The necessary condition for the nanotube formation is the presence of ten alternating PDADMAC and PSS layers on PS particles. If the number of layers is smaller than six, nanotubes are not produced. The amount of the precursor in multilayer polyelectrolyte particles and the time of their heating under a stream of nitrogen and oxygen play an important role in the synthesis of  $\text{Co}_3\text{O}_4$  nanotubes. The morphology of nanostructures also depends substantially on the type of hydrogen-containing  $\text{Co}^{3+}$  complexes inserted into a multilayer polyelectrolyte on the surface

Figure 5. The TEM image of  $\text{CoO}_x$  NT.<sup>255</sup>

of colloidal particles.<sup>256</sup> Cobalt complexes with strong intermolecular hydrogen bonds form one-dimensional  $\text{Co}_3\text{O}_4$  nanotube structures. Complexes, in which hydrogen bonds are weak, if at all present, give rise to short defect-containing nanotubes and destroyed balls.

Nanostructures of  $\text{Co}_3\text{O}_4$  with a large specific surface area are of practical interest, because this  $\text{Co}^{2+}$ - and  $\text{Co}^{3+}$ -containing oxide with the spinel structure serves as a good catalyst for oxidation of CO. Nanosized  $\text{Co}_3\text{O}_4$  fibres can be prepared by the template sol–gel method.<sup>248</sup> An aqueous solution of  $\text{Co}(\text{NO}_3)_2$  (0.3 mmol litre<sup>-1</sup>) and citric acid (0.05 mmol litre<sup>-1</sup>) was subjected to hydrolysis for 1 h, the resulting sol was incorporated into an aluminium template membrane for 10 s, and the membrane was dried in air and annealed at 500 °C for 24 h. Then the membrane was dissolved in alkali to prepare individual  $\text{Co}_3\text{O}_4$  fibres.

#### g. Nickel oxides

Nickel-containing tubulenes can be synthesised by the template method.<sup>257</sup> For example, nickel nanowires were grown starting from C-NT, which were prepared by decomposition of propene on an anodised aluminium membrane.<sup>257</sup> The tubes were filled with nickel metal by decomposition of nickelocene under a stream of hydrogen at 105 °C. Then the aluminium membrane was removed by dissolution in 10 M NaOH at 150 °C in an autoclave. The length of the nickel nanowires thus prepared varies from tens to hundreds of nanometres, the diameter is 4 nm, and the inner size of C-NT is 20 nm, which is uncharacteristic of the template method. The latter usually gives nanowires with a length that coincides with the inner diameter of the channels in the template. The growth of nanowires occurs predominantly along the (111) plane of the crystal structure of nickel metal. The formation of the latter in the vicinity of the open ends of C-NT was not observed. Nickel nanowires are produced inside C-NT by vacuum evaporation of nickelocene.<sup>258</sup>

Decomposition of nickelocene at 275 °C under a water vapour atmosphere followed by deposition of nickel on a carbon film afforded a Ni–C composite.<sup>257</sup> Treatment of the latter with 10 M NaOH at 150 °C in an autoclave produced C-NT with inclusions, which are analogous to nanosized NiO ribbons 4 nm in width and 10–800 nm in length, and nickel metal particles (larger than 10 nm, Fig. 6). The upper and lateral surfaces of the nanoribbons are parallel to the (111) and (202) crystallographic planes, respectively, of NiO, if its axis is oriented along the [211] direction.

The formation of NiO results from oxidation of nickel with atmospheric oxygen, which occur during alkaline treatment of the composite in an autoclave. In the cavity of C-NT with an inner diameter of 20 nm, NiO crystals grow along the tube axis. In

Figure 6. The TEM image of a NiO nanoribbon intercalated into a carbon nanotube.<sup>257</sup>

C-NT with  $D > 20$  nm, platelets with sizes (in the plane) of hundreds of nanometres can be produced. The complete filling of the cavities in C-NT with NiO crystals is needed for the synthesis of nanowires or nanorods. However, this does not occur due to the growth of a thin crystalline NiO plate along the tube axis. The NiO–C-NT nanocomposite can also be prepared by filling carbon nanotubes, which are pre-treated with nitric acid followed by annealing under a stream of argon at 450 °C for 5 h, with nickel nitrate.<sup>259</sup> In this case, nickel oxide completely fills the inner cavity of the tube ( $\sim 3$ –6 nm in diameter) to form elongated nanoparticles (10–40 nm in length). This composite can be used as a catalyst in organic synthesis.

#### h. Copper oxides

Nanosized CuO rods were synthesised<sup>260</sup> according to a rather simple procedure by stirring  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$  and NaOH in the presence of polyethylene glycol (PEG). Then the composite was washed with water and EtOH and dried in air at 60 °C for 3 h. The final product consisted of identical CuO nanorods 8 nm in diameter and 40 nm in length. The type of the nanostructures is determined by PEG, which forms chain aggregates in water. The synthesis of bamboo-like CuO nanoparticles ( $D = 20$ –90 nm,  $L = 250$ –700 nm) was documented.<sup>261</sup> Templates of multilayer C-NT were treated with boiling  $\text{HNO}_3$  (68%) for 24 h, stirred with a  $\text{Cu}(\text{NO}_3)_2$  solution for 48 h, filtered, washed with water and dried at 60 °C for 12 h. Heating under a stream of argon at 450 °C (5 h) followed by burning up of C-NT in air (750 °C, 1 h) afforded copper oxide with the parameters of the monoclinic unit cell  $a = 4.697$ ,  $b = 3.425$ ,  $c = 5.130$  Å,  $\beta = 99.67^\circ$ . The average size of the crystallites was 37 nm (calculated from the width of the (110) reflection), and the crystallites are oriented predominantly along the [101] direction. It should be noted that the sizes of the CuO nanoparticles are much larger than those of the template, which is attributable to the tendency of the system to decrease the surface energy and to the intergrowth of the adjacent CuO nanostructures upon burning up of carbon tubes.

One-dimensional well-ordered CuO nanofibres are produced during autocatalytic growth.<sup>262</sup> Copper nuclei with sizes equal to the pore diameter of the membrane (50–60 and 100–150 nm) were deposited on a copper plate having a polycarbonate (PC) membrane as a template from a  $\text{CuSO}_4$  solution in the electric field of  $15 \text{ V cm}^{-1}$ . Heating of Cu crystallites under an oxygen atmosphere results in their transformation into nanocrystalline CuO fibres with an average length of 2  $\mu\text{m}$  and a packing density of  $10^7$ – $10^8 \text{ cm}^{-2}$ . The diameter of nanofibres corresponds to the average size of copper particles. The solid-phase synthesis of nanosized whiskers ( $D = 2$ –10 nm,  $L > 100$  nm) in the presence of the non-ionic surfactant polyethylene glycol (PEG-400) was also documented.<sup>263</sup>

The CuO/C-NT composite with the mass ratio CuO:C = 3:2, which was prepared by oxidation of Cu/C-NT by heating to 160 °C in air for 12 h, was studied as a cathode material in current sources with a lithium anode.<sup>264</sup> Lithium (1.88 g-at of Li per 6 g-at of C) was inserted into C-NT by the electrochemical method. This amount of lithium corresponds to the capacity of 700 mA h  $\text{g}^{-1}$ . For CuO/C-NT layers, the capacity is 268 mA h  $\text{g}^{-1}$ . Lithium is inserted into the CuO structure at a potential of 1.7–1.0 V and is eliminated at 2.3–2.5 V. The stable operating time of the CuO/C-NT cathode material during cycling is determined by stability of the intercalation compound  $\text{Li}_x\text{CuO}$ , which decomposes into Cu,  $\text{Cu}_2\text{O}$  and  $\text{Li}_2\text{O}$ . In this case, the microstructure of C-NT is of considerable importance. Intercalation and deintercalation of lithium causes destruction of C-NT.

#### k. Zinc oxides

Nanostructured ZnO has attracted considerable attention,<sup>265</sup> because materials based on this compound are widely used in electronics, optoelectronics, optics, solar batteries and sensors and also serve as photocatalysts. Zinc oxide nanorods and nanofibres

were prepared by the hydrothermal method.<sup>266–269</sup> The simplest microemulsion method is the reverse of the micelle formation.<sup>266</sup> Cetyltrimethylammonium bromide (CTAB) was used as a micro-emulsifying agent. Sodium hydroxide was added to a solution of zinc acetate in n-hexanol and n-heptane to pH 14. The mixture was stirred until a  $\text{Zn}(\text{OH})_4^{2-}$  emulsion was formed and then heated in an autoclave at 140 °C for 13 h. The white precipitate that formed was washed and dried *in vacuo* at 60–70 °C. The product consisted of nanowires of hexagonal ZnO ( $D = 30$ –150 nm,  $L$  to 3  $\mu\text{m}$ ) with the growth direction along the ZnO (110) crystallographic plane. Single-crystalline ZnO nanowires ( $D = 80$ –100 nm,  $L \approx 10 \mu\text{m}$ , the [0110] growth direction) were also synthesised by hydrothermal treatment of  $\text{Zn}_4\text{CO}_3(\text{OH})_6 \cdot \text{H}_2\text{O}$ .<sup>269</sup>

Hydrothermal oxidation of zinc metal in the presence of CTAB (180 °C, 20 h) affords ZnO nanorods.<sup>268</sup> Surfactants, such as CTAB and n-hexanol, play an important role in the formation of ZnO nanowires. These surfactants facilitate the orientational growth of ZnO. In the synthesis with the use of zinc metal as a precursor, the surfactants promote erosion of ZnO. Ultrasonic pre-treatment of the reaction mixture before hydrothermal treatment facilitates nucleation and gives rise to a unified morphology of ZnO nanorods in an alkaline solution in the ratio  $\text{Zn}^{2+}:\text{OH}^- = 1:20$  in the presence of ethanol and ethylenediamine.<sup>267</sup> Intergrowths of ZnO rods with a diameter 30–40 nm, a length of 1.5  $\mu\text{m}$  were prepared (the unit cell parameters  $a = 3.25$ ,  $c = 5.21$  Å). These rods exhibit photoluminescence at 385 and 485 nm under excitation with a He–Cd laser at a wavelength of 325 nm.<sup>266</sup>

A zinc oxide tubular material with an outer diameter 450 nm, an inner diameter of 250 nm and an average length of 4  $\mu\text{m}$  was synthesised<sup>270</sup> under hydrothermal conditions (180 °C, 13 h) from an ethanolic solution containing  $\text{Zn}(\text{NH}_3)_4^{2+}$  cations by the reaction

Ammonia that is eliminated plays an important role in the formation of the tubular morphology of ZnO. The reaction performed at a temperature below 180 °C with the use of methanol or propanol instead of ethanol produces the final product consisting only of ZnO nanoparticles.

Zinc oxide nanorods can be prepared by simple thermal decomposition of hydrated zinc acetylacetonate  $\text{Zn}(\text{acac})_2 \cdot n\text{H}_2\text{O}$  in an atmosphere of a  $\text{N}_2$  and  $\text{O}_2$  mixture at a pressure of  $5 \times 10^{-3} \text{ mm Hg}$  and at 130–140 °C on silicon [(100) plane] and sapphire substrates.<sup>271</sup> The ordered ZnO structure ( $D = 60$ –80 nm,  $L = 450$ –500 nm) is prepared on the silicon (100) plane, whereas ZnO nanorods, which are oriented along the  $c$  axis and arranged in an ordered fashion along the  $a$  axis, were grown only on the sapphire (110) plane. Zinc oxide nanorods were grown also on an amorphous  $\text{SiO}_x$  layer of a Si(100) plate heated to 500 °C. These rods show emission and absorption in the UV region at 386 nm and are characterised by a low concentration of oxygen vacancies. The synthesis of high-quality well-oriented nanorods with a controlled diameter (45, 60 or 90 nm) was carried out by varying the vapour temperature (135–138 °C), the flow rate of a  $\text{N}_2/\text{O}_2$  mixture and the substrate temperature. The synthesis at 130–200 °C from  $\text{Zn}(\text{acac})_2$  vapour and products of its partial decomposition [for example,  $\text{Zn}(\text{acac})$ ] affords zinc metal, which is oxidised on the substrate surface followed by the growth of nanostructured ZnO.

Zinc oxide nanowires and nanorods can also be prepared in aqueous solutions of zinc salts.<sup>272, 273</sup> The oppositely charged  $\text{Zn}(\text{NH}_3)_4^{2+}$  and  $\text{Zn}(\text{OH})_4^{2-}$  micelles act as microreactors, resulting in the anisotropic growth of ZnO during a simple solvothermal process.

Nanostructured ZnO was synthesised<sup>274</sup> at room temperature by adding 0.02 M NaOH to a mixture of solutions of  $\text{Zn}(\text{OAc})_2 \cdot 2\text{H}_2\text{O}$  (0.01 mol litre<sup>-1</sup>) and triethanolamine (TEA) (0.07 mol litre<sup>-1</sup>), which was used as a surfactant, and stirring for

30 min. The composite was washed with water and ethanol using ultrasonic treatment and dried at 80 °C. The final product consisted of hexagonal nanorods (the hexagonal system,  $a = 3.249$ ,  $c = 5.209$  Å) with a diameter of 20 nm and a length of up to 200 nm. In the absence of TEA, ZnO nanoparticles were prepared. The optimum TEA:Zn<sup>2+</sup> ratio is smaller than (0.1–1):1.

The solid-phase synthesis of hexagonal ZnO nanorods ( $a = 3.250$ ,  $c = 5.207$  Å;  $D = 40$ –120 nm,  $L$  is up to several micrometres)<sup>275</sup> was carried out with the use of a ZnCl<sub>2</sub>, Na<sub>2</sub>CO<sub>3</sub> and KCl mixture, which was prepared with poly(oxyethylene)-5-nonylphenol or poly(oxyethylene)-9-nonylphenol ether in cyclohexane, as a precursor. The latter gave a precipitate, which was washed with acetone, separated by centrifugation, dried, annealed in air (770 °C, 3 h) and washed with water. The use of NaCl instead of KCl (as a flux), an increase in the temperature to 820 °C or an increase in the annealing time led to the formation of larger nanorods.

The growth of perfect individual ZnO nanorods with  $D = 150 \pm 10$  nm and  $L = 2.17 \pm 0.13$  µm was observed upon decomposition of amorphous tubular Zn(OH)<sub>2</sub> as a precursor.<sup>276</sup> Good reproducibility of the sizes was achieved with the use of sodium dodecylbenzenesulfonate (DBS) as a modifying and protecting agent.

Zinc oxide nanorods with a diameter of 5–300 nm and a length of up to several hundreds of micrometres can be synthesised by the reaction

in the gas phase at 730–1000 °C.<sup>277–280</sup> The growth of ZnO occurs along the  $c$  axis (the [001] direction). For nanostructures synthesised at 1000 °C under argon for 30 min, the following three luminescence bands are observed:<sup>280</sup> a strong band in the UV region (379 nm), a blue band (466 nm with a shoulder at ~452 nm) and a weak yellow band (612 nm). The UV emission is induced by direct exciton recombination, and the blue band appears due to the imperfect ZnO structure. After annealing under oxygen at 500 °C, the blue and yellow luminescence bands are substantially weakened due to a decrease in the concentration of O and Zn defects.

A modification of the chemical vapour-phase synthesis of ZnO nanowires is based on the reaction

at 900 °C under a stream of argon.<sup>281</sup> Oxidation of zinc vapour in the temperature range of 850–925 °C affords high-quality ZnO nanostructures as intergrowths of four nanorods (Fig. 7).<sup>282</sup> The morphology of the particles depends on the conditions of the process.<sup>283</sup> Tetrahedral intergrown T-ZnO nanorods are produced in air (see Table 1), whereas individual nanorods are formed under wet argon and nitrogen. The T-ZnO structure consists of tetrahedrally shaped intergrowths with four 'legs'

Figure 7. The SEM image of an intergrowth of T-ZnO nanorods.<sup>282</sup>

2–3 µm in length and the central core with a size of 70–200 nm.<sup>284</sup>

Oxidation of an aluminium-based melt containing 6% Si, 2% Zn and 0.8% Fe (mass %) produced relatively linear ZnO whiskers 50–500 nm in diameter.<sup>285</sup> The process was carried out at 1100 °C for 1 h under oxygen. The melt was oxidised to form Al<sub>2</sub>O<sub>3</sub> microchannels on the surface. These channels were filled with a liquid alloy, and zinc metal was oxidised to ZnO on the surface of the alloy, resulting in the growth of nanowhiskers tens of micrometres in length. In this example, iron serves as a catalyst, and silicon acts as a promoter of growth of ZnO nanowhiskers.

Zinc oxalate, which was prepared in cyclohexane in the presence of a surfactant, was used as a precursor to prepare ZnO nanowires.<sup>286</sup> Zinc oxalate with an admixture of a flux (NaCl) was heated at 920 °C under a stream of argon. Thermolysis of ZnC<sub>2</sub>O<sub>4</sub> afforded ZnO, which was reduced with carbon of the surfactant to Zn, and the latter went to the gas phase. Zinc and zinc oxide vapours were deposited on the walls of the reactor to form zinc oxide nuclei containing defects in the oxygen sites. Zinc oxide nanowires ( $a = 3.249$ ,  $c = 5.206$  Å,  $D = 15$ –80 nm) were grown when air was passed through the mixture. Depending on the flow rate of argon, either nanowires or nanowhiskers grow on the (101) surface. The addition of a NaCl flux facilitates the formation and nucleation of nanostructured ZnO, hinders particle agglomeration and promotes evaporation of Zn and ZnO.

Crystalline nanowhiskers of hexagonal ZnO were prepared by reduction of ZnS with hydrogen (5% H<sub>2</sub> under argon) at 1300 °C to give Zn followed by oxidation to ZnO in an Ar + 5% O<sub>2</sub> gas mixture.<sup>287,288</sup> The process is autocatalytic and occurs by the vapour–liquid–solid mechanism. The growth of ZnO occurs along the [0001] direction. The outer diameter, the length and the wall thickness of the whiskers range up to 400 nm, 15 µm and 100–150 nm, respectively.<sup>288</sup> The photoluminescence spectrum of the whiskers shows a strong emission band in the UV region (381 nm) and a broad band at 583 nm (green luminescence).

Zinc oxide forms unusually extended and oriented chiral nanostructures.<sup>289</sup> Such nanorods and nanocolumns grow in the presence of citrate ions that control the crystal growth due to adsorption on the (002) surface. The synthesis was carried out with the use of oriented ZnO nanorods, which were grown on a glass substrate in a solution of Zn(NO<sub>3</sub>)<sub>2</sub> (0.03 mol litre<sup>-1</sup>) and hexamethylenetetramine (HMT) (0.03 mol litre<sup>-1</sup>) at 60 °C for 3 days. To grow helical ZnO nanostructures, the substrate was placed in a solution containing Zn(NO<sub>3</sub>)<sub>2</sub> (0.03 mol litre<sup>-1</sup>), HMT (0.01 mol litre<sup>-1</sup>) and sodium citrate (0.001 mol litre<sup>-1</sup>) and the mixture was kept at 95 °C for 1 day. The process was repeated by adding small amounts of sodium citrate. Chiral nanorods 1 µm in length were prepared. The base and top diameters were 500 and 30 nm, respectively. The nanorods were composed of helically arranged platelets with a step height of ~15 nm.

The microwave-induced plasma method was used<sup>290,291</sup> to synthesise ZnO structures with different morphologies (nanowires, nanocables, nanotubes) and specified sizes. Zinc or zinc oxide powder was placed in a quartz tube furnace, through which hydrogen was passed. Microwave heating of the precursor (400 W, 2.45 MHz) up to the plasma formation (1000 °C) led to condensation of Zn vapour in the furnace region with a temperature 500 °C. After evaporation for 30 min, hydrogen flow was terminated, and zinc was oxidised by passing a 1 : 50 oxygen and argon mixture for 15–30 min. Zinc nanowires formed under hydrogen served as a template in the synthesis of nanosized Zn/ZnO cables involving partial oxidation of zinc with oxygen followed by the formation of ZnO NT. The wall thickness of the tubes depends on the time of oxidation occurring along the [001] direction. The average outer and inner diameters of nanotubes were 40 and 10 nm, respectively, and the length was 1 µm. The sizes of the tubes can be varied depending on the conditions of the microwave-induced plasma process, the flow rate of hydrogen and the oxidation time. The microwave-induced plasma method

combined with heating in a furnace allows one to prepare also nanostructured ZnO as aggregates consisting of four nanorods with a diameter of 10–25 nm and a length of up to 160 nm.<sup>291</sup> Cathode luminescence of such structures is characterised by strong UV radiation at 385 nm.

Nanosized whiskers of oxalate  $\text{ZnC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  can be prepared by a chemical method.<sup>292</sup> For this purpose, the  $\text{Zn}(\text{OAc})_2 \cdot 2\text{H}_2\text{O}$  precursor was dispersed in xylene with an admixture of sodium DBS as a template. An ethanolic solution of  $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  was added to the resulting suspension, and the white precipitate consisting of nanosized whiskers ( $D = 200\text{--}300\text{ nm}$ ,  $L$  up to  $20\text{ }\mu\text{m}$ ) was separated by centrifugation, washed and dried *in vacuo* at  $60\text{ }^\circ\text{C}$ . Some whiskers were obtained as tubes with a wall thickness of  $\sim 30\text{ nm}$ . Heating of these nanostructures at  $180$  and  $427\text{ }^\circ\text{C}$  was accompanied by elimination of  $\text{H}_2\text{O}$  and  $\text{CO}_2$ , respectively. The resulting nanostructured ZnO powder ( $50\text{--}60\text{ nm}$ ) was stable up to  $1280\text{ }^\circ\text{C}$ . At a temperature below  $280\text{ }^\circ\text{C}$ ,  $\text{ZnC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  was transformed into  $\beta\text{-ZnC}_2\text{O}_4$  nanowhiskers. The  $\text{ZnC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanoparticles prepared from an aqueous solution had a size and shape, which were determined by a microreactor composed of the surfactant (DBS).

Considerable progress was made in the synthesis of nanostructured ZnO by evaporation of zinc metal and its compounds. Zinc oxide nanowires ( $D < 50\text{ nm}$  and up to tens of micrometres in length) were prepared by heating Zn under a stream of nitrogen or argon in the absence of a catalyst (zinc metal serves as the catalyst, which is then oxidised to ZnO).<sup>293</sup> Heating of a zinc plate at  $900\text{ }^\circ\text{C}$  affords ZnO nanostructures exhibiting a tetrahedral morphology (see Fig. 7).<sup>294</sup> Evaporation of Zn powder at  $800\text{ }^\circ\text{C}$  under argon gives rise to the hexagonal phase of ZnO as wires with a diameter of  $0.2\text{--}0.4\text{ }\mu\text{m}$  and a length of several tens of micrometres.<sup>295</sup> This material exhibits strong green luminescence at  $520\text{ nm}$  and relatively weak UV luminescence near  $370\text{ nm}$ . The former appears due to electron–hole recombination with the involvement of electrons of the charged oxygen vacancies in the ZnO structure. Zinc oxide nanowires ( $30\text{--}60\text{ nm}$  in diameter and tens of micrometres in length), which were prepared by heating Zn powder in the presence of Au nanoparticles as the catalyst at  $900\text{ }^\circ\text{C}$ , also show a strong green emission.<sup>296</sup>

Evaporation of zinc oxide at  $1380\text{ }^\circ\text{C}$  under a stream of argon or *in vacuo*<sup>297–299</sup> affords single-crystalline ZnO nanowires ( $D = 15\text{--}60\text{ nm}$ ,  $L = 10\text{--}70\text{ }\mu\text{m}$ ) with the  $[110]$  growth direction.<sup>298</sup> Samples synthesised *in vacuo* hold promise as materials for short-wavelength nanolasers.<sup>299</sup> Condensation of ZnO vapour in the temperature range of  $900\text{--}1030\text{ }^\circ\text{C}$  gave a mixture of nanosized rods and belts of nanometre to micrometre diameter (width).<sup>300</sup> In the temperature range of  $650\text{--}700\text{ }^\circ\text{C}$ , rods and belts with  $D = 70\text{--}300\text{ nm}$  were grown. More homogeneous materials were produced at  $350\text{--}450\text{ }^\circ\text{C}$  as wires  $15\text{--}40\text{ nm}$  in diameter and  $10\text{--}70\text{ }\mu\text{m}$  in length. The growth direction of ZnO crystals is perpendicular to the  $(01\bar{1}0)$ ,  $(0001)$  and  $(11\bar{2}0)$  planes for the belts, rods and wires, respectively. Crystalline ZnO nanobelts, which were prepared<sup>301</sup> by thermal evaporation of ZnO in pores of an aluminium membrane, had a length of  $10\text{--}100\text{ }\mu\text{m}$ , a width of  $30\text{--}300\text{ nm}$  and a thickness of  $6\text{--}30\text{ nm}$  and contained a smaller number of oxygen defects than powders synthesised under analogous conditions.

Additives of oxides<sup>302</sup> or low-melting point metals<sup>303</sup> in the synthesis of nanostructures from ZnO vapour increase the evaporation rate of the latter and influence the morphology of the final product. Nanosized bridges and nails can be prepared from ZnO on a graphite, silicon or  $\text{SrTiO}_3$  substrate by varying the conditions of the synthesis. Nanobridges are produced by the addition of  $\text{In}_2\text{O}_3$  to zinc oxide at  $1000\text{ }^\circ\text{C}$  and an air pressure of 2 Torr, and nanonails grow at  $950\text{--}970\text{ }^\circ\text{C}$  and  $0.5\text{--}1.0$  Torr. A typical bridge (Fig. 8) is tens of micrometres in length and up to several micrometres in height and width;<sup>302</sup> it consists of a ZnO belt and nanorods ( $50\text{--}200\text{ nm}$  in diameter and up to  $2\text{ }\mu\text{m}$  in length) located at the edges of the belt. Each nanorod belonging to the hexagonal system grows epitaxially along the  $[0001]$  or  $[000\bar{1}]$

**Figure 8.** The SEM images of different types of ZnO bridges; (a) coiled; (b) doubled.

direction. The rows of nanorods are parallel to the  $[01\bar{1}0]$  direction of the belt, which forms a ring in the centre of the bridge (Fig. 8a). Two belts can be linked together perpendicular to each other (Fig. 8b). The epitaxial growth of ZnO nails along the  $c$  axis occurs on a graphite substrate (Fig. 9). These structures are

**Figure 9.** The SEM images of ZnO nanonails.<sup>302</sup>

several micrometres in length, the diameters of the rods are in a range of 150–200 nm, and the diameter and thickness of the hexagonal nail-heads are  $\sim 1\ \mu\text{m}$  and 50–100 nm, respectively.

The characteristic feature of ZnO nanostructures formed in the presence of low-melting point elements is the growth of attached branches of various shapes. In this case, the surface segregation of low-melting point elements plays an important role due to enrichment of the tops of nanostructures in these elements. A three-dimensional self-organised nanosized ZnO-based heterostructure doped with In or Sn was synthesised by condensation from a vapour phase on a graphite substrate.<sup>303</sup> A ZnO,  $\text{In}_2\text{O}_3$  (or  $\text{SnO}_2$ ) and graphite mixture was heated at 1000 °C and condensed at 850 °C by oxidation with atmospheric oxygen to form nanosized In- or Sn-doped ZnO ribbons. Indium-containing comb-shaped heterostructures have a core composed of nanowires ( $D = 10\text{--}15\ \text{nm}$ ) grown along the  $[01\bar{1}0]$  direction. The  $\pm(2\bar{1}\bar{1}0)$  faces of the core are covered with nanoribbons located perpendicular to this face. The chemical composition of the core is described by the formula  $(\text{ZnO})_{11}\text{In}_2\text{O}_3$ . At a higher percentage of indium in the starting mixture, an additional growth of ZnO nanorods with a length of 100–3000 nm on both sides of the nanowires (perpendicular to the ribbon plane) is observed. These nanorods form a straight row. Therefore, the nanorods and nanoribbons grow epitaxially on the core formed by nanowires.

A further increase in the percentage of indium in the starting mixture leads to the formation of nanostructures as four- or six-blade rotors (Fig. 10). The length of such rotors along the central axis is equal to tens of micrometres, and the length of the nanorods forming the blades varies from 200 nm to several micrometres. The terminal blades of the nanorods are ordered in a line and are hexagonal in shape. The core of the rotors consists of  $\text{In}_2\text{O}_3$  belonging to the cubic system with the unit cell parameters  $a = 10.118\ \text{\AA}$ . If the growth of the core occurs along the  $[001]$  direction, there are four equivalent (100) planes, on which ZnO nanorods grow to form a four-blade rotor. If the  $\text{In}_2\text{O}_3$  core grows along the  $[111]$  direction, the resulting nanorotor has six symmetrical blades corresponding to six equivalent (110) planes.

The growth of nanoribbons with a length of 1–20  $\mu\text{m}$  and a width of  $\sim 1\ \mu\text{m}$ , which cover the core of the nanostructure, occurs also in the presence of tin. The core of the structure consists primarily of ZnO and grows in the  $[01\bar{1}0]$  direction, while the

ribbons grow in the  $[2\bar{1}\bar{1}0]$  direction. The Sn:Zn ratio increases from the centre to the ends of the structure, where it is  $\sim 8\%$ .

The self-organised type of the structural configuration of ZnO nanowires and nanoribbons butt-joined together was obtained<sup>304</sup> by thermal evaporation of a ZnO and  $\text{SnO}_2$  mixture in a mass ratio of 1:1 at 1300 °C under a stream of argon (300–400 Torr). Nanostructured oxide ZnO is produced in a furnace in the upper part of the alundum tube at 700–800 °C. Tin particles reduced from  $\text{SnO}_2$  serve as the catalyst for this process. The morphology of the resulting structures appears like a liana: Sn balls are attached to the axial ZnO nanowire ( $D \approx 30\ \text{nm}$ ) by nanoribbons (Fig. 11). The junctions of the ribbons with the axial nanowire are tens of nanometres at size, the width of the ribbons varies from 100 to 200 nm, and the ribbons are arranged about the axial nanowire at approximately 60 degree intervals. In the first step of formation of this configuration, the axial ZnO nanowire rapidly grows along the  $[0001]$  direction under the catalytic action of tin. Then particles of tin melt on the surface of the nanowire and initiate nucleation and epitaxial growth of nanoribbons. In this slower step, tin particles at the ends of the nanoribbons grow in size to form a tadpole-shaped structure (Fig. 11b). The growth of ZnO nanoribbons along six directions,  $\pm[10\bar{1}0]$ ,  $\pm[01\bar{1}0]$  and  $\pm[\bar{1}100]$ , give rise to six symmetrically arranged tadpoles with an angle between the adjacent tadpoles of  $\sim 60^\circ$ .

Semiconducting single-crystalline ZnO wires were synthesised by thermal evaporation of ZnS on a Si(100) substrate in the presence of Au as the catalyst<sup>305</sup> at 1223 K under argon (150 Torr) according to the reactions

The nanowires 20–60 nm in diameter and tens of micrometres in length grow along the  $[001]$  direction and contain a high density of structural defects. Evaporation of a ZnS and  $\text{Fe}(\text{NO}_3)_3$  mixture in

**Figure 10.** The SEM (a and c) and TEM images (b and d) of ZnO nanorotors with six (a and b) and four (c and d) blades.<sup>303</sup>

**Figure 11.** The SEM images of nanosized liana-shaped (a) and tadpole-shaped (b) ZnO heterostructures.

a molar ratio of 1 : 2 (1300 °C, 12 h) under argon containing 5% H<sub>2</sub> (350 Torr) affords whiskers with a diameter of 200–500 nm and tens of micrometres in length.<sup>306</sup> Zinc oxide whiskers do not grow under pure argon or nitrogen. In oxygen, micronic-size ZnO particles are produced by the reactions

Thermolysis of Fe<sub>2</sub>O<sub>3</sub> occurs very slowly, due to which a low O<sub>2</sub> concentration in the gas phase leads to the formation of nanosized ZnO nuclei and growth of oxygen-defect whiskers. Zinc oxide nanobelts, which grew along the [01 $\bar{1}$ 0] direction and were bounded by the  $\pm(0002)$  and  $\pm(01\bar{1}0)$  planes, were synthesised by evaporation of ZnCl<sub>2</sub> in an Ar and O<sub>2</sub> gas mixture in a ratio of 10 : 1 at 700 °C.<sup>307</sup> The resulting material is intended for use in light-emitting and laser diodes.

In the Et<sub>2</sub>Zn and N<sub>2</sub>O vapour phase (1 : 3 ratio, 200 Torr), high-quality ZnO nanorods and layered structures were grown epitaxially.<sup>308</sup> Nanorods with a diameter of 10–50 nm and a height of 0.5–1 µm grow on a sapphire substrate at 500 °C, whereas ZnO layers of identical shape grow at 800 °C. Three-dimensional structures are generally synthesised when the temperature of a sapphire<sup>308</sup> or silicon<sup>309,310</sup> substrate is lower than 700 °C, whereas two-dimensional layered structures grow at higher temperatures.

Evaporation of Zn(acac)<sub>2</sub>·*n*H<sub>2</sub>O at 130–140 °C under an atmosphere of an N<sub>2</sub> and O<sub>2</sub> mixture (in a ratio of 1 : 1, 200 Torr)<sup>311</sup> and with the use of a Si(001) substrate heated to 450 °C produced nanorods with *D* = 45 nm and *L* = 200 nm. The diameter of the nanorods increased with increasing temperature. The epitaxial growth of ZnO nanorods from an organometallic phase occurs also on an Al<sub>2</sub>O<sub>3</sub>(001) substrate at 400 °C.<sup>312</sup> Nanorods of equal length and density and with *D* ≈ 25 nm grow perpendicular to the substrate along the *c* axis of the ZnO lattice.

The growth of nanosized ZnO wires, rods and whiskers on a sapphire substrate by evaporation of zinc oxide was documented.<sup>313–316</sup> Analogous structures were also grown on a silicon substrate.<sup>317–322</sup> A substrate imperfection influences the selectivity of the initial growth of nanowires.<sup>318</sup> On an imperfect Si(100) face consisting of terraces separated by steps, nuclei of ZnO nanowires appear at the edges of the steps along the [01 $\bar{1}$ ] direction and grow perpendicular to the support. Zinc oxide nanowires virtually do not grow on a defect-free Si(100) substrate. Twinned ZnO nanowires, in which the boundary between single-crystalline domains is parallel to the growth axis, grow on a Si substrate during evaporation of Zn under an atmosphere with a low oxygen content.<sup>319</sup> The components of the twin, which have no dislocations and amorphous regions, are parallel to the (0 $\bar{1}$ 14) plane and grow along the [0 $\bar{1}$ 1 $\bar{1}$ ] direction and the (2 $\bar{1}$ 10) plane. The distance between the adjacent planes of the crystal lattice (2.60 ± 0.05 Å) corresponds to the distance between the (0002) planes. This unusual structure serves as a model for studying the electrical charge transport and mass transfer along a single planar defect.

Single-crystalline ZnO nanobelts were prepared<sup>320</sup> on a Si substrate by infrared heating of a Cu–Zn melt under moderate vacuum. Nanostructures grow along the [0001] direction, and their length is twice as large as their width. Long ZnO nanowires can be prepared catalytically on a Si substrate partially covered with gold under an atmosphere of an Ar and H<sub>2</sub>S mixture at a low partial pressure of hydrogen sulfide.<sup>321</sup> A vapour phase was prepared by carbon thermal reduction of ZnO. Nanowires grown under these conditions show blue-green luminescence, whose intensity increases with increasing H<sub>2</sub>S partial pressure in the synthesis of this material.

A substrate and a template composed of anodised aluminium are widely used to grow ZnO nanostructures with different morphologies.<sup>322–325</sup> Polycrystalline ZnO nanowires were prepared on anodised aluminium by vacuum evaporation of ZnO.<sup>322</sup> Nanosized tower-shaped ZnO columns were produced by pyrolysis and oxidation of ZnS.<sup>323</sup> Apparently, these columns grow by layering nanocrystalline zinc oxide. Zinc oxide nanowires (*D* = 40–200 nm) containing a low concentration of oxygen vacancies were also grown on an aluminium substrate by heating a 1 : 1 mixture of ZnO and Zn powders to 500 °C in the presence of water vapour as an oxidiser.<sup>324</sup>

The synthesis of ZnO nanowires with a high degree of crystallinity was carried out on an aluminium substrate in the presence of the NiO catalyst.<sup>325</sup> Zinc metal was evaporated at 450–950 °C under argon. The samples thus prepared have a hexagonal structure, a diameter of 55 nm and a length of 2.6 µm (Fig. 12). At a growth temperature of 500 °C, the nanowires are characterised by the perfect hexagonal morphology. All ends of nanowires are well-formed and can serve as mirror planes for a laser matrix.

**Figure 12.** The SEM image of ZnO nanowires prepared on an aluminium membrane.<sup>325</sup>

Electrochemical deposition using an anodised aluminium template membrane also allows one to prepare ZnO nanomaterials with different morphologies.<sup>326–328</sup> Zinc oxide nanowires consisting of individual crystalline particles were prepared in hexagonal channels of the membrane by electrochemical deposition in a 0.1 M Zn(NO<sub>3</sub>)<sub>2</sub> solution at a voltage of 1 V using a zinc electrode.<sup>327</sup> The composite can be used in optical, electrical and sensor nanodevices. Well-ordered high-density ZnO nanowires with constant dimensions were prepared by electrochemical deposition on a Si substrate using a template composed of anodised aluminium.<sup>329</sup> Electrolysis was carried out in an aqueous Zn(NO<sub>3</sub>)<sub>2</sub> solution, and the membrane pores were filled with the sol that formed upon its hydrolysis.<sup>330</sup> Then the template was successively annealed at 200 °C (1 h) and 400 °C (2 h) and dissolved in 1 M NaOH at 60 °C using ultrasonic stirring to prepare well-crystallised nanowires. The X-ray diffraction pattern of the latter has the (100), (002) and (101) reflections corresponding to the interplanar distances of 2.8, 2.6 and 2.5 Å, respectively.

Treatment of multilayer C-NT with zinc vapour on outer graphite layers afforded ZnO ultrathin films, nanocrystallites (quantum dots), nanowires and nanorods.<sup>331</sup> Nanowires with an average diameter of 30 nm and a length of up to 1.5 µm were grown at 600 °C on the surface of a carbon tube in the absence of a catalyst. Zinc oxide nanorods with a diameter of 80–150 nm and a length of 0.5–1 µm were produced at 800 °C.

Considerable progress was made in the synthesis of composite heterostructured nanomaterials of applied importance. The synthesis of metal–semiconductor heterostructures as nanorods and

nanocables was documented.<sup>332–335</sup> Evaporation followed by condensation of zinc metal vapour on vertically arranged ZnO nanorods afforded a Zn/ZnO composite.<sup>332</sup> In this case, Zn is localised primarily at the tips of nanorods. Gold-coated heterostructured ZnO nanorods had the pronounced Au/ZnO interface.

Pyrolysis of zinc acetylacetonate produced a Zn/ZnO coaxial cable ( $D \approx 30$  nm) with a zinc core and a ZnO shell.<sup>333</sup> The latter has a crystal structure and is transformed into ZnO nanotubes with a wall thickness of 4 nm, which appear due to evaporation of Zn from the cable core. Zinc oxide nanotubes and Zn/ZnO coaxial nanocables were also prepared by thermal reduction of ZnS (1300 °C) under a stream of an Ar + H<sub>2</sub> gas mixture at 300 Torr.<sup>334</sup> The nanocables are several micrometres in length, the core diameter is  $\sim 50$  nm, and the thickness of the outer shell is 5 nm. Hollow ZnO samples with an outer diameter  $\sim 60$  nm and a wall thickness of  $\sim 10$  nm were also synthesised. There is a good epitaxial relationship between the zinc core and the ZnO shell. However, dislocations occur at the Zn/ZnO interface due to incommensurability in the crystal structures of the components. The use of ZnO nanobelts as templates made it possible to synthesise ZnO/ZnS nanocables by a chemical method.<sup>335</sup>

Coaxial structures of more complex composition were prepared<sup>336</sup> by the thermal reaction combined with physical evaporation. A three-layer coaxial nanocable had a gallium core, a Ga<sub>2</sub>O<sub>3</sub> inner layer and an outer shell composed of ZnO. The mechanism of formation and the luminescent properties of this composite were studied. It was suggested that an Al<sub>2</sub>O<sub>3</sub> coating be used to protect ZnO nanorods against contamination and corrosion.<sup>337</sup> The coating was prepared with the use of water vapour and AlMe<sub>3</sub> as a precursor. The reagents were fed into a furnace containing ZnO nanotubes grown on silicon (300 °C, 250–280 Torr) under a stream of argon. The resulting nanotubes have a shell composed of amorphous oxide Al<sub>2</sub>O<sub>3</sub> 46 nm in thickness.

Doping of Zn/ZnO nanocables with copper<sup>338</sup> using CuSO<sub>4</sub> (0.01–0.5 mol litre<sup>-1</sup>) and Cu(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup> (0.1 mol litre<sup>-1</sup>) solutions occurs according to the reaction

Depending on the concentration of the solution, copper-containing clusters are produced, which can form larger structural networks. In the presence of the complex cations Cu(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup>, copper nanorods grow on the surface of cables. This redox reaction occurs both on the damaged surface of Zn/ZnO nanocables and on its ZnO shell.

Considerable progress was made in the practical application of zinc-containing nanostructures.<sup>339–354</sup> It was suggested that well-crystallised ZnO nanowires be used in planar displays.<sup>339</sup> The emission current density of the material is as high as 1 mA cm<sup>-2</sup> at an electric field strength of 11 V  $\mu\text{m}^{-1}$ , which provides sufficient brightness of FET emitters based on this material. The turn-on voltage of glow of these wires is 6 V  $\mu\text{m}^{-1}$  at a current density of 0.1  $\mu\text{A cm}^{-2}$ . For nanosized ZnO needles with tips several nanometres in diameter, the emission current density is as high as 2.4 A cm<sup>-2</sup> at an electric field strength of 7 V  $\mu\text{m}^{-1}$ .<sup>340</sup> Due to a very stable emission current density and a low turn-on field (2.4 V  $\mu\text{m}^{-1}$ ), this nanomaterial holds considerable promise for the construction of field emission displays.

Zinc oxide nanowires with a diameter of 60 nm are highly sensitive to UV radiation, due to which they can be used in optical switching devices.<sup>341</sup> Samples of ZnO nanorods synthesised from an organozinc vapour phase in the absence of a catalyst are characterised by high optical quality.<sup>342</sup> Poly(vinylpyrrolidone)-capped ZnO nanorods are of interest as an optical material.<sup>343</sup> Luminescence of this nanocomposite is observed at a temperature below 50 K.

A nanosized field-effect transistor (FET) was constructed based on ZnO nanobelts 10–30 nm in thickness with gold electrodes.<sup>344</sup> At a threshold input voltage of 15 V, the ratio of the turn-on current to the turn-off current is  $\sim 100$ , and the maximum

conductivity is  $1.25 \times 10^{-3}$  S cm<sup>-1</sup>. Comparative characteristics of diodes composed of ZnO nanorods and Au/ZnO heterostructures were given in the study.<sup>345</sup> Both diodes have nonlinear and asymmetric voltammetric characteristics. However, the Au/ZnO heterostructure is characterised by a higher puncture potential (8 V) compared to that of ZnO nanorods (3 V). Zinc oxide nanowires are of interest as a material for frequency converters in optical chains and logical components in nanosized optoelectronic devices.<sup>346</sup>

A procedure for the design of the nanosized Au(MEA)/(ZnO/PSS)<sub>19</sub>ZnO/Ag device [MEA is mercaptoethylamine and PSS is poly(sodium 4-styrenesulfonate)], which can rectify the current, and its electronic properties were described, and the mechanism of current rectification was proposed.<sup>347</sup> Single ZnO nanobelts can be used as resonators, whose mechanical resonance is induced by an alternating electric field.<sup>348</sup> It was suggested<sup>349</sup> that the Rh–ZnO/C-NT nanocomposite be used as a highly active catalyst for the methanol synthesis (the yield of MeOH with respect to the catalyst is 411.4 mg g<sup>-1</sup> h<sup>-1</sup>, the selectivity is 96.7% at 250 °C). The activity of this material is higher than that of the known Cu–ZnO/Al<sub>2</sub>O<sub>3</sub> catalyst (for the latter, the yield of MeOH is 213.6 mg g<sup>-1</sup> h<sup>-1</sup>). The multilayer structure of a C-NT substrate facilitates rapid transport and proton and electron binding. Zinc oxide nanowires with a large specific surface area is of importance for photocatalysis.<sup>350</sup> The ZnO nanoparticles–acrylic resin composite prepared by ultrasonic stirring of tetrahedral and usual ZnO nanoparticles in a surfactant-containing solution possesses antistatic and antibacterial properties.<sup>351</sup>

## 2. Nanostructures of 4d-metal oxides

### a. Yttrium oxides

Yttrium oxide was prepared<sup>258</sup> as the Y<sub>2</sub>O<sub>3</sub>/C-NT nanocomposite. Carbon nanotubes, which were pre-treated with nitric acid, were filled with yttrium nitrate and heated at 450 °C for 5 h under a stream of argon. X-ray diffraction study of bulky samples determined  $d = 2.65$  Å for the Y<sub>2</sub>O<sub>3</sub> (400) planes.

### b. Zirconium oxides

Hollow zirconium dioxide nanotubes were synthesised<sup>355</sup> using C-NT as a template. Carbon tubes were treated with a 16 M HNO<sub>3</sub> solution, mixed with Zr(OPr<sup>i</sup>)<sub>4</sub> under argon, subjected to ultrasonic treatment for 2 min, washed and dried. Annealing at 450 °C in air afforded the ZrO<sub>2</sub>/C-NT composite. Carbon was removed by heating the product at 700 °C. Zirconium dioxide nanotubes thus prepared had a diameter of 40 nm and a wall thickness of 6 nm (Fig. 13). Electron diffraction study demonstrated that these nanotubes consisted of a 1:1 mixture of the monoclinic and tetragonal phases. Heating of the samples led to their destruction. The problem of the preparation of single-phase nanotubes was resolved by preparing yttrium-stabilised ZrO<sub>2</sub> nanotubes (0.92 ZrO<sub>2</sub> · 0.08 Y<sub>2</sub>O<sub>3</sub>). The latter were synthesised as follows: NH<sub>4</sub>OH was added to a mixed ZrOCl<sub>2</sub> and Y(NO<sub>3</sub>)<sub>3</sub> solution to pH 9, and the resulting gel was mixed with C-NT, dried in air and annealed successively at 450 °C (12 h) and 700 °C (48 h). This method was used to synthesise hollow nanotubes belonging to the cubic system ( $a = 5.116$  Å) with an outer diameter of 40–50 nm and a wall thickness of 6 nm.

Hollow tubes of amorphous ZrO<sub>2</sub> with a length of 40–200  $\mu\text{m}$ , a wall thickness of 0.2–0.7  $\mu\text{m}$  and an outer diameter of 1.3–5.9  $\mu\text{m}$  were prepared with the use of needle-like crystals of ammonium tartrate as a template.<sup>356</sup> Zirconium dioxide was deposited on the surface of these crystals from an ethanolic solution upon the addition of zirconium alkoxide. The template was removed by dissolving in water. The specific surface areas and the pore size of these tubes depend on the alkoxide used, the conditions of deposition of ZrO<sub>2</sub> and the amount of water. Both open and closed composite BN nanotubes, which were filled with nanorods composed of monoclinic ZrO<sub>2</sub>, were synthesised.<sup>357</sup> The diameter of the latter (20–40 nm) corresponds to the inner diameter of BN nanotubes.

**Figure 13.** Images of a hollow  $\text{ZrO}_2$  nanotube;<sup>355</sup> (a) SEM, (b) TEM. The electron diffraction pattern of the sample is shown in the inset.

#### c. Niobium oxides

Hollow amorphous rectangular-shaped  $\text{Nb}_2\text{O}_5$  tubes were prepared analogously to  $\text{ZrO}_2$  tubes using ammonium tartrate as a template.<sup>356</sup> The length and width of the tubes varied in ranges of 40–200 and 1.3–5.9  $\mu\text{m}$ , respectively, the channel size was 1.0–4.9  $\mu\text{m}$ , and the wall thickness was 0.2–0.7  $\mu\text{m}$ . The specific surface area and the pore size of the tubes depend on the composition of niobium alkoxide, and the microporous structure depends on the conditions of its hydrolytic polycondensation.

#### d. Molybdenum oxides

Molybdenum trioxide has attracted interest because of its catalytic, photochromic and electrochromic properties. The composite consisting of carbon nanotubes filled with  $\text{MoO}_3$  single crystals was prepared<sup>358</sup> by heating the corresponding mixture in a quartz tube at 800 °C (3 h). The yield of the target product was ~50%. Infrared heating of a molybdenum foil under moderate vacuum (950–1000 °C, 5 Torr, 1 h) on a tantalum substrate afforded a pale-blue film consisting of quasi-linear  $\text{MoO}_3$  tubes (the orthorhombic system,  $a = 3.95$ ,  $b = 13.88$ ,  $c = 3.70$  Å) with a length of 5–8  $\mu\text{m}$ , an outer diameter of 50–300 nm and an inner diameter of 20–150 nm. Compared to crystalline  $\text{MoO}_3$ , the unit cell parameter  $a$  is smaller by 0.3%, whereas the unit cell parameters  $b$  and  $c$  are larger by 0.16 and 0.1%, respectively, due to the influence of a tubular structure. The nanotubes grow predominantly along the [100] direction. Disturbance of the ordered arrangement of the tubes along the [010] direction due to weak interactions between the oxide (020) planes gives rise to a three-dimensional structure. Nucleation and growth of  $\text{MoO}_3$  nanotubes rather than nanorods or nanobelts was associated with a layered structure and a low concentration of molybdenum trioxide vapour.

Nanosized  $\text{MoO}_3$  fibres were synthesised<sup>358, 359</sup> by the sol–gel method in three steps. The reaction of molybdic acid  $\text{H}_2\text{MoO}_4 \cdot \text{H}_2\text{O}$  with amine  $\text{C}_n\text{H}_{2n+1}\text{NH}_2$  (in a molar ratio of 2:1) in ethanol followed by the addition of water produced the  $\text{MoO}_3$ /amine composite, which was subjected to hydrothermal

treatment in an autoclave at 120 °C for 3–5 days. The product was filtered off, washed with ethanol and diethyl ether and stirred in 33%  $\text{HNO}_3$  at 20 °C for 48 h to prepare fibrous molybdenum trioxide. The  $\text{MoO}_3$ /amine composite  $(\text{C}_{12}\text{H}_{28}\text{N})_{0.5}\text{MoO}_{3.25}$  was prepared using components in a ratio of 3:1. This composite has a laminar structure and contains template molecules between the layers. The morphology of the product is independent of the reaction time (1–14 days) at 100–120 °C, but it strongly depends on the reaction time at 150 °C. Hydrothermal treatment at 180 °C for 7 days led to destruction of the laminar structure and the formation of a black crystalline powder. The template was removed by treatment of the composite with  $\text{HNO}_3$ , which was accompanied by the transformation of the laminar structure into quasi-one-dimensional  $\text{MoO}_3$ , viz., planar-needle- or cylinder-shaped fibres (with a diameter 20–280 nm and a length varying from 350 nm to 15  $\mu\text{m}$ ) formed by threads with  $D = 20$ –50 nm. The morphology of the  $\text{MoO}_3$  fibres remained unchanged upon annealing at 400 °C in air for several hours, and these fibres are of interest as catalysts for oxidation of ethanol and methane.

Calcination of  $\text{MoO}_3(4,4'\text{-bipy})_{0.5}$  single crystals with a layered structure ( $d = 11.2$  Å) in the temperature range of 300–450 °C afforded molybdenum trioxide plates (60–100 nm).<sup>360</sup> In the temperature range of 320–350 °C, the metastable  $\beta$ - $\text{MoO}_3$  phase was prepared. At 380 °C, the latter was transformed into the orthorhombic  $\alpha$ - $\text{MoO}_3$  phase. Nanoplates of these oxides were packed in stacks 50–250  $\mu\text{m}$  in height.

