduction of either the metal or ligand depend on the state (anionic, radical-anionic or neutral) of the ligand and the oxidation state of the central metal atom in the starting complex.

In 2003, selenium- and tellurium-containing ligands (analogues of *o*-aminothiophenol) were synthesised and their complexes with nickel **48** were prepared by the oxidative addition of 2-aminophenyl dichalcogenides to the  $[\text{Ni}(\text{CO})(\text{SePh})_3]^-$  anion.<sup>122</sup>

$\text{X} = \text{Se}, \text{Te}$

The *trans*- $[\text{Ni}(\text{SeC}_6\text{H}_4\text{NH-}o)_2]^-$  and *cis*- $[\text{Ni}(\text{TeC}_6\text{H}_4\text{NH-}o)_2]^-$  complexes [as salts with the  $(\text{PPh}_3)_2\text{N}^+$  cation] were studied by X-ray diffraction. All complexes were also characterised by X-ray electron spectroscopy and DFT calculations. It was concluded that the singly-charged  $[\text{Ni}(\text{SeC}_6\text{H}_4\text{NH-}o)_2]^-$  and  $[\text{Ni}(\text{TeC}_6\text{H}_4\text{NH-}o)_2]^-$  anions are most adequately described as resonance hybrids of nickel(III) bis[*o*-amidochalcogenolate(2-)] and nickel(II) bis[*o*-iminochalcogenobenzosemiquinonate(1-)].

The delocalisation of the metal d-electrons in ruthenium bis(bipyridyl) complexes with redox-active quinoid ligands  $\text{Ru}(\text{bipy})_2\text{LL}$  was calculated.<sup>123</sup>

$\text{X} = \text{NH}, \text{O}, \text{S}$ .

The results of calculations confirmed by UV-Vis spectra of the compounds synthesised demonstrate that the degree of coupling between the  $\pi$ -orbitals of ruthenium and the LL ligand increases in the series  $\text{NH} < \text{O} < \text{S}$ .

### III. Complexes with diimine-containing ligands

#### 1. Complexes of $\alpha$ -diimines and their phosphorus analogues, 2,2'-biphosphines

Complexes of 1,2-diketone derivatives (**49**) and complexes with ligands in which the diimine fragment is involved in the heterocyclic system (**50**, bipy, etc.) are assigned to this structural type.

$\text{R} = \text{Alk}, \text{Ar}$ .

Complexes of 1,4-disubstituted 1,4-diazabutadienes **49** ( $\text{R} = \text{Bu}^t$ ,  $\text{cyclo-C}_6\text{H}_{11}$ ,  $4\text{-MeC}_6\text{H}_4$  and  $2,6\text{-Me}_2\text{C}_6\text{H}_3$ ) with  $\text{PtMe}_2$ ,  $\text{PtMe}_4$  and  $\text{PtMes}_2$  were studied by spectroscopic methods and DFT calculations.<sup>124</sup> These data suggest considerable metal  $\rightarrow$  ligand charge transfer. The results of spectroelectrochemical studies are consistent with reversible oxidation of the ligand to form the  $[\text{Pt}^{\text{II}}\text{L}]^+$  or  $[\text{Pt}^{\text{IV}}\text{L}]^+$  complexes. The reduction of analogous rhenium,<sup>125</sup> ruthenium, osmium, iridium and rhodium<sup>126</sup> complexes is also most adequately described as the reduction of the ligand to form the radical anion.

In complexes **6a–c** containing the terpyridyl fragment in the ligand (see Section II.1), the diimine fragment also undergoes one-electron reduction in the first step.<sup>24</sup>

Heteronuclear alkynyl-bridged complex **51** and its analogue **52** with oxidised iron (from Fe<sup>II</sup> to Fe<sup>III</sup>) were synthesised and characterised by X-ray diffraction.<sup>127</sup>

Vinylidene complex **53** was also documented.<sup>127</sup> This complex is reversibly oxidised at  $-0.19$  V and quasireversibly reduced at  $-1.49$  V. Electrochemical data and results of DFT calculations suggest that the LUMO of the complex is localised predominantly on the  $\pi^*$  orbital of the bipyridyl ligand, whereas the HOMO has the character of the iron(II) d orbital.

Phosphorus analogues of  $\alpha$ -diimines, in particular, 2,2'-biphosphines, can also be considered as non-innocent ligands. For example, 4,4',5,5'-tetramethyl-2,2'-biphosphine (tmbp) is reduced with potassium mirror to the planar radical anion (studied by X-ray diffraction analysis as a lithium salt), in which the unpaired electron (DFT calculations) is delocalised over the PCCP fragment with a large contribution of the phosphorus  $p_\pi$  orbitals.<sup>128</sup> Electrochemical reduction of the Ni<sup>0</sup>(tmbp)<sub>2</sub> complex afforded a 19-electron complex studied by X-ray diffraction. These data are consistent with the results of DFT calculations, which demonstrated that the unpaired electron in the Ni<sup>0</sup>(bp)<sub>2</sub><sup>•-</sup> complex (bp is 2,2'-biphosphine) is delocalised primarily on the ligand.<sup>128</sup> The calculations showed also that the metal–ligand back bonding in Ni<sup>0</sup>(bp)<sub>2</sub> makes a considerable contribution to the metal–ligand bonding.

## 2. Complexes with ligands of the glyoxalbis(2-mercaptoanil) series

Oxidation and reduction of compounds with ligands of the glyoxalbis(2-mercaptoanil) series, which combine the  $\alpha$ -diimine and *o*-aminothiophenol fragments, were studied for the first time by Holm and co-workers<sup>26,129</sup> in 1960s. They demonstrated that the Ni(gma)<sub>2</sub> compound (**1**), analogously to the N<sub>2</sub>S<sub>2</sub> complexes with ligands of the *o*-disubstituted benzene series, is the central member of the electron-transfer series, the final oxidation product being a quinone complex. Holm and co-workers also described the chemical reduction of Ni(gma)<sub>2</sub> with sodium amalgam to the anionic Ni(gma)<sub>2</sub><sup>•-</sup> species. The radical character of the latter was demonstrated by ESR spectroscopy. When discussing the electron distribution in the starting complex and the degree of mixing of the metal and ligand orbitals, the authors considered the delocalised ground state and did not draw an unambiguous conclusion about localisation of the unpaired electron (on either the metal or the ligand) in the reduced radical-anionic form of the complex.

Complex **1** and other Ni<sup>II</sup> diiminodithiolate and diiminodisulfide N<sub>2</sub>S<sub>2</sub> complexes of this type, *i.e.*, with complete  $\pi$ -conjugation between all four donor centres, were synthesised.<sup>3</sup> These complexes were studied by <sup>1</sup>H NMR, ESR and UV spectroscopy, mass spectrometry and electrochemical methods. In solutions of complex **1** in DMF, the ESR signal first appears and then attenuates with time, which is accompanied by an analogous change in the intensity of the absorption band at 931 nm. The electrochemical behaviour also varies with time. After storage of compound **1** in solution for 5 h, the cyclic voltammogram becomes similar to the curve measured for the corresponding diiminodisulfide complex **54**.

The results of this study suggest that non-innocent compounds of the glyoxalbis(2-mercaptoanil)nickel(II) type were synthesised as classical diiminodithiolate structures, but then the ligands were transformed successively (rapidly in solution and slowly in the solid state) into the *o*-iminothiosemiquinonate biradicals and oligomeric structures, the latter remaining unchanged over a long period of time (Scheme 3).

## 3. Complexes of pyridine-2,6-dialdimine and its derivatives

Most complexes with this ligand were described as the five-coordinate [M<sup>II</sup>X<sub>2</sub>L<sup>0</sup>] complexes or the six-coordinate [M<sup>II</sup>L<sub>2</sub><sup>0</sup>]X<sub>2</sub> complexes (M = Mn, Fe, Co, Ni, Cu, Zn or Cd; X = Cl or Br) containing one or two neutral tridentate ligands; and the ligands were always described as redox-innocent.<sup>130–134</sup> However, more recent studies by electrochemical methods and NMR, ESR and

Scheme 3

Mössbauer spectroscopy demonstrated that pyridine-2,6-dialdimines are non-innocent ligands, which can be coordinated to a transition metal ion as the neutral ligand  $L^0$  or the radical anionic ligand  $L^{-\bullet}$ .<sup>134</sup> This was suggested earlier by Toma and co-workers,<sup>130, 131</sup> but has not been strictly proved.

Metal complexes with pyridine-2,6-dialdimine with the general formula  $[M^{II}L_2](PF_6)_n$  ( $M = Mn, Fe, Co, Ni, Cu$  or  $Zn$ ) are reversibly reduced to  $[ML_2]^+$  and  $[ML_2]^0$ .<sup>135</sup> X-ray diffraction study of  $[MnL_2]PF_6$  and  $[CoL_2]PF_6$  demonstrated that the former complex is  $[Mn^{III}(L^{-\bullet})_2]PF_6$  (reduction of the ligand), whereas the latter complex is  $[Co^IL_2]PF_6$  (reduction of the metal).

$R = 4\text{-MeOC}_6\text{H}_4$ .

#### 4. Complexes with pentane-2,4-dionebis(2-alkylisothiosemicarbazone)-type ligands

Template condensation of pentane-2,4-dione with *S*-alkylisothiosemicarbazide hydrochloride in the presence of divalent metal ions ( $Ni$ ,<sup>136, 137</sup>  $Co$ ,<sup>138</sup>  $Fe$ <sup>139–141</sup>) affords complexes containing pentane-2,4-dionebis(2-alkylisothiosemicarbazone) ( $H_3L$ ) as the ligand (Scheme 4).

This ligand exhibits a complex coordination behaviour towards transition metals, because it, first, can exist in different protonated forms,  $(H_3L)^0$ ,  $(H_2L)^-$ ,  $(HL)^{2-}$  and  $(L)^{3-}$ , and, second, can undergo two-electron oxidation also to two different protonated forms,  $(HL)^0$  and  $(L)^-$ .

Mono- and binuclear nickel complexes with the non-innocent pentane-2,4-dionebis(2-alkylisothiosemicarbazone) ligands exist in two forms containing the ligand in different oxidation states,<sup>142</sup> viz., the red-brown  $Ni^{II}(HL)$  complexes **55** sensitive to oxidation with atmospheric oxygen and the paramagnetic black-green oxidised  $Ni(L-L)Ni$  complexes **56** (in this formula, the nickel atom is in the formally trivalent oxidation state; however, in the real complex studied by X-ray diffraction, the ligand is apparently oxidised and the nickel atom is reduced to the oxidation state of +2).

$R = Me, n\text{-dodecyl}$ .

Both oxidation and reduction of the dinuclear complex occur with the involvement of the ligand and with retention of the oxidation state of the nickel atoms.

#### 5. Complexes of bis(arylimino)acenaphthenes

In recent years, bis(arylimino)acenaphthenes (Ar-BIAN) have attracted considerable attention. Their complexes with transition metals can serve as catalysts for some reactions of organic compounds.<sup>143–151</sup>

Compared to other diimine ligands, BIAN derivatives are more rigid molecules (due to the presence of the naphthalene fragment), and this rigidity provides, first, the directionality of the lone electron pairs of the nitrogen atoms favourable for coordination and, second, almost complete inertness to hydrolysis and cleavage of the central C–C bond.<sup>151</sup> (Hydrolysis presents a serious problem in reactions with the use of most diimine ligands as catalysts.)

The neutral  $(Ar-BIAN)ML_n$  complex can *a priori* be represented as a compound of either zero-valent metal **57a** or divalent metal **57b**, i.e., this complex is non-innocent.

Scheme 4

● is a metal ion.

The reactions of Ar-BIAN with zero-valent transition metals generally give rise to diimine structures. An example is palladium complex **58**<sup>146</sup> (the bond lengths are given in Å; dba is dibenzylideneacetone).

Alkali and alkaline-earth metals react with Ar-BIAN to give diamide complexes **59**.<sup>144, 147</sup>

Ar = 2,6-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; M = Mg, Ca.

| M  | C–N / Å      | C=C / Å |
|----|--------------|---------|
| Mg | 1.401, 1.408 | 1.389   |
| Ca | 1.391, 1.402 | 1.409   |

Complexes with Ar-BIAN are very easily reduced, the ligand being subjected to reduction<sup>148–150</sup> and reduction occurring at much less negative potentials than for other diimine ligands. For example, electrochemical studies demonstrated that Re<sup>I</sup>(Ph-BIAN)(CO)<sub>3</sub>Cl is reduced at potentials (–0.65 V), which are 1 V less negative compared to Re<sup>I</sup>(bipy)(CO)<sub>3</sub>Cl (–1.64 V).<sup>150</sup> This is evidence that the  $\pi$ -acceptor properties of Ar-BIAN are much stronger than those of other diimines.

Chemical reduction of free 2,6-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>-BIAN with Na or Li in ethereal solvents involves the successive formation of the radical anion, the doubly-charged anion, the triply-charged radical anion and, finally, the quadruply-charged anion, which were isolated and studied by UV-Vis spectroscopy and X-ray diffraction.<sup>151, 152</sup> The singly-, triply-, and quadruply-charged anions have dimeric structures.

During reduction, the first two electrons are transferred to the diazadiene fragment, and the next two electrons are transferred to the  $\pi$ -system of the naphthalene moiety.<sup>152</sup>

Undoubtedly, the possibility of four-electron reduction indicates that two almost degenerate LUMOs of Ar-BIAN are very low-lying.

#### IV. Pterin complexes

Yet another group of non-innocent nitrogen-containing ligands includes pterins, pteridines and structurally related alloxazines and flavins. In complexes with these ligands, there is a strong interaction between the transition metal ion and the ligand.<sup>153</sup>

Since the degree of electron delocalisation between the metal and the coordinated pterin varies in different complexes, the problem is to determine the formal oxidation states of the metal and the pterin in each particular complex. Evidently, the molecules of pterin, pteridine and their analogues are redox-active, and generally their coordination to transition metals results in a high degree of electron delocalisation between the metal and the ligand.<sup>153</sup> As in the case of other non-innocent ligands, it is most convenient to determine the redox characteristics of transition metals and ligands in metal pterin and metal pteridine complexes by X-ray diffraction and UV-Vis spectroscopy in the visible range. For molybdenum complexes with pterin ligands, the structural criteria for this assignment were reported in the studies.<sup>154, 155</sup>

In particular, UV-Vis and photoelectron spectroscopy demonstrated that the Mo<sup>V</sup>(H<sub>3</sub>pterin<sup>•</sup>) structure is preferable for the molybdenum complex with tetrahydropterin (a fragment of the complex is shown).<sup>153</sup>

The redox-resonance of analogous structures was suggested in the study<sup>156</sup> for the structures of molybdenum complexes with reduced pterin and flavin. A considerable metal  $\rightarrow$  ligand charge transfer and stabilisation of ruthenium, copper and rhenium complexes with the reduced ligand were established by cyclic voltammetry and UV-Vis spectroscopy in the visible region.<sup>157</sup> Iridium,<sup>158</sup> copper,<sup>159–162</sup> iron(II),<sup>160</sup> cobalt(II)<sup>160</sup> and zinc<sup>161</sup> complexes with pterin and pteridine were studied by spectroscopic and electrochemical methods and characterised by X-ray diffraction.

#### V. Porphyrins, corroles and isocorroles

Porphyrins and corroles stabilise high-valence states of coordinated metal atoms. Studies by Raman spectroscopy and DFT calculations demonstrated that the valence orbitals of corroles are qualitatively similar to those of porphyrins.<sup>163</sup> Isocorroles, as a whole, are also similar to corroles, but their ground states differ in symmetry (<sup>2</sup>A'' for corroles and <sup>2</sup>A' for isocorroles), resulting in different  $d_{\pi}-p_{\pi}$  metal–ligand interactions.<sup>163, 164</sup> Porphyrins, corroles and isocorroles can exist in two oxidised radical-cationic forms, which are very similar in energy. For copper corrole and isocorrole complexes, the Cu<sup>II</sup>  $\pi$ -radical cation has a slightly higher energy than the diamagnetic Cu<sup>III</sup> d<sup>8</sup> complex. In contrast, for the nickel complexes, the low-spin Ni<sup>II</sup>-containing  $\pi$ -radical cation has a lower energy than the state with Ni<sup>III</sup>, which is consistent with experimental data.<sup>163</sup>

Metalloisocorrole

Iron-containing metalloporphyrin radical cations are postulated as intermediates in processes catalysed by natural peroxidases, catalases and their synthetic analogues.<sup>165</sup> Formally, the oxidation state of iron in these intermediates is +5. However, it is better to consider the intermediates as Fe<sup>IV</sup>-oxo porphyrin  $\pi$ -radical cations.<sup>166</sup>

It was demonstrated<sup>167</sup> that one-electron reduction of Au<sup>III</sup> complexes with substituted porphyrin ligands occurs in different ways depending on the nature of the substituent in the  $\beta$  positions of the pyrrole fragments of the macrocycle. If the porphyrin moiety contains the electron-donating 3,5-di-*tert*-butylbenzene substituents, the metal atom is reduced to give Au<sup>I</sup> porphyrin. If the ligand contains the electron-withdrawing NO<sub>2</sub> groups, reduction affords the Au<sup>III</sup> complex with the porphyrin  $\pi$ -radical cation.

The Fe<sup>IV</sup> and Mn<sup>IV</sup> triarylcorrole complexes (**60** and **61**) were characterised in the study.<sup>168</sup>

The first oxidation potentials of complexes **61** are higher than that of the corresponding oxo dimer **60**, which confirms the higher oxidation state of the corrole ligand in complexes **61** (the ligand is already oxidised to a radical-like state).<sup>168</sup> This conclusion agrees with the hypothesis proposed by Walker and co-workers<sup>169</sup> that the iron ion in chloro(octaalkylcorrolato)iron(IV) complexes has an intermediate spin ( $S = 3/2$ ) and is antiferromagnetically coupled to the corrole  $\pi$ -radical. Calculations by the DFT method demonstrated that this coupling results from interaction between the metal  $d_{z^2}$  orbital and the  $b_1$ -symmetry  $\pi$  orbital of the corrole. By contrast, the corrole ligand in dimer **60** is not, apparently, a radical.

Two iron octaalkylcorrolate complexes **62a,b** with axial ligands were studied by <sup>1</sup>H NMR and Mössbauer spectroscopy. The temperature dependence of the magnetic susceptibility of these complexes was studied<sup>170</sup> to determine the true electronic configuration of the anionic iron corrolates, *e.g.*, to determine whether they are Fe<sup>IV</sup> corrolates(3<sup>-</sup>) or Fe<sup>III</sup>-corrolates(2<sup>-</sup>) with antiferromagnetic coupling of the electrons of the iron ion to

the electrons of the macrocyclic ligand. In both cases, the total spin is 1.

Magnetic susceptibility measurements and results of DFT calculations provided evidence for the non-innocent properties of the macrocyclic corrolate ligand in chlorine-containing complex **62a**. As for phenylcorrolate complex **62b**, no unambiguous conclusion has been drawn. However, it has been hypothesised that the corrolate in both complexes behaves as a non-innocent ligand, but this behaviour is much more pronounced in the chlorine-containing complex.

In contrast, calculations for the Fe<sup>IV</sup> and Mn<sup>IV</sup> complexes with corrolazine (**63**)

demonstrated<sup>171</sup> that this ligand is much more similar to classical ligands and stabilises a 'more pure' high-valence state of the transition metal ion.

The Cu<sup>II</sup> and Fe<sup>III</sup> complexes with  $\beta$ -octafluorocorrole ligands were synthesised and characterised in the study.<sup>171</sup> Study by NMR spectroscopy and DFT calculations showed that the radical character of the electron-deficient fluorine-containing corrole ligand in the LFeCl complex is much less pronounced than that in the complex with the corresponding nonfluorinated ligand. It was shown that the copper complex with octafluorocorrole can exist in a thermally accessible paramagnetic excited state, in which the ligand is present as a radical.

X-ray diffraction studies<sup>172–177</sup> of metalloporphyrins (M = Zn, Cu, Mg, Fe) revealed considerable bond length alternation in the 16-membered ring of the porphyrin ligands. The structural data, results of various spectroscopic studies<sup>163, 169</sup> and DFT calculations led the authors<sup>170</sup> to the conclusion that the real structures of these complexes are similar to those of lower-valence metal complexes with a  $\pi$ -radical-cationic ligand, *i.e.*, porphyrins and corroles are typical non-innocent ligands (it should be remembered that numerous valence-tautomeric electron distributions can be displayed for high-valence transition metal complexes with porphyrin and corrole ligands).

Simple rules, which allow one to predict whether the spin density is localised on the metal or the ligand in iron complexes with aromatic macrocycles (porphyrins, corroles and chlorins), were formulated<sup>178</sup> using the results of pulse spectroscopy (ESR, ESE, ENDOR).

## VI. Tetracyanoethylene, tetracyanoquinodimethane and tetraiminoethylene complexes

The tetracyanoethylene (TCNE) and 7,7,8,8-tetracyanoquinodimethane (general notation is TCNX) molecules are (see the study<sup>179</sup>) 'the least innocent' organic ligands, because their  $\pi^*$  orbitals are very low-lying. Generally, reactions of easily reducible tetracyanoethylene and 7,7,8,8-tetracyanoquinodimethane with transition metal salts produce mono-, di-, tri- or tetranuclear complexes of the TCNX<sup>•-</sup> radical anions and doubly-charged TCNX<sup>2-</sup> anions,  $\pi$  complexes with coordination at the C=C bond or ion-pair TCNX<sup>•-</sup>(ML<sub>n</sub><sup>+</sup>) compounds without direct coordination.<sup>180</sup>

## The tetranuclear ruthenium complexes with TCNX (64)

were characterised in the studies.<sup>40,181</sup> These complexes were described as completely delocalised symmetrical  $\pi$  systems with the partially reduced ligand and the partially oxidised metal atoms.

These compounds were studied by ESR, NMR and IR spectroscopy and cyclic voltammetry. It is unusual that the first reduction potentials of the tetranuclear complexes are more negative than that of the free ligand (an analogous phenomenon is observed also for the iron complexes with TCNX).<sup>40</sup> This fact is attributable to considerable metal  $\rightarrow$  ligand charge transfer in the resulting complex ( $0 \leq \delta \leq 2$ ).

In the analogous complexes with 1,2,4,5-tetracyanobenzene and 2,3,5,6-tetracyanopyrazine, which were synthesised and described in this study,<sup>40</sup> the degree of metal  $\rightarrow$  ligand charge transfer is much smaller.

The ruthenium complexes with TCNX were characterised also in the studies.<sup>182–185</sup> Analogous conclusions about the metal  $\rightarrow$  ligand charge transfer were drawn on the basis of the results of ESR and IR spectroscopy and electrochemical studies of discrete manganese,<sup>40,184–186</sup> osmium,<sup>187</sup> rhenium<sup>188</sup> and iron<sup>189</sup> complexes. It was hypothesised<sup>189</sup> that the reaction of the  $\text{Fe}^{\text{II}}$  cyclopentadienyl complex with TCNX afforded the radical-anionic iron(III) complex.

Then the ligand is presumably reduced to the doubly-charged anion.

In the present review, we restrict ourselves to the discussion of discrete tetracyanoethylene and tetracyanoquinodimethane complexes. However, a large number of analogous coordination polymers, in which the TCNX ligands serve as bridges, have also been described.<sup>179</sup>

The ground electronic state of related complexes **65** with four imino groups has been described earlier<sup>190–194</sup> as a mixed-valence form, in which one metal atom has the oxidation state of +2, whereas another metal atom is in the oxidation state of +3. However, UV-Vis spectroscopy and semiempirical quantum-chemical calculations provided evidence that such nickel complexes are more adequately described as an identical pair of  $\text{Ni}^{\text{II}}$  centres linked *via* a bridging radical-anionic ligand.<sup>195</sup>

$\text{M} = \text{Ni}, \text{Fe}, \text{Ru}; \text{L} = \text{Hal}^- \text{ or a solvent molecule.}$

## VII. Complexes with nitrogen(II) oxide

The NO species is a typical non-innocent ligand,<sup>196</sup> because it can exist in three forms: diamagnetic  $\pi$ -acceptor cationic, paramagnetic neutral radical and diamagnetic anionic.

The  $[(\text{NC})_5\text{M}(\text{NO})]^{3-}$  complexes ( $\text{M} = \text{Fe}, \text{Ru}, \text{Os}$ ) with  $\text{NO}^\bullet$  as ligands were synthesised and studied by ESR<sup>197–201</sup> and IR<sup>202</sup> spectroscopy, electrochemical methods<sup>202</sup> and DFT calculations.<sup>201</sup> The calculations demonstrated that the spin density is localised predominantly on the nitrosyl fragment of the molecule, and the electronic structures of these complexes are adequately described as a resonance hybrid of two structures, the contribution of the second structure being insignificant.

The binuclear ruthenium complex  $[(\text{NC})\text{Ru}(\text{py})_4(\text{CN})\cdot\text{Ru}(\text{py})_4(\text{NO})](\text{PF}_6)_3$  was synthesised and studied by spectroscopic and electrochemical methods,<sup>203</sup> which revealed a considerable charge transfer from the ruthenium ion, so that the  $\{\text{Ru}^{\text{II}}-\text{NO}^\bullet\}$  resonance structure makes a large contribution to the structure of the complex.

The five-coordinate  $[\text{Fe}(\text{OEP})(\text{NO})]\text{ClO}_4$  complex and the six-coordinate  $[\text{Fe}(\text{OEP})(\text{im})(\text{NO})]\text{ClO}_4$  complex (im is imidazole, OEP is octaethylporphyrin) were synthesised and characterised by X-ray diffraction and spectrophotometry.<sup>204</sup> Mössbauer spectroscopy provided evidence that the oxidation state of iron in the five-coordinate complex is higher than +3. However, the IR spectroscopic data are inconsistent with such a large charge transfer to NO.

The results of X-ray diffraction study and the data from Mössbauer and ESR spectroscopy for the neutral paramagnetic binuclear iron complexes  $[\text{Fe}_2(\mu_2\text{-SR})_2(\text{NO})_4] \cdot n\text{H}_2\text{O}$  ( $n = 1$  or  $2$ ; R is 5-amino-1,2,4-triazol-3-yl, 1,2,4-triazol-2-yl, 1-methyltetrazol-5-yl, benzotriazol-2-yl<sup>205</sup> or benzimidazolyl<sup>206</sup>) indicate that the  $\text{Fe}^+$  ion has the  $d^7$  configuration and the NO groups are electroneutral.

The reaction of the low-spin  $[\text{Fe}^{\text{II}}\text{Cl}(\text{cyclam-ac})]$  complex (cyclam-acH is 1,4,8,11-tetraazacyclotetradecan-1-ylacetic acid) with NO in MeCN produced the octahedral  $[\text{Fe}(\text{NO})(\text{cyclam-ac})]^+(\text{PF}_6^-)$  complex ( $\{\text{Fe}(\text{NO})\}^{\text{ini}}; S = 1/2$ ), which can be subjected to chemical one-electron oxidation to the  $[\text{Fe}(\text{NO})(\text{cyclam-ac})]^{2+}(\text{PF}_6^-)_2$  ( $\{\text{Fe}(\text{NO})\}^{\text{ox}}; S = 0$ ) or  $[\text{Fe}(\text{NO})(\text{cyclam-ac})]^{2+}(\text{Cl}^-)(\text{ClO}_4^-)$  complex and also subjected to chemical or electrochemical one-electron reduction to the neutral  $[\text{Fe}(\text{NO})\cdot(\text{cyclam-ac})]^0$  molecule ( $\{\text{Fe}(\text{NO})\}^{\text{red}}; S = 0$ ).<sup>207</sup>

The oxidation states of iron and the NO ligand can be *a priori* represented as follows (the numbers below the formulae indicate the spin states of the iron ion and NO).

| $\{\text{Fe}(\text{NO})\}^{\text{ox}}$               | $\{\text{Fe}(\text{NO})\}^{\text{ini}}$           | $\{\text{Fe}(\text{NO})\}^{\text{red}}$           |
|------------------------------------------------------|---------------------------------------------------|---------------------------------------------------|
| $\text{Fe}^{\text{II}}\text{NO}^+$<br>0 0            | $\text{Fe}^{\text{II}}\text{NO}^\bullet$<br>0 1/2 | $\text{Fe}^{\text{II}}\text{NO}^-$<br>0 0         |
| $\text{Fe}^{\text{III}}\text{NO}^\bullet$<br>1/2 1/2 | $\text{Fe}^{\text{III}}\text{NO}^-$<br>1/2 0      | $\text{Fe}^{\text{III}}\text{NO}^{--}$<br>1/2 1/2 |
| $\text{Fe}^{\text{IV}}\text{NO}^-$<br>1 1            | $\text{Fe}^{\text{III}}\text{NO}^-$<br>1/2 1      |                                                   |

The electronic structures of these three complexes were established by ESR, UV-Vis, Mössbauer and IR spectroscopy. The crystal and molecular structures were determined by X-ray diffraction. Calculations by the DFT method provided information on the bonding in these haeme-free iron complexes. It was concluded that the oxidised complex (ox) contains the N-coordinated  $\text{NO}^+$  cation, the starting complex (ini) contains the neutral  $\text{NO}^\bullet$  radical, and the reduced complex (red) contains the  $\text{NO}^-$  anion. Therefore, only the NO ligand is involved in redox processes.

## VIII. Conclusion

The aim of the present review is to attract attention to the results of investigations on the nature of bonding between metals and ligands in non-innocent metal complexes synthesised primarily in the last decade. There is a great diversity of structural types of non-innocent ligands, from small molecules (NO) to macrocycles. In most cases, these ligands contain conjugated  $\pi$  systems capable of either accepting or donating electrons. In many cases, ligands rather than the central metal atom are redox-active.

As mentioned above, non-innocence is a property not only of ligands but of complexes as a whole, because the central metal atom can have a strong effect on the electronic structure of the ligand, if there is a strong mixing of the ligand and metal orbitals. Examples are known, where a free ligand is irreversibly reduced (a radical anion is unstable), but reduction of the ligand in a complex becomes reversible (the radical-anionic ligand becomes stable). Due to charge transfer between the metal and the ligand, the valence of the metal in the complex can vary even with changes in the temperature of the sample.

Electrochemical and spectroelectrochemical methods, X-ray diffraction analysis, low-temperature ESR and ENDOR, UV-Vis and near-IR spectroscopy are most informative and are most widely used to study the nature of bonding in non-innocent complexes. After the synthesis of new complexes, for example, of neutral  $[\text{ML}]^0$ , they are usually studied by a combination of the above-mentioned methods and also by quantum-chemical calculations (primarily, the geometry and usually with the use of the DFT method). Electrochemical methods allow generation of the ions and radical ions,  $[\text{ML}]^{2+}$ ,  $[\text{ML}]^+$ ,  $[\text{ML}]^-$  and  $[\text{ML}]^{2-}$ . If these species are stable, their structures are studied by appropriate spectroscopic methods. For example, the paramagnetic singly-charged anion in the nickel bis(dithiolenes)  $[\text{Ni}(\text{S}_2\text{C}_2\text{R}_2)_2]^-$  ( $z = 2-, 1-, 0$ ;  $\text{R} = \text{H}, \text{Me}, \text{CF}_3, \text{CN}, \text{etc.}$ ), which are stable in three redox states,<sup>96, 208</sup> was studied by ESR. The delocalisation of the spin predominantly on the ligand is direct evidence for its non-innocent nature. Calculations and UV-Vis spectra provide information on the structures of diamagnetic complexes. These data demonstrated that doubly-charged anions in nickel complexes with dithiolenes can be considered as normal  $\text{Ni}^{\text{II}}$  complexes with two doubly-charged anionic 1,2-dithiolate ligands. Bonding in neutral complexes remains an open question. One description assumes the biradical structure of the ground state of complexes with unpaired electrons localised on the ligands (primarily on the  $\alpha$ -C atoms bound to the S atoms). An alternative description is based on a delocalised structure including the resonance enedithiolate and diketone forms of the ligand. X-ray diffraction analysis allows one to determine the structural characteristics of the ligand in complexes {for example, for  $[\text{Ni}(\text{S}_2\text{C}_2\text{Me}_2)_2]$  in the

redox states of  $2-, 1-$  and  $0$ }<sup>85</sup> and draw conclusions about their electronic structures. This gives a better insight into the electronic structures and the nature of metal–ligand bonding in non-innocent complexes.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 04-03-32845), the Program ‘Russian Universities’ (Grant 05.03.005) and the Russian Academy of Sciences (Program of the Presidium of the Russian Academy of Sciences ‘Theoretical and experimental study of the nature of chemical bonding and mechanisms of chemical reactions and processes’).

**Abstract.** Data on the synthesis, structure and physicochemical properties of liquid-crystalline ionomers, a new class of mesomorphic polymeric compounds, are summarised. The main classes of the liquid-crystalline ionomers studied to date (including comb-like and linear) and liquid-crystalline chelato-telechelic polymers are considered. It is demonstrated that the ionomer phase state and structure are determined by the ability of ion pairs to form stable ionic aggregates. A new model of the structural organisation of liquid-crystalline ionomers is proposed. The bibliography includes 110 references.

## I. Introduction

Mesomorphic polymeric systems including compounds with liquid-crystalline (LC) type of ordering belong to the most interesting aspects of modern chemistry and physics of high-molecular-mass compounds.<sup>1–5</sup> Based on such systems, new generations of polymeric materials and composites for application in holography, data storage systems, optoelectronics, optical filters and polarisers have been designed (and the work is in progress!). The most promising fields of application of LC polymers include reinforced organic fibre technologies,<sup>6</sup> fabrication of nonlinear optical media, ferroelectrics,<sup>7,8</sup> photonic crystals,<sup>9</sup> materials for recording and storage of optical information,<sup>7,10–12</sup> biologically active compounds,<sup>13</sup> etc.

Introduction of small amounts of metal ions (a few molar per cent) into copolymers of unsaturated hydrocarbons with aliphatic unsaturated acids (first of all, based on ethylene and acrylic acid) leads to fundamental changes in the physicochemical properties of the polymers, namely, a decrease in solubility, an increase in the glass transition temperature and improvement of mechanical characteristics.<sup>14–16</sup> Detailed investigations of such compounds, which were named ionomers, showed that in the solid phase or in nonpolar solvents they form complex ionic aggregates involving charged groups, which to a first approximation can be considered

as noncovalent cross-link points of the polymer chains. It is ionic aggregates that are responsible for specific physicochemical and mechanical properties of ionomers and peculiar features of the supramolecular organisation and structure of such systems.<sup>15–17</sup>

In spite of considerable advances in research on mesomorphic polymers, the structure and properties of ion-containing LC polymers and LC ionomers have not been systematically analysed until recently. Taking into account the incessant interest of researchers in metal-containing polymeric systems,<sup>18</sup> this is more than strange. This review can help to some extent bridge the gap.

The increasing interest in studies of comb-shaped LC ionomers is due to their ability to combine the supramolecular organisation, which manifests itself in the formation of ionic aggregates, with the ordering of side mesogenic fragments, which governs the formation of thermotropic mesophases. Owing to the dual nature of the molecular organisation, the LC ionomers can ‘inherit’ valuable properties and characteristics of both these classes of high-molecular-mass compounds. Because of this, they are of interest for both basic research and applied science as model systems for the design of novel materials and composites based on them.

The variety of molecular architectures of LC ionomers and ion-containing LC polymers is due to the complex chemical structure of this class of high-molecular-mass compounds (Fig. 1). The most important characteristic of these compounds is the content of charged groups in the macromolecules. Note that an old classification, which is nevertheless used in most studies, treats LC ionomers as mesomorphic polymers containing at most 5 mol.%–10 mol.% of charged groups. Polymers containing more than 10 mol.%–20 mol.% of charged groups are called LC ion-containing polymers or LC polyelectrolytes.<sup>19–21</sup> In spite

of the limited use of this classification (see below), we will also use it in this review because it is commonly accepted.