#### e. Cadmium oxides

Cadmium oxide is an n-type semiconductor, which is of interest in the fabrication of light-emitting diodes, diode lasers and field emission displays. Cadmium oxide nanowires were prepared by electrochemical deposition of cadmium metal from the aqueous electrolyte  $\text{CdCl}_2$  (40 g litre<sup>-1</sup>) and  $\text{H}_3\text{BO}_3$  (30 g litre<sup>-1</sup>) on an anodised aluminium membrane at a current density of 1 mA cm<sup>-2</sup> followed by oxidation of Cd in air at 400 °C and dissolution of the membrane in a NaOH solution.<sup>361</sup> Cadmium oxide nanowires had an ordered structure. The diameter of the nanowires was equal to the channel size of the membrane (~60 nm).

Single-crystalline CdO nanowires several micrometres in length (the cubic system,  $a = 4.569$  Å,  $D = 40$ –60 nm) were prepared by oxidation of a mixed Cd (70%) and Te (30%) film electrochemically deposited on an aluminium substrate from a  $\text{CdCl}_2$  and  $\text{TeO}_2$  solution (0.1 and 0.2 mol litre<sup>-1</sup>, respectively, pH 10, 0.2 mA), at 450 °C under an atmosphere of  $\text{O}_2$  and Ar (1:9).<sup>362</sup> Tellurium served as a flux, which facilitates growth of CdO nanowires. Nanostructured oxide CdO was grown as needles by vapour deposition.<sup>363</sup> Single needles with high conductivity were proposed as a material for highly sensitive IR photoprotectors and  $\text{NO}_2$  gas sensors. Semiconducting CdO nanowires hold promise for electronics, optics, sensors and optoelectronic nano-devices.<sup>364</sup>

### 3. Nanostructures of 5d-metal oxides

#### a. Tantalum oxides

Tubulenes of  $\text{Ta}_2\text{O}_5$  were synthesised analogously to  $\text{Nb}_2\text{O}_5$  nanotubes.<sup>356</sup> Nanotubes of complex oxide of composition  $\text{Sr}_{0.8}\text{Bi}_{2.2}\text{Ta}_{2.0}\text{O}_{9+y}$  were also prepared by the template method.<sup>365</sup> A protonated silicon membrane with hexagonal pores having diameters of 2  $\mu\text{m}$  and 800 nm and a depth of 100  $\mu\text{m}$  was used as a template. The precursor was deposited on the template from a solution of Sr, Bi or Ta ethylhexanoate (0.1 mol litre<sup>-1</sup>) in toluene. After two-step pyrolysis of the composite at 100 and 300 °C, the membrane was subjected to thermal treatment in air at 850 °C for 30 min and then the template was removed by dissolving in a HF and  $\text{HNO}_3$  mixture (15 mol.% and 50 mol.%, respectively). Nanotubes of identical shape with a wall thickness smaller than 100 nm, a diameter of up to 2  $\mu\text{m}$  and a length of 100  $\mu\text{m}$  were prepared. Partial removal of the template gives rise to a periodic structure consisting of isolated

nanotubes. Such nanotubes exhibiting both ferroelectric and piezoelectric properties can be used in memory elements.

### b. Tungsten oxides

Heating of a tungsten foil, which contained a SiO<sub>2</sub> plate on its surface, at 1600 °C under argon ( $p_{Ar} = 100$  Torr) afforded a nanostructured WO<sub>x</sub> material ( $x = 0-3$ ).<sup>366</sup> Ultrasonic treatment of the latter led to its decomposition to give needles (5–50 nm in thickness and 20–200 nm in length) and planar polyhedral nanoparticles (10–50 nm in cross-section). The nanoneedles consisted primarily of oxide W<sub>18</sub>O<sub>49</sub>, and nanoparticles contained primarily WO<sub>3</sub>. The process of their formation can be described by the reactions

The epitaxial growth of monoclinic oxides WO<sub>x</sub> (WO<sub>3</sub>, W<sub>18</sub>O<sub>49</sub> and W<sub>3</sub>O) occurs from the gas phase at the W (foil)–SiO<sub>2</sub> plate interface along the [010] crystallographic axis.

Hollow fibres of crystalline oxide W<sub>18</sub>O<sub>49</sub> forming a pine-needle-shaped structure were synthesised<sup>367</sup> by heating WS<sub>2</sub> powder on a tungsten foil at 1300–1400 °C under an atmosphere of argon and oxygen ( $p_{Ar} = 490 \pm 90$ ,  $p_{O_2} = 10$  Torr). The outer diameter of the fibres is 3–10 μm and the length is 0.1–2 mm. The fibres consist of thin whiskers 50–500 nm in diameter (Fig. 14). The formation of hollow W<sub>18</sub>O<sub>49</sub> fibres is attributed to their single-crystalline axial growth, which provides efficient scattering of released heat.

The synthesis of W<sub>18</sub>O<sub>49</sub> nanorods and their optical properties were documented.<sup>368</sup> The starting compounds [W(CO)<sub>6</sub>, Me<sub>3</sub>NO·2H<sub>2</sub>O and oleylamine] were stirred and heated to 270 °C for 2 h. After aging for 24 h, the mixture became viscous and turned bright-blue. This composite was dissolved in toluene, ethanol was added, and a blue precipitate was separated by

centrifugation and purified by reprecipitation with ethanol from toluene. The final powder consisted of nanorods  $4 \pm 1$  nm in diameter and  $75 \pm 20$  nm in length. The electron diffraction pattern of the sample has two intense rings corresponding to  $d = 3.78$  and 1.89 Å, which is indicative of the predominant growth of nanorods in one direction. X-ray diffraction study demonstrated that these nanorods have a structure of W<sub>18</sub>O<sub>49</sub> with the [010] growth direction. The length of the nanorods depends on the temperature of the synthesis ( $25 \pm 6$  nm at 250 °C and  $130 \pm 30$  nm at 270 °C). At temperatures below 250 °C, nanorods do not grow.

Thermal oxidation of tungsten<sup>369</sup> produced WO<sub>2.9</sub> nanorods on Si(001), Si(111) and SiO<sub>2</sub>/Si plates and silver-coated glasses. A tungsten coil was heated to 600–2000 °C by passing current *in vacuo* ( $3 \times 10^{-2}$  Torr). Tungsten oxide vapour was condensed on plates, whose temperature was lower than 200 °C. Single-crystalline WO<sub>2.9</sub> nanorods with a diameter of 20 nm and a length of 400 nm were arranged in an ordered fashion on substrates. For the majority of nanorods, the WO<sub>2.9</sub> [010] crystallographic axes are almost parallel and coincide with their growth direction. There are orientational relationships not only between the nanorods but also between the nanorods and the substrate. Thus, the WO<sub>2.9</sub> [010] axis is parallel to the Si (001) plane. At the tungsten coil temperature of 850 °C, WO<sub>2.9</sub> nanorods were deposited. At a temperature above 1100 °C, WO<sub>2</sub> nanorods began to grow, and these nanorods prevailed at 1450 °C. These results are attributed to the difference in the degree of oxidation of the coil under an atmosphere with a constant concentration of oxygen.

The template method was used to grow WO<sub>3</sub> fibres with a diameter of 20 nm and a length of 50 μm inside the pores of an anodised aluminium membrane.<sup>162</sup> Tungsten hexachloride was dissolved in ethanol and an aqueous pentane-2,4-dione solution was added. Then the membrane was immersed in this mixture for 1 min, dried in air and annealed at 550 °C for 6 h. Hydrated oxide WO<sub>3</sub>·H<sub>2</sub>O was prepared as two-dimensional plates with an average size of 30–100 nm using benzyl alcohol as a template.<sup>156</sup> A WCl<sub>6</sub> and C<sub>6</sub>H<sub>5</sub>CH<sub>2</sub>OH mixture was heated at 100 °C for 48 h, and the precipitate of WO<sub>3</sub>·H<sub>2</sub>O nanoplates that formed was separated by centrifugation, washed with ethanol and dried.

## III. Computer design of structures and electronic properties of oxide nanotubes

### 1. Structural models of inorganic nanotubes

Most of the known inorganic nanotubes were prepared (or predicted) for layered substances and compounds with layered (graphite-like) structures,<sup>31–38</sup> due to which the models of their atomic structures can be constructed and their geometry can be described using approaches and the classification developed for carbon tubes.<sup>2–7</sup>

Models of ideal carbon nanotubes can be built by wrapping atomic ribbons, which are cut out from a hexagonal graphite sheet (the so-called graphene sheet), and cross-linking the broken bonds of the terminal atoms in such a way as to form a cylinder. Depending on the mode of wrapping (the type of graphene-like ribbons), two main types of tubes (chiral and achiral) are constructed. In turn, the latter are divided into the so-called zigzag and armchair NT.

The modes of construction of NT are illustrated in Fig. 15. The **a**<sub>1</sub> and **a**<sub>2</sub> basis vectors of the hexagonal graphene network specify the chiral vector **C**<sub>h</sub> = *n***a**<sub>1</sub> + *m***a**<sub>2</sub>, which lies in the plane of the network and links two crystallographically equivalent positions. The scalar of vector **C**<sub>h</sub> is equal to the cylinder perimeter (the tube cross-section). The diameter (*D*) and the chiral angle (*α*) between the **C**<sub>h</sub> and **a**<sub>1</sub> vectors, which is uniquely related to the **a**<sub>1</sub> and **a**<sub>2</sub> vectors by the *n* and *m* indices, respectively, are the main geometric characteristics of the tubes. The notations (*n,m*)-NT are used in the classification of nanotubes. According to this classification, all (*n,m*)-NT with *n* ≠ *m* ≠ 0 belong to chiral (helical) nanotubes with 0 < *α* < 30°. Achiral (*n,0*)-NT (zigzag) and (*n,n*)-

**Figure 14.** The SEM images of crystalline (a) and hollow (b) W<sub>18</sub>O<sub>49</sub> fibres with a pine texture.<sup>367</sup>

**Figure 15.** Models of the construction (a) and types of carbon nanotubes (b) formed by wrapping a graphene sheet into a cylinder. Terminal structures of achiral armchair, achiral zigzag and chiral nanotubes.

NT (armchair) have  $\alpha = 30$  or  $\alpha = 0^\circ$ , respectively. These tubes are called in accordance with the structure of their cross-sections (zigzag or armchair; see Fig. 15).

This approach can be applied to the construction of atomic structures of nanotubes for typical representatives of layered inorganic compounds. Both homo- and heteroatomic networks (for example, Si or BN) and molecular layers consisting of two (metal diborides), three (d-element dichalcogenides,  $\text{NiCl}_2$ ) or more ( $\text{Bi}_2\text{S}_3$ ) atomic networks can serve as monolayers of the starting crystalline phases, which form NT. A network or a molecular layer can be either planar ( $\text{BC}_x$ ,  $\text{CN}_x$ ,  $\text{B}_x\text{C}_y\text{N}_z$ , etc.) or corrugated (for example, a network of black phosphorus).<sup>36–38</sup>

Tubes of the layered modifications of carbon nitride ( $\text{CN}_x$ ), boron nitride (BN) or boron carbonitrides ( $\text{B}_x\text{C}_y\text{N}_z$ ) isostructural with graphite are the simplest analogues of carbon NT.<sup>31, 369–375</sup> Their atomic structures (taking into account the differences in the interatomic distances in graphite and the above-mentioned B–C–N phases) are analogous to those of C-NT, and the distinguishing features depend on the structural type, the ratio of the elements and the mutual arrangement of their atoms in the cell, i.e., the atomic ordering in the walls of the tubes.

Tubes of hexagonal metal diborides  $\text{MB}_2$  are structurally more complex. Their structures ( $\text{AlB}_2$ , space group  $P6/mmm$ ) consist of the alternating hexagonal networks of metal M and graphite-like boron networks.<sup>106–110, 376</sup> The atomic models of single-layer tubes with formal stoichiometry  $\text{MB}_2$  are derived by wrapping the atomic bilayer  $(\text{MB}_2)_\infty$  of the crystal. These models consist of two coaxial cylinders formed by a planar hexagonal metal network and a planar graphite-like boron network linked to each other. Chiral and achiral  $\text{MB}_2$  NT can be constructed analogously to carbon tubes. In addition, two other configuration types of such tubes can in principle, exist. In these tubes, a

**Figure 16.** Fragments of a crystal (a), a bilayer (b) and atomic models of single-layer tubes (c) and fullerene-like molecules (d) based on metal diborides  $\text{AlB}_2$ .<sup>107</sup>

Two types are shown: a cylinder consisting of metal atoms (a polyhedral shell of the molecule) outside (I) or inside (II) the tube (shell) formed by boron atoms.

‘metallic’ cylinder is located outside (I) or inside (II) the cylinder composed of boron atoms (Fig. 16). This figure also shows models of polyhedral (fullerene-like)  $(\text{MB}_2)_n$  molecules.<sup>107</sup> The hemispheres of these molecules can serve as caps of closed diboride tubes. Like tubes, the  $(\text{MB}_2)_n$  molecules consisting of the concentric spherical  $\text{M}_n$  and  $\text{B}_{2n}$  shells can have two configurations with an  $\text{M}_n$  shell outside (I) or inside (II) the polyhedron composed of boron atoms.

Layered metal dichalcogenides  $\text{MX}_2$  ( $\text{X} = \text{S}, \text{Se}$  or  $\text{Te}$ ) contain the three-atom  $(\text{X}-\text{M}-\text{X})_\infty$  layers. These ‘molecular monolayers’ were wrapped to construct<sup>377–382</sup> models of  $\text{MX}_2$  NT consisting of three coaxial cylinders. The outer and inner cylinders are formed by chalcogen atoms and the central cylinder consists of the metal atoms. Theoretical electron diffraction patterns calculated from these structural models<sup>377</sup> agree well with the experimental patterns. Recently, models for more complex nanotubes of layered metal halide nitrides  $\beta\text{-MNX}$  ( $\text{M} = \text{Zr}$  or  $\text{Hf}$ ;  $\text{X} = \text{Cl}$  or  $\text{Br}$ ) have been proposed.<sup>113</sup> These hypothetical nanostructures (for examples, based on  $\beta\text{-ZrNCl}$ , in which the  $[\text{Cl}-\{\text{ZrN}\}-\{\text{ZrN}\}-\text{Cl}]$  ‘molecular layers’ include six atomic networks) consist of six concentric atomic cylinders ( $\text{Cl}-\text{Zr}-\text{N}-\text{Zr}-\text{N}-\text{Cl}$ , Fig. 17).

Models of single-layer nanotubes as ideal infinite cylinders, which are wrapped up from mono- or polyatomic basis molecular layers, are widely used to describe their electronic properties in terms of the band theory.<sup>6, 28, 31, 33–38</sup>

It is known that the ends of nanotubes can be open or closed. Various terminal structures can have hemispherical, conical or more complex structures. Multilayer nanotubes can consist of a set (up to several tens) of concentric cylinders or exhibit a roll-like, papier-mache or more complex (combined) morphology.<sup>2–38</sup> Nanotubes can be prepared in the isolated form or give various aggregates (bundles, intergrowths, etc.). Unique symbiosis nano-

structures, *viz.*, regular chains of fullerenes (including endohedral fullerenes) encapsulated into nanotubes, have been synthesised and extensively studied.<sup>383–401</sup> These nanostructures are called peapods.

Nowadays, studies on modelling of multilayer tubes and caps of closed NT are extended to nanotubular structures of boron nitride and d-metal disulfides.<sup>33–38, 377–382</sup> Attempts were made<sup>402, 403</sup> to design atomic models of more complex systems, *viz.*, nanotube composites. The structural model of composite silicon oxide nanotubes prepared with the use of a C-NT template is shown in Fig. 18.<sup>402</sup>

**Figure 18.** Model of the composite C/SiO<sub>x</sub> layer (a) and a nanotube constructed from this layer (b).<sup>403</sup>

## 2. Structural models and electronic structures of titanium, vanadium and molybdenum oxide nanotubes

Let us consider atomic models of Ti, V and M oxide nanotubes constructed by the above-described method and the results of theoretical studies of their electronic structures.

### a. Titanium oxide

Structural models of titanium dioxide nanotubes were constructed, their electronic structures and chemical bond parameters were studied, and these materials were compared with hypothetical VO<sub>2</sub> tubes.<sup>404, 405</sup> Models of TiO<sub>2</sub> NT were constructed using the anatase (101) layers, which, like graphene sheets, were wrapped into cylinders to form three-layer (O–Ti–O) tubes of armchair (*n,n*) and zigzag (*n,0*) types (Fig. 19). Models of tubes based on rutile-type VO<sub>2</sub> (space group  $P4_2/mnm$ ,  $a = b = 0.4555$ ,  $c = 0.2851$  nm) were constructed analogously.<sup>406</sup> The electron bands were calculated by the strong-bond method<sup>405</sup> for (*n,0*)- and (*n,n*)-like TiO<sub>2</sub> NT and for VO<sub>2</sub> in the (8,0)–(15,0) and (4,4)–(15,15) series, which corresponds to the  $\sim 0.6$ –2.3 nm range of the nanotube diameters.

The densities of states (DOS) of (*n,n*)- and (*n,0*)-like TiO<sub>2</sub> NT are similar for all nanotubes and show a general resemblance to DOS of crystalline titanium dioxide (anatase).<sup>407</sup> The valence band is formed by the Ti3d and O2p states, and the lower conduction band edge is formed predominantly by the Ti3d states. The forbidden band gap  $\Delta E$  depends most substantially on the type of the atomic configuration and the tube diameter. For nanotubes with the largest diameters,  $\Delta E$  are  $\sim 3.34$  and  $\sim 3.01$  eV for armchair (15,15)- and zigzag (15,0)-NT, respectively, which is comparable with the theoretical ( $\sim 2.0$  eV)<sup>407</sup> and experimental ( $\sim 3.4$  eV)<sup>408</sup> forbidden band gap for anatase. The

**Figure 19.** Structural models of zigzag (15,0) (a) and armchair (15,15) (b) titanium oxide nanotubes.<sup>410</sup>

Empty and solid circles represent O and Ti atoms, respectively. The model of the regular distribution of substitution elements to form rings of M atoms (model I, see the text) is illustrated by a zigzag (15,0) nanotube; the formation of bands of M atoms (model II) along the perimeter or the axis of the tubes alternating with the rings or bands composed of Ti atoms, respectively, is illustrated by an armchair (15,15) nanotube.

forbidden band gap decreases with decreasing diameters of NT, and  $\Delta E$  for armchair NT are larger than those for zigzag NT.

The calculated electronic spectra of VO<sub>2</sub> NT also correspond to the band structures of crystalline vanadium dioxides.<sup>409</sup> The V3d – O2p hybrid bands are completely filled, and the Fermi level ( $E_F$ ) is located in the V3d band. For armchair NT, the density of states near the Fermi level is rather low, whereas  $E_F$  for zigzag NT is in the region of a local DOS maximum. It should be noted that the analogous near-Fermi maximum of the density of states is responsible for phase instability of crystalline VO<sub>2</sub>.<sup>409</sup>

The dependence of the total electronic energy  $E_{\text{tot}}$  on the diameters of TiO<sub>2</sub> NT is shown in Fig. 20;  $E_{\text{tot}} \propto 1/D^2$ , which is indicative of a decrease in stability of nanotubes with decreasing  $D$ . Armchair nanotubes are more stable at small diameters ( $D < 1$  nm),<sup>404,405</sup> whereas zigzag tubes are more stable at large  $D$ . On the contrary, armchair nanotubes are more stable for all VO<sub>2</sub> NT. Analysis of the parameters of interatomic interactions demonstrated that the Ti–O (V–O) bonds play the major role in the nanotubes under consideration, whereas the Ti–Ti (V–V) bond populations are an order of magnitude smaller, and the O–O bonds are absent. The M=O bonds with the oxygen atoms belonging to the inner (O<sup>in</sup>) or outer (O<sup>out</sup>) oxygen cylinders are strongly polarised and differ in population (Table 4).<sup>405</sup>

Chemical modifications by introducing guest atoms or molecules into the inner cavities of NT, between the walls of multilayer NT or into intertubular regions between the adjacent nanotubes in their associates, as well as through adsorption of foreign atoms or

**Table 4.** Bond populations ( $e^-$ ) for cylindrical single-layer V<sub>2</sub>O<sub>5</sub> nanotubes.

| (12,12)   | 1.239                                   | 1.035                                    | 0.853                | 0.845                 |
| (13,13)   | 1.239                                   | 1.035                                    | 0.852                | 0.844                 |

**Note.** The populations of the bond for the V<sup>in</sup> and V<sup>out</sup> atoms (in VO<sub>5</sub> pyramids) and the pair bonds between the vanadium atoms and the terminal O(1) atoms of the V=O vanadyl groups, which form the ‘outer’ and ‘inner’ oxygen cylinders of the nanotubes, are given.

**Figure 20.** Plots of the forbidden band gap for TiO<sub>2</sub> NT (a) and the total band energy per (Ti,V)O<sub>2</sub> unit (b, c) vs. the diameters of TiO<sub>2</sub> (a, b) and VO<sub>2</sub> tubes (c).<sup>404</sup>

(1) An armchair configuration [( $n,n$ ) NT], (2) a zigzag configuration [( $n,0$ ) NT].

molecules on the surface or at the ends of NT or through the replacement of atoms in NT with atoms of other elements (doping of NT), provide efficient ways of controlling the properties of oxide NT. The latter approach was used *in situ* in a number of known procedures for the preparation of NT, in particular, in the template synthesis.

First results of quantum-chemical modelling of the electronic structures and chemical bond parameters of doped TiO<sub>2</sub> nanotubes were reported.<sup>410</sup> Silicon, germanium, vanadium and chromium were considered as elements replacing titanium, which allowed the authors<sup>410</sup> to discuss the results of both isoelectronic substitution ( $\text{Ti} \rightleftharpoons \text{Si, Ge}$ ) and electron doping ( $\text{Ti} \rightleftharpoons \text{V, Cr}$ ) of TiO<sub>2</sub> tubes. The structural models of the armchair (15,15) and zigzag (15,0) TiO<sub>2</sub> nanotubes were used as the starting models.<sup>404,405</sup>

The electronic properties of (15,0) and (15,15) tubes with composition Ti<sub>0.5</sub>M<sub>0.5</sub>O<sub>2</sub> were analysed depending on the mode of distribution of the substitution elements M (Si, Ge, V or Cr) in three Ti positions, which gives rise to rings (model I) or bands (model II) of M atoms along the perimeter or the axes of the tubes alternating with the rings or bands of Ti atoms, respectively (see Fig. 19). The electronic spectra of analogous TiO<sub>2</sub> and (Ti<sub>0.5</sub>M<sub>0.5</sub>)O<sub>2</sub> NT for both models of ordering of the substitution atoms remain unchanged upon isoelectronic substitution (doped tubes are semiconductors), and  $\Delta E$  changes by no more than 0.1 eV. The main differences concern the fine features of DOS distributions in the centre and near the lower valence band edge and are associated with the presence of (Si,Ge)p states. The electron doping ( $\text{Ti} \rightleftharpoons \text{V, Cr}$ ) has a radically different effect: the lower conduction band edge is partially filled and all (Ti<sub>0.5</sub>M<sub>0.5</sub>)O<sub>2</sub> tubes become metal-like.

The total electronic energy  $E_{\text{tot}}$  depends only slightly on the type of ordering of substitution atoms (models I or II), whereas doped armchair (15,15) (Ti<sub>0.5</sub>M<sub>0.5</sub>)O<sub>2</sub> tubes become more stable [for ‘pure’ TiO<sub>2</sub> NT, the zigzag (15,0) configuration is energetically more favourable].<sup>404</sup> It was hypothesised<sup>410</sup> that the substitution can provide a way of changing the type of the atomic configuration of dioxide tubes. It was also expected that doping of oxide nanotubes will be accompanied by the appearance of defects, which are responsible for the difference in the morphology of real NT and the ideal model of cylinders wrapped from polyatomic layers.

In addition to tubular nanostructures, cage nanoparticles [fullerene-like molecules (FM)] based on d-metal oxides (TiO<sub>2</sub>,

$\text{V}_2\text{O}_5$ ,  $\text{Co}_3\text{O}_4$ ,  $\text{MnO}_2$ , etc.) have been synthesised in recent years. In the context of the present review, these nanostructures are of interest as possible prototypes of the caps of the corresponding oxide nanotubes.

The structural models of  $\text{TiO}_2$ -based FM were proposed<sup>411,412</sup> and their electronic structures were calculated by quantum-chemical methods. These particles  $[(\text{TiO}_2)_n]$ , where  $n = 12, 16, 36, 48$  or  $64$  were built from fragments of the anatase (101) layer. They can be described as ‘three-shell’ cage molecules consisting of concentric polyhedral shells, the outer and inner shells being formed by oxygen atoms, whereas the medium shell being formed by titanium atoms (Fig. 21). The titanium and oxygen atoms have predominantly coordination numbers of 6 and 3, respectively. Each FM of stoichiometric composition includes also a group of four Ti and O atoms with coordination numbers of 5 and 2, respectively. The total energy of FM per atom ( $E_{\text{tot}}/N$ , where  $N$  is the number of atoms) decreases with increasing size of FM, i.e., stability of the molecules increases. The energy difference between HOMO and LUMO of the molecules is comparable with the forbidden band gap of the crystalline and tubular forms of  $\text{TiO}_2$ . The spectrum of  $\text{TiO}_2$  FM is characterised by molecular orbitals located between the main groups of occupied and free molecular orbitals.<sup>411</sup> Their appearance is associated with the change in the coordination number of the atoms occupying the vertices of polyhedral particles.

The dependence of the spectrum of  $(\text{TiO}_2)_n$  FM on the coordination numbers of the atoms was simulated<sup>412</sup> using the  $\text{Ti}_{64}\text{O}_{124}$  [i.e.,  $(\text{TiO}_2)_{64} - 4\text{O}$ ] and  $\text{Ti}_{64}\text{O}_{130}$  [i.e.,  $(\text{TiO}_2)_{64} + 2\text{O}$ ] molecules. In these molecules, four oxygen atoms with a coordination number of 2 are removed or two oxygen atoms are added to complete the environment of the Ti atoms with a coordination number of 5 to an octahedron. The forbidden band gap  $\Delta E$  is most substantially affected by the changes in the coordination number of the atoms (0.03 and 1.39 eV for the  $\text{Ti}_{64}\text{O}_{124}$  and  $\text{Ti}_{64}\text{O}_{130}$  molecules, respectively). Calculations of the orbital overlap populations (OOP) demonstrated that Ti–O interactions are the main covalent bonds in  $(\text{TiO}_2)_n$  FM. Some (non-equivalent) bonds are comparable in the orbital overlap population. The orbital overlap populations of the Ti– $\text{O}^{\text{out}}(2)$  bonds increase by more than 25% compared to those of the Ti– $\text{O}^{\text{out}}(3)$  bonds as the coordination numbers of the atoms decrease. However, the total

**Figure 21.** Structure of the fullerene-like  $(\text{TiO}_2)_{64}$  molecule (a); the structures of the outer (b), medium (c) and inner (d)  $(\text{TiO}_2)_{64}$  shells composed of O, Ti and O atoms, respectively.<sup>412</sup> Non-equivalent types of the Ti(1), Ti(2), O(1) and O(2) atoms with coordination numbers of 6, 5, 3 and 2, respectively are shown.

bond population of the oxygen atoms with a coordination number of 3 [ $\text{O}^{\text{out}}(3)$  type] is higher than that of the atoms with a coordination number of 2 [ $\text{O}^{\text{out}}(2)$ ] ( $\sim 0.399$ – $0.387$  and  $\sim 0.334$  e<sup>−</sup>, respectively).

## b. Vanadium oxides

Compared to classical carbon NT, the tubular structures of vanadium oxides have important distinguishing features. The available  $\text{VO}_x$  nanotubes are composed of many layers (the walls of the tubes contain from a few to tens of molecular layers) and are open. Ideal concentric cylinders are rare among such tubes. The morphology of these tubes is generally similar to a roll shape, and the constituent molecular layers contain different types of defects. It is also of importance that the elemental composition of  $\text{VO}_x$  NT is determined by the procedure used for the synthesis and the resulting ‘vanadium oxide’ tubes should be assigned to nanotube composites, in which the  $\text{VO}_x$  molecular layers are separated by organic template layers (amines, diamines, etc.). These structural and compositional features of vanadium oxide tubes make it difficult to construct their atomic models and study their electronic properties.

Simplified models of vanadium oxide tubes, viz., families of cylindrical structures, constructed by wrapping the  $\text{V}_2\text{O}_5$  (010) monolayer, were proposed.<sup>413</sup> Orthorhombic crystals of  $\text{V}_2\text{O}_5$  contain quasi-two-dimensional (010) layers formed by distorted  $\text{VO}_5$  pyramids. The  $\text{V}_2\text{O}_5$  units contain three structurally non-equivalent oxygen atoms: the terminal O(1) atoms of the vanadyl ions and the  $\mu_2$ -O(2) and  $\mu_3$ -O(3) atoms (Fig. 22). Wrapping of the (010) layer gives rise to tubes consisting of five coaxial cylinders ( $\text{O}^{\text{in}} - \text{V}^{\text{in}} - \text{O}^{\text{c}} - \text{V}^{\text{out}} - \text{O}^{\text{out}}$ ). In these tubes, the outer and inner cylinders ( $\text{O}^{\text{out}}$  and  $\text{O}^{\text{in}}$ , respectively) are formed by the O(1) atoms of the vanadyl groups, and the central cylinder ( $\text{O}^{\text{c}}$ ) is formed by the O(2) and O(3) atoms. These cylinders are separated by the outer and inner (with respect to  $\text{O}^{\text{c}}$ , respectively) cylinders consisting of vanadium atoms ( $\text{V}^{\text{in}}$  and  $\text{V}^{\text{out}}$ , respectively). By analogy with carbon NT, it is possible to construct three groups of quasi-one-dimensional  $\text{V}_2\text{O}_5$  structures: achiral armchair ( $n,n$ ), zigzag ( $n,0$ ) and chiral ( $n,m$ ) nanotubes.

The electronic structures of a series of ( $n,0$ )- and ( $n,n$ )-like  $\text{V}_2\text{O}_5$  nanotubes with indices in the ranges from (6,0) to (12,0) and from (2,2) to (13,13) (which correspond to the ranges of the outer diameters of the tubes ( $D^{\text{out}}$ ), 1.17–1.78 and 1.01–4.75 nm, respectively) were studied.<sup>413</sup> The valence band of the  $\text{V}_2\text{O}_5$  (010) molecular layer, like that in the  $\text{V}_2\text{O}_5$  crystal,<sup>414–424</sup> belongs to the hybrid V3d–O2p type and is completely occupied. The forbidden band gap of the  $\text{V}_2\text{O}_5$  (010) monolayer is  $\sim 2.5$  eV. The V–O covalent bonds are the strongest bonds in this layer, the V–V bonds are an order of magnitude weaker, and interactions

**Figure 22.** Atomic models of quasi-one-dimensional nanostructures of vanadium pentaoxide (cross-sections).<sup>425</sup> (a) A monolayer, (b) cylindrical (26,26) NT, (c, d) roll-like NT with distances between the adjacent walls of 1.5 and 0.45 nm, respectively.

between the oxygen atoms are antibonding. There is anisotropy in the V—O bond populations: the V—O(3) and V—O(1) bonds are the strongest and weakest bonds, respectively.

The dependence of  $E_{\text{tot}}$  on the diameters of  $\text{V}_2\text{O}_5$  NT takes the form  $E_{\text{tot}} \propto 1/D^2$  typical of nanotubular structures,<sup>2–7</sup> which is indicative of destabilisation of  $\text{V}_2\text{O}_5$  tubes as their diameter decreases. For vanadium oxide tubes with  $D > 1$  nm, the armchair-type atomic configurations are more stable. All cylindrical  $\text{V}_2\text{O}_5$  NT are semiconductors. For example,  $\Delta E$  for the tubes with the largest diameters (minimum wall curvature) considered in the study<sup>411</sup> are  $\sim 2.67$  and  $\sim 2.95$  eV for armchair (13,13) NT and zigzag (12,0) NT, respectively, which is comparable with  $\Delta E$  ( $\sim 2.5$  eV) of the  $\text{V}_2\text{O}_5$  (010) monolayer. The forbidden band gap decreases with decreasing tube diameter. It should be noted that this dependence of  $\Delta E$  on the diameter is also typical of semiconducting nanotubes of layered metal dichalcogenides.<sup>377–382</sup> The populations of the V—O bonds depend on their orientation relative to the tube axis and the coordination mode of the atoms belonging to the outer or inner atomic cylinders (see Table 4). The populations of the V—O<sup>in</sup> bonds are higher than those of the V—O<sup>out</sup> bonds. This is indicative of high reactivity of the outer oxygen atoms of the vanadyl groups and the probable distortion of the ideal structure of the outer oxygen shell due to relaxation processes and the formation of O atom vacancies.

The experimentally observed roll morphology is reflected in particular atomic models of  $\text{VO}_x$  NT.<sup>425</sup> To construct these models, the ideal cylindrical zigzag (26,0) and armchair (26,26)  $\text{V}_2\text{O}_5$  nanotubes with inner diameters of 2.958 and 8.712 nm, respectively, were cut along the axis and rolled up into helical forms shown in Fig. 22. The electronic structures of such tubes reflect the total densities of states presented in Fig. 23. It can be seen that the spectra of vanadium oxide nanorolls contain additional states near  $E_F$ , some of which, depending on the atomic configuration of the roll, can be filled. The latter fact should affect

substantially, in particular, the electrophysical properties of nanostructures. This modification of the spectrum of rolls (compared to cylindrical tubes) is associated with the presence of broken bonds in their inner and outer cross-sections, the differences in the curvature radius of individual layers of the  $\text{V}_2\text{O}_5$  molecular ribbons, which form the roll, and the interactions between the adjacent layers in the roll.

### c. Molybdenum oxides

Models of achiral NT were constructed<sup>426</sup> on the basis of the crystal structure of orthorhombic molybdenum trioxide (space group  $Pbnm$ , unit cell parameters  $a = 3.92$ ,  $b = 13.94$ ,  $c = 3.66$  Å), which is composed of layers of edge-sharing  $\text{MoO}_6$  octahedra. This monolayer was used to construct possible types of  $\text{MoO}_3$  tubes from coaxial  $(\text{O—Mo—O})_\infty$  atomic cylinders with different types of helicoid ordering of the chains of  $\text{MoO}_6$  octahedra (Fig. 24). Unlike the above-considered NT,  $\text{MoO}_3$  tubes are perforated. Their walls contain pores inside the rings formed by the  $[\text{MoO}_6]$  polyhedra, which provides an interesting possibility for intercalation with various atoms.

Calculations<sup>426</sup> of the electronic structures of  $(n,0)$ - and  $(n,n)$ -like  $\text{MoO}_3$  nanotubes ( $3 < n < 24$ ) showed that the forbidden band gap ( $\sim 3$ – $4$  eV) depends most substantially on the atomic configuration and the tube diameter and increases with increasing diameter. The dependence of  $E_{\text{tot}}$  on  $D$  is nearly linear, i.e., it

**Figure 23.** Total densities of states in  $\text{V}_2\text{O}_5$  NT;<sup>425</sup> (a) cylindrical (26,26) NT, (b and c) roll-like tubes with distances between the adjacent walls of 1.5 and 0.45 nm, respectively. The densities of states near  $E_F$  are shown in the insets.

**Figure 24.** Structure of the molecular monolayer of molybdenum trioxide;<sup>426</sup>

$a_1$  and  $a_2$  are the basis vectors of the network of Mo atoms (a). The atomic models of armchair (5,5) (b) and zigzag (10,0) (c)  $\text{MoO}_3$  nanotubes viewed from the side and the top.

differs sharply from the analogous dependences ( $\propto 1/D^2$ ) known for carbon and non-carbon NT of other layered compounds (BN, MoS<sub>2</sub>, etc.). Evidently, this is associated mainly with the characteristic features of chemical bonding in MoO<sub>3</sub>, primarily, with the fact that there is no pronounced anisotropy in intra- and interlayer interactions. That is why MoO<sub>3</sub> were prepared experimentally<sup>358</sup> using MoO<sub>3</sub>/carbon NT nanotube composites as templates. Apparently, this characteristic feature is responsible for the observed<sup>358, 359</sup> polyhedral morphology of the Mo—O<sub>3</sub> tubes. In all MoO<sub>3</sub> NT, Mo—O interactions play the major role,<sup>426</sup> whereas Mo—Mo and O—O covalent bonds are virtually absent.

#### IV. Conclusion

Nowadays, studies of transition metal oxide nanostructures of transition metal oxides are aimed primarily at developing procedures for their synthesis and investigating the morphology of the products. Titanium, vanadium and zinc oxides have been studied most extensively. Titanium-dioxide-based nanostructures have promise as photocatalysts and materials for photoelements. The tubular forms of vanadium oxides allow enhancement of the activity of catalysts and an increase in the cathode capacity of chemical current sources. Zinc oxide nanostructures, which are used in electronics, optics, photocatalysis, solar batteries and sensors, have attracted considerable attention.

A great deal of experimental and theoretical data on metal oxide nanotubes and related nanostructures have been accumulated within a short period after the synthesis of the first materials of this class. Methods for the synthesis of these materials were developed, their morphology and properties were studied, the atomic models were constructed and characteristic features of the electronic structures and chemical bonding in oxide nanotubes were revealed. Various oxide nanostructures and nanocomposites as tubes, ribbons, rods and more complex geometric forms were synthesised, and ways of modifying these properties were proposed.

The results of investigations are of importance for the development of chemistry of metal oxides at nanoscale and for an understanding of the specific properties of nanotubular oxides compared to their crystalline forms and offer considerable possibilities for the technological use of such materials.

As opposed to classical carbon nanotubes and nanotubular structures of layered inorganic compounds, the most efficient procedures for the synthesis of metal oxide nanotubes are the template and chemical methods. In modern studies, considerable attention is being given to the template method, which allows the preparation of oxides and nanocomposites of a desired geometric shape. However, the structures of the tubes thus prepared are far from the ideal cylindrical shape, and they generally include template substances. Chemical methods for the synthesis of nanotubes are also being successfully developed. Intercalation compounds as sols or gels serve as main precursors.<sup>203</sup> The chemical methods allow one to perform syntheses in a wide temperature range and in various solvents and to use and remove templates. The drawback of the chemical hydrothermal method is that nanostructures contain components of the reaction medium. Nowadays, it is difficult to give preference to a particular method of synthesis, because materials science and technological studies of oxide nanotubes lag behind.

In the chemistry of nanotube forms of metal oxides, the immediate aims are to devise procedures for the synthesis of nanostructures with a desired morphology, including more complex geometric forms and their associates. Hence, new methods of synthesis, which will enable one to change the size and form of nanostructures as desired, are of great importance for studies in this field. Systematic investigations of the properties of oxide nanostructures and their dependence on the size and morphology are of equal importance.

The presence of non-compensated bonds of the surface atoms of oxide nanostructures open possibilities for preparing new

substances possessing unusual adsorption and chemical activity. The synthesis of complex oxide nanotubes would be expected<sup>427</sup> to provide new ingenious solutions of problems associated with the design of such materials.

A further development of structural and electronic models of oxide NT taking into consideration the specific features of their real morphology and composition is of great importance. This problem is directly related to elucidation of microscopic mechanisms of formation and growth of oxide NT and the processes of their association giving rise to compact materials (bundles, films or crystals).

**Abstract.** The possibilities of investigations of the nanostructure of matter by pulsed EPR spectroscopy based on the measurement of the dipole–dipole coupling between the spins of unpaired electrons are considered. Using these methods, one can determine the conformations of long-chain organic biradicals and biomolecules (either doubly spin-labelled or containing paramagnetic metal ions) and study the supramolecular structure of matter, *i.e.*, peptide clustering, heterogeneity of polymer packing, structural details of photosynthetic reaction centres and other complex systems. Investigations of the photoinduced spin-correlated radical pairs also reveal the regularities of charge transfer in these systems. The methods are characterised by high accuracy of measurements (0.03 nm) and can be used for measuring distances in the 1.5–10 nm range. The bibliography includes 148 references.

## I. Introduction

Research on the structure of matter in the nanometre range of distances (1–10 nm or 10–100 Å) is necessary for the determination of biomolecule conformations, elucidation of the nanostructure of other complex molecular systems and solution to various problems of supramolecular chemistry. If a system under study is crystallisable, good results can be obtained using conventional X-ray crystallography.<sup>1</sup> Two-dimensional crystals are studied by electron crystallography<sup>2</sup> or scanning tunnelling microscopy.<sup>3</sup> Multidimensional NMR spectroscopy allows the structure of biomolecules of mass up to 100 kDa to be determined.<sup>4</sup> As for disordered media, objects with sizes ranging between 5 and 100 nm are studied by small-angle X-ray scattering (SAXS)<sup>5</sup> and small-angle neutron scattering (SANS).<sup>6</sup> Resonant fluorescence energy transfer is used to determine distances between chromophores in the range from 1 to 10 nm.<sup>7</sup>

If a system contains paramagnetic centres (*e.g.*, free radicals and ions), distances between them can be measured by EPR

spectroscopy. The use of this method is based on studies of the dipole–dipole (d–d) interaction between electron spins. Knowing the distances between paramagnetic centres in pairs or clusters (many biomolecules contain paramagnetic metal ions), it is possible to determine certain parameters of the supramolecular structure. Often, physicochemical and biophysical studies are carried out by the spin label and spin probe techniques, which involve introduction of paramagnetic centres into the system under study. Pairs of paramagnetic centres can also appear as a result of charge separation in photosynthesis, which involves formation of radical anion–radical cation pairs.

The dipole–dipole interaction between electron spins in a pair of paramagnetic centres is characterised by the parameter

$$\frac{\mu_0}{4\pi} \frac{g_e^2 \beta^2}{r^3},$$

where  $\mu_0$  is the magnetic permeability of vacuum,  $g_e$  is the  $g$ -factor of free electron,  $\beta$  is the Bohr magneton and  $r$  is the distance between the paramagnetic centres in the pair. Continuous-wave EPR spectroscopy is used for measuring distances in a pair of electron spins up to 1–1.5 nm range.<sup>8</sup> This limit is due to a masking effect of inhomogeneous broadening of the EPR lines owing to unresolved hyperfine coupling with the nuclei of the matrix, which can be as high as  $\sim 0.5$  mT for organic media.

Pulsed EPR methods based on electron spin echo (ESE) spectroscopy<sup>9,10</sup> are much more sensitive to the dipole–dipole interactions. When using such methods, the dipole–dipole interaction must be compared with the homogeneous broadening, which is much smaller ( $\sim 0.01$  mT) for organic media. From here the upper boundary of the measured distances is  $\sim 5$ –10 nm. The lower boundary (about 1.5 nm) is governed by the temporal resolution of the instrument ( $\sim 10^{-8}$  s). In this review we summarise the results obtained by ESE spectroscopy for long-chain organic biradicals and radical pairs in solids. The distances between paramagnetic centres in the systems under study lie between  $\sim 2$  to 8 nm.

An advantage of ESE spectroscopy is a high accuracy of measurements in this range of distances. For instance, for  $r \sim 3$  nm the error may be only  $\sim 0.03$  nm. High resolution of the method allows one to reveal some fine details in the nanostructure of matter, which cannot be detected by other methods. Besides, ESE studies do not require a specific sample preparation procedure (*e.g.*, crystallisation, high degree of purification, *etc.*).

The possibility of using ESE spectroscopy in studies of pairs of paramagnetic centres has long been established. A study of  $\text{SO}_4^- \cdots \text{SO}_4^-$  pairs stabilised in a UV irradiated  $\text{H}_2\text{S}_2\text{O}_8$  single crystal was reported in 1969.<sup>11</sup> Small width of the EPR spectrum (the possibility of excitation by MW pulses), the absence of magnetic nuclei and spatial orientation of pairs created prerequisites for successful determination of the distances in the pairs by conventional two-pulse ESE spectroscopy. However, the method appeared to be inappropriate for analysis of free radicals in polyoriented organic systems due to large linewidth in the EPR spectrum, masking effect of electron–nuclear interactions and the ‘dead’ time problem. Other experimental techniques were developed later, in particular, the Pulsed Electron–Electron Double Resonance (PELDOR),<sup>12,13</sup> the ‘2 + 1’ (see Ref. 14) and double-quantum coherence<sup>15,16</sup> methods as well as approaches based on solid-state NMR pulse sequences.<sup>17</sup> A conventional two-pulse method permits investigations of spin-correlated radical pairs in photosynthetic reaction centres.<sup>18</sup> Here, it is possible to eliminate the problems characteristic of polyoriented organic systems (see above).<sup>19</sup> The effects of partner spin relaxation in a radical–metal ion pair were first reported in Ref. 19. Later the procedure was essentially modified<sup>20</sup> (relaxation probe method). The relaxation effects were also used in the selective hole ‘burning’ technique<sup>21</sup> and dipolar relaxation-induced modulation enhancement.<sup>22</sup>

At present, ESE spectroscopy is widely used in studies of the nanostructure of complex molecular systems. Thermally equilibrated radical pairs and biradicals are most often studied by the PELDOR method while spin-correlated radical pairs are investigated by the two-pulse echo technique. A large number of reviews on current research are available (see, e.g., Refs 23–35), most of them being published recently. The aim of this review is to describe (i) all ESE spectroscopy-based methods of analysis of the nanometre range of distances and (ii) systems studied by these methods.

## II. The EPR spectrum of a radical pair

Biradicals and radical pairs differ from one another in the presence or absence of covalent bonds between paramagnetic fragments, respectively. For magnetic resonance, this difference is insignificant; therefore, in the text below we will use the term ‘a radical (or paramagnetic) pair’ (RP) except for the cases where we deal with particular chemical structures.

### 1. The spin Hamiltonian of a radical pair

The magnetic dipole–dipole interaction between the magnetic moments of electrons is the main interaction in long-chain biradicals and RPs. The classical expression for the energy of two interacting dipoles has the form

$$E_d = \frac{\mu_0}{4\pi} \frac{r^2 \boldsymbol{\mu}_1 \boldsymbol{\mu}_2 - (\boldsymbol{\mu}_1 \mathbf{r})(\boldsymbol{\mu}_2 \mathbf{r})}{r^5}, \quad (1)$$

where  $\mathbf{r}$  is the radius vector connecting two particles with the dipole moments  $\boldsymbol{\mu}_1$  and  $\boldsymbol{\mu}_2$ , respectively.

The energy of two dipoles with the same spatial orientation is given by

$$E_d = \frac{\mu_0}{4\pi} \frac{\mu_1 \mu_2}{r^3} (1 - 3 \cos^2 \theta), \quad (2)$$

where  $\theta$  is the angle between the direction of the dipole axis and the radius vector  $\mathbf{r}$ .

In quantum mechanics, expression (1) is replaced by the Hamiltonian

$$H_d = \frac{\mu_0}{4\pi} g_1 g_2 \beta^2 \frac{r^2 \mathbf{S}_1 \mathbf{S}_2 - (\mathbf{S}_1 \mathbf{r})(\mathbf{S}_2 \mathbf{r})}{r^5}, \quad (3)$$

where  $g_1$  and  $g_2$  are the  $g$ -factors of particles 1 and 2, respectively, and  $\mathbf{S}_1$  and  $\mathbf{S}_2$  are the spin operators of these particles.

The systems considered in this review are characterised by long spin–spin separations and weak exchange interaction, which can be ignored.

The wave functions of unpaired electrons are distributed in space; for some molecules, the distributions can be rather broad. Nevertheless, here on we will always use the point dipole approximation, which assumes that the whole spin density of unpaired electrons is localised at a point. This is a reasonable approximation in all practically valuable cases (see below).

In the framework of yet another approximation the electron–electron dipole–dipole interaction will be considered small compared to the Zeeman interaction between electron spins and the magnetic field, *i.e.*

$$\frac{\mu_0}{4\pi} \frac{g_e \beta}{r^3} \ll B_0,$$

where  $B_0$  is the magnetic field strength. This approximation *a priori* holds for the distances in RPs considered in this review; therefore, we can use the perturbation theory assuming that Hamiltonian (3) is small compared to the Hamiltonian of the Zeeman interaction. Expression (3) can be essentially simplified if we neglect the components with zero contributions in the first-order perturbation theory. Expression (3) written in spherical coordinates with the  $Z$  axis parallel to the magnetic field direction takes the form

$$H_d = \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3} (1 - 3 \cos^2 \theta) \left[ S_{1z} S_{2z} - \frac{1}{4} (S_{1+} S_{2-} + S_{1-} S_{2+}) \right]. \quad (4)$$

Here we used the projections of the spin operators on the  $Z$  axis and the raising–lowering operators.

Relationship (4) is analogous to expression (2), but this analogy is incomplete, because the terms containing the raising–lowering operators have no classical analogues (they reflect the particle identity). The matrix elements involving these operators become significant only if the  $g$ -factors of two electrons are similar, so that the Zeeman energy difference  $|g_1 - g_2| \beta B_0$  becomes comparable with the energy of the dipole–dipole interaction. This is the case for strong spin–spin coupling (or the equivalent spin approximation). If

$$\frac{\mu_0}{4\pi} \frac{g_e^2 \beta^2}{r^3} \ll |g_1 - g_2| \beta B_0,$$

the coupling is weak (inequivalent spins). Note that this review concerns weakly coupled systems only.

The Hamiltonian (4) can be re-written using the total spin operator  $\mathbf{S} = \mathbf{S}_1 + \mathbf{S}_2$ ,

$$H_d = \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{4r^3} (1 - 3 \cos^2 \theta) (3S_z^2 - \mathbf{S}^2). \quad (5)$$

### 2. Energy levels and the EPR spectrum of a radical pair in magnetic field

Consider a radical pair comprising two radicals with different  $g$ -factors. The Hamiltonian of the RP in magnetic field, written in frequency units, has the form

$$\frac{H}{\hbar} = \omega_1 S_{1z} + \omega_2 S_{2z} + \frac{1}{4} \varepsilon_d (3S_z^2 - \mathbf{S}^2), \quad (6)$$

where  $\omega_1$  and  $\omega_2$  are the resonance frequencies of two radicals in the absence of the dipole–dipole interaction and  $\varepsilon_d$  is the magnitude of the dipole–dipole interaction

$$\varepsilon_d = \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar} (1 - 3 \cos^2 \theta).$$

We will write the solution to the Hamiltonian (6) using the wave functions of the triplet

$$|T_+\rangle = |\alpha\alpha\rangle,$$

$$|T_0\rangle = \frac{1}{\sqrt{2}}(|\alpha\beta\rangle + |\beta\alpha\rangle),$$

$$|T_-\rangle = |\beta\beta\rangle$$

and singlet

$$|S\rangle = \frac{1}{\sqrt{2}}(|\alpha\beta\rangle - |\beta\alpha\rangle),$$

states of the RP ( $\alpha$  and  $\beta$  are the electron spin projections)

$$|1\rangle = |T_+\rangle,$$

$$|2\rangle = \cos\phi|S\rangle + \sin\phi|T_0\rangle,$$

$$|3\rangle = -\sin\phi|S\rangle + \cos\phi|T_0\rangle,$$

$$|4\rangle = |T_-\rangle,$$

where

$$\tan 2\phi = \frac{2\Delta\omega}{\varepsilon_d}, \Delta\omega = \omega_1 - \omega_2.$$

Note that for weak coupling  $\phi \approx \pi/4$ , and the wave functions  $|2\rangle$  and  $|3\rangle$  are transformed into  $|\alpha\beta\rangle$  and  $|\beta\alpha\rangle$ , respectively. The energy levels are shown in Fig. 1 and the energies are given by

$$E_1 = \frac{1}{2}(\omega_1 + \omega_2) + \frac{1}{4}\varepsilon_d, \quad (8)$$

$$E_2 = -\frac{1}{4}\varepsilon_d + \frac{1}{4}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2},$$

$$E_3 = -\frac{1}{4}\varepsilon_d - \frac{1}{4}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2},$$

$$E_4 = -\frac{1}{2}(\omega_1 + \omega_2) + \frac{1}{4}\varepsilon_d.$$

The expressions for six possible energy differences are as follows

$$E_{12} = \frac{1}{2}(\omega_1 + \omega_2) + \frac{1}{2}\varepsilon_d - \frac{1}{4}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2}, \quad (9)$$

$$E_{13} = \frac{1}{2}(\omega_1 + \omega_2) + \frac{1}{2}\varepsilon_d + \frac{1}{4}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2},$$

$$E_{24} = \frac{1}{2}(\omega_1 + \omega_2) - \frac{1}{2}\varepsilon_d + \frac{1}{4}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2},$$

$$E_{34} = \frac{1}{2}(\omega_1 + \omega_2) - \frac{1}{2}\varepsilon_d - \frac{1}{4}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2},$$

$$E_{14} = \omega_1 + \omega_2,$$

**Figure 1.** Schematic view of spin energy levels of a radical pair (biradical) in magnetic field. Shown are the resolved EPR transitions.

$$E_{23} = \frac{1}{2}\sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2}.$$

The first four differences correspond to the allowed single-quantum transitions (see Fig. 1) and the last two differences correspond to the forbidden two-quantum and zero-quantum transitions.