Specific features of mesophase formation in comb-shaped and linear LC polymers have been reported.<sup>4,22</sup> With allowance for this fact it is logical to classify LC ionomers based on such a macromolecular topology parameter as the position of mesogenic groups (in the backbone, in side chains, *etc.*). Below we will show an important role of the chemical nature of the monomer units bearing charged groups, in particular, the charge of counterions, and of the distance between the monomer unit and the polymer backbone (the length of the spacer).

The authors of this review have first analysed the state-of-the-art in the field of research on thermotropic LC ionomers using the published data and the results of their own studies. First, we outline the fundamentals of physical chemistry of random amorphous ionomers and then consider thermotropic LC ionomers with various molecular architectures. The emphasis is placed on the publications reported in the last 10–15 years, because the pioneering studies on the physical chemistry of thermotropic LC ion-containing polymers and LC ionomers date back to the late 1980s and early 1990s. Thus, the authors have tried to make the review accessible to a broader spectrum of readers and, at the same time, to present a comprehensive treatment of the subject and report recent advances in this interesting field of polymer science.

## II. Fundamentals of chemistry and physics of ionomers

### 1. Ionomers and polyelectrolytes

Traditionally, macromolecules containing charged groups are divided into two large classes, polyelectrolytes and ionomers.<sup>14,16</sup> Initially, ionomers included random copolymers comprised of monomers of the ethylene series and unsaturated acids (acrylic acid, methacrylic acid) in which a fraction of the protons of carboxyl groups (up to 10 mol.%) is replaced by alkali or alkali-earth metal ions. Such ion-containing copolymers are practically insoluble in conventional organic solvents.

Polyelectrolytes comprised<sup>14</sup> high-molecular-mass compounds containing a large amount of ionogenic groups, which can dissociate in polar solvents, *e.g.*, salts of polyvinylsulfonic acid, polyacrylic acid and salts of polybases, *e.g.*, quaternised (alkylated) polyvinylpyridine, *etc.* However, later this definition was recognised to be unsatisfactory, because essential differences in characteristics of the compounds belonging (from the standpoint of this definition) to the same class, were established.<sup>16</sup>

Basic to the modern classification of ion-containing macromolecules is the state of the charged groups they bear. To illustrate the fruitfulness of this approach, we will consider the simplest model of an ion pair as a constituent of a macromolecule (Fig. 2). According to the Coulomb law, the interaction energy of the point charges  $q_1$  and  $q_2$  of the ionogenic group and the counterion, respectively, separated by the distance  $r$  in the medium with the dielectric constant  $\epsilon$  is given by<sup>23</sup>

$$U_q = \frac{1}{4\pi\epsilon_0} \frac{q_1 q_2}{\epsilon r}. \quad (1)$$

The ratio of the attraction energy between the counterion and the oppositely charged ionogenic group of the polymer (electrostatic attraction factor) to the average thermal energy of the counterion (thermal factor) has the form

$$\frac{2}{3} \frac{U_q}{kT} = \frac{1}{6\pi\epsilon_0 k} \frac{q_1 q_2}{\epsilon r T}. \quad (2)$$

Two most important particular cases where this ratio is (i) much more and (ii) much less than unity are illustrated in Fig. 3. The former case (the electrostatic factor much exceeds the thermal factor) is characteristic of contact ion pairs. The latter case is typical of a dissociated pair in which the Coulomb attraction between ions cannot hold them together and the external ion not

**Figure 2.** Model of an ion pair in a macromolecule. Backbone (1), charged ionogenic fragment (2) and counterion (3).

**Figure 3.** Ion pairs in the ionomer (a) and polyelectrolyte (b) regimes. Ratio (2):  $\gg 1$  (a) and  $\ll 1$  (b).

involved in covalent bonding with the polymer chain can experience Brownian motion.

From expression (2) it follows that contact ion pairs will mainly exist in condensed media with low dielectric constant ( $\epsilon \approx 1$ ) at moderate temperatures, which is characteristic of the vast majority of organic compounds with the hydrocarbon skeleton in the solid phase or in nonpolar solvents. In modern literature, this state (or mode) is called the ionomer state (mode) and the corresponding high-molecular-mass compounds are called ionomers.<sup>16</sup>

Individual ion pairs are electric dipoles because the positive and negative charges are separated by the distance  $r$  (see Fig. 2). The electrostatic interaction energy of coplanar electric dipoles (Fig. 4) is given by<sup>24</sup>

$$U_d = \frac{1}{4\pi\epsilon_0} \frac{\mu_A \mu_B}{\epsilon d^3} (2 \cos \theta_A \cos \theta_B - \sin \theta_A \sin \theta_B), \quad (3)$$

where  $\mu_A$ ,  $\mu_B$  are the dipole moments of the ion pairs A and B,  $d$  is the distance between the centres of the dipoles, and  $\theta_A$  and  $\theta_B$  are the angles between the axes of the dipoles and the line connecting their centres.

From Eqn (3) it follows that at the dipole–dipole separations  $d \approx 5-10$  Å at  $r \approx 1-2$  Å,  $\epsilon = 1$  the attractive energy of the ion pairs is comparable with the energy of hydrogen bonding,<sup>25,26</sup> which plays the key role in biochemistry, in the supramolecular structural organisation and in physical chemistry of liquid crystals.<sup>27-30</sup> It will be shown below that it is the dipole–dipole interaction of ion pairs that governs the specific features of the physicochemical properties and the supramolecular structure of ionomers.

High dielectric constants of media ( $\epsilon \gg 1$ , polar solvents) and an increase in temperature cause dissociation of ion pairs. This

**Figure 4.** Electrostatic interaction between dipoles A and B.

mode is called polyelectrolyte mode and the corresponding compounds are called polyelectrolytes.<sup>16,24</sup> A macromolecule can contain thousands of ionogenic groups; therefore, it is clear that charges distributed over the polymer chain strongly affect the conformation and physicochemical properties of the polymer. For instance, it is repulsion between the similarly charged groups that is responsible for the well-known swelling of polyelectrolytes.<sup>31,32</sup>

Thus, depending on the particular conditions (primarily, on the dielectric constant of the medium and temperature), counterions near the charged groups of the same macromolecule can exist as free ions and as constituents of stable ion pairs. Correspondingly, such systems can possess the properties of both ionomers and polyelectrolytes. It seems likely that different conditions (modes) for the existence of ionogenic polymers rather than different classes of these compounds should be discriminated.<sup>16</sup> Since the ordering of macromolecules of thermotropic LC polymers occurs in the solid phase due to the interaction of anisometric mesogenic groups rather than in a particular range of concentrations, as for lyotropic liquid crystals, in the text below we will consider only the ionomer state of polymers and relevant features of their morphology and physicochemical properties.

## 2. Main models for the structure of ionomers

Pioneering experimental studies on the synthesis and properties of ionomers showed that introduction of charged groups into random alkene–unsaturated carboxylic acid copolymers leads to a decrease in their solubility and to an increase in the glass transition temperature.<sup>15</sup> One of the most significant factors indicating a complex supramolecular structure of ionomers is the detection of a characteristic maximum at small scattering angles in their X-ray diffraction patterns. The presence of this maximum, which is called the ‘ionic peak’, is indicative of the formation of ordered ionic aggregates within the nonpolar polymer matrix. Besides, analysis of the temperature dependences of the mechanical loss factor  $\tan \delta$  for these thin samples revealed two clearly seen maxima, which allowed the microphase separation in the samples to be suggested.<sup>15</sup> The model of formation of ionic aggregates in the polymer matrix has played an important role in the development of the concepts of structural organisation of ionomers.

One of the first and most significant theoretical studies in the field of physical chemistry of ionomers is the study by Eisenberg.<sup>24</sup> The model is based on the concepts of aggregation of ion pairs driven by the electrostatic dipole–dipole interaction (see above). Small aggregates comprising a few charged functional groups and corresponding counterions connected by strong Coulomb interactions were named ‘multiplets’. In the original model, Eisenberg assumed that an increase in the content of ion pairs in the polymer matrix will favour further electrostatic aggregation of multiplets, resulting in clustering. Clusters containing tens of multiplets can be treated as domains of a new phase dispersed in the initial polymer.

To explain the influence of multiplets on the polymer matrix, in the study cited it was assumed that the conformational mobility of the polymer chain in the vicinity of a multiplet is significantly restricted compared to the conformational mobilities of distant fragments of the macromolecule. Therefore, steric interaction between the polymer chains coordinated to the multiplet through their own ion pairs and noncoordinated chains in the environment affects the polymer matrix oppositely to the effect of plasticiser because any multiplet becomes surrounded by a ‘shell’ comprised of chain fragments with restricted mobility (Fig. 5).

The thickness of the region of restricted mobility in the vicinity of the multiplet is primarily determined by the flexibility of the polymer chains, namely, the higher the flexibility the thinner the multiplet shell. The range of action of a multiplet (distance at which the polymer chains ‘feel’ the effect of the multiplet) can hardly be determined quantitatively, but it must correspond to the persistence length of the polymer in the solid phase or the length of

**Figure 5.** Structure of multiplets according to Eisenberg.<sup>17,24</sup>

Multiplet core (1), multiplet shell (region of restricted mobility of the polymer chains) (2) and isolated ion pair (3).

the Kuhn segment.<sup>†</sup> The formation of the core of a multiplet is accompanied by attraction of all neighbouring charged groups; therefore, the shell of the multiplet must be considerably depleted of ions.

From the aforesaid it follows that the effect of a multiplet comprised of a few ion pairs on the polymer matrix is weaker than the effect of a larger ionic aggregate. The smallest aggregate comprising two ion pairs, a quadruplet, plays the role of a conventional intermolecular cross-link, thus causing relevant changes in the physicochemical characteristics of the polymer sample. Generally, the region of restricted mobility of the polymer chains surrounding the multiplet is small and cannot be characterised by its own glass transition temperature; however, the presence of such regions favours an increase in the glass transition temperature of the whole polymer sample in accord with the mechanism considered above.<sup>24</sup>

The Eisenberg model provides no unambiguous interpretation of X-ray scattering data, but permits a qualitative explanation for the ‘microscopic’ two-phase morphology of ionomers. The model gave an impetus to further development of the theory of ionomers in the studies by Forsman,<sup>33</sup> Dreyfus,<sup>34</sup> Datye and Taylor,<sup>35</sup> Earnest *et al.*,<sup>36</sup> Squires *et al.*,<sup>37</sup> Marx *et al.*,<sup>38</sup> Yarusso and Cooper,<sup>39</sup> Ding *et al.*,<sup>40</sup> MacKnight *et al.*,<sup>41</sup> Roche *et al.*,<sup>42</sup> *etc.*

In 1989, Eisenberg’s group proposed an improved model of ionomers,<sup>17</sup> which is used at present. The model considers a number of factors responsible for the formation of multiplets, *e.g.*, the force of electrostatic interaction between charged groups, the concentration of ions (ion pairs) in the polymer, the chemical nature of the polymer matrix and steric factors.

The most important factor is the force of electrostatic interaction between ion pairs, which is determined by the size of ion and by the contribution of the covalent component to the ion–ion interaction. It is assumed that ions of small radii interact more efficiently and form stronger aggregates than do large charged groups. If the Coulomb forces between the ion dipoles are too weak to overcome the ‘elastic’ resistance of the polymer chains to which they are connected, no aggregation occurs.

Low dielectric constant and low glass transition temperature of the initial (non-ionised) polymer favour the formation of multiplets. An important role of the parameter  $\epsilon$  was mentioned above and the glass transition temperature correlates with the ease of deformation of the polymer chains, *viz.*, the higher the  $T_g$  the more difficult is to force the polymer chains to change their

<sup>†</sup> The persistence length is a measure of chain curvature of rigid-chain macromolecules. It is defined as half the length of the Kuhn segment, *i.e.*, the polymer chain segment in which the memory of the chain direction is retained.

positions at normal temperatures. Clearly, plasticisers present in a polymer composite can strongly influence the formation of ionic aggregates.

For the polymer chains of ionomers with bulky substituents one should expect the formation of very small multiplets. At the same time for the ionomers in which the charged groups are connected to the backbone through long and flexible side bridges (spacers), steric hindrances are weaker and large multiplets can form.<sup>43,44</sup> This is quite important for considering the molecular architecture of LC ionomers and for the interpretation of experimental data.

The average distance between multiplets must decrease on an increase in the concentration of ion pairs in the polymer matrix, which causes the shells of the neighbouring multiplets to overlap (Fig. 6). An increase in the number of overlapped fragments leads to the formation of extended regions in which the mobility of the polymer chains is restricted. Rather large regions with own glass transition temperatures are treated as clusters, *i.e.*, microdomains of a certain phase.<sup>17</sup>

**Figure 6.** Transition from isolated multiplets (a) to clusters (b) caused by an increase in the content of ion pairs in polymer. Dashed lines denote individual multiplet shells; clusters are shaded light grey.

A salient feature of the Eisenberg model is the absence of constraints imposed on the geometry (shape) of multiplets and clusters (ionic aggregates of various shape can be formed).<sup>17</sup> In the modern version of this model, in contrast to the first formulation<sup>24</sup> and a number of more recent studies,<sup>33–37</sup> electrostatic interactions between multiplets are not treated as *causa proxima* for clustering. It is assumed that multiplets in the cluster do not form a single aggregate and only contact one another owing to the overlap of their shells (*i.e.*, regions of restricted mobility of the polymer chains, see Fig. 6).<sup>17</sup>

Thus, the main elements of supramolecular organisation of ionomers are ionic aggregates comprising charged groups (multiplets and clusters). They strongly influence the surrounding polymer matrix, being responsible for the changes in its physicochemical properties (increase in the glass transition temperature, two-phase micromorphology, *etc.*).

Traditionally, LC polymers containing a low proportion of charged groups are treated as LC ionomers (see above). With allowance for the aforesaid, one can use this definition in a broader sense and consider LC ionomers as a specific class of high-molecular-mass compounds characterised by coexistence of the regions of LC ordering and ionic aggregates (multiplets or clusters of various shape). Below we will consider three main groups of LC ionomers, namely, comb-shaped ionomers (see Fig. 1 a), ionomers with mesogenic groups in the backbone (see Fig. 1 b) and telechelic polymers (see Fig. 1 c).

### III. Thermotropic comb-shaped liquid-crystalline ionomers

The macromolecules of comb-shaped LC ionomers (see Fig. 1 a) contain two main types of side substituents, *viz.*, anisometric hard fragments (mesogenic groups) connected to the backbone through flexible spacers and charged ionogenic functional groups. They are responsible for the formation of LC order and the supramolecular structure characteristic of ionomers, respectively. Such a molecular architecture opens the possibility of using these compounds as promising models for studying the role of electrostatic interactions during the formation of mesophases in polymeric systems. Indeed, the concentration of charged groups can be varied with ease in the synthesis of LC ionomers; the upper limit of this concentration is governed by the proportion of functional fragments in the polymer matrix. This feature of the systems under study permits not only investigations of their phase states and structures upon a gradual change in the polymer composition but also, *e.g.*, efficiently influences the magnetic properties of ionomers containing transition-metal ions (see below). Besides, metal atoms can be introduced into virtually any part of a macromolecule (into the backbone, spacers, *etc.*); a vast variety of types of their bonding with the polymer substrate should also be pointed out. In other words, in comb-shaped LC ionomers it is possible to independently vary the nature and concentration of metal ions without changing the structure of the mesogenic fragment. This permits separate studies of the contributions of (i) mesogenic groups of the polymer matrix and (ii) metal atoms into the final characteristics of a compound.

#### 1. Metal-containing comb-shaped liquid-crystalline ionomers

There are only a few publications on the synthesis and investigations of comb-shaped LC ionomers available at the moment. Systematic studies in this field have been carried out by some research groups headed by Zhao (Canada),<sup>45–49</sup> by Zentel (Germany)<sup>50–55</sup> and by the authors of this review.<sup>56–64</sup> These studies concerned the synthesis and investigations of the general physicochemical characteristics<sup>61,62,65,66</sup> of LC ionomers containing alkali,<sup>45–49,56,58</sup> alkaline-earth,<sup>60</sup> transition-metal<sup>50–55,61–63</sup> and rare-earth metal ions.<sup>64</sup> The most important results of these investigations and the corresponding model for structural organisation of comb-shaped LC ionomers will be discussed below. This model, which is based on the concepts of formation of ionic aggregates and microphase separation of charged groups, relates the physical characteristics of a polymer to the concentration, chemical nature and charge of the metal ions and to the distance between the charged groups and the polymer backbone.

##### a. Liquid-crystalline ionomers containing alkali metals

Pioneering studies concerned with analysis of the phase characteristics and structure of comb-shaped LC ionomers containing metal ions were reported in the early 1990s. Zhao and Lei<sup>45,46</sup>

synthesised such compounds using radical copolymerisation of a mesogenic monomer with methacrylic acid.

$x = 12$ .

Subsequent partial neutralisation of carboxyl groups of polymer **1** thus obtained with potassium carbonate in a benzene–methanol (95 vol.% : 5 vol.%)<sup>45</sup> mixture gave comb-shaped thermotropic LC ionomers **1-K(x)** containing at most 10 mol.% of potassium ions.<sup>‡</sup> An increase in the degree of neutralisation of carboxyl groups led to an increase in the glass transition temperature,  $T_g$ , and in a decrease in the clearing point,  $T_c$  (*i.e.*, narrowing of the temperature range in which the mesophase exists (Fig. 7).

**Figure 7.** Phase diagram of LC ionomers **1-K(x)** containing potassium ions.<sup>45</sup>

Hereafter the following notations are used: I is isotropic melt, S is smectic phase and G is glassy state.

Another approach to the synthesis of ionomers involved partial alkaline hydrolysis of the side fragments of comb-shaped LC polymers **2** and **3**, which also leads to generation of charged groups.<sup>46</sup> The degree of hydrolysis was monitored using <sup>1</sup>H NMR spectroscopy, which revealed selective cleavage of the side groups of the LC polymers **2** and **3** (position of preferred hydrolytic cleavage of mesogenic groups under the action of alkali is shown by a dashed line). In the case of polymer **3**, charged groups appeared in close proximity to the backbone, whereas for polymer **2**, charged groups were distant from the backbone.

In contrast to LC ionomers **1-K** considered above, an increase in the content of sodium ions in the hydrolysis products of

polymers **2** and **3** was accompanied by not only a decrease in the thermal stability of the liquid-crystalline phase but also a marked decrease in the glass transition temperature. Probably, hydrolysis of bulky side substituents favoured an increase in the kinetic flexibility of the backbone,<sup>46</sup> which leads to a decrease in  $T_g$ . Besides, the glass transition temperature could be strongly influenced by water molecules retained in the course of hydrolysis (they play the role of a plasticiser for ionic aggregates and, correspondingly, enhance the mobility of polymer chains).<sup>17</sup>

Based on the results obtained, Zhao and Lei concluded that the character of the influence of ionic aggregates on the formation of mesophase in comb-shaped LC ionomers is as follows. In accordance with the Eisenberg model (see above) they assumed that the mobility of mesogenic groups in comb-shaped macromolecules strongly depends on the conformational capabilities of the backbone in spite of the presence of flexible spacers. Mobility restrictions of the chains involved in the formation of multiplets cause defects in the packing of side mesogenic groups. As a consequence, the LC phase of ionomers becomes less stable with an increase in the content of the metal ion and its transition to isotropic melt is observed at lower temperatures as compared with the neutral polymer.<sup>46</sup> And although this explanation for the effect of ionic aggregates on the phase state of LC ionomers is questionable, it is based on commonly accepted concepts from physical chemistry of random ionomers<sup>17</sup> and is undoubtedly characterised by predictive power. This permits the use of the Zhao model for the interpretation of new experimental data.

A drawback of these methods for the synthesis of LC ionomers is the possibility of the hydrolytic cleavage of bonds in different positions of side groups with formation of products in which the charged groups are at different distances from the backbone. Investigations of such compounds revealed no influence of the position of the ionogenic groups on the physicochemical properties of the polymer phase. Besides, the polymer matrix must be purified of low-molecular-mass by-products and hydrolysis cannot be used for introduction of the transition metal and rare-earth metal ions, which significantly reduces the number of compounds to be studied. An exchange reaction involving an alkali<sup>46</sup> also seems to be somewhat inappropriate, because a strong base favours the occurrence of side reactions and the water molecules released play the role of a polar plasticiser and can therefore change the physicochemical properties of synthesised LC ionomers.

Recently, structurally similar polymeric systems have been investigated by researchers working at the Polymer Science Division (Department of Chemistry, M V Lomonosov Moscow State University), Institute of Macromolecular Compounds of the Russian Academy of Sciences and the Institute of Physics (Saint-Petersburg State University). Russian researchers first carried out a complex study of the dependence of the phase characteristics and structure of LC ionomers on the structure of initially functionalised LC copolymers (*i.e.*, on the chemical nature of mesogenic groups, length of aliphatic spacers, concentration of functional carboxyl groups), and on the concentration and charge (valency) of the metal ions.

It should be noted that the ionomers studied always contained not only loose and/or contact ion pairs but also a proportion of non-ionised carboxyl groups.

#### Mesogenic groups

<sup>‡</sup> Hereafter, hyphens in the notations of ionomers are followed by the type of counterion and its content (in mol.%) given in parentheses.

## Ionogenic groups

## Organic ions

R = H, CN ( $n = 3, 9$ ),

$\text{H}_3\text{N}^+(\text{CH}_2)_n\text{Me}$  ( $n = 9, 17$ );

counterions are  $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{Rb}^+$ ,  $\text{Ca}^+$ ,  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ .

Comb-shaped LC ionomers were synthesised using an original two-step procedure.<sup>56, 58, 67</sup> The first stage involved a radical

**Table 1.** Random LC copolymers studied in Refs 56–65.

copolymerisation of two monomers (of, *e.g.*, acrylic or methacrylic series), one containing a mesogenic substituent (anisometric hard fragment) and the other bearing a functional substituent containing one or several ionogenic groups. In the second step the functionalised LC copolymers **4**–**10** thus obtained (see Table 1) were introduced into exchange reactions of functional carboxyl groups with metal acetates or metal acetylacetonates or with organic amine derivatives. For instance, metal-containing LC ionomers were obtained<sup>56,58</sup> by adding a dilute solution of an acetate,  $M(OAc)_n$ , or acetylacetonate,  $M(acac)_n$ , in EtOH or THF to a dilute solution of the functionalised LC copolymer in dehydrated THF and subsequent stirring of the mixture for some hours and removal of low-molecular-mass reaction products *in vacuo*. This procedure offers a number of advantages over the alkaline hydrolysis of ester bonds considered above, because only functional carboxyl groups, whose proportion is specified in the stage of synthesis of LC copolymers, can react with salts of weak acids, and this method permits introduction of various metal ions  $M^{n+}$ . Acetic acid or acetylacetone released in the course of the reaction do not lead to hydrolytic cleavage of the side mesogenic groups, which is confirmed by the absence of hydrolysis products in the reaction mixture. The exchange reaction is characterised by high conversion. This is indicated by the absence of the unreacted salt in the polymer matrix after annealing of the polymer, confirmed by the data of polarisation optical microscopy and X-ray scattering.

Thus, the synthetic technique proposed allows a controlled amount of metal ions to be introduced into the macromolecules of comb-shaped LC copolymers with retention of the side mesogenic groups. By monitoring the formation of charged groups in macromolecules (as a rule, by IR spectroscopy<sup>56,67</sup>) it is possible to establish the type of coordination between carboxylate ions and metal ions from the stretching vibration frequencies  $\nu_{COO^-}$ . As applied to carboxylate complexes of the metal salts of low-molecular-mass monocarboxylic fatty acids,<sup>68</sup> the monodentate coordination corresponds to the stretching vibration frequencies lying in the ranges  $\nu_a = 1600$ – $1630$  and  $\nu_s = 1350$ – $1380$   $cm^{-1}$ ; the frequency difference  $\Delta = \nu_a - \nu_s$  in this case is  $230$ – $300$   $cm^{-1}$ . In the case of bidentate chelate coordination of the  $M^{n+}$  ion the band frequencies  $\nu_a$  and  $\nu_s$  approach each other (to  $1500$ – $1530$  and  $1440$ – $1470$   $cm^{-1}$ , respectively).

In particular, the exchange reaction between ionogenic LC copolymer **4a** and sodium acetate is accompanied by the appearance of an absorption band of the carboxylate ion at  $1578$   $cm^{-1}$ , the band intensity increasing with an increase in the metal content (Fig. 8*a*). The formation of carboxylate ions was also indicated by a decrease in the intensity of the low-frequency and high-frequency wings of the complex band  $\nu_{C=O}$  ( $1770$ – $1690$   $cm^{-1}$ ) corresponding to free ( $1740$   $cm^{-1}$ ) and hydrogen bonded ( $1703$   $cm^{-1}$ ) carboxyl groups of the initial LC polymer **4a**.<sup>56,67</sup> Low frequency difference between the LC ionomers **5-Rb** and **5-Na** containing fragments of alkoxybenzoic acid ( $\Delta = \nu_a - \nu_s = 46$ – $53$   $cm^{-1}$ ) is an indication of bidentate chelate coordination. For **5-Rb**, the antisymmetrical and symmetrical stretching bands of carboxylate ions are shifted by  $34$   $cm^{-1}$  to the high-frequency region compared to the frequencies of ionomers containing lithium ions (Fig. 8*b*).

The authors of this review have synthesised metal-containing comb-shaped LC ionomers following the procedure mentioned above and studied their phase behaviour, structural and physicochemical characteristics. Differential scanning calorimetry (DSC) curves of a liquid-crystalline copolymer **4c** and ionomers **4c-Na** with various content of sodium ions are shown in Fig. 9. The DSC curves exhibit clearly seen characteristic transitions corresponding to the glass transition temperatures and endothermic peaks corresponding to the clearing point, *i.e.*, transition of the LC phase into isotropic melt. The introduction of alkali metal ions into the polymer matrix leads to marked broadening of the temperature interval of existence of the mesophase. For instance, the heat of transition to the isotropic phase ( $\Delta H = 1$ – $1.5$   $J g^{-1}$ )

**Figure 8.** IR spectra of LC copolymers **4a** and LC ionomers **4a-Na** (a) and copolymer **5** (b) and ionomers **5-Li** and **5-Rb** (b).<sup>67</sup> (a): **4a** (1), **4a-Na**(4%) (2), **4a-Na**(10%) (3) and **4a-Na**(20%) (4); (b): **5** (solid line), **5-Li** (1) and **5-Rb** (2).

**Figure 9.** DSC curves of liquid-crystalline copolymer **4c** (1) and ionomers **4c-Na**(5%) (2) and **4c-Na**(10%) (3).<sup>57</sup>

obtained for the initial LC copolymer is characteristic of the nematic mesophase, being consistent with the polarisation microscopy data (Fig. 10*a*). At the same time, ionomers are characterised by higher  $\Delta H$  values ( $\Delta H = 1.5$ – $2.5$   $J g^{-1}$ ), which points to changes in their structure with an increase in the content of metal ions.

The liquid-crystalline phase of ionomers **4-Na** has a fan texture (Fig. 10*b*); its SAXS diffraction patterns exhibit an intense maximum corresponding to the period  $d_1 = 34.6 \pm 0.1$  Å (Fig. 11). Comparison of these data with the calculated length of mesogenic groups ( $\sim 18$  Å) suggests a layered packing of the polymer chains with partial overlap of side groups for **4-Na**.<sup>56,58</sup> The 2D X-ray diffraction pattern of an oriented sample clearly demonstrates that diffuse large-angle and small-angle reflections are split in mutually perpendicular directions. Such a character of the X-ray diffraction pattern indicates that mesogenic groups of the polymer are oriented along the magnetic field direction and permits unambiguous identification of the LC phase as smectic A (SmA).

**Figure 10.** Characteristic optical textures of LC ionomers based on copolymer **4**.<sup>57</sup> Texture: marble (a) and fan (b); magnification 200.

**Figure 11.** SAXS diffraction patterns (Cu  $K\alpha$ -radiation) of LC ionomers **4**-Na containing 1.2 (1), 5.0 (2) and 10.1 (3) mol.% of sodium ions (a) and 2D X-ray diffraction pattern of LC ionomer **4**-Na (2.3%) oriented in a magnetic field (b).<sup>57</sup> The arrow denotes the magnetic field direction.

The phase diagrams of ionomers **4**-Na differing in degree of polymerisation  $P_w$  and content of carboxyl groups in the initial copolymer are shown in Fig. 12. Construction of typical phase diagrams of the ionomers based on the fractions of LC copolymers **4a–d** with a similar content of carboxyl groups and different molecular masses (MM) (Fig. 12a) revealed the following.<sup>56</sup> First, replacement of protons in the functional carboxyl groups by  $\text{Na}^+$  ions led to an increase in the temperature interval of existence of the mesophase<sup>§</sup>

<sup>§</sup> The clearing point  $T_c$  and the glass transition temperature  $T_g$  respectively determine the upper and lower bounds of the existence region of mesophase in LC polymers.

**Figure 12.** Phase diagrams of LC ionomers **4a**-Na (a), **4e**-Na (b) and **4f**-Na (c).

$$\Delta T = T_c - T_g.$$

Second, an increase in the content of sodium ions led to a nearly linear increase in the clearing point, whereas the glass transition temperature increased to some extent at  $\text{Na}^+$  content of 2 mol.%–5 mol.% and then remained unchanged. Third, introduction of metal ions into the polymer matrix led to a change in the phase state of the polymer, namely, not only the nematic phase but also the SmA phase was formed starting from a  $\text{Na}^+$  content of 1.2 mol.%. The general pattern of the phase behaviour of LC ionomers **4**-Na was almost independent of the MM, whereas the clearing points of different fractions varied over a wide range upon variation of  $P_w$  (Fig. 13).

An extremely low concentration of charged groups inducing the appearance of a smectic phase should be pointed out. LC ionomers **4a–d**-Na are characterised by a similar content of sodium ions at which transition from the nematic to smectic mesophase occurs ( $< 1.2$  mol.%). Nevertheless, even copolymers of identical composition contain different amounts of charged groups per macromolecule owing to a low degree of polymerisation and low concentration of metal ions. For instance, ionomers **4a**-Na(2%) with  $P_w = 100$  contain on average two sodium ions per polymer chain, whereas the ionomers **4c**-Na(2%) ( $P_w = 45$ ) and **4d**-Na(2%) ( $P_w = 25$ ) contain the same number of sodium ions per two and four polymer chains,

**Figure 13.** 'Liquid crystal–isotropic melt' transition temperature plotted vs. degree of polymerisation of LC ionomers **4**-Na(10%).<sup>56, 57</sup>

respectively. Thus, in the last-mentioned ionomer there are two polymer chains per  $\text{Na}^+$  ion, *i.e.*, 50% of the total amount of polymer chains contain no charged groups at all. Meanwhile, even such a small amount of charged groups is sufficient to change the phase behaviour of ionomers and to form a layered packing of the side mesogenic fragments. This observation has played a significant role in the development of model concepts of the structural organisation of LC ionomers (see below).

As shown above (see Section II), the modern theory of melts of random linear ionomers postulates the formation of ionic aggregates (multiplets, clusters) from charged groups in a nonpolar polymer matrix.<sup>16,17</sup> To a first approximation these aggregates can be treated as non-covalent cross-link points of the backbones. The authors assumed that it is the charged multiplets that have the structure-forming effect on the macromolecular system, resulting in broadening of the temperature interval of existence of the LC phases and in the appearance of the smectic phase.<sup>56</sup>

Often, the formation of smectic mesophases in comb-shaped LC polymers is attributed to microphase separation of the polymer chains and side mesogenic fragments.<sup>3,5</sup> The formation mechanism<sup>57</sup> of a smectic (lamellar) packing of side mesogenic groups involves the formation of a small amount of the simplest multiplets (quadruplets) comprising two ion pairs. Fixation of two polymer chains due to the formation of a quadruplet leads to a decrease in the entropy of macromolecules and facilitates the interaction of next ion pairs, resulting in the formation of a new ionic cross-link. Owing to a low degree of polymerisation (at most 100) the macromolecules of LC ionomers include only a few Kuhn segments.<sup>69</sup> Therefore, the presence of even a small amount of ionic cross-links must cause a substantial reduction of the number of possible conformations and rectification of the backbones of LC ionomers (because the number of segments between ionic cross-link points is insufficient for the formation of a bent chain fragment or a loop). It was theoretically substantiated<sup>70</sup> and experimentally proved<sup>71</sup> that the polymer chains of linear ionomers in the vicinity of multiplets are strongly rectified and their root-mean-square radii of gyration in the melt are larger than that of non-ionised copolymer. Rectification of polymer chains also reduces the translational mobility of side mesogenic groups, which apparently favours a transition from the nematic to smectic mesophase.

The molecular organisation of LC ionomers in the smectic mesophase is schematically shown in Fig. 14. Here, we deal with a 'shortcake'-type packing of macromolecules, which comprises layers formed by nonpolar (hydrophobic) mesogenic groups and layers formed by the main chains bearing ion pairs and functional carboxyl groups. It is logical to assume that an increase in polarity of the main polymer chains as a result of the presence of carboxyl groups and the appearance of charged groups will stabilise the layered structure, *i.e.*, favour broadening of the temperature interval in which the smectic mesophase exists.

The formation of multiplets was indirectly confirmed by a decrease in the solubility of ionomers in organic solvents and by an increase in the glass transition temperatures (see Fig. 12), which indicates that the polymer chains become more rigid. From the phase diagrams it is seen that changes in the glass transition temperature are most pronounced in a rather narrow range of compositions, being a maximum at 5 mol.% of  $\text{Na}^+$  and then reaching a plateau. Probably, this means that at high content of charged groups in the polymer matrix the average distance between ionic cross-links of the polymer chains becomes shorter than the length of the Kuhn segment.

The size and structure of the multiplets responsible for the phase state of LC ionomers must depend on the chemical nature of metal atoms. Fig. 15*a* presents the phase diagram of LC ionomers **4c-Rb** containing  $\text{Rb}^+$  ions whose ionic radius exceeds that of  $\text{Na}^+$  ion and Figure 15*b* demonstrates the dependences of the clearing point on the concentration of alkali metal cation for related ionomers **4c-Rb** and **4c-Na**.

Figure 14. Model of the structure of smectic ionomer.

Multiplets (1), individual ion-containing groups (2), aggregation region of mesogenic groups in smectic layer (3) and aggregation region of the polymer chains and ion-containing groups in the interlayer space (4);  $d$  is the thickness of the smectic layer.

Figure 15. Phase diagram of LC ionomers **4c-Rb** (a) and clearing points ( $T_c$ ) of ionomers **4c-Na** and **4c-Rb** plotted vs. metal content (b).<sup>58</sup> Metal (M): Rb (1) and Na (2).