According to relationships (7), for a thermally equilibrated system the allowed transition intensities are determined by the  $\sin^2\phi$  or  $\cos^2\phi$  factors because only the matrix elements between the triplet states differ from zero. Thus, the EPR spectrum of a radical pair consists of two doublets with a splitting of  $\varepsilon_d$  in each (Fig. 2a). In weakly coupled systems, all lines have the same intensities.

**Figure 2.** EPR spectrum of thermally equilibrated radical pair (a) and spin-correlated radical pair (b).

The EPR spectrum of a spin-correlated RP produced from an initial singlet state is shown in Fig. 2b. Such spin-correlated RPs are considered in more detail in Section III.

As will be shown below, all ESE methods are characterised by temporal dependences of the  $\cos \varepsilon_d t$  type for thermally equilibrated RPs and of the  $\sin \varepsilon_d t$  type for spin-correlated RPs. The Fourier transformation of such dependences creates a doublet at frequencies  $\pm \varepsilon_d$  in the EPR spectra. The doublet is symmetrical with respect to zero frequency for thermally equilibrated RPs and antisymmetrical for spin-correlated RPs. By analogy with solid-state NMR spectra this doublet is often called the Pake doublet. However, this is an incomplete analogy, because in NMR we always deal with strong coupling and the splitting in the doublet is  $(3/2)\varepsilon_d$ . In our case the total splitting in the doublet is  $2\varepsilon_d$ ,<sup>†</sup> and we will call this doublet the dipolar doublet.

### 3. Dipolar doublet in polyoriented system

For a polyoriented system the dependence of the line intensities of the dipolar doublet in the EPR spectra of an RP on the frequency  $\omega$  can be determined by averaging over all spatial orientations of the RP

$$f(\omega) = \frac{1}{4\pi} \int_0^\pi d\theta \sin\theta \int_0^{2\pi} d\varphi \left[ \delta(\omega - \varepsilon_d) \pm \delta(\omega + \varepsilon_d) \right] \propto \quad (10)$$

$$\propto \left( 1 - \frac{4\pi}{\mu_0} \frac{r^3 \hbar}{g_1 g_2 \beta^2} \omega \right)^{-1/2} \pm \left( 1 + \frac{4\pi}{\mu_0} \frac{r^3 \hbar}{g_1 g_2 \beta^2} \omega \right)^{-1/2}$$

<sup>†</sup> Historically, the transformation over  $\tau$  was accepted in ESE spectroscopy, although the transformation over  $2\tau$  is more correct (in this case, the splitting in the doublet is  $\varepsilon_d$ ).

(the ‘plus’ sign is used for thermally equilibrated pairs and the ‘minus’ sign is used for spin-correlated pairs). The frequency,  $\omega$ , of two resonance lines varies from

$$\omega_{\perp} = \pm \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar}$$

to

$$\omega_{\parallel} = \mp 2 \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar}$$

[here, the signs have another meaning, namely, the upper (lower) sign is used for the first (second) term in Eqn (10)]. The first limit corresponds to  $\theta = \pi/2$  (perpendicular orientation of RP). Here, a singularity appears in the spectrum. The second limit corresponds to  $\theta = 0$  or  $\theta = \pi$  (parallel orientation of RP) and determines the edges of the spectrum.

Almost always the spectrum is additionally broadened due to spin relaxation or distance distribution. A calculated spectrum for which the additional broadening was simulated by a Gaussian function with the half-width (between the points with maximum slopes) given by

$$0.05 \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar},$$

is shown in Fig. 3.

**Figure 3.** Dipolar doublet in polyoriented sample. Thermally equilibrated radical pair (1) and spin-correlated radical pair (2). The frequency axis is labelled in

$$\frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar}$$

units.

Often, only the singularity can be observed in the experimental spectrum because of relatively low intensities of other lines; knowing its position, it is possible to immediately determine the distance  $r$ .

The expressions for  $\omega_{\perp}$  and  $\omega_{\parallel}$  with allowance for the dipole–dipole and exchange ( $J$ ) interactions in the pair take the form:<sup>18</sup>

$$\omega_{\perp} = \pm \left( \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar} - 2J \right), \quad (11)$$

$$\omega_{\parallel} = \pm \left( -2 \frac{\mu_0}{4\pi} \frac{g_1 g_2 \beta^2}{r^3 \hbar} - 2J \right).$$

Therefore, having established positions of the spectral singularity and the spectrum edges, one can determine the exchange interaction.

#### 4. On the accuracy of the point dipole approximation

The point dipole approximation assumes that the whole spin density is localised at a certain point. Let us estimate the error introduced by the spin density distribution over the molecule. The measured parameter is  $\varepsilon_d$ , which is proportional to  $1/r^3$  ( $r$  is the distance from a given spin to the partner spin). As the distance changes by  $\Delta r$  due to the spin density distribution, the variation,  $\Delta \varepsilon_d$ , is to a first approximation proportional to  $-3\Delta r/r^4$ . If the origin is at the ‘centre of gravity’ of the spin density (*i.e.*, the average value,  $\langle \Delta r \rangle$ , over the molecule is taken to be zero), the mean value  $\langle \Delta \varepsilon_d \rangle$  in this approximation will also be zero. In the second approximation,  $\langle \Delta \varepsilon_d \rangle$  is proportional to  $6\langle \Delta r^2 \rangle/r^5$ . As a result of this variation of  $\varepsilon_d$ , the distance measured in the point dipole approximation will have a systematic negative error

$$\delta r = -\frac{1}{3} \langle \Delta \varepsilon_d \rangle r^4 = -2 \frac{\langle \Delta r^2 \rangle}{r}.$$

Evaluation of the  $\delta r$  parameter for the radicals with an RMS spin density distribution width of  $\langle \Delta r^2 \rangle = (1.5 \text{ \AA})^2$  and a spin–spin separation of 30 Å using this expression gives a value of  $-0.15 \text{ \AA}$ . If the spin density distribution is known and can be taken into account in calculations of the dipole–dipole interaction, this small error can be made even smaller.

### III. Experimental methods based on electron spin echo envelope modulation

If a MW pulse is applied to a spin system in the magnetic field at a frequency equal to the spin resonance frequency, the free induction signal is produced. The signal is maximum at a magnetisation flip angle of  $90^\circ$  and decreases with time owing to two reasons, (i) irreversible relaxation due to stochastic processes and (ii) phase defocusing due to static inhomogeneity of the resonance frequencies in the sample. Defocusing is reversible; application of a  $180^\circ$  pulse again produces the free induction signal at some delay after the second pulse. The delay time ( $\tau$ ) equals the time interval between two pulses. This signal is called the spin echo (Fig. 4 a).

**Figure 4.** ESE pulse sequences used in studies of the dipole–dipole interaction between electron spins in radical pair. Conventional two-pulse sequence (a), two-frequency double resonance (PELDOR) (b) and magnetic-field-jump PELDOR (c).

The origination of the echo signal is readily understandable from the following simple considerations. After application of the first pulse each spin precesses in its own local magnetic field as a result of static inhomogeneity of the resonance frequencies. Let us denote the deviation of the resonance frequency of a certain spin from the carrier frequency of the spectrometer as  $\Delta\omega_0$ . At the instant of application of the second pulse the phase change becomes equal to  $\Delta\omega_0\tau$  (see Fig. 4a). If  $\Delta\omega_0\tau \gg 1$ , the free induction signal decreases to zero because of averaging over all spins. Application of the second  $180^\circ$  pulse leads to phase reversal and the phase becomes equal to  $\pi - \Delta\omega_0\tau$ . Then, the phase changes again, namely, it changes with time as  $\pi - \Delta\omega_0\tau + \Delta\omega_0(t - \tau)$ , where  $t$  is the time passed from the first pulse. At  $t = 2\tau$ , all spins have the same phases equal to  $\pi$  and independent of  $\Delta\omega_0$ . This means the refocusing and the appearance of the echo signal.

The situation described above corresponds to a two-level spin system, for which the distribution over the energy difference between the levels ( $\Delta\omega_0$  distribution) owing to various additional interactions is only possible. The situation becomes more complicated [as in the case of, e.g., a radical pair (see Fig. 1)], if there are a number of energy levels and the MW pulses excite different transitions. This is accompanied by additional effects due to pulse-assisted alternation of magnetic interactions in the pair. In the text below we will show that such effects cause modulation of the echo signal decay on change in  $\tau$ .

In this Section both spins in the pair are assumed to have rather long relaxation times ( $> 10^{-6}$  s).

### 1. Modulation in two-pulse electron spin echo technique

The simplest experimental method suitable for studying the dipole–dipole interaction between spins in a pair is a conventional two-pulse echo technique. Application of the second pulse causes not only the precession phase reversal but also changes the orientation of the partner spin in the pair. As a result, the precession frequency is shifted by a value of  $\varepsilon_d$  and the spin-precession phase at  $t = 2\tau$  is  $\pi \pm \varepsilon_d\tau$  rather than  $\pi$ . The measured signal is proportional to  $\cos \varepsilon_d\tau$ , which means oscillation of the spin echo signal decay with  $\tau$ . This phenomenon is termed an Electron Spin Echo Envelope Modulation (ESEEM).

Detailed calculations of ESEEM were carried out for spins in a thermally equilibrated pair<sup>11</sup> and for a more general case of arbitrary populations of the energy levels.<sup>36</sup> The effect of the flip angle of the first pulse was not considered in detail;<sup>11</sup> it was postulated to be the same as in the case of a single spin. In a more recent study<sup>36</sup> it was shown that this effect is more complex in character. However, the study<sup>36</sup> did not consider the effect of the flip angle of the second pulse, although earlier<sup>11</sup> mention was made of such an effect. Probably, both results obtained for arbitrary flip angles are inexact. For a conventional pulse sequence ( $90^\circ - \tau - 180^\circ - \tau$  - echo) both calculations lead to the same results. The echo signal of a thermally equilibrated radical pair is given by

$$E(2\tau) = \sin^2 2\phi \cos \varepsilon_d\tau + \cos^2 2\phi \cos \left( \frac{1}{2} \sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2} \tau \right) \cos \varepsilon_d\tau - \cos 2\phi \sin \left( \frac{1}{2} \sqrt{\varepsilon_d^2 + 4(\Delta\omega)^2} \tau \right) \sin \varepsilon_d\tau. \quad (12)$$

Note that the second and third terms on the right side of Eqn (12) at  $\tau \neq 0$  are efficiently averaged owing to large inhomogeneous broadening ( $\Delta\omega\tau \gg 1$ ). Only the first term is retained, which is proportional to  $\cos \varepsilon_d\tau$ . This is consistent with the simple qualitative consideration given above and, apparently, must be valid for all flip angles of the magnetisation vector. In the case of weak coupling ( $\phi \approx \pi/4$ ) the role of the second and third terms is even less significant. In strongly coupled systems (this case is left out of consideration in this review) the signal is proportional to  $\cos(3/2)\varepsilon_d\tau$ , as mentioned above.

However, practical implementation of this two-pulse approach to studies of the dipole–dipole interaction in RPs faces some difficulties. First, MW pulses have a limited amplitude (usually, less than 1 mT) while the signal of, e.g., nitroxyl biradicals has a total width of about 7 mT. Therefore, the probability of excitation of the partner spin in a pair (this is the necessary condition for applicability of this approach) is low. As a result, the effect of the signal decay modulation as compared to the large portion of non-modulated decays of single spins becomes weak. Second, not only the electron–electron but also the electron–nuclear interactions contribute to modulation. For nitroxyl biradicals, this contribution predominates.<sup>22</sup> Third, there is the ‘dead’ time problem, namely, the system’s response cannot be measured immediately after the pulse is applied owing to transient processes in the cavity (usually, at  $\tau < 100$  ns). It should be noted that reliability of the results of mathematical extrapolation to the ‘dead’ time region always casts some doubt.

There are a few studies on the observation of the modulation induced by electron–electron dipole–dipole interaction in two-pulse ESE spectra. Among them is a pioneering study<sup>11</sup> of RPs in single crystals containing no magnetic nuclei. A peak observed after Fourier transformation of the signal decay for nitroxyl biradicals dissolved in liquid crystals was attributed to the dipole–dipole interaction in the pair.<sup>26</sup> This peak was also recorded for polyoriented nitroxyl biradicals.<sup>22</sup> The contribution of this type of modulation was very small<sup>22,26</sup> compared to the contribution of the electron–nuclear interaction.

Note that in the case of two-pulse ESE of photochemically generated spin-correlated RPs the difficulties mentioned above can be almost completely eliminated (see below).

The search for solutions to the problems posed in studies of radical pairs by the conventional two-pulse ESE method stimulated development of modified experimental techniques.

### 2. Pulsed electron–electron double resonance

PELDOR<sup>12,13</sup> was the first modification of the ESE technique elaborated for the study of the ESEEM induced by the electron–electron dipole interaction. In this case the echo signal is excited using a conventional two-pulse sequence and an additional 180 pump pulse is applied at some other resonance frequency (see Fig. 4b). The spins producing the echo signal are called A-spins and the partner spins in the pair (to which in this case the additional pulse is applied) are called B-spins.

The results of this experiment can be represented with ease using the phase ratios assuming weak spin–spin coupling. At time  $t$ , the phase of the A-spin after the first pulse is  $[\Delta\omega_0 \pm (1/2)\varepsilon_d]t$  (the ‘plus’ or ‘minus’ sign depends on the projection of the B-spin). After the action of the  $180^\circ$  pulse applied at the B-spin frequency at time  $T$  the shift of the precession frequency due to the dipole–dipole interaction changes its sign and the phase at time  $\tau$  (before application of the second pulse at the A-frequency) is given by

$$\varphi_A = \Delta\omega_0\tau \pm \frac{1}{2}\varepsilon_d T \mp \frac{1}{2}\varepsilon_d(\tau - T).$$

After the second pulse applied at the A-frequency one has

$$\varphi_A = \pi - \Delta\omega_0\tau \pm \frac{1}{2}\varepsilon_d T \pm \frac{1}{2}\varepsilon_d(\tau - T) + \Delta\omega_0(t - \tau) \mp \frac{1}{2}\varepsilon_d(t - \tau).$$

From here it follows that at  $t = 2\tau$

$$\varphi_A = \pi \mp \varepsilon_d T.$$

The echo signal is proportional to  $\cos \varepsilon_d T$ , which means a modulation of the signal on change in time  $T$  at a frequency  $\varepsilon_d$ .

In the experiment, the pump pulse excites only a portion of the partner spins of a given A-spin. We will denote it  $P_B$ . Then, the probability of non-modulated signal decay is  $(1 - P_B)$  and the probability of modulated signal decay is  $P_B$ ; the total signal is given by

$$V(T) = 1 - P_B + P_B \cos \varepsilon_d T. \quad (13)$$

The advantage of the PELDOR technique is the absence of electron–nuclear modulation. Indeed, application of a pulse at the B-spin resonance frequency does not change the electron–nuclear interactions of the A-spin. It is also important that in this case the ‘dead’ time problem is almost eliminated because the pulse at the B-frequency can be applied immediately after the first pulse at the A-frequency. The remaining uncertainty is due to the finite pulse duration. It can also be decreased by using an additional refocusing pulse at the A-spin frequency (see dashed lines in Fig. 4*b*) and by positioning the pump pulse between the second pulse at the A-frequency and the additional pulse.<sup>37</sup> The position of the pump pulse can coincide with that of the echo signal excited by the first and second pulses at the A-frequency, which must correspond to zero time. Yet another advantage of the technique is that the signal modulation is not superimposed with the spin relaxation induced signal decay (as in the two-pulse method considered above).

At present, the PELDOR method is most widely used in studies of thermally nonequibrated systems.

Except for the action on the B-spins at some other resonance frequency, the magnetic field can be changed in a stepwise fashion, as in the X- (see Ref. 38) and W-band EPR studies.<sup>39</sup> The pulse sequence is shown in Fig. 4*c*. The A-spins were excited using the three-pulse stimulated echo sequence. The magnetic field jump synchronised with the 180° pump pulse was positioned between the second and third pulses. Due to the shift of the resonance field the 180° pump pulse affected only the B-spins. The three-pulse (instead of the two-pulse scheme, as in two-frequency PELDOR) scheme for excitation of the A-spins is used because the magnetic field jump in the two-pulse modification of the technique causes significant phase distortions for the A-spins. According to the three-pulse scheme, the magnetisation between the second and third pulses is retained along the Z axis of the rotating frame and the phase does not increase. The time  $\tau$  between the first and the second pulses can be varied. Modulation is due to both the electron–electron and electron–nuclear interactions. The two mechanisms can be discriminated by switching the pump pulse off. Since both mechanisms are independent, their effect on the observed echo decay modulation must be multiplicative. This approach was employed in a magnetic-field-jump PELDOR study of rigid biradical **B1**.<sup>38</sup>

The ESE signal decays of **B1** in protonated and deuterated solvents are shown in Fig. 5. The initial decays (see curves 1 and 2) exhibit only the modulation at the frequencies of electron–nuclear interactions, while the result of division (curve 3) is independent of the type of isotopes. Therefore, the observed ESEEM can be treated as electron–electron modulation. The results of Fourier transformation are shown in Fig. 6 (spectra I and II). Sharp lines seen in the spectrum correspond to singularities of the dipolar doublet (see Fig. 3*a*). The distance between paramagnetic fragments —  $r = 19.0 \pm 1.6$  Å was determined from positions of these singularities.

The dipolar doublets in spectra I and II exhibit no shoulders, which must appear according to theory (see Fig. 3). The absence of shoulders seems to be due to low intensities, which can be increased by orienting biradicals in the sample in such a manner that the line connecting both spins is parallel to the magnetic field direction. This can be done by placing the radical into a liquid crystal oriented in such a way that the axis of its director is parallel to the direction of the external magnetic field. The results of investigation of biradical **B1** are also shown in Fig. 6 (spectrum

**Figure 5.** Magnetic-field-jump PELDOR signal decays obtained for biradical **B1** in toluene (*a*) and deuterated (*b*) toluene at 77 K.<sup>38</sup> Signal decays obtained by  $\tau$  scanning (see Fig. 4*c*) (1); the same, but the pump pulse  $\pi_B$  is switched off (2); and curve 1 divided by curve 2 (3). The vertical axes are given in relative units for curves 1 and 2 and in absolute units for curves 3. Dashed lines denote the results of signal recovery during the ‘dead’ time.

III).<sup>38</sup> As can be seen, the shoulders became much more intense. Exchange interaction was found to be zero from the shoulder positions using expressions (11).

**Figure 6.** Results of cosine Fourier transformation of experimental data in the time domain.<sup>38</sup> Experimental data: curve 3 in Fig. 5*a* (I), curve 3 in Fig. 5*b* (II); and data for biradical **B1** in oriented liquid crystal (the biradical axis is nearly parallel to the magnetic field direction) (III).

The advantage of the magnetic-field-jump PELDOR over the two-frequency PELDOR technique consists in the possibility of using a scanning pump<sup>38</sup> owing to an increase in the portion of spins (radical pairs) to be excited. Here, the 'dead' time can also be eliminated using an additional refocusing pulse. A drawback of the technique is the effect of relaxation processes on the echo decay.

A comparative PELDOR study of biradicals in two (X and S) EPR bands was carried out.<sup>40</sup> Since the electron–nuclear modulation depends on the MW band while the electron–electron modulation is independent of it, this approach can be employed to determine the contribution of electron–electron modulation.

The PELDOR technique cannot be used in studies of RPs with a relatively narrow EPR spectrum (less than 2 mT), where the excitation pump pulses and the reading pulses are superimposed and the effects observed are hard to interpret. Such spectra are typical of free radicals in photosynthetic reaction centres. It is more appropriate to study these systems by 'single-frequency' methods involving identical excitation of both A- and B-spins (see below).

### 3. The '2 + 1' method

The '2 + 1' method<sup>14,27</sup> is much like the PELDOR technique considered above. It employs the same pulse sequences (see Fig. 4b), but the pulses are applied at the one resonance frequency; *i.e.*, the basis pulse sequence is as follows: pulse 1 –  $T$  – pulse (+1) –  $(\tau - T)$  – pulse 2 –  $\tau$  – echo. The echo signal appears after application of two pulses (pulse 1 and pulse 2); the additional pulse (pulse +1) is necessary to achieve alternation of the dipole–dipole interaction. Experiments involve variation of the time  $T$  at constant  $\tau$ . The ESEEM occurs by the same mechanisms as in the PELDOR experiments; however, here both partner spins are excited identically.

In addition to the possibility of studying narrow spectra, the '2 + 1' method (compared to PELDOR) does not require an additional generator and special cavity. However, it also has significant drawbacks. First, the '2 + 1' technique is not free from electron–nuclear ESEEM. Elimination of this type of modulation requires special procedures, *e.g.*, comparison with a reference sample in which no dipole–dipole interaction occurs. Second, the dipole–dipole interaction alternates under the action of not only pulse +1 but also the second pulse (see above). Correct allowance for interference between these two effects is not always possible. For instance, if in polyoriented medium there are two types of pairs, with long and short distances, the major contribution to the echo signal will come from the pairs with the long distance, because the signal from the pairs with the short distance is rapidly damped due to alternation (see above). Therefore, in the presence of a distance distribution the distribution function will be significantly distorted. The PELDOR method is free from this drawback, because it usually involves observation at the edge of the spectrum, where only a small portion of A spins is excited.

### 4. Double-quantum coherence method

Using an appropriately designed pulse sequence, it is possible to excite a coherence between the highest and lowest levels in the scheme shown in Fig. 1.<sup>15,16,26</sup> A commonly used pulse sequence for this experiment (see Fig. 7a) includes four pulses. Three of them ( $\pi/2$  pulses) create a stimulated echo signal. The additional  $\pi$ -pulse is applied at the midpoint of the time interval between the second and third pulses.

The first two pulses create the double-quantum and zero-quantum coherences. They are refocused after applying the  $\pi$ -pulse and create a single-quantum coherence after application of the  $\pi/2$  pulse observed as an echo signal. The contribution of the double-quantum coherence is selected using the pulse phase cycling from one series to another. Experiments involve variation of the time  $\tau$ ; the signal is modulated at the  $\varepsilon_d$  frequency.

**Figure 7.** ESE pulse sequence used in studies of dipole–dipole interaction between electron spins in a radical pair.

Double-quantum coherence method (a), solid echo technique (b) and selective hole 'burning' (c).

In order to avoid the loss of signal during the 'dead' time, an additional refocusing (fifth) pulse or a six-pulse sequence is used, in which the double-quantum coherence is created by three  $(\pi/2 - \tau/2 - \pi - \tau/2 - \pi/2)$  rather than two pulses.<sup>26</sup> The advantage of the double-quantum coherence method is the absence of the interference effects described in the preceding chapter. However, in this case the electron–nuclear ESEEM occurs too. A drawback of the technique consists in a large number of phase change cycles (a total of sixty-four cycles), which can introduce an additional error. Besides, the phenomenon is characterised by a rather complicated theoretical description and the lack of a clear insight.

### 5. Solid-state NMR pulse sequences method

A Single-Frequency Technique for Refocusing (SIFTER) the dipole–dipole interactions was proposed.<sup>17</sup> It is based on the 'solid echo' and Jeener–Broekaert solid-state NMR pulse sequences. Consider the effects produced taking solid echo as an example.

The pulse sequence used in NMR is  $(\pi/2)_x - \tau - (\pi/2)_y - \tau - \text{echo}$ . It permits refocusing of the dipole–dipole interaction between two nuclear spins (*e.g.*, protons in a bound water molecule in a crystal hydrate). The echo signal on the left and on the right of its maximum is modulated at the frequency of the dipole–dipole interaction. No 'dead' time problem is posed when observing this modulation. This gave an impetus to use of this pulse sequence in EPR as well.<sup>17</sup> However, this approach is only applicable to a pair of equivalent spins, when  $\Delta\omega \ll \varepsilon_d$  (as in solid-state NMR). The reverse holds for EPR, which deals with inequivalent spins in the pair. This problem can be solved by adding two more refocusing  $(\pi)_x$  pulses (see Fig. 7b). At  $\tau_2 = \tau_1$ , the solid echo appears. This signal is created in such a fashion that static scatter of the resonance frequencies over the sample (except for their shift induced by the dipole–dipole interaction in the RP) has no effect on its shape. By varying the difference between two delays

$$t = \tau_2 - \tau_1$$

the observed signal can be modulated by the dipole–dipole interaction. This is performed at a constant total delay  $\tau_2 + \tau_1$ , which allows the relaxation effect to be excluded.

Selection of an informative signal is achieved by phase cycling (a total of three cycles). In order to suppress the electron–nuclear modulation of the decay, measurements are carried out at different total delays  $\tau_2 + \tau_1$ . Electron–nuclear ESEEM depends on this parameter, while the electron–electron ESEEM is independ-

ent of it. Therefore, averaging of the results obtained must lead to selection of the desired effect. For instance, the results of averaging over twenty-five values of this parameter were reported.<sup>17</sup>

This method is characterised by much simpler experimental design compared to the double-quantum coherence technique, because the number of phase change cycles decreases. However, theoretical description remains complicated and no clear representation of the phenomenon is available (the results can hardly be obtained without the density matrix formalism).

Thus, analysis of different methods of investigation of thermally equilibrated systems showed that PELDOR is the most convenient method. It provides a clear picture of the phenomenon and essentially simplified theoretical description. Besides, the electron–nuclear modulation effects are nearly completely eliminated. The only limitation of this approach is inapplicability to systems with narrow EPR spectra of RPs (biradicals).

## 6. Modulation of two-pulse out-of-phase electron spin echo for spin-correlated radical pairs

A chemical or photochemical reaction can produce spin-correlated radical pairs. An example is provided by photosynthesis in plants and bacteria. The process involves absorption of a light quantum followed by formation of a primary electron-donor radical cation and an electron, which is then consecutively trapped by different acceptor molecules to give corresponding radical anions. Initially, the pair is generated in the singlet spin state.

In this case only two inner energy levels are populated (see scheme in Fig. 1). In accord with the portion of the singlet state [see Eqns (7)] the populations of four levels are as follows:  $p_1 = 0$ ,  $p_2 = \cos^2\phi$ ,  $p_3 = \sin^2\phi$  and  $p_4 = 0$ . These populations are not thermally equilibrated; as a consequence, this gives rise to the spin polarisation effect. In weakly coupled systems this population distribution means that if one spin is in the  $\alpha$  state, the second spin is in the  $\beta$  state, and *vice versa*. Therefore, such pairs are called spin-correlated pairs. In addition to the nonequilibrated populations, quantum-mechanical coherence of energy levels also occurs. However, these effects are rapidly damped (it takes less than 100 ns) and consideration of these phenomena goes beyond the scope of this review. The EPR spectrum of a spin-correlated radical pair exhibits two absorption and two emission lines (see Fig. 2b), all line intensities being equal.

Calculations of the echo signals of spin-correlated states for a conventional two-pulse sequence (see Fig. 4a) were carried out.<sup>36,41–43</sup> We cite below the results<sup>36</sup> where coherence effects were averaged. Let us denote arbitrary initial populations as  $p_1$ ,  $p_2$ ,  $p_3$  and  $p_4$ . Application of two pulses ( $\theta_1$  and  $180^\circ$ ) along the  $X$  axis of the rotating frame creates an echo signal at  $t = 2\tau$  with projections on the  $Y$  (in-phase echo) and  $X$  (out-of-phase echo) axes. The intensities of these signals are proportional to the corresponding magnetisations

$$\begin{aligned} M_x &= P \sin 2\theta_1 [S_0 \sin^2 2\phi + \cos 2\phi (S_{-1} \cos^2 \phi - S_{+1} \sin^2 \phi)] + \\ &+ \sin \theta_1 (p_2 - p_3) \sin^2 2\phi \cos 2\phi \left( S_0 - \frac{1}{2} S_{+1} - \frac{1}{2} S_{-1} \right), \quad (14) \\ M_y &= (p_4 - p_1) \sin \theta_1 \times \\ &\times [C_0 \sin^2 2\phi + \cos 2\phi (C_{-1} \cos^2 \phi - C_{+1} \sin^2 \phi)], \end{aligned}$$

where

$$P = -\frac{1}{2}p_1 + p_2 \sin^2 \phi + p_3 \cos^2 \phi - \frac{1}{2}p_4,$$

$$S_q = \sin \left( -\varepsilon_d \tau + q \frac{1}{2} \sqrt{\varepsilon_D^2 + 4(\Delta\omega)^2} \tau \right),$$

$$C_q = \cos \left( -\varepsilon_d \tau + q \frac{1}{2} \sqrt{\varepsilon_D^2 + 4(\Delta\omega)^2} \tau \right).$$

In thermodynamic equilibrium one has  $p_2 = p_3$ ,  $P = 0$  and the out-of-phase echo is absent; the expression for  $M_y$  coincides

with Eqn (12). In contrast to this, only the out-of-phase echo is present for a spin-correlated radical pair born in the singlet state.

For inequivalent spins (weak coupling case), expressions (14) are significantly simplified:

$$M_x = -\frac{1}{2}(-p_1 + p_2 + p_3 - p_4) \sin 2\theta_1 \sin \varepsilon_d \tau, \quad (15)$$

$$M_y = (p_4 - p_1) \sin \theta_1 \cos \varepsilon_d \tau.$$

An example of experimentally observed modulation is shown in Fig. 8 (an RP in Photosystem I). Figure 9 presents the results of Fourier transformation of these experimental data.

An amazing feature of the ESE in spin-polarised RPs is the absence of electron–nuclear modulation effects. First of all, this follows from good correspondence between the experimental and calculated spectra in the frequency domain (see Fig. 9 and curve 2 in Fig. 3); Fig. 9 exhibits no peaks that could be attributed to electron–nuclear interaction. A comparison of isotopically substituted samples ( $^{14}\text{N}/^{15}\text{N}$ , see Ref. 18 and  $^1\text{H}/^2\text{H}$ , see Ref. 44) led to identical results. Computer simulation<sup>45</sup> revealed that the absence of electron–nuclear modulation effects is due to polarisation of corresponding electron–nuclear transitions and mutual cancellation of corresponding peaks in the frequency spectrum of a polyoriented sample.

**Figure 8.** Out-of-phase echo signal modulation for  $\text{P}_{700}\text{A}_1^-$  spin-correlated radical pair in Photosystem I.

Dashed line denotes the signal interpolated to the 'dead' time region.

**Figure 9.** Results of sine Fourier transformation of the data shown in Fig. 8.

Yet another feature of the method is a sine-type dependence of the ESE signal amplitude on time  $\tau$ . This allows the signal amplitude at  $\tau = 0$  to be determined immediately (it with necessity equals zero). Thus, signal extrapolation to the 'dead' time region is reduced to a simpler case of interpolation (see Fig. 8).

Eventually, the linewidth in the spectrum of free radicals in photosynthetic reaction centres is of the order of 1–2 mT, which corresponds to the amplitudes of experimentally used MW pulses (excitation band). This means good conditions for excitation of both radicals in RP.

All these features of ESE experiments with spin-polarised RPs make the technique a rather efficient tool for investigation of structural features of the reaction centres.

## 7. Free induction decay modulation under selective excitation

This method employs the pulse sequence shown in Fig. 7c.<sup>46</sup> The first small-amplitude  $180^\circ$  pulse selectively excites only one transition of a radical pair (see Figs 1 and 2). The action of this pulse is similar to 'burning' of a narrow hole in the spectrum. The second large-amplitude pulse excites all four transitions of the RP (non-selective pulse). It plays a dual role, *viz.*, creates a free induction signal and changes the dipole–dipole interaction in the RP. Frequency interference between different transitions leads to modulation of the free induction decay at the frequency  $\varepsilon_d$ .<sup>46</sup> The technique provides a better signal-to-noise ratio for spin-correlated RPs compared to two-pulse ESE<sup>46</sup> and permits studies of zero-quantum and two-quantum relaxation times of RPs.

## IV. Experimental methods based on spin relaxation

Methods employing the partner spin relaxation effects can be divided into two groups, namely, with fast and slow relaxation of B-spins. In the latter case both the A- and B-spins can be of the same type. The fast-relaxation case corresponds to the exchange narrowing of the splitting due to the dipole–dipole interaction, when  $\varepsilon_d^2 T_{1B} \ll 1$ . Slow relaxation means that the reverse inequality holds. Rapidly relaxing spins are characteristic of metal ions. Slowly relaxing spins are typical of free radicals and also metal ions. Methods employed in the case of fast relaxation are based on the A-spin longitudinal ( $T_1$ -effects) and transverse ( $T_2$ -effects) relaxation rate measurements. In the case of slow relaxation, two methods are used, *viz.*, selective hole 'burning' and dipolar modulation enhancement in stimulated ESE.

### 1. A-Spin longitudinal relaxation rate measurements.

#### $T_1$ -Effects

In the case of fast B-spin relaxation ( $\varepsilon_d T_{1B} \ll 1$ ) the A-spin longitudinal relaxation rate ( $T_{1A}^{-1}$ ) is related to the B-spin longitudinal ( $T_{1B}$ ) and transverse ( $T_{2B}$ ) relaxation times as follows:<sup>47</sup>

$$\frac{1}{T_{1A}} = \frac{1}{T_{1A}^0} + S_{rmB}(S_B + 1) \frac{\mu_0^2}{16\pi^2} \times \left[ \frac{b^2 T_{2B}}{1 + (\omega_B - \omega_A)^2 T_{2B}^2} + \frac{c^2 T_{1B}}{1 + \omega_A^2 T_{1B}^2} + \frac{e^2 T_{2B}}{1 + (\omega_B + \omega_A)^2 T_{2B}^2} \right], \quad (16)$$

where  $T_{1A}^0$  is the time  $T_{1A}$  in the absence of B-spin,  $S_B$  is the B-spin and  $\omega_A$  and  $\omega_B$  are the A-spin and B-spin resonance frequencies, respectively

$$b^2 = \frac{1}{6} g_A^2 g_B^2 \beta^4 \frac{(1 - 3 \cos^2 \theta)^2}{\hbar^2 r^6},$$

$$c^2 = 3 g_A^2 g_B^2 \beta^4 \frac{\sin^2 \theta \cos^2 \theta}{\hbar^2 r^6},$$

$$e^2 = \frac{3}{2} g_A^2 g_B^2 \beta^4 \frac{\sin^4 \theta}{\hbar^2 r^6}.$$

The  $T_{1A}$  time is measured in the signal recovery experiments after pulse saturation (or inversion). There are two types of experiments, (i) using an ESE spectrometer with pulsed signal detection (usually, by the spin echo technique) and (ii) using a pulsed EPR spectrometer with signal detection using a small-amplitude continuous-wave MW field. Various types of EPR spectrometers have been described.<sup>48</sup>

Determination of the distance  $r$  from expression (16) requires knowledge of the parameters  $T_{2B}$ ,  $T_{1B}$ ,  $\omega_A$  and  $\omega_B$ . Extended (in the frequency domain) spectra must be averaged over  $\omega_A$  and  $\omega_B$ . A severe problem consists in that not all B-spin transitions are observed experimentally. For instance, large zero-field splitting allows only one transition between the sublevels  $m_S = \pm 1/2$  to be observed in the EPR X-band even for the Kramers ions, such as  $\text{Fe}^{3+}$ . Other non-observable transitions can also contribute to B-spin relaxation. Yet another important problem is complexity of the measurements with allowance for spectral diffusion, which is due to the excitation of a certain portion only of an inhomogeneously broadened EPR spectrum.

For these reasons, the results obtained using this approach are not always reliable and some of them were found to be erroneous. Therefore, in the present review the results obtained by this method are cited only in the case of some comparative experiments.

### 2. A-spin transverse relaxation rate measurements.

#### $T_2$ -Effects, relaxation probe method

If  $T_{1B}|\omega_A - \omega_B| \gg 1$  (recall that  $\varepsilon_d^2 T_{1B}^2 \ll 1$ ), the transverse relaxation rate is given by<sup>47</sup>

$$\frac{1}{T_{2A}} = \frac{1}{T_{2A}^0} + \frac{1}{2T_{1A}} + S_B(S_B + 1) \times \frac{\mu_0^2}{16\pi^2} g_B^2 g_A^2 \beta^4 T_{1B} \frac{(1 - 3 \cos^2 \theta)^2}{3\hbar^2 r^6}, \quad (17)$$

where  $T_{2A}^0$  is the  $T_{2A}$  time in the absence of B-spin.

The transverse relaxation is measured from the ESE signal decay. This approach requires only knowledge of  $T_{1B}$ .

A measuring technique<sup>49</sup> involves determination of  $T_{1B}$  from the transverse relaxation of A-spins in the sample with uniform random spatial distribution of both types of spins. For such samples, the expression for the echo signal decay has the form<sup>9</sup>

$$v_{\text{random}}(2\tau) = \exp \left[ -\frac{16\pi\sqrt{\pi}}{27} \sqrt{S_B(S_B + 1)} \times \frac{\mu_0}{4\pi} \frac{g_B g_A \beta^2}{\hbar} C_B \sqrt{2\tau T_{1B}} \right], \quad (18)$$

where  $C_B$  is the concentration of B-spins.

From here  $T_{1B}$  can be found with ease. The technique has the advantage of self-consistency. In the case of pair and uniform spatial distribution, only one parameter (A-spin transverse relaxation rate) is to be measured and the same relaxation mechanism occurs. Here, the problem of inobservability of some B-spin transitions (see above) is by default completely eliminated. A limitation of the method consists in the necessity of preparing samples with uniformly distributed B-spins.

Often, radical and radical ion pairs produced in radiation-induced and photochemical reactions in solids are characterised by a large scatter of distances. The dependence of  $(T_{2A})^{-1}$  on the separation in the RP [see Eqn (17)] allows one to set the problem of determination of the distance distribution function for RPs. This can be done by varying the temperature and thus the  $T_{1B}$  time, provided the physical properties of the sample do not change. The A-spins in the vicinity of B-spins do not contribute to the ESE signal. Thus, B-spins will be surrounded by a region of 'invisibility' for A-spins, the size of the region being varied with temperature. This approach can be called the relaxation probe method. Usually, the  $T_{1A}$  and  $T_{2A}^0$  times depend on temperature much more weakly than  $T_{1B}$  (recall that usually the A-spins are the

organic radical spins and the B-spins are metal-ion spins). The distance distribution function for RPs can to a good accuracy be estimated by comparing the data of two experiments<sup>49</sup> as

$$n(r) = \frac{dv_{\text{pair}}(2\tau)}{d[\ln(v_{\text{random}}(2\tau))/C_B]}, \quad (19)$$

where  $v_{\text{pair}}(2\tau)$  is the ESE decay for the sample with the pair distribution under study.

### 3. Selective hole ‘burning’

Selective hole burning is used in the case of slow B-spin relaxation ( $\varepsilon_d^2 T_{1B}^2 \gg 1$ ). Here, from Eqn (17) it follows that  $T_{1B} \gg T_{2A}$ , *i.e.*, the spin–lattice relaxation of B-spins is slow on the ESE time scale. Since the B-spins are usually the metal-ion spins with broad EPR spectra, in this chapter the possibility of their excitation by applying MW pulses will be ignored. This is the main difference of the technique in question from the selective excitation method considered above.

The pulse sequence employed in the selective hole ‘burning’ technique<sup>21</sup> is shown in Fig. 7c. The first small-amplitude pulse ‘burns’ a narrow hole in the EPR spectrum, the hole width being of the same order of magnitude as the pulse amplitude. After time  $T$  the hole is broadened due to a change in the dipole–dipole interaction owing to spin–lattice relaxation induced fluctuations of the B-spin orientation.

Consider the A-spin whose resonance line is shifted by  $\pm(1/2)\varepsilon_d$  owing to the interaction with the B-spin (in our case the spin B is  $1/2$ ). After time  $T$ , the B-spin will change its value to the opposite with the probability  $(1/2)[1 - \exp(-T/T_{1B})]$  and will retain it with the probability  $(1/2)[1 + \exp(-T/T_{1B})]$ . Thus, if initially the hole was described in the frequency domain by the function  $h_0(\omega)$ , after time  $T$  it will be given by

$$h_T(\omega) = \frac{1}{2} \left[ 1 + \exp\left(-\frac{T}{T_{1B}}\right) \right] h_0(\omega) + \frac{1}{2} \left[ 1 - \exp\left(-\frac{T}{T_{1B}}\right) \right] \left[ \frac{1}{2} h_0(\omega - \varepsilon_d) + \frac{1}{2} h_0(\omega + \varepsilon_d) \right].$$

Application of the second pulse causes the free induction decay (without changing the interactions in the system, because the excitation of B-spins is ignored), which corresponds to the Fourier image of the EPR spectrum. If we consider the difference between the signals in the presence and in the absence of the first selective pulse, the free induction decay can be described by the expression

$$H_T(t) = \int_{-\infty}^{\infty} d\omega [1 - h_T(\omega)] \cos \omega t = \frac{1}{2} \left[ 1 + \exp\left(-\frac{T}{T_{1B}}\right) \right] + \frac{1}{2} \left[ 1 - \exp\left(-\frac{T}{T_{1B}}\right) \right] \cos \varepsilon_d t. \quad (20)$$

Thus, the free induction decay is modulated at the frequency  $\varepsilon_d$  and the larger the  $T/T_{1B}$  ratio, the larger the modulation depth.

Usually, substantial inhomogeneous broadening in EPR causes the free induction decay to be very short and to damp during the ‘dead’ time. But in the case in point the decay signal is observed due to the fact that it is created only by those spins whose resonance frequencies lie in a narrow spectral interval determined by the width of the hole.

### 4. Relaxation induced dipolar modulation enhancement and stimulated echo experiment

Consider a three-pulse sequence for stimulated ESE,  $\pi/2 - \tau - \pi/2 - T - \pi/2$ -echo. In the interval between the second and third pulses the B-spin changes its orientation with the probability  $(1/2)[1 - \exp(-T/T_{1B})]$  and retains it with the probability  $(1/2)[1 + \exp(-T/T_{1B})]$ . Analysis of the spin precession

phases between the first and second pulses, on the one hand, and after the third pulse on the other hand leads to the following expression for the echo signal decay

$$E(2\tau + T) = \frac{1}{2} \left[ 1 + \exp\left(-\frac{T}{T_{1B}}\right) \right] + \frac{1}{2} \left[ 1 - \exp\left(-\frac{T}{T_{1B}}\right) \right] \cos \varepsilon_d \tau, \quad (21)$$

which means modulation at the  $\varepsilon_d$  frequency with scanning  $\tau$ .<sup>22</sup> This permits determination of  $\varepsilon_d$ . The larger the  $T/T_{1B}$  ratio, the more pronounced the effect observed; therefore, this approach can be called Relaxation Induced Dipolar Modulation Enhancement (RIDME).

Expressions (20) and (21) are similar. This is not surprising because both methods, selective hole ‘burning’ and RIDME, are based on the same physical principle, being different in detection technique. Modulation is due to stochastic spin relaxation between pulses rather than the coherence effects upon excitation of different transitions in the spin system (see above).

There is an analogy with the PELDOR method, which involves an artificial change in the dipole–dipole interaction caused by application of the MW pulse. In the RIDME case the dipole–dipole interaction is changed by a natural process, spin–lattice relaxation. The advantage of the RIDME method is a much larger portion of the B-spins involved in modulation ( $P_B$ ). From Eqns (20) and (21) it follows that this portion can be as high as 50%. (*cf.*  $P_B = 10\% - 20\%$  for X-band PELDOR).

Due to inhomogeneous line broadening in high-field EPR the  $P_B$  parameter in the PELDOR becomes small and the modulation effect cannot be observed. For both relaxation methods described above (selective hole ‘burning’ and RIDME) this parameter is independent of the EPR frequency band. In particular, a high-field (4.5 T) RIDME EPR study was reported.<sup>50</sup>

A drawback of the relaxation methods is that other mechanisms, *e.g.*, intramolecular motions can also contribute to the relaxation observed.<sup>51</sup> Separation of these undesired contributions requires elaboration of additional experimental procedures. For instance, separation of the contributions of B-spin relaxation and methyl group rotation in a RIDME study<sup>50</sup> involved measurements of the temperature dependences of these contributions. The temperature behaviour of intramolecular motions obeys the Arrhenius relation while the  $T_1$  time of free radicals is usually proportional to  $T^2$ . In the latter case the temperature dependence is much weaker and by lowering temperature one can eliminate the contribution of intramolecular motions. A selective hole ‘burning’ study was reported, in which the contributions of other mechanisms were separated using a reference sample depleted of the particles bearing B-spins.<sup>52</sup>

### 5. Out-of-phase stimulated electron spin echo for triplet spin-correlated radical pairs

If a photoinduced spin-correlated pair comprises a radical and a short-lived triplet molecule, only the in-phase echo signal is initially observed.<sup>53</sup> Then, the out-of-phase stimulated echo signal appears, which proceeds in parallel with the decay of the triplet state. Variation of the time  $\tau$  leads to modulation of both the in-phase and the out-of-phase echo signals at the frequency of the dipole–dipole interaction.

The modulation mechanism of the in-phase echo signal is similar to the RIDME mechanism (see above). The difference consists in that the RIDME modulation is due to a spontaneous shift of the spin resonance frequency caused by the spin–lattice relaxation induced change in the dipole–dipole interaction while in this case modulation is due to the change in the dipole–dipole interaction caused by the decay of the paramagnetic triplet state. The out-of-phase echo signal and its modulation are due to not only this reason but also the spin polarisation of the initial state of

the triplet–triplet RP. The in-phase and out-of-phase signals are described by the following equations:<sup>53</sup>

$$M_y = n_0 + (n_1 + n_{-1}) \exp(-KT) + (n_1 + n_{-1})[1 - \exp(-KT)] \cos \varepsilon_d \tau, \\ M_x = (n_1 - n_{-1})[1 - \exp(-KT)] \sin \varepsilon_d \tau,$$

where  $n_1$ ,  $n_0$  and  $n_{-1}$  are the initial populations of the corresponding triplet states of the RP and  $K$  is the decay constant of the triplet state.

Note that the out-of-phase signal appears only in the presence of the dipole–dipole interaction and only as a result of the decay of the triplet state. Besides, spin polarisation in the system is required.

Selective hole ‘burning’ experiments similar to those described above for spin-correlated RPs can be carried out with triplet RPs.<sup>54</sup> In this case the free induction decay signal becomes modulated.

## V. Conformations of long-chain biradicals and doubly spin-labelled and metal-containing biomolecules

### 1. Long-chain nitroxyl biradicals

Long-chain biradicals with single bonds in their structures can adopt a variety of conformations characterised by different biradical length. The distance between the terminal paramagnetic fragments can be used for characterisation of the conformational structure. The results of measurements of these distances in the shape-persistent biradicals, which are assumed to adopt only one conformation, are usually in good agreement with the results of structure simulations.<sup>17, 22, 55, 56</sup>

Flexible long-chain biradicals can adopt a larger number of conformations. In this case one must introduce a distance distribution function between paramagnetic fragments. Mathematically, this is an inverse problem of solving the Fredholm integral equation of the first kind. To this end, different methods were proposed, in particular, a truncated expansion of the kernel of the integral equation,<sup>57</sup> a discrete integral transformation of the equation with appropriately chosen transformation kernel (analogous to Fourier transformation)<sup>33, 58</sup> and the Tikhonov regularisation.<sup>33</sup>

All these methods involve rather complicated computational procedures. If a narrow distance distribution is assumed, its width can be estimated immediately from the modulation decay.<sup>38</sup> This approach was employed in a magnetic-field-jump PELDOR study<sup>38</sup> of a shape-persistent biradical **B1** (see above) and a flexible radical **B2**.

The ESE signal decays for **B1** are shown in Fig. 5 and the results of Fourier transformation are presented in Fig. 6. For the **B2** radical the modulation damped much faster than for **B1**. This can be associated with the presence of a distance distribution. The spin–spin separation estimated from the peak position in the frequency domain for **B2** was 20.5 Å. Damping of modulation for the shape-persistent biradical is due to scatter of the dipole frequencies caused by polyorientation of the sample. Any additional damping can be associated with the distance distribution. A comparison of the signal decays for **B2** and **B1** gave the distribution width  $\Delta r = 3$  Å.<sup>38</sup>

### Conformations of biradical

were studied by PELDOR.<sup>58, 59</sup> This biradical contains  $n$  methylene groups ( $n = 8–20$ ). The average distances between the radical fragments were calculated from the frequency spectra obtained after the Fourier transformation of the decay traces. These data were compared with the results of calculations for the limiting case of completely stretched *trans*-conformation and with the results of the calculations of conformational statistics at the glass transition temperature of the polystyrene matrix. The results of distance measurements were found to be similar (within the limits of experimental error) to the calculated conformational statistics.

The distance distribution function for  $n = 10$  was determined by the integral transformation and using the Tikhonov regularisation.<sup>33, 58</sup> Both methods gave similar results, namely, at  $n = 10$ , the width of the distribution function at half-height was  $\sim 5$  Å at the average spin–spin separation  $r = 21$  Å.

Determination of the distance distribution function in a sample with a complex mutual spatial distribution of RPs faces an additional problem of separation of the intrapair and pair–pair interactions. This is a complicated problem because of complex correlations between the radial and angular variables. However, angular spin–spin correlations of RPs can be neglected if the modulation depth of the echo signal decay is low.<sup>58</sup>

The PELDOR method is appropriate for measuring the dipole–dipole interaction not only in nitroxyl biradicals but also in biradicals containing paramagnetic metal ions as partner spins. As mentioned above, it is required that spin relaxation of the ion during the period of action of the pulse sequence be slow and the EPR spectrum be relatively narrow. A pulsed EPR study of a terpyridine-based Cu(II) complex containing phenylene- and ethynylene-based shape-persistent groups attached on two sides and two terminal nitroxyl labels was reported.<sup>60</sup> The observed decay modulation was interpreted as a result of dipole–dipole interactions in the copper–nitroxyl (distance 24.3 Å) and nitroxyl–nitroxyl (distance 48.6 Å) pairs.

The PELDOR method also allows the conformational structure of spin-labelled polymers (in essence, they are polyradicals) to be investigated. This can be done by monitoring the signal decay kinetics, which become non-exponential in the case of linear polymers (the cubic root of the time under the exponent). It is this decay law that was established in studies of spin-labelled poly(4-vinylpyridine) in a glassy solution.<sup>61</sup>

### 2. Doubly spin-labelled peptides and RNA

Recent development of biochemical methods of selective spin label attachment to specified fragments of biomolecules led to the wide use of this approach.<sup>62, 63</sup> The secondary structure of a doubly spin-labelled peptide can be established by studying the dipole–dipole interaction between the spin labels. If the distance between spin labels is shorter than 15 Å, continuous-wave EPR studies are carried out; for some results, see Ref. 64. If this distance exceeds 15 Å, the dipole–dipole interaction remains unresolved in continuous-wave EPR and one must use pulsed EPR spectroscopy.

A number of studies of doubly spin-labelled peptide trichogin GA IV have been reported.<sup>65–70</sup> This compound is a peptide antibiotic of fungal origin, rich in aminoisobutyric (Aib) acid, and possesses antibacterial and antifungal properties. Such peptides can produce ionic channels in membranes, which make them permeable and cause cell death.

A distinctive feature of trichogin GA IV is relatively small chain length. The length of the peptide is small compared to the membrane thickness; therefore, the mechanism of membrane permeability is still unclear. The peptide structure comprises three aminoisobutyric acid residues.

In the chemical synthesis these residues are replaced by structurally similar nitroxyl spin labels TOAC.<sup>68</sup>

Two types of trichogin were used, namely, substituted trichogin (F-trichogin with *n*-octanoyl group replaced by Fmoc) and unsubstituted compound. Besides, the 1,2-aminoleucinol (Lol) residue was replaced by the L-leucine methyl ether (Leu-OMe) residue. These substitutions did not change the bioactivity of the peptides.<sup>71</sup>

Studies of doubly labelled (at positions 1 and 4, 4 and 8 and 1 and 8) peptides were performed. The first two types of biradicals were investigated by continuous-wave EPR<sup>64</sup> and the last type was studied by pulsed EPR spectroscopy owing to large spin-spin separation.