Comparison of the phase diagrams in Figs 12*a* and 15*a* shows that the phase behaviour of both types of LC ionomers obeys the same pattern. At the same time it is clearly seen that the clearing points of the ionomers containing  $\text{Na}^+$  ions are somewhat higher than those of their  $\text{Rb}^+$ -containing analogues (Fig. 15*b*). A higher rubidium concentration required for induction of the smectic phase should also be pointed out. We believe that this experimental result can serve as an additional substantiation of the formation of ionic aggregates in LC ionomers.<sup>58</sup>

**Role of polymer composition.** The results and model concepts considered above provide an incomplete explanation for the extremely low content of metal ions, which favours induction of the smectic mesophase in the LC ionomers **4-Na**. In this connection it is interesting to compare the character of the phase behaviour of ionomers with different side groups or differing in ratio of functional (ionogenic) and mesogenic fragments taking into account the published data for related comb-shaped LC ionomers.<sup>45,46</sup>

The effect of the composition and molecular architecture of the initial LC copolymers on the phase behaviour of corresponding ionomers was considered taking copolymers **4e–f** with smaller, compared to **4a–d**, initial content of carboxyl groups (see Fig. 12*b,c*) as examples.<sup>56</sup> As can be seen in these phase diagrams, the increase in the clearing point with an increase in the content of metal ions becomes less pronounced (especially, for **4e-Na**), whereas induction of the smectic mesophase for **4f-Na** requires a higher concentration of  $\text{Na}^+$ ; ionomers **4e-Na** retain the initial nematic phase over the whole range of investigated concentrations. Thus, a decrease in the total number of functional carboxyl groups in the initial LC copolymers **4a–f** makes the effect of metal ions much weaker, which is consistent with the concepts of microsegregation in comb-shaped polymeric systems (see Fig. 14).

The dependence of the phase state of LC copolymers **4** on the content of acrylic acid units (Fig. 16) shows that copolymers containing 30 mol.% carboxyl groups are near the induction region of the smectic mesophase. This means that a slight increase in polarity of polymer chains owing to introduction of additional carboxyl or ion-containing groups is sufficient for the formation of layered order. It is this effect that is achieved by replacing a small proportion of carboxyl protons by alkali metal ions. At the same time, polymer chains of the LC copolymers with a low content of acid groups are less prone to microphase separation and the induction of the smectic phase requires introduction of a much higher amount of charged groups into their macromolecules.

**Figure 16.** Phase diagram of copolymers **4** with different content of acrylic acid monomer units.<sup>59</sup>

It should be noted that consideration of the phase behaviour of LC ionomers in the framework of the modern theory of ionomers is consistent with its interpretation based on the concepts of microphase separation. Undoubtedly, the concept of microphase separation is more general in character because it can be applied to a broad range of polymeric systems containing structural units of different chemical nature. At the same time, model concepts in the field of physical chemistry of ionomers show how general regularities of the microphase separation work as applied to ion-containing macromolecules.

The model considered permits a clear interpretation of the increase in the clearing point of LC ionomers with an increase in the content of metal ions. Indeed, thermally induced disordering of the LC phase due to localisation of the mesogenic groups and main polymer chains in individual layers requires that not only the lateral interactions between mesogenic groups be overcome but also the layer comprising the main polymer chains and multiplets be broken down. The observed dependence can be explained by increasing the role of this additional structure-forming factor with an increase in the concentration of metal ions.

**Role of the side chain length.** From the modern theory of ionomers<sup>17</sup> and results of experimental studies<sup>43,44</sup> it follows that an increase in the distance between charged groups and the polymer backbone can lead to more efficient formation of ionic aggregates due to lower steric hindrance. The influence of this effect on the phase behaviour of LC ionomers was studied taking copolymers<sup>67</sup> with functional groups linked to the backbone through flexible methylene spacers  $(\text{CH}_2)_n$  as examples.

The phase diagram of LC ionomers **6-Na** containing charged carboxyl groups separated from the backbone by two methylene links is shown in Fig. 17*a*. An increase in the proportion of charged groups in the polymer matrix causes a slight increase in the clearing point. At the same time these ionomers form only the nematic phase in the whole investigated range of  $\text{Na}^+$  concentrations, which is confirmed by the polarisation microscopy and SAXS data.

**Figure 17.** Phase diagrams of LC ionomers **6-Na** (*a*), **7-Na** (*b*) and **8-Na** (*c*).<sup>56,67</sup>

Thus, in contrast to the ionomers **4-Na** and **4-Rb** containing functional carboxyl groups directly connected to the backbone, ionomers **6-Na** with distant ionogenic groups exhibit no induction of the smectic mesophase with an increase in the concentration of charged groups in the polymer matrix. The different character of the influence of metal ions on the phase behaviour of LC ionomers is schematically shown in Fig. 18 as the ‘range of action’ of multiplets on the polymer matrix. As can be seen, in the case of ionomers **4-Na** and **4-Rb** multiplets are formed in the vicinity of the backbone and can therefore decrease its entropy to the greatest extent by reducing the number of accessible conformations. At the same time in the ionomers with distant charged fragments (**6-Na**) this effect is weakened due to the presence of flexible spacers between multiplets and the backbone.

These effects must be even more pronounced with an increase in the distance between charged carboxyl fragments and the backbone. For instance, an increase in the concentration of sodium ions in LC ionomers **7-Na** with a long spacer  $(\text{CH}_2)_6$  leads to reduction of the clearing point and only the initial nematic phase is retained over the whole range of compositions studied (Fig. 17*b*). Thus, ionic aggregates formed in the ionomers under consideration play a destabilising role and cause disordering of the mesophase. A conclusion about the destabilising effect of the charged groups distant from the backbone on the ordering of side mesogenic groups in comb-shaped LC ionomers was also drawn earlier.<sup>46</sup>

**Figure 18.** Schematic representation of the effect of ionic multiplets on the polymer matrix.<sup>67</sup> Functional groups are bonded to the backbone (a), charged groups are distant from the backbone (b).

It was interesting to check for this effect in copolymers with a smectic rather than nematic ordering type of the side mesogenic groups. Figure 17c shows retention of the smectic mesophase in LC ionomers **8-Na** in the Na<sup>+</sup> concentration range 0 mol.%–25 mol.%; however, an increase in the content of metal ions in the polymer matrix leads to a decrease in the clearing point and breakdown of the liquid-crystalline state.<sup>56</sup>

Thus, by placing charged groups at longer distances from the backbone it is possible to efficiently influence the temperature range of existence of the mesophase in LC ionomers. As the length of a flexible spacer between charged carboxylate ions and the backbone increases, the trend towards formation of smectic phases becomes less pronounced; the clearing point decreases as the content of charged groups in the polymer matrix increases. Hence, the key parameters responsible for the formation of ionic aggregates and their influence on the phase state of ionomers include not only the composition of the polymer matrix, the chemical nature of the metal and the concentration of metal ions but also the distance between functional ionogenic groups and the backbone. In the text below we will show that most of these regularities governing the structure and properties of LC ionomers containing alkali metal ions also hold for more complex systems containing multiply charged ions.

#### b. Liquid-crystalline ionomers containing calcium ions

An increase in the content of Ca<sup>2+</sup> ions in LC ionomers **4b-Ca** to 3 mol.% causes an increase in the melting point of the LC phase<sup>60</sup> (Fig. 19a). According to solid-state <sup>1</sup>H NMR spectroscopy data, the incorporation of Ca<sup>2+</sup> into the macromolecules **4b** not only presents no obstacles to the orientation of their side mesogenic groups in the magnetic field but is also accompanied by an increase in the orientation order parameter of the LC ionomers **4b-Ca**(3%). These results confirm the structure-forming effect of Ca<sup>2+</sup> ions on the polymer matrix by the mechanism of ion association and microphase separation, which was considered above taking LC ionomers containing alkali metal ions as examples. But in contrast to Na<sup>+</sup>-containing ionomers a further increase in the concentration of Ca<sup>2+</sup> ions (> 3 mol.%) does not lead to an increase in the clearing point; this parameter reaches a constant value and then remains unchanged.

**Figure 19.** Phase diagram of LC ionomers **4b-Ca** (a), model of ionic cross-link (b) and the simplest multiplet (c) in LC ionomers containing calcium ions.<sup>60</sup>

This feature of the phase behaviour of Ca<sup>2+</sup>-containing ionomers can be explained by a higher coordination ability of the doubly charged ions compared to alkali metal cations.<sup>60</sup> According to dynamic light scattering data, exchange of the polymer protons by singly charged ions (Na<sup>+</sup>, Rb<sup>+</sup>) in a dilute solution causes no aggregation of macromolecules that exist as isolated coils and the multiplets are formed only after removal of the solvent as a result of bringing ion pairs closer to one another. If we deal with multiply charged ions characterised by stronger coordination ability, polymer chains can approach one another in the course of the synthesis of ionomers with the formation of salt ionic cross-links (Fig. 19b) or more complex aggregates (Fig. 19c). Indeed, an increase in the molecular mass of such ionomers in solution was detected by gel-permeation chromatography and by light scattering. During removal of the solvent the aggregates formed in the stage of ion exchange can lead to a sterically unfavourable arrangement of macromolecules and induce the appearance of defects in the packing of the side mesogenic fragments, thus leading to destabilisation of the mesophase formed. Mutual compensation of the stabilising contribution of ionic aggregates (due to the microphase separation and chain stiffening mechanism) on the one hand and an increase in the number of defects on the other hand corresponds to reaching a plateau in the clearing point plot of ionomers containing Ca<sup>2+</sup> cations (see Fig. 19a).

**Figure 20.** Phase diagrams of LC ionomers containing transition metal ions: **4c-Cu** (a) and **4b-Co** (b).<sup>61–63</sup>

### c. Liquid-crystalline ionomers containing transition metal ions

The temperature dependences obtained for the liquid-crystalline ionomers containing doubly charged transition metal ions (Fig. 20) are in general similar to those found for  $\text{Ca}^{2+}$ -containing ionomers.<sup>60</sup> At the same time, optical polarisation microscopy and microcalorimetry data revealed breakdown of the liquid-crystalline phase at a concentration of  $\text{M}^{2+}$  ( $\text{M} = \text{Co}$ ,  $\text{Ni}$  or  $\text{Cu}$ ) ions of nearly 12 mol.%. This is probably due to the formation of coordination bonds between the  $\text{M}$  atom and oxygen atoms and terminal CN groups in the mesogenic fragments of the copolymer. A trend towards an increase in the coordination numbers of  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$  and  $\text{Cu}^{2+}$  ions to 4–6 was confirmed by the UV spectra of films and solutions of the corresponding ionomers.

Strong coordination bonds between transition metal atoms and the polymer matrix can cause a considerable increase in the concentration of defects in the matrix and produce steric strain. If the formation of an ionic cross-link involving a  $\text{Ca}^{2+}$  ion leads to fixation of two  $\text{COO}^-$  groups (and corresponding polymer chains), a transition metal atom can form additional bonds with a number of neighbouring mesogenic groups. At a sufficiently high concentration of transition metal ions (from 10 mol.%–15 mol.% in the compounds we have studied), enhanced defect formation in the mesophase leads to complete disordering.<sup>61–64</sup>

Important experimental information on the supramolecular organisation of comb-shaped LC ionomers, the state of charged groups in them and the influence of such groups on the polymer matrix can be obtained by studying the magnetic properties of corresponding derivatives containing  $\text{Cu}^{2+}$  ions.

The energy of exchange interaction between metal atoms in ferromagnets and antiferromagnets is known to be comparable with the thermal energy, which gives rise to co-operative magnetic phenomena.<sup>72, 73</sup> (In ferromagnets, the atomic magnetic moments are directed parallel to one another, while in antiferromagnets they are directed antiparallel and compensate one another.) A measure of the degree of correlation of the atomic magnetic moments is the exchange parameter  $J$ . Note that isolated transition metal atoms (e.g., in a dilute solution) are not involved in the exchange interactions and, hence, can not induce co-operative magnetic phenomena.

Undoubtedly, investigations of the magnetic properties of LC ionomers are of considerable interest, because this makes it possible to establish the spin state of their metal atoms. The magnetic properties of compounds are described using a number of models of interacting metal atoms.<sup>73</sup> The simplest dimer model allows for the magnetic exchange between two metal atoms, while a more complex one-dimensional (1D) model considers infinite chains of interacting particles.

The temperature dependences of the magnetic susceptibility of LC ionomers **4c-Cu** in the temperature range 4.2–300 K (Fig. 21) revealed the absence of a maximum value and a low room-temperature magnetic moment characteristic of antiferromagnets. The experimental values of the magnetic susceptibility were approximated using the dimer model and the 1D Heisenberg model.

**Table 2.** Results of approximation of the data on the magnetic susceptibility of LC ionomers **4-Cu** using the 1D Heisenberg model and the dimer model.<sup>62</sup>

| Ionomer           | Model | $\sigma^2$ | $-J/\text{cm}^{-1}$ | $C_m(\%)$ | $C_j(\%)$ | $-\theta/\text{K}$ |
|-------------------|-------|------------|---------------------|-----------|-----------|--------------------|
| <b>4-Cu(9.9%)</b> | 1D    | 0.8        | 178                 | 3.6       | 96.4      | 2.9                |
|                   | dimer | 28.0       | 349                 | 15.3      | 84.7      | 26.0               |
| <b>4-Cu(5.0%)</b> | 1D    | 0.9        | 148                 | 5.3       | 94.7      | 5.0                |
|                   | dimer | 20.5       | 265                 | 12.7      | 87.3      | 16.3               |
| <b>4-Cu(2.5%)</b> | 1D    | 1.5        | 116                 | 4.7       | 95.3      | 4.1                |
|                   | dimer | 1.8        | 264                 | 22.2      | 77.8      | –28.0              |

**Note.** Notations are as follows:  $\sigma^2$  is the root-mean-square deviation of experimental data from the dimer model and 1D Heisenberg model;  $J$  is the magnetic exchange parameter;  $C_m$  and  $C_j$  are the concentrations of isolated and magnetically coupled copper ions; and  $\theta$  is the Curie–Weiss constant.

**Figure 21.** Magnetic moment (1) and magnetic susceptibility (2) of LC ionomer **4c-Cu**(9.9%) plotted vs. temperature.<sup>61</sup>

Full and open circles denote experimental data. Solid and dashed lines denote fits of experimental data by the 1D Heisenberg model and the dimer model, respectively.

Analysis of the approximation parameters (Table 2) showed that LC ionomers **4c-Cu** containing 2.5 mol.%–9.9 mol.% of copper atoms are antiferromagnets with high exchange parameters. At  $\text{Cu}^{2+}$  content from 5.0 mol.% to 9.9 mol.%, the temperature dependence of the magnetic susceptibility of ionomers is correctly described by the 1D Heisenberg model, whereas the use of the dimer model leads to marked deviations from the experimental curve. This unambiguously indicates that copper ions exist in LC ionomers in the form of complex aggregates.<sup>62</sup>

Low concentration (< 15%) of the  $\text{Cu}^{2+}$  ions not involved in the magnetic exchange should be pointed out. In the model of structural organisation of LC ionomers shown in Fig. 22 these ions correspond to isolated ionic cross-links. This fact is very important because it shows that steric hindrance in comb-shaped polymers with bulky side fragments (including the systems under study) does not preclude a trend towards formation of multiplets by the charged groups. At the same time it was impossible to propose an accurate structural model for magnetically interacting centres because of a limited number of compounds. Probably, copper atoms in the polymer matrix can be involved in both direct (if brought to close proximity) and indirect exchange through oxygen bridges of the ester groups.<sup>74</sup>

The magnetic properties of the LC ionomer **4-Cu**(2.2%) with low metal content are somewhat different from those considered above. This ionomer is also an antiferromagnet, but the root-mean-square deviations of the experimental data from both the Heisenberg model and the dimer model in this case are the same.

**Figure 22.** Model of LC ionomers containing  $\text{Cu}^{3+}$  ions (see Ref. 61). Multiplet (1) and isolated cross-link (2).

Thus, none of the models provides a correct description of the magnetism of compound **4-Cu**(2.2%). But it should be noted that manifestation of the antiferromagnetic properties at so low a copper content confirms the ability of charged groups to form aggregates (multiplets), because isolated copper atoms are not involved in co-operative magnetic interactions (see above).

Yet another approach to the synthesis of LC ionomers containing ferrocene in the side groups (**11a–c**) was reported in studies by Zentel *et al.*<sup>50–55</sup> (Scheme 1). The oxidation of ferrocene fragments to give cationic ferrocenium groups leads to some broadening of the interval of existence of the SmA phase and to a slight increase in the clearing points (Table 3). This can be explained by ordering of the mesogenic groups in the backbone (for details, see Section IV). The introduction of bulky isometric ferrocene fragments into the LC copolymer must lead to defect formation in the packing of the anisometric mesogenic groups. At the same time the oxidation of ferrocene groups produces ion pairs which tend to form aggregates that in turn form corresponding microphases. Thus, bulky ferrocene fragments can be treated as excluded from the mesophase and thus can affect its liquid-crystalline characteristics to a much lower extent.<sup>55</sup>

The formation of ionic aggregates in the ferrocene-containing LC ionomers investigated by the Zentel group was confirmed by

**Table 3.** Compositions and transition temperatures of comb-shaped ferrocene-containing LC polymers according to  $^1\text{H}$  NMR data (see Ref. 54).

| Polymer    | $y$ (mol. %) | Phase transitions   |                                                               |

<sup>a</sup> The counterion is given in parentheses. <sup>b</sup> With decomposition.

the results of dynamic mechanical measurements, small-angle X-ray scattering and by the orientation features of nematic samples in electric field.<sup>54</sup> The temperature dependences of the mechanical loss factor  $\tan \delta$  and the elastic modulus showed that the LC ionomers studied obey the regularities known for weakly cross-linked polymeric systems. At the same time studies on the orientation of samples in electric field revealed an interesting feature that is atypical of conventional LC polymers, *viz.*, the Frederix transition threshold<sup>¶</sup> was almost independent of the presence of charged groups.<sup>54</sup> These experimental results were explained by the possibility of breakdown of ionic aggregates and formation of new aggregates in other domains of the polymer matrix upon the motion of the polymer chains under the action of external field. At the same time the influence of the multiplet structure manifests itself as a considerable (by an order of magnitude) increase in the reorientation time of the LC ionomers.

Dielectric spectroscopy studies and thermodepolarising current measurements were carried out to obtain information on the molecular mobility of copper-containing LC ionomers and to establish how ionic aggregates influence the local and segmental motions of the polymer chains and side mesogenic groups.<sup>65</sup> The incorporation of copper ions into the LC copolymer **4** led to a slight decrease (by 3–4 °C) in the temperatures of co-operative  $\alpha$ - and  $\delta$ -processes (Fig. 23), which respectively reflect the segmental mobility of the backbone and the reorientation of the side

<sup>¶</sup> The critical strength of external field at which the orientation of mesogenic fragments (direction of director) in liquid crystal sample changes.

**Figure 23.** Depolarisation current plotted vs. temperature for copolymer **4** (a) and ionomer **4-Cu**(2.5%) (b).<sup>65</sup> Polarisation temperature is 60 °C and the electric field strength is 50 (1), 100 (2) and 300 V mm<sup>-1</sup> (3).

mesogenic groups of the copolymer, which proceeds at higher temperatures. At the same time studies of LC ionomer **4-Cu**(2.5%) at 74 °C revealed yet another intense co-operative  $\rho$ -process (also dipole in nature), which was characterised by significantly restricted molecular mobility compared to the  $\alpha$ - and  $\delta$ -processes.

The results obtained are consistent with the Eisenberg model of amorphous ionomers (see above), according to which the polymer chains in the multiplet shell are characterised by restricted mobility (see Fig. 5). The high-temperature process detected in the thermodepolarising current curves seems to correspond to the dynamics of the polymer chains in the regions of restricted segmental mobility in the multiplet shell. The temperatures of the local processes associated with the rotational mobility of the side mesogenic groups along the long axis and with the mobility of the methylene spacers are almost independent of the content of copper ions in the **4-Cu** ionomers.

All the LC ionomers discussed above belong to the acrylic and methacrylic series with nearly the same type of molecular architecture. Information on the systems with polysiloxane backbone<sup>75</sup> and comb-shaped LC ionomers with the charged groups localised within the backbone<sup>76</sup> is scarce. It is interesting that in last case the glass transition temperature and the clearing point of the liquid-crystalline phase depend only slightly on the structure of the side mesogenic fragments. This may be due to strong microsegregation of charged mesogenic fragments and poly(ethylene oxide) blocks incorporated into the backbone.

The results obtained in studies of comb-shaped metal-containing LC ionomers were analysed by the Zhao<sup>45–48</sup> and Zentel<sup>50–55</sup> groups and by the authors of this review. It was unambiguously shown that correct prediction of the physicochemical properties and structure of these compounds requires taking into account not only the concentration of charged groups but also some additional factors, *e.g.*, the chemical structure of macromolecules, the structure of functional (ionogenic) fragments, methods of synthesis, *etc.* The phase state and the structure of this class of comb-shaped polymers are primarily determined by competition between such processes as the formation of mesophase due to the dispersion interactions of mesogenic fragments, the ionic aggregation of charged groups and the microphase separation of the backbone and the side fragments.

We believe, and this was confirmed by the results of investigations of LC ionomers of different chemical nature (see Table 1), that prediction of the structural features and phase behaviour of these compounds first of all requires taking into account positions of the charged groups relative to the backbone and the ability of the starting polymer to form a smectic order (so named smectogeneity). For instance, the formation of smectic packing is characteristic of comb-shaped ionomers with high content of acrylic acid units (>30 mol.%) and cyanobiphenyl mesogenic fragments because of (i) the microphase separation between the polar chains and nonpolar side groups and (ii) ionic

aggregation. At the same time a decrease in polarity of the backbone makes this tendency much less pronounced.

A fundamentally different situation occurs for those LC ionomers in which functional groups are distant from the backbone. Irrespective of the phase character of the initial copolymer these compounds exhibit a decrease in the clearing point with an increase in the content of the charged groups owing to the disordering effect of ionic aggregates on the surrounding mesogenic fragments.

The phase behaviour and structure of the systems with multiply charged metal ions depend on the structure of the polymer matrix in a more complex fashion. This is associated with the possibility of formation of ionic cross-links or coordination bonds. It seems to be that the most important feature of such compounds is breakdown of the mesophase (amorphisation) at high concentrations of transition (or rare-earth) metals. This imposes limitations on the design of functional materials or composites based on LC ionomers containing multiply charged metal ions.

## 2. Comb-shaped liquid-crystalline ionomers containing organic counterions

A conventional method of preparation of thermotropic comb-shaped LC polymers involves the chemical addition of mesogenic groups to the side aliphatic branchings of comb-shaped polymers (Fig. 24a).<sup>3–5,7</sup> At the same time an approach to the design of comb-shaped LC copolymers by electrostatically binding diphilic molecules to the polymer chain with the formation of polycomplexes (Fig. 24b) has been intensively elaborated in the last decade. Research groups headed by Paleos,<sup>77,78</sup> Ujiie,<sup>79,80</sup> Bazuin<sup>81–83</sup> and Talrose<sup>84–88</sup> contribute largely to the development of this avenue. Physicochemical studies of various aspects of the structure formation and lyotropic mesomorphism in solutions of such polycomplexes can in fact be treated as a specific, important field of polymer science. It is necessary to emphasise that the subject of investigations carried out by all the research groups mentioned above is thermotropic mesomorphism, *i.e.*, the ability of polymeric systems to form LC phases in a particular temperature range under solvent-free conditions.

**Figure 24.** Schematic representation of the molecular structure of comb-shaped LC polymers with covalent (a), electrostatic (b) and mixed (c) type of addition of side groups.

Considerable advances in the design and synthesis of a novel class of thermotropic liquid-crystalline ion-containing polymers have been made by Russian scientists.<sup>84–88</sup> Polycomplexes obtained *via* molecular self-organisation of a polymer matrix and a low-molecular-mass amine form a smectic-type LC phase. It should be noted that the individual components of the complexes form no thermotropic mesophases. Conventionally used polymer matrixes include amorphous polyacids (polyacrylic acid, polymethacrylic or polymalonic acid) and polyvinylsulfonates. Amines can be chosen from a broader range of compounds, namely, from primary to quaternary amines with various structures of the lyophobic molecular fragment. The reaction between the polyacid and amine usually results in proton-transfer complexes.

It should be noted that basic to the mesomorphism revealed is the marked diphilicity of the polycomplex and the corresponding

microsegregation processes rather than the rigidity or geometric anisotropy of the side groups. Such ionic complexes represent microheterogeneous systems in which the layered structures formed due to packing of the side chains are 'reinforced' with a network of electrostatic interactions and hydrogen bonds.<sup>85</sup> If one uses linear long-chain aliphatic amines, crystallisation of the complex involving the formation of crystalline or rotationally-crystalline phases is highly possible. At the same time it is assumed that incorporation of one or two aromatic or cyclohexane rings into the amine molecule must cause appreciable changes in the symmetry of the alkyl fragment, thus making crystallisation of the polycomplex less probable.<sup>84</sup>

Ion-containing polymeric LC systems obtained by non-covalent binding of the polymer chains to low-molecular-mass compounds are of considerable interest. Investigations of the properties of comb-shaped LC polymers of mixed structure (one type of the side groups of a macromolecule are covalently bonded while the other type of the side groups are attached through electrostatic interactions; Fig. 24 c)<sup>89–92</sup> are also of great importance. Polymeric systems containing relatively low concentrations of charged groups can be considered as a specific class of LC ionomers with organic counterions.

Mesomorphous ion-containing polycomplexes and comb-shaped LC ionomers with organic counterions exhibit a number of salient features distinguishing them from the metal-containing ionomer systems considered above. If the phase states and the structure of metal-containing ionomers depend on the chemical nature and concentration of metal ions and on the structure and mesomorphous characteristics of the polymer matrix, in the case of ionomers with organic counterions one should also allow for the concentration and structure of low-molecular-mass complexant. As will be shown below, long aliphatic or aromatic fragments of counterions can be involved in the formation of mesophase and also act as bulky packing defects of the side mesogenic groups.

#### a. Synthesis of liquid-crystalline ionomers containing organic ions

Ion-containing complexes of polyacids with low-molecular-mass amines are obtained by mixing the initial components in the same solvent (ethanol, chloroform, pyridine) followed by concentration of the mixture or by the deposition of the polymer complex in an appropriate solvent (ethyl acetate, diethyl ether).<sup>83</sup> For instance, the reaction between amines and polyacrylic acid

was detected<sup>84–88</sup> from opalescence and precipitation on mixing transparent solutions of the initial components in ethanol. Even at a large excess of amine in the initial solutions the characteristic composition of the solid complex corresponds to a 2 : 1 polyacid : amine ratio (two carboxyl groups per amino group).<sup>84</sup> At the same time for mixtures of polymethacryloyl- $\alpha$ -aminocarboxylic acids with cetylamine  $\text{CH}_3(\text{CH}_2)_{15}\text{NH}_2$  (see Ref. 88), complexes of all polyacids studied contain 60 mol.%–70 mol.% of amine. Thus, the degree of substitution of carboxyl groups in these compounds depends only slightly on such characteristics of the polymer matrix as the distance between the COOH groups and the polymer chain.

Based on the results obtained in studies of model compounds (malonic and glutaric acids), it was proposed that non-stoichiometric complexes of polyacids are essentially stabilised by the intermolecular hydrogen bonds.<sup>84</sup> Seemingly, the case in point is the formation of a Y-shaped bond, because the proton involved in the strong hydrogen bond can form an additional H-bond with strong acceptors.

The reactions between polyacids and low-molecular-mass amines in a medium with low dielectric constant (THF) were also studied.<sup>89–94</sup> Good solubility of the polymer complex formed allowed complexes of controllable (stoichiometric) composition to be synthesised. The character of the polyacid–amine bond was studied in detail taking complexes of polymers **4d** and **10** with low-molecular-mass primary and tertiary amines as examples.

Analysis of the IR spectra of the products of the reaction between a nematic copolymer **4d** (based on acrylic acid and units containing mesogenic cyanobiphenyl groups) and octadecylamine  $\text{CH}_3(\text{CH}_2)_{17}\text{NH}_2$  (**13**) revealed<sup>89</sup> the absence of the antisymmetrical and symmetrical vibrational bands of  $\text{NH}_2$  groups (at 3340 and 3260  $\text{cm}^{-1}$ , respectively) characteristic of the spectrum of the low-molecular-mass amine (Fig. 25). The spectrum of ionomer **4d**·**13** exhibited reduced intensities of the  $\nu_{\text{C=O}}$  stretching bands of carboxyl groups. These data unambiguously point to the formation of an ionic complex *via* protonation of the amine  $\text{NH}_2$  groups by the carboxyl groups of copolymer **4d**. A polymer chain fragment of ionomer **4d**·**13** is schematically shown below for the case of incomplete substitution of carboxyl groups of the copolymer **4d**.

**Figure 25.** IR spectra of LC copolymer **4d** (1), ionomer **4d**·**13** (9%) (2) and low-molecular-mass amine **13** (3).<sup>89</sup>

In order to compare the ratios of the carboxyl groups involved and not involved in the formation of hydrogen bonds, differential IR spectra of mixtures containing different amine concentrations were studied.<sup>89</sup> A greater decrease in the band intensity of H-bonded carboxyl groups (at 1704 cm<sup>-1</sup>) means that they are more accessible to complexation. An analogous conclusion was drawn<sup>84</sup> for the complexes of compound **12** with salts of tertiary amines (**14–16**) differing in the structure of the lyophobic fragment of the molecule.

The reaction between polyacid **12** and photochromic tertiary amine **15** was confirmed by IR spectroscopic data (Fig. 26).<sup>92</sup> An increase in the concentration of tertiary amine **15** in the mixture of compounds **12** and **15** leads to a decrease in the intensities of the  $\nu_{O-H}$  and  $\nu_{C=O}$  stretching bands in the regions 3100–3700 and 1650–1750 cm<sup>-1</sup>, respectively. These changes are due to the decrease in the amount of carboxyl groups of polyacid **12** with an increase in the concentration of tertiary amine. The spectra of the complex obtained exhibit no intense  $\nu_{C-H}$  band of the methylene group at the nitrogen atom of the initial amine (at 2788 cm<sup>-1</sup>). The formation of a proton-transfer complex is also indicated by the appearance of the N–H stretching bands at 2505 and 2610 cm<sup>-1</sup>. A similar character of products of the reaction between acid **12** and a tertiary amine was revealed in studies.<sup>85–87</sup>

**Figure 26.** Fragments of IR spectra of polymer **12**, photochromic tertiary amine **15** and their mixtures with different content of amine **15**.<sup>92</sup> Content of amine **15** (mol.%): 100 (**1**), 0 (**2**), 29 (**3**) and 44 (**4**).

#### b. Structural organisation of liquid-crystalline ionomers containing organic ions

We will consider salient features of the phase behaviour of LC ionomers containing organic ions taking ionic complexes of nematic copolymer **4** with primary amine **13**<sup>59, 89, 90</sup> as examples. Mixtures with octadecylamine concentrations from 6 mol.% to 29 mol.% were obtained in THF solutions for this system. Investigations of samples with different concentrations of amine **13** allowed us to establish how sequential ‘build-up’ of a comb-shaped polymer by non-mesogenic low-molecular-mass amine molecules (see Fig. 24c) affects the state and thermal stability of the mesophase. This approach provides an effective method of

**Figure 27.** Phase diagrams of LC ionomers **4d·13** (**a**), **4a·13** (**b**) and LC copolymer **9** (**c**).<sup>89, 93</sup>

structure modification of comb-shaped LC copolymers and opens prospects for additional functionalisation of these compounds.

The phase diagrams of the LC ionomers **4·13** obtained using fractions of copolymer **4** with different molecular masses are shown in Fig. 27.<sup>89, 90</sup> Noteworthy is the disappearance of the nematic phase characteristic of the initial ionogenic copolymer and the formation of the SmA phase at concentrations of amine **13** of 5 mol.%–14 mol.%. Thus, the phase states of LC ionomers containing organic ions and metal cations obey similar patterns, namely, an increase in the content of charged groups is accompanied by an increase in the ordering of the side mesogenic fragments.

With allowance for the (i) phase transformations and structures of metal-containing LC ionomers (see above) and (ii) model concepts proposed for their interpretation, the formation of the smectic mesophase in the systems based on copolymers with organic counterions seems to be quite reasonable. Indeed, the formation of supramolecular aggregates and microphase separation, which plays a key role in the formation of mesophase, are primarily governed by the presence of ion pairs rather than the nature of the functional groups and counterions they are comprised of. Hence, all considerations concerning the character of the effect of the concentration of charged groups, the composition of the polymer matrix and the distance between functional groups and the backbone must also hold for the complexes of polymers with organic amines. The correctness of this approach is apparently confirmed by the features of the phase diagrams in the systems **4·13** (see above). However, the nature of the counterion can also influence the phase state of the complexes obtained and impart them in some cases the properties characteristic of the organic amine added.

Thus, the formation of the SmA phase in the LC ionomers **4·13** is governed by ionic aggregates. The effect of the aliphatic groups of octadecylamine manifests itself at high concentrations of this compound, which is associated with manifestation of the effects of microphase separation in the side groups of the comb-shaped polymer. If the concentration of amine **13** exceeds 24 mol.%, more ordered smectic mesophases (SmB, SmE) are formed. Samples with the degree of polymerisation  $P_w = 25–59$  form the smectic B phase while those characterised by  $P_w = 100$  form the smectic E phase. Apparently, the formation of these ordered mesophases is due to the microsegregation of long methylene chains of amine **13**.

This assumption was tested taking copolymers **9** of a mesogenic monomer 4-[(4'-cyano-1,1'-biphenyl-4-yl)oxy]butyl acrylate with *N*-octadecylacrylamide as examples. In these copolymers, the

octadecylamide fragment is chemically bonded to the polymer chain (Fig. 27 *c*). Microcalorimetric and X-ray diffraction studies showed that copolymer **9** forms an ordered mesophase with hexagonal packing of the side groups. However, this occurs at a much higher content of non-mesogenic monomer units (>40 mol.%) compared to the series **4**–**13** (25 mol.% of amine **13**). An increase in the content of aliphatic units in LC copolymers **9** leads to a faster (compared to ionomers **4**–**13**) decrease in the clearing points. A broad range of the nematic phase (>40 mol.%) and the absence of induction of the SmA phase in copolymers **9** should also be pointed out.

In a continuation of these investigations, comb-shaped functionalised LC complexes containing tertiary amine molecules **14**–**16** with azobenzene fragments were obtained.<sup>91,94</sup> Photochromic organic counterions were chosen to attain two goals, *viz.*, the incorporation of ion-containing groups simulating the structure of low-molecular-mass liquid crystals and the use of the ability of *para*-substituted azobenzene derivatives to undergo *cis*–*trans*-isomerisation and photo-orientation on exposure to polarised laser light.<sup>95</sup> The LC ionomers obtained are light-sensitive materials and can be used for recording and storage of optical information. A study of the kinetic curves of growth and of the relaxation of photo-induced birefringence revealed the influence of the electrostatic binding of the photochromic molecules with the polymer matrix on the character of photo-optical processes.<sup>91,92</sup>

The phase diagrams of the mixtures based on nematic compound **4c** and smectic compound **10** with low-molecular-mass components **14** and **15** are shown in Fig. 28. Irrespective of the phase state of the initial copolymer an increase in the concentration of dye in the mixture causes a monotonic decrease in the clearing point and the glass transition temperature; at a content of the photochromic component in the 15 mol.%–34 mol.% it undergoes partial crystallisation. All the mixtures based on the ordered smectic phase retain an orthorhombic pattern of packing of the side mesogenic groups in the smectic layer. An increase in the content of amine **16** only leads to thickening of the smectic layer due to the 'build-up' of the copolymer by photochromic amine groups, which are longer than the biphenyl mesogenic groups of the initial LC copolymer **10**. It should be emphasised that the addition of amine **15** (5 mol.%) to nematic polymer **4c** is accompanied by a change in the phase state, *viz.*, the formation of smectic phase and complete disappearance of nematic phases.