The conformation of spin-labelled F-trichogin-1,8

was studied by three-pulse PELDOR in various glassy solvents at 77 K. As a rule, no Fourier transformation was performed and the analysis was carried out in the time domain. The ESEEM observed in chloroform-DMSO solution was ascribed to the dipole-dipole interaction with the interspin separation of  $\sim 20$  Å.<sup>65</sup> The modulation damping was associated with the distance distribution of width  $\sim 2$  Å. It should be noted that only 25% of the labelled molecules are characterised by these parameters of the distribution function, while the remaining 75% of molecules are characterised by a broader distribution.

Doubly labelled trichogin-1,8 and F-trichogin-1,8 were also studied in other polar glassy solvents, *viz.*, methanol, ethanol, trifluoroethanol and in chloroform/DMSO mixtures with different component ratios.<sup>66</sup> It was found that modulation significantly differs depending on the type of the molecule and the matrix. For F-trichogin-1,8, modulation is observed only in the chloroform/DMSO mixture, whereas for trichogin-1,8 it is observed in all matrices, but with different oscillation frequencies. The distances between paramagnetic fragments vary from 15.3 Å in trifluoroethanol to 21.8 Å in ethanol.

These distances can be compared with the structural parameters of peptides, established by X-ray scattering.<sup>69,70</sup> Using commonly accepted values for the peptide backbone torsion angles in the secondary structures ( $\alpha$ - $3_{10}$ -,  $2_7$ - and  $2_5$ -helices), one can calculate the interspin distances.<sup>65,69,70</sup> Based on the results of calculations, it was concluded that trichogin-1,8 and F-trichogin-1,8 adopt the  $2_7$ -helix conformation in all matrices except for trifluoroethanol, where the peptides adopt the  $3_{10}$  conformation.

The conformation of the same doubly labelled peptide in a tetrameric cluster formed in a matrix of low polarity (chloroform/toluene mixture) was studied.<sup>67</sup> The distance  $r = 15.7$  Å is similar to the value 14 Å calculated for the  $3_{10}$ -helix.

The structures of doubly spin-labelled proteins (lysozyme T4 mutants) were studied using the double-quantum coherence technique<sup>72</sup> in the 9 and 17 GHz bands. The distances found lie

in the range from 20 Å (mutant 65/76) to 47 Å (mutant 61/135). High-quality spectra obtained made it possible to determine the distance distribution function. Analysis of this function revealed a variety of conformations of these molecules. The experimental results were compared with the results of molecular modelling.

The pioneering study<sup>73</sup> of spin-labelled RNA was carried out by the PELDOR method and involved two types of RNA with known molecular structures, labelled with nitroxyl labels in two positions of the uridine residue. According to structural data, the distance between paramagnetic fragments must be 35 Å for one type of RNA while the other type is characterised by a broad distance distribution. The results obtained coincided with the expectations, namely, the signal modulation observed in the former case corresponded to a distance of  $35 \pm 2$  Å, whereas in the latter case no modulation was observed.

The PELDOR method was employed in determining the distance between two tyrosyl radicals in ribonucleic reductase *E. coli*.<sup>74</sup> The distance between two radicals found from the peak position in the frequency domain was  $33.5 \pm 0.4$  Å. The modulation depth showed that at least 25% of radicals were in dimeric form (monomeric radicals can also be present in this system).

### 3. Metal-containing biomolecules

Many proteins and enzymes contain paramagnetic metal ions. If such ions form pairs and clusters, the mutual arrangement of these objects in space can be studied by EPR. In metal-containing biomolecules, the second spin can be delivered by incorporating a nitroxyl spin label. In some cases diamagnetic ions in proteins can be replaced by paramagnetic ions, *e.g.*, Zn(II) by Co(II) and Mg(II) by Mn(II).

The spin relaxation of spin labels was studied over a wide temperature range in order to realise both fast and slow ion relaxation.<sup>75–78</sup> Transverse relaxation was studied by two-pulse sequence and longitudinal relaxation was studied by the saturation-recovery technique. Low-spin iron(III) porphyrins were investigated.<sup>75</sup> Raising the temperature from 8 to 120 K led to a decrease and then to an increase in  $T_2$ . Experimental data were analysed using the measured Fe(III) relaxation times. The distance in the metal-ion pair was estimated at 10.5–15 Å. High-spin iron(III) porphyrins were also studied.<sup>76</sup> Axial ligands were fluorine, chlorine and bromine. The temperature dependence of  $T_2$  exhibited a minimum near 6 K. The experimental data were analysed using independently determined iron relaxation rates. The interspin distances were between 11.6 and 15.0 Å, which is in agreement with the values obtained for low-spin iron (see above). A study<sup>77</sup> of low-spin methemoglobins spin-labelled at the cysteine  $\beta$ -93 position revealed a decrease and then an increase in  $T_2$  value with an increase in temperature from 6 to 120 K. The distance in the spin label-ion pair (15–15.5 Å) was determined analogously. These distances in high-spin fluoro- and aquamethemoglobins increased to 15.8–17.5 Å.<sup>78</sup>

The PELDOR method was employed to study the dipole-dipole interaction between two paramagnetic centres (PCs) in [3Fe–4S](+) and [NiF] clusters in *Desulfovibrio vulgaris* Miazaki *F. hydrogenase*.<sup>79</sup> The distance between PCs, known from X-ray data, differs from the PELDOR measured value. Probably this is due to specific exchange binding in the iron/sulfur cluster. Nevertheless, such studies make it possible to collect information on the internal structure of multinuclear metal clusters.

The Mo(V)/Fe(III) state of sulfite oxidase was studied by the PELDOR method in different (X- and C-) MW bands at 4.2 K.<sup>80</sup> A-Spins were the Fe(III) ion spins. Analysis of the decay curves suggested multiple conformations of the flexible loop connecting the Mo and Fe.

## VI. Cluster nanostructures

### 1. Peptide clustering in non-polar media

Peptides can form clusters or aggregates; this property can play the determining role for their physiological functions. ESE

spectroscopy provides a unique possibility of studying the clustering of spin-labelled peptides. All known experimental techniques employed in such studies are based on the same principle. We will consider it taking the PELDOR method as an example.

The echo signal from radicals in an RP is given by expression (13). Assume that a cluster comprises  $N$  particles and that the probability of simultaneous excitation of more than one B-spin is low, *i.e.*,  $P_B N \ll 1$ . Then, for the  $n$ th particle ( $n = 1, 2, \dots, N$ ) one has

$$V_n(T) = \prod_{k \neq n} \left[ 1 - P_B + P_B \cos(\varepsilon_d^{nk} T) \right],$$

where  $\varepsilon_d^{nk}$  is the parameter of the dipole–dipole interaction with the  $k$ th spin.

This expression should be averaged over all possible pairs. At low  $P_B$ , the averaging can be performed independently for each pair

$$V(T) = \left[ 1 - P_B (1 - \cos(\varepsilon_d T)) \right]^{N-1}.$$

From this it follows that at  $t \rightarrow \infty$  the quantity  $V(T)$  tends to the limit

$$(1 - P_B)^{N-1} \approx 1 - (N-1) P_B. \quad (23)$$

The number,  $N$ , of particles in the cluster can be estimated from the asymptotic (long-time) ESE kinetics.

This approach was used in PELDOR and continuous-wave EPR studies of the aggregation of spin-labelled peptide trichogin GA IV (see Section V) in glassy polar and low-polar solutions at 77 K.<sup>81</sup> It was hypothesised that the peptide forms channels in membranes by forming a bundle comprising a number of molecules with polar groups directed to the interior and hydrophobic groups pointing to the exterior. However, numerous previous studies revealed no aggregation. Two types of solvents were a chloroform/toluene (7:3) and a chloroform/toluene/ethanol (3.5:1.5:5) mixture. The choice of the mixture compositions was determined by two factors, the peptide solubility and the formation of glassy state on freezing. The first mixture was a medium of low polarity while the second mixture was a polar liquid. Peptides were spin labelled at positions 1 and 4.

Continuous-wave EPR studies of various media at 77 K revealed the absence of spectral differences. The PELDOR data are shown in Fig. 10. A smooth signal decay observed in the polar matrix is characteristic of uniform intermolecular distribution. In the non-polar matrix, a dramatic signal decay occurs at times 100–150 ns, which is much more pronounced than that of F-trichogin-1,8 biradical shown for comparison.

This behaviour can be explained by aggregation of molecules in the non-polar matrix. Using expression (23) and the data for a model biradical system, one can immediately estimate the number

**Figure 10.** Two-frequency PELDOR signal decays obtained for peptide glassy solutions with scanning time  $T$  (see Fig. 4b) at 77 K.<sup>81</sup> F-trichogin-4 (1) and trichogin-4 (2) in chloroform/toluene mixture; F-trichogin-4 (3) and trichogin-4 (4) in chloroform/toluene/ethanol mixture and doubly labelled peptide F-trichogin-1,8 in methanol (5).

of molecules in the aggregate. Indeed, in both cases the portion,  $P_B$ , of excited spins (in this case,  $N = 2$ ) can be found from the asymptotic data for the biradical given identical experimental conditions with allowance for similar EPR spectral pattern. Knowing  $P_B$  from the asymptotic data (see Fig. 10), one can immediately determine  $N \approx 4$  in the solution of low polarity. Thus, this peptide forms tetrameric clusters in the glassy solution of low polarity.

The signal modulation observed in the experiments (see Fig. 10, curves 1 and 2) can be explained by narrow distribution of the distances between spin labels in the cluster structure. The cluster size estimated from the initial decay rate (at times shorter than 150 ns) is 30–36 Å. The distances determined from the decay modulation for F-trichogin-4 and trichogin-4 are 23.5 and 26.0 Å, respectively.<sup>81</sup>

It is noteworthy that these solvents exhibit significantly different room-temperature continuous-wave EPR spectra.<sup>81</sup> The EPR lines in the spectrum of the solvent of low polarity are much broader; this is similar to line broadening due to slowing down of the orientation motion, which is known in the EPR of spin labels and probes. This should be expected in the case of clustering, because the orientation relaxation time is proportional to the particle size according to the Stokes–Einstein–Debye relation. The cluster size was estimated from the broadening of the continuous-wave EPR spectra.<sup>82</sup> The results of measurements coincided with the estimate of the number of molecules in the cluster ( $N \approx 4$ ). Therefore, the results obtained by both continuous-wave EPR of liquids at room temperature and by PELDOR of glassy frozen solutions substantiate the peptide clustering.

Analogous measurements were carried out for mixtures of other solvents of low polarity, namely, chloroform/toluene, carbon tetrachloride/toluene and dichloroethane/toluene.<sup>83</sup> In all cases, aggregation was revealed, with  $N \approx 3.1–4.3$  depending on the system. The modulation observed corresponded to inter-spin distances of 23, 26 and 33 Å, respectively (one distance or a set of distances depending on the system).

Aggregation of spin-labelled zervamicin IIA (a hexadecapeptide of fungal origin) was investigated.<sup>84</sup> This compound is known to form hollow channels in phospholipid double layers. The PELDOR study of frozen glassy mixtures in the toluene/methanol system at 77 K revealed aggregation. The average distance between spin labels was 25–35 Å (depending on the mixture composition). It was concluded that peptide molecules have an antiparallel orientation and that the increase in the methanol concentration in the mixture led to loosening in the cluster structure.

No aggregation of spin-labelled trichogin dimers (covalent compounds comprising two molecules linked ‘head-to-tail’) in methanol was observed, but it did occur in a chloroform/toluene mixture (2 to 3 molecules).<sup>85</sup> The distances between spin labels in clusters were found to be in the range from 30 to 45 Å. An increase in the peptide concentration in non-polar solvents led to formation of tetrameric clusters.<sup>86</sup>

A double-quantum coherence ESE study<sup>16</sup> revealed clustering of peptides MTSL–CPPPPC–MTSL in a glycerol/water/trifluoroethanol mixture at  $-82^\circ\text{C}$ . An increase in the peptide concentration from 0.75 to 3 mmol g<sup>-1</sup> was followed by the appearance of the double-quantum coherence signals from both intramolecular and intermolecular pairs. In the latter case the parameters of the signal indicated a high local spin concentration. Clustering was observed in a polar matrix. A structurally similar peptide MTSL–CPPPPC–MTSL showed no aggregation.<sup>16</sup>

## 2. Nanostructure of ionomers

Ionomers are polymers with terminal ion groups.<sup>87,88</sup> Their structures contain clusters of ion groups of the size of a few nanometres separated by distances of the same order. Both these parameters of the nanostructure can be evaluated using ionic spin probes.<sup>33,89,90</sup> A study of ionomers based on a polyisoprene/polystyrene copolymer showed that ion groups can cap one or

both chain ends or be situated at the polyisoprene/polystyrene interface. It was shown that the surface of ion clusters is accessible to ionic probes.<sup>91</sup>

Experiments<sup>33,89,90</sup> were carried out using the PELDOR method. The concentration of spin probes was chosen to provide on the average two probes per cluster. The temporal evolution of the PELDOR signal was treated as a result of manifestation of the pair distribution function represented by a superposition of two Gaussian curves and a uniform distribution. The Gaussian curves corresponded to the distances  $r_1 \approx 2$  nm and  $r_2 \approx 5-7$  nm, where  $r_1$  is the characteristic interparticle distance in the cluster and  $r_2$  is the characteristic intercluster distance.

A comparative experiment with a non-polar spin probe revealed only a uniform distribution. The results obtained for three ionic spin probes characterised by increasing distance between the nitroxyl and ionic groups substantiated the interpretation mentioned above. A shift of the first distribution peak towards longer distances<sup>89</sup> was interpreted as additional evidence for the fact that the probe is situated on the surface (with the nitroxyl group directed inside the polymer chains) and that this peak should be attributed to the cluster size. SAXS data<sup>91</sup> are consistent with the PELDOR data<sup>33</sup> given some assumptions concerned with specific features of the interpretation of the results obtained by both methods.

Studies of polymers with different molecular masses and, hence, different chain lengths revealed that the cluster size is independent of the molecular mass except for the cases where the size of the ionic group is much shorter than the chain length. The cluster-cluster distance must be a linear function of the chain length. Such a correlation established for polymers with ionic caps at one end<sup>33</sup> has the form

$$r_2 \sim M^{0.334},$$

where  $M$  is the molecular mass of the cluster. Polymers ion-capped at both chain ends (an anion at one end and a cation at the other end of the polyisoprene/polystyrene copolymer) exhibited no correlation between  $r_2$  and  $M$ . This is due to specific features of the polymer packing, which is characterised by the formation of the polyisoprene/polystyrene interface containing surface ionic groups. In this case an increase in  $M$  can have no effect on the mutual arrangement of clusters on the surface.

## VII. Stable paramagnetic pairs in photosynthetic reaction centres of plants and bacteria

### 1. Radicals and ions in photosynthetic reaction centres

Photosynthesis in higher plants, algae and some bacteria occurs in the photosynthetic reaction centres. These are protein complexes containing a number of cofactors that absorb the energy of a light quantum and participate in subsequent charge separation, producing radical pairs comprised of paramagnetic radical cations and radical anions. Besides, the RC structure *a priori* contains paramagnetic ions. Therefore, EPR spectroscopy can be an efficient tool of research on the structure and operation of RC.<sup>92-95</sup>

The RC structure was the subject of a number of X-ray studies (see, *e.g.*, Refs 96-102 and references cited therein). These methods require crystallisation of samples. The spatial resolution varies from 2 to 4 Å depending on the complexity of the system and the quality of the crystals. Molecular modelling<sup>103</sup> is also a useful tool in structure analysis; here, conclusions about the structure of more complex systems are drawn based on the known data of relatively simple systems (purple bacteria RC).

Pulsed EPR studies of RC offer the following advantages. First, preparation and modification of samples (by *e.g.*, artificial replacement of cofactors) are much less labour-consuming processes compared to their crystallisation (corresponding artifacts are also ruled out). Second, higher spatial resolution permits refinement of the supramolecular structure established by other methods and in some cases facilitates the interpretation of data. Third,

the observation of photo- and thermally induced structural rearrangements becomes possible. Finally, it is possible to investigate the interrelations between the structure and the functioning of the RC, because EPR studies are directly related to the cofactors responsible for electron transfer.

The bacterial RC has the simplest structure. Corresponding data were obtained with the highest resolution, 2.3-3 Å.<sup>96-99</sup> The RC contains a primary electron donor, namely, a bacteriochlorophyll dimer, which is usually denoted as  $P_{870}$  (the subscript denotes the maximum wavelength of the optical absorption band, expressed in nanometres). Absorption of a light quantum produces a radical cation  $P_{870}^+$  and an electron, which migrates along the chain of other cofactors. The migrating electron consecutively forms corresponding radical anions. First, it arrives at the bacteriochlorophyll molecule adjacent to the dimer, then at the bacteriopheophytine molecule, at the primary quinone acceptor,  $Q_A$ , and at the secondary quinone acceptor,  $Q_B$ . Each charge separation step involves two particles (a radical pair). The dimer cation is reduced owing to electron transfer from the nearest cytochrome molecule. After absorption of two light quanta the doubly reduced  $Q_B$  is protonated to quinone and leaves the reaction centre. Its position is then occupied by another quinone from the so-called quinone pool, and the process can proceed again. The bacterial RC also contains a paramagnetic non-heme Fe(II) ion. All cofactors have their 'twins' arranged symmetrically with respect to the line connecting the centre of  $P_{870}$  and the iron ion (symmetry group  $C_2$ , the  $P_{870}$  dimer also has a symmetrical structure). Thus, there are two pathways, A and B, the charge separation process following only the former. The reason why pathway B is not involved is still unclear.

Photosynthesis in higher plants is a much more complicated process and involves consecutive operation of two RC, photosystem II (PS II) and photosystem I (PS I). It is known that operation of these RCs results, in particular, in the evolution of oxygen from water molecules. This occurs in the so-called oxygen-evolving complex (tetranuclear manganese cluster).

The structure of PS I was established by X-ray analysis with a 4 Å resolution.<sup>100</sup> In PS I, an electron is initially transferred from the primary chlorophyll donor  $P_{700}$  to the chlorophyll molecule ( $A_0$ ) and then to the phyloquinone molecule ( $A_1$ ). This results in a  $P_{700}^+A_1^-$  pair.

The structure of PS II was also established by X-ray analysis with a 3.7-3.8 Å resolution.<sup>101,102</sup> The protein backbone of PS II contains a number of cofactors analogous to the bacterial RC, *i.e.*, the chlorophyll electron donor  $P_{680}$ , pheophytine, plastoquinone and non-heme iron(II). It is believed that these cofactors also form a structure with a  $C_2$  symmetry, which is similar to the bacterial RC. Plastoquinone  $Q_B$  is transformed into plastoquinol, which becomes an electron donor for PS I *via* cytochrome  $b_6f$ ;  $P_{680}^+$  is reduced by tyrosine  $Y_Z$ . There is yet another symmetrically arranged tyrosine molecule  $Y_D$  whose function is unclear as yet.

The oxidation of the manganese cluster occurs in a stepwise manner on consecutive absorption of light quanta. As a result, absorption of four light quanta leads to splitting of two water molecules into four protons and four electrons *via* five intermediate states, namely,  $S_0$ ,  $S_1$ ,  $S_2$ ,  $S_3$ ,  $S_4$  (transition from the  $S_4$  state to the  $S_0$  state is a dark transition) and eventually gives an oxygen molecule.<sup>104</sup> A number of models for the operation of this cluster are available (see, *e.g.*, Ref. 105).

Under laboratory conditions, different states of the  $S_0-S_4$  cycle can be achieved by specific biochemical treatment, irradiation and freezing. A broad multicomponent EPR signal of tetranuclear manganese cluster with spin 1/2 is observed in the  $S_2$  state.

### 2. Stable paramagnetic pairs

$P_{870}^+-Q_A^-Fe^{2+}$  pairs in the RC of purple bacteria *Rhodobacter sphaeroides* R26 were studied<sup>106</sup> using the selective hole 'burning' technique. A distance of  $26 \pm 2$  Å determined in the experiments is in good agreement with the data of X-ray analysis. This was

treated as a substantiation of correctness of the method employed; later, this technique was used in studies of other systems.

The  $Y_Z$ – $Mn_4$  pair in PS II was investigated by saturation–recovery ESE<sup>107</sup> and a 15 Å distance was determined. Possible sources of errors in the technique were reported in another study.<sup>108</sup> It should be noted that the dipole–dipole interaction in this pair is well observed by continuous-wave EPR; analysis of the lineshape by different authors gave a distance of  $\sim 8$  Å.<sup>109–112</sup>

Measurements for the  $Y_D$ – $Mn_4$  pair in PS II were carried out by different ESE spectroscopy methods, in particular, the selective hole ‘burning’ technique.<sup>52</sup> In this approach, it is of crucial importance to exclude all sources of hole broadening except for those associated with the dipole–dipole interaction. This was achieved by comparing the spectra obtained with the spectra of a sample containing no manganese complex. To attain a better agreement with the experiments, it was assumed that the manganese complex is characterised by non-exponential spin-lattice relaxation with a small contribution (12%) of a ‘long-tail’ component. In addition, a distance distribution in the range 4–6 Å was assumed. Measurements for the  $S_2$  state gave a distance of 28 Å. A similar value of  $27 \pm 0.2$  Å was obtained by the PELDOR method.<sup>113</sup>

The results of these investigations revealed an essentially unsymmetrical arrangement of  $Y_D$  and  $Y_Z$  with respect to the manganese complex. A rather long distance from the complex to  $Y_D$  suggests that the latter is not involved in primary electron transfer.

The dipole–dipole interaction in the  $Y_D$  and  $Y_Z$  pairs in PS II was studied by the ‘2 + 1’ method<sup>114</sup> using samples depleted of manganese complex. A distance of  $\sim 30$  Å was determined. This approach was employed also to study oriented membranes.<sup>115</sup> The angle between the radius vector of the pair and the normal to the membrane surface was found to be  $100 \pm 2^\circ$ .

Oriented membranes depleted of manganese complex were studied by the ‘2 + 1’ technique.<sup>116</sup> The angle between the vector connecting  $Y_D$  and  $Chl_Z$  and the normal to the membrane was found to be  $50 \pm 5^\circ$ . The separation in the pair, obtained for a polyoriented sample, was  $29.4 \pm 0.5$  Å.<sup>116, 117</sup> The distance in the  $Y_D$ – $Q_A^-$  radical pair studied by the same method was  $38.8 \pm 1.1$  Å.<sup>117</sup>

The  $Y_D$ – $Fe(II)$  pairs in PS II were investigated by the selective hole ‘burning’ technique.<sup>106</sup> The distance was  $42 \pm 2$  Å. Calculations carried out with allowance for zero-field splitting gave a value of 0.81 for the effective spin of the ion.

Data for the  $Y_Z$ – $Fe(II)$  and  $Y_D$ – $Fe(II)$  pairs were obtained using the saturation–recovery method.<sup>118</sup> As mentioned above, the technique is inappropriate for obtaining reliable quantitative data, but qualitative information can appear to be useful. Samples depleted of manganese complex were studied. In the mutants containing no  $Y_D$  it is possible to characterise the  $Y_Z$ – $Fe(II)$  pair. It was found that  $Y_Z$  and  $Y_D$  obey identical saturation–recovery kinetics. This suggests that both tyrosines are at equal distances from  $Fe(II)$ , being arranged symmetrically with respect to  $Fe(II)$ .

## VIII. Photoinduced spin-correlated pairs in photosynthetic reaction centres of plants and bacteria

Isolated RC make it possible to investigate short-lived RPs produced after absorption of a light quantum in the course of electron transfer. For instance, no electron transfer beyond  $Q_A$  occurs in bacterial RC at low temperatures; the  $P_{870}^+Q_A^-$  pair has a lifetime of 30 ms and disappears *via* reverse recombination. The distance in the pair ( $\sim 25$  Å) makes it a convenient subject for ESE spectroscopy studies. Since the pair was born in the singlet spin state, the spins are not thermally equilibrated and we deal with a spin-correlated pair. Therefore, the use of ESE spectroscopy is of additional interest for studying spin correlation effects.

The ESE signal of a radical pair in photosynthetic RC was first detected by Thurnauer and Norris.<sup>119</sup> It was found that the signal phase is shifted by  $90^\circ$  compared to the signals of thermally equilibrated systems (the out-of-phase signal). The nature of the signal and of the phase shift remained unclear at that time. The theory of ESE in spin-correlated radical pairs was developed much later<sup>41, 42</sup> and it does predict the out-of-phase signal for spin-correlated RPs (see Section III).

This theory also predicts that an increase in the interval between pulses will cause modulation of the two-pulse ESE signal (ESEEM) at the frequency of the dipole–dipole interaction in the pair. However, first experimentally observed ESEEM<sup>120</sup> was attributed to the electron–nuclear interaction and not analysed. A long time after it was established that the electron–nuclear interaction in spin-correlated RPs does not manifest itself and the observed modulation is completely governed by the electron–electron interaction in the pair.<sup>18, 44</sup> This was substantiated not only by good agreement between the experimental and theoretical dipolar doublet but also by the results of the  $^{14}N/^{15}N$  and H/D isotope substitution experiments.<sup>18, 44</sup>

The reason for the absence of the electron–nuclear contribution in ESEEM (which strongly complicates measurements of the dipole–dipole interaction in thermally equilibrated pairs) seems to be polarisation of electron–nuclear transitions, whose lines are mutually cancelled in the frequency domain of a polyoriented sample.<sup>45</sup>

Numerous studies of RPs in photosynthetic RC by the out-of-phase ESE decay modulation have been carried out since publication.<sup>18</sup> Because of the absence of an electron–nuclear contribution, correspondence between the width of the EPR spectrum and the excitation bandwidth of an ESE spectrometer and ease of signal interpolation to the ‘dead’ time (see Section IV) the dipolar doublet appears to be similar to the theoretical one (see Figs 3 and 9). Not only the perpendicular but also the parallel orientation is well resolved. This permits determination of the distance in the pair with a very high accuracy (up to a few fractions of an Ångström) and analysis of subtle effects due to structural changes under the action of external factors.

Three types of RC, namely, bacterial, PS I and PS II ones are characterised by production of structurally similar RPs in the initial steps of electron transfer. Pairs comprised of a primary electron donor and a primary quinone acceptor are convenient for ESE studies.

### 1. Bacterial reaction centres

At low temperatures, no electron transfer from  $Q_A$  to  $Q_B$  occurs in the reaction centres of purple bacteria *Rhodobacter sphaeroides* R26, and a radical pair  $P_{870}^+Q_A^-$  with a lifetime of 30 ms is produced; then, it disappears *via* reverse recombination. This pair was studied in Zn-substituted samples.<sup>18, 44, 121, 122</sup> The out-of-phase echo signal was detected, which was strongly modulated with  $\tau$ . The distances in the pair were determined by analysing the dipolar doublet in the frequency domain. The structures of these RC were established by X-ray diffraction; therefore, one of the goals was to evaluate the new experimental technique.

It was found that the distances in the pair, obtained in different studies, are also different. According to X-ray scattering data, the distance in the pair must be 28.1 (see Ref. 98) or 29.2 Å,<sup>99</sup> but the dipole–dipole interaction in the pair corresponded to a shorter distance.<sup>18</sup> The distance in freshly prepared samples was 28.9 Å,<sup>122</sup> being in good agreement with the X-ray structural data. These discrepancies were attributed to ‘ageing’ of the sample, *i.e.*, a change in its structure in the course of long-term storage (the authors of study<sup>18</sup> used the samples kept at a liquid nitrogen temperature for months). The distance 28.4 Å<sup>44, 121</sup> is similar, within the limits of error, to the results obtained in Ref. 122.

Good correspondence with the X-ray structural data suggests that the method based on the out-of-phase echo signal decay modulation provides correct information on the distances in the

pair. It should be noted that these methods are used to study different systems. X-Ray analysis deals with a crystalline sample, does not involve exposure to light and no charges are produced in the system. ESE investigations are usually carried out with amorphous samples (although it can also be crystalline, see below), being aimed at studying a pair comprising two oppositely charged particles. Therefore, the results obtained also mean that these differences cause no pronounced structural changes. In particular, the electrostriction effects in the course of charge separation must be insignificant.

A study of the RC of *Rhodospseudomonas viridis* bacteria in Zn-substituted samples treated with *o*-phenanthroline in order to block electron transfer to  $Q_B$  was reported.<sup>123</sup> The distance in the  $P_{680}^+Q_A^-$  pair also appeared to be similar to that determined by X-ray scattering.<sup>124</sup>

The temperature dependence of the shape of the dipolar doublets found for the bacterial RC at cryogenic temperatures<sup>122</sup> was interpreted as a result of rearrangement of the RC protein backbone on changes in the temperature.

## 2. Reaction centre of PS I

Spin-correlated pairs  $P_{700}^+A_1^-$  in PS I have been the subject of considerable research.<sup>44, 121, 125–130</sup> It was found that the shape of the dipolar doublets in the Fourier transformed ESEEMs of these systems (see Fig. 9) is similar to the theoretical shape, *i.e.*, these doublets are nearly unbroadened due to other interactions (see Fig. 3). Here, spectral lines are much narrower than in the spectra of similar pairs in bacterial RC or in the reaction centre of PS II (see below). Temperature dependence was also not observed for this spectrum. Small linewidths allowed the distance in the pair to be determined with record (for this range) accuracy, namely,  $25.4 \pm 0.3$  Å.<sup>44, 121</sup> Nearly the same results were obtained in another study.<sup>125</sup> A decrease in  $r$  compared to the bacterial RC must be pointed out.

This accuracy also nearly corresponds to the width of the distance distribution in the pair. So narrow distribution for rather long distances seems to be non-trivial. It should be emphasised that the case in point is an amorphous system ( $\sim 60\%$  of the total volume is occupied by glycerol, a cryoprotector, which facilitates a low-temperature glass transition). This means that large biomolecules in an amorphous environment can exhibit a high level of structural organisation in the nanometre range of distances.

Studies of reaction centres in which phyloquinone was replaced by various synthetic quinones showed<sup>125, 128, 129</sup> that the distances in RPs in these systems remained constant within the limits of experimental error. This means that synthetic quinones are incorporated at the same binding site as the native quinones. From the EPR spin polarisation data<sup>93</sup> it follows that native and synthetic quinones are oriented in different way. The same distances in these two cases mean that the operation of  $A_1$  as electron acceptor is independent of the binding direction of quinone.<sup>128</sup>

Single crystals of the reaction centre of PS I (symmetry group  $P6_3$ , two PS I trimers in the unit cell) were studied.<sup>127</sup> Rotation of the crystal revealed a strong orientation dependence of the dipolar doublet, which allowed determination of the orientation of the axis connecting both particles in the pair. The angle was  $27 \pm 5^\circ$  relative to the  $c$  crystallographic axis and its projection on the  $ab$  plane is parallel to the  $a$  axis.

The results obtained permitted a quite correct determination of two possible positions of phyloquinone  $A_1$  in the electron transfer chain, which appeared to be related by pseudo- $C_2$  symmetry of chlorophyll cofactors. This was used in the interpretation of X-ray scattering data.<sup>131</sup>

A study of oriented membranes<sup>130</sup> showed that the angle between the direction of the  $P_{700}A_1$  pair and the normal to the membrane is  $24 \pm 4^\circ$ . Based on these results and X-ray scattering data, the direction of electron transfer in RC was suggested.

## 3. The reaction centre of PS II

Absorption of a light quantum in PS II produces a  $P_{680}^+Q_A^-$  radical pair (see Refs 130, 132–134). The width and shape of rather broad lines observed in experiments depend on the sample preparation procedure.<sup>132</sup> If the linewidths were markedly different from the theoretical values, the presence of two different types of pairs with the distances between paramagnetic centres ranging from 26 to 29 Å was assumed.<sup>132</sup> The distances in the pair obtained in other cases were  $r = 27.4 \pm 0.3$  Å,<sup>130, 133</sup>  $27.2 \pm 1$  Å,<sup>132</sup>  $27.7 \pm 0.7$  Å.<sup>134</sup> As can be seen, these results are in good agreement with one another, although one study<sup>132</sup> was carried out at 80 K and other studies near room temperature.<sup>133, 134</sup> In respect of a large linewidth the accuracy of measurements reported in Refs 130 and 133 seems to be overestimated.

The angle between the normal to the membrane and the axis of the  $P_{680}^+Q_A^-$  pair in oriented membranes was found to be  $21 \pm 5^\circ$ .<sup>130</sup>

Transformation of the dipolar doublet with an increase in the delay after application of a laser pulse with the characteristic time of the order of 1 ms was reported.<sup>133, 134</sup> This can be explained by the reduction of  $P_{680}$  tyrosine  $Y_Z$  with the formation of the  $Y_Z^{ox}O_A^-$  pair. Analysis of the dipolar doublet for this pair revealed a distance of  $34 \pm 1$  Å.<sup>134</sup>

## 4. The Kleinfeld effect

The kinetics of back recombination of the  $P_{870}^+Q_A^-$  and  $P_{870}^+Q_B^-$  pairs in the reaction centres of purple bacteria differ significantly depending on whether the sample was frozen in the light or in the dark.<sup>135</sup> It is believed that this is due to photo-induced structural changes. X-Ray studies of samples frozen in the light or in the dark were reported.<sup>136</sup> In the latter case, the  $P_{870}^+Q_B^-$  pairs were produced.  $Q_B^-$  was found to be shifted by 5 Å from the fixed position of the neutral molecule  $Q_A$ .

Comparative out-of-phase ESE investigations of the  $P_{870}^+Q_A^-$  pairs in the samples frozen in the light or in the dark were reported. No changes in the distance were detected in study<sup>137</sup> while a possible increase in the distance by  $0.4 \pm 0.2$  Å was pointed out in another study.<sup>138</sup> In this case the higher accuracy of measurements was due to the fact that two spectra with practically identical shapes were compared. However, the value determined was found to be too small to explain the Kleinfeld effect by changes in the distance between the  $P_{870}$  and  $Q_A$  cofactors. Probably, the reason consists in the motion of some polar groups of the molecules involved in charge transfer.

## 5. Temperature dependence of the supramolecular structure of bacterial reaction centres

The dipolar doublets in bacterial RC exhibit marked temperature dependences.<sup>18, 122</sup> Below 100 K the doublets are considerably broadened. This can be attributed to the appearance of a distance distribution. Comparison with the results of model calculations showed that the width of the distribution function increases from  $\sim 1$  to  $\sim 4$  Å as the temperature decreases to 15 K. At  $T < 100$  K, the distribution shape is temperature dependent; a hysteresis was observed on temperature variation.

These data point to the low-temperature dynamics of proteins constituting the RC backbone and containing (in this case) the  $P_{870}$  and  $Q_A$  cofactors under study. Certain indications of the low-temperature protein dynamics were obtained by different methods, *e.g.*, spectral hole 'burning' in optical spectra and photon echo,<sup>139–141</sup> IR echo,<sup>142, 143</sup> single-molecule spectroscopy,<sup>144</sup> Mössbauer spectroscopy,<sup>145</sup> *etc.* However, in all these cases the dynamics were studied in the atomic scale of distances. But the distances in the  $P_{870}^+Q_A^-$  pair show that these effects can be co-operative, being governed by the motion of a certain molecular cluster of nanometre size.

A study<sup>146</sup> similar to that reported in Ref. 122 was carried out at temperatures  $\sim 15$  K and below. It was found that lowering the temperature in the range 13–20 K causes a pronounced line narrowing of the dipolar doublet. This is an indication of a more

ordered state on lowering the temperature. A transition from one state to the other becomes fully reversible. Visually, it is similar to transformation of a crystal into a highly viscous liquid (this is also substantiated by the temperature hysteresis mentioned above). Such low-temperature structural transitions were not reported earlier.

This means that the energy landscape of the protein RC involves very low barriers. A photon echo study<sup>139</sup> of myoglobin revealed low barriers (about several tens of Kelvin).

An observable transition must be characterised by some possibility of structural rearrangements in the nearest environment of protein (in the nanometre range of distances). Dynamic heterogeneity in disordered molecular media, which can arise in this range of distances, has been the subject of intensive discussions.<sup>147, 148</sup>

## IX. Conclusion

Pulsed EPR spectroscopy methods based on the electron spin echo technique permit investigations of biomolecule conformations, nanostructure of polymers and the supramolecular structure of such complex objects as photosynthetic reaction centres in plants and bacteria. These methods make it possible to determine the distances between paramagnetic fragments ranging from 15 to ~100 Å with a high accuracy (e.g., 0.3 Å at  $r \approx 25$  Å in studies of spin-correlated radical pairs in PS I). High resolution allows one to obtain information on fine changes in the nanostructure of matter, occurring under the action of external factors. A marked example is provided by the dynamics of the nanostructure of a bacterial photosynthetic reaction centre at cryogenic temperatures.

Basic to the use of these methods is the presence in the system of free radicals or ions that form pairs or clusters. This situation can be realised naturally (in, e.g., photosynthetic reaction centres or in metal-containing biomolecules) or created artificially by introducing spin probes and labels (usually, based on nitroxyl radicals). At present, a wide use of spin labels is due to the development of biochemical methods of site-directed spin labelling.

Many different methods of investigation of the dipole–dipole interaction between paramagnetic centres have been proposed. The choice of a particular method for studying a given system is governed by the width of the signal in the EPR spectrum and by the relaxation times. Other properties of the system, e.g., the possibility of carrying out comparative experiments in the absence of the dipole–dipole interaction can also play a significant role. When choosing a method of investigation, simplicity of theoretical description and the absence of the masking effects produced by other interactions (in particular, electron–nuclear interaction) are of great importance. The best results in studies of nitroxyl biradicals (most widely used systems) are obtained by the PELDOR technique. Conventional two-pulse ESE spectroscopy is more convenient in studies of photoinduced spin-correlated radical pairs.

Recent advances made by researchers from different laboratories point to great prospects for structural studies of complex molecular systems by pulsed EPR spectroscopy.

The author of this review expresses his gratitude to academician Yu D Tsvetkov for his interest in this study and helpful discussions. **Abstract.** The published data on the intramolecular Diels–Alder reaction in compounds of the 2-alkenylfuran series are generalised. The methods and conditions for the preparation of tricyclic systems are considered. The effects of the substituents in the furan and the unsaturated fragments on the cycloaddition are discussed. The application of this reaction to the synthesis of alkaloids and terpenoids is exemplified. The bibliography includes 168 references.

## I. Introduction

In 1928, O Diels and K Alder<sup>1</sup> discovered the [4 + 2]-cycloaddition reaction, one of the most interesting and important, from a practical standpoint, transformations in classical organic chemistry. A quarter of a century later, Alder reported<sup>2</sup> on accomplishing, for the first time, an intramolecular version of this reaction. The same year, Dunlop published an 800-page treatise on the chemistry of furan.<sup>3</sup> This monograph provided numerous examples of intermolecular condensations where the furan ring acted as a diene. However, it was not until 1961 that the first reports on the successful involvement of furan derivatives in the intramolecular Diels–Alder reaction appeared.<sup>4</sup>

Subsequent years were marked by an increasing number of publications devoted to the intramolecular [4 + 2]-cycloaddition of furan derivatives containing unsaturated fragments. Here we shall list only the most important of them. The comprehensive reviews by Dean<sup>5,6</sup> generalise the data on the synthesis and reactivities of furan systems published between 1968 and 1979. A special chapter in the review by Kappe *et al.*<sup>7</sup> summarises the data on intramolecular cycloaddition of various unsaturated fragments (alkene, alkyne, allene) to the furan ring. The reviews<sup>8,9</sup> are devoted to the use of five-membered rings (including furan) in organic synthesis and in the synthesis of natural compounds. Some features of the [4 + 2]-cycloaddition are considered by Dell.<sup>10,11</sup> The published data on the intramolecular Diels–Alder

reaction are generalised in the reviews,<sup>12–15</sup> much attention is paid to the cyclisation of alkenylfurans. The review published in 1986 (in Japanese)<sup>16</sup> is an overview of the published data on intramolecular cyclisation of furan derivatives only. The stereochemical aspects of intramolecular [4 + 2]-cycloaddition are highlighted in the review by Craig.<sup>17</sup> And, finally, we mention the recently published papers,<sup>18,19</sup> one of which is devoted to the synthesis and reactivities of 7-oxabicyclo[2.2.1]hept-2-enes (including annelated heptenes), while the other deals with the transannular Diels–Alder reaction, and a brief survey<sup>20</sup> of studies by Padwa *et al.* on the cyclisation of *N*-alkenyl-2-aminofurans.

The aim of this review is to generalise the experimental results of the intramolecular cycloaddition in compounds of the alkenylfuran series. The thermal and catalytic cycloaddition reactions in 2-alkenylfurans **1** will be considered where the furan ring plays the role of a diene (Scheme 1).

Scheme 1

This conversion results in the tricyclic compounds **2–4** containing a five-, a six- or a seven-membered ring, respectively, annelated to the 7-oxabicyclo[2.2.1]hept-2-ene fragment. The annelated ring may contain heteroatoms (as a rule, oxygen, sulfur or nitrogen).

It is noteworthy that all the attempts to use this method for the preparation of this type of derivative with a four-membered third ring were unsuccessful, while the synthesis of furan derivatives with a more than seven-membered annelated ring has not been documented so far. This review encompasses the data, most of which were published mainly between 1988 and 2003.

## II. The transannular Diels–Alder reactions in alkenylfurans

It was not until 1996 that a new report on the transannular cycloaddition in the furan series came out following the pioneering works dating back to the 1960's.<sup>21</sup> Using <sup>1</sup>H NMR spectroscopy, it was demonstrated that the macrocyclic ester **5** containing a furan fragment and the transannular cycloadduct **6** are in equilibrium at elevated pressure. Presumably, the formation of compound **6**, which is unstable at atmospheric pressure and contains two seven-membered lactone rings fused to the oxabicycloheptene ring, is unfavourable.

The tetracycles **7** contained two five- and/or six-membered annelated rings (in one case together with a diastereomer **8**).<sup>22</sup> The macrocyclic allenic ketones **9** were used as the starting compounds, they underwent cyclocondensation into the corresponding furans **10** catalysed by silver salts in the presence of CaCO<sub>3</sub> in aqueous acetone (Scheme 2).

Scheme 2

(a) AgNO<sub>3</sub>, CaCO<sub>3</sub>, Me<sub>2</sub>CO, H<sub>2</sub>O; (b) CHCl<sub>3</sub>, 25 °C, 52 h; (c) PhMe, 80 °C, 3 h; MOM is methoxymethyl.

| R    | n | m | Conditions of cycloaddition | Yield (%) |                 |
|------|---|---|-----------------------------|-----------|-----------------|
|      |   |   |                             | <b>10</b> | <b>7</b>        |
| H    | 1 | 1 | b                           | 80–90     | 100             |
| MOMO | 1 | 1 | b                           | 80–90     | 100             |
| MOMO | 2 | 1 | c                           | 95        | 93 <sup>a</sup> |
| MOMO | 2 | 2 | c                           | 95        | 96              |

<sup>a</sup> Compound **8** was also obtained in 5% yield.

Like the original allenes **9**, the furans **10** contained a *cis*-CH=CH bond. At room temperature or upon brief heating, these compounds cyclise into the tetracyclic derivatives **7**. It is of note that the mixture of the diastereomers **7** and **8** (95 : 5) is formed only from the furan with *n* = 1, *m* = 2; in all other cases, this reaction occurs stereoselectively and yields only one diastereomer. The isomers of the macrocycles **10** having a *trans*-configuration of the endocyclic double bond do not undergo the Diels–Alder condensation.<sup>22</sup>

Toró *et al.* suggested<sup>23,24</sup> that the transannular Diels–Alder reaction was used in the synthesis of the diterpene (+)-chatancin **11** isolated from the corals *Sarcophyton sp.* The reaction sequence relied on the retrosynthetic analysis of the natural diterpene and

included the intramolecular transesterification of compound **12**, which is the intermediate cyclisation product of the alkenylfuran **13**.

A large series of model furans **14** containing alkenyl substituents have been synthesised.

(a) Cs<sub>2</sub>CO<sub>3</sub> (10 equiv.), MeCN, Δ; R<sup>1</sup> = H, Bn, Bz; R<sup>2</sup> = H, E; R<sup>3</sup> = Pr<sup>i</sup>, R<sup>4</sup> = H; R<sup>3</sup>–R<sup>4</sup> = S(CH<sub>2</sub>)<sub>3</sub>S; E = CO<sub>2</sub>Me.

The intramolecular nucleophilic substitution of chlorine in the substituted furans **14** gives the macrocycles **15** (yields 15%–46%). Depending on the nature of the substituents in the alkenyl fragment [e.g., for R<sup>1</sup> = Bn, R<sup>2</sup> = H, R<sup>3</sup>–R<sup>4</sup> = S(CH<sub>2</sub>)<sub>3</sub>S] and the reaction conditions (e.g., under high dilution, 2 mmol litre<sup>–1</sup>), the latter can be isolated from the reaction mixture. However, compounds **15** are prone to further spontaneous intramolecular cyclisation. This affords mixtures in which the geometrical isomers **16** and **17** (total yield 80%–93%) predominate. It has been found that the conversions **15** ⇌ **16** ⇌ **17** were reversible, and that the isomer ratio depended on the polarity of the solvent used. However, the attempts to apply the retrosynthetic scheme to the synthesis of the target diterpene have been unsuccessful so far.<sup>24</sup>

## III. Tandem intramolecular cycloaddition in bisfurans

A series of transformations given below represents a two-step one-pot synthesis of bisfuran systems. Formally, the definition 'intramolecular cycloaddition of unsaturated compounds to bisfurans' can only be applied to the second step of this reaction, since the first step represents an intermolecular process. Examples of these elegant domino syntheses are scarce due to the low availability of difuryl derivatives. For the first time, the tandem intramolecular cycloaddition in bisfurans was described<sup>25</sup> for the reaction of (*E,E*)-4-oxohepta-2,5-diene (**18**) with 1,1-difurylthane **19** at elevated pressure. Diepoxyanthracene **20** is formed in a nearly quantitative yield.

A detailed study of this type of intramolecular cycloaddition was carried out by the Canadian chemists Lautens and Fillion,<sup>26, 27</sup> who developed efficient procedures for the synthesis of difuryls **21** including those containing heteroatoms in the bridging alkanediyl chains.

$\text{X} = \text{CH}_2, \text{O}, \text{S}, \text{NBn}, \text{NC}_6\text{H}_4\text{OMe-4}$ ;  $\text{R}^1 = \text{H}, (\text{CH}_2)_3\text{Cl}$ ;  
 $\text{R}^2 = \text{H}, \text{Me}, \text{Ac}, \text{CO}_2\text{H}, \text{CO}_2\text{Me}, \text{SO}_2\text{Ph}$ ;  
 $\text{R}^3 = \text{Ac}, \text{CO}_2\text{H}, \text{CO}_2\text{Me}, \text{SO}_2\text{Ph}, \text{Ts}$ .

Alkynes containing electron-withdrawing substituents add to difuryls **21** in a regio- and stereospecific manner to give the *exo,exo*-adducts **22** (yields 63%–83%). The adduct of methyl 4-oxopent-2-ynoate ( $\text{R}^2 = \text{CO}_2\text{Me}$ ,  $\text{R}^3 = \text{Ac}$ ) with 1,3-bis(2-furyl)propane ( $\text{X} = \text{CH}_2$ ), which represents a mixture of two stereoisomers (4:1), is an exception. The introduction of even one electron-donor substituent into the alkyne component results in complete inhibition of the cycloaddition reaction.

No sequential pincer-type [4 + 2]-cycloaddition occurs with 1,2-bis(2-furyl)ethane and 1,4-bis(2-furyl)butane (**23**).<sup>26, 27</sup> The reaction with an equimolar amount of dimethyl acetylenedicar-

boxylate (DMAD) yields linear adducts to one or two alkyne molecules (compounds **24** and **25**, respectively).

| <i>n</i> | Yield (%) |           |
|----------|-----------|-----------|
|          | <b>24</b> | <b>25</b> |
| 2        | 38        | 16        |
| 4        | 38        | 22        |

## IV. Oxabicycloheptenes fused to various rings

### 1. Five-membered rings

#### a. Synthesis of 3-aza-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes

The intramolecular cyclisation of substituted *N*-allylfurfuryl-amines **26**, which yields 5,7*a*-epoxyisoindoles (3-aza-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes) **27**, is the most studied intramolecular [4 + 2]-cycloaddition reaction in the 2-alkenylfuran series by virtue of high availability of the starting compounds (unsaturated fufurylamines) and smooth reaction (Table 1).

It has been found that the thermal intramolecular Diels–Alder cycloaddition of the non-substituted allylfurfurylamine and its *n*-alkyl derivatives cannot be realised even under drastic conditions.<sup>28, 29</sup> A prerequisite for the cyclisation is the presence

**Table 1.** Cyclisation of substituted allylfuran-2-ylmethylamines **26**.

<sup>a</sup> In the case of compounds **26i–o**, the reaction was carried out in an NMR tube until equilibrium was reached. The reaction time is not indicated; the calculated yields are given; <sup>b</sup> the formation of the reaction product takes place even at 20 °C.

of a bulky group R (compounds **26b–e**) or a substituent able to induce the transition of the nitrogen atom into the planar state (compounds **26f–o**)<sup>28–31</sup> (see Table 1).

In contrast to *N*-aralkyl derivatives, the cyclisation of amides and sulfonamides **26f–o** occurs more smoothly: the reaction is usually complete within several hours at 70–110 °C.<sup>28,31</sup> This cycloaddition is reversible, but, as can be evidenced from the data listed in Table 1, the reaction equilibrium is always shifted towards the cycloadduct (the yields of the isoindoles **27f–o** are no less than 60%).

Thermal cyclisation of *N*-allyl-*N*-furfurylamine hydrochlorides **28** in 3 M HCl is accompanied by aromatisation of the tricycles **29** resulting in the isoindolium salts **30** in good yields.<sup>32,33</sup>

$R^1, R^2 = \text{H, Me, Et, Allyl, Pr}^i, \text{Bu}^n, \text{Bu}^i, \text{Ph};$   
 $R^1-R^2 = (\text{CH}_2)_5, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2.$

UV spectroscopic studies have shown<sup>34,35</sup> that the rate of formation of epoxides **29** ( $\text{H}_2\text{O}$ , 83 °C) depends on the nature of the substituents ( $R^1, R^2$ ) at the nitrogen atom and decreases in the order:  $(\text{CH}_2)_5 > \text{O}[(\text{CH}_2)_2]_2 > \text{Et}$ ,  $\text{Et} > \text{Me}$ ,  $\text{All} > \text{Me}$ ,  $\text{Me} > \text{Me, Ph}$ .

The regularities of the cyclisation of the substituted *N*-allyl-furfurylamines **31** into 3-aza-10-oxabicyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes **32** have been studied in detail.<sup>36–40</sup>

$R^1 = \text{H, Me, OMe, I, NO}_2; R^2 = \text{Ac, Cl}_3\text{CCO, 4-MeC}_6\text{H}_4;$   
 $R^3 = \text{H, PhSO}_2; R^4, R^5 = \text{H, Me}; R^6 = \text{H, CH}=\text{CH}_2.$

It has been established<sup>36</sup> that electron-withdrawing groups at position 5 of the furan ring ( $R^1$ ) increase, while electron-donor groups, contrariwise, decrease the activity of the diene fragment in the [4+2]-cycloaddition reaction. Thus the reaction rates and the yields of the cycloaddition products of 5-nitro- and 5-iodofurfurylamines **31** are higher than those of the 5-methyl- or 5-methoxy derivatives. Studies of the substituent effect in the dienophilic fragment of furans **31** on the cyclisation have shown<sup>36,39</sup> that the yields of the adducts **32** decrease drastically (from 75% to 0%) for a compound with  $R^1 = R^3 = R^6 = \text{H}$ ,  $R^2 = 4\text{-MeC}_6\text{H}_4$  with an increase in the number of the methyl groups at the double bond, *i.e.*, on going from the *N*-allyl- to the but-2-enyl- and then to the isopentenyl substituent. This fact is attributed<sup>36</sup> to greater steric hindrance created by the alkyl substituents in the transition state. In the case of the *N*-acyl derivatives **31**, the yields of the products **32** are rather high (62%–83%) irrespective of the sizes and electronic effects of the substituents  $R^3$  and  $R^6$ . Interestingly, epoxyisoindoline **32** ( $R^1 = \text{OMe}$ ,  $R^2 = 4\text{-MeC}_6\text{H}_4$ ,  $R^3 = R^5 = R^6 = \text{H}$ ,  $R^4 = \text{Me}$ ) is unstable and undergoes quantitative dehydration into the corresponding isoindole in the course of chromatographic isolation.<sup>36,38</sup> The aromatisation of some other 3-aza-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes **32** demands acidic conditions (*e.g.*,  $\text{HBr} - \text{AcOH}$ ).<sup>37,38</sup>

A one-pot procedure for the synthesis of epoxyisoindolines **32**, which involves alkylation of *N*-aryl-*N*-furfurylamines with allyl bromide in boiling benzene, has been developed.<sup>41</sup> The intermediate *N*-allyl derivatives **31** ( $R^3 = R^4 = R^5 = \text{H}$ ) are converted into the corresponding oxabicycloheptenes **32** as a result of intramolecular [4+2]-cycloaddition.