In these LC ionomers photochromic amines are not only involved in microphase separation and ionic aggregation but also induce the formation of defects during the ordering of side fragments, which governs the formation of mesophase. The role of defects can be played by bulky fragments of quaternary ammonium cations arranged near the polymer chain. Besides, long aliphatic bridges between the azobenzene fragment and the tertiary amino group hamper simultaneous packing of the photo-

chromic and mesogenic groups of LC copolymers, which manifests itself in a decrease in the clearing point and the enthalpy of melting of the LC phase with an increase in the content of amine. The use of amine **16**, containing a shorter spacer, is accompanied by a slight decrease in this negative influence. For example, an increase in the amine content in smectic ionomers **10**–**16** is accompanied by a much lower decrease in the clearing temperatures than in ionomers **10**–**14** (Fig. 28 *b*).

#### IV. Liquid-crystalline ionomers with mesogenic groups in the main chain

A significant role in the development of approaches to the synthesis of ferrocene-containing LC ionomers has been played by the studies of Zentel *et al.*<sup>55,96–99</sup> who showed that incorporation of ferrocene fragments into the polymer backbone followed by their oxidation produces no pronounced changes in the phase state of the systems under study.<sup>97,98</sup> This may be due to considerable steric hindrance to the formation of ionic aggregates in related polymeric systems. It is known that the macromolecules of LC polymers with mesogenic groups in the backbone adopt extended conformations. Due to the entropy and steric factors, this can be a possible reason for hindered interaction of charged groups, resulting in the formation of multiplets.

In order to reduce steric hindrance in the formation of ionic aggregates, a series of linear LC copolymers **17a–f** was obtained<sup>98</sup> by polycondensation. In these macromolecules, the ferrocene fragments were separated from the backbone through a flexible aliphatic bridge (CH<sub>2</sub>)<sub>*m*</sub>.

The ferrocene groups were oxidised by mixtures of *p*-benzoquinone with sulfuric or methylsulfonic acids or by a mixture of copper(II) perchlorate and perchloric acid.

The effect of the nature of the oxidant counterion Ox on the phase behaviour, structure and thermal stability of LC ionomers (**17a–f**)·Ox can be followed from the data listed in Table 4. In the case of the hydrosulfate and methylsulfonate counterions the compounds obtained are stable on heating above the clearing point, whereas systems with the perchlorate counterions slowly decompose under identical conditions. Irrespective of the nature of the counterion incorporation of charged groups into the macromolecule leads to some increase in the glass transition and clearing temperatures. If an increase in *T<sub>g</sub>* is typical of ionomers, an increase in *T<sub>c</sub>* is associated with microsegregation of the ferrocene fragments (see above), which facilitates packing of the mesogenic groups in the linear polymer (Fig. 29).

For the systems with charged groups smaller than ferrocene ions one can expect the formation of more stable ionic aggregates. Sulfite and phosphate groups were chosen<sup>99</sup> as candidates. The initial LC polymer **18**, to which charged groups were attached, forms a nematic rather than smectic mesophase unlike the derivatives **17a–f**. With allowance for this fact it was proposed that the formation of ionic aggregates in this polymer matrix will be associated with lower steric constraints and smaller entropy limitations.

**Figure 28.** Phase diagram of LC ionomers **4c**–**15** (*a*) and dependence of clearing point on concentration of photochromic component for LC ionomers **10**–**14** (*1*) and **10**–**16** (*2*) (*b*).<sup>91,94</sup>

<sup>a</sup> Compound was not obtained.**Figure 29.** Schematic illustration of microsegregation of ionic multiplets and mesogenic groups in linear ferrocene-containing LC ionomers.<sup>97</sup>

Experiments showed that the LC ionomers **19** and **20** with sulfite ions exhibit a monotonic increase in the clearing point and a decrease in the glass transition temperature with an increase in the content of charged units. This was explained by the impossibility of efficient formation of ionic clusters in the absence of a spacer connecting the charged groups to the polymer backbone (reduction of  $T_g$ ) and by an increase in the anisometry of macromolecules upon incorporation of charged fragments (increase in  $T_c$ ), because these fragments are more anisometric than the mesogenic groups themselves.

The opposite was observed for LC ionomers **21a,b** with the phosphate charged groups separated from the backbone by flexible spacers. The glass transition temperatures of ionomers considerably increase compared to the  $T_g$  value of the uncharged polymer. This was associated with the formation of ionic clusters. At the same time the clearing point of compound **21a** somewhat

decreases while ionomer **21b** forms no LC phase at all, which can be explained by the undesired steric effect of the bulky counterion.<sup>99</sup> However, since these polymers contain charged groups in all monomer units, the interpretation of their properties based only on the model of random ionomers may be to some extent incorrect.

$M^+ = (1/2) Ba^{2+}$  (**21a**),  $NH_2(C_6H_{12})_2^+$  (**21b**).

The phase behaviour of structurally similar LC ionomers **22** was also studied.<sup>100</sup> It was established that an increase in the content of charged groups in these systems is accompanied by a decrease in the glass transition and clearing temperatures and the systems become more prone to thermal degradation. The decrease in  $T_g$  was associated with a decrease in the molecular mass of ionomers on an increase in the content of charged groups. At the same time, the overall narrowing of the temperature range of the existence of mesophase is due to undesired influence of ionic aggregates which play the role of packing defects in the mesogenic fragments. An additional confirmation of this conclusion is provided by the fact that the temperatures of transition to the isotropic phase for a number of ionomers with similar molecular masses decreased to a greater extent as the proportion of charged groups increased.<sup>100</sup> Thus, the model assuming the formation of microphases comprising ionic aggregates and corresponding improvement of packing of mesogenic groups (see above)<sup>55</sup> is inapplicable to these ionomers.

Important information on the ionic dissociation in LC ionomers **22** was obtained in solution studies of the behaviour of macromolecules. The solubility of samples of compounds **22** in chloroform decreased in a regular fashion with an increase in the content of charged groups and the concentration dependence of

the reduced viscosity was strongly different from the linear dependence characteristic of the initial polymer. Additional experiments showed that at low concentration of ionomer **22** in solution intramolecular ionic interactions favour a decrease in the size of the polymer coil, whereas at high concentrations of the ionomer the interaction of macromolecules is accompanied by a dramatic increase in the reduced viscosity. Thus, solutions of these LC ionomers excellently obey the regularities established in studies of amorphous random ionomers.<sup>16</sup>

Analysis of the data on the LC ionomers with mesogenic groups in the backbone provides an additional confirmation of the occurrence of ionic association in mesomorphous polymeric systems. However, a correct interpretation of the changes in the phase behaviour and structure, induced by the incorporation of charged groups in the polymer, requires taking into account a number of factors similarly to the case of comb-shaped ionomers.

## V. Thermotropic liquid-crystalline chelato-telechelic polymers

The so-called LC chelato-telechelic polymers (see Fig. 1c) represent a specific class of liquid-crystalline ionomers with unusual chemical structure and a vast variety of supramolecular structures. These are ionic complexes of anisometric low-molecular-mass compounds (mesogenic groups) with terminal functional groups of the polymer chains (Fig. 30). Intensive studies of these compounds have been carried out in a research group headed by Jerome.<sup>101–105</sup>

Liquid-crystalline chelato-telechelic ionomers are usually characterised by a low content of charged groups. The SAXS diffraction pattern of these compounds exhibit a characteristic 'ionic peak' (Fig. 31). Possible types of structural organisation<sup>105</sup> of these compounds are schematically shown in Fig. 32.

As mentioned above, the ionic peak is a direct indication of the formation of ionic aggregates (multiplets and clusters) responsible for specific features of the structure and physicochemical properties of ionomers. At the same time, microcalorimetric, polarisation microscopy and X-ray scattering data unambiguously confirm the possibility for mesophases to exist in such polymeric systems. The formation of smectic mesophases only was observed for all studied compounds as a result of combination of ionic interactions and microsegregation. It should be noted that the ionic and mesogenic (*i.e.*, corresponding to the packing of mesogenic groups) reflections can appear in the diffraction

**Figure 30.** Chemical structure of linear LC chelato-telechelic polymers containing carboxyl groups ( $X^- = \text{COO}^-$ ) and sulfonic acid groups ( $X^- = \text{SO}_3^-$ ).<sup>105</sup>

patterns of LC chelato-telechelic polymers together or separately, which points to a complex character of supramolecular organisation of this type of compounds.<sup>105</sup>

According to Gohy and Jerome,<sup>105</sup> the key factors responsible for the supramolecular structure of LC chelato-telechelic polymers are the tendency of mesogenic fragments to form a liquid-crystalline order and the ionic aggregation of charged groups precluding this ordering (see Fig. 32). Some other factors, *e.g.*, the character of the bonds between functional groups of the polymer and mesogenic fragments, the glass transition temperature of the polymer (*i.e.*, the backbone flexibility), the molecular mass of the polymer and the mass fraction of mesogenic groups in the polymer matrix should also be taken into account. Let us consider them in more detail.

Let a terminal group of a polymer be connected to the mesogenic fragment owing to the formation of an ion pair with large dipole moment. In such polymeric systems, one should first of all expect the formation of ionic aggregates, which can suppress the structural organisation of mesogenic fragments, all things being equal.<sup>105</sup> This is characteristic of, *e.g.*, LC chelato-telechelic polymers with terminal sulfonic acid groups, whereas typical of

**Figure 31.** SAXS diffraction pattern of LC chelato-telechelic polymers.<sup>105</sup>

**Figure 32.** Supramolecular organisation of LC chelato-telechelic polymers according to SAXS data.<sup>105</sup> Multiplets (*a*) and layered organisation in the smectic mesophase (*b*). For notations, see Fig. 30.

carboxylate ions is full suppression of ionic association in favour of mesophase formation or coexistence of both these types of supramolecular organisation. In polymers with terminal carboxyl groups, the average distance between mesogenic groups is, for steric reasons, shorter than in the polymers containing sulfonic acid groups. This can facilitate effective side interactions resulting in liquid-crystalline ordering.<sup>103, 105</sup>

X-Ray diffraction patterns exhibiting ionic peaks are more typical of ionomers containing sulfonic acid groups bonded to polystyrene chains, whereas for more flexible polyisoprene macromolecules the formation of mesophase becomes possible. By decreasing the molecular mass of the polymer one can attain the appearance of an ionic peak, but this will lead to a regular decrease in the glass transition temperatures.

At very low concentration of mesogenic groups dispersed in the polymer matrix, they can no longer interact in a co-operative fashion and the formation of mesophase becomes impossible. In the case of LC chelato-telechelic polymers the content of mesogenic groups is unambiguously related to the molecular mass of the polymer chains and the amount of terminal functional groups per chain. In order to estimate the upper limit of the molecular mass at which the mesophase can still be formed, one should take into account the size of smectic layers formed by the mesogenic groups. Gohy and Jerome<sup>105</sup> believe that if the chain length is such that the polymer coil can not be effectively arranged within the layer of mesogenic groups, their coexistence is impossible. Clearly, the critical length depends on the chemical nature of the polymer used.

The dependence of the ionic peak position on the molecular mass of the polymer chains provides with information on the structure of ionic aggregates. In LC chelato-telechelic polymers the multiplets are cylindrical particles of radius  $\sim 3.5$  nm and a shell (region of restricted mobility of polymer chains<sup>17</sup>) size of  $\sim 5.5$  nm rather than spherical or lamellar entities.<sup>105</sup> Unfortunately, the length of such aggregates was not reported in the review cited.<sup>105</sup>

It is noteworthy that mesophase formation in the classical comb-shaped LC polymers is usually possible at a content of mesogenic groups of at least 50 mass%–80 mass% (this value decreases to 5 mass%–40 mass% for LC chelato-telechelic polymers<sup>101–105</sup>). Unusually low content of mesogens necessary for mesophase induction in such polymeric systems was explained<sup>101–105</sup> by strong microsegregation of charged mesogenic groups and the main polymer chains.

## VI. Conclusion

Analysis of the published data and the results obtained by the authors permits a step forward in the development of model concepts of the structure and physical chemistry of LC polymers and amorphous ionomers and their use for the description of specific features of the phase behaviour of comb-shaped LC ionomers. Using the methods of synthesis of LC ionomers considered in the review and the laws of mesophase formation, one can obtain novel metal-containing mesomorphous polymers and predict possible changes in the phase behaviour and structure of these compounds due to electrostatic interactions between charged groups. The review can be useful for those researchers who work in the field of design of new-generation LC polymers and materials based on them, *i.e.*, films, coatings, membranes, *etc.*

Investigations of LC ionomers containing transition metal ions make it possible to synthesise polymeric materials with controllable magnetic properties and to obtain mesomorphous nanocomposites which can find application as catalysts, nonlinear optical media, anisotropic conducting films and coatings. These fields are quite promising, as shown by studies on specific features of the state, structure and physicochemical properties of LC ionomers in the condensed phase.

Of considerable interest also are investigations of dilute solutions and gels of LC ionomers. In the text above we have

pointed to the dual nature of these macromolecules, which is due to the presence of hydrophobic mesogenic fragments responsible for the formation of the LC phase and hydrophilic functional groups, which are prone to form ionic multiplets. The diphilic nature of macromolecules predetermines an increased ability of a polymer to microsegregation, which leads to formation of a complex hierarchy of liquid-crystalline structures in the condensed phase. In solutions of LC ionomers the conformational state of macromolecules can be controlled by choosing particular solvent/precipitant ratios for selective solvation of functional groups. It is quite interesting to specify a conformation in solution by fine adjustment of hydrophobic–hydrophilic balance and then to try to ‘solidify’ it in the condensed state of the polymer by gradually removing or slowly displacing a certain solvent. This approach seems to be highly efficient for control of the character of packing and the size of liquid-crystalline nanostructures formed.

Unfortunately, such experiments have not been reported so far. However, similar, in some sense, investigations have long and successively been carried out by researchers from the Netherlands and Finland.<sup>106</sup> The focus of these studies has been design of self-organised supramolecular structures as a result of hydrogen bonding between block copolymer polyelectrolytes and low-molecular-mass non-mesogenic amphiphilic compounds. In such systems, phase separation due to variation of temperature causes the formation of optically anisotropic films comprising a number of types of lamellar nanostructures of different size (50 to 350 Å). These films closely resemble smectic mesophases of LC compounds and some block copolymers. Transitions between different structural types cause considerable (up to two orders of magnitude) changes in the electrical conductivity of the films. This offers interesting perspectives for the design of conducting polymer membranes in which the type of supramolecular organisation responsible for conductivity can be specified in solution.

Probably, an analogous approach can also be realised in the case of comb-shaped LC copolymers bearing functional groups by employing hydrogen bonding between these groups and corresponding dopants and introduction of charges into the polymer chain. Such ternary copolymers could also serve as models for some complex bioactive systems combining the ability of self-organisation and molecular recognition mechanisms.

In Japan, Prof. Osada and his collaborators do research in a related field. They design and study gel-like mesomorphous systems taking gels of comb-shaped LC polymers with mesogenic side fragments and functional carboxyl groups in the backbone (acrylic acid) or in side branchings as examples.<sup>107–109</sup> Strictly speaking, these compounds are not LC ionomers because the backbone contains no charged groups, but they belong to an interesting class of mesomorphous systems potentially capable of forming ionomers. Such copolymers readily form various types of mesophases and at low concentration of hydrophobic mesogenic groups some of them can dissolve in water giving anisotropic gels. Combination of the anisotropy of properties (in particular, birefringence) with a rather high molecular mobility allows LC gels to behave similarly to conventional low-molecular-mass liquid crystals and produce a fast response to the action of external (electric, magnetic, mechanic) fields accompanied by a change in the shape and size of the initial sample. Great prospects for the use of such systems in the design of novel ‘smart’ materials and possible fields of application have been outlined.<sup>110</sup>

**Abstract.** The mechanisms of promotion of cobalt catalysts used in the synthesis of hydrocarbons from CO and H<sub>2</sub> by Group VIII metals and rhenium are considered. The properties of the catalytic systems thus prepared are analysed. The bibliography includes 75 references.

## I. Introduction

Catalytic processes form the groundwork of petrochemistry and are widely employed in chemical technologies. Further perfection of the existing processes and enhancement of their efficiencies are impossible without application of novel catalysts with higher reactivities and selectivities to production. The solution of these practical tasks requires detailed analysis of structures and properties of catalytic systems, the methods for their preparation and activation, *etc.* Elucidation of relationships between the structures of active surfaces and properties of various catalysts and development of fundamentals of the selection of catalysts are central problems on the agenda of the present-day science of catalysis.

A search for reasonable alternative raw materials to crude oil, such as natural gas, coal, biomass, *etc.*, has received wide consideration in recent decades. Conversion of these basic raw materials into a carbon monoxide–hydrogen mixture (the so-called synthesis gas) and its use in preparation of hydrocarbon derivatives by the Fischer–Tropsch synthesis is one of their most promising applications. This trend competes favourably with conventional oil processing technologies used in liquid fuel production and organic synthesis. Today, the development of highly efficient and highly selective catalysts able to optimise the Fischer–Tropsch synthesis is a task of paramount importance.

At present, synthesis gas is employed for the preparation of aliphatic hydrocarbons on iron and cobalt catalysts. Co-containing systems are used as selective catalysts in the synthesis of linear

alkanes. However, many currently known Co-catalysts manifest low activities in the synthesis of n-paraffins.

Bimetallic cobalt catalysts have a number of advantages over monometallic systems, being wide-ranging with regard to activity and selectivity. One of the ways to increase the efficiency of Co-catalysts in the synthesis of hydrocarbons from CO and H<sub>2</sub> is doping by Group VIII transition metals. In turn, rationalisation of a search for highly reactive bimetallic catalysts puts forward the necessity to establish a correlation between the physicochemical and catalytic properties of catalytic systems, *i.e.*, their activities and selectivities in the processes under consideration.

This review covers the data published over the past 10–15 years devoted to cobalt-containing catalytic systems employed in the synthesis of liquid hydrocarbons from carbon monoxide and hydrogen. A separate chapter is devoted to the mechanisms of promotion of these catalysts by noble metals and rhenium.

## II. General information on the Fischer–Tropsch process

The conversion of synthesis gas can in general be described in terms of reductive oligomerisation of carbon monoxide on a heterogeneous catalyst:

Depending on the nature of the catalyst, reagent ratios and reaction conditions (temperature, pressure, *etc.*), the Fischer–Tropsch process yields hydrocarbons (alkanes, alkenes) and/or oxygen-containing products (alcohols, aldehydes, ketones, acids, esters, *etc.*).<sup>1</sup> As a rule, this synthesis does not afford individual products but, rather, a vast array of substances differing in the length of their alkyl chains typical of polymerisation reactions. The molecular mass distribution of these conversion products is well described by simple equations for polymerisation reactions which take into account the probability of chain growth and chain termination.

As regards the thermodynamics of the Fischer–Tropsch process, the hydrocarbons synthesised from CO and H<sub>2</sub> may possess any chain length, degree of saturation (with the exception of acetylene) and structures.<sup>1</sup> The Fischer–Tropsch synthesis normally yields alkenes as primary products; their subsequent hydrogenation affords alkanes.

Classical Fischer–Tropsch syntheses make use of metal catalysts (the latter are often referred to as ‘contacts’) based on iron, cobalt, nickel and ruthenium. The former two catalysts have found wide application in various industrial processes.

Received 24 September 2004

Uspekhi Khimii 74 (6) 634–645 (2005); translated by R L Birnova

The use of iron-based catalysts usually affords hydrocarbon mixtures with a high content of alkenes and branched paraffins as well as oxygen-containing products.<sup>1–3</sup> Cobalt-containing systems are considered to be the most efficient catalysts for the production of hydrocarbons from carbon monoxide and hydrogen, since they enable highly selective synthesis of saturated long-chain linear hydrocarbons:

The Fischer–Tropsch synthesis involves some side reactions, *viz.*:

1) hydrogenation of carbon monoxide to methane:

2) the Bell–Boudouard reaction (disproportionation of CO):

3) water gas equilibrium:

Synthesis of paraffins from CO and H<sub>2</sub> may be accompanied by secondary reactions over the whole range of temperatures used and includes the formation and hydrogenation of lower alkenes, partial hydrocracking and dehydrogenation of alkanes formed, hydrogen-transfer rearrangements, *etc.*

The actual composition of the products prepared from CO and H<sub>2</sub> differs substantially from the theoretical equilibrium composition. This reaction is kinetically controlled and the final composition of its target products is determined by the nature of the catalyst and the reaction conditions. In turn, the properties of Co-catalysts used in the Fischer–Tropsch syntheses strongly depend on the nature of substrates, percentage of the active metal components and sample activation conditions.

### III. Bimetallic cobalt catalysts

#### 1. Promotion by iron-subgroup metals

Recently, the attention of investigators has become focused on bimetallic catalysts for the Fischer–Tropsch synthesis. First, by varying the metal ratios, one can change their catalytic properties.<sup>4–7</sup> Second, combination of several active components in a catalyst makes it more stable and resistant against poisoning and coking.<sup>8</sup>

The Fischer–Tropsch synthesis involves preliminary reduction (or activation) of heterogeneous catalysts. All the catalysts undergo chemical transformations (so-called phase changes) upon reduction and subsequent synthesis of hydrocarbons from CO and H<sub>2</sub>. For example, reduced Fe-samples interact with synthesis gas to yield carbides and oxides; the activity of a catalyst increases upon preliminary carbide formation on its surface. On the contrary, cobalt catalysts are much less prone to form carbides and carbide formation prior to the synthesis markedly decreases their activity. Nevertheless, simultaneous introduction of iron and cobalt into the catalyst allows conversion of synthesis gas into hydrocarbons.<sup>9, 10</sup>

The activity and selectivity of cobalt catalysts is enhanced upon promotion by Group VIII transition metals and rhenium. The Fischer–Tropsch synthesis (250 °C, 10 atm) in the presence of various catalysts was studied by Ishihara *et al.*<sup>11</sup> It was shown that 10% Co/SiO<sub>2</sub> and 10% Fe/SiO<sub>2</sub> manifested unusually lower activities in comparison with those reported by other authors (see Refs 12–16): the conversion of carbon monoxide on these catalysts was as low as 5.2% and 0.2%, respectively. Introduction of two metals (Fe and Co) into the catalyst increased its activity in comparison with the monometallic systems, being dependent on the metal ratio. A decrease in the mass ratio Fe:Co from 3.0 to 0.35 (at the total metal content in the catalyst of 10%) resulted in an increase in CO conversion from 7.7% to 21.5%, in the selectivity of formation of hydrocarbons containing no less than two carbon atoms (C<sub>2+</sub>) from 49.8% to 71.6% and a decrease in

the methane content in the reaction products from 50.2% to 28.4%. It is noteworthy that the increased yields of paraffins C<sub>2</sub>–C<sub>5</sub> and decreased yields of hydrocarbons C<sub>6+</sub> was concomitant with a decrease in the relative content of Fe in the bimetallic contact.

The same authors<sup>11</sup> investigated also the properties of 10% Co–Ni-containing systems manifesting higher activities in the Fischer–Tropsch synthesis than the monometallic catalysts Co/SiO<sub>2</sub> and Ni/SiO<sub>2</sub>. It was found that with an increase in the mass ratio Co:Ni from 0.35 to 3.0 at the total metal content of 10%, the extent of CO conversion increased showing a maximum (32.3%) at Co:Ni = 1. All the samples of this series manifested similar selectivities in the synthesis of hydrocarbons C<sub>2+</sub> (67%–71%). However, the compositions of the products prepared on Co–Ni-contacts differed from those synthesised on Fe–Co, *viz.*, the former contained less alkenes and more hydrocarbons C<sub>6+</sub>. Heavier (in comparison with the monometallic samples) hydrocarbons were synthesised in the presence of a Co–Ni-catalyst.

X-Ray phase analysis has shown<sup>11</sup> that the surfaces of reduced monometallic catalysts Co/SiO<sub>2</sub>, Ni/SiO<sub>2</sub> and Fe/SiO<sub>2</sub> contained oxide phases. In the case of bimetallic samples, reduction brought about alloying of cobalt with iron or nickel. This favoured the reduction of iron and cobalt oxides to metals so that no oxide phases remained on the surface of the cobalt catalysts. Alloying of Co with Ni also facilitated their reduction which resulted in the increase in the amount of the activated reagents (hydrogen and carbon monoxide) (data from thermoprogrammed desorption of CO and H<sub>2</sub>) in parallel with the increase in the catalyst activities. It has been found<sup>17, 18</sup> that alloy particles present on the surface of Fe–Co-contacts differ in size. Under the conditions used, no carbide phases are formed from these metals, and the metals manifested enhanced hydrogenating activities in comparison with surface sites containing the carbide phase.

Studies of Co–Ni-catalysts supported on ZrO<sub>2</sub> have shown<sup>19</sup> that the increase in the Co content due to the increase of the mass ratio Co:Ni from 0.3 to 2.4 resulted in a twofold decrease in the content of the light hydrocarbons C<sub>1</sub>–C<sub>4</sub> in the products, while that of paraffins C<sub>5+</sub> increased from 35% to 63%. The degree of CO conversion did not change under these conditions and constituted 4%–5% at 250 °C and ambient pressure. Using thermoprogrammed reduction (TPR, see below), it was found that Ni promotion of Co/ZrO<sub>2</sub> catalysts induced a marked shift of the TPR signals towards the low-temperature region. Based on these data, it was suggested that nickel favours the reduction of cobalt oxide due to hydrogen spillover effect. As nickel is reduced earlier than cobalt, it begins to adsorb and activate hydrogen as a result of which the latter migrates towards cobalt oxide.

These examples clearly demonstrate that introduction of a second metal into Co-based catalysts not only increases their activities, but also allows control over their selectivities in the formation of a vast array of hydrocarbons.

#### 2. Promotion by noble metals and rhenium

Introduction of a tenth and even a hundredth of percent of noble metals into cobalt catalysts changes significantly their physicochemical and catalytic properties. It was found<sup>20, 21</sup> that Co-catalysts promoted by Pt, Rh, Pd, Ru and Re manifest high activities and selectivities in the syntheses of aliphatic hydrocarbons with various structures (both liquid and solid), which allows these processes to be conducted at relatively low temperatures (190–200 °C).

##### a. Studies of bimetallic cobalt catalysts by physicochemical methods

Promotion of cobalt catalysts was studied using various physicochemical methods, in the first place, by thermoprogrammed reduction (TPR). This method is used in the analysis of reducing potentials of catalysts as well as for establishing the compositions of non-reduced catalysts.

**Figure 1.** TPR spectra of the catalysts Co/Al<sub>2</sub>O<sub>3</sub> (1) and Co–Ru/Al<sub>2</sub>O<sub>3</sub> (2) recorded after calcination of the samples (300 °C, 14 h).<sup>22</sup>

The TPR spectrum of 20% Co/Al<sub>2</sub>O<sub>3</sub> prepared by impregnation of the support with cobalt nitrate is shown in Fig. 1 (curve 1).<sup>22</sup> The addition of 0.5% Ru (from the corresponding nitrosyl nitrate) to this catalyst favoured its easier reduction as can be evidenced from the nearly 100 °C shift of the TPR signal of the Co–Ru contact towards lower temperatures (see Fig. 1, curve 2). Cobalt oxide in the composition of the bimetallic sample was almost completely reduced to Co<sup>0</sup>, while the degree of reduction of a non-promoted catalyst was only 60%. It was supposed<sup>22</sup> that ruthenium formed upon reduction of its oxide prior to cobalt adsorbs and activates hydrogen. Hydrogen migrates towards Co<sub>3</sub>O<sub>4</sub> by a spillover mechanism and thus favours its easier reduction. Quite probably, ruthenium also either inhibits the formation of cobalt compounds that are difficult to reduce, e.g., by preventing the interaction of cobalt oxide with Al<sub>2</sub>O<sub>3</sub> to yield a Co–Al spinel, or favours their partial reduction. The absence of high-temperature peaks at >450 °C in the TPR spectrum of the Co–Ru-catalyst and the presence of a signal with  $T_{\text{max}} = 600$  °C in the TPR spectrum of the monometallic cobalt sample corroborates this hypothesis. According to hydrogen chemisorption data, the number of metallic cobalt atoms on the surface of a cobalt catalyst increases threefold upon promotion with ruthenium.

In the TPR spectra of palladium- or ruthenium (0.3%)-promoted Co samples, two signals were also shifted towards the low-temperature region in comparison with the monometallic catalyst (10% Co/Al<sub>2</sub>O<sub>3</sub>).<sup>23</sup> In the ruthenium-promoted catalyst, the first signal was shifted by 46 °C, while the shift of the second signal was 9 °C. The shifts were even more pronounced (195 and 72 °C, respectively) for the Co–Pd contact.

The effects of palladium additives to the catalyst Co/SiO<sub>2</sub> prepared by the sol–gel method (Fig. 2) have been studied by Guzzi *et al.*<sup>24</sup> The presence of a very broad peak in the TPR spectrum of a monometallic Co-contact (curve 1) points to a high degree of dispersion of cobalt particles. Introduction of Pd and subsequent reduction of the catalyst increases the content of metallic cobalt in the sample. At the mass ratio Co : Pd = 2 (see Fig. 2, curve 2), the peak corresponding to the reduction of cobalt oxide was shifted from 450 °C to 375 °C (Fig. 2, curve 1). It is noteworthy that the reduction of the monometallic catalyst 5% Pd/SiO<sub>2</sub> occurred at 150 °C (Fig. 2, curve 5). With a further increase in the Pd content, the shift of the characteristic peak was even more pronounced, *viz.*, up to 350 °C (Fig. 2, curves 3, 4). In the authors' opinion, a shoulder at 220 °C suggests the formation of bimetallic particles Co–Pd; this conclusion was confirmed by X-ray photoelectron spectroscopic (XPS) data.

The formation of bimetallic particles under TPR conditions was also observed in the analysis of rhodium-containing Co-catalysts.<sup>25–27</sup> The samples for this study were prepared on different oxide supports, e.g., SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>. (A more detailed

**Figure 2.** TPR spectra of the samples Co/SiO<sub>2</sub> (1); Co–Pd/SiO<sub>2</sub> (2–4); Pd/SiO<sub>2</sub> (5).<sup>24</sup> The Co : Pd atomic ratios are equal to 2 (2), 1 (3) and 0.5 (4).

description of characteristic features of these catalytic systems will be given below).

As a case in point, let us consider the results of a TPR analysis of Co/SiO<sub>2</sub> and Rh/SiO<sub>2</sub> samples and a bimetallic catalyst (Co–Rh/SiO<sub>2</sub>) prepared by impregnation with cobalt nitrate and rhodium chloride (total metal content was 4.9%, the atomic ratio Co : Rh was 1 : 1) (Fig. 3).<sup>25</sup> In this study, complete reduction of the catalyst Rh/SiO<sub>2</sub> occurred at 140 °C. The reduction of Co–Rh/SiO<sub>2</sub> occurred at a lower temperature (237 °C) than reduction of the monometallic cobalt sample (327 °C), which suggests that cobalt nitrate and cobalt oxide are reduced at higher rates in the presence of rhodium. It was found also<sup>25</sup> that the reduced catalyst Co–Rh/SiO<sub>2</sub> contains bimetallic particles, their inner part is enriched with metallic rhodium, while the outer layer is enriched with cobalt (see below, Section IV).

The addition of platinum to Co-containing systems also facilitates the reduction of cobalt oxides.<sup>28–30</sup> The results of a TPR study of the promoting effect of platinum on Co-catalysts are shown in Fig. 4.<sup>28</sup> A comparison of the TPR spectra of the monometallic sample (9% Co/Al<sub>2</sub>O<sub>3</sub>) (Fig. 4, curve 2) and the catalyst (9% Co–0.4% Pt/Al<sub>2</sub>O<sub>3</sub>) (Fig. 4, curve 3) shows that in

**Figure 3.** TPR spectra of the catalysts Co/SiO<sub>2</sub> (1), Rh/SiO<sub>2</sub> (2) and Co–Rh/SiO<sub>2</sub> (3).<sup>25</sup>

**Figure 4.** TPR spectra of the samples  $\text{Co}_3\text{O}_4$  (1), 9%  $\text{Co}/\text{Al}_2\text{O}_3$  (2), 9.2%  $\text{Co}-0.4\%$   $\text{Pt}/\text{Al}_2\text{O}_3$  (3), 8.9%  $\text{Co}/\text{SiO}_2$  (4), 8.7%  $\text{Co}-0.4\%$   $\text{Pt}/\text{SiO}_2$  (5).<sup>28</sup>

the latter case the peaks corresponding to the reduction of Co oxide phases are shifted towards the low-temperature region by more than 100 °C. The peak corresponding to the reduction of  $\text{Co}_3\text{O}_4$  is shifted from 377 to 207 °C, while the peak corresponding to the mixed cobalt–aluminium oxide is shifted from 717 to 587 °C. The TPR spectrum of the Co–Pt sample contained an additional signal (at 417 °C), which was assigned<sup>28</sup> to the reduction of  $\text{Co}_3\text{O}_4$  without involvement of platinum. Similar dependences were observed when  $\text{SiO}_2$  was used as a substrate, *viz.*, the peak corresponding to the platinum-promoted reduction of  $\text{Co}^{3+}$  to  $\text{Co}^{2+}$  was shifted from 327 to 147–177 °C (see Fig. 4, curves 4 and 5), while the shift of the peak assigned to the reduction of  $\text{Co}^{2+}$  to  $\text{Co}^0$  was less pronounced (from 397 to 357 °C).

As with platinum, promotion of the cobalt catalyst (20%  $\text{Co}-1\%$   $\text{Re}/\text{Al}_2\text{O}_3$ ) by rhenium shifted the signals in the TPR spectra towards the low-temperature region in comparison with the monometallic sample (Fig. 5).<sup>31</sup> However, in contrast to plati-

**Figure 5.** TPR spectra of the samples  $\text{Co}_3\text{O}_4$  (1),  $\text{Co}/\text{Al}_2\text{O}_3$  (2),  $\text{Re}/\text{Al}_2\text{O}_3$  (3) and  $\text{Co}-\text{Re}/\text{Al}_2\text{O}_3$  (4).<sup>31</sup>

num, which favours the reduction of the dominant cobalt oxide phases on the surface of a bimetallic contact at lower temperatures, rhenium brings about the reduction of both the highly dispersed surface phase of Co ( $T_{\text{max}} = 727$  °C for the monometallic sample, the TPR signal was shifted by 200 °C) and the spinel  $\text{CoAl}_2\text{O}_4$ . In the presence of rhenium, the latter was reduced practically completely as can be evidenced from the absence of signals at temperatures above 800 °C. It is noteworthy that the TPR spectrum of a monometallic Re sample displays a single signal at 425 °C.

Promotion of the catalyst 8.7%  $\text{Co}/\text{Al}_2\text{O}_3$  by platinum and rhenium increases the degree of reduction ( $R_{\text{Co}}$ ) and dispersity ( $D$ ) of metallic cobalt.<sup>32</sup> The former value reflects the number of metallic cobalt atoms with respect to the total content of cobalt atoms in the catalyst, while the latter indicates the number of surface metal atoms with respect to the total number of metallic cobalt atoms.

| Additive            | Without additive | 1% Pt | 1% Re |
|---------------------|------------------|-------|-------|
| $R_{\text{Co}}$ (%) | 52               | 79    | 78    |
| $D$ (%)             | 6.7              | 13.9  | 16.5  |

These data confirm the promoting effects of Pt and Re on the reduction of cobalt oxides.

However, some authors hold the opinion<sup>33</sup> that unlike noble metals, rhenium does not influence the reduction of cobalt catalysts. The extent of cobalt reduction was not changed upon addition of 0.6% Re to 5%  $\text{Co}/\text{Nb}_2\text{O}_5$  and constituted 48%. The TPR spectra of monometallic Co and a rhenium-promoted catalyst were also virtually identical. It should be noted however that the addition of rhenium to a Co-catalyst increased the dispersity of metallic cobalt from 8% to 12.5% in parallel with a decrease in the size of cobalt crystallites from 12 to 8 nm.

The TPR method was used to study the formation of bimetallic catalysts  $\text{Co}-\text{M}/\text{SiO}_2$  ( $\text{M} = \text{Pt}, \text{Ru}, \text{Rh}, \text{Pd}$ ).<sup>34</sup> The samples were prepared by repeated impregnation of the support with the salts  $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ ,  $\text{RhCl}_3 \cdot 4\text{H}_2\text{O}$ ,  $\text{RuCl}_3$ ,  $\text{PdCl}_2$  or the  $\text{Pt}(\text{acac})_2$  complex. After each (except for the last) impregnation, the samples were calcined at 450 °C. The results of these studies are presented in Figs 6 and 7 where the TPR spectra are superimposed for convenience. It was found that cobalt nitrate and cobalt oxide were present on the surface of the non-reduced catalyst  $\text{Co}/\text{SiO}_2$  (see Fig. 6, curve 1). The former underwent reductive decomposition ( $T_{\text{max}} = 235, 278$  °C), while the stepwise reduction of the latter to  $\text{Co}^0$  ( $\text{Co}_3\text{O}_4 \rightarrow \text{CoO} \rightarrow \text{Co}^0$ ) occurred at  $T_{\text{max}} = 330$  and 412 °C. Co–support compounds that are difficult to reduce ( $T_{\text{max}} = 479$  °C) were also found on the surface. The addition of platinum, palladium or rhodium (see Fig. 6, curves 2–4) to a monometallic catalyst resulted in an appreciable shift of the overall TPR spectrum towards the low-temperature region and the appearance of isolated signals at temperatures

**Figure 6.** TPR spectra of the samples  $\text{Co}/\text{SiO}_2$  (1) and  $\text{Co}-\text{M}/\text{SiO}_2$ , where  $\text{M} = \text{Rh}$  (2),  $\text{Pd}$  (3) and  $\text{Pt}$  (4).<sup>34</sup>

**Figure 7.** TPR spectra of the samples Co/SiO<sub>2</sub> (1) and Co-Ru/SiO<sub>2</sub> (2).<sup>34</sup>

below 200 °C in the former two cases (Pt and Pd). This peak corresponds to the reduction of platinum (palladium) oxide or mixed Co-Pt(Pd) oxides. The presence of a noble-metal phase on the surface of a substrate led the authors to postulate its role in the autocatalytic reduction of Co samples. Ruthenium formed no individual phase on the surface of a bimetallic contact and had virtually no effect on the reduction of the dominant cobalt phases as can be judged from the similarity of the TPR spectra of Ru-containing and Ru-free samples (see Fig. 7). Presumably, the properties of reduced bimetallic cobalt-containing catalysts depend on the nature of the promoter. Based on these data, the authors proposed a model of formation of active sites for a series of Co-M/SiO<sub>2</sub> catalysts (M = Pt, Ru, Rh, Pd) (see below).<sup>34</sup>

Thus, introduction of Pd, Rh, Ru, Pt and Re into cobalt catalysts results in considerable changes in their physicochemical properties. In the presence of noble metals, the reduction of cobalt oxides on the surface of a catalyst occurs more easily in the stage of activation due to hydrogen spillover. The number of active sites on the surface of cobalt catalysts increases with the increase in the degree of cobalt reduction rate and dispersity. This effect contributes significantly to the enhancement of activity of catalytic systems.

### b. Studies of bimetallic cobalt catalysts in the Fischer-Tropsch synthesis

Changes in the physicochemical properties of cobalt catalysts upon introduction of noble metals or rhenium result in changes in their catalytic properties. The use of such modified systems in hydrocarbon syntheses from CO and H<sub>2</sub> makes it possible to increase the activity of catalysts and the selectivity of formation of liquid hydrocarbons (C<sub>5+</sub>).

The effects of platinum and rhenium additives on the activities of Co-catalysts in the Fischer-Tropsch synthesis with 10% Co/Al<sub>2</sub>O<sub>3</sub> and 10% Co/SiO<sub>2</sub> as the original systems have been studied.<sup>28, 29, 32</sup> The catalysts were prepared by co-impregnation, drying and calcination in a flow of air (400 °C, 2 h) with subsequent reduction by hydrogen (14–16 h, *T* = 350 °C). The specific activities of Al<sub>2</sub>O<sub>3</sub>-based catalysts in the hydrocarbon synthesis from CO and H<sub>2</sub> (220 °C, 1 atm) at the molar ratio H<sub>2</sub>:CO = 7.3 were shown to increase substantially upon addition of 1% platinum or rhenium [from 18.4 for the monometallic sample to 36.8 and 38.3 μmol CO (g Co s)<sup>-1</sup>, respectively].<sup>32</sup> According to other authors,<sup>29</sup> the addition of 1% Pt to 10% Co/Al<sub>2</sub>O<sub>3</sub> increases the catalytic activity from 11 to 19 μmol CO (g Co s)<sup>-1</sup> (200 °C, 1 atm, H<sub>2</sub>:CO = 2). A 3–5-fold increase in the catalytic activity was also observed after addition of 0.4% Pt to 9% Co/Al<sub>2</sub>O<sub>3</sub> (SiO<sub>2</sub>) (210 °C, 1 atm, H<sub>2</sub>:CO = 7).<sup>28</sup>

The addition of small amounts of palladium or ruthenium (0.1%–0.7%) to 10% Co/Al<sub>2</sub>O<sub>3</sub>(SiO<sub>2</sub>) prepared by impregnation

with cobalt nitrate allows one to increase the extent of conversion of carbon monoxide and the yield of hydrocarbons C<sub>5+</sub> in the Fischer-Tropsch synthesis. Thus the extent of CO conversion on a Co-Pd-contact (200–210 °C, 1 atm, H<sub>2</sub>:CO = 2) was > 80%, and the yield of hydrocarbons C<sub>5+</sub> reached 95–97 g m<sup>-3</sup> (see<sup>†</sup>) (cf. 70% and 55 g m<sup>-3</sup>, respectively, for a non-promoted Co-catalyst). The selectivity of the synthesis of liquid hydrocarbons in the presence of Co-Ru-catalysts exceeded 80%.<sup>23, 35–38</sup> The effects of minor concentrations of Pt (0.1%–0.7%) on the activity of a cobalt catalyst (10% Co/SiO<sub>2</sub>) have been studied.<sup>39</sup> It was found that the contact 10%Co-0.7%Pt/SiO<sub>2</sub> manifested the highest activity in the hydrocarbon synthesis from CO and H<sub>2</sub> (200 °C, 1 atm, H<sub>2</sub>:CO = 2). With this catalyst, the yields of the liquid hydrocarbons increased to 92 g m<sup>-3</sup> at the degree of CO conversion rate of 87%, while the selectivity of their formation was 71%. The fractional compositions of the reaction products did not depend on the concentrations of Pd, Ru and Pt added to the Co-catalyst, viz., the content of hydrocarbons C<sub>5</sub>–C<sub>10</sub> was 65%–70%, that of hydrocarbons C<sub>11</sub>–C<sub>18</sub> was 27%–32%, while that of the C<sub>19+</sub> fraction was insignificant (1%–4%).<sup>36–39</sup>

The activities of Co/SiO<sub>2</sub> catalysts promoted by the platinum-group metals in the Fischer-Tropsch synthesis have been compared.<sup>34</sup> In all cases, the introduction of a second metal (Pt, Rh, Pd, Ru) resulted in a significant increase of the activities and selectivities of the bimetallic catalytic systems. Catalysts of this series manifested the following properties in the hydrocarbon synthesis from CO and H<sub>2</sub> (190–200 °C, 1 atm, H<sub>2</sub>:CO = 2):

1) the yields of liquid hydrocarbons (g m<sup>-3</sup>) decreased in the following order:

Co-Pt (139) > Co-Ru (129) > Co-Rh (124) > Co (118) > Co-Pd (82);

2) the selectivities of the formation of liquid hydrocarbons (%) decreased in the following order:

Co-Pt (81) > Co-Ru (77) > Co (76) > Co-Rh (72) > Co-Pd (60).

The liquid products obtained in the presence of the bimetallic catalysts contained predominantly saturated hydrocarbons with normal structures (64%–74%).

There is a large body of evidence in the current literature concerning Co-Ru catalysts of the Fischer-Tropsch synthesis.<sup>22, 40–51</sup> The synergism of catalytic effects of cobalt and ruthenium reported by most investigators suggests that bimetallic contacts exceed their monometallic counterparts in both activity and selectivity.

The addition of ruthenium to the catalyst 11.6% Co/TiO<sub>2</sub> (SiO<sub>2</sub>) changed the atomic ratio Ru:Co from 0.001 to 0.014.<sup>43</sup> In all cases, the rate of hydrocarbon synthesis<sup>‡</sup> (200 °C, 20 atm, H<sub>2</sub>:CO = 2) showed a tendency to increase. Thus for Ru:Co = 0.0067, this increased twofold, i.e., from 3.9 × 10<sup>-4</sup> to 6.4 × 10<sup>-4</sup> s<sup>-1</sup>. Under these conditions, the degree of carbon monoxide conversion increased from 49% to 51%, while the selectivity of liquid hydrocarbon synthesis reached 85%–86%. Calcination of a bimetallic Co-Ru-catalyst prior to reduction (1 h, 300 °C) brought about a further twofold increase in the reaction rate: the degree of conversion of CO and the selectivity of the synthesis of the hydrocarbons C<sub>5+</sub> amounted to 61% and 91%, respectively. These parameters were compared<sup>43</sup> to those obtained under similar conditions with 1.1% Ru/TiO<sub>2</sub>.<sup>44</sup> The extent of CO conversion on Ru/TiO<sub>2</sub> was 35%, i.e., lower than on the bimetallic contact with nearly the same selectivity (93% and

<sup>†</sup> The activities of the catalysts of the Fischer-Tropsch synthesis are usually estimated by the yields of the hydrocarbons [g per 1 m<sup>3</sup> of synthesis gas (CO + 2 H<sub>2</sub>) corrected to normal conditions (n.c.)]. The theoretical yield of the hydrocarbons is 208.5 g m<sup>-3</sup> (n.c.).

<sup>‡</sup> In this case, the synthesis rate is expressed by a value termed as 'reaction turnover number', i.e., the number of reaction acts per unit time.

91%). It is of note that the dispersity of the cobalt catalyst was not changed upon promotion by ruthenium.

Based on the data from electron microscopy, X-ray absorption spectroscopy and thermogravimetric analysis, it was suggested<sup>43</sup> that more rapid reduction of cobalt oxide requires a contact between Co and Ru to yield a mixed oxide upon calcination of bimetallic samples prior to reduction. Such treatment triggers the migration of ruthenium and cobalt oxides over the catalyst surface resulting in the formation of mixed Co–Ru oxides ( $\text{Co}_{3-x}\text{Ru}_x\text{O}_4$ , where  $0 < x < 1$ ). The presence of ruthenium decelerates deactivation of the catalyst due to coking. As a consequence, the activity of the Co–Ru-contact and the selectivity of formation of liquid hydrocarbon increase.

The properties of mono- and bimetallic catalysts containing 6% Co and/or 2% Ru supported onto  $\text{SiO}_2$  or  $\text{Al}_2\text{O}_3$  were examined under differential, static and flowing regimes.<sup>45,46</sup> In all the three cases, the bimetallic catalysts manifested the highest selectivities in the Fischer–Tropsch synthesis, the highest selectivity (69%) of the synthesis of hydrocarbons  $\text{C}_{2+}$  in a flow reactor (240–280 °C, 1 atm,  $\text{H}_2:\text{CO} = 1$ ) being manifested by the bimetallic contact Ru–Co/ $\text{Al}_2\text{O}_3$ . In addition, in this case the highest yield of alkenes (19%) was achieved. The activities of the catalysts Ru/ $\text{Al}_2\text{O}_3$  and Ru–Co/ $\text{Al}_2\text{O}_3$  appeared to be similar as could be judged from the extent of conversion of carbon monoxide: the extent of CO conversion ( $K_{\text{CO}}$ ) was 14% and 16%, respectively, which markedly exceeded that for Co/ $\text{Al}_2\text{O}_3$  ( $K_{\text{CO}} = 8.2\%$ ). The degree of cobalt reduction in the bimetallic contact was higher in comparison with the corresponding monometallic catalyst, which can be attributed to the activation of  $\text{H}_2$  on the surface of ruthenium and its subsequent spillover to cobalt oxide as well as to the formation of Ru and Co alloys as can be evidenced from the appearance of signals corresponding to mixed clusters  $\text{RuCo}^+$  in the mass spectra of secondary ions.

Co–Ru-Catalysts prepared on mixed oxide supports ( $\text{ThO}_2\text{--Al}_2\text{O}_3$  and  $\text{La}_2\text{O}_3\text{--Al}_2\text{O}_3$ ) also exceeded monometallic Co-samples in activity; the selectivity of formation of liquid hydrocarbons reached 79%.<sup>47–49</sup> The activity and selectivity of a bimetallic Co–Ru-sample increased noticeably after calcination and subsequent reduction.

It is of note that the temperature of preliminary calcination of a cobalt-containing catalyst influences the extent of cobalt reduction and, as a consequence, its catalytic activity. The properties of a contact 20% Co–0.5% Ru/ $\text{Al}_2\text{O}_3$  employed in the synthesis of hydrocarbons from CO and  $\text{H}_2$  (220 °C, 1.8 atm,  $\text{H}_2:\text{CO} = 10$ ) have been investigated.<sup>50</sup> With an increase in the calcination temperature from 250 to 400 °C, the peaks in the TPR spectra were shifted towards higher temperatures (Fig. 8), while the extent of Co reduction decreased from 77% to 59%. This was accompanied by a decrease in the extent of carbon monoxide conversion (from 11% to 5%), reaction rate [from 50 to 23  $\mu\text{mol CO (g Co s)}^{-1}$ ] and selectivity of methane synthesis (from 84% to 73%).

Besides, catalytic properties of bimetallic contacts strongly depend on the method of preparation and the nature of the substrates and the starting metal salts. Thus the catalyst 20% Co–0.5% Ru/ $\text{Al}_2\text{O}_3$  was prepared from different ruthenium derivatives, viz.,  $\text{Ru(NO)(NO}_3)_3$  and  $\text{RuCl}_3$ , using combined or sequential impregnation.<sup>22</sup> The Fischer–Tropsch synthesis was carried out at 220 °C, 1 atm and the  $\text{H}_2:\text{CO}$  ratio = 2. The catalyst prepared by co-impregnation with  $\text{Co(NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and  $\text{RuCl}_3$ , drying (5 h, 115 °C) and calcination (2 h, 300 °C) manifested the highest activity. The reaction rate on this catalyst was 0.342 g  $[-\text{CH}_2-]$  (g of catalyst h)<sup>–1</sup>.

Samples containing 5% Co on  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  or aluminosilicate ( $\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$ ) were prepared by impregnating the support with a solution of cobalt carbonyl in n-hexane. The addition of 0.5% Pd to such a catalyst increased its activity and the yield of liquid hydrocarbons.<sup>51</sup> The bimetallic contact with  $\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$  as a support manifested the highest activity in the Fischer–Tropsch synthesis (210 °C, 1 atm,  $\text{H}_2:\text{CO} = 2$ ) which increased from

**Figure 8.** TPR spectra of the sample Co–Ru/ $\text{Al}_2\text{O}_3$  calcined at different temperatures: non-calcinated (1); 250 °C (2); 300 °C (3); 350 °C (4); 400 °C (5).<sup>50</sup>

$6.6 \times 10^{-3}$  to  $8.7 \times 10^{-3}$  mmol CO (g of Co s)<sup>–1</sup> in comparison with the monometallic Co-sample. The yield of liquid hydrocarbons increased from 57 to 72 g m<sup>–3</sup>, while the selectivity of their formation increased from 33% to 42%. The extent of cobalt reduction increased from 55% to 62%. Presumably,<sup>51</sup> Co–Pd-clusters are formed on the surface of this catalyst and autocatalytic reduction of Co occurs by spillover of hydrogen adsorbed on palladium.

It has been found<sup>24</sup> that the rate of hydrocarbon synthesis from CO and  $\text{H}_2$  (250 °C, 1 atm,  $\text{H}_2:\text{CO} = 2$ ) increased 35-fold upon addition of palladium to a catalyst Co/ $\text{SiO}_2$  (the atomic ratio Pd : Co = 1 : 2, total metal content = 5%). This was accompanied by a sharp (from 91% to 59%) decrease in the methane content, a marked (from 1% to 26%) increase in the n-paraffin ( $\text{C}_{2+}$ ) content in the reaction products and an increase in the hydrocarbon chain length (the probability coefficient for the chain growth,  $\alpha$ , increased from 0.29 to 0.78). Methane was the only product formed on a monometallic Pd-sample (yield 100%).

Ion exchange of solutions of  $\text{Co(NH}_3)_6\text{Cl}_3$  and  $\text{RuCl}_3$  in 8%  $\text{NH}_4\text{OH}$  was employed for the preparation of a series of catalysts (3% Co/ $\text{SiO}_2$ , 3% Co–3% Ru/ $\text{SiO}_2$  and 3% Ru/ $\text{SiO}_2$ ) for the Fischer–Tropsch synthesis (250 °C, 21 atm,  $\text{H}_2:\text{CO} = 2$ ).<sup>52</sup> The activity of the Co–Ru contact exceeded that of the non-promoted Co-sample 4.6-fold and was nearly twice as low as that of the monometallic Ru-sample ( $K_{\text{CO}}$  were 9.6%, 2.1% and 18.7%, respectively). Methane (71%) was formed predominantly on Co-catalysts; the reaction products contained 25% of hydrocarbons  $\text{C}_{2+}$  and 4% of alcohols. Upon addition of Ru, the amount of methane formed decreased twofold (36%), while that of hydrocarbons  $\text{C}_{2+}$  increased 1.7-fold. Other reaction products included alcohols (MeOH, EtOH,  $\text{Pr}^n\text{OH}$ ); their total content was 20%. The Ru/ $\text{SiO}_2$  sample manifested the highest selectivity in the synthesis of paraffins (63%), virtually no alcohols were formed.

Hydrocarbons  $\text{C}_{2+}$  were predominantly formed on catalysts prepared by spraying carbonyls  $\text{Co}_{4-n}\text{Ru}_n\text{H}_n(\text{CO})_{12}$  ( $n = 0\text{--}4$ ) or  $\text{Co}_2\text{Ru}_2(\text{CO})_{13}$  onto  $\text{SiO}_2$  under identical conditions (250 °C, 21 atm,  $\text{H}_2:\text{CO} = 2$ ) (see Ref. 53). These catalysts differed from those prepared by ion exchange<sup>52</sup> in lower methane yields (13%–25%) and higher selectivities with respect to hydrocarbons  $\text{C}_{2+}$  (64%–79%). The content of oxygen-containing reaction products and  $\text{CO}_2$  was insignificant (0.2%–5%).

Ion-exchange and impregnation were used for the preparation of Pt–Co-catalysts on zeolite NaY.<sup>54</sup> Synthesis of hydrocarbon from CO and  $\text{H}_2$  was carried out at 232 °C, 10 atm and

H<sub>2</sub>: CO = 2. In the former case, methanol was the major product (50%). Methane (51%) and hydrocarbons C<sub>2+</sub> (49%) were formed on a catalyst prepared by impregnation, oxygen-containing products were formed in trace amounts. The difference in the reaction of the target products are usually attributed to the difference in the sizes of the bimetallic Co–Pt-particles formed in the course of the preparation procedure. If ion-exchange is used, the size of the particles is less than 2.5 nm, which can be attributed to the small size of zeolite NaY pores. If the catalysts are prepared by impregnation, their particles have a larger size (~ 20 nm) and are localised on the zeolite surface.

It has been found<sup>55</sup> that a catalyst prepared by co-precipitation of cobalt and cerium oxides manifested high activity in the Fischer–Tropsch synthesis. The reaction products comprised lower alkenes and higher n-alkanes; the amount of CO<sub>2</sub> was negligible. The activities of such a catalyst increased threefold upon promotion by 0.3% Ru [from Ru<sub>3</sub>(CO)<sub>12</sub>] and remained virtually unchanged over 100 h, the degree of CO conversion being > 40%. However, the selectivity of the synthesis catalysed by a promoted sample did not change. TPR studies have shown<sup>55</sup> that the temperature of CeO<sub>2</sub> reduction decreased in the presence of Co<sub>3</sub>O<sub>4</sub> on the surface of a non-promoted catalyst, while the addition of Ru decreased the reduction temperatures of both Co<sub>3</sub>O<sub>4</sub> and CeO<sub>2</sub> due to hydrogen spillover. As a result, the surfaces of Ru-promoted contacts contained more Co<sup>0</sup> particles than non-promoted samples, which increased their catalytic activities.

It has been shown<sup>56</sup> that introduction of 0.2% ruthenium, platinum or palladium strongly affected the catalytic and physicochemical properties of 10% Co/SiO<sub>2</sub> prepared from a cobalt acetate–cobalt nitrate mixture. According to the extent of carbon monoxide conversion (%) in the methanation reaction (240 °C, 1 atm, H<sub>2</sub>: CO = 2), all the catalysts of this series can be arranged in the following order: Co–Ru (72) > Co–Pd (58) > Co–Pt (50) > Co (34) > Ru (3). It is noteworthy that the turnover number of the most reactive Co–Ru-sample ( $12.7 \times 10^{-2} \text{ s}^{-1}$ ) exceeded that of the monometallic Co-catalyst ( $9.3 \times 10^{-2} \text{ s}^{-1}$ ). For the Co–Pt- and Co–Pd-contacts, the turnover numbers are equal to  $4.2 \times 10^{-2}$  and  $5.9 \times 10^{-2} \text{ s}^{-1}$  respectively.

The higher activity of the Co–Ru-contact in comparison with a monometallic sample was attributed<sup>56</sup> to the increase in the extent of cobalt reduction (from 50% to 100%) upon promotion by Ru and the increase in the size of Co crystallites from 12 to 13 nm. In Pt- and Pd-promoted cobalt catalysts, the extent of cobalt reduction also increased to 56% and 53%, respectively, but the size of crystallites decreased to 4 and 6 nm. IR spectroscopic studies have shown that CO adsorption on Co–Ru-catalysts is of a bridging type (an intense band at 1950 cm<sup>-1</sup>). It was suggested<sup>56</sup> that the bridge form exceeds the linear form in reactivity. High catalytic activity of the Co–Ru-contact can be explained by the increase in the number of bridging-type CO-absorbing sites. In the bridge form, carbon monoxide readily dissociates into carbon and oxygen.

Nb<sub>2</sub>O<sub>5</sub> prepared by calcination of niobic acid in an air flow (550 °C, 2 h) was used as a support for cobalt-containing catalysts.<sup>33</sup> Samples containing 5% Co and 0.6% ruthenium or rhenium were prepared by co-impregnation of niobium oxide with aqueous solutions of cobalt nitrate and the corresponding metal chlorides. Hydrocarbons were synthesised at 220 °C, 1 atm and H<sub>2</sub>: CO = 2. Promotion of Co-catalysts by ruthenium or rhenium increased the selectivity of synthesis of liquid hydrocarbons C<sub>5+</sub> from 55% to 60% and 81%, respectively. The selectivity of methane formation on a Co–Ru-contact decreased from 10% to 3.5% in comparison with the monometallic sample. However, the introduction of Pd, Pt and Rh into the catalyst Co/Nb<sub>2</sub>O<sub>5</sub> increased its activity in the Fischer–Tropsch synthesis in parallel with the increase in the selectivity of formation of liquid hydrocarbons and lower alcohols (MeOH, EtOH).<sup>57</sup> TPR and XPS studies of this effect revealed that promotion by noble metals

favours the reduction of Co<sup>3+</sup> and Co<sup>2+</sup> phases on the catalyst surface.

It is important to note that cobalt catalysts promoted by noble metals can be regenerated directly in the reactor in the course of operation.<sup>58,59</sup> At 200 °C, 5.5 atm and the volume velocity of synthesis gas of 1200 h<sup>-1</sup> (volume velocity is the volume of a gas that has passed through a unit of catalyst volume per unit time), the extent of conversion of carbon monoxide on Co–Ru/TiO<sub>2</sub> was 26% for the atomic ratio Co:Ru of 10–400, while the selectivity with respect to liquid hydrocarbons was 85.7%. Regeneration of the deactivated catalyst with hydrogen was performed in the same reactor at 190–260 °C which provided a 90%–100% recovery of the catalytic activity. This is of considerable practical importance, since large capacities of modern reactors for conducting large-scale Fischer–Tropsch syntheses create inevitable problems connected with the loading/unloading of the catalysts in the course of their regeneration.

It may be concluded from these data that introduction of noble metals into Co-catalysts significantly increases their activities and selectivities in the Fischer–Tropsch synthesis. Physicochemical studies have shown that introduction of noble metals (or Re) into bimetallic cobalt catalysts facilitates reduction of surface oxide phases and increases the extent of reduction and/or dispersity of cobalt independently of the preparation procedure (impregnation or ion exchange),<sup>50–52</sup> cobalt source (carbonyl, nitrate, acetate, etc.),<sup>60,61</sup> the nature of supports and activation conditions.<sup>47, 62</sup>

The mechanism of this promoting effect is not clearly understood yet. Neither do the above-described data provide explicit evidence in favour of one of the two mechanisms underlying this effect, *viz.*, hydrogen spillover from a noble metal to cobalt (see Refs 19–24, 28, 31 and 32) or direct interaction between metals resulting in the formation of bimetallic particles.<sup>25–27</sup> Let us consider these mechanisms in more detail.

#### IV. Mechanisms of promotion of cobalt catalysts by noble metals and rhenium

The phenomenon of hydrogen spillover on Al<sub>2</sub>O<sub>3</sub> and SiO<sub>2</sub> coated with platinum, rhodium, rhenium and nickel is well established.<sup>63–66</sup> Spillover represents migration of hydrogen atoms from one adsorption site to another across the surface. Depending on conditions, the migrating hydrogen exists as H<sup>+</sup>, H<sup>-</sup> and H<sup>•</sup>. There is evidence that the spillover rate of activated hydrogen atoms depends on the state of the surface which is the hydrogen acceptor. In particular, this depends on the degree of hydroxylation of the support surface and increases markedly following preliminary adsorption of water. It is believed that the surface OH-groups form bridges through which the atomic hydrogen migrates to the adsorption sites of a support. Alternatively, it is water molecules that create the active sites enabling additional spillover.

The effect of rhenium on the reduction of a catalyst Co/Al<sub>2</sub>O<sub>3</sub> was studied using TPR.<sup>31</sup> Treatment of Co–Re/Al<sub>2</sub>O<sub>3</sub> with water and drying at 97 °C favours its reduction owing to hydrogen spillover from rhenium to cobalt oxide. In the authors' opinion, the magnitude of the promoting effect of Re depends on the efficiency of hydrogen transport from the reduced promoter to cobalt oxide. To test this hypothesis, Co/Al<sub>2</sub>O<sub>3</sub> and Re/Al<sub>2</sub>O<sub>3</sub> mixtures were prepared by two different methods, *viz.*, mechanical mixing of sample powders and fine grinding to a state where the particle size was smaller than the size of the original particles. TPR analysis showed that the extent of cobalt reduction increased upon direct interaction of metal particles which can be achieved if the second preparation procedure is used. The TPR spectrum of the bimetallic catalyst prepared by mechanical mixing was similar to that of the monometallic catalyst except that the former contained an additional peak at 447 °C corresponding to the reduction of rhenium oxides. Thus, rhenium has no effect on the extent of cobalt reduction.

The promoting effect of rhenium was observed for the catalysts prepared by fine grinding. The TPR spectra of mono- and bimetallic samples differed in that the peak at 727 °C of a Co/Al<sub>2</sub>O<sub>3</sub> sample corresponding to reduction of the cobalt–aluminate surface phase was shifted by 200 °C towards the low-temperature region upon addition of Re, while the 927 °C peak characteristic of CoAl<sub>2</sub>O<sub>4</sub> reduction was absent. This suggests that cobalt reduction on modified catalysts occurs more smoothly due to hydrogen spillover from metallic rhenium to cobalt oxide.<sup>31</sup>

However, other investigators (see Refs 25–27, 67–70) explain also the promoting effects of noble metals on Co-catalysts by the formation of reactive bimetallic particles on the catalyst surface. Let us consider the mechanism of formation of some bimetallic Co catalysts promoted by Group VIII metals.

A series of Co–Rh-catalysts on various supports (Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub> and TiO<sub>2</sub>) were examined using TPR and thermoprogrammed oxidation (TPO).<sup>25–27</sup> Bimetallic catalysts prepared by co-impregnation of supports with the corresponding metal salts are reduced at lower temperatures in comparison with their monometallic counterparts independently of the nature of the support and of whether they underwent preliminary calcination or not. Thus, rhodium catalysed the reduction of both the salt and cobalt oxide, although the nature of the support is also important. Thus the catalyst Co/Al<sub>2</sub>O<sub>3</sub> forms spinel-like compounds of the CoAl<sub>2</sub>O<sub>4</sub> type that are difficult to reduce; in Co/SiO<sub>2</sub> catalysts, complete reduction of cobalt ions occurred; the formation of a mixed oxide CoRh<sub>2</sub>O<sub>4</sub> was recorded on TiO<sub>2</sub>. Notwithstanding, van't Blik *et al.*<sup>25–27</sup> have developed a general model of structural changes in these catalysts under different pretreatment regimes (Fig. 9). This model has got the name 'a cherry pit model'.

Within the framework of this model, after impregnation of a support (TiO<sub>2</sub>, SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub>) with salts [RhCl<sub>3</sub> or Co(NO<sub>3</sub>)<sub>2</sub>] cobalt and rhodium ions occupy adjacent positions. The outer layers of bimetallic Co–Rh-particles formed upon reduction are enriched with Co<sup>0</sup>, whereas the kernels ('cherry pits') consist predominantly of metallic rhodium. If Al<sub>2</sub>O<sub>3</sub> is used as a support, cobalt partly reacts with Al<sub>2</sub>O<sub>3</sub> before Co–Rh-particles are formed; the resulting spinel CoAl<sub>2</sub>O<sub>4</sub> is not reduced even at 500 °C.

Although the structures of bimetallic particles remain unchanged upon passivation of the reduced catalysts, Co<sup>0</sup> is oxidised to a significantly greater extent than rhodium as a result of which a rhodium-enriched 'cherry pit' appears to be covered with cobalt oxide. Thus, passivated Co–Rh-particles consist of a

rhodium core and a cobalt oxide shield (see Fig. 9). Complete oxidation of the catalyst brings about structural changes in bimetallic particles, resulting in the formation of adjacent metal oxides. Thus, Rh<sub>2</sub>O<sub>3</sub> localised on the catalyst surface becomes fully exposed.

Unlike rhodium, the ruthenium component of bimetallic catalysts may come into contact with cobalt to yield alloys. Studies by XPS and mass spectrometry of Co–Ru-catalysts and secondary ions revealed<sup>67</sup> that the state of metals, their surface concentrations and distribution across the layer depend on the nature of the support used (Al<sub>2</sub>O<sub>3</sub> or SiO<sub>2</sub>). This can be explained by different dispersities of the metal particles and different types of interactions, metal–support and metal–metal. For example, mass spectra of samples on an Al<sub>2</sub>O<sub>3</sub> support contain peaks with the mass numbers (*m/z*) 86, 102 and 129, which correspond to the clusters CoAl<sup>+</sup>, CoAlO<sup>+</sup> and CoAl<sub>2</sub>O<sup>+</sup>, thus suggesting the formation of surface aluminates. The reduced cobalt reacts with Ru<sup>0</sup> to form Ru–Co microcrystallites as can be judged from the appearance in their mass spectra of a peak with *m/z* 160 assigned to the cluster RuCo<sup>+</sup>. Based on these data, the authors have developed a layer-by-layer model for the Co–Ru-catalyst:<sup>67</sup>

An alternative model for the formation of bimetallic catalysts has been proposed.<sup>68–70</sup> The structures of the contacts Pt–Co/Al<sub>2</sub>O<sub>3</sub> and their catalytic activities in the Fischer–Tropsch synthesis were studied by TPR and XPS. The catalysts prepared by impregnation of alumina with Co(NO<sub>3</sub>)<sub>2</sub> and H<sub>2</sub>PtCl<sub>6</sub> possessed variable compositions Pt<sub>1–x</sub>Co<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> (total metal content was 10%) and were active as regards the synthesis of hydrocarbons and alcohols from CO and H<sub>2</sub>. Methanol was mainly formed on samples where the platinum content exceeded that of cobalt (Pt > Co); for Co > Pt, hydrocarbons and higher alcohols were the main reaction products.

Studies of monometallic Co-catalysts revealed that mild (297 °C, 1 h) calcination of cobalt nitrate results in its conversion into [Co(III) and Co(II)] oxides. Part of CoO formed a highly dispersed difficult-to-reduce phase on the surface of the support (Al<sub>2</sub>O<sub>3</sub>), predominantly as a monolayer. With an increase in the cobalt content in the catalyst, Co<sub>3</sub>O<sub>4</sub> crystallites are predominantly formed.

Hydrogenation of a monometallic Co-sample at 300 °C yields only CoO. Reduction of a platinum-promoted catalyst under similar conditions converts Co<sub>3</sub>O<sub>4</sub> into Co<sup>0</sup>. The cobalt surface phase (CSP), which is firmly bound to Al<sub>2</sub>O<sub>3</sub>, is not reduced even in the presence of Pt.

Two mechanisms of surface conversions at different molar ratios of Pt and Co (Pt > Co and Co > Pt) have been pro-

**Figure 9.** A model of formation of a Co–Rh-catalyst.<sup>25,27</sup>

(1) RhCl<sub>3</sub> + Co(NO<sub>3</sub>)<sub>2</sub>, (2) Co-enriched shell, (3) Rh-enriched core, (4) Co<sub>3</sub>O<sub>4</sub>, (5) Rh<sub>2</sub>O<sub>3</sub>.

**Figure 10.** Conversion of Pt- and Co-phases on the surface of the contact Pt–Co/Al<sub>2</sub>O<sub>3</sub> upon its reduction at different ratios of the metals: Pt > Co (a) and Co > Pt (b).<sup>68,70</sup>

(1) CPS, (2) Pt ions, (3) Pt<sup>0</sup>, (4) cobalt oxide, (5) Co<sup>0</sup>, (6) bimetallic phase Co<sup>0</sup>–Pt<sup>0</sup>.

posed<sup>68–70</sup> (Fig. 10). In the first case, the surface Co monolayer is formed upon calcination (CSP), whereas platinum ions exist as particles of a fairly large size. CSP is not reduced upon treatment of the catalyst with hydrogen (300 °C, 1 h), but becomes partly covered by Pt<sup>0</sup> formed upon conversion of platinum ions.

In the second mechanism ( $\text{Co} > \text{Pt}$ ), calcination of the catalyst yields CSP, platinum ions and  $\text{Co}_3\text{O}_4$ . Under mild conditions ( $300^\circ\text{C}$ ), no reduction of CSP takes place, but Pt ions and cobalt oxide are reduced to  $\text{Pt}^0$  and  $\text{Co}^0$ , respectively, and the metal particles interact. It was supposed<sup>68-70</sup> that partial shielding of Pt by metallic cobalt and formation of a bimetallic phase ( $\text{Co}^0-\text{Pt}^0$ ) occurs.