Acylation of furfurylamines **33** by  $\alpha,\beta$ -unsaturated carboxylic acid anhydrides or chlorides **34** (usually, by maleic, fumaric, acrylic and cinnamic acid derivatives) affords the unsaturated amides **35**. As the double bonds of the latter are activated by the electron-withdrawing carbonyl group, the unsaturated fragment becomes an active dienophile. As a rule, the amides of the type **35** cannot be isolated, since they are immediately cyclised into azaoxatricyclo[5.2.1.0<sup>1,5</sup>]decenones **36** (Table 2).

The effect of the substituents in the dienophilic fragment of *N*-furfurylamides **35** on the yield of epoxyisoindolones **36** has been studied in detail.<sup>42–51</sup> The data presented in Table 2 prompt the following conclusions.

1. The presence of a substituent  $R^4$  at the nitrogen atom is a prerequisite for the formation of epoxyisoindolones **36**. If  $R^4 = \text{H}$ , the reaction is stopped in the step of formation of the amide **35**.

2. Electron-withdrawing substituents in the dienophilic fragment favour the cycloaddition. If two such substituents are present at the double bond of the acylating reagent **34**, no heating is required for the cycloaddition, which occurs spontaneously at room temperature.<sup>42,45,48–50</sup> Thus the presence of an electron-withdrawing  $\text{CF}_3$ -group in the alkenyl fragment increases significantly the yield of the Diels–Alder adduct in comparison with its analogue possessing a donor Me-group (see Table 2).<sup>43</sup> Even weak donor substituents in the alkenyl fragment, *e.g.*, methyl groups, decelerate the cycloaddition reaction (long-term heating at 80–110 °C is required), however, without any appreciable effect on the product yield. No examples of successful cycloaddition in alkenylfurans containing two donor substituents in the dienophilic fragment are documented in the literature.

3. The data on the effects of substituents in the furan ring on the [4+2]-cycloaddition in compounds **35** are ambiguous. The published data<sup>44,47,52</sup> suggest that the donor substituents at positions 4 (see Ref. 47) and 5 (see Refs 44 and 52) of furan favour intramolecular cycloaddition. With the exception of 2-alkenyl-5-nitrofurans,<sup>53</sup> only one example of a successful synthesis of 3a,6-epoxyisoindolones **36** starting from *N*-alkenylfurfurylamines containing an electron-withdrawing substituent in the furan ring has been described in the literature.<sup>52</sup>

4. The sizes of substituents at the double bond are less critical for the reaction than their electronic effects.

Special mention should be made of the efficient one-step synthesis of substituted 4-oxo-3-aza-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes **36**, by the reaction of *N*-benzyl-*N*-furfurylamines with  $\alpha,\beta$ -unsaturated acids in the presence of a catalytic system DIC–DIEA–DMAP (see Table 2).<sup>44</sup> This reaction proceeds under mild conditions in good yields.

**Table 2.** Preparation of substituted azaoxatricyclo[5.2.1.0<sup>1,5</sup>]decenones **36**.

<sup>a</sup> The acylation was carried out using a corresponding anhydride; <sup>b</sup> toluene can also be used as a solvent; <sup>c</sup> the intermediate amide **35** was isolated;<sup>d</sup> a 1,3-diisopropylcarbodiimide (DIC)–diisopropylethylamine (DIEA)–4-dimethylaminopyridine (DMAP) system was used as a catalyst.Abbreviations: Cy is cyclo-C<sub>6</sub>H<sub>11</sub>, Ment is menthyl, 2-Th is 2-thienyl, *m*-Tol is 3-MeC<sub>6</sub>H<sub>4</sub>, MeAll is CH<sub>2</sub>=CMeCH<sub>2</sub>.

A similar intramolecular cycloaddition in *N*-furfuryl- $\beta$ -chloroacrylamides **37** is the key step in the synthesis of the antibiotic ivermectin of the penicillin series possessing a broad spectrum of antiparasitic activities.<sup>54</sup> The chloro-substituted tetracyclic compounds **38** are formed as mixtures of diastereomers.

$R^1 = \text{H, Pr}^i$ ;  $R^2 = \text{Me, CH}_2\text{OBn}$ .

The regioselectivity of the cycloaddition of citraconic (methylmaleic) anhydride to furfurylamines **39** in benzene has been studied.<sup>52, 55</sup> Depending on the temperature and the nature of the substituents in the furan ring, this reaction follows one of two pathways to yield isomeric methyl-substituted epoxyisindolinones **40** and **41** (Table 3).

The yields of the cycloaddition products **40** and **41** depend on the electronic effects of the substituents in the furan ring: donor groups (*e.g.*, SMe) favour the cycloaddition, while electron-withdrawing groups ( $\text{CO}_2\text{Alk}$ ) hinder this process. Their position (3 or 4) has no appreciable effect on the reaction (see Table 3).

This reaction occurs in two steps. The first step includes the acylation of furfurylamine. NMR spectroscopic studies (the reaction in an NMR tube) have shown that the cycloaddition of citraconic anhydride to *N*-benzylfurfurylamine **39** ( $R^1 = R^2 = R^3 = \text{H}$ ,  $R^4 = \text{Bn}$ ) is reversible.<sup>55</sup> In the majority of cases, the amine attacks both carbonyl groups of the anhydride at room temperature (25 °C), *i.e.*, the acylation is non-regioselective and yields two regioisomers, *i.e.*, **40** and **41**. With an increase in the temperature, the thermodynamically less stable isomer **40** undergoes degradation to the starting furfurylamine **39** which undergoes acylation and cyclisation to yield eventually the isomer **41**. This process is discussed in detail by Murali *et al.*<sup>52</sup>

3*a*,6-Epoxyisindolinones **42** and **43** have recently been synthesised using the four-component Ugi reaction.<sup>56</sup>

**Table 3.** Cycloaddition of citraconic anhydride to furfurylamines **39**.

This multicomponent synthesis is carried out under mild conditions and, depending on the nature of the starting compounds (it is the aldehyde and the amine components that are usually varied), affords high yields of epoxyisindolinones **42** or **43**. The introduction of substituted substrates enables variation of substituents at positions 2, 3, 6 and 7 of the oxazatricyclo[5.2.1.0<sup>1,5</sup>]decene system.

This conversion was also accomplished in a solid-phase version where the AgroGel-Rink resin was used.<sup>56, 57</sup> In this case, the role of the amine component is played by glycineamide **44** bound to the polymeric support.

(P) is a polymeric support; TMOF is trimethyl orthoformate; HOAt is 1-hydroxy-7-azabenzotriazole.

Two modifications of this reaction exist. One of them represents a solid-phase version of the Ugi reaction (route *a*) with the direct formation of the products **45**; the second variant is a consecutive two-step process (route *b*). In the latter case, the reactions of the intermediate furfurylamine **46** with acrylic acid derivatives also yield epoxyisindolinones **45**. Acylation of the amine with maleic anhydride gives the polymer-bound compounds **47** containing an additional functionalisation site, *i.e.*, a carboxy group. In the final step, the reaction product is liberated from the polymeric substrate by treatment with trifluoroacetic acid. The acids **47** were used as starting compounds for the synthesis of a large library of amides and esters.<sup>57</sup>

A series of original investigations<sup>58–60</sup> have been carried out by Spanish chemists who were the first to perform the synthesis of non-substituted 3-aza-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-ene **48** (R<sup>1</sup> = R<sup>2</sup> = H) and to isolate its optical isomers in the individual state.<sup>58</sup> An (–)-8-aminomenthol derivative was used as a chiral inducer in the asymmetric synthesis (Scheme 3).

Acylation of optically active 2-furyltetrahydro-1,3-oxazines **49** with unsaturated acid chlorides gives intermediate alkenylfurans **50** which are spontaneously converted into isomeric oxazinoisindoles **51**. The latter are formed in high yields as mixtures of two diastereomers; their ratios depending on the temperature of the reaction, the nature of the solvent and the Lewis acid used as a catalyst. Toluene, CH<sub>2</sub>Cl<sub>2</sub> or hexane are used as solvents; the non-catalysed cycloaddition proceeds smoothly at 0 °C and that in the

R<sup>1</sup>, R<sup>2</sup> = H, Me; Cat = ZnCl<sub>2</sub>, Ti(OPr<sup>i</sup>)<sub>4</sub>, BF<sub>3</sub>·Et<sub>2</sub>O, Et<sub>2</sub>AlCl, Me<sub>3</sub>Al, AlCl<sub>3</sub>; PCC is pyridinium chlorochromate.

Scheme 4

presence of catalysts at  $-23^{\circ}\text{C}$ .<sup>59</sup> Reduction of the 1,3-oxazine fragment in the polycycles **51** with aluminium hydride yields individual optically active stereoisomeric amino alcohols **52** (yields 80%–94%). Subsequent oxidation of the hydroxy group with pyridinium chlorochromate and base-catalysed retro-Michael reaction yield the target compounds **48** (see Scheme 3).<sup>58, 59</sup>

The [4+2]-cycloaddition of the structurally similar isomeric alkenylfurans **53** and **54**, which are devoid of the carbonyl group, takes place only upon long-term boiling in toluene, resulting in fused hexahydroisindoles **55** and **56**, respectively. It is interesting to note that hexahydroepoxyisindole **48** formed upon oxidation and alkaline degradation of the polycycle **55** (R<sup>1</sup> = H, R<sup>2</sup> = Ph) is unstable and undergoes spontaneous retro-Diels–Alder reaction to alkenylfuran **57**. Oxaazatricyclodecenes **58** were obtained from oxasinoisindoles **56** (Scheme 4). Cycloaddition of *N*-furfurylidenetriptamines served as a basis for the development of an elegant procedure for the preparation of fused tetrahydro- $\beta$ -carbolines and the shortest route to the construction of the carbon skeleton of the natural alkaloid noryochimbine.<sup>61, 62</sup>

Acylation of furyl-substituted tetrahydro- $\beta$ -carbolines **59** (synthesised by the Pictet–Spengler method) with maleic anhydride or  $\alpha,\beta$ -unsaturated acid chlorides gives the amides **60** and **61**.<sup>62</sup> Intramolecular cycloaddition in these amides yields the corresponding adducts **62** and **63** containing both tetrahydrocarboline and isindole rings (Table 4, route *a*). Such an approach enables the construction of a noryochimbine skeleton with a broad array of substituents in both the indole and isindole fragments (Scheme 5).

In some cases, furyl-substituted tetrahydro- $\beta$ -carbolines are prepared *in situ* (route *b*). Although this approach has been

applied to compounds that are not characterised by a broad array of substituents, it enabled one-step synthesis of the derivatives **62** (see Table 4).<sup>61</sup> Azomethines derived from tryptophan **64** were acylated with maleic anhydride under mild conditions. The intermediate *N*-acyl derivatives **65** underwent the Pictet–Spengler cyclisation and the intramolecular Diels–Alder cycloaddition to give the heterocyclic adducts **62** in high yields.

An interesting example of an intramolecular attack of an *N*-cyclopropylidene dienophile on the furan ring of the alkenes **66** has been described.<sup>63</sup> This reaction yields epoxyisindolines **67** only at elevated pressure, not at atmospheric pressure.

Conversions of 2-alkenylfuran metal complexes are documented.<sup>49, 50, 64</sup> Heating of the coordination molybdenum, tungsten and manganese carbonyl compounds **68** in inert solvents yields hydrogenated epoxyisindoles **69** (Table 5). These complexes are crystalline compounds that are relatively stable in air. No cyclisation of *N*-unsubstituted analogue **68** (R<sup>1</sup>, R<sup>2</sup> = H, X = O) occurs even upon long-term heating; the same was observed with certain metal complexes (see Table 5). The nitrogen atom in the complexes **68** does not undergo inversion, therefore, the derivatives **69** are formed as pairs of geometrical isomers that can be separated by chromatography.

**Table 4.** Preparation of isindolotetrahydrocarbolines **62** and **63**.

The cyclisation of tungsten pentacarbonyl complexes occurs most easily. The cyclopentadienyl–molybdenum complex possessing stronger electron-donor properties and manganese carbonyl complexes are characterised by moderate reactivities. The organometallic complex **69** (R<sup>1</sup> = All, R<sup>2</sup> = H) can easily be oxidised to the amide **70** by treatment with (NH<sub>4</sub>)<sub>2</sub>Ce(NO<sub>3</sub>)<sub>6</sub>.

Cyclisation of *N*-furfuryl-*N*-phenylfumaramide acid and the corresponding ethyl ester at high pressures has been studied.<sup>65</sup> The kinetic parameters of this reaction were established at different temperatures and pressures.

#### b. Synthesis of 3,10-dioxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes

The intramolecular cycloaddition of furfuryl esters of α,β-unsaturated acids is more complex than that of their nitrogen analogues and is studied in lesser detail. Like the cyclisation of nitrogen-containing alkenylfurans, this reaction yields only *exo*-isomers of 3,10-dioxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes.

Acylation of furfuryl alcohols with acryloyl chloride and fumaric acid monomethyl ester chloride afforded the unsaturated esters **71** (X = O); their intramolecular cyclisation yielded the diastereomers **72** and **73** (Table 6).<sup>66,67</sup> A similar reaction of the allylic derivative **71** (R<sup>1</sup>–R<sup>3</sup> = H, X = 2 H) (170–200 °C, 18 h) also resulted in a mixture of compounds **72** and **73** (X = 2 H) in a total yield of 35%.<sup>67</sup>

**Table 6.** Intramolecular cyclisation of furfuryl esters **71**.

<sup>a</sup> The reaction was carried out on diatomite in the absence of solvent; <sup>b</sup> the products **72** and **73** were not isolated and their ratio was not determined.

This reaction was studied in an NMR tube (CD<sub>3</sub>CN, 25 °C) by determining the half-conversion times (*t*<sub>1/2</sub>) of the starting compounds **71**. It was found that the cyclisation rates of the non-substituted (R<sup>1</sup> = R<sup>2</sup> = H) and monomethyl-substituted (R<sup>1</sup> = Me, R<sup>2</sup> = H) esters **71** were very low: *t*<sub>1/2</sub> = 665 and 133 h, respectively. In contrast, in the case of dimethyl, cyclobutane and cyclopentane derivatives [R<sup>1</sup>–R<sup>2</sup> = Me<sub>2</sub>, (CH<sub>2</sub>)<sub>3</sub>, (CH<sub>2</sub>)<sub>4</sub>] the intramolecular Diels–Alder reaction occurred fast: the conversion of the starting compounds was complete within less than 11 h. However, the reaction rate dropped drastically (*t*<sub>1/2</sub> = 145 h) on going to the cyclopropane homologue **71** [R<sup>1</sup>–R<sup>2</sup> = (CH<sub>2</sub>)<sub>2</sub>]. These findings led Jung *et al.*<sup>66–68</sup> to suggest that the *gem*-dialkyl substituents R<sup>1</sup> and R<sup>2</sup> strongly influence the formation of the cycloadducts **72** and **73**.

This phenomenon is often referred to as the Thorpe–Ingold effect (or the internal angle compression effect). Its essence is that the so-called internal angle *Q* (*Q*<sub>1</sub> < *Q*<sub>2</sub> < *Q*<sub>3</sub>) decreases with an increase in the number and sizes of substituents at the sp<sup>3</sup>-hybridised carbon atom in the side chain.

R = Alk.

For the cases under consideration, the magnitude of the internal angle *Q* depends on the nature of the substituents R and decreases in the following order: H, H > H, Alk > Alk, Alk. The ordering of the transition state, *i.e.*, the entropy factor, increases with the decrease in the internal angle *Q*, as a result of which the rate of the intramolecular [4+2]-cycloaddition in this series of compounds also increases.

The cyclisation of optically active furfuryl esters has been studied.<sup>68</sup> At high temperatures and at elevated pressure, the racemic mixtures of the enantiomeric esters **71** are converted into the diastereomeric adducts **72** and **73** (see Table 6), while the cycloaddition of chiral starting compounds occurs stereoselectively. By illustration, the cycloaddition of the *S*-enantiomer **74** gives only one *exo*-isomer **75**.<sup>68</sup>

Cyclopropenylideneethyl furfuryl ethers **76** enter into the Diels–Alder reaction in the same manner as their nitrogen analogues **66**, *i.e.*, at elevated pressure. The *exo*-adducts **77** are formed in virtually quantitative yields.<sup>63</sup>

R<sup>1</sup> = H, Me, OMe; R<sup>2</sup> = H, Me.

The intramolecular cyclisation in the series of 2-allyloxymethylfuran metal complexes has also been described. However, thermolysis of the tungsten-containing complex **78** yields, in addition to the expected *exo*-adduct **79** (10%), the complex **80** (5%) as a result of extrusion of one CO ligand.<sup>49</sup>

### c. Synthesis of 3-thia-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes

Before 2003, there were only three publications devoted to the synthesis of oxabicycloheptene systems annulated with the tetrahydrothiophene ring.<sup>69–71</sup> The reason for the low interest in reactions of alkenyl furfuryl sulfides **81** is not clear, since alkyla-

tion of furfurylmethanethiols with alkenyl halides normally proceeds in good yields. Subsequent intramolecular [4 + 2]-cycloaddition affords the Diels–Alder adducts **82**, which are also *exo*-isomers.

| Me                                                                  | Me                 | Me                 | 92        | 69     |

It is noteworthy that in the case of 3-substituted furans **81** (R<sup>3</sup> = Alk, Br) the yields of the sulfides **82** are significantly higher. This fact is attributed to the interaction between the bulky sulfur atom and the  $\alpha$ -methylene fragment, on the one hand, and the substituent R<sup>3</sup>, on the other hand, which leads to the approximation of the alkenyl and diene fragments in the starting alkenylfuran. In addition, the structure of the adduct **82** is such that the steric interaction between these substituents decreases.

Attempts to perform the cyclisation of sulfides of the type **83** were unsuccessful: the products **82** were either not formed at all, or were formed in trace amounts (< 5%).

R = (*E*)-CH=CHMe, CMe=CH<sub>2</sub>, CH=CHMe<sub>2</sub>,  
(CH<sub>2</sub>)<sub>n</sub>CH=CH<sub>2</sub> (n = 1, 2).

#### d. Synthesis of 10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-enes

In one of the earliest studies<sup>72</sup> devoted to the synthesis of oxatricyclodecene systems the effects of substituents in the substrate molecule on the intramolecular cyclisation were investigated. It was found that the unsubstituted alkenylfuran **84** could not be converted to the tricyclic compound **85** (and/or **86**). The presence of at least two substituents in the side alkenyl chain is a prerequisite for the cyclisation of compound **84**.

The addition, to the reaction medium, of  $\alpha$ - or  $\beta$ -cyclodextrin ( $\alpha$ -CD or  $\beta$ -CD), a cyclic oligomer built up of six or seven 1,4-linked  $\alpha$ -D-glucopyranose residues, significantly (by 10%–20%) increases the yield of the isomeric cycloadducts **85** and **86**.<sup>72</sup> In the authors' opinion, the effect of cyclodextrins can be attributed to the incorporation of the starting alkene molecule into the cavity of the carbohydrate macromolecule as a result of which the alkene and the furan fragments are brought closer to each other. The size

of the  $\beta$ -cyclodextrin cavity is probably best suited to the binding of 2-alkenylfuran and its use should be preferred.

The effects of solvents on the cyclisation of furan **84** [R<sup>2</sup>–R<sup>3</sup> = S(CH<sub>2</sub>)<sub>3</sub>S] have been studied.<sup>73</sup> The best yields of the epimers **85** and **86** were attained with protic solvents (water–ethanol, ethylene glycol); their ratios do not depend on the nature of the solvent. The cycloaddition rate of alkenylfurans **84** increases with an increase in the size of the substituents R<sup>2</sup> and R<sup>3</sup>, with a concomitant shift of the reaction equilibrium towards the cyclisation products,<sup>74</sup> apparently due to the manifestation of the *gem*-dialkyl effect (see above).

The effect of substituents in the alkyl chain and their relative position on the composition of the intramolecular [4 + 2]-cycloaddition products of the isomeric dithianes **87** (the *syn*-isomer) and **88** (the *anti*-isomer) has been studied.<sup>75</sup> These reactions afford the diastereomeric pairs **89–90** and **91–92**, respectively.

X = OR<sup>2</sup>, Y = H (**87**, **89**, **90**); X = H, Y = OR<sup>2</sup> (**88**, **91**, **92**).

| R <sup>1</sup> | R <sup>2</sup> | t / days | Ratio   |         | Yield (%) |
|----------------|----------------|----------|---------|---------|-----------|
|                |                |          | 89 : 90 | 91 : 92 |           |
| H              | H              | 2        | 1 : 1   | —       | 95        |
|                |                | 4        | —       | 1 : 1   | 95        |
| Bn             | Bn             | 3        | 1 : 99  | —       | 82        |
|                |                | 2        | —       | 1.1 : 1 | 84        |
| Ac             | Ac             | 4        | 1 : 3.4 | —       | 80        |
|                |                | 2        | —       | 2 : 1   | 90        |
| THP            | Bn             | 2        | 1 : 99  | —       | 91        |
|                |                | 3        | —       | 9 : 1   | 89        |

THP is tetrahydropyranyl.

It has been found<sup>75</sup> that an increase in the size of the substituents R<sup>1</sup> and R<sup>2</sup> in *syn*-alkenylfurans **87** favours the formation of the diastereomers **90** with a *trans*, *trans*-configuration of the substituents OR<sup>1</sup> and OR<sup>2</sup> relative to the epoxide bridge. In the case of benzyl substituents, the reaction proceeds in a stereoselective manner and yields only compounds **90**. The stereodirection of the intramolecular cycloaddition of the *anti*-isomers **88** also depends on the size of the substituents R<sup>1</sup> and R<sup>2</sup>, but this effect is not as pronounced as in the previous case and the yield of the adduct **91** is increased. It was found also that the change in the solvent polarity (methylcyclohexanone and aqueous ethanol were used) had no appreciable effect on the stereospecificity of the cycloaddition reaction.

Cyclisation of 4-[(2-furyl)hydroxymethyl]-5,5-dimethylhex-1-ene **93a** in benzene and in toluene at 80 and 111 °C afforded only one geometrical isomer (**94**) in 70% and 60% yields, respectively. The lower yield of the adduct **94** at higher temperatures was

thought to be due to the retro-Diels–Alder reaction.<sup>76</sup> Cyclisation of 5-(2-furyl)pent-1-enes **93b–d** containing a 4-sulfonyl group (benzene, 80 °C) yielded mixtures of isomers **95** and **96**.<sup>77</sup>

| Compound <b>93</b> | R <sup>1</sup> | R <sup>2</sup>                  | R <sup>3</sup> | Product        | Yield (%) | Ref. |
|--------------------|----------------|---------------------------------|----------------|----------------|-----------|------|
| <b>a</b>           | OH             | Bu <sup>t</sup>                 | H              | <b>94</b>      | 70        | 76   |
| <b>b</b>           | H              | SO <sub>2</sub> Me              | OH             | <b>95 + 96</b> | 78        | 77   |
| <b>c</b>           | H              | SO <sub>2</sub> Ph              | OH             | <b>95 + 96</b> | 93        | 77   |
| <b>d</b>           | H              | SO <sub>2</sub> Bu <sup>t</sup> | OH             | <b>95 + 96</b> | 97        | 77   |

It is of note that  $\delta$ -alkenylfuran **93** (R<sup>1</sup> = OH, R<sup>2</sup> = R<sup>3</sup> = H) gives no intramolecular cycloaddition products.<sup>76</sup>

The addition of trimethylsilyl cyanide (TMSCN) to furyl ketone **97** in the presence of zinc iodide is accompanied by intramolecular cycloaddition.<sup>77</sup> A mixture of the adducts **98** and **99** (1.9:1), which differ in the orientation of the cyano- and TMSO-groups relative to the epoxide bridge, is formed in 61% yield.

It has been shown<sup>78</sup> that [2-(2-furyl)ethyl] vinyl ketones **100**, the carbonyl group of which is conjugated with the double bond, are not converted into the derivatives **101** either upon long-term heating in toluene or at elevated pressures (CH<sub>2</sub>Cl<sub>2</sub>, 20 °C, 24 h, 1.9 GPa).

R = H, Me.

Intramolecular cyclisation of alkenylfuran **102** in the presence of  $\beta$ -cyclodextrin occurs in a stereoselective manner and yields the tricyclic *exo*-adduct **103**.<sup>79</sup>

Cyclisation of 2-alkenylfurans [c]-fused to other carbo- and heterocycles has been investigated.<sup>80–87</sup> The cycloaddition of dihydroisobenzofuran **104** is preceded by dehydration by camphorsulfonic acid. The isobenzofuran **105** formed is unstable and is converted into a mixture of *exo*- (**106**) and *endo*-epoxy derivatives (**107**).<sup>80</sup>

CSA is camphorsulfonic acid.

The German chemists Friedrichsen *et al.*<sup>81–83</sup> have carried out the synthesis of 2-alkenylfurans fused to the thiophene ring. These compounds underwent the intramolecular Diels–Alder reaction.

R = H, Me.

Acid-catalysed conversion of unsaturated thiophenecarbaldehydes **108** to intermediate 4-alkenylthieno[2,3-*c*]furans **109** is the key step in this reaction sequence. Further cycloaddition yields the tetracycle **110**, which is immediately dehydrated to yield fused benzothiophenes **111**.

A preparative procedure for the synthesis of 4,6-dihydrothieno[3,4-*c*]furan 1,1-dioxide **112** (see Ref. 84) developed in 1990 has made it possible to study the intramolecular cycloaddition of its derivatives **113**.<sup>85–87</sup>

| R <sup>1</sup> –R <sup>2</sup>     | Reaction conditions            | Yield (%) |
|------------------------------------|--------------------------------|-----------|
| O                                  | <i>o</i> -xylene, 140 °C, 48 h | 0         |
| S(CH <sub>2</sub> ) <sub>2</sub> S | <i>o</i> -xylene, 140 °C, 2 h  | 74        |
|                                    | PhMe, 110 °C, 8 h              | 70        |
|                                    | PhH, 80 °C, 144 h              | 70        |
| CN, Me <sub>3</sub> SiO            | PhH, 80 °C, 24 h               | 63        |

It was found that the thermal Diels–Alder reaction is inapplicable to the ketone **113** (R<sup>1</sup>–R<sup>2</sup> = O). The presence of an sp<sup>3</sup>-hybridised carbon atom at the α-position of the substituent at position 2 of the furan ring is a prerequisite for the successful realisation of this reaction. The dienes **114** are formed as a result of sulfur(IV) oxide extrusion from the intermediate Diels–Alder adduct **115**. As the extrusion of SO<sub>2</sub> is carried out at high temperatures, *o*-xylene appears to be the solvent of choice for this reaction (b.p. = 140 °C).

An interesting example of an intramolecular cycloaddition in furans **116** and **117** containing a cyclopropylidene fragment has been described.<sup>88</sup> At elevated pressure, this reaction occurs in a stereoselective manner. X-Ray diffraction analysis revealed that compounds **118** and **119** are *exo*-adducts, the 4,5-methylene groups of which have a *trans*-configuration with respect to the epoxide bridge. The attempts at the intramolecular cyclisation of furans **116** and **117** at normal pressure were unsuccessful.

R<sup>1</sup> = H, OMe; R<sup>2</sup> = H (**116**, **118**); R<sup>1</sup> = H, R<sup>2</sup>–R<sup>2</sup> = (CH<sub>2</sub>)<sub>2</sub> (**117**, **119**).

| R <sup>1</sup> | R <sup>2</sup> –R <sup>2</sup>  | Reaction conditions                                            | Yield (%) |
|----------------|---------------------------------|----------------------------------------------------------------|-----------|
| H              | 2 H                             | PhMe, 110 °C                                                   | 0         |
|                |                                 | <i>n</i> -C <sub>5</sub> H <sub>12</sub> , 90 °C, 43 h, 1 GPa  | 32        |
| OMe            | 2 H                             | <i>n</i> -C <sub>5</sub> H <sub>12</sub> , 85 °C, 20 h, 1 GPa  | 95        |

#### e. Synthesis of 3-aza- and 3-oxa-4-thia-10-oxatricyclo-[5.2.1.0<sup>1,5</sup>]dec-8-enes

Only two examples of the synthesis of systems containing two additional heteroatoms, *viz.*, N, S or O, S, in the 10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-ene structure are known. 3-Aza-4-thia-10-oxatricyclo[5.2.1.0<sup>1,5</sup>]dec-8-ene 4,4-dioxides (**120**) were synthesised by Wibbeling *et al.*<sup>89,90</sup>

| R           | Reaction conditions                                    | Yield (%) | Ref. |
|-------------|--------------------------------------------------------|-----------|------|
| H           | PhMe, 110 °C, 12 h                                     | 0         | 89   |
| Me          | PhMe, 110 °C, 7 h                                      | 29        | 89   |
| Bn          | PhMe, 110 °C, 30 h                                     | 91        | 89   |
| S(–)CH*MePh | PhMe, 110 °C, 16 h                                     | 73        | 91   |
|             | CH <sub>2</sub> Cl <sub>2</sub> , 20 °C, 14 h, 1.3 GPa | 94        | 91   |

Cyclisation of vinylsulfonamides **121** into tricyclic compounds **120** is reversible; the reaction equilibrium depends on the size of the substituent R at the nitrogen atom: the larger the size the higher the concentration of the *exo*-adduct, sultam **120**.<sup>89</sup> The configuration of a chiral substituent at the nitrogen atom in the sulfonamide **121** is retained in the course of cyclisation; the optically active substrate yields a mixture of diastereomeric adducts.<sup>90</sup>

Furfuryl vinylsulfonates **122** are unstable<sup>91</sup> and cyclise *in situ* into isomeric thiocholanes **123** and **124**, which differ in the position of the oxygen atom at the sulfur atom relative to the epoxide bridge, under very mild conditions. Conditions have been found that favoured stereoselective formation of the epimer **123**. Where the double bond of the alkenyl fragment had the *E*-configuration, the reaction was carried out in the presence of 2,6-di-*tert*-butyl-4-methylphenol, a radical reaction inhibitor and an antioxidant. It is of note that the sulfur atom in the tricycles **123** and **124** is not inverted at room temperature as can be judged from the X-ray diffraction data.<sup>91</sup>

| R <sup>1</sup>     | R <sup>2</sup>     | Reaction conditions                                            | Yield (%) |     |
|--------------------|--------------------|----------------------------------------------------------------|-----------|-----|
|                    |                    |                                                                | 123       | 124 |
| CO <sub>2</sub> Me | H                  | CH <sub>2</sub> Cl <sub>2</sub> , 0.1 equiv. BHT, –30 °C, 19 h | 71        | 12  |
|                    |                    | CH <sub>2</sub> Cl <sub>2</sub> , 0.1 equiv. BHT, –77 °C, 9 h  | 77        | 0   |
| H                  | CO <sub>2</sub> Me | CH <sub>2</sub> Cl <sub>2</sub> , –50 °C, 19 h                 | 47        | 0   |

BHT is 2,6-di-*tert*-butyl-4-methylphenol.

In conclusion, mention should be made of the studies devoted to the theoretical aspects of the intramolecular Diels–Alder reaction of 2-alkenylfurans which yields oxabicycloheptenes fused to five-membered rings.

The dependence of this process on the Thorpe–Ingold effect (changes in the internal angle *Q* as the function of substituents in the alkenyl fragment, see Section IV.1.b) and the ‘reactive rotamer effect’, *i.e.*, the stabilities of the reactive *gauche*-conformers leading to the transition state, was studied by Jung *et al.*<sup>92–95</sup> The latter was demonstrated in the studies of kinetics of the intramolecular cyclisation of ethyl 6-(2-furyl)-6,6-*R,R'*-4-oxohex-2-enoates and furfuryl fumarates. The observed effect can be interpreted in the following way. Alkenylfurans exist predominantly in the *anti*-conformation (X and Y are the diene and the dienophile, respectively).

The cycloaddition occurs when the molecule **A** adopts a much less favourable *gauche*-conformation **B**. The introduction of alkyl substituents at the carbon atoms in the alkenyl chain levels off the energies of the *anti*-(**C**) and *gauche*-(**D**) conformations due to steric interactions, this effect being directly correlated with the size of the substituents. This favours the attainment of the transition state and, correspondingly, the cyclisation.

Dolata<sup>96</sup> has developed an axiomatic model of this reaction which takes into account the energy characteristics of the transition state (a combination of WIZARD and MM2 programmes). This model can be used for predicting the stereochemistry of the adducts formed with a high degree of probability.

It has been demonstrated<sup>97,98</sup> that the rate of intramolecular cyclisation of *N*-alkyl-*N*-furfurylacrylamides increases when the reaction is carried out in water or aqueous alcohols. In the authors' opinion, the abnormally high rate of the cycloaddition in water is due to stabilisation of the transition state as a result of the formation of hydrogen bonds and reduction of the hydrophobic surface of the substrate in the course of activation (since this reaction is accompanied by the reduction of the molecular volume).

Interesting results illustrating the effect of complexation on the intramolecular cyclisation of (*E*)-3-(*N*-furfurylcarbamoyl)-acrylic acid have been reported.<sup>99</sup> It was found that the cyclisation rate decreased in the presence of *N,N'*-bis(2-methylpyridin-6-yl)terephthalamide and increased in the presence of *N,N'*-bis(2-methylpyridin-6-yl)isophthalamide due to the ability of the latter to stabilise the transition state owing to complexation. Similarly, terephthalamide stabilises the starting *N*-furfurylfumaramide and thus hinders the cyclisation.

## 2. Six-membered rings

### a. Synthesis of 3-aza-11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes

The formation of six-membered nitrogen-containing rings by intramolecular cycloaddition of furan derivatives requires more drastic conditions (*e.g.*, high temperature, high pressure) than the annelation of five-membered rings. The reaction products also contain predominantly *exo*-isomers.

Studies of the intramolecular cycloaddition of *N*-furfurylamides **125** containing a  $\beta,\gamma$ -double bond in the acyl fragment revealed<sup>100</sup> that *N*-unsubstituted derivatives ( $R^1 = H$ ) do not react even under drastic conditions, whereas *N*-substituted furfurylamides **125** yield hydrogenated epoxyisoquinolinones **126**.

DBAn is 10,11-dihydro-5*H*-dibenzo[*a,d*][7]annulen-5-yl.

The intramolecular cyclisation of furyloxazolidones **127a–d** containing a non-activated alkenyl fragment at the nitrogen atom has been described.<sup>79</sup> The structure of the cycloadduct depends on the substituents in the furan and alkenyl fragments of the original molecule. In the case of furyloxazolidone **127a** ( $R^1 = H$ ), the reaction stops at the *exo*-tetracycle **128**. In the presence of a methoxy group (compounds **127b,d**) at position 5 of furan, the primary adduct **128** eliminates a molecule of water or methanol to give a mixture of hydrogenated isoquinolinoxazolidones **129** and/or **130**. A phenyl substituent at the double bond of the oxazolidones inhibits this reaction; no cycloadducts are formed from compound **127a**, while oxazolidone **127d** gives a hydroxy derivative **130d** in low yield. All these reactions were carried out in sealed tubes.

| Compound <b>127</b> | $R^1$ | $R^2$ | Reaction conditions                                   | Product [yield (%)]              |
|---------------------|-------|-------|-------------------------------------------------------|----------------------------------|
| <b>a</b>            | H     | H     | PhMe, 200 °C, 130 h                                   | <b>128</b> (56)                  |
|                     |       |       | H <sub>2</sub> O, $\beta$ -CD (1 equiv.) <sup>a</sup> | <b>128</b> (84)                  |
| <b>b</b>            | OMe   | H     | PhH, 165 °C, 120 h                                    | <b>129</b> (40), <b>130</b> (55) |
| <b>c</b>            | H     | Ph    | PhMe, > 250 °C                                        | —                                |
| <b>d</b>            | OMe   | Ph    | PhMe, > 250 °C, 90 h                                  | <b>130</b> (13)                  |

<sup>a</sup> The following temperature conditions were used: 55 °C, 30 h; 75 °C, 60 h; 90 °C, 3 days.

Enantiomers of 3-aza-11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-ene (**131** and **132**) were synthesised and isolated in the individual state.<sup>101</sup> The starting amino alcohol **133** was synthesised from the optically active (–)-8-aminomenthol. Its reaction with furfural

(a): 1) AlH<sub>3</sub>, 2) PCC, 3) KOH.

yields alkenylfuran **134**, which yields a mixture of intramolecular cycloaddition products **135** and **136** upon heating to 160 °C.

The diastereomers **135** and **136** were separated chromatographically and converted into the target tricycles **131** and **132** using the aforementioned reaction sequence (see Section IV.1.a).

The recently published papers<sup>102, 103</sup> are devoted to the synthesis and analysis of chemical properties<sup>104, 105</sup> of 4-spiroannellated epoxyoctahydroisoquinolines **137** (Table 7).

The formation of compounds **137** from homoallylamines **138** (R<sup>1</sup> = H) occurs under the action of carboxylic anhydrides (or chlorides) *via* the intermediate *N*-acyl derivatives **139**, which could be isolated in none of the cases studied. The best yields (50%–70%) of the Diels–Alder adducts were obtained when the reaction was carried out in boiling acetic anhydride. It was found<sup>102</sup> that the size of the spiro-fused ring and the nature of the acyl radical R<sup>2</sup> have little effect on the reaction (see Table 7). The failure to perform the cyclisation of the methallyl-substituted analogues **138** (R<sup>1</sup> = Me) under identical conditions can be explained by steric reasons. In this case, the reaction stops in the step of formation of the *N*-acetyl derivatives **139**.

In a similar way, mono- and disubstituted furfurylamines **140** were transformed to hydrogenated epoxyisoquinolines **141** (yields 34%–42%).<sup>102</sup>

R<sup>1</sup> = Ph, 4-PhC<sub>6</sub>H<sub>4</sub>; R<sup>2</sup> = H, Me, Ph.

#### b. Synthesis of 4-aza-11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-en-5-ones

There are only a few examples of the synthesis of these tricyclic systems.<sup>106, 107</sup> One of the first reports describes unsuccessful attempts of monocyclisation of *N*-unsubstituted acrylamide **142** (R<sup>1</sup> = R<sup>2</sup> = H). However, the *N*-methyl derivative gives the tricyclic adduct **143** in quantitative yield. The methyl group at the double bond of the alkenyl substituent considerably hinders this reaction: the expected epoxyoctahydroisoquinolone **143** (R<sup>1</sup> = R<sup>2</sup> = Me) could only be isolated in low yield.

R<sup>1</sup> = Me: R<sup>2</sup> = H (100%), Me (12%).

Synthesis of analogues of berberine alkaloids involved the intramolecular cyclisation of unsaturated furylacetetic amides **144**.<sup>106</sup> They cyclise on heating in toluene to give epoxyoctahydro-

R = H, Me, 3,4-(MeO)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>(CH<sub>2</sub>)<sub>2</sub>.

**Table 7.** Preparation of 4-spiroannellated 3-aza-11-oxatricycloundecenes **137**.

<sup>a</sup> The yields of compounds **139** are indicated.

droisoquinolones **145**; opening of the oxygen bridge upon treatment with acetic anhydride results in diene **146**. These compounds can also be prepared in one step by heating alkenylfurans **144** with an excess of acetic anhydride.

Acylation of the amide **147** with acryloyl chloride yields the tricyclic compound **148** in one step. In both cases considered, the [4+2]-cycloaddition is stereoselective: compounds **145** and **148** represent *exo*-adducts.

R = 3,4-(MeO)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>(CH<sub>2</sub>)<sub>2</sub>.

The thermal intramolecular [4+2]-cycloaddition in the amides **149** occurs smoothly; the reaction products are formed in high yields.<sup>107, 108</sup> The hydrogenated *N*-acetyloxyisoquinolone **150** was prepared by treatment of alkenylfuran **149** (R<sup>2</sup> = H) with acetic anhydride (yield 47%) (Scheme 6).

The stereoselectivity of the intramolecular cycloaddition of *N*-acryloylfuryl ethylamine **149** (R<sup>2</sup> = Bn) depends on the steric effect of the substituent R<sup>1</sup>. Of the four possible geometric isomers, in the case of small groups (R<sup>1</sup> = H, Me, CN), the *exo,anti*-adduct **151** is predominant. The selectivity of the cycloaddition decreases with an increase in the size of the substituent. For R<sup>1</sup> = Et, *exo,syn*- (**152**) and *endo,anti*-adducts (**153**) appear; for R<sup>1</sup> = Ph, the latter becomes predominant. It is interesting to

Scheme 6

R<sup>1</sup> = H, Bn; TBS is *tert*-butyldimethylsilyl.

| R <sup>1</sup> | Product [yield (%)]                               |
|----------------|---------------------------------------------------|
| H              | <b>151</b> [90]                                   |
| Me             | <b>151</b> [74]                                   |
| Et             | <b>151</b> [42], <b>152</b> [22], <b>153</b> [20] |
| Ph             | <b>151</b> [8], <b>153</b> [42]                   |
| CN             | <b>151</b> [87]                                   |

note that the *endo,syn*-isomer **154** was found in none of the cases studied. The yields of compounds were determined after separation of the isomers by column chromatography.

### c. Synthesis of 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes containing heteroatoms

This section considers annelation of an additional six-membered ring containing different heteroatoms (except for nitrogen considered above) to 7-oxabicyclo[2.2.1]hept-2-enes.

Esterification of alcohols **155** with ethylenesulfonyl chloride yields the corresponding esters **156**.<sup>109</sup> However, these undergo intramolecular cycloaddition in the course of isolation; the Diels–Alder *exo*-adducts (sultones **157**) are formed in high yields.

| R               | T / °C | t / h | Yield (%) |
|-----------------|--------|-------|-----------|
| Me              | 25     | 3     | 90        |
| Et              | 25     | 3     | 92        |
| Pr <sup>i</sup> | 0      | 1     | 87        |

A similar conversion of sulfinates **158** prepared from 2-(2-furyl)ethanol **159** and unsaturated sulfinyl chlorides has been described.<sup>91</sup> The presence of tetravalent sulfur hinders the intramolecular cycloaddition in comparison with sulfonates **156**; this reaction occurs either on heating or in the presence of Lewis acids as catalysts. The *exo*-adducts **160** are usually formed as mixtures of two isomers, like compounds **123** and **124** (see above), which differ in the relative positions of the S = O (or S<sup>+</sup>–O<sup>–</sup>) bond and the epoxide bridge. The isomer ratio depends on the reaction conditions and the catalyst used.<sup>91</sup>

The stereochemistry of the intramolecular Diels–Alder reaction of diastereomeric amides **162** (R<sup>2</sup> = Me) prepared from the optically active (*S*)-(–)- $\alpha$ -methylbenzylamine has been studied. A detailed analysis of the diastereomeric composition of the tricyclic sultams **161** formed is carried out.<sup>90</sup> It is noteworthy that the cyclisation of *N*-phenethyl-substituted alkenylfurans **162** requires more drastic conditions than that of their *N*-benzyl analogues;<sup>89</sup> however, the yields of the adducts **161** are high in all cases.

A series of novel oxabicycloheptanes containing an oxygen atom or oxygen and silicon atoms in the annelated six-membered rings were prepared by intramolecular cycloaddition of methyl-enecyclopropylmethyl furyl ethers **164** at elevated pressure.<sup>88</sup> As in the previous cases, *exo*-3,11-dioxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes **165**, the fused cyclopropane ring of which occupies the *trans*-position relative to the epoxide bridge, are formed selectively.

The equilibrium between the sulfide **166** and the intramolecular cycloaddition product **167** in chloroform has been studied at different temperatures.<sup>110</sup> It was found that the equilibrium is established slowly and the concentration of the Diels–Alder adduct **167** increases with a decrease in the temperature. After 70 h at 25 °C, the ratio **166**:**167** was 72 : 28, whereas after 53 h at 60 °C it had changed to 56 : 44. The adduct **167** formed with diastereoselectivity > 99% was isolated by column chromatography on silica gel (eluent, heptane–Et<sub>3</sub>N) (yield 71%).

A similar reversible intramolecular [4 + 2]-cycloaddition was described for the *ortho*-substituted cinnamates **168a,b**.<sup>111</sup> Upon boiling in toluene (**168b**, 7 h) or xylene (**168a**, 47 h), these compounds are converted to fused heterocycles **169** in low yields.

X = O (**a**, 8%), NEt (**b**, 34%).

The cyclisation of unsaturated furan derivative **170** can be achieved only at elevated pressure.<sup>112</sup> The *exo*-adduct **171**, which represents an individual stereoisomer, is formed in 28% yield.

MEM = CH<sub>2</sub>O(CH<sub>2</sub>)<sub>2</sub>OMe.

#### d. Synthesis of 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes

The intramolecular Diels–Alder reaction of unsaturated furan derivatives that results in 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes is explored much better (in a large measure, owing to the studies by Keay *et al.* and by De Clercq *et al.*) than the cyclisation of their aforementioned heterocyclic analogues. This can be attributed to the fact that the hydrogenated epoxynaphthalenes thus formed are easily converted into polysubstituted decalins which represent structural fragments of steroids and terpenes. This reaction is attractive from the synthetic standpoint, since the formation of *exo*-adducts occurs with high stereoselectivity with only few exceptions. Successful intramolecular cycloaddition usually requires the presence of electron-withdrawing groups at the double bond of the alkenyl substituent. There are only a few examples concerning successful cyclisation of alkenylfurans containing non-activated unsaturated fragments.<sup>113, 114</sup> Thus cyanotrimethylsilyloxyhexenyl derivative **172** undergoes slow cyclisation on heating at 120 °C to yield a mixture of isomers **173** and **174**. The stereoselectivity of this reaction is rather low: the *exo:endo* ratio is 88 : 12 and the total yield is 77%.<sup>114</sup>

Attempts to perform the intramolecular cycloaddition of acylfuran **175**, which is a furan **172** analogue, failed. Epoxyoctahydronaphthalenes **176** and **177**, which represent the desilylation products of the isomers **173** and **174**, are quantitatively converted into acylfuran **175** upon retro-Diels–Alder reaction at high temperatures.

Stereoselective cyclisation of 2-alkenylfuran **178**, which contains a dienophile fragment activated by a nitro group, occurs smoothly even at 25 °C and yields tricyclic *exo*-adduct **179**.<sup>115</sup> In all probability, the transition state that would yield the *endo*-isomer is destabilised by the 1,3-diaxial interaction of the oxygen atom of the epoxide bridge with the nitro group.

In one of the pioneering works<sup>116</sup> devoted to the synthesis of unsubstituted 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-ene, the thermal intramolecular cyclisation of 3-furylpropylvinyl ketone **180** ( $\text{R}^1\text{--}\text{R}^7 = \text{H}$ ) under variable conditions was studied. This reaction was found to be reversible; the best yield of the adduct **181** (> 70%) was attained in boiling  $\text{CH}_2\text{Cl}_2$  or at room temperature in the presence of Florisil® (a weak Lewis acid which represents a mixture of magnesium silicates). The equilibrium could be shifted towards the adduct **181** ( $\text{R}^1\text{--}\text{R}^7 = \text{H}$ ) only at elevated pressure.<sup>78, 117</sup> Using NMR spectroscopy, it was shown that 10 min exposure of the ketone **180** ( $\text{R}^1\text{--}\text{R}^7$ ) at room temperature and 1 GPa resulted in its quantitative cyclisation to yield a mixture of *exo*- and *endo*-epoxyoctahydronaphthalenes **181** and **182** (95 : 5).<sup>78, 117</sup>

The intramolecular Diels–Alder reaction of substituted 3-furylalkylvinyl ketones **180** yields four stereoisomeric cycloadducts, *viz.*, compounds **181**–**184** (in the absence of substituents, the *exo*-structures are degenerate). This process was studied in great detail (see Table 8; the cited data were predominantly taken from the works by Keay *et al.*).

In addition to the experimental work,<sup>118–125</sup> the same group of investigators have performed a series of theoretical calculations<sup>127, 128</sup> of the effects of substituents  $\text{R}^1\text{--}\text{R}^7$  and reaction conditions (*e.g.*, the use of Lewis acids as catalysts, variation of temperature) on the intramolecular Diels–Alder reactions of methyl-substituted 3-furylpropylvinyl ketones **180**, which yield 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes.

Based on the data obtained (Table 8), the following conclusions can be made. Lewis acids shift the equilibrium of the intramolecular cycloaddition of alkenylfurans **180** towards the adducts **181** and **182**. These included  $\text{ZnI}_2$  (see Refs 121 and 125),  $\text{SnCl}_4$ ,  $\text{BF}_3 \cdot \text{OEt}_2$ ,  $\text{TiCl}_4$ ,<sup>121</sup>  $\text{Et}_2\text{AlCl}$ ,  $\text{MeAlCl}_2$ ,<sup>120–123</sup> 2 M  $\text{CaCl}_2$ ,<sup>118, 119, 121</sup> Florisil,<sup>120, 121, 123, 124</sup> molecular sieves 3 Å<sup>125</sup> and some other catalysts in various solvents in the temperature interval from –78 to 80 °C (see Table 8). Hexane and toluene are undesirable as solvents for this reaction. Dichloromethane proved to be the solvent of choice, while ethyl- and methylaluminium dichlorides ( $\text{RAlCl}_2$ ,  $\text{R} = \text{Me}, \text{Et}$ ) and Florisil were the most efficient catalysts. A high degree of conversion of the substrates was also observed in the presence of titanium chloride or boron trifluoride etherate, but this was accompanied by resinification even at low temperatures.<sup>121</sup>  $\text{MeAlCl}_2$  manifested the highest catalytic activity from –78 to 65 °C,<sup>120</sup> while Florisil ensures good yields of the Diels–Alder adducts **183** and **184** at room or elevated temperatures (25–40 °C).

Interestingly, the cyclisation rate depended on the amount of the catalyst used. For example, the yield of the Diels–Alder adducts with 10 mol.% of  $\text{MeAlCl}_2$  was higher than in the presence of its 110% molar excess.<sup>121</sup> In this case, the equilibrium  $\text{183} \rightleftharpoons \text{180}$  was established after 5 min and the product : substrate ratio was ~1 : 2. A second stereoisomer (compound **184**, 14%) was detected in the reaction medium after 5 min in the presence of 0.1 equiv. of  $\text{MeAlCl}_2$ ; its concentration dropped to zero with time.<sup>121–123</sup> The NMR<sup>127</sup> and quantum chemical calculations<sup>128</sup> suggest that the position of equilibrium of the cycloaddition is controlled by the Lewis acid. The amount of catalyst required for this reaction is determined by the relative basicities of the functional groups in the starting compounds and cyclisation products, since the latter form complexes with the Lewis acid. If the basicities of the functional groups in the final product are lower than in the original alkenylfuran **180**, the epoxyoctahydronaphthalene–Lewis acid complex formed easily dissociates with the regeneration of the catalyst. In this case, the latter should be used in catalytic amounts in order to promote the reaction. If the basicities of the functional groups in the product exceed those in the original alkenylfuran **180**, the complex formed is stable and 1 equiv. of the Lewis acid should be added.

No unambiguous conclusions concerning the effect of substituents on the cyclisation of alkenylfurans **180** can be made. It is evident, however, that the introduction of methyl groups ( $\text{R}^5 = \text{R}^6 = \text{Me}$ ) into the alkenyl fragment of furan **180** favours the reaction due to manifestation of the *gem*-dialkyl effect.

It was demonstrated<sup>124</sup> that in the presence of a 10-fold excess (by weight) of Florisil an equilibrium was established between alkenylfuran **180** and the *exo*-adducts **181** and **183**; the yields of the latter increase with temperature and reaction time.