The formation of Co–Pt particles was confirmed by EXAFS (Extended X-Ray Absorption Fine Structure) and X-ray diffraction analysis of Pt<sub>0.6</sub>Co<sub>0.4</sub> samples.<sup>71</sup> The size of Co–Pt-particles in this catalyst was 15 nm (*cf.* ~11 nm in the Pt<sub>0.5</sub>Co<sub>0.5</sub> contact). Additional evidence in favour of formation of Co–Pt-particles on the surface of the PtCo<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts ( $x = 0-0.67$ ) was obtained using XPS.<sup>72</sup>

As a matter of fact, the two models of formation of the Co–Rh catalysts, which imply appearance of different types of bimetallic particles, are essentially similar. Whereas the ‘cherry pit’ model<sup>25–27</sup> suggests the presence of a core consisting of metallic rhodium and an outer shell enriched with cobalt, in the second model metallic cobalt particles partly shield reduced platinum to form a Co<sup>0</sup>–Pt<sup>0</sup> interface (see Refs 69 and 70).

A model for active sites formation in the catalysts Co/SiO<sub>2</sub> promoted by noble metals (Pd, Pt, Rh, Ru) has been developed by Lapidus *et al.*<sup>34</sup> According to the previously postulated mechanism of hydrocarbon synthesis from CO and H<sub>2</sub> in the presence of Co-catalysts,<sup>16,73,74</sup> the synthesis of liquid hydrocarbons occurs on a bifunctional active site, *i.e.*, a polymerisation site. This site is localised at the interface between metallic cobalt and the oxide (the latter behaves as a Lewis acid). The electron density of cobalt ions in such a site is shifted towards the oxide, as a result of which the metal acquires a partial positive charge ( $\delta^+$ ).

Some characteristics of oxide phases on the surfaces of reduced catalysts were obtained by TPR of samples following preliminary reduction under isothermal conditions (TPRPR) (Table 1). As can be seen, the TPR spectrum of a Co/SiO<sub>2</sub> sample following reduction at 450 °C contains four signals with  $T_{\text{max}} = 127, 210, 388$  and  $561$  °C. The second and the third peaks correspond to the reduction of underreduced Co<sup>2+</sup> ions and Co<sub>3</sub>O<sub>4</sub>, respectively. It is known that the latter manifests the properties of a Lewis acid. The high-temperature peak corresponds to the reduction of mixed Co-support oxides, while the low-temperature signal with  $T_{\text{max}} = 127$  °C corresponds to the easily oxidisable species Co<sup>δ+</sup>, which represents a constituent of the polymerisation site. Its oxidation can occur under the action of, *e.g.*, water released in the course of reduction. Thus, the polymerisation site is predominantly localised at the Co<sup>δ+</sup>-Co<sub>3</sub>O<sub>4</sub> interface on the surface of a reduced catalyst Co/SiO<sub>2</sub>.<sup>34</sup>

The addition of platinum increases the concentrations of both  $\text{Co}^{\delta+}$  (manifested in the appearance of an additional peak in the low-temperature region I) and  $\text{Co}_3\text{O}_4$ , the acidic component of the

bifunctional centre (see Table 1), that is, increases the number of polymerisation sites. The yield of liquid hydrocarbons increases from 118 (in the case of a non-promoted sample) to 139 g m<sup>-3</sup>, while the selectivity of their formation in the Fischer–Tropsch synthesis increases from 76% to 81%.<sup>34,75</sup>

The content of  $\text{Co}_3\text{O}_4$  in Co–Pd-catalysts decreased (the peak at 406 °C was characterised by  $S = 28\%$ ). In this case, the oxide phases were largely represented by  $\text{Co}^{2+}$  and  $\text{CoO} \cdot x\text{H}_2\text{O}$  species, which did not manifest the properties of Lewis acids. This circumstance might account for the relatively low activity of these catalysts in the synthesis of liquid hydrocarbons  $\text{C}_{5+}$  (the yields of  $\text{C}_{5+}$  decreased to  $82 \text{ g m}^{-3}$  and the selectivity, to 60%).

The introduction of rhodium into the contacts  $\text{Co/SiO}_2$  had no effect on the content of  $\text{Co}^{8+}$  (the total area of the low-temperature peaks in their TPR spectra was 10%, see Table 1), whereas that of  $\text{Co}_3\text{O}_4$  increased from 33 (in the case of the non-promoted sample) to 40%. The ratios of metallic and oxide phases in the bifunctional centre changed thereby with a concomitant increase in the catalytic activity. However, the oxide phases of  $\text{Co-Rh}$  contain predominantly  $\text{Co(II)}$  and  $\text{CoO} \cdot x\text{H}_2\text{O}$  (the total area of the peaks in regions II and III is 49%). This may be the reason for the lower selectivity of this catalyst as regards synthesis of liquid hydrocarbons (72%) in comparison with the monometallic sample ( $\text{Co/SiO}_2$ ).

The concentration of  $\text{Co}^{\delta+}$  on the surface of Co–Ru-samples ( $S = 5\%$ ) is twice as low as that in monometallic Co-catalysts (12%). Nevertheless, it is quite probable that high content of  $\text{Co}_3\text{O}_4$  (53%) significantly increases the probability of formation of catalytic sites of the type  $\text{Co}^{\delta+} - \text{Co}_3\text{O}_4$ . As a consequence, the yields of liquid hydrocarbons on Co–Ru-catalysts were only somewhat higher ( $129 \text{ g m}^{-3}$ ), while the selectivity of their formation was virtually the same (77%) in comparison with monometallic samples.

It may thus be concluded that the introduction of noble metals into monometallic cobalt catalysts changes the mode of formation of their active surfaces.<sup>16, 34</sup> Hydrogenation of Co-M/SiO<sub>2</sub> (M = Pt, Pd, Rh, Ru) brings about the formation, on their surface, of bifunctional centres (Co<sup>δ+</sup> - Co<sub>3</sub>O<sub>4</sub>), which play the role of polymerisation sites in the Fischer-Tropsch syntheses.

\* \* \*

The data presented above provide an illustrative example of the interest of investigators in the study of bimetallic Co-containing catalysts for the synthesis of hydrocarbons from CO and H<sub>2</sub> and in the elucidation of mechanisms of their promotion by noble metals and rhenium.

In summary, the following conclusions can be made. The introduction of platinum-containing metals into Co-catalysts facilitates the reduction of cobalt derivatives and increases their catalytic activities. There is still no consensus, however, concerning the reasons for the promoting effect of rhenium for Co-catalysts. Some authors hold the opinion<sup>31,32</sup> that, similar to noble metals, rhenium facilitates reduction of the cobalt oxide phases on the surface of the catalysts by hydrogen spillover from rhenium to cobalt, while other authors suggest<sup>33</sup> that Re increases

**Table 1.** Temperatures of the peaks ( $T$ ) and their relative areas ( $S$ ) obtained by deconvolution of the TPR spectra of the reduced catalysts Co–M/SiO<sub>2</sub> (I–V are the temperature regions where hydrogen adsorption takes place).

the dispersity of cobalt and diminishes the size of Co crystallites without any effect on reduction.

Thus, there are several viewpoints concerning the mechanisms of action of Group VIII metal-promoted cobalt catalysts in the synthesis of hydrocarbons from CO and H<sub>2</sub>. This problem may be solved in the near future through wide purpose-oriented application of modern physicochemical methods.

**Abstract.** State-of-the-art studies on the synthesis, properties and the computer design of nanotube forms of transition metal oxides are analysed. Main methods for the preparation of oxide nanotubes and related quasi-one-dimensional nanostructures (nanobundles, nanoribbons, *etc.*) are discussed. Data on the morphology and physicochemical properties of these materials and prospects for their technological applications are summarised. The results of the computer design of atomic structures and results of quantum-chemical calculations of electronic structures and chemical bond parameters of Ti, V and Mo oxide nanotubes and their fullerene-like molecules are considered. The bibliography includes 427 references.

## I. Introduction

The discovery (in 1991) of quasi-one-dimensional (1D) nanostructures, *viz.*, carbon nanotubes (NT),<sup>1</sup> and the design of nanomaterials with unique properties<sup>2–28</sup> have stimulated theoretical and experimental studies aimed at searching for and preparing analogues of such materials based on other simple substances and inorganic compounds. The advances made in this field by the early 20th century have been covered in reviews.<sup>29–39</sup>

Nanotubes of numerous inorganic compounds were synthesised. Nanotubes of  $\text{MoS}_2$ ,<sup>40</sup> other layered d-metal dichalcogenides  $\text{MX}_2$  ( $\text{M} = \text{Mo}, \text{W}$  or  $\text{Ta}$ ;  $\text{X} = \text{S}$  or  $\text{Se}$ )<sup>41–55</sup> and hexagonal boron nitride (BN), boron carbide ( $\text{BC}_x$ ) and boron carbonitride ( $\text{B}_x\text{C}_y\text{N}_z$ ) were among the first to be prepared.<sup>56–63</sup> Nanotube forms of numerous chalcogenides were synthesised:  $\text{InS}$ ,<sup>64</sup>  $\text{ZnS}$ ,<sup>65</sup>  $\text{Bi}_2\text{S}_3$ ,<sup>66</sup>  $\text{ReS}_2$ ,<sup>67</sup>  $\text{W}_x\text{Mo}_y\text{C}_z\text{S}_2$ ,<sup>68</sup>  $\text{ZrS}_2$ ,  $\text{HfS}_2$ ,<sup>69,70</sup>  $\text{NbSe}_2$ ,<sup>71–73</sup>  $\text{TiS}_2$ ,  $\text{TiSe}_2$ ,<sup>74–76</sup>  $\text{MoTe}_2$ ,<sup>77</sup>  $\text{WSe}_2$ ,<sup>78</sup>  $\text{MoS}_{2-x}\text{I}_y$ ,<sup>79</sup>  $\text{CdS}$ ,  $\text{CdSe}$ ,<sup>80,81</sup>  $\text{Ag}_2\text{S}$ <sup>82</sup> and  $\text{Li}_2\text{MoS}_2$ .<sup>83</sup> The synthesis of  $\text{NiCl}_2$  nanotubes was also documented.<sup>84–86</sup> Tubular forms of semiconducting materials, such as  $\text{SiGe}$ ,  $\text{InAs/GaAs}$ ,  $\text{InGaAs/GaAs}$ ,  $\text{SiGe/Si}$  and  $\text{InGeAs/GaAs}$ ,<sup>87–89</sup> are also known.

Cobalt,<sup>90</sup> antimony,<sup>91</sup> tellurium<sup>92–94</sup> and bismuth<sup>95–97</sup> nanotubes were synthesised. The atomic structures, electronic

properties, stability factors and possible procedures for the preparation of nanotubes of metals ( $\text{Na}$ ,  $\text{Cu}$ ,<sup>98</sup>  $\text{Ni}$ ,<sup>99</sup>  $\text{Ag}$ ,  $\text{Au}$ <sup>100,101</sup> and  $\text{Bi}$ <sup>102,103</sup>), boron,<sup>104</sup> silicon,<sup>105</sup> metal diborides  $\text{MB}_2$  ( $\text{M} = \text{Mg}, \text{Al}, \text{Sc}, \text{Ti}$  and  $\text{Zr}$ ),<sup>106–110</sup>  $\text{CaSi}_2$ ,<sup>111</sup> ternary silicides with  $\text{AlB}_2$ :  $\text{Sr}(\text{Ga}_x\text{Si}_{1-x})_2$  and  $\text{Ca}(\text{Al}_x\text{Si}_{1-x})_2$  structures,<sup>112</sup> layered metal halide nitrides  $\beta\text{-MNX}$  ( $\text{M} = \text{Zr}$  or  $\text{Hf}$ ;  $\text{X} = \text{Cl}$  or  $\text{Br}$ )<sup>113</sup> and high-temperature superconducting complex ceramics<sup>114</sup> were theoretically predicted.

In recent years, p-, d- and f-metal ( $\text{Al}$ ,  $\text{Ge}$ ,  $\text{Ti}$ ,  $\text{Nb}$ ,  $\text{Ta}$ ,  $\text{Zr}$ ,  $\text{V}$ ,  $\text{Mo}$ ,  $\text{Dy}$ ,  $\text{Tb}$ , *etc.*) oxides, along with the above-mentioned substances and compounds, have found wide application in the design of nanostructured functional materials as films, nanorods, mesoporous systems, nanoclusters and nanocrystallites and their various associates. Some of these nanosized materials can be prepared with the use of carbon nanotubes. For example, these compounds can be prepared as nanofibres and nanotubular ceramics by filling inner (and intertubular) cavities in carbon tubes (or their bundles) with oxides  $\text{V}_2\text{O}_5$ ,  $\text{MoO}_3$ ,  $\text{PbO}$  or  $\text{Bi}_2\text{O}_3$  followed by the removal of the carbon shell by chemical methods. The design of various nanocomposites based on or involving metal oxides has attracted considerable attention.

One of the main lines of investigation of nanostructured metal oxides is the preparation of their nanotube forms. Phases, which have (like graphite) layered (quasi-two-dimensional, 2D) structures and are characterised by pronounced anisotropy of interatomic interactions, are generally considered as substances or compounds promising for the preparation of such tubular forms.<sup>6–9, 18, 29–39</sup> The anisotropy of interatomic interactions is determined by a combination of strong covalent (or covalent-ionic) bonds and weak van der Waals interactions between the layers. These structural features and characteristics of chemical bonding are less typical of metal oxides than, for example, of d-element dichalcogenides. Hence, methods for the preparation of metal oxide nanotubes have essential distinguishing features and often produce hollow nanotubes along with a broad range of other quasi-one-dimensional nanostructures (nanorods, nanoribbons, *etc.*)

It should be noted that data on the synthesis, structures, properties and fields of application of carbon NT are summarised in monographs<sup>3–7</sup> and numerous reviews,<sup>8–32</sup> whereas publications, in which the results of studies of non-carbon nanotubes were generalised, are scarce<sup>29–39</sup> and were devoted primarily to the most well-studied groups of such materials, *viz.*, nanotubes (and fullerene-like clusters) of graphite-like boron nitrides, carbides and carbonitrides and d-metal dichalcogenides. Selected results of the synthesis and investigations of oxide NT were included in the reviews.<sup>37,38</sup> The review<sup>39</sup> dealt with practical procedures for the

preparation and modelling of titanium and vanadium oxide nanotubes.

In the present review, we consider the state-of-the art studies of all known nanotube forms of transition metal oxides. Main methods for the preparation of oxide nanotubes and related quasi-one-dimensional nanostructures (nanofibres, nanorods, nanoribbons, *etc.*) are summarised. Data on the morphology and physicochemical properties of such materials are discussed. The possible fields of technological applications are considered. The results of computer design of atomic structures and quantum-chemical calculations of electronic structures and chemical bond parameters of Ti, V and Mo oxides nanotubes and related fullerene-like molecular clusters are analysed.

It should be noted that the known nanotube forms of oxides are not limited to transition metal oxides considered below. Nanotubes and nanotube composites of p-element (aluminium, silicon and gallium) oxides have attracted considerable attention.<sup>115–125</sup> The studies aimed at synthesising nanotubes of f-element oxides (for example,  $\text{Tb}_2\text{O}_3$ <sup>126</sup> and  $\text{Dy}_2\text{O}_3$ <sup>127</sup>) are presently underway. However, data on the structures and properties of 1D forms of these oxides are scarce, and analysis of such materials is beyond the scope of the present review.

## II. Synthesis and properties of nanotubes and related nanostructures of metal oxides

The classification of nanosized materials used in the literature and their principal geometric parameters are given in Table 1. Nowadays, the main lines of investigation of nanostructured metal

**Table 1.** Structural types of nanosized materials and their geometric parameters.

| Structural type        | Description <sup>a</sup>                                                                                                                                  |
|------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|
| Nanotubes              | tubular structures with an outer diameter of up to 100 nm, $L < 1 \mu\text{m}$                                                                            |
| Nanorods               | quasi-one-dimensional cylindrical structures, $D < 100 \text{ nm}$ , $L < 1 \mu\text{m}$                                                                  |
| Nanowire               | the same, $D < 100 \text{ nm}$ , $L > 1 \mu\text{m}$                                                                                                      |
| Nanofibres             | threads, $D \leq 50 \text{ nm}$ , $L > 1 \mu\text{m}$                                                                                                     |
| Nanoparticles          | compact particles, $D < 10 \text{ nm}$                                                                                                                    |
| Nanopowder             | the same, $D < 100 \text{ nm}$                                                                                                                            |
| Nanodots               | crystals with sizes up to 100 nm                                                                                                                          |
| Nanowhiskers           | needle-like structures with a length of several millimetres and a base thickness of $< 100 \text{ nm}$                                                    |
| Nanoribbons            | structures as planar ribbons with a thickness of up to 100 nm and a width larger than the thickness                                                       |
| Nanocolumns            | nanostructures with $D \leq 100 \text{ nm}$ , $L > D$                                                                                                     |
| Nanocable              | structures with a morphology of a coaxial cable, $D \leq 100 \text{ nm}$                                                                                  |
| Nanobridges            | structures with a morphology analogous to a bridge construction with a length of tens of micrometers containing 'details' with a diameter of up to 100 nm |
| Nanonails              | nail-like structures, $D \leq 100 \text{ nm}$                                                                                                             |
| 4(6)-Fold nanorotors   | nanostructures as four(six)-blade rotors; the constituent diameter is up to 100 nm                                                                        |
| Tetrapod nanostructure | nanostructures consisting of four nanorods ( $D \leq 100 \text{ nm}$ ) sharing a centre                                                                   |
| Nanocomposite          | material consisting of particles of different compounds with sizes up to 100 nm                                                                           |

<sup>a</sup>  $D$  is the diameter,  $L$  is the length.

oxides are as follows: the development of methods for their synthesis and study of the morphology and physicochemical characteristics of the products. Progress in the synthesis of oxide nanotube materials with reproducible properties determines to a large extent the prospects of their practical use.

Modern investigations of nanotubular oxides and related materials are aimed at developing and improving particular synthetic schemes and extending the range of oxides, whose nanotube forms can be prepared. In most original publications, procedures for the preparation of nanotubes of a particular oxide and their selected characteristics (generally, the elemental composition, the morphology and the structural parameters) were reported. Experimental data accumulated in this new field do not allow one to reveal general regularities of the formation of particular nanostructures and decide which methods for their synthesis are most efficient and universal. Hence, in the present review, we summarise methods for the preparation of nanotubular oxides and related quasi-one-dimensional forms. A comparison and critical analysis of these methods are beyond the scope of this review.

Modern methods for the preparation of nanosized forms of simple and complex oxides can be classified into two main groups, *viz.*, chemical and template methods. The chemical synthesis involves the spontaneous formation of nanostructures in reactions of the starting reagents existing in different states (aqueous or aqueous-organic media, solid or vapour phases, during thermolysis of salts, *etc.*). The template method is based on the formation of nanostructures on the surfaces of solid materials (organic and inorganic), which dictate the size and morphology of the reaction products. In particular, organic molecules can serve as templates. Such molecules are inserted into layered structures of oxides, thus making it possible to change the form of nanotubes in their synthesis. Among these methods, vapour condensation of oxides and their electrochemical deposition also hold promise.

Below we consider methods for the synthesis and properties of three main groups of 1D nanostructures formed by first-, second- and third-row transition metal oxides. Main data on their compositions and morphology are given in Table 2.

### 1. Nanostructures of 3d4s-metal oxides

#### a. Titanium oxides

Nanosized forms of titanium dioxide can be prepared by both chemical and template methods. Well-crystallised nanotube forms of  $\text{TiO}_2$  can be synthesised by hydrothermal reactions of titanium dioxide (anatase or rutile) powder with an aqueous NaOH solution.<sup>128–134</sup> For various tubes, the O : Ti atomic ratio differs from those observed in crystalline anatase or rutile.<sup>128</sup> Generally, multilayer tubes with an interlayer distance of  $\sim 0.75 \text{ nm}$  and an average diameter ( $D$ ) of  $\sim 9 \text{ nm}$  are produced.<sup>129</sup> The mechanism of their formation involves the rolling-up of the (100) plane of  $\text{H}_2\text{Ti}_3\text{O}_7$  about the [001] direction. The ends of the tubes are open and their walls are corrugated.<sup>134</sup> The morphology of the tubes depends on the size and structure of the starting  $\text{TiO}_2$  nanoparticles.<sup>130</sup>

Ultradispersed rutile with an average particle size of  $7.2 \text{ nm}$  gives longer nanotubes compared to those formed by anatase or large rutile particles. Nanotubes with  $D \approx 8–10 \text{ nm}$  and a length ( $L$ ) of  $\sim 100 \text{ nm}$  were synthesised<sup>131</sup> by keeping  $\text{TiO}_2$  with a specific surface area of  $50 \text{ m}^2 \text{ g}^{-1}$  in a  $10 \text{ M NaOH}$  solution at  $110^\circ\text{C}$  for 20 h. The morphology of the resulting samples depends on the  $\text{TiO}_2$  structure type, and their properties depend on subsequent acid and thermal treatment.<sup>132, 133</sup> For example, after treatment with a  $\text{H}_2\text{SO}_4$  solution followed by annealing at  $300^\circ\text{C}$ ,  $\text{TiO}_2$  nanotubes show high catalytic activity in esterification of cyclohexanol with acetic acid,<sup>132</sup> whereas the starting anatase is inactive in this catalytic process.

Hydrothermal treatment of  $\text{TiO}_2$  powders ( $4.0–18.5 \text{ nm}$ ) in a NaOH solution at  $110^\circ\text{C}$  for 20 h followed by washing with dilute  $\text{HNO}_3$  affords multilayer anatase nanotubes  $500 \text{ nm}$  in length.<sup>133</sup> The use of  $\text{HNO}_3$  instead of  $\text{HCl}$  results in the formation of more

**Table 2.** Main methods of synthesis and morphology of nanostructured transition metal oxides.

| Oxide                                                                                                        | Method of synthesis | Morphology                             | Oxide                                                                | Method of synthesis | Morphology                                |

dispersed NT powder. Titanium dioxide nanotubes prepared by the chemical method consist of 2–5 monolayers and have an inner diameter of 4.2–5.9 nm.<sup>135</sup> Such materials with a specific surface area of 379 m<sup>2</sup> g<sup>-1</sup> hold promise in photocatalysis.

Films of oriented TiO<sub>2</sub> NT were prepared by the hydrochemical method (titanium foil, which contained TiO<sub>2</sub> nanoparticles deposited from an aqueous suspension, was subjected to hydrothermal treatment in 10 M NaOH at 95–160 °C).<sup>136</sup> Most of these nanotubes are open and consist of several layers. The outer and inner diameters of NT are 12 and 3.7 nm, respectively. The distance between the layers is 0.78 nm. The nanotubes are characterised by the monoclinic unit cell of H<sub>2</sub>Ti<sub>3</sub>O<sub>7</sub> with the unit cell parameters  $a = 16.03$ ,  $b = 3.75$ ,  $c = 9.19$  Å,  $\beta = 101.45^\circ$ . The most probable<sup>137</sup> composition of these nanotubes is Na<sub>2</sub>Ti<sub>3</sub>O<sub>7</sub>; the Na<sup>+</sup> ions are removed by acid treatment. The distance between the layers in these nanotubes is independent of the number of layers and the inner and outer diameters of TiO<sub>2</sub> NT and is determined by OH<sup>-</sup> groups. Taking into account the Ti–OH bond lengths and the van der Waals radius of the O atom, the interlayer distance should be equal to

0.63 nm, but it increases to 0.8 nm due to repulsion between the OH<sup>-</sup> groups. The sodium cations play a decisive role in structure stabilisation.<sup>138</sup> Unmodified TiO<sub>2</sub> nanotubes exist only in an amorphous state<sup>139</sup> and are destroyed during crystallisation.

Anatase nanotubes prepared under hydrothermal conditions have a high capacity for lithium cations in electrochemical intercalation.<sup>140</sup> The insertion of Li<sup>+</sup> into TiO<sub>2</sub> NT occurs at a voltage of lower than 2.2 V. At a voltage of about 1.7 V, voltammetric curves have a plateau, which indicates that the electrochemical resistance reaches a minimum. These nanostructures were proposed as light-sensitive materials for solar batteries.<sup>141</sup>

Nanosized rods of rutile TiO<sub>2</sub> ( $D = 4-6$  nm,  $L = 50-150$  nm) were prepared<sup>142</sup> in air under atmospheric pressure by the reaction of 15 M HNO<sub>3</sub> with an aqueous TiCl<sub>4</sub> solution (3 mol litre<sup>-1</sup>) with stirring (100–250 °C, 6–24 h). The sizes of nanorods are independent of the temperature and time of hydrolysis. These nanorods belong to the rutile modification and are characterised by the [110] growth direction. Mixing of TiCl<sub>4</sub> and HNO<sub>3</sub> solutions leads to oxolation of the [TiO(OH<sub>2</sub>)<sub>5</sub>]<sup>2+</sup>

complex ion and isolation of rutile as brushes. The anisotropic growth was accounted for by selective absorption of  $\text{Cl}^-$  and  $\text{NO}_3^-$  anions and  $[\text{TiO}(\text{OH})_2]^{2+}$  cations on the (110) and (111) surfaces, respectively.

Thermolysis of titanium tetraisopropoxide  $[\text{Ti}(\text{OPr}^i)_4]$  vapour in the presence and in the absence of  $\text{NH}_3$  at 500 °C affords  $\text{TiO}_2$  nanowires ( $D = 50\text{--}100\text{ nm}$ ,  $L = 0.5\text{--}2\text{ }\mu\text{m}$ ) on the WC substrate.<sup>143</sup> Thermolysis at 600 and 400 °C gives nanoparticles and thin films, respectively, of the anatase modification. In the presence of  $\text{NH}_3$ , thinner and longer nanorods are produced. The formation of 1D structures of  $\text{TiO}_2$  is catalysed by cobalt admixtures.

A crystalline  $\text{TiO}_2$  nanowire was prepared<sup>144</sup> by annealing  $\text{TiS}_2$  in the presence of a flux (NaCl) and in the absence of a flux under an atmosphere of  $\text{NH}_3$ . In the former case, titanium disulfide was mixed with NaCl powder in a mass ratio of 1:3.5 and heated at 820 °C for 2.5 h. In the latter case,  $\text{TiS}_2$  was heated at 820 and 970 °C. The precipitates were washed with an HCl solution, water and ethanol and dried at 85 °C. Samples prepared in the presence of the flux crystallised in the anatase modification with the unit cell parameters  $a = 3.782$ ,  $c = 9.502\text{ }\text{\AA}$ , whereas samples synthesised in the absence of the flux crystallised in the rutile modification ( $a = 4.953$ ,  $c = 2.958\text{ }\text{\AA}$ ). Titanium dioxide nanoparticles are predominantly produced in the absence of NaCl. Anatase nanowires (smooth and straight) have a diameter of 20–200 nm and an  $L/D$  ratio of  $\approx 500$ . Rutile nanowires with  $D = 150\text{ nm}$  and a length of several micrometres were prepared at 970 °C. The formation of  $\text{TiO}_2$  nanostructures also occurs through the intermediate  $\text{Na}_2\text{TiO}_3$  phase during its exchange interaction with HCl.

An amorphous  $\text{TiO}_2$  gel prepared by hydrolysis of  $\text{Ti}(\text{OPr}^i)_4$  in an ethanolic solution was used as a precursor for the preparation of interconnected structured nanosized fibres.<sup>145</sup> The precursor (0.1–0.3 g) was mixed with a 5–15 M NaOH solution (20 ml) and subjected to hydrothermal treatment at 100–180 °C for 48 h. The powder that precipitated was filtered off, washed with water and 0.1 M HCl to pH < 7 and dried *in vacuo* at 100 °C for no less than 10 h. The resulting twisted fibres with a thickness of 5–30 nm and a length from tens to hundreds of micrometres, which are wrapped together to form superstructured materials, have a layered structure with an interlayer distance of 0.7 nm and contain defects and dislocations. Alkaline treatment of the precursor (at a temperature higher than 180 °C) afforded thin ribbon structures 30–200 nm in width and from a few to tens of micrometres in length. A change in the NaOH concentration has no effect on the morphology of the product. The specific surface area of the nanofibres was 267, 354 and 375  $\text{m}^2\text{ g}^{-1}$  at the synthesis temperatures of 100, 130 and 150 °C, respectively.

In the synthesis by the chemical method,  $\text{TiO}_2$  nanotubes are formed at the instant crystalline  $\text{TiO}_2$  reacts with a NaOH solution and transforms to the amorphous state. The reaction of an amorphous  $\text{TiO}_2$  gel with NaOH produces well-interconnected fibres, in which the Ti atoms are octahedrally coordinated by two types of oxygen atoms, *viz.*, the bridging  $\mu_2\text{-O}$  atoms, through which the Ti atoms of the adjacent octahedra are linked to each other, and the  $\text{OH}^-$  groups. The presence of hydroxyl groups is a distinguishing feature of the ' $\text{TiO}_2$ ' gel. The reaction of the latter with NaOH is accompanied by cleavage of some Ti–OH and Ti–O–Ti bonds, with the result that the  $\text{TiO}_6$  octahedra are linked into chains with long-range order, and the latter are partially transformed into layered structures. After lithium ion intercalation into nanofibres, the latter can be used as an electrode material in lithium cells and as atmospheric oxygen and nitrogen separators.

The template method has gained wide acceptance in the synthesis of  $\text{TiO}_2$  nanotubes.<sup>146, 147</sup> Chiral organic compounds **1a–c** can be used as templates.<sup>148, 149</sup>

$\text{X}^- = \text{PF}_6^-$ , (1*R*,2*R*) (**a**);  $\text{ClO}_4^-$ : (1*R*,2*R*) (**b**), (1*S*,2*S*) (**c**).

In alternative methods, a 25% aqueous  $\text{NH}_4\text{OH}$  solution or 2 M HCl was added to a solution of  $\text{Ti}(\text{OPr}^i)_4$  and compound **1a** in ethanol.<sup>148</sup> The resulting mixture was heated at 80 °C, homogenised, cooled to 25 °C, dried in air for 10 days and warmed at 50 °C *in vacuo* for 5 h. The dry sample was kept at 200 °C or 450 °C for 2 h. In the course of the sol–gel synthesis, template **1a** is self-organised to form a three-dimensional network of helical fibres ( $D = 50\text{--}300\text{ nm}$ ) stabilised by hydrogen bonds involving  $\text{NH}_2^+$  groups. The fibre structure was absent after heating of samples, which were pre-treated with an acid, at 450 °C. However, hollow fibres with an outer diameter of 150–600 nm and a length of up to 200  $\mu\text{m}$  are retained upon alkaline treatment. The inner diameter of  $\text{TiO}_2$  fibres (50–300 nm) is, apparently, dictated by the sizes of the template network.

The sol–gel synthesis with the use of chiral molecules **1b** and **1c** as templates produced chiral helical-like  $\text{TiO}_2$  NT (Fig. 1).<sup>149</sup> Derivatives of *trans*-(1*R*,2*R*)- and *trans*-(1*S*,2*S*)-1,2-diaminocyclohexane give left- and right-handed helical fibres stabilised by intramolecular hydrogen bonds between the amino groups. The synthesis was carried out by stirring a mixture of solutions of enantiomers (1 mol litre<sup>-1</sup>),  $\text{Ti}(\text{OPr}^i)_4$  (5 mol litre<sup>-1</sup>),  $\text{H}_2\text{O}$  (2.5 mol litre<sup>-1</sup>) and  $\text{NH}_4\text{OH}$  (0.4 mol litre<sup>-1</sup>) in ethanol at 0 °C followed by heating to 80 °C. The resulting transparent solution was slowly cooled to 25 °C and the resulting gel was dried

**Figure 1.** The SEM images of  $\text{TiO}_2$  fibres prepared from enantiomers **1b** (**a**) and **1c** (**b**).<sup>149</sup>

Hereinafter, SEM is scanning electron microscopy.

at 25 °C for 10 days and then kept at 50 °C *in vacuo* for 5 h. To remove the templates, the xerogel was washed with acetone and calcined at 200 °C for 2 h and at 450 °C for 24 h. The resulting fibres have an outer diameter of 100–600 nm, an inner diameter of 30–180 nm and a length of up to 30 µm. This method was used also to synthesise chiral vanadium and tantalum oxide nanotubes.

Well-ordered helical-like ribbons and nanotubes were prepared<sup>150</sup> by sol–gel polymerisation of  $\text{Ti}(\text{OPr})_4$  in template gels of neutral dibenzo-30-crown-10 bound to cholesterol. The synthesis successively produces  $\text{TiO}_2$  ribbons, twisted ribbons and open nanotubes with helical (right-handed) chirality ( $D \approx 500$  nm). After removal of the template by annealing under a nitrogen atmosphere at 500 °C for 4 h, hollow helical ribbons and hollow nanotubes with a distance of 8–9 nm between the walls were obtained. Apparently, oligomeric  $\text{TiO}_2$  particles are adsorbed on both sides of the corresponding structures from the template gel with a thickness of 8–9 nm and, consequently, the resulting tubes contain micro- and macropores. The mechanism of formation of helical ribbons and nanotubes involves adsorption of ‘oligomeric’ titanium dioxide particles on a tubular structure of an organic gel and their further growth through sol–gel polymerisation.

The use of laurylamine hydrochloride as a template and  $\text{Ti}(\text{OBu}^n)_4$  as a precursor made it possible to prepare  $\text{TiO}_2$  microtubes with mesoporous walls.<sup>151</sup> The outer diameter of the tubes was 2–8 µm. Their walls (0.2–2 µm in thickness) consist of cylindrical channels with the same diameter of 3.2 nm. These microtubes are thermally stable up to 773 K, have a specific surface area of 390 m<sup>2</sup> g<sup>−1</sup> and consist of anatase with a low degree of crystallinity. The pore volume is 0.586 ml g<sup>−1</sup>.

Ultrathin nanosized titanium dioxide layers were synthesised with the use of carboxylate latex and tobacco mosaic virus (TMV) particles as templates.<sup>152</sup> The latex and TMV particles on a substrate were coated with ultrathin  $\text{TiO}_2$  layers by the sol–gel method and subjected to plasma treatment. The resulting hollow titanium spheres were linked to form nanotubes. After oxidative removal of the template, a rod-like  $\text{TiO}_2$  structure with  $D = 20$ –30 nm was obtained. It is preferable to use oxygen plasma to retain the tubular structure after removal of the template.

Anatase nanoparticles prepared by gradual hydrolysis of a  $\text{TiF}_4$  solution (0.04 mol litre<sup>−1</sup>, pH 2) after the addition of  $\text{NH}_4\text{OH}$  (0.1 mol) were deposited on the surface of various templates,<sup>153,154</sup> such as organic (cotton, silk or wool) or polymeric<sup>155</sup> fibres, aluminium porous membranes, plant fibres, *etc.* After immersion of the template into a solution and storage at 60 °C for 1–48 h, the hydrolysis product undergoes dehydration, and an anatase layer appears on the surface. Organic compounds were removed by annealing in air at 500 °C, and aluminium metal was dissolved in ammonia water (pH 12). Traces of fluorine were removed by calcination in air at a temperature higher than 300 °C. The use of cotton threads as a template results in the formation of hollow  $\text{TiO}_2$  fibres consisting of anatase particles with a diameter of 20–50 nm; their inner diameter corresponds to the thread size. The wall thickness of  $\text{TiO}_2$  depends on the deposition time. The hollow structure is destroyed at sizes greater than 500 nm. The specific surface area of these nanotubes is 50–70 m<sup>2</sup> g<sup>−1</sup>, and their walls contain microscopic pores.

Studies of the photocatalytic activity of anatase as films and nanotubes formed on wool in oxidation reactions of NO demonstrated that the activity on nanotubes increases by a factor of almost nine. Anatase nanotubes with an inner diameter of 50–150 nm were prepared on an aluminium membrane with a channel diameter of ~200 nm. The specific surface area of the material is 100–140 m<sup>2</sup> g<sup>−1</sup>. The use of leaf fibres as a template gives rise to a honeycomb structure consisting of  $\text{TiO}_2$  nanotubes.

Nanosized crystalline anatase is generally prepared by the non-hydrolytic sol–gel method.<sup>156</sup> In a conventional method,  $\text{TiCl}_4$  is added with stirring to benzyl alcohol at room temperature, and then the mixture is warmed to 40 °C and subjected to

aging for 7–14 days. The resulting suspension is centrifuged and the precipitate consisting of  $\text{TiO}_2$  particles with a diameter of 4–5 nm is washed with ethanol and dried.

An anodised porous aluminium plate was used<sup>157</sup> as a template to prepare compact open anatase nanotubes with an inner diameter of 50–70 nm and a wall thickness of 3–10 nm. The pores of the  $\text{Al}_2\text{O}_3$  surface layer (70 nm in diameter and 10–12 µm in depth) were filled with liquid  $\text{Ti}(\text{OPr})_4$  and heated at 500 °C for 1 h under a stream of  $\text{O}_2$ . Decomposition of  $\text{Ti}(\text{OPr})_4$  on the surface of  $\text{Al}_2\text{O}_3$  afforded a  $\text{TiO}_2$  layer. Then anodised aluminium was partially and completely dissolved in a mixture of phosphoric (6 mass%) and chromic (1.5 mass%) acids. Etching at 80 °C for 15 min, as a rule, completely removed the template without destruction of  $\text{TiO}_2$  nanotubes.

Hydrolysis of  $\text{TiF}_4$  in an  $\text{HCl} + \text{NH}_4\text{OH}$  solution with pH 1.6 at 60 °C produced<sup>158</sup> single-crystalline  $\text{TiO}_2$  nanotubes on an anodised aluminium membrane with a pore diameter of 100 nm and a length of 60 µm. The product was washed with water and dried at 60 °C for 24 h. Nonuniformly distributed irregularly shaped columnar crystals of  $\text{TiO}_2$  containing straight  $\text{TiO}_2$  nanotubes with a cavity extended in the axial direction grew on the upper surface of the membrane. The outer and inner diameters of the nanotubes were 20–40 and 4–5 nm, respectively. The interlayer distances in the walls ( $3.6 \pm 0.1$  Å) corresponded to the interplanar distance  $d_{101}$  of anatase. Larger isolated tetragonal crystals of anatase appeared on the lower surface of the membrane.

Titanium dioxide nanotubes of the anatase modification were also prepared in nanosized channels of a porous aluminium membrane, which was stored in a  $\text{TiF}_4$  solution (0.04 mol litre<sup>−1</sup>, pH 2) at 60 °C for 24 h.<sup>159</sup> The template was dissolved in an aqueous ammonia solution (pH 12) at room temperature. The inner diameter of the nanotubes (Fig. 2) is 50–150 nm, the walls consist of  $\text{TiO}_2$  particles with a size of 10–20 nm and the pore diameter is smaller than 10 nm. The size of the inner channels in the tubes depends on the time of deposition of  $\text{TiO}_2$ . If the deposition time is longer than 12 h, compact rods grow. The morphology of the nanotubes is retained because they are prepared without calcination. This material is of interest for photocatalytic gas reactions and liquid filtration. The photoelectrochemical characteristics of  $\text{TiO}_2$  nanotubes and nanorods were studied,<sup>160</sup> and the dependence of the photocurrent on the potential was demonstrated to be analogous to that observed for nanocrystalline films.

The mechanism of formation and the microstructure of  $\text{TiO}_2$  nanotubes prepared according to the above-considered procedure<sup>159</sup> were investigated.<sup>161</sup> The outer and inner diameters of the

**Figure 2.** The SEM image of  $\text{TiO}_2$  nanotubes synthesised on anodised aluminium as a template.<sup>159</sup>

samples were 9 and 5 nm, respectively. These nanotubes with an interlayer distance of  $\sim 7.1$  Å, which is twice as large as the analogous distance along the [101] direction in anatase ( $a = b = 3.78$ ,  $c = 9.52$  Å), are structurally similar to carbon nanotubes and are formed by rolled-up planar  $\text{TiO}_2$  layers. Taking into account the crystallographic parameters of anatase and rutile ( $a = b = 0.459$ ,  $c = 0.295$  nm), it can be concluded that the anatase modification is more favourable for the formation of  $\text{TiO}_2$  nanotubes. This conclusion is supported by the fact that the surface energy of anatase is lower than that of rutile.<sup>161</sup>

The model of  $\text{TiO}_2$  nanotube formation can be represented by the 3D  $\rightarrow$  2D  $\rightarrow$  1D scheme. A three-dimensional (3D) anatase crystal reacts with a NaOH solution to form a laminar two-dimensional (2D) structure, which is bent so as to bind unsaturated bonds of the terminal atoms. Further rolling-up results in the formation of a tubular structure. There are two possible 2D  $\rightarrow$  1D transformations giving rise to concentric and non-concentric structures. Only non-concentric structures were experimentally observed.<sup>161</sup>

An ethanolic solution of  $\text{Ti}(\text{OPr}^i)_4$ , to which an HCl solution in ethanol is added at 15 °C, can be used as a precursor in the synthesis of  $\text{TiO}_2$  nanotubes.<sup>162</sup> An aluminium membrane was placed in the resulting sol for 5–60 s. Then the membrane was dried and annealed at 400 °C for 6 h. Immersion of the membrane into the sol for 5 and 60 s affords nanotubes and nanofibres, respectively. In the case of an intermediate immersion time (25 s), nanotubes with thick walls grow. The sol temperature and the time of membrane immersion also influenced the morphology of nanostructures and the wall thickness of  $\text{TiO}_2$  nanotubes. In membrane pores with a size of 22 nm, bundles of 2–4, 10 or a larger number of fibres grow as long prismatic crystals with the rare and metastable anatase-like orientation of the (001) plane with the [110] direction. After irradiation with sunlight, fibrillar  $\text{TiO}_2$  exhibits high catalytic activity in decomposition of salicylic acid, which is associated with its larger specific surface area. This method can also be used to prepare photocatalytically active  $\text{TiO}_2$  nanowires.<sup>163</sup>

In the synthesis of  $\text{TiO}_2$  NT by colloidal heterocoagulation, carbon nanotubes (C-NT) were used as a template. A  $\text{TiO}_2$  gel with an admixture of NaOH was added dropwise to an aqueous suspension of carbon nanotubes, which were pre-treated with ammonia, and polyethyleneamine  $(\text{CH}_2\text{CH}_2\text{NH})_n$  at pH 8. The negatively charged  $\text{TiO}_2$  particles were deposited on the walls of the carbon nanotubes and cover them uniformly. The resulting composite contained  $\sim 1.5$  mass% C-NT, had a low specific gravity, was easily separated from the reaction mixture and possessed photocatalytic properties.<sup>164–166</sup>

Nanoparticles of anatase  $\text{TiO}_2$  were prepared on carbon nanotubes<sup>167</sup> in water by hydrolysis of dihydroxy titanium bis(ammonium lactate)  $[\text{MeCH}(\text{O}^-)\text{CO}_2\text{NH}_4]_2\text{Ti}(\text{OH})_2$  and dispersion of C-NT (90–100 °C, 20 h). Carbon nanotubes coated with titanium dioxide and ultradispersed  $\text{TiO}_2$  were separated by centrifugation and dried *in vacuo*; the size of the resulting particles was in a range of 2–10 nm.

The  $\text{TiO}_2$ – $\text{SiO}_2$  nanotube composite with a coaxial structure was synthesised on anodised aluminium.<sup>168</sup> In the first step,  $\text{SiO}_2$  nanotubes were obtained in pores (with a size of 200–250 nm) of anodised aluminium. Then  $\text{TiO}_2$  nanotubes grew on their inner shell. The formation of this nanotube composite depends on the presence of Ti–O–Si bonds and the amorphous character of the  $\text{SiO}_2$  layer. This method allows one to prepare tubes with the more complex  $\text{TiO}_2$ – $\text{SiO}_2$ – $\text{TeO}_2$  composition.<sup>169</sup>

Silicon-containing titanium dioxide nanotubes can be prepared by the sol–gel method in the absence of a template.<sup>170</sup> For this purpose, butanediol,  $\text{Si}(\text{OEt})_4$  and  $\text{Ti}(\text{OPr}^i)_4$  in ratios of 2: (0 at.%–10 at.% Si): 1 were stirred at room temperature and kept for several days until a dry gel was obtained. The dry gel, which was pre-heated with a rate of 5 K min<sup>−1</sup>, was crystallised at 400–600 °C for 1 h to form nanotubes and nanoparticles (for pure  $\text{TiO}_2$  and  $\text{TiO}_2$  + 10 at.% Si, only nanoparticles were

prepared). The inner and outer diameters of  $\text{TiO}_2$  NT containing 5 at.% Si were 3 and 13 nm, respectively. The amount of silicon plays an important role in the nanotube formation. The specific surface area of the samples prepared at 600 °C increases with increasing amount of silicon from 1.6 ( $\text{TiO}_2$ ) to 110.66 m<sup>2</sup> g<sup>−1</sup> ( $\text{TiO}_2$  + 10 at.% Si). In this case, the pore size decreases, which is associated with suppression of growth of  $\text{TiO}_2$  nanoparticles in the presence of silicon.

Iron-doped  $\text{TiO}_2$  nanotubes with a diameter of up to 10 nm and a length of 200 nm were synthesised<sup>171</sup> by the hydrothermal method in an alkaline medium. Iron-containing anatase and rutile powders with a particle size of 30 and 42 nm, respectively, were used as precursors. A procedure was developed<sup>172</sup> for the synthesis of a nanocomposite in the form of Au/ $\text{TiO}_2$  nanowires 60 µm long. These nanowires contain the smooth surface formed by anatase and the gold core ( $D = 210$  nm, which corresponds to the pore diameter of an aluminium membrane). The thickness of the shell consisting of  $\text{TiO}_2$  particles with sizes 10–15 nm is 40 nm. The ordered structure of the composite was achieved by layer-by-layer deposition of cationic polyelectrolytes and a titanium-containing precursor on gold nanowires.

A semiconductor/metal nanocomposite was prepared<sup>173</sup> from semiconducting  $\text{TiO}_2$  nanotubes filled with polypyrrole nanowires (the latter were grown by chemical polymerisation<sup>174</sup>). This nanocomposite is as an efficient photocatalyst, because it has a large specific surface area and the conducting core.

A composite consisting of polyaniline (PAni) nanotubes ( $D = 90$ –130 nm) filled with  $\text{TiO}_2$  nanoparticles ( $\sim 10$  nm) was synthesised in the presence of  $\beta$ -naphthalenesulfonic acid ( $\beta$ -NSA) as an admixture.<sup>175</sup> Titanium dioxide powder was added to a  $\beta$ -NSA solution ( $10^{-3}$  mol litre<sup>−1</sup>), the mixture was treated ultrasonically until a homogeneous suspension was prepared, an aniline and water mixture ( $10^{-3}$  mol litre<sup>−1</sup>) was added, and oxidative polymerisation was carried out by adding  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  ( $2 \times 10^{-3}$  mol). The precipitate of the PAni– $\beta$ -NSA– $\text{TiO}_2$  nanotube composite that formed was filtered off, washed with water and ethanol and dried *in vacuo* at 20 °C. The morphology, size, conductivity and hydrophobicity of the composite are determined by the amount of  $\text{TiO}_2$  nanoparticles in the tubes. At a  $\text{TiO}_2$  concentration lower than 0.08 mol litre<sup>−1</sup>, the resulting amorphous composite consisted of hollow fibres. In the concentration range of 0.04–0.06 mol litre<sup>−1</sup>, the composite consisted of nanotubes. At a concentration of 0.12 mol litre<sup>−1</sup>, the composite contained granules. X-ray powder diffraction study revealed an impurity of crystalline  $\text{TiO}_2$ .

The conductivity of the composite depends on its morphology and the percentage of  $\text{TiO}_2$ . The conductivity is  $4.4 \times 10^{-3}$  and  $1.2 \times 10^{-1}$  S cm<sup>−1</sup> for granules and nanotubulenes, respectively. The conductivity decreases with increasing  $\text{TiO}_2$  concentration. The temperature dependence of the conductivity of the composite in the range of 300–77 K is typical of semiconductors with the hopping charge-transfer mechanism. The hydrophilicity of the composite can be varied by varying the  $\text{TiO}_2$  content in the composite.

Nanowires of the anatase/poly(vinylpyrrolidone) (PVP) composite with a porous structure were prepared<sup>176</sup> by electrocentrifugation.<sup>177</sup> Titanium tetraisopropoxide was mixed with acetic acid and ethanol, PVP was added, and the mixture was homogenised for 1 h. Then the mixture was placed in a centrifuge and nanofibres were collected on an aluminium foil at 30 kV. Traces of PVP were removed from the nanofibres by heating them in air at 500 °C for 3 h, which led to a decrease in the diameter of nanofibres from  $78 \pm 9$  to  $53 \pm 8$  nm.

The fibre thickness of the  $\text{TiO}_2$ /PVP composite and anatase nanofibres can be varied in the ranges of  $(52 \pm 11)$ – $(374 \pm 66)$  and  $(33 \pm 6)$ – $(192 \pm 69)$  nm, respectively. Their sizes depend on the parameters of electrocentrifugation, the  $\text{Ti}(\text{OPr}^i)_4$  concentration and the rate at which PVP is added in the course of preparation of the precursor. Titanium dioxide nanoparticles are involved in the formation of composite fibres with a size of  $\sim 10$  nm. The surface

porosity of  $\text{TiO}_2$  nanofibres can be varied as desired by changing the rate of hydrolysis of  $\text{Ti}(\text{OPr})_4$  in fibres through changes in atmospheric humidity. Composite fibres up to several centimetres in length are prone to form a nonwoven structure, which can be used as a sensor after deposition on a substrate. When annealed, this structure is transformed into a ceramic membrane without deterioration of porosity. In this case, fibres can partially melt, which enhances the mechanical strength of the membrane.

Noteworthy is the electrochemical method for the preparation of  $\text{TiO}_2$  nanotubes by anodic oxidation of titanium metal strips in an aqueous electrolyte containing 0.5 mass %–3.5 mass % HF.<sup>178</sup> A porous  $\text{TiO}_2$  layer that appeared on the metal surface represents a high-density homogeneous lattice consisting of parallel tubes. The upper ends of the tubes are open, whereas the lower ends are closed. The average diameter of the tubes (25–65 nm) increases with increasing voltage of anodic oxidation, but the length of the tubes is determined by the thickness of the oxide layer and is independent of the electrolysis time.

Amorphous  $\text{TiO}_2$  nanotubes can be prepared by anodic oxidation of a titanium foil in 0.5% HF at a potential of 12–20 V using a platinum cathode.<sup>179</sup> The length of nanotubes is  $\sim 400$  nm,  $D = 46$ –76 nm, and the wall thickness is 17–27 nm. Annelation of these nanotubes at 500 °C under an oxygen stream affords the anatase and rutile modifications. The former modification is concentrated on the walls of nanotubes, whereas the second modification is concentrated on the barrier layer. The nanotubes are stable up to 600 °C and are of interest as materials for resistive hydrogen sensors.<sup>180, 181</sup> A  $\text{TiO}_2$ -NT-based sensor has the highest sensitivity for hydrogen at 375 °C, which increases with decreasing diameter of the tubes. The hydrogen sensor is completely reversible, its response time is 150 s, the hysteresis is absent, and the sensitivity threshold is  $10^{-4}$ . The sensor is highly selective for hydrogen compared to  $\text{CO}$ ,  $\text{CO}_2$  and  $\text{NH}_3$ , but is responsive also to  $\text{O}_2$  at the high concentration of the latter.

Electrochemical oxidation of a TiN layer on a silicon substrate with the use of a nanoporous anodised  $\text{Al}_2\text{O}_3$  film as a template afforded nanosized  $\text{TiO}_x$  crystallites<sup>182</sup> with  $D \approx 60$  nm belonging to the hexagonal system. This method is suitable also for the preparation of nanocrystallites of other semiconducting oxides.

Titanium dioxide nanoparticles were synthesised in mesopores of  $\text{Al}_2\text{O}_3$  with the use of a new precursor, *viz.*, bis(tolueno)-titanium, which served as a molecular source of  $\text{Ti}^{IV}$ .<sup>183</sup> Insertion of the precursor into mesopores of an aluminium template leads to elimination of titanium metal, which is oxidised to  $\text{TiO}_2$  (anatase) with a particle size of  $\sim 2$  nm. This material readily adsorbs UV radiation.

Various geometric structures can be prepared from  $\text{TiO}_2$  nanoparticles.<sup>184–189</sup> A simple chemical method for the synthesis of needle-like samples<sup>184</sup> consists in mixing  $\text{Ti}(\text{OPr})_4$  and  $\text{Si}(\text{OEt})_4$  solutions in ethanol with admixtures of HCl and  $\text{H}_2\text{O}$  to prepare a composite with the molar ratio  $\text{TiO}_2:\text{SiO}_2 = 4:1$ . Hydrolysis and gel formation in moist (70%) air at 40 °C for 5 days followed by annealing at 600 °C (2 h) and storage of anatase that formed in an autoclave in an aqueous NaOH solution (a Teflon vessel) at 20, 60 or 110 °C for 20 h afforded well-crystallised  $\text{TiO}_2$  with a specific surface area of  $400 \text{ m}^2 \text{ g}^{-1}$ . After washing with 0.1 M HCl and water, the product exhibited high photocatalytic activity. The synthesis with the use of 10 M NaOH at 60–110 °C for 20 h produced ‘needles’ with a tubular structure ( $D \approx 8$  nm,  $L \approx 100$  nm). Analogous anatase samples were also prepared without the addition of  $\text{SiO}_2$  to the starting reaction mixture.

Ultrasonic treatment allows one to prepare nanotube forms of  $\text{TiO}_2$  not only as nanotubes but also as whiskers.<sup>185</sup> Particles ( $D \approx 20$  nm) prepared by thermal treatment of titanium hydroxide at 650 °C for 1 h (17% of anatase and 83% of rutile) serve as a precursor. To produce whiskers, a sample was placed in a 10 M NaOH solution, heated to 80 °C and subjected to ultrasonic treatment at an output power of 560 W for 80 min (treatment at an output power of 280 W for 60 min gave nanotubes). The

precipitate that formed was washed with 0.1 M  $\text{HNO}_3$  and water, kept at 110 °C for 4 h on an oil bath, washed once again and dried *in vacuo* (12 h). The sizes and composition of the whiskers depend on the time of washing with water in the first step. After 6 h,  $L \approx 1 \mu\text{m}$ ,  $D \approx 60$  nm, and the composition is  $\text{H}_2\text{Ti}_3\text{O}_7 \cdot 0.5 \text{H}_2\text{O}$ . An increase in the washing time to 8 h leads to a decrease in the diameter of whiskers to 5 nm and the  $\text{TiO}_2$  composition (the so-called B modification).<sup>186</sup> Storage of a sample at 110 °C for 4 h followed by washing with 0.1 M  $\text{HNO}_3$  for 2 h and with water for 14 h results in the formation of open sodium-free nanotubes with  $D \approx 5$  nm,  $L \approx 200$ –300 nm and the ratio  $\text{Ti}:\text{O} = 1:2$ .

Titanium dioxide whiskers cannot be prepared without ultrasonic treatment. Treatment of a  $\text{TiO}_2$ -containing NaOH solution affords sodium titanate consisting of layers of  $\text{TiO}_6$  octahedra, between which alkali metal cations are located. In an  $\text{HNO}_3$  solution, ion exchange occurs to give  $\text{H}_2\text{Ti}_3\text{O}_7 \cdot 0.5 \text{H}_2\text{O}$ . Ultrasonic treatment not only accelerates the reaction between the starting components but also facilitates a particular orientational growth of titanate layers. After washing of the sample with water, the resulting  $\text{TiO}_2$  layers increase in size and roll up into nanotubes.

Titanium dioxide whiskers can also be prepared by treating a  $\text{TiOCl}_2$  precipitate, which is prepared by the reaction of  $\text{TiCl}_4$  with a 5 M aqueous ammonia solution, in an autoclave.<sup>187</sup> To prepare anatase and rutile whiskers, titanium oxochloride is pre-calcinated at 450 and 800 °C, respectively. Whiskers ( $D < 20$  nm) as bundles are produced under hydrothermal conditions at 100 °C for 12 h along with  $\text{TiO}_2$  nanotubes 60–100 nm in length and 10–30 nm in diameter. An increase in the temperature leads to an increase in the amount of nanotubes in the samples, their length becomes as large as 150 nm, and the diameter is 15–20 nm. At 200 °C, the amount of tubes is larger than the amount of spherical particles (which are always present in samples), their length increases to 200–500 nm, and the inner diameter is 7–8 nm. An increase in the temperature leads to an increase in the size of the tubes, but the rate of their formation decreases. This is associated with the predominant formation of less soluble spherical particles ( $\text{TiO}_2$  crystal nuclei). Since the lattice parameter of anatase  $c \gg a$ , its powder more easily forms nanotubes, which is attributed to the anisotropy of growth of  $\text{TiO}_2$  particles during the autoclave treatment.

Nanosized  $\text{TiO}_2$  ribbons with a length from a few to tens of micrometres, a thickness of several nanometres and a width of 30–200 nm were prepared by the hydrothermal method from titanium dioxide powder in a NaOH solution.<sup>188</sup> A  $\text{TiO}_2$  gel, crystalline anatase or an anatase and rutile mixture were used as the starting titanium compound. The precursor (0.3 g) was mixed with a NaOH (5–15 M) solution (20 ml) and subjected to hydrothermal treatment at 180–240 °C for 1–2 days, and the products were washed with water and 0.1 M HCl. It was found that the temperature and the alkali concentration have no effect on the morphology of ribbons, which can roll up about the [001] direction. The corrugated surface of such ribbons results from cluster condensation. These thin ( $\leq 5$  nm) ribbons can be doped with various elements, which is of considerable importance in the synthesis of functional materials.

The sol–gel method is most widely used in the synthesis of nanotube forms of  $\text{TiO}_2$  with different geometry. The drawbacks of this method as applied to the preparation of nanorods are that the template pores are difficult to fill with a high-concentration gel and that the use of dilute gels leads to the formation of cracks and defects. The template pores can be filled using electrophoresis of sol–gel nanocomposites. However, this procedure is unsuitable for the preparation of nanorods with  $D < 20$ –50 nm.

The synthesis of single-crystalline  $\text{TiO}_2$  nanorods by the sol–gel method was performed under cathodically induced conditions.<sup>189</sup> The electrolyte was prepared by dissolving titanium metal powder in  $\text{H}_2\text{O}_2$  and ammonia, the resulting yellow gel was dissolved in 4 M  $\text{H}_2\text{SO}_4$ , and then  $\text{KNO}_3$  was added to the

solution to pH 2–3. The pores (12–50 nm) of an anodised aluminium membrane were filled using the electrochemical method at room temperature at potentials ( $V$ ) from  $-0.9$  to  $-1.2$  V. At  $V < -0.9$  V, electroreduction of nitrate ions occurred at the cathode

which was accompanied by the formation of titanium hydroxide sol and gel

Annelation of a sample (450 °C, 24 h) gave  $\text{TiO}_2$  nanowires of the anatase modification with  $D \approx 40$  nm and a length of 2–10  $\mu\text{m}$  depending on the electrolysis time (0.5–3 h). A high gel density in template pores prevents the formation of defects and cracks during heating.

Electrochemical deposition of a titanium hydroxide gel in pores of poly(methyl methacrylate) using gold electrodes afforded  $\text{TiO}_2$  nanotubes.<sup>190</sup> An electrolyte with pH 2.5 was prepared under nitrogen from  $\text{NaHCO}_3$  and a  $\text{TiCl}_3$  solution in hydrochloric acid. The electrochemical reaction

was carried out at an anode potential of +0.5 V. Amorphous  $\text{TiO}_2$  nanotubes were prepared by removing the polymer using dissolution in acetone at 40 °C. Heating of these nanotubes at 450 °C for 1 h afforded intergrown anatase nanotubes with an outer diameter of 120 nm and a wall thickness of 25 nm. At short distances between the pores of the polymer, a compact porous  $\text{TiO}_2$  film was obtained.<sup>190</sup>

The influence of the molar ratio of the starting components on the morphology of  $\text{TiO}_2$  nanorods and nanotubes, which were synthesised from a sol by the template method on anodised aluminium, was studied.<sup>191</sup> The sol was prepared by adding a  $\text{Ti}(\text{OPr}^i)_4$  solution in ethanol to an ethanol, water and acetylacetone mixture. The amount of perfect nanorods ( $D = 200$ –250 nm) formed by particles with a size of  $\sim 20$  nm can be increased by increasing the percentage of ethanol in the sol. This can be achieved with the use of the starting molar ratio  $\text{Ti}(\text{OPr}^i)_4$ :acetylacetone: $\text{H}_2\text{O}$ :EtOH = 1:1:3:(20–40). An increase in the percentage of acetylacetone in the  $\text{TiO}_2$  sol (1:2:3:20) results in the formation of  $\text{TiO}_2$  nanotubes with thin walls (15–20 nm), which are easily broken and cracked.

Titanium dioxide nanowires were synthesised by deposition of a precursor on the corrugated surface of a polymeric template (based on azobenzene-functionalised epoxide resin) or silicon dioxide followed by calcination at 500 °C in air for 3 h.<sup>192</sup> The precursor was prepared as a sol by hydrolysis of a  $\text{Ti}(\text{OPr}^i)_4$  solution in isopropanol in a moist air atmosphere. Nanowires grow on a polymer template but do not grow on  $\text{SiO}_2$ . An increase in the isopropanol concentration in the sol results in the formation of cracks parallel to grooves in the template.

Considerable progress was made in the synthesis of nanostructures of complex titanium oxides.<sup>193–198</sup> For example, nanorods of titanic acid  $\text{H}_2\text{Ti}_3\text{O}_7$  were synthesised by the hydrothermal method<sup>193</sup> involving mixing of anatase with 10 M NaOH and heating at 130 °C for 72 h. The precipitate that formed was washed with water to prepare tubular particles 9 nm in diameter and hundreds of nanometres in length. Alkaline treatment of  $\text{TiO}_2$  gives rise to Ti–O–Na bonds, which are cleaved in water due to the replacement of  $\text{Na}^+$  ions with  $\text{H}^+$  ions. This results in the formation and subsequent rolling-up of laminar particles. In an acidic medium, the formation of nanotubes is not accelerated, but the resulting nanotubes contain numerous defects.

The formation of a disordered intermediate phase containing sodium ions is an important step in the formation of these nanotubes. The synthesis with the use of amorphous  $\text{TiO}_2$  as a precursor does not afford nanotubes, because  $\text{TiO}_2$  is recrystal-

lised into needle-like brookite. The use of KOH or LiOH instead of NaOH leads to the formation of nanorods and platelets or nanoparticles, respectively. Therefore, a high concentration of  $\text{Na}^+$  cations and a strongly alkaline medium are essential conditions for the nanotube formation. All  $\text{H}_2\text{Ti}_3\text{O}_7$  nanotubes are open and are formed by rolling up  $\text{TiO}_2$  layers with an interlayer distance of  $\sim 7.8$  Å.

The  $\text{H}_2\text{Ti}_3\text{O}_7$  phase belongs to the monoclinic system with the unit cell parameters  $a = 16.03$ ,  $b = 3.75$ ,  $c = 9.19$  Å and  $\beta = 101.45^\circ$ . The formula of this weak acid is generally represented as hydroxide  $\text{Ti}_3(\text{OH})_2\text{O}_5$  stable in an alkaline medium. Its monolayer is formed by corrugated ribbons consisting of  $\text{TiO}_6$  octahedra sharing edges (three octahedra in width), which form stepwise planes separated by  $\text{H}^+$  ions. In the polymeric titanate ion  $(\text{Ti}_3\text{O}_7^{2-})_n$ , the atomic layers roll up about the [001] direction of the crystal structure of  $\text{H}_2\text{Ti}_3\text{O}_7$ . An interesting feature of these nanotubes is the simultaneous presence of an interlayer space and a quasi-one-dimensional inner channel. Titanate  $\text{H}_2\text{Ti}_3\text{O}_7$  is a potential protonic electrolyte for fuel cells. In a concentrated NaOH solution, the nanotube material  $\text{Na}_2\text{Ti}_2\text{O}_4(\text{OH})_2$  was produced from polycrystalline  $\text{TiO}_2$  at 110 °C for 20 h.<sup>194</sup> Treatment of this material with an HCl solution at pH 1 gives rise to the orthorhombic tubular structure of  $\text{H}_2\text{Ti}_2\text{O}_4(\text{OH})_2$ .

The reaction of nanodispersed  $\text{TiO}_2$  (4 nm) with a 4–10 M KOH solution in an autoclave at 160–180 °C for 48 h affords the monoclinic  $\text{K}_2\text{Ti}_8\text{O}_{17}$  phase.<sup>195</sup> This phase consists of nanostructures analogous to twisted and bent ribbons (a few micrometres in length and tens of nanometres in width and thickness) extended along the [010] direction. The synthesis by this method in a NaOH solution produced nanosized belts of titanate  $\text{Na}_2\text{Ti}_4\text{O}_9$  with a width of 100–500 nm and a thickness of 30 nm. In these structures, the  $\text{Na}^+$  ions can be replaced by most cations. Potassium titanate shows chemoluminescence at 270 °C, which is 140 °C lower compared to that observed for  $\text{TiO}_2$  nanopowders. For this phase, photoluminescence at an excitation wavelength of 401 nm and an emission wavelength of 612 nm was observed for the first time.

The low-temperature hydrochemical method afforded  $\text{SrTiO}_3$  and  $\text{BaTiO}_3$  nanotubes with an outer diameter of 8–15 nm, an inner diameter of 4–7 nm and a length of 50–500 nm.<sup>196</sup> They have a cubic perovskite structure with the unit cell parameter  $a$  of 3.889 and 3.975 Å for  $\text{SrTiO}_3$  and  $\text{BaTiO}_3$ , respectively. The samples contain impurities of an amorphous product, the starting reagents and carbonates. The synthesis was carried out by stirring  $\text{SrCl}_2$  or  $\text{Ba}(\text{OH})_2$  and  $\text{TiO}_2$  NT solutions under argon or nitrogen for 6–20 h. Then pH of the suspension was brought to 12 and 10 by the addition of NaOH or HCl, respectively, and the precipitate was separated by decantation, washed with water and dried. Crystalline  $\text{SrTiO}_3$  and  $\text{BaTiO}_3$  nanorods (the unit cell parameter  $a$  is 3.90 and 4.03 Å, respectively) can also be prepared by thermolysis of  $\text{Sr}(\text{OPr}^i)_2$  and  $\text{Ba}(\text{OPr}^i)_2$  in the presence of oleic acid at 280 °C for 6 h.<sup>197</sup> Isolated nanorods have a diameter of 5–60 nm and a length of 10  $\mu\text{m}$ . These materials can be used as nanosized ferroelectrics and memory elements.<sup>198</sup>

## b. Vanadium oxides

The first vanadium(V) oxide nanotubes have been synthesised only recently.<sup>199</sup> The sol–gel method giving rise to xerogels with a pronounced quasi-one-dimensional structure proved to be efficient in the synthesis of such nanotubes.<sup>200</sup> A combination of the sol–gel process with hydrothermal treatment at 180 °C for 5 h produced nanowires of composition  $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$  ( $0.3 \leq n \leq 1.7$ ) with the [010] growth axis.<sup>201,202</sup>

Extensive experimental data<sup>203</sup> on the chemistry of intercalates based on the  $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$  xerogel provided the basis for developing new procedures for the synthesis of nanotube forms of vanadium oxide.<sup>204</sup> Evidently, the layered structure of a xerogel, in which the distances between the V–O layers are controlled by organic molecules, plays the key role in the design of vanadium

oxide nanotubes. Organic guest molecules serve as templates, thus determining the structure of a multilayer nanotube composite.

Primary amines  $C_nH_{2n+1}NH_2$  ( $4 \leq n \leq 22$ ) and  $\alpha,\omega$ -diamines  $H_2N(CH_2)_nNH_2$  ( $14 \leq n \leq 20$ ) were proposed as templates for these syntheses.<sup>204–208</sup> An ethanolic solution of vanadium(V) triisopropoxide  $VO(OPr^i)_3$  and amine in a molar ratio of 2:1 was stirred for 1 h under an inert atmosphere and then subjected to hydrolysis. After 12–96-h aging of the system, an orange composite was obtained, which was subjected to hydrothermal treatment in an autoclave at 180 °C for 2–7 days to prepare a black product, *viz.*, single-phase nanotubes with a length of up to 15  $\mu m$ , an outer diameter of 15–150 nm and an inner diameter of 5–50 nm. The walls of these tubes consisted of 2–30 layers of crystalline vanadium oxide, between which intercalated amine and diamine molecules are located. The distance between the layers (1.7–3.8 nm) is proportional to the length of the guest molecule. The general formula of such nanotubes can be represented as  $VO_xO_{y/2}(C_nH_{2n+4}N)_y$  or  $VO_x(C_nH_{2n+4}N)_y$ , where  $2.30 \leq x \leq 2.47$  and  $0.25 \leq y \leq 0.30$ , respectively. In the case of diamines, the tubes have thicker walls and a smaller inner diameter.

Vanadium–oxygen layers of the nanotubes under consideration consist of  $VO_4$  tetrahedra and  $VO_5$  tetragonal pyramids. The vanadium oxide tubes are stable after removal of amines but decompose at a temperature above 250 °C. Unlike mesoporous metal oxides with a laminar structure, these composites are characterised by a tubular morphology and well-structured walls. It is believed<sup>201</sup> that twisted layers of vanadium oxides are very flexible, and they can be stretched and involved in numerous exchange reactions.

In the above-described procedure for the synthesis of nanotubes, vanadium(V) oxochloride and oxide are also used as precursors.<sup>209</sup> In the first step,  $VOCl_3$  or  $V_2O_5$  is mixed with primary amine  $C_nH_{2n+1}NH_2$  under an inert atmosphere, and the mixture is hydrolysed with an acetate buffer (pH 7) or water. The next step involves hydrothermal treatment at 180 °C for 7 days. Elemental analysis demonstrated that the composition of the nanotubes synthesised from  $VOCl_3$  corresponded to the formula  $VO_{2.45 \pm 0.05}(C_nH_{2n+4}N)_{0.27 \pm 0.01}$  ( $11 \leq n \leq 16$ ). The tubes prepared from  $V_2O_5$  had the composition  $VO_{2.43 \pm 0.03} \cdot (C_nH_{2n+4}N)_{0.27 \pm 0.01}$  ( $11 \leq n \leq 20$ ).

The morphological characteristics of vanadium oxide nanotubulenes depending on the type of the precursor and the nature of the template are given in Table 3. The multilayer walls of these well-crystallised open tubes consist of rolled-up vanadium–oxygen layers built from  $VO_4$  squares with the unit cell parameter  $a = 6.1$  Å.<sup>210</sup> The tubes composed of ideal cylindrical layers are rarely produced (< 1%), and these tubes contain no more than six layers. Nanotubes of  $VO_x$  are more often composed of rolled-up layers and are characterised by the roll morphology.

The majority of vanadium oxide tubes contain various defects. An isolated layer forms an inner part of the tube, whereas its outer surface is generally transformed into a roll of two layers between which amine molecules are located. These tubes are characterised

by the formation of bundles and intergrowths. A roll of one  $VO_x$  layer can go to the adjacent tube with a change in the direction of rolling. This pair of tubes sharing layers is often observed in  $VO_x$  nanotubes with intercalated diamines after ion exchange. Aromatic amines can also be used as templates in the synthesis of  $VO_x$  nanotubes.<sup>211</sup> For example, the reaction of  $VO(OPr^i)_3$  with 3-phenylpropylamine followed by hydrolysis and hydrothermal treatment of the product affords nanotubes containing defects in the structure of the walls.