The cyclisation of methyl-substituted alkenylfurans **180** [ $\text{R}^1(\text{R}^3, \text{R}^7) = \text{Me}$ ] was studied under varied conditions including aqueous media and elevated pressure.<sup>118, 119</sup> These studies showed that the presence of methyl groups in both the furan ring and at the double bond of the starting compounds prevents the formation of

**Table 8.** Cyclisation of 3-furylpropyl vinyl ketones **180**.

<sup>a</sup> The yields of isolated products are indicated; the compositions of the reaction mixtures were determined by <sup>1</sup>H NMR spectroscopy; <sup>b</sup> the yield of the adduct **181** calculated with respect to the amount of alkenylfuran **180** introduced into the reaction is indicated; <sup>c</sup> fluorosil is fluoroalkylsilicon; <sup>d</sup> the reaction does not occur.

the Diels–Alder adducts (see Table 8). The reaction equilibrium can be shifted towards the tricycles **181** either by increasing the pressure (1.25 GPa) or by conducting the reaction at room temperature in water with the addition of 2 M calcium chloride. It is interesting to note that no epoxynaphthalene **181** is formed in the presence of β-cyclodextrin or upon boiling in 2 M CaCl<sub>2</sub>.<sup>119</sup>

The cyclisation of alkenylfurans **180** containing an acetyl group at the double bond [R<sup>1</sup>(R<sup>2</sup>) = Ac] occurs at 1.9 GPa and yields a mixture of the *exo*- and *endo*-adducts **181** and **182**. The latter revert to the starting compounds at atmospheric pressure.<sup>78, 117</sup>

The cyclisation of 1,4-diketone **180** (R<sup>1</sup> = Ac, R<sup>6</sup> = OMe) was studied in detail.<sup>125</sup> It was established that the cycloaddition is successful only in the presence of Lewis acids, ZnI<sub>2</sub> being the most active (the yield of the adduct **181** was 67%).

These results were successfully applied to the total synthesis of 1,4-epoxycadinane, a terpene isolated from the brown alga *Dilophus fasciola*.<sup>123, 124</sup>

1,4-Epoxycadinane

Some chemical properties of 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes have been studied. Thus the reactions of epoxyoctahydronaphthalenes **181** and **183** (see Refs 118, 121, 124 and 125) with nucleophiles (primarily, with organolithium and organomagnesium derivatives),<sup>129</sup> and the Wagner–Meerwein rearrangement of compounds **181** were reported.<sup>130</sup>

The intramolecular cycloaddition in the keto ester **185**, a structural analogue of the above-described ketones **180**, in the presence of ZnI<sub>2</sub> is accompanied by desilylation. This reaction yields the tetracyclic lactone **186**.<sup>125</sup>

Only one paper<sup>131</sup> describes the effects of the substituents at position 3 of the furan ring on the course of the intramolecular Diels–Alder reaction of furylpropyl isopropenyl ketones **187**. In the presence of methylaluminium dichloride, the cyclisation proceeds stereoselectively and yields the *exo*-adducts **188**. For R = CH<sub>2</sub>OAlk, the yield of the product **188** was nearly quantitative. However, the reaction did not go to completion if an ester group (CO<sub>2</sub>Pr<sup>i</sup>) was introduced into the furan ring. In this case, the tricyclic ketone **188** was isolated from the reaction mixture in a moderate yield.

R = CH<sub>2</sub>OMe, CH<sub>2</sub>OBn, CO<sub>2</sub>Pr<sup>i</sup>.

The catalytic cyclisation of the optically active alkenylfuran **189** yields a mixture of diastereomeric methyl-substituted 11-oxatricyclo[6.2.1.0<sup>1,6</sup>]undec-9-enes **190** and **191** (Scheme 7).<sup>132</sup>

Several publications are devoted to the intramolecular cyclisation of furans [c]-annulated to partially hydrogenated benzene or thiophene rings.<sup>80, 85, 133</sup>

Upon boiling in toluene in the presence of catalytic amounts of camphorsulfonic acid, dihydroisobenzofuran **192** is converted into a mixture of spirans **193** and **194**.<sup>80</sup> Initially, dehydration results in unstable isobenzofuran **195**, which undergoes further rapid intramolecular cyclisation to the spiro-annulated octahydroepoxyphenanthrene **193**. The latter is partly aromatised

The stereodirection of the cycloaddition of furyl-substituted cyclopentanes has been studied by De Clercq *et al.*<sup>134–139</sup> This reaction is the key step in the total synthesis of a series of tetracyclic natural compounds, *e.g.*, 11-ketosteroids (including

adrenosterone) and diterpenoids. The natural antibiotic fusidic acid (ent-fusidic acid) and substituted gibberelins (ent-gibberellins) that possess phytohormonal properties and are used as plant growth factors provide illustrative examples of such compounds.

The intramolecular cyclisation of the water-soluble hydroxy ketones **198** into diastereomeric *exo*-adducts **199** and **200** was studied.<sup>134,135</sup> For compound **198** (R<sup>1</sup> = R<sup>2</sup> = H, R<sup>3</sup> = OH), this reaction is stereoselective and yields only the *exo*-adduct **200**. Water appeared to be the best solvent for this reaction. NMR studies have shown that compound **200** (R<sup>2</sup> = H, R<sup>3</sup> = OH) is formed in water within 10 min, whereas in chloroform or dichloromethane the equilibrium is shifted towards the starting furyl-containing cyclopentane **198**.<sup>134</sup>

R<sup>1</sup> = H, Me.

| R <sup>2</sup>                     | R <sup>3</sup> | Reaction conditions                               | Ratio<br>198 : 199 : 200 | Product<br>[yield (%)] | Ref. |
|------------------------------------|----------------|---------------------------------------------------|--------------------------|------------------------|------|

|                                    |                | (CD <sub>3</sub> ) <sub>2</sub> SO, 25 °C, 3 days | 0 : 0 : 100              | <b>200</b> [50]        | 134  |
|                                    |                | D <sub>2</sub> O, 25 °C, 10 min                   | 0 : 0 : 100              | <b>200</b> [>95]       | 134  |
| O(CH <sub>2</sub> ) <sub>2</sub> O |                | CH <sub>2</sub> Cl <sub>2</sub> , 25 °C, 7 days   | 25 : 20 : 55             | —                      | 135  |
|                                    |                | PhH, 80 °C, 24 h                                  | 13 : 80 : 5              | —                      | 135  |

In the case of the dioxolane derivative **198** [R<sup>1</sup> = H, R<sup>2</sup>–R<sup>3</sup> = O(CH<sub>2</sub>)<sub>2</sub>O], the ratio of the substrate and the cyclisation products **199** and **200** in the reaction mixture depends on the reaction conditions.<sup>135</sup> The methyl group at the double bond of the vinyl fragment (R<sup>1</sup> = Me) fully inhibits the [4 + 2]-cycloaddition.<sup>134</sup>

It is of note that attempts to perform cycloaddition in compounds **201a–d**, the precursors of unsaturated ketones **198**, failed.

R<sup>3</sup> = H: R<sup>1</sup> = H, R<sup>2</sup> = OH (**a**), OTBS (**b**);

R<sup>1</sup>–R<sup>2</sup> = O (**c**); R<sup>1</sup> = H, R<sup>2</sup> = OTBS, R<sup>3</sup> = Ac (**d**).

Epoxy derivatives of diterpenes of the gibberellin series **202** were prepared in high yields from furyl-substituted bicyclo[3.2.1]octanes **203**.<sup>136–138</sup> This reaction occurred stereospecifically as *exo*-cycloaddition in boiling benzene or upon heating in aqueous solutions in the presence of  $\beta$ -cyclodextrin.

In conclusion of this section, let us consider the synthesis of homoketosteroid precursors, *viz.*, hydrogenated epoxyphenanthrenes, by catalytic cycloaddition of ketones **204**.<sup>139</sup> Dimethylaluminium chloride proved to be the best catalyst for this reaction. The ratio and the yield of the *exo*-addition products **205** and **206** depended on the amount of the catalyst and the reaction temperature.

### 3. Seven-membered rings

There are very a few examples of the annelation of seven-membered rings **4** upon the intramolecular Diels–Alder reaction in the series of 2-alkenylfurans. This may be due to enhanced (in comparison with five- and six-membered analogues) effects of entropic factors upon closure of seven-membered rings. Very often, such conversions require elevated pressure; the polycycles **4** formed are not always stable under ordinary conditions (see also Section II, synthesis of compound **6**). Moreover, in this case the intramolecular cycloaddition occurs with a rather low stereoselectivity and yields *exo*- and *endo*-adducts. Before 2003, there were no reports of successful annelation of eight-membered rings to 7-oxabicyclo[2.2.1]hept-2-ene by intramolecular [4 + 2]-cycloaddition.

#### a. Synthesis of 5-aza-12-oxatricyclo[7.2.1.0<sup>1,7</sup>]dodec-10-en-6-ones

A description of this heterocyclic system, which has been prepared by the cyclisation of *N*-(3-furylpropyl)acrylamides **207** in boiling benzene, can be found in only one early publication.<sup>140</sup> This reaction did not occur if the double bond in the alkenyl fragment of the molecule **207** (*e.g.*, crotylamide derivatives) was not terminal. No spectral confirmation of the structure and stereochemistry of the tricyclic lactams **208** synthesised was provided.

R = Me (45%), Bn (75%).

#### b. Synthesis of 12-oxatricyclo[7.2.1.0<sup>1,7</sup>]dodec-10-en-6-ones

The first synthesis of tricyclic 12-oxatricyclo[7.2.1.0<sup>1,7</sup>]dodec-10-en-6-ones by intramolecular cyclisation of 4-furfurylbutyl vinyl ketones **209a–f** was carried out in 1985.<sup>141</sup> The isomeric cycloaddition products *endo*- (**210**) and *exo*-adducts (**211**) (see compounds **209a–f**, Table 9) appeared to be unstable and rapidly reverted to the starting ketones **209** at atmospheric pressure. The half-life of the more stable *endo*-adduct **210a** (R<sup>1</sup>–R<sup>3</sup> = H) was 1100 min, that of the *exo*-isomer **211a** was 90 min.

The double bonds in the adducts **210e,f** and **211e,f** were reduced under conditions of catalytic hydrogenation without isolation of the adducts from the reaction mixture. Interestingly, these compounds were not detected later<sup>78</sup> (see Table 9). The hydrogenated derivatives **212** and **213** are fairly stable and were used for the preparation of terpenoids of the daphnane series.<sup>78, 117</sup>

In addition to high pressure, the efficiency of the cycloaddition of alkenylfurans **209** can be increased if methylaluminium dichloride is used as a catalyst.<sup>121, 122</sup> The degree of conversion of the non-substituted compound **209a** at low temperature in the presence of 0.1 equiv. of MeAlCl<sub>2</sub> reaches >90%. The ratio of the *endo*- and *exo*-adducts is variable in this case, but the *endo*-isomers usually predominate.

A series of interesting experiments aimed at the annelation of seven-membered rings upon [4 + 2]-cycloaddition have been carried out by Harwood *et al.*<sup>142–144</sup> In elaborating a new approach to the synthesis of phorbol-type diterpenes (irrigants isolated from different species of the African spurge, *Euphorbia coerulescens*, *E. coperi*, *E. frankian*, *E. resinifera*), these authors investigated the intramolecular Diels–Alder reaction of ketals **214** (see Table 9).

**Table 9.** Cyclisation of substituted 7-(2-furyl)hept-1-en-3-ones.

<sup>a</sup> CH<sub>2</sub>Cl<sub>2</sub> was used as solvent; <sup>b</sup> the compositions of the reaction mixtures were determined using <sup>1</sup>H NMR spectroscopy; <sup>c</sup> the reaction does not occur; <sup>d</sup> hydrogenation *in situ*; <sup>e</sup> CHCl<sub>3</sub> was used as solvent.

As for the above-described conversions of alkenylfurans **209**, in certain cases (*e.g.*, for derivatives **214b,c**), the cycloadducts **215** and **216** formed were not isolated in the individual state, but their equilibrium mixture with the starting compound was subjected to catalytic hydrogenation into derivatives **217** and **218**.

## V. Intramolecular cyclisation of *N*-alkenyl-2-aminofurans

Several novel types of intramolecular cycloaddition of substituted furans were disclosed in the past 8 years. It is well-known that, *N*-unsubstituted 2-furylamines are unstable under ordinary conditions, therefore, their reactions are virtually unexplored. In 1997, Padwa and coworkers developed a simple preparative procedure for the synthesis of unsaturated 2-furylcarbamates **219**,<sup>145, 146</sup> which proved to be exceptionally reactive dienes.

Boc is *tert*-butoxycarbonyl.

In contrast to the above-considered cyclisation reactions, the intramolecular cycloaddition of *N*-substituted 2-furylcarbamates **219** seldom yields the annelated oxabicycloheptene **220**. The latter undergoes spontaneous opening of the epoxide bridge; the ambident ion **221** formed is stabilised in various ways, *e.g.*, by conversion into hexahydroindolone **222**.

In the majority of cases, the intramolecular cycloaddition in *N*-alkenyl-2-furylamides and -carbamates **223a,b** differing in the lengths of the alkenyl chains occurs in boiling benzene or toluene; sometimes, this is carried out in a sealed tube. In the presence of 4–5 M ethereal lithium perchlorate, the temperature can be

Scheme 8

reduced; sterically hindered alkenylfurans react under these conditions.<sup>147</sup> The mechanism of the catalytic effects of ethereal  $\text{LiClO}_4$  and other examples are considered in a review.<sup>148</sup>

Depending on the nature of substituents  $\text{R}^1 - \text{R}^5$  in the starting furans **223a,b**, eight products **224–229** can be obtained,<sup>147, 149–158</sup> six of which are formed upon cleavage of the epoxide bridge in the primary adducts **229a,b**, (Scheme 8). It is of note that the intermediate epoxyindole **229a** could be isolated in only one case.<sup>151</sup> The intramolecular cycloaddition always proceeds *via* the intermediate *exo*-transition state. The reaction conditions and the product yields are presented in Table 10.

Based on these data, the following general conclusions have been made. The annelation of five-membered rings to oxabicycloheptene proceeds more smoothly than that of six-membered rings, which often results in mixtures of reaction products. The reaction occurs with furans containing both electron-withdrawing ( $\text{CO}_2\text{Alk}$ ) and electron-donor ( $\text{SMe}$ ) groups. Thus, the nature of the substituent at position 5 of the furan ring affects neither the reaction conditions nor the yield of the cycloadducts. Bulky substituents at the amide nitrogen atom ( $\text{R}^2$ ) and radicals at the double bond ( $\text{R}^4$  and  $\text{R}^5$ ) of the dienophile do not inhibit this reaction either.

In the case of  $\text{R}^4 = 3,4-(\text{MeO})_2\text{C}_6\text{H}_3$  [or  $3,4-(\text{OCH}_2\text{O})\text{C}_6\text{H}_3$ ], compounds **226**, which represent close precursors of the alkaloids mesembrine and crinine, respectively, are formed. The former were isolated from South African plants of the Mesembryanthemaceae family (genus *Sceletium*); the latter were found in the bulbs and seeds of the African lily *Crinum bulbispermum* (Amaryllidaceae). Total synthesis of these and other structurally similar alkaloids by intramolecular cycloaddition of *N*-alkenylaminofurans **223** has been described.<sup>19, 153, 154</sup>

The Diels–Alder reaction of 5-substituted *N*-alkenyl-*N*-furyl-sulfonamides is also accompanied by conversions of the primary adducts.<sup>147, 150</sup> In the case of 5-nitro derivatives, **230a,b**, the elimination or migration of the nitro group in the intermediate tricycles **231a,b** and subsequent oxygen-induced aromatisation result in a mixture of mono- (**232a,b**) and disubstituted (**233a,b**) indolines ( $n = 1$ ) or tetrahydroquinolines ( $n = 2$ ) (Scheme 9).<sup>147</sup>

An unexpected elimination of the *N*-*tert*-butoxycarbonyl group was observed in the cyclisation of 5-methyl- and 5-nitro-phenyl-substituted furylcarbamates **234** leading to 3,3a,4,5-tetrahydro-2*H*-indoles (**235**) in good yields.<sup>150</sup>

It is interesting to note that the thermal cyclisation of the *N*-butenyl analogue yields an unstable adduct of the type **229a** (see above); the latter is further aromatised into the corresponding indoline.<sup>152</sup>

Scheme 9

**Table 10.** Cyclisation of acylated (*N*-alkenyl)aminofurans **223a,b**.

<sup>a</sup> The substituent R<sup>1</sup> for the reaction product is indicated; in the starting furan, R<sup>1</sup> = H; <sup>b</sup> OBO is 2,6,7-trioxabicyclo[2.2.2]octane; <sup>c</sup> the concentration of LiClO<sub>4</sub> in diethyl ether is indicated; <sup>d</sup> the yield of methyl 1-benzoyl-5-hydroxy-2,3,4,5-tetrahydro-1*H*-indole-5-carboxylate was also obtained, yield 52%.

Alkylfurylcarbamates **236** and **237** and a tryptamine derivative **238** underwent intramolecular cycloaddition.<sup>140, 153</sup> These conversions yield the adducts **239–241**, which represent synthons for the preparation of the polycyclic alkaloids dendrobine (found in the Chinese orchid *Dendrobium nobile*), aspidospermidine and dehydrotubifoline isolated from South American tree-frogs.

R = H, Pr<sup>i</sup>

Dendrobine

Alkenylfurylcarbamates for intramolecular Diels–Alder reactions can be prepared *in situ*. The sequence of transformations<sup>155</sup> begins with the intermolecular [4 + 2]-cycloaddition of protected 4-dimethylaminobuta-1,3-dien-2-ol **242** to furylcarbamate **243**.

Dimethylamine and the protecting silyl group are eliminated from compound **244** under the action of hydrofluoric acid resulting in cyclohexenone **245**. The latter undergoes thermal cycloaddition to be further converted into the tricyclic indole derivatives **246**.

The cycloaddition of a carbamate **243** homologue, *viz.*, methyl 4-(*tert*-butoxycarbonyl-2-furyl)amino-2-methylenbutyrate (**247**), carried out in an alcoholic medium (MeOH or BnOH) yields mixtures of monoalkylated 5,6-dihydroxy derivatives **248** and **249** (but not the ketones of the type **228**, see above).<sup>150, 154</sup> The total yield of these compounds is 80%–85%; the ratio of the *trans*- and *cis*-isomers is 3 : 1 in both cases.

The cyclisation of 2-aminofurans can be used for the synthesis of azaphenanthrene systems.<sup>152</sup> Thus the cyclisation of the *N*-non-substituted alkenylfuran **250a** occurs under more drastic conditions (160 °C, 4 days) than that of its ethoxycarbonyl analogue

**250b** (110 °C, 24 h). The yields of the substituted phenanthridines **251** are high in both cases.

$R^1 = R^2 = \text{H, } R^3 = \text{O (a, 97\%); } R^1 = \text{CO}_2\text{Et, } R^2 = \text{OCH}_2\text{O, } R^3 = 2 \text{ H (b, 79\%)}$

The intramolecular Diels–Alder reaction in the series of furan derivatives annelated to nitrogen-containing heterocycles with *N*-alkenyl substituents, *viz.*, furopyrrrolines **252** and furotetrahydropyridines **253**, has been described.<sup>156–160</sup> Conversions of such systems lead to polyheterocyclic compounds. Unfortunately, the starting fused heterocycles are not easily accessible, which restricts significantly prospects of their practical application in the synthesis of biologically active compounds.

If the furan ring contains electron-withdrawing groups ( $\text{CO}_2\text{Alk}$ ), the cycloaddition stops at the formation of epoxy derivatives of the tetracyclic compounds **254**.

**254:**  $R = \text{Bu}^t$  (70%), Me (24%).

Contrariwise, electron-donor groups (*e.g.*, MeO) make the Diels–Alder adducts **255** unstable, which results in spontaneous cleavage of the epoxide bridge. These compounds are stabilised upon elimination of methanol.<sup>156, 157</sup> It was shown that the formation of hydrogenated pyridoquinoline from methoxy-substituted furotetrahydropyridine occurs under more drastic conditions than that of pyrrolo[3,2,1-*ij*]quinoline **256a** (Scheme 10).

| Compound <b>256</b> | <i>n</i> | Reaction conditions | Yield (%) |
|---------------------|----------|---------------------|-----------|
| <b>a</b>            | 1        | 110 °C, 0.5 h       | 58        |
| <b>b</b>            | 2        | 180 °C, 12 h        | 30        |

The [4 + 2]-cycloaddition of various *N*-acylazinofurans **257** [*e.g.*, hydrogenated furopyridines ( $n = 1$ ) and furoazepines ( $n = 2$ )] containing an electron-donor MeS group at position 5 of the furan ring was studied.<sup>158–160</sup> These compounds afforded both the Diels–Alder adducts and their subsequent conversion products. It is interesting to note that, in contrast to the methoxy derivatives **255**, the sulfur-containing analogues **258** undergo a 1,2-shift of the thiomethyl group to yield oxo amides **259** (Table 11).

**Table 11.** Cyclisation of *N*-acylazinofurans **257**.

<sup>a</sup> The configuration of the SMe group was not determined.

Substituents at the double bond of the unsaturated fragment in the fused furans **257** and the size of the annelated ring have no appreciable effect on the yield of the tricyclic compounds **258** and **259**.

An elegant stereoselective synthesis of the tetracyclic system **260** upon heating of furotetrahydropyridine **261** can be mentioned in conclusion of this section.<sup>158</sup>

## VI. Intramolecular cycloaddition in furylalkyldehydrobenzenes

This is one of the least investigated intramolecular cycloaddition reactions in the furan series; the first report appeared in 1981.<sup>161</sup> It is of note that no information about this type of cyclisation is given in a recent review<sup>162</sup> of dehydrobenzene reactions published in 2003.

Several approaches to the generation of furylalkyldehydrobenzenes of the type **262** exist. The two major types include decomposition of the corresponding diazonium salts prepared from substituted anthranilic acids and dehalogenation of furyl-containing *ortho*-dihalobenzenes. The intermediate dehydrobenzenes **263** are formed smoothly upon heating of the diazonium salts **264** in the presence of propylene oxide which binds the evolving hydrogen chloride. Further boiling in dichloroethane gives the thermal cyclisation products, *viz.*, the epoxytetracycles **265** (yields 74%–90%). Similar compounds are formed in good yields upon treatment of dibromo-derivatives **266** with butyllithium.

Both approaches were employed by Australian chemists in the synthesis of naphtho[1,8-*bc*]pyran,<sup>161, 163, 164</sup> which is a skeleton of isoprenoids biflorin and mansonones E, I and F possessing a rare *o*-quinonoid structure. Biflorin was isolated from the blossoms and leaves of *Capraria biflora* L., while mansonones E, I and F

R = (CH<sub>2</sub>)<sub>2</sub>CH=CHMe<sub>2</sub> (biflorin), Me (mansonone F);  
R<sup>1</sup> = Me: R<sup>2</sup> = H (mansonone E), OH (mansonone I).

were isolated from the wood of the African tree *Mansonia altissima*.

The length of the chain linking the dehydrobenzene fragment to the furan ring is critical for the cyclisation.<sup>161</sup> No intramolecular Diels–Alder cyclisation occurred of furylalkoxydehydrobenzene formed upon diazotisation of anthranilic acid **267a** with isoamyl nitrite; instead, only diazoquinone **268** was obtained as the elimination product of the furfuryl substituent. However, the annelation of the seven-membered ring in a diazonium salt prepared from the derivative **267b** was more successful: the adduct **269** was formed in good yield.<sup>161</sup>

$n = 1$  (a),  $3$  (b).

The conversion of *o*-furylpropylaminohalobenzenes **270** into fused azepines **271** (Table 12) containing an epoxynaphthalene fragment has been described.<sup>165</sup> Lithium diisopropylamide (LDA) and lithium-2,2,6,6-tetramethylpiperidide (LiTMP) in THF proved to be the most suitable bases for generating dehydrobenzene **272**. The yields of naphthoazepines **271** were low.

B is a base.

Short communications<sup>166, 167</sup> outline approaches to the synthesis of the partly hydrogenated phenalenes **273** and the fused indole systems **274**, respectively. These syntheses employed con-

ventional techniques for the generation of the dehydrobenzene intermediates.

Tf is trifluoromethylsulfonyl,  
TBAF is tetrabutylammonium fluoride.

The labile adduct **274** was synthesised in quantitative yield.

Intramolecular cyclisation in epoxynaphthalenes **275a–d** fused to a silaoxacyclohex(hept)ane fragment has recently been described.<sup>168</sup> The intermediate furyl-substituted dehydrobenzenes **276** were generated by treatment of compounds **277** with *tert*- or *sec*-butyllithium in THF from  $-95$  to  $-10$  °C.

| Compound <b>275</b> | $n$ | R <sup>1</sup> | R <sup>2</sup> | Yield (%) |

<sup>a</sup> THF was used as solvent; <sup>b</sup> DMSO was used as solvent.

\* \* \*

The data reviewed clearly demonstrate that the intramolecular Diels–Alder reactions of alkenylfurans provide an efficient and often the only way to fused 7-oxabicycloheptane systems.

The best results are achieved with substrates containing a three-membered chain between the dienophile (alkenyl) and the diene (furan) fragments (annulation of five-membered rings). The cyclisation that yields six-membered derivatives is less smooth. In any case, a decrease in the degree of freedom of unsaturated fragments (e.g., as a result of introduction of additional substituents, complex formation or the presence of sp<sup>2</sup>-hybridised atoms) favours cyclisation. The contribution of electronic factors that is critical for intermolecular interactions from the standpoint of boundary orbital theory fades into the background in the case of intramolecular interactions. With rare exception, the stereochemistry of intramolecular [4 + 2]-cycloaddition usually follows the Diels–Alder *endo*-rule.

**Abstract.** The advances in the synthesis and studies of the properties of polyquinolines and polyanthrazolines are reviewed. The main attention is given to polymers prepared by the Friedlander reaction from the AB- and AA–BB-type monomers, *viz.*, rigid-rod polyquinolines, polyether quinolines, cardo polyquinolines and polymers containing tetraphenylsilyl and perfluorotetramethylene fragments. The approaches to the design of reactive oligo- and polyquinolines, the terminal groups of which have a curing effect on these systems, are considered. The use of polyquinolines for the preparation of composite and electroluminescent materials is discussed. The bibliography includes 155 references.

## I. Introduction

Polyheteroarylenes (PHA) based on quinolines (polyquinolines, PQ) and anthrazolines (polyanthrazolines, PAZ) present substantial interest for both fundamental and applied investigations<sup>1–6</sup> due to their high heat resistances and high thermal stabilities.<sup>7</sup>

In the early stage (the 1970's), PQ and PAZ were used predominantly for the preparation of polymeric materials (films, fibres, composites, *etc.*) for the aerospace industry. Later (the 1990's), more attention was placed on their use for the preparation of materials for high-tech industrial domains, for optoelectronics, in particular.<sup>8,9</sup>

The results obtained in both stages of the investigations of these compounds are considered in this review.

## II. Synthesis of polyquinolines and polyanthrazolines manifesting high heat resistances and high thermal stabilities

The past four decades have been marked by the synthesis of diverse PHA.<sup>10–19</sup> Some of them, *e.g.*, polyimides,<sup>20–25</sup> polyazoles,<sup>26–30</sup> polyphenylquinoxalines,<sup>31–33</sup> *etc.*), have found application in the design of materials retaining their operating characteristics at temperatures around 300 °C. To a considerable extent, such compounds satisfied the needs of the aircraft industry and rocket engineering for thermostable polymeric materials, but more recent demands are for materials able to withstand higher temperatures. Therefore, the efforts of investigators have switched over to a search for polymers surpassing the well-known PHA in heat resistances and thermal stabilities. Identification of the least stable fragments in the polymeric chains of conventional PHA and their replacement by more thermostable units seemed to be the most rational solution to this problem.

In-depth studies of the decomposition mechanisms of different classes of PHA have shown that the decomposition involves predominantly the heterocyclic fragments,<sup>34–42</sup> which suggests that it is the heterocyclic fragments of PHA that should be replaced by more thermostable components. A comparison of the thermal stabilities of various carbo- and heterocycles<sup>43,44</sup> has shown that quinoline is one of the most heat-resistant compounds.<sup>44</sup> The first attempt at synthesising polymers containing quinoline rings in the main chains starting from benzidine and bis( $\beta$ -diketones), *viz.*, 4,4'-bis(acetoacetyl)diphenyloxide and 4,4'-bis(acetoacetyl)diphenylethane, was undertaken by Korshak *et al.*<sup>45</sup> (Scheme 1).

The polyanils formed in the first step were soluble in cresol, DMSO and H<sub>2</sub>SO<sub>4</sub> (the reduced viscosities of their solutions in H<sub>2</sub>SO<sub>4</sub> were 0.6–0.8 dl g<sup>–1</sup>), while polyquinolines prepared by thermal cyclisation of polyanils *in vacuo* were insoluble in either of these solvents, which significantly limited their processing into articles.

Some time later, Shopov<sup>46</sup> succeeded in obtaining a soluble PQ by extrapolation of the Pfitzinger reaction<sup>47</sup> to the polymer synthesis.

Scheme 1

R = O, CH<sub>2</sub>CH<sub>2</sub>; PPA is polyphosphoric acid.

The carboxy-substituted PQ represented a dark-brown powder which was soluble in DMF, pyridine, DMSO and aqueous alkali and underwent decarboxylation to the target PQ upon heating to 300 °C. Unfortunately, no comprehensive analysis of the properties of the polymers obtained was reported.<sup>45, 46</sup>

Yet another approach to the synthesis of PQ was realised by Stille *et al.*,<sup>1–5, 48–52</sup> this was based on the Friedlander reaction.<sup>1–5, 53–56</sup> In its classical version, this reaction consists of an alkali-catalysed condensation of aromatic *o*-aminocarbonyl compounds with methylene ketones.<sup>54–56</sup>

Formally, this reaction results in a Schiff base which undergoes subsequent aldol condensation<sup>57</sup> with involvement of the carbonyl group and the reactive methylene group.<sup>58</sup> It was shown<sup>59–64</sup> that acids are as effective as catalysts of the formation of the quinoline rings as alkalis.

The preparation of PQ by the Friedlander reaction may include both homocondensation of compounds containing *o*-aminocarbonyl and oxomethylene fragments<sup>51, 65–68</sup> and co-condensation of bis(*o*-aminocarbonyl) and bis(oxomethylene) derivatives.<sup>48–52</sup> In both cases, synthesis of the starting compounds presents the major problem, since substituted *o*-aminocarbonyl derivatives are difficult to access.<sup>58, 64</sup>

### 1. Synthesis of polyquinolines by homocondensation of AB-type monomers

5-Acetyl-2-aminobenzophenone (**1a**),<sup>51, 65, 69</sup> 4'-acetyl-4-amino-3-benzoylbiphenyl (**1b**),<sup>65</sup> 4'-acetyl-4-amino-3-benzoyldiphenyl oxide (**1c**)<sup>66</sup> and 9-(4-acetylphenyl)-9-(4-amino-3-benzoylphenyl)fluorene (**2**) were used as the AB monomers in the synthesis of PQ.<sup>68</sup> Homocondensation of the first three compounds in

*m*-cresol – polyphosphoric acid (PPA) or *m*-cresol – P<sub>2</sub>O<sub>5</sub> mixtures (according to <sup>31</sup>P NMR data, these systems represent mixtures of mono- and di-*m*-cresyl phosphate)<sup>52</sup> at 120–130 °C yielded the fibre-forming PQ **3a–c** containing lateral phenyl groups.

(a) PPA (or P<sub>2</sub>O<sub>5</sub>), *m*-cresol, 120–130 °C;

5-Acetyl-2-aminobenzophenone (**1a**) yielded the polyquinoline **3a**, which precipitated from the reaction mixture after 24–30 h. The intrinsic viscosities of its solutions in sulfuric acid were 1.3–3.6 dl g<sup>–1</sup>. According to X-ray diffraction data, the crystallinity of the polymer **3a** was close to 65%, as a result of which it was soluble only in sulfuric acid. The high crystallinity of the polymer **3a** is largely determined by the symmetry of its macromolecule due to the formation of only one geometric isomer of the PQ in the Friedlander reaction,<sup>51, 54</sup> while three isomers of polyquinolines, which are structurally similar to polyquinolines, are formed.<sup>31–33</sup>

Dynamic thermogravimetric analysis (TGA, ΔT = 5 °C min<sup>–1</sup>) revealed that the mass loss of the polymer **3a** began at 520 °C in air and at 570 °C in nitrogen; at 800 °C, the mass losses were 20%. Such a high thermal stability of polymer **3a** is explicable, especially if one takes into consideration the high extent of cyclisation<sup>51</sup> and high thermal stability of the quinoline ring.<sup>44</sup> The high rigidity and crystallinity of the PQ formed account for its high glass-transition (T<sub>g</sub> = 415 °C) and melting (T<sub>m</sub> = 552 °C) temperatures<sup>1, 49, 65</sup> and limited solubility significantly complicates its processing into articles.

The PQ **3b**, the homocondensation product of 4'-acetyl-4-amino-3-benzoylbiphenyl (**1b**), manifests similar characteristics. The comparative characteristics of the polymers **3a, b** are listed in Table 1.

Somewhat better solubilities of rigid-rod homocondensation products of the AB-type monomers could be achieved if copolycondensation of compounds **1a** and **1b** was carried out. Thus the random copolymer of 5-acetyl-2-aminobenzophenone (**1a**) with 4'-acetyl-4-amino-3-benzoylbiphenyl (**1b**) was soluble not only in sulfuric acid, but also in trifluoroacetic acid (see Table 1). The observed better solubilities of rigid-rod random copolymers in comparison with those of homopolymers is in keeping with previously reported data.<sup>70, 71</sup>

**Table 1.** Some characteristics of polyquinolines **3a,b**.<sup>65</sup>

| Polymer          | Solubility <sup>a</sup>                                              | [ $\eta$ ]/dl g <sup>-1</sup><br>(see <sup>b</sup> ) | $T_g$ /°C<br>(DSC <sup>c</sup> ) | $T_m$<br>/°C | $T_d$ /°C (see <sup>d</sup> )<br>(TGA) |                |

| See <sup>e</sup> | CF <sub>3</sub> CO <sub>2</sub> H,<br>H <sub>2</sub> SO <sub>4</sub> | 4.9                                                  | 330                              | 520          | 555                                    | 580            |

<sup>a</sup> In this case, the ability of the solvent to form 5% solutions of polymers is meant.

<sup>b</sup> The intrinsic viscosities [ $\eta$ ] were measured in concentrated H<sub>2</sub>SO<sub>4</sub> at 25 °C.

<sup>c</sup> DSC is differential scanning calorimetry.

<sup>d</sup> The temperature at which the initial mass loss of the polymer was observed.

<sup>e</sup> A random copolymer (1 : 1) of the monomers **1a** and **1b**.

The polyquinoline **3c** based on 4'-acetyl-4-amino-3-benzoyldiphenyl oxide (**1c**) is soluble in chloroform, THF and DMF, and holds more promise as regards its processing. The high solubility of this polyheteroarylene may be attributed to the presence of ether bonds, which is consistent with the results of other authors.<sup>72</sup> The glass-transition temperature ( $T_g$ ) of polymer **3c** is 235 °C; however, this compound has an amorphous structure and does not melt according to data from differential scanning calorimetry (DSC); its initial decomposition temperature is 513 °C.

The introduction of 'cardo' groups,<sup>73</sup> of fluorene groups in particular, is yet another approach to the enhancement of the solubilities of PQ derived from AB-type monomers.<sup>68</sup> The corresponding monomer, 9-(4-acetylphenyl)-9-(4-amino-3-benzoylphenyl)fluorene (**2**) was prepared by an eight-step synthesis starting from fluorenone. Homocondensation of this monomer in a mixture of *m*-cresol with di-*m*-cresyl phosphate afforded a cardo polyquinoline containing fluorene groups. This polymer is amorphous, it is soluble in strong acids and *m*-cresol, and its  $T_g$  is 365 °C. However, the low characteristic viscosity of solutions of this polymer ([ $\eta$ ] = 0.24 dl g<sup>-1</sup>) is its drawback.

A much larger panel of PQ has been synthesised by reactions of bis(*o*-aminocarbonyl) compounds with diacylarylenes and diphenacylarylenes.

## 2. Synthesis of polyquinolines by co-condensation of bis(*o*-aminocarbonyl) compounds with diacyl- and diphenacylarylenes

### a. Rigid-rod polyquinolines

Polycondensation of 3,3'-dibenzoylbenzidine with various diacylarylenes affords rigid-rod poly(2,6-quinolines) with high glass-transition temperatures and limited solubilities.<sup>65</sup>

R = H, Ar =  $\text{—}(\text{C}_6\text{H}_4)_x\text{—}$ , where  $x = 1$  (**a**), 2 (**b**), 3 (**c**), 4 (**d**);

R = Ph, Ar =  $\text{—}(\text{C}_6\text{H}_4)_y\text{—}$ , where  $y = 1$  (**e**), 2 (**f**).

Some characteristics of rigid-rod PQ **4a–f** are listed in Table 2. Anisotropic solutions of these polymers in a *m*-cresol–di-*m*-cresyl phosphate mixture were used for the spinning of high-quality fibres.<sup>65</sup>

Poly(3,6-quinolines) **5a,b** were prepared by the reaction of 3,3'-dibenzoylbenzidine with diphenacylarylenes, viz., 1,4-diphenacylbenzene and 4,4'-diphenacylbiphenyl in a *m*-cresol–di-*m*-cresyl phosphate mixture.<sup>74</sup>

**Table 2.** Some characteristics of rigid-rod poly(2,6-quinolines) **4a–f**.<sup>65</sup>

| Polymer   | R  | Ar | Solubility <sup>a</sup>        |                                   | [ $\eta$ ]/dl g <sup>-1</sup><br>(see <sup>b</sup> ) | $T_g$ /°C<br>(DSC) | $T_m$ /°C | $T_d$ /°C (TGA) |                |

| <b>4e</b> | Ph |    | ins                            | s                                 | 17.0                                                 | 370                | 555       | 580             | 590            |
| <b>4f</b> | Ph |    | ps                             | s                                 | 22.0                                                 | 360                | —         | 570             | 595            |

<sup>a</sup> Hereinafter, ps is partly soluble, s is soluble, ins is insoluble. <sup>b</sup> The intrinsic viscosities [ $\eta$ ] were measured in CF<sub>3</sub>CO<sub>2</sub>H at 25 °C.

| Polymer   | <i>x</i> | Solubility                                          | $[\eta]$<br>/dl g <sup>-1</sup> | $T_g$ /°C<br>(DSC) | $T_m$ /°C | $T_d$ /°C |                |
|-----------|----------|-----------------------------------------------------|---------------------------------|--------------------|-----------|-----------|----------------|
|           |          |                                                     |                                 |                    |           | air       | N <sub>2</sub> |
| <b>5a</b> | 1        | H <sub>2</sub> SO <sub>4</sub>                      | 0.5                             | 370                | 550       | 570       | 575            |
| <b>5b</b> | 2        | <i>m</i> -cresol,<br>H <sub>2</sub> SO <sub>4</sub> | 2.4                             | 390                | 530       | 570       | 585            |

The PQ **5a** prepared from 1,4-diphenacylbenzene is poorly soluble in H<sub>2</sub>SO<sub>4</sub>, while the PQ **5b** based on 4,4'-diphenacylbiphenyl is soluble in both H<sub>2</sub>SO<sub>4</sub> and *m*-cresol. Polyquinolines **5a,b** have high glass-transition and melting temperatures; their initial thermal and thermooxidative decomposition temperatures are also high.<sup>74</sup>

Insufficient solubilities and high glass-transition temperatures of rigid-rod polyquinolines **4a–f** and **5a,b** made their processing problematic. Therefore, a search for approaches to the enhancement of the working characteristics of PQ was undertaken. Thus rigid-rod PQ **6a–c** containing extended arylene oxide fragments in the side chains were prepared by the condensation of 3,3'-diaroylbenzidines with 4,4'-diacetylbiphenyl.<sup>75</sup>

(a) *m*-cresyl phosphate, *m*-cresol, 136–138 °C, 48 h.

The glass-transition temperatures of polymers **6a–c** are in the interval 307–342 °C, while their melting temperatures are in the interval 416–505 °C. The solubilities of these phenyl PQ are similar to those of rigid-rod PQ containing lateral phenyl groups.<sup>65</sup>

### b. Poly(ether quinolines)

The introduction of ether bonds into macromolecules of PQ, *i.e.*, the synthesis of poly(ether quinolines) (PEQ) has significantly improved their solubilities. Such polymers are formed by the above-considered polycondensation of diphenacylarylenes with bis(*o*-aminocarbonyl) compounds where 4,4'-diamino-3,3'-dibenzoylbiphenyl was replaced by 4,4'-diamino-3,3'-dibenzoyldiphenyl ether (**7**).

The oxide (**7**) was synthesised by two methods.<sup>51</sup> One of them included direct benzylation of 4,4'-diaminodiphenyl ether under drastic conditions to give compound **7**, which was difficult to purify (yields 6%–13%).

The second approach consisted of the reaction of 4,4'-diaminodiphenyl ether with phenylacetonitrile and subsequent reduction of the 5,5'-oxybis(3-phenyl-2,1-benzisoxazole) (**8**) formed, resulting in the monomer **7** (yield 85%).<sup>51</sup>

The synthesis of poly(ether 3,6-quinolines) **9a–c** from 4,4'-diamino-3,3'-dibenzoyldiphenyl ether (**7**) has been described.<sup>74</sup>

| Polymer   | Ar | Solubility        | $[\eta]$<br>/dl g <sup>-1</sup> | $T_g$ /°C<br>(DSC) | $T_m$ /°C | $T_d$ /°C |                |
|-----------|----|-------------------|---------------------------------|--------------------|-----------|-----------|----------------|
|           |    |                   |                                 |                    |           | air       | N <sub>2</sub> |
| <b>9a</b> |    | CHCl <sub>3</sub> | 0.7                             | 312                | —         | 535       | 570            |
| <b>9b</b> |    | TCE               | 3.6                             | 325                | —         | 530       | 550            |
| <b>9c</b> |    | CHCl <sub>3</sub> | 1.2                             | 255                | —         | 530       | 575            |

Poly(ether quinolines) **9a–c** were soluble not only in H<sub>2</sub>SO<sub>4</sub> and *m*-cresol, but also in chloroform and tetrachloroethane (TCE). Their glass-transition temperatures were in the range 255–325 °C; their melting temperatures could not be determined, presumably due to the lower crystallinities of these flexible-chain polymers in comparison with the rigid-rod polymers.<sup>76</sup> Solutions of PEQ in *m*-cresol, chloroform and tetrachloroethane were used for the preparation of strong transparent films by casting.

The reaction of 4,4'-diamino-3,3'-dibenzoyldiphenyl ether (**7**) with diacylarylenes in *m*-cresol–PPA and *m*-cresol–P<sub>2</sub>O<sub>5</sub> mixtures was used for the synthesis of phenyl-substituted poly(ether 2,6-quinolines) **10a–g**.<sup>77,78</sup> The reaction conditions and the main characteristics of some of these compounds are listed in Table 3.

**Table 3.** Conditions of the synthesis and some characteristics of phenyl-substituted poly(ether 2,6-quinolines) **10**.<sup>78</sup>

| Polymer    | Ar                                                                                | R  | Conditions |        | Solubility        | $[\eta]$ /dl g <sup>-1</sup> | $T_g$ /°C | $T_m$ /°C | $T_d$ /°C |

|            |                                                                                   |    | 130        | 48     | CHCl <sub>3</sub> | 1.6                          |           |           |           |
| <b>10e</b> |  | Ph | 130        | 21     | <i>m</i> -cresol  | 3.4                          | 345       | 475       | 535       |
| <b>10f</b> |  | Ph | 130        | 21     | <i>m</i> -cresol  | 4.1                          | 351       | 480       | 540       |
| <b>10g</b> |  | Ph | 130        | 24     | CHCl <sub>3</sub> | 2.0                          | 305       | 476       | 530       |

These polymers were soluble in chloroform and *m*-cresol. Even PEQ **11** was soluble in both sulfuric and formic acids and *m*-cresol.<sup>78</sup>

It was shown that the solubilities of phenyl-substituted PEQ were lower than those of the analogues devoid of the phenyl groups, which is in contrast with the data for other classes of rigid-rod polymers.<sup>31–33, 79, 80</sup> This can be attributed to the higher proneness of the former to aggregation due to hindered rotation of the quinoline rings.

Further increase in the number of ether bonds in the main chains of PEQ was achieved using resorcinol bis(4-amino-3-benzoylphenyl) ether as a monomer. Its condensation afforded PEQ **12**, which is soluble not only in formic acid and chloroform, but also in *N*-methyl-2-pyrrolidone (*N*-MP).<sup>81</sup> The softening temperature of PEQ **12** is 135 °C.

A method for the synthesis of 4,4'-bis(2-aminobenzoyl)di-phenyl ether (**13**) was developed by Norris and Stille.<sup>51</sup>

Its reaction with diacetylenes yielded the polymers **14a–e** containing 2,4-substituted quinoline fragments.<sup>48–50</sup>

This reaction proceeds especially smoothly in mixtures of *m*-cresol with PPA or P<sub>2</sub>O<sub>5</sub>; the formation of a protonated form of PEQ in these media is an essential feature as a result of which the polymer remains in the solution up to the end of the reaction. The reaction conditions and some characteristics of the PEQ synthesised are listed in Table 4.

**Table 4.** Conditions of the synthesis and some characteristics of PEQ **14a,c–e**.<sup>50</sup>

| Polymer    | Conditions |        | $[\eta]^a$<br>/dl g <sup>−1</sup> | $T_g$<br>/°C | $T_m$<br>/°C     | $T_d$<br>/°C |
|------------|------------|--------|-----------------------------------|--------------|------------------|--------------|
|            | $T$ /°C    | $t$ /h |                                   |              |                  |              |

<sup>a</sup> The intrinsic viscosity was measured in *m*-cresol.

<sup>b</sup> An amorphous polymer.

The polyquinolines **14a–e** have amorphous structures and are easily soluble in *m*-cresol and chloroform. Their softening temperatures are much lower than those of rigid-rod PEQ.

Properties of the PEQ polymer **14a** have been studied in much more detail.<sup>48–50</sup> The relatively high molecular mass (~50 000) and its good solubility in *m*-cresol and chloroform made it possible to use it as a starting material for the preparation of strong elastic films and fibres; subsequent orientation of the latter noticeably increased their crystallinities.<sup>50,77</sup> The polymer **14a** possessed high thermal stability upon dynamic and isothermal TGA. Thus dynamic TGA (air,  $\Delta T = 5^\circ\text{C min}^{-1}$ ) revealed that its initial decomposition temperature was 510 °C; a 10% mass loss in nitrogen occurred at 800 °C. According to data from isothermal TGA, the polymer retained its stability upon heating at 300 °C in circulating air over 100 h. It decomposed at 360 °C, the mass loss after 21 h being 10%. Complete decomposition of the polymer occurred after 39 h.

The reaction of 4,4'-bis(2-aminobenzoyl)diphenyl ether (**13**) with 1,4-diphenylacetylbenzene and 4,4'-diphenylacetyl biphenyl afforded phenyl-substituted poly(2,4-quinolines) **15a,b**.<sup>48–50, 69</sup>

The polymers **15a,b** are soluble in *m*-cresol; their intrinsic viscosities are 0.26 and 0.57 dl g<sup>−1</sup>, respectively. The polymer **15a** was not obtained in a crystalline state; its glass-transition temperature was 273 °C; the glass-transition and melting temperatures of the polymer **15b** were 345 and 500 °C, respectively.<sup>68</sup> Strong elastic films could be prepared from 15%–25% solutions of these PEQ in CHCl<sub>3</sub> or a (3 : 1) TCE–*m*-cresol mixture, which became opaque upon slow evaporation of the solvents due to partial (~20%) crystallisation.

According to dynamic TGA ( $\Delta T = 5^\circ\text{C min}^{-1}$ ) the decomposition of the polymer **15a** in air and in nitrogen began at 530–545 °C and at 530–570 °C, respectively. In nitrogen, the mass loss of the polymer at 800 °C was only 15%–26%. According to the data from isothermal TGA, no mass loss of the polymer **15b** in circulating air occurred over 100 h at 300 °C; over the same time at 371 °C, the mass loss was 48%.

### c. Polyquinolines containing cardo, tetraphenylsilyl and perfluorotetramethylene groups

A series of cardo polymers<sup>82,83</sup> and PQ containing tetraphenylsilyl<sup>84</sup> and perfluorotetramethylene groups have been synthesised in order to improve the processibility of high-molecular-weight PQ.<sup>85,86</sup>

9,9-Bis(4-acetylphenyl)fluorene and 9,9-bis(4-acetylphenyl)-10-anthrone<sup>82</sup> were synthesised aimed at the preparation of cardo PQ. These were further introduced into reactions with bis(*o*-aminobenzophenones).<sup>82</sup>

The majority of the cardo PQ thus prepared were soluble not only in *m*-cresol, but also in chloroform and TCE.

The introduction of cardo groups has made it possible to increase the glass-transition temperatures of PQ by 40–70 °C in comparison with PEQ. The PQ based on cardo diacetyl derivatives are characterised by extremely high thermostabilities; their decomposition began at the temperatures above 550 °C. The decomposition temperatures of anthronyl-containing PQ are 30–50 °C lower than those of fluorene-containing PQ.

By virtue of their high molecular masses (up to  $5.25 \times 10^5$  Da), some of these polymers<sup>83</sup> were successfully used for the preparation of strong films.

Polyquinolines prepared from cardo bis(*o*-amino ketones), viz., 9,9-bis(4-amino-3-benzoylphenyl)fluorene (**16**) and 9,9-bis(4-amino-3-benzoylphenyl)-10-anthrone (**17**),<sup>82</sup> were soluble in chlorinated hydrocarbons and thermostable (up to 520–580 °C). Their glass-transition temperatures were 310–420 °C.

The use of comonomers each containing cardo groups for the synthesis of PQ has led to the polymers **18** which are soluble in chlorinated solvents (CHCl<sub>3</sub>, TCE). Some properties of the cardo PQ **18** are listed in Table 5.

Studies of rigid-rod cardo PQ by dynamic TGA revealed that the polymers containing one cardo and one 4,4'-biphenyl group in the repeating unit of the polymer possessed better mechanical properties than the flexible-chain polymers containing one cardo and one 4,4'-diphenylene oxide group or two cardo groups in the polymer unit.

The silicon-containing diacetyl monomers **19** and **20** were synthesised<sup>84</sup> and introduced into the acid-catalysed polycyclocondensation with bis(*o*-aminobenzophenones) **7** and **16**

resulting in PQ **21–24**.

**Table 5.** Some characteristics of cardo PQ **18**.<sup>82</sup>

| X | Y | $[\eta]$ / dl g <sup>-1</sup> | $T_g$ / °C | $T_d$ / °C |
|---|---|-------------------------------|------------|------------|
|   |   | 0.58                          | 390        | 580        |
|   |   | 0.70                          | 385        | 530        |
|   |   | 1.30                          | 405        | 540        |
|   |   | 0.53                          | 390        | 520        |

Both homo- and block-copolymers with fluorene-containing cardo blocks were prepared by condensation of equimolar amounts of compounds **7** and **16** with the diacetyl monomers **19** and **20** in *m*-cresol–di-*m*-cresyl phosphate at 140 °C.

The solubilities of the polymers **21–24** exceed those of the majority of PQ.<sup>1–5</sup> In addition, these compounds swell strongly in many solvents, such as *m*-cresol, chloroform, dichloromethane, *N*-MP, DMF, benzene and chlorobenzene.

Easily processable polyquinolines **25** ( $T_g$  = 142–183 °C) were prepared from comonomers **26** containing perfluorotetramethylene groups.<sup>85, 86</sup>

Polymers **21–25** were used for the preparation of high-quality films<sup>50, 69, 77, 79</sup> and fibres<sup>50, 69, 77, 87</sup> some of which manifest high thermal characteristics.<sup>50, 69, 77, 87, 88</sup>

However, introduction of ether bonds or perfluoroalkylene groups aimed at improving the processability of PQ results in a decrease in the glass-transition or softening temperatures and, consequently, their operating temperatures. These can be increased by crystallisation of amorphous polymers. However, its practical realisation is rather a difficult task; therefore, an alternative approach, viz., post-moulding curing of amorphous polymers, has been developed.