The structural characteristics of nanotubes can be varied as desired by changing the pH of the  $V_2O_5$  gel through the addition of ammonia.<sup>212</sup> In a neutral or weakly acidic medium, nanotubes with an interlayer distance proportional to the length of the  $(CH_2)_n$  chain are produced. The nanotubes synthesised at pH 9–10 have a unique structure of the walls, which consist of  $VO_x$  layers regularly alternating with intercalated amine and ammonia molecules (interlayer distances are 20 and 9 Å, respectively). The tubes formed in the presence of ammonia have a much larger outer diameter (larger than 250 nm) and smaller length (2–5  $\mu m$ ) compared to the nanotubes prepared at pH 4–8 (Fig. 3). The general formula of these nanotubes can be represented as  $[(NH_4)_yVO_x][(RNH_3)_xVO_x]$  (R is a hydrocarbon fragment).

Derivatives of *trans*-(1*R*,2*R*)- and *trans*-(1*S*,2*S*)-1,2-diamino-cyclohexane were proposed<sup>49</sup> as templates for the synthesis of the helical chiral structure of  $VO_x$  NT. The *R,R*- and *S,S*-enantiomers always give the left- and right-handed helices, respectively.

The synthesis of  $VO_x$  nanotubes from a  $V_2O_5 \cdot nH_2O$  gel ( $n \approx 300$ ), which was prepared by dissolution of vanadium(V) oxide in hydrogen peroxide, was documented.<sup>213,214</sup> A solution of hexadecylamine ( $0.45 \text{ g ml}^{-1}$ ) in acetone (the molar ratio V : amine = 2 : 1) was added to this gel, the mixture was stirred at room temperature for 16 h, and the composite was subjected to hydrothermal treatment at 150 or 180 °C for 2–10 days. The resulting black powder was washed with ethanol and cyclohexane and dried *in vacuo* at 80 °C for 5 h. The interlayer distance in  $VO_x$  NT decreases from 37 to 32 Å with increasing temperature and time of the hydrothermal process.

The X-ray powder diffraction patterns of the resulting nanotubes are typical of layered compounds. They contain intense 00*l* reflections (reflections from atomic planes) and weak *hk*0 reflections determined by a two-dimensional structure of the layer. The alkylamine molecule is perpendicular to the planes of  $VO_x$ , because the interlayer distance is close to the chain length of the amine (33 Å). Water molecules located between the layers along

**Table 3.** Morphological characteristics of V–O nanotubulenes ( $C_nH_{2n+1}NH_2$  template).<sup>209</sup>

| Precursor     | <i>n</i>           | Outer diameter of NT /nm | Inner diameter of NT /nm | Number of layers | Length of NT / $\mu m$ |
|---------------|--------------------|--------------------------|--------------------------|------------------|------------------------|
| $VO(OPr^i)_3$ | $4 \leq n \leq 22$ | 15–150                   | 5–50                     | 2–30             | 1–15                   |
| $VOCl_3$      | 11                 | 50–100                   | 15–35                    | 10–20            | 1.5–5                  |
|               | 16                 | 80–100                   | 20–35                    | 11–14            | 0.8–1.5                |
| $V_2O_5$      | 11                 | 70–140                   | 20–35                    | 9–13             | 2–12                   |
|               | 12                 | 50–90                    | 15–35                    | 7–13             | 1–3                    |
|               | 16                 | 70–100                   | 20–45                    | 6–13             | 1–2                    |
|               | 20                 | 60–90                    | 20–45                    | 6–10             | 1–3                    |

**Figure 3.** The TEM image of cross-sections of  $VO_x$  NT.<sup>212</sup> Hereinafter, TEM is transmission electron microscopy.

with protonated amines increase this distance to 37 Å. The inner and outer diameters of the nanotubes are 30–40 and 50–130 nm, respectively, the length is 1–10 µm, and the number of the layers varies from 5 to 25.

Vanadium(V) oxide powder can be used as a precursor in the synthesis of VO<sub>x</sub> nanotubes.<sup>215–217</sup> In this case, V<sub>2</sub>O<sub>5</sub> and hexadecylamine are mixed in water, the mixture is heated in an autoclave at 140 or 180 °C for 24 h or 3 days, respectively, and the resulting black product is washed with water and dried at 70 °C. The product consists of nanotubes with a length of 1–10 µm and a diameter of 30–100 nm depending on the conditions of the synthesis, the template type, the precursor concentration and the reaction time. The walls of these nanotubes are formed by 3–10 VO<sub>x</sub> layers with interlayer distances of 35.3 Å. The ESR spectra of these samples contain a single line without hyperfine structure, which is typical of interacting V<sup>4+</sup> ions. This is indicative of the close arrangement of paramagnetic centres (*d* < 0.7 nm) and the occurrence of spin–spin coupling interaction. The *g* factor (1.961) is equal to that of the VO(H<sub>2</sub>O)<sub>5</sub><sup>2+</sup> ion (1.962).

Hydrothermal treatment of a V<sub>2</sub>O<sub>5</sub>, MoO<sub>3</sub> and hexadecylamine mixture (180 °C) for one week afforded V<sub>0.99</sub>Mo<sub>0.01</sub>O<sub>2.45</sub>(C<sub>16</sub>H<sub>36</sub>N)<sub>0.27</sub> nanotubes with a diameter 30–10 nm and a length of 2–8 µm.<sup>217</sup> The interlayer distance in these nanotubes determined by X-ray and electron diffraction is 34 and 29.3 Å, respectively. The unit cell parameter *a* of the two-dimensional tetragonal unit cell in the layer is 6.23 Å.

Manganese-containing VO<sub>x</sub> nanotubes of composition Mn<sub>0.1</sub>VO<sub>2.5+δ</sub>·*n*H<sub>2</sub>O were synthesised by the ion exchange method from the layered V<sub>2</sub>O<sub>5+δ</sub>(C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub><sup>+</sup>) precursor.<sup>218</sup> Their largest diameter is 100 nm and the length is 1.3 µm. The nanotubes contain defects as partially broken zigzag layers with a tetragonal structure (*a* = 6.157(3) and *c* = 10.52(3) Å). This compound with a tubular morphology was tested as a cathode material for electrochemical lithium intercalation. At a potential of ~2 V, 0.5 mol of Li per mole of V<sub>2</sub>O<sub>5</sub> are reversibly inserted into VO<sub>x</sub> nanotubes. The cell capacity is 140 A h kg<sup>-1</sup>.

Reaction products of multilayer VO<sub>x</sub> nanotubes, which contain α-monoamines with a chain length of 4–22 carbon atoms between the layers (for example, C<sub>12</sub>-VO<sub>x</sub> contains alkylamine with 12 carbon atoms), with salt solutions were studied.<sup>219</sup> This process was demonstrated to be accompanied by intercalation of alkali (Na<sup>+</sup>, K<sup>+</sup>), alkaline earth (Mg<sup>2+</sup>, Ca<sup>2+</sup>, Sr<sup>2+</sup>) and transition metal (Fe<sup>2+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>, Cu<sup>2+</sup>, Sm<sup>3+</sup>, Tb<sup>3+</sup>) cations with a decrease in the interlayer distance in the tubes to 0.9–1.2 nm. The intercalated K<sup>+</sup> cations bound to crown ether can be partially replaced with dodecylamine with the result that the initial interlayer distance is restored. The reactions with RbCl, CsCl, AgNO<sub>3</sub>, SrCl<sub>2</sub> and BaCl<sub>2</sub> solutions lead to destruction of nanotubes, whereas ZnCl<sub>2</sub> and Pb<sup>2+</sup> salts are not intercalated. The largest atomic cation : V ratio in the insertion compounds is as high as 0.27.

Nanotubes intercalated with Na<sup>+</sup>, K<sup>+</sup> and Cu<sup>2+</sup> ions were prepared by the ion exchange method at the molar ratio VO<sub>x</sub> : MCl<sub>*n*</sub> = 1 : 4.<sup>220</sup> These cations in the samples account for 0.26, 0.27 and 0.12, respectively. The unit cell parameters for the intercalated tubes are as follows (the parameters of the starting nanotubes are given for comparison):

|                                    | <i>a</i> /Å | <i>c</i> /Å |
|------------------------------------|-------------|-------------|
| C <sub>12</sub> -VO <sub>x</sub>   | 6.12(1)     | 27.1(2)     |
| Na <sub>0.26</sub> VO <sub>x</sub> | 6.05(1)     | 9.2(1)      |
| K <sub>0.27</sub> VO <sub>x</sub>  | 6.11(1)     | 9.6(1)      |
| Cu <sub>0.12</sub> VO <sub>x</sub> | 6.08(2)     | 10.6(2)     |

The Raman spectra of VO<sub>x</sub> nanotubes show a broad low-intensity band at 995 cm<sup>-1</sup> (V=O) and two broad bands at 800–600 and 500–200 cm<sup>-1</sup> (V–O–V). These broad bands are associated with high disorder of the atomic structure of the tubes.<sup>220</sup> Galvanostatic studies of these materials provided evidence that the redox process is reversible (more than 100 cycles) in

current sources with a lithium anode. The discharge capacity is 120–150 A h g<sup>-1</sup> and the maximum lithium content is 0.5 Li<sup>+</sup> per vanadium atom.

Multilayer Cu–VO<sub>x</sub> and Fe–VO<sub>x</sub> nanotubes were prepared<sup>221</sup> by stirring (20 h) a dodecylamine–VO<sub>x</sub> NT suspension in aqueous-alcoholic CuCl<sub>2</sub> and FeCl<sub>3</sub> solutions followed by filtration, washing and drying in air at 60 °C. The starting nanotubes (primarily, open) have an outer diameter of 60–100 nm, an inner diameter of 15–40 nm and a length of 1–3 µm. Their walls consisted of 6–12 rolled-up layers of vanadium oxides with cracks and dislocations; the average interlayer distance (~30.2 Å) is indicative of the perpendicular arrangement of the dodecylamine molecules. The starting dodecylamine–VO<sub>x</sub> nanotubes are characterised by the tetragonal unit cell (*a* = 6.12, *c* = 33.71 Å). The Cu- and Fe-containing nanotubes have the same structure, the interlayer distances are 10.9 and 10.5 Å, respectively, the inner diameter varies in the range of 40–65 nm and the outer diameter varies in the range of 60–80 nm.

The structural changes resulting from the transformation of a dodecylamine–VO<sub>x</sub> xerogel into nanotubes followed by intercalation with Cu<sup>n+</sup> and Fe<sup>n+</sup> cations were studied by IR spectroscopy. The main absorption bands for the dodecylamine–VO<sub>x</sub> composite are observed at 998, 957, 733, 531 and 838, 809, 635 cm<sup>-1</sup>, and the main absorption bands for the dodecylamine–VO<sub>x</sub> nanotubes are observed at 1001, 792, 721, 573 and 487 cm<sup>-1</sup>. The spectra of the nanotubes also show the shift of the N–H stretching band from 3049 to 3127 cm<sup>-1</sup> and changes in the 1600–1500 cm<sup>-1</sup> region of bending vibrations associated with the difference in the environment about the NH<sub>3</sub><sup>+</sup> groups. After ion exchange (Cu–VO<sub>x</sub> NT), new bands appear at 3571, 3440 and 1615 cm<sup>-1</sup>, which correspond to O–H stretching vibrations and H–O–H bending vibrations. In the region of V–O bonds, two new bands at 755 and 526 cm<sup>-1</sup> (a shoulder at 590 cm<sup>-1</sup>) correspond to V–O–V and V–O–Cu bending vibrations, and the V=O band is shifted from 1001 to 1007 cm<sup>-1</sup>. For the Fe–VO<sub>x</sub> nanotubes, the shifts of the bands are insignificant (997, 576, 495 cm<sup>-1</sup> and 3384, 3203 and 1614 cm<sup>-1</sup>). This indicates that the Fe<sup>n+</sup> cations are bound to the VO<sub>x</sub> layers.

X-ray photoelectron spectroscopy demonstrated<sup>221</sup> that intercalated nanotubes contain a large amount of tetravalent vanadium. Copper atoms exist primarily in the monovalent state, and Cu<sup>2+</sup> cations and copper clusters are also present in small amounts. In Fe–VO<sub>x</sub> nanotubes, iron atoms exist in the Fe<sup>0</sup>, Fe<sup>2+</sup> and Fe<sup>3+</sup> states. Analysis of the N1s band shows that trace amounts of amines are present in the samples. The compositions of NT were represented as VO<sub>2.3</sub>(C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub>)<sub>0.38</sub>, VO<sub>1.53</sub> < *x* < 2.1(C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub>)<sub>0.21</sub>Cu<sub>0.08</sub>(H<sub>2</sub>O)<sub><0.56</sub> and VO<sub>2.08</sub> < *x* < 2.68(C<sub>12</sub>H<sub>25</sub>NH<sub>3</sub>)<sub>0.13</sub>Fe<sub>0.19</sub>(H<sub>2</sub>O)<sub><0.33</sub>. The chlorine content in the intercalates was lower than 0.01 mol.

Upon heating in air to 180 °C, Cu–VO<sub>x</sub> NT remain unchanged. The weight loss (~9%) occurs due to elimination of water coordinated to copper cations. At about 350 °C, the weight loss is 17%, residual water and organic molecules are eliminated, and the tubular structure is destroyed to form the unstructured V<sub>2</sub>O<sub>5-x</sub>/CuO composite. Under nitrogen, the weight loss in Cu–VO<sub>x</sub> NT occurs in the temperature range of 180–650 °C, and thermolysis affords Cu and V<sub>2</sub>O<sub>3</sub>. The process gives rise to V<sub>2</sub>O<sub>3</sub> nanotubes consisting of V<sub>2</sub>O<sub>3</sub> crystallites with a size of 3–5 nm. These nanotubes are thermally stable under nitrogen up to 650 °C, and copper metal nanoparticles are present inside the nanotubes. The Cu–VO<sub>x</sub> nanotubes are catalytically active in decomposition of HCN giving rise to Cu(CN)<sub>2</sub>. Additional data on copper-containing VO<sub>x</sub> nanotubes were reported in the study.<sup>222</sup>

The VO<sub>x</sub> nanotubes are structurally related to BaV<sub>7</sub>O<sub>16</sub>·*n*H<sub>2</sub>O<sup>223</sup> and (en)V<sub>7</sub>O<sub>16</sub>.<sup>224</sup> The (V<sub>7</sub>O<sub>16</sub>)<sub>*n*</sub> layers form a framework of the tube, whereas the amine molecules are inserted between the layers. These isotropic layers formed by the equivalent planes, which are composed of VO<sub>5</sub> square pyramids on

both sides of the layer, roll up to compensate free bonds of the terminal atoms giving rise to a tubular morphology.

The (en)V<sub>7</sub>O<sub>16</sub> compound is an example of structures characterised by strong electrostatic interactions between the negatively charged VO<sub>x</sub> layers and the ethylenediamine cations. This compound crystallises in the triclinic system with the unit cell parameters  $a = 6.161(2)$ ,  $b = 6.170(2)$ ,  $c = 19.111(7)$  Å,  $\alpha = 96.138(9)$ ,  $\beta = 92.819(9)$ ,  $\gamma = 90.067(9)^\circ$ . (In an independent electron diffraction study, the following unit cell parameters were determined:  $a \approx b \approx 6.15$ ,  $c \approx 18.5$  Å,  $\alpha \approx 98$ ,  $\beta \approx 93$ ,  $\gamma \approx 90^\circ$ .) Each V<sub>7</sub>O<sub>16</sub> layer consists of two planar sheets, which, in turn, are composed of VO<sub>5</sub> square pyramids linked *via* VO<sub>4</sub> tetrahedra. However, (en)V<sub>7</sub>O<sub>16</sub> was not prepared in pure form, and the NH<sub>2</sub> groups in this compound are protonated. The model of intercalated vanadium oxide nanotubes can be derived from the (en)V<sub>7</sub>O<sub>16</sub> structure. The unit cell parameters for C<sub>12</sub>-VO<sub>x</sub> nanotubes are  $a = 6.152$ ,  $c = 54.80$  Å, the space group is  $P4_2/m$ . The nanotube formation is favoured by a large interlayer distance (larger than 1.6 nm), as well as by the presence of amines and diamines containing long alkyl chains, which are inserted in the nanotubes.

Nanostructured vanadium oxide was synthesised using carbon nanotubes as a template.<sup>225,226</sup> The procedure involves coating of carbon NT with a V<sub>2</sub>O<sub>5</sub> gel followed by removal of carbon by calcination in air at 700 °C. To create acid centres on the surface of C-NT, the pre-treatment with boiling HNO<sub>3</sub> was carried out for 24 h. The diameter of the nanotubes thus prepared was 20–55 nm and the length was 2–3 µm. The orthorhombic system and the unit cell parameters  $a = 11.44$ ,  $b = 3.54$ ,  $c = 4.35$  Å were determined by electron diffraction.

Oxide  $\gamma$ -V<sub>2</sub>O<sub>5</sub> forms a layered orthorhombic structure with the unit cell parameters  $a = 9.946$ ,  $b = 3.585$ ,  $c = 10.042$  Å. The shortest interatomic distances (in Å) in the VO<sub>5</sub> pyramids of vanadium oxides are as follows:

| Oxide                                                     | V=O   | V–O(–V) | O...O        |
|-----------------------------------------------------------|-------|---------|--------------|
| $\gamma$ -V <sub>2</sub> O <sub>5</sub> (V <sub>1</sub> ) | 1.547 | 1.726   | 1.891, 1.986 |
| $\gamma$ -V <sub>2</sub> O <sub>5</sub> (V <sub>2</sub> ) | 1.581 | 1.848   | 1.898, 1.967 |
| $\alpha$ -V <sub>2</sub> O <sub>5</sub>                   | 1.576 | 1.778   | 1.878, 2.018 |

Nanorods and nanowires of  $\gamma$ -V<sub>2</sub>O<sub>5</sub> were synthesised<sup>227</sup> under mild conditions using the micelle method. The average lengths of the nanorods and nanowires were 90 nm and 1 µm, respectively. The sizes of these nanostructures depend on the time during which particles are kept in a micellar solution. The syntheses were carried out in a colloidal sodium bis(ethyl-2-hexyl)sulfosuccinate–isooctane–H<sub>2</sub>O solution, where the first component served as a stabilising surfactant, to which a solution of VO(OPr<sup>i</sup>)<sub>3</sub> in isooctane ( $5 \times 10^{-3}$  mol litre<sup>-1</sup>) was added at 20 °C for 24 h and 100 days, respectively. Well-crystallised nanorods, whose axes are parallel to the [101] direction, and nanowires extended along the [100] direction were synthesised.

The IR spectra of the nanorods are similar to those of the nanowires. The 1750–1000 cm<sup>-1</sup> region shows bands assigned to surfactants and bending vibrations of water molecules (1630 cm<sup>-1</sup>). The V–O stretching vibrations are observed at 1022, 1000, 963, 745 and 537 cm<sup>-1</sup>. X-ray photoelectron spectroscopy demonstrated that vanadium in these nanostructures exists in the pentavalent state; the bond energies of the 2p doublet are 518.8 and 525 eV.

Nanorods of  $\gamma$ -LiV<sub>2</sub>O<sub>5</sub>, which crystallise in the orthorhombic system and have a diameter of 30–40 nm and a length of 0.4–2 µm, were synthesised by the solvothermal method<sup>228</sup> with the use of ethanol as the solvent, which served simultaneously as a reducing agent:

A 1:1 LiOH and V<sub>2</sub>O<sub>5</sub> mixture in ethanol was kept in an autoclave at 160 °C for 24 h, and the precipitate was filtered off,

washed with ethanol and dried at 100 °C. The nanorods thus prepared were tested as a cathode material in a cell with a lithium anode. In the potential range of 1.5–4.2 V, the discharge capacity of the cell was 259 mA h g<sup>-1</sup>. In the first five charge–discharge cycles, the discharge capacity rapidly decreased and then remained constant (199 mA h g<sup>-1</sup> after 20 cycles).

Nanosized crystalline mixed-oxidation-state vanadium oxide was prepared by the addition of VOCl<sub>3</sub> to benzyl alcohol at room temperature and heating of a solution to 120 °C.<sup>156</sup> After aging, the precipitate was separated by centrifugation, washed with ethanol and dried.

Nanorods of NaV<sub>2</sub>O<sub>5</sub> (the orthorhombic system, the unit cell parameters  $a = 11.293$ ,  $b = 3.606$ ,  $c = 4.798$  Å) were produced by the hydrothermal method.<sup>229</sup> Their geometric parameters are determined primarily by pH and the concentration of the reducing agent (NH<sub>2</sub>OH). The magnetic properties of the samples were determined in the temperature range from 2 K to room temperature.

Single-crystalline samples of tubes with composition Na<sub>2</sub>V<sub>3</sub>O<sub>7</sub> were grown *in vacuo* from a Na<sub>1.9</sub>V<sub>2</sub>O<sub>5</sub> melt as black fibres several millimetres in length.<sup>230,231</sup> Fibre bundles can be easily separated into individual crystalline fibres with  $D < 100$  µm. The crystals belong to the trigonal system,  $a = 10.886$ ,  $c = 9.538$  Å,  $Z = 6$ , and consist of VO<sub>5</sub> square pyramids sharing edges and vertices to form parallel tubes with an inner diameter of  $\sim 0.5$  nm. The Na ions are located along the axis of the tube and between the tubes. This material should have an unusual ionic conductivity and properties of a low-dimensional quantum magnet and can be involved in ion-exchange reactions. The electronic and vibrational characteristics of Na<sub>2</sub>V<sub>3</sub>O<sub>7</sub> NT were studied.<sup>231</sup> The electronic structure of Na<sub>2</sub>V<sub>3</sub>O<sub>7</sub> is similar to that of nanotubular vanadates. The optical absorption spectrum shows a band at  $\sim 1.2$  eV, which was assigned to V(d → d) transitions, and bands at 3.3 and 3.9 eV assigned to O2p → V3d transitions.

Chemical vapour deposition from a  $\beta$ -diketonate complex and vanadyl acetylacetonate mixture on a glass substrate afforded nanowires of the  $\beta$  phase of Na<sub>x</sub>V<sub>2</sub>O<sub>5</sub> with  $D = 20$ –200 nm and  $L = 10$ –30 nm.<sup>232</sup> A single-phase sample of  $\beta$ -Na<sub>x</sub>V<sub>2</sub>O<sub>5</sub>, in which the growth orientation along the  $[h0l]$  direction prevails, was prepared only at 550 °C. A decrease in the temperature to 540 °C results in the appearance of an impurity as V<sub>2</sub>O<sub>5</sub> platelets.

Complex manganese vanadium oxide Mn<sub>7-2/3x</sub>(OH)<sub>3</sub>·(VO<sub>4</sub>)<sub>4-2x</sub>(V<sub>2</sub>O<sub>7</sub>)<sub>x</sub>, where  $x = 0.2$ , with a hexagonal structure also exhibits a tubular morphology (Fig. 4).<sup>233</sup> This oxide was synthesised by hydrothermal treatment of an alkaline solution (pH 10.2) containing V<sub>2</sub>O<sub>5</sub>, MnSO<sub>4</sub> and tetrabutylammonium cations (the template) in a molar ratio of 1:1:4 at 165 °C for 72 h.

Figure 4. The SEM image of (Mn,V)O<sub>x</sub> NT.<sup>232</sup>

Nowadays, most studies of  $\text{VO}_x$  nanotubes are aimed at developing procedures for the synthesis and investigating the morphology of samples. Data on their physicochemical properties are scarce.<sup>234</sup> The prospects of the use of vanadium oxide tubulenes as cathode materials for lithium cells,<sup>235–238</sup> semiconductors for the production of FET transistors<sup>239</sup> and catalysts for oxidation<sup>227</sup> were estimated. Studies of the cathode properties of  $\text{VO}_x$  nanotubes in chemical current sources with a lithium anode demonstrated that vanadium (which initially consisted of 60% of  $\text{V}^{5+}$  and 40% of  $\text{V}^{4+}$ ) is reduced to the tetra- and trivalent states.<sup>240</sup> The theoretical cathode capacitance is  $240 \text{ mA h g}^{-1}$  and the experimental capacitance is  $210 \text{ mA h g}^{-1}$ . During the first twenty discharge cycles (5 h), the discharge capacity increased.

At a potential below 2 V, the cathode material contains  $\text{V}^{5+}$ ,  $\text{V}^{4+}$  and  $\text{V}^{3+}$  derivatives. Consequently, vanadium can be reduced further, which accounts for the observed increase in the discharge capacity. When charging the current source, the charge is localised in the  $\text{V}(3d)$  band.<sup>241</sup> The C-NT/aerogel/ $\text{V}_2\text{O}_5$  nanocomposite exhibits good cathode properties at a high discharge rate.<sup>242</sup> At a current density of  $112 \text{ mA g}^{-1}$ , the discharge capacity of this cathode is higher than  $560 \text{ mA h g}^{-1}$ . For the graphite/aerogel/ $\text{V}_2\text{O}_5$  composite, the discharge capacity is  $450 \text{ mA h g}^{-1}$ . The resistance of electrodes composed of the C-NT/aerogel/ $\text{V}_2\text{O}_5$  composite is four times lower, which is primarily responsible for the improvement of their characteristics.

Nanosized oxide tubes and rods are promising modules for nanotechnologies.<sup>243</sup> Nanowires prepared on a  $\text{Si}/\text{SiO}_2$  substrate have a symmetric nonlinear voltammetric parameter and high resistance.<sup>244</sup> Measurements performed in the temperature range of 100–300 K provided evidence for the hopping mechanism of conductivity. Small-radius polarons migrate between  $\text{V}^{4+}$  and  $\text{V}^{5+}$  with an activation energy of 0.11 eV. The electrical characteristics of  $\text{V}_2\text{O}_5$  nanowires with a ribbon structure formed on a  $\text{Si}/\text{SiO}_2$  substrate were studied<sup>240, 244, 245</sup> (the length of the ribbons is a few micrometres, the width is 10 nm and the thickness is 1.5 nm). The conductivity of the fibres from such ribbons is  $20.5 \text{ S cm}^{-1}$  and the contact resistance between the fibres is 62 M $\Omega$ . In strong electric fields ( $E > 10^5 \text{ V cm}^{-1}$ ), the conductivity depends nonlinearly on the length of nanofibres. An analogous dependence has been observed earlier for  $\text{V}_2\text{O}_5$  films. In the region adjacent to the electrodes ( $L < 300 \text{ nm}$ ), non-Ohmic transport can occur.

### c. Chromium oxides

A composite consisting of carbon nanotubes filled with chromium oxide  $\text{CrO}_3$  was synthesised in air at room temperature.<sup>246</sup> For this purpose, C-NT were treated with a paste consisting of  $\text{CrO}_3$  and  $\text{HCl}$  (12 M) in a molar ratio of 2 : 1. The tubes were filled over a period of time from 3 h to 2 days. The material is formed by the following reaction of  $\text{CrO}_3$  with  $\text{HCl}$ :

Initially, chromium oxochloride and unconsumed  $\text{CrO}_3$  are inserted between bundles of carbon nanotubes to form intercalation compounds. The  $\text{CrO}_2\text{Cl}_2$  compound is sensitive to light, gradually decomposes, releases chlorine and oxidises carbon:

Oxidation of carbon atoms is induced by defects and impurities on the surface of C-NT, due to which the tubes contain pores. As a result, concentrated  $\text{CrO}_3$  solutions can penetrate into their inner cavity. The latter reaction competes with filling of the tubes. The structure of C-NT remains intact upon mild oxidation of carbon. Chromium trichloride was washed with water. The resulting composite is stable *in vacuo* under ion bombardment, as well as in air and in polar solvents, such as water, ethanol and acetone.

### d. Manganese oxides

Nanoribbons of complex manganese magnesium oxide of composition  $\text{Mg}_{2.11}\text{Mn}_{5.46}\text{O}_{12} \cdot x\text{H}_2\text{O}$ , with a length varying from a few to tens of micrometres, a width of 20–100 nm and a specific surface area of  $81 \text{ m}^2 \text{ g}^{-1}$  were synthesised.<sup>247</sup> The compound crystallises in the pseudoorthorhombic (monoclinic) system with the unit cell parameters  $a = 9.7$ ,  $b = 2.9 \text{ \AA}$ ,  $\beta = 90^\circ$ ; the parameter  $c$  was not determined. The average oxidation state of Mn is +3.62. The nanosized crystalline ribbons contain tunnels with equal diameter extended along the  $a$  axis, which are arranged in an ordered fashion about the  $b$  axis. The size of the framework of the tunnel structure is  $6.9 \times 6.9 \text{ \AA}$ . The synthesis was carried out in an autoclave at 120, 150 and  $200^\circ\text{C}$  using layered microporous  $\text{MgO}$  and a  $(\text{Et}_4\text{N})_x\text{MnO}_y$  gel as precursors. Heating of the nanoribbons at 40–130  $^\circ\text{C}$  was accompanied by elimination of physically adsorbed water (5%). Water located in the tunnels was removed ( $\sim 11\%$ ) in the temperature range of 130–420  $^\circ\text{C}$ , and destruction accompanied by elimination of coordinated water and oxygen occurred at 420–560  $^\circ\text{C}$ . Relatively active oxygen chemisorbed in tunnels was eliminated at 480  $^\circ\text{C}$ , and oxygen involved in the crystal structure was eliminated at 550  $^\circ\text{C}$ . The catalytic activity of the nanoribbons in oxidation of benzyl alcohol to benzaldehyde was studied; the degree of conversion was as high as 45%.

Nanofibres of nanostructured  $\alpha\text{-MnO}_2$  were synthesised<sup>248</sup> by the template method. An aluminium membrane was placed in a sol (which was prepared by stirring fumaric acid,  $\text{KMnO}_4$  and a  $\text{H}_2\text{SO}_4$  solution for 10 min) for 10 s. Then the membrane was dried and heated in air at 500  $^\circ\text{C}$  for 24 h. The resulting manganese dioxide layers were separated and treated with a 6 M  $\text{NaOH}$  solution to remove the residual aluminium template.

### e. Iron oxides

Macroscopic hollow fibres of hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) with a diameter of 4–10  $\mu\text{m}$ , a wall thickness of 1–2  $\mu\text{m}$  and a length of up to 20 cm were synthesised.<sup>249</sup> Reduction of hematite with hydrogen affords hollow fibres of  $\alpha\text{-Fe}$ . Iron alkoxide  $\text{Fe}(\text{OEt})_3$ , which was dissolved in ethanol and mixed with 2-methoxyethanol (MOE) in the molar ratio  $\text{Fe}^{3+} : \text{MOE} = 1 : 3$ , was used as a precursor in the synthesis. Within 2 h after dissolution of the red precipitate in acetic acid ( $\text{Fe}^{\text{III}} : \text{AcOH} = 1 : 10$ ), a sol appeared. The sol was transformed into green fibres of the gel at 40  $^\circ\text{C}$  during several days. After removal of organic components at 200  $^\circ\text{C}$ , amorphous fibres were obtained. At 300 and 400  $^\circ\text{C}$ , the fibres were transformed into  $\beta\text{-Fe}_2\text{O}_3$  and  $\alpha\text{-Fe}_2\text{O}_3$ , respectively. Final thermal treatment of the fibres was carried out at 500–700  $^\circ\text{C}$ .

The mechanism of formation of hollow fibres can be represented by the following sequence of transformations:

The ROH (MOE) molecules form hydrogen bonds with the polymeric  $\text{Fe}(\text{OAc})_3$  units, resulting in the formation of an ethanol sol. Further polymerisation affords fibres containing large amounts of ethanol and acetate anions. Heating of the composite leads to diffusion of sol particles, evaporation of organic compounds and formation of tubes, which are transformed into hollow polycrystalline fibres by thermal decomposition of acetate with elimination of  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Hollow fibres were observed also after storage of gels in air for one month.

Nanoparticles of  $\alpha\text{-Fe}_2\text{O}_3$  with a size of smaller than 100 nm were deposited<sup>250</sup> as round-shaped particles with a size of  $\sim 1 \mu\text{m}$  on the (001) crystallographic face of silicon from a ferrocene, xylene and water vapour mixture at 1000  $^\circ\text{C}$ . In the absence of water vapour, carbon nanotubes are produced. Water vapour reacts with silicon of the substrate giving rise to round-shaped templates to which  $\text{Fe}_2\text{O}_3$  nanoparticles are bound as a result of selective etching and oxidation of  $\text{Fe}^0$  with  $\text{H}_2\text{O}$  vapour. It was also found<sup>251</sup> that  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles ( $\sim 5 \text{ nm}$ ) prepared by

hydrolysis of  $\text{FeCl}_3$  in the presence of *n*-octylamine undergo aggregation. Highly crystalline  $\alpha\text{-Fe}_2\text{O}_3$  nanotubes were prepared<sup>252</sup> by hydrothermal treatment of  $\text{Fe}(\text{NO}_3)_3$  in cavities of C-NT and in a NaOH solution.

Nanowires of cobalt ferrite  $\text{CoFe}_2\text{O}_4$  with an average diameter of 50 nm and a length of up to a few micrometres were synthesised under mild conditions inside C-NT.<sup>253</sup> Carbon nanotubes with an outer diameter of 120 nm and an inner diameter of 60 nm were filled with aqueous  $\text{Co}(\text{NO}_3)_2$  and  $\text{Fe}(\text{NO}_3)_2$  solutions in a molar ratio of 1 : 2 and heated in air at 100 °C. The amount of cobalt and iron salts recalculated for the metals accounts for 30% of the mass of C-NT. Thermal treatment of long-fibre  $\text{CoFe}_2\text{O}_4$  nanowires (with a diameter of ~60 nm, which is equal to the inner diameter of the template tube) at 450 °C afforded cobalt ferrite nanoparticles as capsules 10 nm in size. Biological macromolecules, for example, hollow protein tubes of tobacco mosaic virus, can also be used as a template for the preparation of iron oxide nanotubes.<sup>254</sup>

#### f. Cobalt oxides

It was found<sup>255</sup> that the trivalent cobalt complex  $\text{CoL}(\text{en})_2(\text{BF}_4)_2$

[where  $\text{L} = \text{NH}_2\text{CH}(\text{CO}_2\text{H})\text{CH}_2\text{S}$ ] can be readily inserted into polyelectrolyte (PE) layers of colloidal particles, is deposited on these particles and serves as a precursor of  $\text{CoO}$  NT. The starting composite was prepared by the addition of poly(diallyldimethylammonium chloride) (PDADMAC) to an aqueous suspension of polystyrene particles (PS) with stirring followed by centrifugation to remove an excess of PDADMAC and layer-by-layer deposition of poly(sodium 4-styrenesulfonate) (PSS) and  $\text{CoL}(\text{en})_2(\text{BF}_4)_2$  onto PS particles. After drying at room temperature in air, spherical particles of modified PS form a necklace-like structure (Fig. 5). [In the absence of the cobalt(III) complex, this structure is not formed, because hydrogen bonds of the cobalt-containing precursor in the composite play the key role.] The use of Co complexes, which are not involved in hydrogen bonding, led to the formation of hollow spheres. Calcination of modified PS particles at 385 °C under nitrogen and oxygen for 2 and 6 h, respectively, afforded  $\text{Co}_3\text{O}_4$  tubulenes with  $D = 200\text{--}400$  nm and  $L = 3\text{--}4$   $\mu\text{m}$ .