#### d. Reactive oligo- and polyquinolines

Reactive oligo- and polyquinolines can be prepared by several methods. These include

(1) introduction of terminal arylcyanate groups into PQ with subsequent cyclotrimerisation resulting in internodal *sym*-triazine fragments (Scheme 2);<sup>89</sup>

(2) introduction of biphenylene fragments,<sup>52,90–94</sup> which undergo ring-opening at 350–400 °C to generate biradicals that further recombine into dimers and/or polymers;<sup>90–96</sup>

(3) introduction of terminal biphenylene groups and triple C–C bonds into the main chains of PQ.<sup>94</sup> This enables cross-linking of the polymers, if the reactions are carried out at high temperatures<sup>95</sup> or in the presence of nickel catalysts;<sup>97</sup>

(4) introduction of hexaarylbenzene fragments into macromolecules of PQ<sup>98</sup> using 1,2-bis[4-(acetylphenoxy)phenyl]-3,4,5,6-tetraphenylbenzene as a comonomer for PQ synthesis.

These hexaarylbenzene fragments are effective cross-linking agents, which enable preparation of polymers with enhanced thermal and mechanical properties, especially at temperatures exceeding the glass-transition temperatures of the original PQ;<sup>99</sup>

(5) introduction of terminal [2.2]paracyclophane groups<sup>100</sup> with subsequent curing of reactive PQ obtained due to the opening of the [2.2]paracyclophane rings.

All these approaches seem to hold much promise with regard to the design of novel composites with enhanced thermal and mechanical characteristics.<sup>94</sup>

In addition to thermal and mechanical properties, considerable attention of investigators is given to the electrophysical characteristics of PQ.<sup>98,101</sup> Thus materials with conductivities of

11  $\Omega\text{ cm}^{-1}$  could be prepared by doping PQ devoid of bridging groups with AsF<sub>5</sub>, iodine, sodium naphthalenide and anthracenide.<sup>98,101–107</sup> Among those, rigid-rod PQ prepared by doping with sodium anthracenide manifested the highest conductivities. However, PQ containing bridging groups possessed low permittivities ( $\epsilon \sim 2.8$ )<sup>108</sup> comparable to those of the best fluorine-free PHA.<sup>109</sup>

#### e. Polyanthrazolines

The Friedlander reaction was successfully employed in the synthesis of polymers containing both substituted and non-substituted anthrazoline or isoanthrazoline rings in the main chains. Thus the reaction of 4,6-diaminoisophthalaldehyde with diacetylarenes in hexamethyl phosphorotriamide (HMPA)<sup>110,111</sup> yielded the polymers **27a–c**.

The polyanthrazolines thus prepared possessed high thermostabilities: according to dynamic TGA ( $\Delta T = 10\text{ }^\circ\text{C min}^{-1}$ ), the mass loss in air began at 450 °C, whereas in an inert atmosphere the 5% mass loss was observed at 600–650 °C. However, these polymers were soluble only in sulfuric acid. They sedimented from reaction solutions, which prevented the formation of high molecular mass products; the inherent viscosities of their solutions in sulfuric acid did not exceed 0.26 dl g<sup>–1</sup>. Polyanthrazolines prepared from dibenzoylphenylenediamines instead of dialdehydodiamines as

$n = 4, 10, 11$ .

Acid- or base-catalysed reactions of 4,6-diaminoisophthalaldehyde with bis(phenylacetyl)arenes gave the phenyl-substituted PAZ **28a–f**,<sup>113</sup> which manifested better solubilities than their analogues bearing no phenyl groups.

Therefore, phenylated PAZ prepared from 4,6-dibenzoyl-1,3-phenylenediamine (**29**) and 2,5-dibenzoyl-1,4-phenylenediamine (**30**) as monomers in the presence of acid catalysts were used in further studies.<sup>113</sup>

ClC(=O)c1cc([N+](=O)[O-])cc([N+](=O)[O-])c1C(=O)Cl
 $\xrightarrow{\text{PhH, AlCl}_3}$ 
ClC(=O)c1cc([N+](=O)[O-])cc([N+](=O)[O-])c1C(=O)Ph
 $\xrightarrow{[\text{H}]}$ 
Nc1cc(N)cc(C(=O)Ph)c1C(=O)Ph
**29** (76%)

The scheme illustrates the synthesis of 2,6-bis(aminocarbonyl)-4,4'-biphenyl (29) and 2,6-bis(aminocarbonyl)-4,4'-biphenyl (30) from phthalic anhydride derivatives.

1. Phthalic anhydride reacts with PhH and AlCl<sub>3</sub> to form 2,6-bis(benzoyloxycarbonyl)phthalic acid (31) and 2,6-bis(benzoyloxycarbonyl)phthalic acid (32).

2. 31 reacts with SOCl<sub>2</sub> to form 2,6-bis(benzoyloxycarbonyl)-4,4'-biphenyl-2,6-dicarboxylic acid (33).

3. 33 reacts with NH<sub>3</sub> to form 2,6-bis(benzoyloxycarbonyl)-4,4'-biphenyl-2,6-diamine (29) (86% yield).

4. 32 reacts with SOCl<sub>2</sub> to form 2,6-bis(benzoyloxycarbonyl)-4,4'-biphenyl-2,6-dicarboxylic acid (34).

5. 34 reacts with NH<sub>3</sub> to form 2,6-bis(benzoyloxycarbonyl)-4,4'-biphenyl-2,6-diamine (30) (72% yield).

$$n \text{ Ph(O)C-C}_6\text{H}_2\text{(NH}_2\text{)}_2\text{-C(O)Ph} + n \text{ Me-C(=O)-Ar-C(=O)-Me} \xrightarrow{\text{Cat}}$$

Isomeric PAZ **36** and **37** containing four phenyl substituents in each polymeric fragment were prepared by the reaction of diamine **29** with 1,4-bis(phenylacetyl)benzene and 1,4-diphenylbenzene.<sup>1,2,111,113</sup>

The main characteristics of these polymers differ only insignificantly from those of the aforementioned phenylated PAZ **35a–f**.

The substitution of 2,5-dibenzoyl-1,4-phenylenediamine (**30**) for 4,6-dibenzoyl-1,3-phenylenediamine (**29**) gave polyisoanthrazolines **38**,<sup>1,113</sup> due to their greater symmetries, they possessed lower solubilities than those of the isomeric PAZ. The thermal characteristics of polymers **30** are similar to those of other PAZ.

### III. Polyquinolines possessing electroluminescent properties

Polymers possessing electroluminescent properties attracted attention as materials for electrooptics, for the preparation of light-emitting diodes (LED), in particular.<sup>115–124</sup>

Considering that the majority of conjugated electroluminescent polymers form and transport 'holes' much more efficiently than electrons,<sup>125–127</sup> the construction of polymers with enhanced electron-transport properties is a topical task. It was found that polyquinolines with different structures possess remarkable electron-transport properties<sup>8,9,128,129</sup> and can be used for the preparation of electron-transport layers for LED.

The polymers **39** and **40a–k** were the subject of investigation in one of the first systematic studies of PQ and PAZ possessing high photoluminescent properties.<sup>8,9,130</sup>

In-depth studies of these polymers, which differ in the lengths of their conjugation chains, have shown that the widths of their optical forbidden bands differed by 1.0 eV. Thus the width of the optical forbidden band ( $E_g$ ) of PQ **40b** containing a biphenyldiyl fragment was equal to 2.81 eV, while that of PAZ **40j** containing a dithienylvinylene fragment was 2.0 eV. Substitution of the thiophene groups for the phenylene groups caused a noticeable long-wavelength shift of the absorption maximum ( $\lambda_{\text{max}}$ ) (by 64–106 nm) with concomitant narrowing of the forbidden band by 0.3–0.5 eV. Some characteristics of these PQ are presented in Table 6.

Table 6. Optical characteristics of conjugated PQ.<sup>9</sup>

| Polymer    | $\lambda_{\text{max}}$ (film) | $\lambda_{\text{max}}$ (solution) | $E_g$ | $\log \epsilon$ |
|------------|-------------------------------|-----------------------------------|-------|-----------------|
| <b>39</b>  | 410                           | 389                               | 2.65  | 4.16            |
| <b>40a</b> | 398                           | 405                               | 2.78  | 4.63            |
| <b>40b</b> | 394                           | 429                               | 2.81  | 4.83            |
| <b>40c</b> | 399                           | 436                               | 2.72  | 4.86            |
| <b>40d</b> | 408                           | 467                               | 2.65  | 4.88            |
| <b>40g</b> | 370                           | 389                               | 3.01  | 4.68            |
| <b>40h</b> | 441                           | 493                               | 2.49  | 4.78            |
| <b>40i</b> | 468                           | 546                               | 2.33  | 5.06            |
| <b>40j</b> | 469                           | 567                               | 2.26  | —               |
| <b>40k</b> | 484                           | 578                               | 2.23  | 5.00            |

The monomers **41** were synthesised, and a novel procedure for the introduction of the acetylenic fragments into PQ was proposed, which consisted of polycondensation with 5,5'-diacetyl-2,2'-bithiophene.<sup>131</sup>

$R^1 = R^2 = \text{H}$ ;  $R^1 = \text{OMe}$ ,  $R^2 = \text{H}$ ;  $R^1 = \text{H}$ ,  $R^2 = \text{F}$ .

An attempt has been made to overcome the limited solubilities of rigid-rod conjugated PQ by modifying them through introduction of alkyl substituents.<sup>132–139</sup> However, no enhanced solubility was observed for PQ **42** containing *tert*-butyl substituents in the *para*-position of the phenyl rings.<sup>133, 134</sup> Notwithstanding, this PQ was used for the preparation of electroluminescent films with a light-yellow emission ( $\lambda_{\text{max}} = 554$  nm), proton/electron quantum efficiency of 0.26% and a brightness of 280 cd m<sup>-2</sup> at a current density of 100 mA cm<sup>-2</sup>.

The increase in the solubility of PQ is better achieved by introducing higher alkyl (*e.g.*, octyl) substituents.<sup>135</sup>

The polymer **43** thus prepared was soluble in formic acid and other protic solvents as well as in THF, toluene and CHCl<sub>3</sub>. The absorption maximum of a solution of PQ **43** was 414 nm. Green emission ( $\lambda_{\text{max}} = 510$  and 530 nm) was observed for a solution and a thin polymeric film, respectively.

Considerable attention has also been given to PQ that contained fluorene groups with alkyl substituents.<sup>136–138</sup>

Polyquinolines with the general formula **44** containing 9,9-di(*n*-hexyl)fluorene fragments were prepared by the reaction of 2,7-diacetyl-9,9-di(*n*-hexyl)fluorene with diaminobenzoyl compounds.<sup>136, 137</sup>

X is a bond, O, S, CH = CH.

The PQ formed are soluble in CHCl<sub>3</sub>, THF and chlorobenzene; their glass-transition temperatures lie in the range 195–243 °C. The electroluminescence spectra of PQ are charac-

terised by blue emission (432 nm). The use of [4,4'-diamino-3,3'-bis(4'-octyloxybiphenyl-4-yl)carbonyl]biphenyl as a monomer allowed introduction of additional 4-octyloxybiphenyl groups into PQ **45**, which is soluble in CHCl<sub>3</sub>, THF and dimethylacetamide.<sup>138</sup>

The electroluminescence maximum of PQ **45** lies around 530 nm (green emission). Mixing of this PQ with polyvinylcarbazole results in a blue shift of the maximum due to the dilution effect.<sup>139</sup>

The effectiveness of formation of polymeric mixtures for the enhancement of the electroluminescent properties of the target materials has been reported.<sup>140, 141</sup>

## IV. Conclusion

The data considered in the present review illustrate the indisputable progress in the area of the synthesis of PQ and PAZ and their use in the preparation of unique materials, *e.g.*, fibres, films, composite materials and electroluminescent systems.

Novel promising areas for the application of PQ have recently been outlined. In the first place, these include the construction of second<sup>142–145</sup> and third<sup>146–148</sup> generations of materials for non-linear optics.

Of considerable interest are the data related to the use of pyrrole-containing PQ for complex formation with strong acids.<sup>149</sup> Such complexes were used for the preparation of proton-exchange membranes,<sup>149</sup> which represent the most important components of fuel cells relevant to the key technologies of the 21st century.<sup>150–154</sup> Thus a proton-exchange membrane based on complex **46** manifests enhanced proton conductivity ( $1.5 \times 10^{-5}$  Ω cm<sup>-1</sup> at 157 °C),<sup>149</sup> which surpasses that of the known polybenzimidazole–H<sub>3</sub>PO<sub>4</sub> complexes ( $7 \times 10^{-5}$  Ω cm<sup>-1</sup> at 150 °C).<sup>155</sup>

The remarkably high thermal conductivity of PQ·H<sub>3</sub>PO<sub>4</sub> membranes opens up promising opportunities for their wide applications.

**Abstract.** The state-of-the-art of investigations into the development and perfection of volatile corrosion inhibitors is analysed. The characteristic features of metal protection by these compounds and the effects of their chemical structures on the properties are discussed. The problems of adsorption and protective post-effect of volatile corrosion inhibitors are considered. The bibliography includes 133 references.

## I. Introduction

Atmospheric corrosion, which occurs not only under thick (phase-type) films but also under thin (adsorption-type) water films, is the most common type of corrosion.<sup>1–6</sup> The use of volatile corrosion inhibitors (VCIs) for metal protection from atmospheric corrosion started in the 1940s when Shell Co. patented the use of amine nitrites for this purpose.<sup>1</sup>

Volatility is the main distinctive feature of VCIs in comparison with traditional metal corrosion inhibitors in aqueous solutions.<sup>7–12</sup> The ability of VCIs to propagate, upon evaporation, throughout a system to be protected predetermines their major advantage: it is unnecessary to apply such inhibitors on metal surfaces and no special measures are needed to remove them.<sup>1</sup> The latter feature is of importance where VCIs are used to protect military equipment during long-term storage, since this can quickly be put into operation as required.<sup>13, 14</sup>

In the storage and transportation of articles (the so-called temporary protection) or operation of bulky extended constructions and pipelines that contact corrosive vapours and gases, VCIs that spontaneously enter various crevices and interstices are adsorbed on metal surfaces from the vapour phase and create there thin protective films. It is important that the VCI vapour can saturate a corrosive liquid that is often condensed in hardly accessible places, thus ensuring the required protection in the liquid phase as well. It is due to this feature that VCIs are used in power engineering<sup>†</sup> and for the protection of inner surfaces of pipelines.

Depending on the structure that determines the saturated vapour pressure ( $p^0$ ) together with other characteristics, VCIs form adsorption layers of different thicknesses on the surface to be protected. In the corrosion protection of high-precision metal articles (for example, bearings, electrical or radio equipment and particularly electronic equipment that usually operates in moderately-corrosive environments), certain classes of VCIs form nano-sized protective layers upon adsorption, which is the most attractive feature. These VCIs can be used to protect ‘clean’ metallic surfaces where paint coatings are unacceptable. It was also reported<sup>15</sup> that in some cases VCIs improve the efficiency of organic coatings as well.

The majority of complex articles consist of various metals and alloys; for this reason, the so-called versatile VCIs have been developed. Both individual chemical compounds, such as hexamethyleneimine *m*-nitrobenzoate, benzimidazole and certain thiazoles as well as mixtures, *e.g.*, of 1,2,3-benzotriazole (BTA) which is an efficient corrosion inhibitor of many non-ferrous metals with VCIs that reliably protect only ferrous metals (amines, amine nitrites, *etc.*), became popular.<sup>1, 2, 16, 17</sup> However, the majority of these VCIs have low volatility, which limits their scope. In view of this, functionalised alkylamines were studied as VCIs and it was proved that incorporation of an additional functional group into an alkylamine molecule increases the protective ability of VCIs with respect to a wide range of metals and alloys and also makes it possible to optimise their volatility. As a result of these studies, versatile new-generation VCIs have been elaborated: dialkylamino ketones,<sup>1, 18</sup> dialkylamino nitriles,<sup>19</sup> *etc.*<sup>15</sup>

The scope of VCIs has expanded considerably over recent years. In addition to the traditional packing papers and porous carriers,<sup>1, 2, 20</sup> polymeric films containing volatile inhibitors as additives find general use.<sup>21–25</sup> The advantages of such materials over paper are obvious, though the introduction of a VCI into a polymer has some specific features, and not every inhibitor maintains its highly protective properties upon thermal treatment during the film preparation. Water-soluble VCIs were also recommended for modifying acrylate or alkyd films that have been suggested instead of preservative oils or paint coatings applied from organic solvents.<sup>26, 27</sup> Modified thin coatings ( $\delta \leq 25 \mu\text{m}$ ) can be used for the protection of metal articles during sea transportation or storage in air. Such coatings are advantageous due to their environmental safety, as regards both their application and removal, which is effected by aqueous washing solutions.

<sup>†</sup> The use of ammonia and volatile amines for the anti-corrosion protection of inner surfaces of steam-power plants and tubes started back in the 1920s.<sup>6</sup>

Volatile corrosion inhibitors are often used in combination with usual (contact-type) inhibitors to protect pipelines and equipment of water-supply systems. They are used to slow down corrosion not only in liquids but also in vapours.<sup>28,29</sup> Such protection becomes necessary where tanks or pipes are partially filled with water or where they are operated intermittently, for example, in seasonal operation. Sometimes, during shutdowns of boilers, turbines and other equipment, they are dried with air saturated with VCI vapour; this is more efficient in terms of corrosion protection than ordinary drying.<sup>30</sup> We have found that compounds that form azeotropic mixtures with water can be employed as VCIs,<sup>31</sup> which should help broaden the scope of VCIs. Under certain conditions, such VCIs ensure the metal protection even under heavy condensation of water vapour. In closed systems, aqueous solutions of these VCIs that protect the metal surface without deliberate drying will be convenient for hydrotesting, for example, of power equipment and other types of bulky equipment.

Increasing interest in VCIs is also being felt in the gas industry where they are used to protect the inner surfaces of steel pipelines, both as such and as part of film-forming blends.<sup>32–39</sup> It is important that VCIs are applicable for steel protection from hydrogen sulfide corrosion and from the quite peculiar carbon dioxide corrosion. An efficient method was described<sup>40</sup> for the use of VCIs for protecting the outside surface of an oil pipeline where it crossed a roadway. Mechanical damage is avoided in such cases by mounting a special duct around the pipeline; a VCI is introduced into the annular space in-between.

Volatile corrosion inhibitors were used as the basis for development of a novel type of anticorrosion agents, *viz.*, migrating corrosion inhibitors (MCIs).<sup>41–45</sup> These have been developed for the protection of steel reinforcement in concrete against corrosion, which is a pressing scientific and technical problem of current city- and bridge-building. For example, according to data from Ref. 43, ~200 million dollars is spent annually in the USA to repair bridges where chloride-induced destruction of reinforced concrete has occurred. The first MICs contained volatile amine carboxylates or alkanolamine carboxylates as the most important components that diffused through concrete pores (including vapour diffusion), reached the surfaces of reinforcing steel and inhibited its corrosion. Such inhibitors should not only possess high self-diffusion coefficients, be poorly adsorbed on cement stone and be well adsorbed on steel, but should also be competitive in these parameters with chlorides, which induce most often the corrosive destruction of reinforcing steel in concrete. It should be remembered that reinforcing steel could be corroded initially and that corrosion stimulation that often occurs due to its localisation is unacceptable in reinforced-steel structures, particularly in strained ones.

To date, the mechanism of action of MCIs has been studied insufficiently and its discussion is beyond the scope of this review. However, there is no doubt that this mechanism has much in common with that of VCIs. Obviously, the development of more efficient VCIs would also favour progress in the protection of reinforced-steel structures.

The requirements for corrosion protection have increased during the last decade, especially in terms of environmental safety. This certainly gives impetus to the development of new efficient and environmentally safe compositions and protective agents and favours the development of the theoretical basis of the VCI action. This provides prospects for rapid progress in this field.

## II. Specific features of vapour-phase metal protection by inhibitors

If the space to be protected can be sealed, at least partially, this is a direct indication for the use of VCIs. Depending on the conditions, VCI vapour fills the entire volume by diffusion or with a gas stream. It is the diffusability of the inhibitor vapour that determines the advantages of VCIs over other types of inhibitors

and governs some of their specific parameters, such as the protection radius ( $l_{pr}$ ), passivation time, *etc.*<sup>46–50</sup>

The kinetics of VCI vapour diffusion plays an important role in anti-corrosion protection from the onset of its contact with the metal. Volatile corrosion inhibitors are often used to preserve complex items that may fail due to even minor damage.<sup>25,51</sup> Therefore, it is a prerequisite of protection that an inhibitor be accumulated on a metal surface in an amount sufficient to suppress corrosion before the first corrosion sites appear on the surface. It should be noted that, though the mathematical tools for the description of diffusion processes have been developed to a considerable extent, the first attempts to simulate this condition were undertaken from the late 1980s to the early 1990s.<sup>46–50</sup> A series of studies<sup>47–50</sup> on quasi-steady evaporation of a VCI droplet inside a metallic sphere coated with a water film were the most successful. This model assumed that the surface electrolyte contained an inhibitor in a minimum protective concentration ( $C_{pr}$ ) to prevent metal corrosion.

The analytical solution for the problem has the form

$$l_{pr} = \lambda \sqrt{\frac{Dp^0}{C_{sat} \ln(1 - C_{pr}/C_{sat})}} \quad (1)$$

and defines the relationship between the VCI efficiency expressed as a function of  $l_{pr}$ , the diffusion coefficient ( $D$ ) of VCI vapour in air, the saturation pressure  $p^0$ , the solubility ( $C_{sat}$ ) and the  $C_{pr}$  value under conditions affecting the coefficient  $l$  (temperature, thickness of the moisture film on the metal, *etc.*). Analysis of the possible variation ranges of these parameters<sup>52</sup> showed that  $D$  affects the protection efficiency the least.

This model provides a fairly good description of the trend of the effects of the base parameters on the protective properties of VCIs provided heat exchange and mass exchange with the environment can be neglected, *e.g.*, in the conservation of metal articles under atmospheric conditions. Generally,<sup>1,53</sup> after the article and a VCI source are sealed, the system is kept for some time at a constant temperature in order to allow the inhibitor vapour to reach the surface. Thus  $l_{pr}$  can be regarded as the main criterion of the VCI efficiency, and approaches to enhance protection that follow from Eqn (1) (an increase in the inhibitors'  $p^0$  and their protective capability in thin electrolyte films, uniform spatial distribution of VCI sources, *etc.*) prove to be efficient.

On the other hand, sealed systems where protection is only determined by the initial period of contact of a metal with a VCI are rather rare in real technics. The role of heat transfer and mass transfer processes in initiating corrosion of real systems protected by VCIs consists of violation of the protection conditions ( $C_{inh} > C_{pr}$ ) due to a decrease of the inhibitor concentration in the surface electrolyte ( $C_{inh}$ ) or an increase in  $C_{pr}$  with time.<sup>31,54</sup>

Evaporation of VCI from the space that is protected through a permeable packing is a reason for a decrease in  $C_{inh}$ . Hence, inhibitors with  $p^0 > 13.3$  Pa cannot normally ensure long-term vapour-phase protection.<sup>1</sup> However, corrosion can also be initiated in an unsealed system due to the ingress of aggressive atmospheric components, including water, into such a system.

The introduction of VCIs into a space that is protected is accompanied by their interaction with water contained in the internal environment, formation of solutions, and a decrease in the humidity of the gas phase. These processes usually affect only slightly the corrosivity of the environment<sup>55</sup> but they favour the diffusion of water into the system. Obviously, if the relative humidity of the environment exceeds that above a VCI solution with a concentration of  $C_{pr}$ , gradual dilution of the latter with atmospheric moisture will result in the initiation of corrosion even if the inhibitor is not removed from the space that is protected.

Analysis of basic models has shown that the rate of water diffusion into a space that is protected can appreciably exceed the rate of VCI evaporation and determine the kinetics of its dilution in a system and the protection period. In fact, mass exchange of a quasi-equilibrium system containing a VCI that is miscible with

water in all proportions, with a water-saturated external atmosphere is described<sup>54</sup> by the following equation

$$\frac{N_{\text{H}_2\text{O}}}{N_{\text{inh}}} = \frac{D_{\text{H}_2\text{O}} p_{\text{H}_2\text{O}}^0}{D_{\text{inh}} p_{\text{inh}}^0}, \quad (2)$$

where  $N$  is the number of moles of the inhibitor or water, respectively (depending on the subscript) that diffuse through the barrier material per unit time. An approximate calculation showed that in the case of mass transfer through open pores and violated integrity of the barrier material, the  $N_{\text{H}_2\text{O}}/N_{\text{inh}}$  ratio can reach  $10^5$ . The success in the combined use of VCIs and desiccants for metal protection shows that diffusion of water contributes the most to the rate of a decrease in the  $C_{\text{inh}}$ , at least for VCIs with comparatively small  $p^0$  values.<sup>30</sup>

If the ingress of water into the system decreases  $C_{\text{inh}}$ , the diffusion of acid gases ( $\text{SO}_2$ ,  $\text{NO}_2$ ,  $\text{CO}_2$ ,  $\text{H}_2\text{S}$ , etc.) into it increases the corrosivity of the medium and hence increases  $C_{\text{pr}}$ . This can also result in the corrosion initiation. Binding of such gases by inhibitors, many of which are organic bases (or contain them as components), favours their diffusion into the space that is protected.<sup>1, 16, 52, 56</sup>

Metal protection by a volatile inhibitor can also be violated by heat exchange between the system and the environment. It is well known that abundant condensation of water vapour due to temperature fluctuations is very unfavourable for vapour-phase protection.<sup>18, 57</sup> However, the majority of researchers had previously limited themselves merely to the statement of this fact and simulation of such conditions in VCI efficiency preliminary tests.<sup>16, 51, 56</sup>

The analysis of mechanisms of corrosion initiation by heat exchange that we have carried out<sup>31</sup> has shown that the temperature gradient on a metal results in a redistribution of water and a VCI in the surface electrolyte, similar to that occurring during distillation of solutions. The evaporation is intensified on heated areas and the vapour phase is enriched in the more volatile component of the mixture and its surface concentration decreases. If  $p_{\text{inh}}^0 > p_{\text{H}_2\text{O}}^0$ , a decrease in  $C_{\text{inh}}$  below  $C_{\text{pr}}$  can stimulate corrosion. On the other hand, on cooled surfaces where vapour condenses the surface electrolyte becomes enriched in the volatile component. This may result in the violation of vapour-phase protection if  $p_{\text{inh}}^0 < p_{\text{H}_2\text{O}}^0$ .

There are a number of ways to prevent corrosion that appears by this mechanism. One of them involves the use of VCIs that are irreversibly adsorbed on the metal and have a protective post-effect. If the temperature difference on the metal occurs occasionally and afterwards the system comes to a near-equilibrium state, such a post-effect can protect the article. However, this does not guarantee that the article will remain preserved. No matter what the VCI post-effect, possible heat-exchange can initiate corrosion.

Yet another possibility for vapour-phase metal protection under heat-exchange conditions is the use of VCIs with  $p^0$  and vaporisation enthalpy ( $\Delta H_v$ ) values similar to those of water. In this case, the composition of the surface electrolyte is identical to that of the vapour above it. Evaporation and condensation can neither change  $C_{\text{inh}}$  nor cause corrosion. However, perfect ideal matching of  $p^0$  and  $\Delta H_v$  is only realised for optical isomers and it is practically impossible to select a VCI that satisfies this condition.

The third way, new in principle, for metal protection by volatile corrosion inhibitors under heat exchange conditions is the above-mentioned one, *viz.*, the use of inhibitors that form azeotropic mixtures with water. If the content of these VCIs allows their equilibrium concentrations in the surface electrolyte to exceed the concentrations of the azeotropic mixtures ( $C_{\text{az}}$ ) and  $C_{\text{az}} > C_{\text{pr}}$ , no heat-exchange mode initiating corrosion can be attained in the entire possible temperature range of the environment. In fact, irrespective of whether the azeotropic mixture is characterised by a maximum or minimum in the composition–pressure diagram, the surface electrolyte that meets the condition

$$C_{\text{inh}} > C_{\text{az}} > C_{\text{pr}}, \quad (3)$$

can be distilled to give pure VCI and its solution with a concentration of  $C_{\text{az}}$ . If  $C_{\text{az}} > C_{\text{pr}}$ , the vapour-phase protection cannot be violated by heat exchange. The specific features of metal protection by such inhibitors have been little studied to date, but the prospects associated with them make these studies of high priority.

### III. The effect of chemical structures of volatile corrosion inhibitors on their protective properties

In practice, systems protected by VCIs are as a rule subject to a complex of external effects that alter the metal storage life. However, an analysis of the mechanisms of violation of vapour-phase protection described above allowed us to mark the most important characteristics that determine the VCI efficiency, *viz.*, evaporability; inhibitory properties in the surface electrolyte, including the anticorrosion post-effect; solubility in water and ability to form azeotropic mixtures. These characteristics are determined by the chemical structure of VCIs.

An analysis of structure–property relationships plays an important role in the development of efficient corrosion inhibitors for various media.<sup>7, 11, 20, 37, 58, 59</sup> Since the characteristic features of a VCI include its volatility and ability to form protective layers on the metal from the vapour phase, the assessment of the effect of the inhibitor's chemical structure on  $p^0$  is of particular importance in the case of vapour-phase protection.

#### 1. Vaporisation of volatile corrosion inhibitors and dependence of their volatility on the chemical structure

The ability to form vapours (due to evaporation or sublimation), which is often (not quite correctly) called volatility, is a characteristic property of VCIs.<sup>1, 10, 16</sup> Volatility is quantitatively expressed as  $p^0$ . The volatility required for the vapour-phase protection ( $p^0 > 1.3 \times 10^{-3}$  Pa, or  $1.3 \times 10^{-4}$  Pa according to other data)<sup>1, 16</sup> can come from the compound itself or from its hydrolysis products. For example, nitrite–carbamide or nitrite–hexamethylenetetramine mixtures owe their ability to provide vapour-phase protection to the formation of volatile ammonium nitrite in reactions with water:<sup>16, 20</sup>

Vaporisation of individual organic compounds devoid of ionic bonds usually consists of the transfer of their molecules to the gas phase.

Sublimation of salt-type VCIs is associated with their dissociation. The vapours of onium salts consist of non-associated acids and bases;<sup>16, 59</sup> partial pressures of the vapours of these compounds can differ by several orders of magnitude. For example, the vapour of ammonium benzoate consists almost completely of ammonia for which the vapour pressure is  $p = 22.7$  Pa. The value of  $p$  for benzoic acid ( $2.67 \times 10^{-6}$  Pa) is negligibly small. A similar situation characterises hexamethylenonium and diethylammonium *m*-nitrobenzoates. Conversely, vapours of cyclohexylammonium benzoate and octanoate and monoethanolammonium benzoate are enriched in the respective acids.

Several experimental methods have been developed for measuring  $p^0$  that depend on the nature of the compound and on the temperature. Unfortunately, they are rather laborious, require special instruments, and are not always accurate. Therefore, semiempirical computational methods are used to assess the volatility of organic compounds. They are mainly based on measurements of boiling points ( $T_b$ ) of compounds.<sup>60–64</sup>

The effect of temperature on  $p^0$  obeys the Clausius–Clapeyron equation

$$\ln p^0 = -\frac{\Delta H_v^\circ}{RT} + \frac{\Delta S_v^\circ}{R} = -\frac{\Delta G_v^\circ}{RT}, \quad (6)$$

where  $\Delta H_v^\circ$ ,  $\Delta S_v^\circ$ ,  $\Delta G_v^\circ$  are the standard enthalpy, entropy and free energy of vaporisation (evaporation or sublimation), respectively. The equation is fairly well approximated by linear relationships  $\ln p^0 - 1/T$ . The linearity results from weak temperature dependences of  $\Delta H_v^\circ$  and  $\Delta S_v^\circ$ ; it is observed in a wide temperature range above or below compounds' melting points. In accordance with Trouton's rule of the approximate constancy of the boiling entropies for different chemical compounds, it is possible to assess  $\ln p^0$  roughly, based on  $T_b$ .<sup>63</sup>

A greater accuracy is achieved by methods that take into account the specific features of compounds (*e.g.*, chemical similarity method and simulation methods).<sup>60–65</sup> Models implemented as equations, nomograms or special software products<sup>64</sup> facilitate considerably the search for efficient VCIs. However, one cannot use these methods to predict the expediency of synthesising new compounds for creating VCIs. This can be done provided one has knowledge of the regularities relating the chemical structure of an organic compound to its volatility.

In recent years, quantitative structure–activity relationships (QSAR) have been used rather extensively to assess the volatility of organic compounds. These relationships are commonly obtained using quantum mechanical calculations,<sup>64,66</sup> structural topological and/or topochemical analysis.<sup>64,67–72</sup>

The prediction of  $p^0$  makes use of the principle of additivity of the contributions of molecular structural fragments to the thermodynamic characteristics<sup>73–76</sup> that determine the volatility of organic compounds. However, this postulate has recently been called into question, at least with respect to the free energy of vaporisation. In fact, it has been shown<sup>77,78</sup> that variation of substituents in different classes of liquid organic compounds results not in equal but rather in proportional changes of this parameter and the related  $p^0$  value, *i.e.*, linearity of the free energy (LFE) of evaporation.

There is a series of papers<sup>77–80</sup> dealing with the development of methods for the quantitative assessment of  $p^0$  values for organic VCIs based on the LFE principle. A new scale of structural characteristics of substituents, *viz.*, the scale of volatility constants  $\xi_R$ , has been introduced. The  $\xi_R$  values were computed using  $p^0$  data at 293 K for liquid monosubstituted benzenes chosen as the standard series

$$\xi_R = \log p^{0,R} - \log p^{0,H}, \quad (7)$$

where indices R and H refer to substituted and non-substituted compounds, respectively. This approach made it possible to assess  $p^0$  values for liquid organic VCIs from their formulae and data required for calculating correlations of the type

$$\log p^{0,R} = \alpha + \kappa \xi_R, \quad (8)$$

where

$$\alpha = \log p^{0,H},$$

and  $\kappa$  is a constant characterising the series in question. It is important that the  $\xi_R$  scale that has been elaborated is versatile and can be used for both aromatic and aliphatic/alicyclic compounds, including polysubstituted ones. The contributions of spatially separated substituents ( $R^1$  and  $R^2$ ) in such compounds are independent and additive

$$\log p^{0,R^1,R^2} = \alpha + \kappa \sum \xi_R. \quad (9)$$

Adjacent substituents can partially shield each other from intermolecular interactions, affecting  $\alpha$  and  $\kappa$  values and sometimes impairing the accuracy of data description. However, in most cases, the accuracy is sufficient for predicting the volatility of VCIs. This statement is demonstrated in Fig. 1.

Studies in this field resulted in the creation of an advanced system for the prediction and directed modification of the

**Figure 1.** Dependences of  $\log p^0$  on  $\sum \xi_R$  for primary (1), secondary (2) and tertiary amines (3).

volatility of liquid organic corrosion inhibitors.<sup>77–80</sup> It was shown that the fulfilment of the LFE principle for the evaporation process results from the isoentropicity, that is, constancy of the standard entropy for a series of related compounds. This allowed a quantitative *a priori* assessment of the volatility of organic compounds in a broad temperature range above the boiling points by correlation methods,

$$\log p_{(T)}^{0,R} = A_1 + \frac{B_1}{T} + C_1 \xi_R + \frac{D_1 \xi_R}{T}, \quad (10)$$

where  $A_1$ ,  $B_1$ ,  $C_1$  and  $D_1$  are constants. It is important that this type of correlation relationship can be derived from data on boiling points of organic compounds under vacuum distillation conditions.

The approach elaborated for the prediction of  $p^0$ , together with the methods for reconstructing relationships of types (8)–(10) in the absence of data allowing one to determine them directly, often makes it possible to reject non-promising VCIs before synthesising them.

However, this system is unsuitable for salts of organic acids and bases that are perhaps the most promising class of volatile inhibitors of atmospheric corrosion. The results of a recent study (Ref. 59) provide possibilities for the quantitative assessment of their volatility. An analysis of a system 'salt of a weak acid and a weak base—its saturated aqueous solution—vapour' has led to the conclusion that it is possible to compute the pressure and composition of the saturated vapour of salt-type VCIs that do not undergo irreversible reactions with water. Computation is based on the solubilities of the salt and its constituent acid and base, as well as their  $p^0$  and  $pK_a$  values.

## 2. Effects of basicity and hydrophobicity on the functional properties of volatile corrosion inhibitors

Obviously, by no means every volatile compound can provide vapour-phase protection of a metal. An inhibitor should possess properties required for slowing down (or suppressing) surface reactions that cause metal corrosion. No matter for what purpose and in what form a VCI is used, other conditions being equal, it will protect the metal the more reliably the more strongly it inhibits corrosion in the surface (phase- or adsorption-type) moisture. Therefore, studies on the effect of the chemical structures of organic compounds on their inhibitory properties are of primary importance for developing new VCIs.

Diverse semiempirical QSAR approaches to this problem exist. They have been analysed in relation to metal corrosion inhibitors in aqueous and aqueous–organic solutions in a number of papers.<sup>7,11,57,58,81</sup> One can distinguish two main directions of

these studies. One of these, which has been developing intensely over the past decade, is based on the use of quantum chemical methods.<sup>81–87</sup> However, these methods are not yet used to create VCIs. Yet another direction, which has been developed more thoroughly, is based on Pearson's concept of hard and soft acids and bases and on the LFE principle.<sup>7, 11, 57, 58, 83, 88–90</sup>

The effect of the chemical structure of a VCI on its inhibitory properties depends considerably on the metal that is protected and on corrosion conditions. Perhaps, the relationship between the protective properties of organic compounds and their  $pK_a$  values is deduced most often; in the majority of cases, the efficiency of inhibitors similar in chemical nature increases with an increase in the basicity of compounds.

For ammonia and lower amines, which constitute the most common class of VCIs, corrosion protection of metals is to some extent associated with the ability of VCIs to alkalinise aqueous solutions.<sup>1, 6, 10, 17, 91</sup> A moderate increase in pH of surface moisture films decreases the corrosivity of the medium with respect to both steel and other materials. In this case, corrosion problems appear only for aluminium and only under conditions of abundant condensation of water. The alkalification factor is important not only in the protection against atmospheric corrosion, but also in the protection of steel equipment from carbon dioxide-induced corrosion in steam-condensate systems, refinery units, and oil-and-gas pipelines.<sup>92–95</sup>

One should not underestimate the possibility of pH control of the protective properties of salt-type VCIs as well. It is not incidental that hydrolysis of the majority of them produces alkaline medium; their anions are often oxidants that alkalinise the near-surface layer upon reduction.

On the other hand, it has long been known<sup>1, 17, 18</sup> that the effect of  $pK_a$  on the protective properties, even for individual amines, is not reduced to an increase in pH by these compounds. Following adsorption on the metal surface, they ensure metal protection at lower pH values than an alkali.<sup>96, 97</sup> It should be noted that the increase in the protective effect of volatile amines with an increase in their  $pK_a$  often remains high in electrolytes with the same pH.<sup>96</sup> This can be explained by an increase in the amine adsorptivity with an increase in the electron density on the nitrogen atom, as can be measured by the ability of the compound to bind a proton. In this case, the beneficial effect of the amine basicity on the steel protection by these compounds is observed not only in solutions, but also in a humid atmosphere.<sup>52</sup>

The importance of the VCI adsorption itself has been demonstrated<sup>38, 39, 97</sup> in the protection of steel from carbon dioxide-induced corrosion, *i.e.*, under conditions where pH control was traditionally considered to play the major role.<sup>92</sup> It turned out that the order of steel protection efficiency of amines in the vapour phase differs from the basicity series. For instance, dibutylamine ( $pK_a = 11.25$ ) is the best VCI among butylamine derivatives, whereas tributylamine ( $pK_a = 11.04$ ) is the worst, and its protection efficiency is even lower than that of butylamine ( $pK_a = 10.78$ ).<sup>97</sup> It is of note that VCIs that are efficient in a carbon dioxide atmosphere include not only amines but also some carboxylic acids that cannot decrease the acidity of the medium but are readily adsorbed on steel, such as lauric acid.<sup>38, 98</sup> This suggests that basicity is not always the dominant parameter of the inhibitory action of VCIs. This conclusion is not unexpected. It is well known that the reactivity of organic compounds cannot be described by basicity alone.<sup>99–101</sup>

Therefore, different characteristics of substituents were considered in studies on organic inhibitors. In particular, correlations between the efficiency of metal corrosion inhibition and electronic  $\sigma$ -constants of substituents have repeatedly been established.<sup>7, 37, 57, 58, 102</sup> The type of constants that describe such relationships and the character of their effect change depending on the charge-transfer effects occurring in the compounds, the nature of adsorption bonds and the specific features of inhibitors' protective action. It is unlikely that VCIs are different from other organic inhibitors in this respect, and it is not by chance that both

salts of substituted benzoic acids<sup>7</sup> and volatile Schiff bases<sup>11, 102</sup> are among the compounds studied in most detail.

On the other hand, the use of  $\sigma$ -constants of substituents for the description of the protective properties of inhibitors by LFE methods is not always sufficient. One of the reasons is that adsorption of an inhibitor from an aqueous solution can be accompanied by partial dehydration of its molecules or ions, hence the affinity of an inhibitor for water is very important for metal protection.<sup>7, 11</sup> In order to take these factors into account, hydrophobicity constants derived from the distribution ratios of substituted organic compounds in the biphasic system octanol–water<sup>101</sup> are often used in addition to electronic parameters of substituents. This approach allows one to improve the accuracy of quantitative 'structure–protective effect' relationships, *e.g.*, in the case of salts of substituted aromatic acids.<sup>7</sup> An increase in Hansch's hydrophobicity of substituents also increases the ability of inhibitors to stabilise oxide films on metals, including those formed in air.

The hydrophilic–hydrophobic balance of VCIs becomes particularly important in the case of vapour-phase protection. The ability of inhibitors adsorbed from the vapour phase to hydrophobise a metal surface is considered to be an additional protection factor. While it is sufficient to use the  $pK_a$  values of volatile amines for describing their inhibitory effect with respect to steel in chloride solutions,<sup>96</sup> the role of hydrophobicity may become considerable in the case of vapour-phase protection.

The reasons for the beneficial effect of the VCI hydrophobicity on the efficiency of steel protection in humid atmospheres are clear.<sup>103</sup> It is known that the physical adsorption on non-porous adsorbents is enhanced with an increase in the length of the alkyl substituent. The non-specific interaction of VCIs with a metal surface increases in parallel with the hydrophobicity, since introduction of a hydrophobic hydrocarbon fragment into an organic molecule increases its polarisability and attraction to the adsorbate caused by electron density fluctuations.<sup>104</sup> Furthermore, an increase in hydrophobicity increases the ability of VCIs to displace adsorbed water from the metal surface and impart water-repellent properties to it. However, the contribution of the hydrophobising action of VCIs should not be overestimated. If organofluorine and organosilicon compounds that are not widely used as VCIs are excluded from consideration, this is not a major contributing factor in metal-protection processes.

The basicity and hydrophobicity also affect the solubility of VCIs in surface water films and in condensed phases, which affects the kinetics of VCI propagation in the space that is protected,<sup>47–50, 52</sup> mass exchange with the environment,<sup>54</sup> interphase distribution of the inhibitor, and eventually protection efficiency. The effect of VCI solubility on vapour-phase metal protection is complex and depends on specific conditions. However, it is obvious that a VCI should be soluble in aqueous electrolyte solutions in order to provide fast and efficient corrosion inhibition.

The solubility of VCIs, many of which are weak electrolytes, also depends on their ability to undergo ionisation in water. However, the solubilities of compounds belonging to the same reaction series and possessing similar  $pK_a$  values, often differ considerably. For example, an increase in the length of the hydrocarbon substituent in primary amines, starting from propylamine, almost does not affect their basicities but decreases the solubility. According to Abramzon,<sup>105</sup> changes in the hydrophilic–hydrophobic balance of monofunctional aliphatic compounds upon increase in the number of C–H bonds by one result in the increase in the standard free energy of dissolution ( $\Delta G_{\text{sol}}^\circ$ ) by  $\sim 1.76 \times 10^6 \text{ kJ mol}^{-1}$ . Accordingly, the saturation concentration ( $C_{\text{sat}}$ ) for compounds rather poorly soluble in water, which is described by Eqn (11)

$$\ln C_{\text{sat}} = -\frac{\Delta G_{\text{sol}}^\circ}{RT}, \quad (11)$$

also changes. From the structural formula and solubility of one member of the series one can assess  $C_{\text{sat}}$ . Unfortunately, this approach does not allow one to predict the solubility changes when heteroatoms are introduced in a molecule and is of little use for aromatic compounds.

In the latter case, it is reasonable to use correlations based on the LFE principle. It has been shown<sup>106</sup> that the change in  $C_{\text{sat}}$  due to structure variation for liquid aromatic compounds that are not ionised in water is described by the Hansch equation

$$\ln C_{\text{sat}} = a + b\pi_R, \quad (12)$$

where  $a$  and  $b$  are constants for a given series,  $b < 0$ ; and  $\pi_R$  is the substituent's hydrophobicity.

Combination of the methods described makes it possible to optimise the properties of VCIs in a certain range (which is currently rather narrow) by modifying their chemical structures. It should be taken into account here that a decrease in the inhibitor's solubility with an increase in hydrophobicity may result in the loss of protective properties. This situation is particularly characteristic of corrosive media where the  $C_{\text{pr}}$  values of inhibitors are high. However, it was noted<sup>96</sup> that complete protection of steel in 0.005 M aqueous solution of NaCl, e.g., by tributylamine, was impossible, due to the low  $C_{\text{sat}}$  value. A similar situation has been reported in vapour-phase protection.<sup>103</sup> Steel corrosion was not suppressed in the vapour phase even above saturated solutions of *n*-nonylamine and *n*-decylamine, whereas butylamine which is more hydrophilic and has a similar basicity prevents corrosion at a concentration as low as 0.14 mol litre<sup>-1</sup>.

It is impossible to optimise the chemical structure of organic compounds for creating more efficient VCIs without revealing the specific features of their adsorption on metals that are protected. Furthermore, it has become clear in recent years that VCIs can have a rather prolonged protective post-effect. This opens new prospects for their application and calls for studies of VCI desorption from the surface of metals and oxides.

#### IV. Adsorption and desorption of volatile corrosion inhibitors

From the very first years of investigations into VCIs, their adsorption was studied by both direct and indirect methods, among which electrochemical methods, including those applied to processes occurring under thin moisture films,<sup>1</sup> were of considerable importance. It has been shown that, first, it takes a long time (hours or even days) to form protective films on metals placed in a VCI atmosphere and, second, once such films have been formed, corrosion on these samples begins, following removal of VCI vapour, later than on metals that have not been subjected to pre-treatment with the VCI. Unfortunately, the advantages of employment of this phenomenon in the practice of vapour-phase anti-corrosion protection were underestimated for a long time.

Obviously, the reason for the VCIs' post-effect is determined by the character of their adsorption on metals. If we take into account that this effect is much more pronounced on iron and steels than on zinc and aluminium, it is reasonable to assume that chemisorption of the VCIs on the surface occurs. However, not only chemisorption prevents desorption of VCIs.

In fact, the adsorption of *N,N*-diethylaminoethanol vapour (in the range of  $p/p^0$  from 0.1 to 0.9) on the surface of naturally oxidised iron powder results virtually in a monolayer but increases 4–5-fold at  $p/p^0 = 1.0$  (Fig. 2).<sup>107</sup> This is close to the ellipsometric estimate of its adsorption on an iron surface in air.

Evacuation of the inhibitor vapour resulted in its total desorption, which suggests the reversibility of adsorption, at least in the absence of an access of air and in a relatively short-term experiment (~5 days). On the other hand, adsorption of water on an iron powder that has preliminarily adsorbed no more than a monolayer of this VCI occurs in a different way than on its clean surface. Despite VCI desorption, the maximum mass gain is ~5 times smaller than that upon water adsorption by a surface

**Figure 2.** Adsorption isotherms of *N,N*-diethylaminoethanol on the surface of naturally oxidised iron powder at 13 (1) and 22 °C (2).<sup>107</sup>

free from the inhibitor (Fig. 3). Evacuation results in a 'zero' mass for a given experiment, that is, the mass of the sample that has already adsorbed the VCI (0.14 mg g<sup>-1</sup>). Hence, the VCI studied decreases the limiting adsorption of water even at low inhibitor coverage, which may be explained by the adsorption of water molecules on the same surface-active centres as the VCI. This property of VCIs is of key importance, since it is known that a considerable increase in the corrosion rate of a metal in water vapour occurs after at least 2–4 monolayers of adsorbed water have been formed on the metal surface.

If iron powder has first adsorbed 0.26 mg g<sup>-1</sup> of the VCI, which corresponds to the plateau on the adsorption isotherm of *N,N*-diethylaminoethanol at 13 °C (see Fig. 2), evacuation of the vapour does not restore the original mass of the sample. This suggests that either partially irreversible VCI adsorption occurs under the effect of water vapour or that additional oxidation of iron with water stimulated by traces of the VCI takes place. Obviously, under real conditions of anticorrosion protection, the adsorption of VCIs is complicated by the presence of oxygen and other gases in the atmosphere. A volatile corrosion inhibitor can react with them, while the surface can catalyse the process.

In fact, the results of studies on the adsorption–desorption kinetics of various VCIs on the surface of naturally oxidised iron (Fig. 4) by ellipsometric methods confirm that the formation of adsorption layers takes rather a long time (several days are required even for fairly volatile compounds). Furthermore, these results suggest the polymolecular adsorption of amine-type VCIs and adsorption irreversibility to a considerable degree for many well-known VCIs. Attention should be paid to the fact that the

**Figure 3.** Adsorption isotherms of water vapour on the original sample of iron powder (1) and on a sample with preliminary adsorption of *N,N*-diethylaminoethanol (2).<sup>107</sup>

For convenience in the comparison of isotherms, the changes in the sample mass refer to the zero coordinate corresponding to the original mass of the sample that has adsorbed the VCI (0.14 mg g<sup>-1</sup>).

**Figure 4.** Kinetics of VCI adsorption–desorption on iron surface under atmospheric conditions.<sup>107</sup>

(1) 2-Aminoethanol, (2) *N*-ethyldiethanolamine, (3) *N,N*-diethylaminoethanol, (4) *N,N*-diethylaminopropionitrile, (5) 4-diethylamino-3-methylbutan-2-one. The variations in ellipsometric angle  $\Delta$  have been converted to the thickness of adsorption layers  $d$  using Drude's approximation:  $d = -\alpha(\Delta - \Delta_0) = -\alpha\delta\Delta$ .

irreversibility of *N,N*-diethylaminoethanol adsorption was clearly higher than that measured in the above adsorption measurements *in vacuo*. In this case, longer exposure of a sample in VCI vapour favours not only the chemisorption of the amine, but also increases the probability of formation of a structured polymolecular adsorption film by the inhibitor. This follows from the results of studies on the mechanism of action of yet another well-known amine-type VCI, *viz.*, *N,N*-diethylaminopropionitrile.<sup>19</sup>

The interaction of *N,N*-diethylaminopropionitrile with an iron surface was studied by XPS and ellipsometry.<sup>108</sup> In addition, IR spectra of a  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> powder impregnated with the VCI were measured immediately after drying following exposure in air for different periods of time. These studies resulted in the conclusion that a film consisting of a chemisorbed and a physically adsorbed layer is formed on the oxidised iron. The formation of the first layer is due to hydrolysis of *N,N*-diethylaminopropionitrile; as a result, compounds that are less volatile than the original compound but have a higher protective effect in aqueous solutions, that is, diethylaminopropionamide and possibly the diethylaminopropionate anion, are adsorbed on the surface. This chemisorbed layer is formed in 1.5–2 days; it does not undergo desorption *in vacuo* and it is not removed upon washing with ethanol or upon prolonged (up to 8 months) exposure to a dry atmosphere.

The physically adsorbed layer is also non-uniform. Taking into account the ability of the CN group in *N,N*-diethylaminopropionitrile to add another VCI molecule due to the formation of both a donor–acceptor bond with the nitrogen atom of the amino group and a 'paired dipole bond' with the CN group oriented antiparallel, it was assumed that associates with increased viscosity are formed atop the chemisorbed layer. They are soluble in ethanol but almost cannot be removed *in vacuo*. This layer should provide good screening of the metal surface preventing the penetration of a corrosive medium. On the other hand, *N,N*-diethylaminopropionitrile remains partly unbound and, being rather volatile, is desorbed from the surface not only *in vacuo*, but also on storage in air.

A study on the formation of adsorption layers in *N,N*-diethylaminopropionitrile vapour<sup>109</sup> showed that the characteristic electron binding energies in the spectra of an iron surface are almost the same irrespective of whether the VCI is adsorbed from the liquid or vapour phase. However, the spectra of O1s electrons change as the exposure time increases. As in the case of VCI

application by the contact technique, the intensity of lines in the high-energy region of the spectrum ( $E_b = 532–534$  eV) increases, which is explained by the adsorption of oxygen-containing hydrolysis products on iron. The spectra of rinsed and non-rinsed samples were identical after exposure for 30 h. After exposure for 300 h, the high-energy region of the spectrum becomes predominant. However, unlike the case of VCI adsorption from the liquid phase, the low-energy region of the spectrum corresponding to iron oxides is retained.

After adsorption of *N,N*-diethylaminopropionitrile vapour on iron, as upon contact application of the inhibitor, the Fe2p<sub>3/2</sub> spectrum contains both the lines corresponding to the original iron sample ( $E_b = 707$  and 711.5 eV) and, when exposed for periods from 10 min to 300 h, 'shoulders' in the region of 708–710 eV due to the appearance of nucleophilic species on the iron surface. For samples washed with ethanol, the intensities of lines in the spectrum of Fe2p<sub>3/2</sub> electrons remain virtually unchanged for all exposure times. For non-washed samples, the spectrum of Fe2p<sub>3/2</sub> electrons after the first 30 h of exposure differs only slightly from the corresponding spectrum for the washed samples. After exposure for 48 hours, the content of iron in the layer in question on non-washed samples quickly decreases and then remains unchanged (Fig. 5). The maximum in the spectrum ( $E_b = 711.5$  eV) also persists after exposure for 300 h. This makes it different from the spectra obtained upon contact application of the VCI. In the latter case, a low-energy shift of the maximum was observed as early as after 36 h of exposure. Furthermore, the high-energy region of the spectrum corresponding to oxides was retained after exposure of iron in the vapour phase.

The kinetic regularities of variations in the relative content of the elements analysed are the same as for adsorption of this VCI from the liquid phase. Starting from the first minutes of exposure, the concentrations of nitrogen, oxygen and carbon (the curves for carbon are not shown in Fig. 5), measured on the surfaces washed with a solvent, increase abruptly, whereas the content of iron decreases. After ~30 h, these parameters level off. After the first 30 h of adsorption, the curves for washed and non-washed samples almost do not differ from each other, but for non-washed samples the relative concentrations of the elements stabilise after a longer period, as a rule, after 2 days.

**Figure 5.** Variation in the concentration of iron (1, 1') and the relative content of oxygen (2, 2') and nitrogen (3, 3') on an iron surface exposed to *N,N*-diethylaminopropionitrile vapour. (1–3) After washing with ethanol (1'–3') without washing.

A comparative analysis of the effect of the VCI from the liquid and vapour phases on iron showed that the mechanism of formation and growth of protective layers does not depend on the way the inhibitor was applied on the surface. However, it affects the ratio of the chemisorbed and physically adsorbed VCI. In fact, chemisorption of the inhibitor after a 300-hour exposure is higher if the film is formed from the vapour phase, whereas the physically adsorbed VCI layer is thicker upon contact application. This is probably due to the fact that, unlike the case of gradual adsorption of *N,N*-diethylaminopropionitrile vapour, the contact application of the inhibitor favours the association of VCI molecules. In the latter case, the thickness of the physically adsorbed layer prevents the access of water from the atmosphere followed by hydrolysis of the VCI. This can explain the smaller concentration of chemisorbed species.

The results of ellipsometric measurements (Fig. 4) showed that, once a polymolecular film of *N,N*-diethylaminopropionitrile has been formed from the vapour phase, its desorption does not exceed 28% and occurs most intensively during the first three days. The remaining film is strongly bound to the surface of the iron sample.

We also observed an important contribution of chemical transformations to the protective effect of VCIs for one of the most efficient versatile inhibitors of atmospheric corrosion, *viz.*, 4-diethylamino-3-methylbutan-2-one.<sup>110</sup> The adsorption of this VCI on iron also results in a polymolecular protective film. The adsorption is largely irreversible (see Fig. 4) due to oxidation, dimerisation, condensation and perhaps more profound chemical transformations of unsaturated ketones formed upon the dissociative adsorption of the VCI. It is no wonder that this inhibitor has a long post-treatment effect (Table 1).

It was previously assumed that lower amines are prone to desorption. Hence, metal protection requires that they are always present in the corrosive medium, whereas their higher homologues can provide metal protection due to the post-treatment effect, *i.e.*

by irreversibly adsorbed molecules.<sup>111</sup> Most often, this is actually the case. For example, allylamine ( $pK_a = 9.42$ ) does not show any protective post-treatment effect and even stimulates copper corrosion. However, diallylamine ( $pK_a = 9.29$ ) or *n*-heptylamine, which possess higher hydrophobicities, show post-treatment effects not only on steel but also on zinc. *n*-Octylamine protects steel even more efficiently. In fact, a steel sample exposed for 12 days in *n*-octylamine vapour did not undergo corrosion for over 30 days in a VCI-free atmosphere with a 100% relative humidity.<sup>110</sup>

Such a strong adsorption of amines on the surface of oxidised steel depends on their nature and agrees well with our concepts about interactions of a hard base with a hard acid; the role of the latter, unlike iron itself, is played by its oxidised surface.<sup>103</sup> The energy characteristics of such an interaction have not yet been studied in sufficient detail. So, its calorimetric estimate based on the integral heat of adsorption of both liquid amines (heat of immersion) and their vapours deserves attention. It has been shown<sup>112</sup> that the amino group in *n*-octylamine provides the major contribution to the heat of adsorption on a naturally oxidised iron powder. The value of this parameter for *n*-octylamine is noticeably higher than those of non-polar *n*-undecane and even polar octanol. Therefore, both the high potential of dispersive interaction with the  $C_8$  hydrocarbon radical and the specific interaction of the amino group with electron-withdrawing surface sites are responsible for the high energy of adsorptive interaction of the alkylamine with the iron powder studied.

Such sites can include coordination-unsaturated ion-atoms of iron with incomplete d-shells, which enter into donor–acceptor interactions with nitrogen atoms of the amino groups. It has been shown that Fe(II) and Fe(III) sites are present on the surface of oxidised finely dispersed iron, *e.g.*, in an IR-spectroscopic study of CO and NO adsorption.<sup>113</sup> Under atmospheric conditions, these centres are blocked with water molecules that cannot be removed by low-temperature evacuation and are desorbed only partially upon evacuation at 100 °C. It should be noted that the collective properties of the surface and adsorbate are strongly affected by the formation of donor–acceptor bonds by these compounds and the ionisation potential of the organic compound.<sup>114</sup>

According to estimates,<sup>112</sup> the total heat of adsorption and condensation of *n*-octylamine is as high as 44 kJ mol<sup>−1</sup>; this can suggest its ability to be chemisorbed on an oxidised iron surface (taking into account partial irreversibility of amine adsorption). Interestingly, the irreversibility of adsorption increases in the series *n*-octylamine < cyclohexylamine < primary aliphatic amines  $C_{10}–C_{13}$ . In these cases, the fractions of strongly adsorbed compounds are 25%, 40% and 60% of their total content, respectively. It was noted that the adsorption energies are virtually the same for amines with different hydrocarbon radicals. Hence, electron-withdrawing sites are arranged rather sparsely on the surface, which allows them to easily interact with the amino groups despite considerable size differences in the ‘landing sites’ that are about 30, 60 and 80–90 Å<sup>2</sup> for cyclohexylamine, *n*-octylamine and aliphatic amines  $C_{10}–C_{13}$ , respectively.

In this case, it was also noted that the adsorption of water on the surface of a powder modified by *n*-octylamine was lower than that on the original adsorbent. It would seem that this difference is attributable to the fact that water cannot totally displace chemisorbed VCI molecules. However, the fact of the partially irreversible adsorption of water implies that its interaction with the surface is more complex. Presumably, the adsorbed VCI facilitates additional oxidation of iron or undergoes protonation to give the octylammonium ion and a surface hydroxy group.

On the other hand, elongation of the alkyl fragment in the molecules decreases the volatility of amines and their solubility in water; therefore, higher amines can only be used at high temperatures, *e.g.*, in the protection of power plants. It is more efficient to use certain heteroalkylated amines as VCIs: under ordinary conditions, even hydrophilic ethylenediamine can provide a long-

**Table 1.** Protective post-effect of VCIs under 100% relative humidity in the absence of forced condensation of moisture on the samples.

| Volatile inhibitor                 | $\tau$ /months | Sample |    |    |

**Note.** The following notation is used:  $\tau$ , exposure time; two plus signs, absence of corrosion; one plus sign, small corrosion damage; one plus-minus sign, poor metal protection; one minus sign, no protection; two minus signs, corrosion stimulation.

lasting protective post-treatment effect on low-carbon steel (Table 1).

Thus, by creating adsorption layers from a VCI-containing vapour phase, it is possible to provide a prolonged post-treatment metal-protection effect. This refers not only to protection from atmospheric corrosion. Studies on a VCI in a carbon dioxide atmosphere have shown<sup>115</sup> that the irreversibility of VCI adsorption is much higher than in air. In fact, the adsorption of 2-aminoethanol is enhanced according to a power law in both cases, though it is somewhat more slow in a carbon dioxide atmosphere. After the cell has been unsealed and the VCI has been removed from it, 2-aminoethanol is desorbed gradually (Fig. 4). However, in air, desorption is incomplete even after 14 days, though the irreversibility of its adsorption is not high: the desorption coefficient  $K_d$  that expresses the fraction of the desorbed VCI exceeds 80%. The desorption of 2-aminoethanol becomes even less ( $K_d \approx 14\%$ ) if the protective film on the metal surface was formed in a carbon dioxide atmosphere.<sup>115</sup>

This suggests the formation of stronger bonds of the VCI with carbonate compounds that are formed on iron.<sup>116</sup> The results of FTIR studies on the reaction of  $\text{CO}_2$  with 2-aminoethanol on naturally oxidised iron confirmed that amino alcohol carbonates could be formed on the surface.<sup>115</sup> Presumably, the long-term protective post-treatment effect of some other VCIs in the carbon dioxide atmosphere is due to similar reasons. For example, after exposure of low-carbon steel electrodes to vapour of aliphatic amine 'A' ( $K_d \approx 7\%$ ), the corrosion current in the corrosive aqueous solution containing (per litre) 0.25 g  $\text{AcOH}$  + 5 g  $\text{NaCl}$  + 0.04 g  $\text{Na}_2\text{S}$  ( $p_{\text{CO}_2} = 1 \text{ atm}$ ) changes only slightly during the first 200 hours, whereas it increases almost threefold for the electrodes that have not been treated with the inhibitor.<sup>39</sup> Subsequently, the corrosion current gradually increases due to the inhibitor desorption, but even after 350 h, it is still 1.5-fold smaller than that for the untreated metal. Similar results that prove the possibility of the long-term post-treatment effect of VCIs were obtained in a study<sup>117</sup> where protective films were obtained using comparatively concentrated aqueous solutions ( $4 \text{ g litre}^{-1}$ ) of the same VCIs. The data obtained are still insufficient for drawing the conclusion that it is preferable to create protective VCI layers from the vapour phase, but the prospects of using 'self-organisation' effects for this purpose deserve attention. In recent years, these effects have attracted the particular attention of scientists in various fields of chemistry,<sup>118</sup> including those who deal with the anti-corrosion protection of metals.<sup>119–124</sup>

In this respect, the formation of protective layers on metals by benzotriazole (BTA), which is one of the most famous copper alloy corrosion inhibitors,<sup>7,10,11</sup> commonly used for corrosion prevention in aqueous solutions, is of interest. For this reason, the interaction of its solutions with copper is usually studied. However, despite its relatively low volatility ( $p_s \approx 1.3 \cdot 10^{-3} \text{ Pa}$  at  $25^\circ\text{C}$ ), it is an excellent VCI and is used to suppress the corrosion of copper, zinc and their alloys.<sup>1,16</sup> The protective properties of BTA have long been attributed to the formation of a polymeric film of its complex with metal cations. Numerous justifications for this point of view have been considered in reviews.<sup>125–128</sup> However, the opinions regarding the structure of the resulting film remained controversial, which was partially due to differences in the conditions of film formation and the impossibility of detailed determination of their composition and morphology by *in situ* methods.

The adsorption of BTA was studied<sup>128,129</sup> from the vapour phase on the 110 face of a copper single crystal in an ultrahigh vacuum directly in the chamber of an instrument that makes it possible to analyse the surface by a scanning tunnel microscope, as well as by slow-electron diffraction and UV photoemission methods. It was shown that in  $\sim 85 \text{ min}$  a monolayer was formed on copper where the BTA molecules were arranged parallel to the metal surface ('planar adsorption'). After that, slow changes in the spectra were observed during 125 min of exposure; the changes became noticeable between 120 and 185 min due to the formation

of a second layer where two BTA molecules are arranged on one BTA molecule of the first layer binding with it through nitrogen atoms. It is believed that this kind of polymerisation of the adsorbate changes the orientation of its molecules on the surface and favours  $\pi$ -bonding of the molecules with the surface, while the ligand's electrons are transferred to the lowest unoccupied d-orbitals of copper.

It is of note that, as shown by X-ray photoelectron spectroscopy (XPS),<sup>130,131</sup> certain azoles that are less volatile but more hydrophobic than BTA, e.g., 3,5-diphenyl-4*H*-1,2,4-triazole or 2,5-bis(2-pyridyl)-1,3,4-oxadiazole, can also be chemisorbed on a steel surface.

Of sulfur-containing volatile compounds, thiophene ( $p^0 = 2.3 \text{ Pa}$ ) has long been known as a steel corrosion inhibitor; its adsorption from the vapour phase on the faces of single-crystal iron was studied<sup>132</sup> by several methods in an ultrahigh vacuum chamber. This compound, when chemisorbed on an iron surface through S–Fe bonds, first loses hydrogen  $\alpha$ -atoms and then  $\beta$ -atoms.  $\alpha$ -Dehydrogenation results in polymeric chain structures where the thiophene rings are oriented horizontally or vertically, depending on the temperature.

Although adsorption studies from the vapour phase in an ultra-high vacuum are undoubtedly valuable, it should be noted that the results obtained do not always allow one to draw conclusions on the nature and character of a bond between a VCI and an oxide-coated hydroxylated metal surface under atmospheric conditions. If water is present in the gas phase, the situation can be different as well. An obvious example is the adsorption of silanes on hydroxylated iron from the vapour phase which is not accompanied by chemisorption even at elevated temperatures (up to  $80^\circ\text{C}$ ).<sup>133</sup> In the case of joint adsorption of silanes and water vapour, the former are hydrolysed to give silanols  $\text{R}_4\text{--}_n\text{Si(OH)}_n$  that undergo condensation with the hydroxylated surface followed by polymerisation.

\* \* \*

The scope of VCI application has been rapidly expanding over recent years. However, this is hindered by the insufficient development of the theory of vapour-phase protection. Many physicochemical aspects of mechanisms of action of VCIs are still understood only roughly. Therefore, it should be acknowledged that total algorithmisation of designing optimal molecular structures of VCIs for solving particular practical problems remains a task for tomorrow. In the authors' opinion, the current priority tasks include the development of methods for predicting the formation of azeotropes of organic compounds with water, mathematical description and experimental simulation of conditions of vapour-phase metal protection, development of the theory of the mutual influence of components of mixed inhibitors and studies on the VCI adsorption and mechanisms of the post-treatment effect.

**Abstract.** The review summarises the results of experimental and theoretical investigations dealing with phase equilibria and the synthesis and prediction of new compounds and phases in the vanadium–carbon system. The generalised thermodynamic characteristics of disordered cubic vanadium monocarbide  $VC_y$  and lower hexagonal vanadium subcarbide  $V_2C_{y'}$ , which are the most important compounds in the V–C system, are surveyed. The crystal structures of all known and possible compounds formed by vanadium and carbon, including the  $V_8C_{12}$  molecular cluster, are discussed in detail. The phase diagrams for the V–C system taking into account ordering of nonstoichiometric vanadium carbide  $VC_y$  are considered. The bibliography includes 149 references.

## I. Introduction

Group IV and V d-transition metal carbides are strongly non-stoichiometric interstitial compounds.<sup>1–4</sup> Cubic (with the B1-type structure) vanadium carbide  $VC_y$  is one of the most interesting compounds of this type. This compound not only has wide practical application but also has been extensively studied by both experimental and theoretical methods.

In 1830, N Selfström isolated a black powder from metallurgical slags from Swedish blast furnaces. This powder contained an unknown element, which was later called vanadium. More recently, this powder was demonstrated to be  $V_2O_5$ . In pure form, vanadium was isolated by H Roscoe in 1869. In the early 20th century, it was found that doping of steels with vanadium (in an amount from 0.2 mass % to 0.5 mass %) increases their hardness, toughness, shock strength and resistance to abrasion and wear. Hence, vanadium-containing steels have found wide application in defence technology and engine building, in particular, in the manufacture of air engines and car motors. Detailed investigations demonstrated that the hardness properties of steels are improved because vanadium reacts with carbon dissolved in steels

and forms grains of hard and refractory vanadium carbide. Initially, it was speculated that such carbide phases as  $V_2C_3$ ,  $V_4C_3$  and  $V_5C_4$  were formed.<sup>5–7</sup> However, more recent studies revealed the formation of vanadium carbides, which have basic structures of lower hexagonal carbide  $V_2C_{y'}$  or higher cubic carbide  $VC_y$ . Vanadium carbides are poorly soluble in iron, which hinders the growth of large crystals. This is favourable for the formation of a homogeneous fine-grained structure in steels.

Cubic vanadium carbide  $VC_y$ , like most other transition metal carbides, was synthesised for the first time by H Moissan<sup>8</sup> in 1893 by heating  $V_2O_5$  with coal in the absence of air. It was believed that the composition of the carbide synthesised was close to  $VC_{1.0}$ . However, more recent studies demonstrated that vanadium carbide prepared by carbothermal reduction contains a large amount of oxygen.

The history of investigations of vanadium carbides and the V–C system can be arbitrarily divided into three periods.

In the first period, from the late 19th century up to 1940, vanadium carbide, like carbides and nitrides of other transition metals (titanium, zirconium, hafnium, niobium and tantalum), was considered as a usual chemical compound with constant composition. At that time, most studies were concerned with the determination of crystal structures and unit cell parameters of vanadium carbide samples prepared by one method or another. It was believed that vanadium carbide had the stoichiometric VC composition.

At the end of the first period (1930–1940), researchers started studies of the thermodynamic and various physical properties of carbides and nitrides and revealed numerous discrepancies in the results of investigations of the properties of vanadium carbide. These discrepancies could not be accounted for by experimental errors, the use of various experimental approaches or the presence of impurities in the samples under investigation. Detailed crystal-chemical studies demonstrated that the observed discrepancies were associated with the difference in the carbon content of carbides. It appeared that the composition of vanadium carbide (as well as of all Group IV and V transition metal carbides and nitrides) can vary over a wide range with retention of the crystal structure. The lower boundary of the homogeneity region of cubic vanadium carbide  $VC_y$  was long thought to be  $VC_{0.75}$ . Based on this fact, the authors of the early studies<sup>7,9</sup> suggested the existence of the  $V_4C_3$  phase. Nowadays, it is known that the  $VC_{0.65}$  composition corresponds to the lower boundary of the homogeneity region of cubic vanadium carbide. The precise position of the upper boundary has long remained unknown, but it was hypoth-

*Uspekhi Khimii* 74 (8) 768–796 (2005); translated by T N Safonova

esised that this boundary is most likely close to the stoichiometric composition  $VC_{1.0}$ .

In the second period (1940–1970), investigations of strongly nonstoichiometric carbides were almost completely concerned with composition–property relationships. Interest in carbides quickened in 1960s, when the influence of the composition on the crystal-chemical, thermodynamic, thermophysical, electrical, magnetic, optical, mechanical and other properties of these compounds were extensively studied. At the same time, the main qualitative views of the nature of chemical bonding in nonstoichiometric carbides were formulated. At the end of the second period, many researchers mistakenly believed that nonstoichiometric carbides had been completely studied. In 1962, the first version of the phase diagram for the V–C system was published.<sup>10, 11</sup> In this diagram, the regions of existence of cubic  $VC_y$  and hexagonal  $V_2C_{y'}$  ( $\beta$ - $V_2C$ ) vanadium carbides were shown (Fig. 1). This diagram has remained virtually unchanged for more than two decades.

**Figure 1.** Phase diagram of the V–C system at temperatures higher than 800 K, which was constructed without considering ordered phases.<sup>10</sup>

Once wide homogeneity regions had been found for nonstoichiometric carbides, it was long thought that carbon atoms and structural vacancies (vacant interstitial sites in the metal sublattice) are randomly distributed in the lattice. However, crystallographic studies published in the late 1960s and onward demonstrated that, under particular conditions, interstitial atoms and vacancies can be redistributed over sites of the crystal lattice and form different types of ordered structures. It is nonstoichiometric vanadium carbide in which the first ordered carbide phase, *viz.*,  $V_8C_7$ , was discovered in 1966.<sup>12</sup> More recently (in 1968), the ordered  $V_6C_5$  phase was found.<sup>13</sup> These studies marked the beginning of the third period of investigations of nonstoichiometric carbides dealing with ordering and its influence on the properties of nonstoichiometric compounds. Nowadays, it is evident that, at temperatures lower than 1000 K, an ordered state of nonstoichiometric carbides is in thermodynamic equilibrium, whereas a disordered state is metastable in this temperature range.

Studies of the properties of nonstoichiometric carbides depending on the distribution of carbon atoms and vacancies demonstrated that the changes in the properties upon ordering are comparable in magnitude with the changes in these properties associated with variations in the composition of nonstoichiometric carbide within the homogeneity region of an ordered phase.

Therefore, the change in the composition of carbides, on the one hand, and redistribution of atoms and vacancies in the crystal lattice of carbides, on the other hand, are two equally probable ways of controlling the properties of these substances. However, the characteristic feature of ordering as a way of providing fine control over the properties of nonstoichiometric carbides is that it changes the properties of carbides, while the chemical composition remains unchanged.

In the last decade of the 20th century, a large number of ordered phases of nonstoichiometric carbides, which have been found experimentally, and the development of methods of calculations of phase equilibria made it possible to construct the phase diagrams for the M–C systems ( $M = \text{Ti, Zr, Hf, V, Nb or Ta}$ ),<sup>1–4, 14–34</sup> which take into account not only the presence of strongly nonstoichiometric carbides  $MC_y$  ( $MC_y \square_{1-y}$ , where  $\square$  is a structural vacancy) but also their ordering at temperatures lower than 1200–1300 K.

In 1992, a new class of molecular metal carbon nanoclusters  $M_8C_{12}$  was discovered (see Refs 35 and 36) and the stable molecular cluster  $V_8C_{12}$  was detected in vaporisation products of the V–C system.

Therefore, considerable information on phase equilibria and compounds in the V–C system had been accumulated by the turn of the 20th century. The phase diagram for this system appeared to be much richer and more complex than had been assumed earlier. The aim of the present review is to generalise experimental and theoretical data on compounds and phases in the V–C system published in the last 15 years with consideration for the earlier results. Emphasis is given to the phase equilibria and crystal structures of phases and compounds consisting of vanadium and carbon.

## II. Phase diagrams for the V–C system at temperatures higher than 1000 K and thermodynamic properties of disordered carbides $VC_y$ and $V_2C_{y'}$

### 1. Phase diagrams

The V–C system is among the best-studied systems formed by transition metals and carbon. The first version of the phase diagram for the V–C system (see Fig. 1), which takes into consideration the presence of the cubic and hexagonal carbide phases  $VC_y$  and  $V_2C_{y'}$  ( $\beta$ - $V_2C$ ) characterised by homogeneity regions, was proposed in the study.<sup>10</sup> Later on, phase equilibria in this system were considered in the studies,<sup>37–39</sup> where 17 samples with different vanadium and carbon contents, their phase compositions and structures were studied by X-ray diffraction, differential thermal analysis and the metallographic method. The phase equilibria in the V–C system were analysed in the study.<sup>40</sup>

The melting point of vanadium metal determined in different studies is  $2161 \pm 10$ ,<sup>10</sup>  $2199 \pm 6$  (see Refs 37–39) or 2183 K.<sup>40</sup> The addition of carbon to vanadium leads to a decrease in the melting point to the eutectic temperature [ $1923 \pm 7$ ,<sup>37–39</sup> 1921 (see Ref. 40) or 1923 K (see Ref. 41)]. The  $L \rightleftharpoons V + V_2C_y$  eutectic mixture contains  $\sim 15$  at.% carbon.<sup>37, 38, 40, 41</sup> An increase in the carbon content leads to an increase in the melting point from the eutectic temperature to the temperature of the peritectoid transformation  $L + VC_y \rightleftharpoons V_2C_{y'}$ , which was evaluated at 2438 (see Ref. 10) or  $2460 \pm 10$  K.<sup>37–39</sup> Congruently melting carbide  $VC_{0.74-0.77}$ ,<sup>37, 38</sup>  $VC_{0.81}$  (see Ref. 40) or  $VC_{0.83}$  (see Ref. 41) has the highest melting point [ $2921 \pm 12$ ,<sup>37–39</sup> 2929 (see Ref. 40) or 3073 K,<sup>41</sup> respectively]. The temperature of the eutectic  $L \rightleftharpoons VC_y + C$  containing  $49.5 \pm 0.5$  at.% or 53.5 at.% carbon is  $2898 \pm 12$  (see Refs 37 and 38) or 2943 K,<sup>40</sup> respectively.

The phase diagrams for the V–C system, which were proposed in the studies<sup>41, 42</sup> with consideration for possible ordered vanadium carbide phases, are presented in Figs 2 and 3. The first attempt to construct a region of the phase diagram for the V–C system corresponding to the co-existence of the ordered  $V_6C_5$  and

**Figure 2.** Phase diagram of the V–C system at temperatures higher than 800 K.<sup>41</sup>

$\alpha$ -V<sub>2</sub>C ( $\beta'$ -V<sub>2</sub>C) and  $\beta'$ -V<sub>2</sub>C ( $\beta_h$ -V<sub>2</sub>C) are the low-temperature orthorhombic and high-temperature hexagonal ordered phases, respectively, of lower hexagonal disordered carbide V<sub>2</sub>C<sub>y</sub>' ( $\beta$ -V<sub>2</sub>C); V<sub>6</sub>C<sub>5</sub> and V<sub>8</sub>C<sub>7</sub> are the ordered phases of nonstoichiometric cubic carbide VC<sub>y</sub>; V<sub>4</sub>C<sub>3-x</sub> ( $x = 0.2-0.5$ ) is an individual compound belonging to the rhombohedral (trigonal) system, which presumably has the composition VC<sub>0.67</sub>; the composition and the temperature range of existence of the V<sub>4</sub>C<sub>3-x</sub> compound presented in the figure are inconsistent with the most reliable experimental data.

**Figure 3.** Phase diagram of the V–C system at temperatures higher than 1000 K.<sup>42</sup>

$\alpha$ -V<sub>2</sub>C ( $\beta'$ -V<sub>2</sub>C) is the orthorhombic ordered phase of lower hexagonal carbide V<sub>2</sub>C<sub>y</sub>' ( $\beta$ -V<sub>2</sub>C); V<sub>6</sub>C<sub>5</sub> and V<sub>8</sub>C<sub>7</sub> are the ordered phases of nonstoichiometric cubic carbide VC<sub>y</sub>;  $\zeta$  is the rhombohedral (trigonal) phase  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> ( $x = 0.2-0.5$ ), whose composition corresponds to V<sub>3</sub>C<sub>2</sub> (VC<sub>0.67</sub>); the position of the  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> phase presented in the figure is inconsistent in the composition and temperature range with experimental data.

V<sub>8</sub>C<sub>7</sub> phases was made in the study.<sup>43</sup> In the publication,<sup>41</sup> an ordered region was hypothesized to exist in the phase diagram, and this region was identical to that reported in the study.<sup>43</sup> In the review,<sup>40</sup> the ordering was not discussed at all and was not reflected in the phase diagram of the V–C system.

Analysis of the phase diagram presented in Fig. 2 shows that hexagonal lower carbide V<sub>2</sub>C<sub>y</sub>' ( $\beta$ -V<sub>2</sub>C) has a rather extended homogeneity region from VC<sub>0.45-0.46</sub> to VC<sub>0.52-0.56</sub> at 1200 K. The homogeneity region of V<sub>2</sub>C<sub>y</sub>' is expanded with increasing temperature. At 1923 K (the temperature of the eutectic  $L \rightleftharpoons V + V_2C_{y'}$ ), hexagonal carbides VC<sub>0.36-0.37</sub> and VC<sub>0.52-0.58</sub> correspond to the lower and upper boundaries of the homogeneity region, respectively. A decrease in the temperature can be accompanied by ordering of lower hexagonal carbide V<sub>2</sub>C<sub>y</sub>' giving rise to the orthorhombic ordered  $\alpha$ -V<sub>2</sub>C ( $\beta'$ -V<sub>2</sub>C) phase.<sup>44</sup> The precise temperature of the disorder–order phase transition V<sub>2</sub>C<sub>y</sub>'  $\rightleftharpoons$   $\alpha$ -V<sub>2</sub>C ( $\beta'$ -V<sub>2</sub>C) is unknown. According to the results of different studies, this temperature varies from 1100 to 1600 K. Data on the crystal structures of the  $\beta'$ -V<sub>2</sub>C ( $\beta_h$ -V<sub>2</sub>C) and  $\beta$ -V<sub>2</sub>C (V<sub>2</sub>C<sub>y</sub>') phases are also available in the literature. Both phases have a hexagonal metal sublattice, but differ in the distribution of carbon atoms. The former phase is an  $\epsilon$ -Fe<sub>2</sub>N-type ordered hexagonal phase, and the latter phase is a disordered hexagonal phase with the L'3 (W<sub>2</sub>C) structure. From this fact it follows that the  $\beta'$ -V<sub>2</sub>C ( $\beta_h$ -V<sub>2</sub>C)  $\rightleftharpoons$   $\beta$ -V<sub>2</sub>C (V<sub>2</sub>C<sub>y</sub>') transformation can occur. These hypothetical phase equilibria are shown in Fig. 2 by dashed lines.

Cubic carbide VC<sub>y</sub> has a wide homogeneity region from VC<sub>0.72</sub> to VC<sub>0.88</sub> at 1500 K and from VC<sub>0.60</sub> to VC<sub>0.87</sub> at  $\sim 2450$  K. This is the only compound among strongly nonstoichiometric carbides, which is characterised by the upper boundary of the homogeneity region most remote from the stoichiometric composition MC<sub>1.0</sub>. At temperatures lower than 1500 K, the homogeneity region of nonstoichiometric cubic carbide VC<sub>y</sub> has two ordered phases, viz., V<sub>6</sub>C<sub>5</sub> with monoclinic<sup>43,45</sup> or trigonal<sup>13</sup> symmetry and the cubic V<sub>8</sub>C<sub>7</sub> phase.<sup>12,46-49</sup> The ordered V<sub>6</sub>C<sub>5</sub> phases are characterised by a rather extended homogeneity region, whereas the homogeneity region of the V<sub>8</sub>C<sub>7</sub> phase is small.

The phase diagrams (see Figs 2 and 3) show also the  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> phase consistent with the VC<sub>0.67</sub> composition (V<sub>3</sub>C<sub>2</sub>). This phase has a rhombohedral (trigonal) structure and is an individual compound of the V–C system, although it is sometimes erroneously called (see, for example, Ref. 42) the ordered carbide phase VC<sub>y</sub>. The  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> phase does not belong to ordered phases of cubic carbide, because its metal sublattice has trigonal rather than cubic symmetry. According to the results of the study,<sup>10</sup>  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> exists only at temperatures lower than 1617 K and decomposes through a peritectoid reaction at  $T \geq 1617$  K. However, the  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> phase was observed at higher temperatures (up to 1870 K) in the studies.<sup>38,50,51</sup> According to the latest and most reliable experimental data,<sup>52</sup> the  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> phase contains 37.9 at.% C and has a very narrow ( $\sim 0.4$  at.% C) homogeneity region from VC<sub>0.605</sub> to VC<sub>0.615</sub>. The minimum temperature, at which this phase was detected after 78-hour annealing, is 1540 K. The temperature of peritectoid decomposition of the  $\zeta$ -phase during heating is 2150 K.<sup>52</sup> Therefore, the composition and the temperature range of existence of the  $\zeta$ -V<sub>4</sub>C<sub>3-x</sub> phase in the diagrams of the V–C system (see Figs 2 and 3) are not quite correct. Data on the crystal structures of the phases in the V–C system and the special points in its phase diagram at  $T > 1000$  K are given in Tables 1 and 2.

The phase equilibria associated with ordering of nonstoichiometric vanadium carbide VC<sub>y</sub> and occurring at temperatures lower than 1300–1400 K have been described in detail<sup>1,3,4,15,19,28,47,48,53,54</sup> and will be considered below.

**Table 1.** Crystal structures of the phases existing in the V–C system at temperatures higher than 1000 K.

| Phase                                                          | [C] (at. %) | Space group             | Pearson symbol | Lattice type                                          |

**2. Structures and thermodynamic properties of disordered vanadium carbides**

**a. Structures**

Cubic (*B1* structure type) disordered vanadium monocarbide VC<sub>y</sub> is the most important compound existing in the V–C system at temperatures higher than 1000 K (Table 3). The width of the homogeneity region of VC<sub>y</sub> depends on the temperature. The solid-state synthesis of vanadium monocarbide is generally carried out at ~2000 K followed by quenching to room temperature, which makes it possible to retain cubic carbide VC<sub>y</sub> in the disordered state. At 2000 K, disordered cubic vanadium carbide has a homogeneity region from VC<sub>0.65</sub> to VC<sub>0.88</sub>. This region ( $0.65 \leq y \leq 0.88$ ) was reported in most of the published data. The unit cell of VC<sub>y</sub> can be described as two face-centred (metal and non-metal) sublattices, which are shifted with respect to each other by one-half of the lattice period (Fig. 4). In the metal

**Figure 4.** The unit cell of cubic disordered nonstoichiometric vanadium monocarbide VC<sub>y</sub> [the *B1* structure type (NaCl)]. All sites of the metal sublattices are occupied by vanadium atoms, the sites of the non-metal sublattice are randomly (with probability *y*) occupied by carbon atoms.

sublattice, all sites are occupied by vanadium atoms. In the non-metal (carbon) sublattice, the number of sites is larger than the number of interstitial atoms. In the disordered state (which is thermodynamically at equilibrium only at  $T > 1300$ –1400 K, whereas it is retained as a quenched metastable state at lower temperatures), the carbon atoms are randomly distributed over the sites, and all sites of the non-metal sublattice are occupied with the same probability equal to *y* (the relative carbon content of VC<sub>y</sub>). This provides retention of cubic symmetry of the disordered non-metal sublattice and signifies that all sites of the carbon sublattice in disordered VC<sub>y</sub> are crystallographically equivalent. The typical X-ray diffraction pattern of homogeneous cubic vanadium carbide is shown in Fig. 5. A high degree of homogeneity of carbide VC<sub>0.83</sub> is evidenced by splitting of the  $K_{\alpha 1}$  and  $K_{\alpha 2}$  doublets observed already for the (311)<sub>B1</sub> reflection. The crystal

**Figure 5.** X-Ray diffraction pattern of disordered homogeneous carbide VC<sub>0.83</sub> with a *B1*-type cubic structure (Cu  $K\alpha_{1,2}$  radiation).  $a_{B1} = 0.41596$  nm.<sup>25</sup>

**Table 3.** Characteristics of cubic and hexagonal disordered nonstoichiometric vanadium carbides.

| Phase                          | Symmetry  | Space group           | Lattice type                   | Atom | Position and multiplicity | Atomic coordinates |          |          | Probability of occupancy |

**Figure 6.** Plot of the parameter  $a_{B1}$  of the basic cubic crystal lattice vs. the composition of carbide  $VC_y$  in quenched disordered (1) and annealed ordered (2) states.<sup>25</sup> The boundaries of the homogeneity region of carbide  $VC_y$  are shown by vertical bars.

lattice period of both disordered and ordered  $VC_y$  increases with increasing carbon content (Fig. 6).

Lower vanadium carbide  $V_2C_{y'}$  ( $\beta$ - $V_2C$ ), which is also called semicarbide or subcarbide, has a hexagonal structure of the  $L/3$  ( $W_2C$ ) type. In this structure, carbon atoms randomly occupy no more than one-half of all octahedral interstitial sites in the metal sublattice (Fig. 7). Since it cannot be unambiguously determined which sites of the non-metal sublattice are occupied by carbon atoms, and which sites are, on the contrary, vacant, the probability of finding a carbon atom in each site of the non-metal sublattice of lower vanadium carbide  $V_2C_{y'}$  is  $y'/2$  (see Table 3). The width of the homogeneity region of disordered lower vanadium carbide quenched to high temperatures is small, from  $VC_{0.42}$ – $0.45$  to  $VC_{0.50}$ . The volume of its unit cell enriched in carbon slightly increases. The unit cell parameters of the carbide of stoichiometric composition  $V_2C$  ( $VC_{0.50}$ ) are larger than those of  $V_2C_{0.94}$  ( $VC_{0.47}$ ) ( $a = 0.2902$  and  $c = 0.4577$  nm as opposed to  $a = 0.2885$  and  $c = 0.4571$  nm). The X-ray diffraction pattern of disordered lower vanadium carbide  $V_2C$  ( $VC_{0.50}$ ) with a hexagonal lattice of the  $L/3$  ( $W_2C$ ) type is shown in Fig. 8.

The thermodynamic properties of nonstoichiometric vanadium carbides vary substantially within their homogeneity regions. Hence, investigations, in which the measured thermody-

**Figure 7.** Hexagonal (space group  $P6_3/mmc$ ) structure of the  $L/3$  ( $W_2C$ ) type of lower vanadium carbide  $V_2C_{y'}$ . Metal atoms form a hexagonal close-packed lattice, in which one-half or less than one-half of octahedral interstitial sites are randomly occupied by carbon atoms.

**Figure 8.** X-Ray diffraction pattern of disordered homogeneous lower vanadium carbide  $V_2C$  ( $VC_{0.50}$ ) with a  $L/3$ -type hexagonal structure (Cu  $K\alpha_{1,2}$  radiation).  $a = 0.2902$  nm,  $c = 0.4577$  nm.

amic characteristics were assigned to a particular composition of carbide in the known structural (disordered or ordered) state, are of great interest. The temperature and concentration dependences of the thermodynamic characteristics of disordered carbides allow the quantitative description of high-temperature phase equilibria involving  $VC_y$  and  $V_2C_{y'}$ . Besides, disorder–order phase transformations and transitions between ordered phases can be directly studied with the use of these data. However, available results of experimental thermodynamic investigations of nonstoichiometric vanadium carbides, whose compositions and crystal structures were well characterised, are scarce.

## b. Enthalpy of formation

The enthalpies of formation of cubic carbide  $VC_y$  with different carbon contents were determined<sup>55,56</sup> by calorimetry from the thermal effects of combustion in oxygen:

| Carbide     | $\Delta H_{f, 298}^\circ / \text{kJ mol}^{-1}$ | Carbide     | $\Delta H_{f, 298}^\circ / \text{kJ mol}^{-1}$ |
|-------------|------------------------------------------------|-------------|------------------------------------------------|
| $VC_{0.72}$ | $-90.5 \pm 5.6$                                | $VC_{0.82}$ | $-111.7 \pm 4.1$                               |
| $VC_{0.76}$ | $-108.2 \pm 7.0$                               | $VC_{0.84}$ | $-98.9 \pm 4.2$                                |
| $VC_{0.77}$ | $-101.6 \pm 5.4$                               | $VC_{0.88}$ | $-100.3 \pm 5.9$ (see Ref. 55)                 |
| $VC_{0.80}$ | $-96.7 \pm 12.0$                               | $VC_{0.88}$ | $-112.2 \pm 4.7$ (see Ref. 56)                 |

The empirical dependence of the enthalpy of formation on the composition of cubic carbide  $VC_y$  for the range  $0.72 \leq y \leq 0.88$  was described<sup>56</sup> by a linear function

$$\Delta H_{f, 298}^\circ(y) = -48.3 - 66.3y \pm 6.7 \text{ (kJ mol}^{-1}\text{)}.$$

In the study,<sup>57</sup> the enthalpy of formation of carbide  $VC_{0.88}$  was estimated at  $-100.9 \pm 2.9 \text{ kJ mol}^{-1}$ .

However, analysis of the experimental results<sup>55–57</sup> taking into account experimental errors demonstrated<sup>58</sup> that the enthalpy of formation of cubic  $VC_y$  is square function of the carbon content and, for the range  $0.70 \leq y \leq 0.88$ , takes the form

$$\Delta H_{f, 298}^\circ(y) = 104.78 - 437.73y + 224.02y^2 \text{ (kJ mol}^{-1}\text{)}. \quad (1)$$

As mentioned above, the characteristic feature of cubic carbide  $VC_y$  is that the upper boundary of its homogeneity region corresponds to  $VC_{0.875}$  and is far from the equiatomic composition  $VC_{1.0}$ . All attempts to synthesise stoichiometric carbide  $VC_{1.0}$  failed. However, the thermodynamic characteristics were theoretically estimated. The enthalpy of formation of hypothetical carbide  $VC_{1.0}$  was evaluated<sup>59</sup> at  $-117.2 \pm 41.9 \text{ kJ mol}^{-1}$ . In the study,<sup>60</sup> the energy of formation of structural vacancies in cubic carbide  $VC_y$  was calculated from the experimental data<sup>56</sup> and the

standard enthalpy of formation  $\Delta H_{f,298}^\circ$  of the stoichiometric compound  $\text{VC}_{1.0}$  was estimated at  $-105.9 \pm 2.9 \text{ kJ mol}^{-1}$ . According to the results of the study,<sup>60</sup> the enthalpy of formation linearly depends on the composition of cubic carbide  $\text{VC}_y$  in the composition region from  $\text{VC}_{0.65}$  to  $\text{VC}_{1.0}$ .

$$\Delta H_{f,298}^\circ(y) = -91.4 - 14.5y \text{ (kJ mol}^{-1}\text{)}. \quad (2)$$

It should be noted that the enthalpy difference between carbide  $\text{VC}_{0.88}$  and hypothetical  $\text{VC}_{1.0}$  calculated by Eqns (1) and (2) is small (2.0 and 1.7  $\text{kJ mol}^{-1}$ , respectively). The small enthalpy difference corresponds to the small difference in the free energy of formation of these compounds, which can be compensated by the contribution of the configurational entropy of non-stoichiometric carbide. As a result, carbide  $\text{VC}_{0.88}$  can have a lower free energy than stoichiometric carbide  $\text{VC}_{1.0}$ , due to which imperfect carbide  $\text{VC}_{0.88}$  rather than stoichiometric carbide  $\text{VC}_{1.0}$  exists in equilibrium with carbon. This situation cannot occur, for example, in the case of carbide  $\text{TiC}_y$ , because its free energy depends more strongly on the composition compared to vanadium carbide. This is evident from the enthalpy differences. For titanium carbides  $\text{TiC}_{0.88}$  and  $\text{TiC}_{1.0}$ , this difference is  $16.5 \text{ kJ mol}^{-1}$ ,<sup>28</sup> i.e., it is 7–8 times larger than that for carbides  $\text{VC}_{0.88}$  and  $\text{VC}_{1.0}$ .

The dependence of the enthalpy of formation (in  $\text{kJ mol}^{-1}$ ) on the composition of lower carbide  $\text{V}_2\text{C}_{y'} \equiv \text{VC}_y$  ( $y \leq 0.5$ ) determined in the study<sup>61</sup> can be described by the following function:

$$\Delta H_{f,298}^\circ(y) = -42.2 - 53.7y \pm 2.6,$$

according to which the enthalpy of formation of carbide  $\text{V}_2\text{C}$  ( $\text{VC}_{0.5}$ ) is

$$\Delta H_{f,298}^\circ \text{V}_2\text{C} = 2 \Delta H_{f,298}^\circ \text{VC}_{0.5} = -138.1 \text{ kJ mol}^{-1}.$$

Apparently, this value is underestimated in magnitude. In the study,<sup>57</sup> the enthalpy of formation of  $\text{V}_2\text{C}$  was estimated at  $-147.4 \pm 21.0 \text{ kJ mol}^{-1}$ , which is more realistic.

### c. Enthalpy (heat content)

The enthalpies ( $H_T^\circ - H_{298}^\circ$ ) of cubic  $\text{VC}_y$  with different carbon contents were measured at 500–1500,<sup>62</sup> 1300–2500 (see Ref. 63) and 400–1100 K (see Ref. 64) and approximated by the polynomials

$$H_T^\circ - H_{298}^\circ = A + BT + CT^2 + DT^{-1}. \quad (2a)$$

In the study,<sup>62</sup> the enthalpies of several samples of lower vanadium carbide  $\text{V}_2\text{C}_{y'}$  ( $\text{VC}_y$  for  $y \leq 0.5$ ) with different carbon contents were also measured. The measured temperature depend-

ences ( $H_T^\circ - H_{298}^\circ$ ) show a jump increase in the enthalpy at  $\sim 1385 \text{ K}$  associated with the disorder–order transition. The polynomials proposed in this study, can be considered as suitable for the description of the enthalpy in the temperature range from 300 to 1385 K. The polynomials reported in the studies<sup>62,63</sup> do not quite satisfy the evident normalisation condition at  $T = 298 \text{ K}$

$$H_T^\circ - H_{298}^\circ \equiv 0.$$

Hence, in the present review, the preliminary results of measurements<sup>62,63</sup> were processed taking into account this condition. The polynomial coefficients are given in Table 4.

The enthalpies of vanadium carbides containing small amounts of oxygen and nitrogen, for example, of  $\text{V}(\text{C}_{0.995}\text{O}_{0.002}\text{N}_{0.003})_{0.813}$ , were measured in the study.<sup>64</sup> The composition of the latter carbide was written as  $\text{VC}_{0.813}$ . However, the carbon content in this formula is overestimated. Hence, the index for carbon presented in Table 4 is written according to its actual content.

The empirical temperature and concentration dependence of the enthalpy (in  $\text{kJ mol}^{-1}$ ) of disordered cubic carbide was obtained from the data given in Table 4,

$$\begin{aligned} (H_T^\circ - H_{298}^\circ)_{\text{VC}_y} = & (-7.69 + 26.95 \times 10^{-3}T + \\ & + 11.84 \times 10^{-6}T^2 - 416T^{-1}) + \\ & + (0.24 - 18.29 \times 10^{-3}T - 11.75 \times 10^{-6}T^2 + 1864T^{-1})y + \\ & + (-12.66 + 42.47 \times 10^{-3}T)y^2. \end{aligned} \quad (3)$$

This dependence allows one to estimate the enthalpy of  $\text{VC}_y$  for all  $y$  in the temperature range from 300 to 2000 K.

The enthalpy ( $H_T^\circ - H_{298}^\circ$ ) <sub>$\text{V}_2\text{C}$</sub>  (in  $\text{kJ mol}^{-1}$ ) of hexagonal carbide  $\text{V}_2\text{C}$  ( $\beta\text{-V}_2\text{C}$ ) is twice as high as the enthalpy of hexagonal  $\text{VC}_{0.5}$

$$(H_T^\circ - H_{298}^\circ)_{\text{V}_2\text{C}} = 2(H_T^\circ - H_{298}^\circ)_{\text{VC}_{0.5}}.$$

The temperature dependence, which was determined from the results of the study<sup>62</sup> and refined taking into account the normalisation condition ( $H_T^\circ - H_{298}^\circ \equiv 0$  at  $T = 298 \text{ K}$ ), takes the form

$$\begin{aligned} (H_T^\circ - H_{298}^\circ)_{\text{V}_2\text{C}} = & -33.58 + 83.12 \times 10^{-3}T + \\ & + 1.7 \times 10^{-6}T^2 + 2580T^{-1}. \end{aligned} \quad (4)$$

This dependence is valid for the temperature range from 300 to 1600 K.

**Table 4.** Coefficients of the temperature dependence of enthalpy for hexagonal ( $\text{VC}_{0.42}$ ,  $\text{VC}_{0.45}$ ,  $\text{VC}_{0.51}$ ) and cubic vanadium carbides  $\text{VC}_y$  [see Eqn (2a)].

<sup>a</sup> The compositions of carbides  $\text{VC}_y$  determined in the study<sup>64</sup> are given in accordance with the real carbon content.

The enthalpies of hexagonal carbide VC<sub>0.46</sub> and cubic carbides VC<sub>0.71</sub>, VC<sub>0.83</sub> and VC<sub>0.86</sub> in the temperature range of 400–1300 K were also experimentally determined in the studies.<sup>65,66</sup> These enthalpies are apparently slightly underestimated.

#### d. Heat capacity and entropy

The heat capacities of hexagonal and cubic vanadium carbides VC<sub>0.46</sub>, VC<sub>0.53</sub>, VC<sub>0.71</sub>, VC<sub>0.83</sub> and VC<sub>0.86</sub> were measured<sup>65,67</sup> in the temperature range from 10 to 300 K by adiabatic calorimetry. The preliminary results of measurements were described in the publication.<sup>67</sup> The tabulated heat capacities, enthalpies and entropies of these carbides (Tables 5 and 6) were published in the study.<sup>65</sup> The experimental error was no higher than 1%.

**Table 5.** Heat capacities  $C_p$  (J g-atom<sup>-1</sup> K<sup>-1</sup>),  $\Delta S_T^\circ = S_T^\circ - S_{10}^\circ$  (J g-atom<sup>-1</sup> K<sup>-1</sup>) and  $H_T^\circ - H_{10}^\circ$  (J g-atom<sup>-1</sup>) for hexagonal carbides VC<sub>0.46</sub> and VC<sub>0.53</sub> in the temperature range of 10–300 K.<sup>65,67</sup>

| 250 | 17.16              | 2223.2                     | 14.19              | 16.78              | 2089.2                     | 13.73              |
| 273 | 17.99              | 2625.1                     | 15.70              | 17.72              | 2487.0                     | 15.24              |
| 298 | 18.80              | 3085.7                     | 17.33              | 18.54              | 2939.1                     | 16.87              |
| 300 | 18.86              | 3127.5                     | 17.46              | 18.62              | 2976.8                     | 17.00              |

The temperature dependence of the heat capacity (in J mol<sup>-1</sup> K<sup>-1</sup>) of hypothetical stoichiometric vanadium carbide VC<sub>1.0</sub> was calculated.<sup>60</sup>

$$C_p(T) = 38.4 + 0.017T - 1351.5T^{-1}. \quad (5)$$

The heat capacity of this carbide determined at 300 K (39.0 J mol<sup>-1</sup> K<sup>-1</sup>) is, apparently, overestimated. For comparison, the heat capacities of carbides VC<sub>0.71</sub>, VC<sub>0.83</sub> and VC<sub>0.86</sub> were evaluated at 30.50, 31.95 and 32.10 J mol K<sup>-1</sup>, respectively.<sup>65</sup>

The heat capacities of ordered carbides VC<sub>0.79</sub>, VC<sub>0.83</sub> and VC<sub>0.87</sub> were measured<sup>25,26,68,69</sup> in the temperature range from 300 to 1570 K by differential scanning calorimetry. The temperature dependences of the heat capacity at  $T > 1300$  K show peaks characteristic of order–disorder phase transitions.

The heat capacities of VC<sub>0.76</sub>, VC<sub>0.80</sub>, VC<sub>0.85</sub> and VC<sub>0.87</sub> in the temperature range of 1–20 K were measured in the study.<sup>70</sup> At  $T < 5$  K, the heat capacity is described by the dependence

$$C_p(T) = \gamma T + \alpha T^3 + \beta T^5.$$

**Table 6.** Heat capacities  $C_p$  (J g-atom<sup>-1</sup> K<sup>-1</sup>),  $\Delta S_T^\circ = S_T^\circ - S_{10}^\circ$  (J g-atom<sup>-1</sup> K<sup>-1</sup>) and  $H_T^\circ - H_{10}^\circ$  (J g-atom<sup>-1</sup>) for cubic carbides VC<sub>0.71</sub>, VC<sub>0.83</sub> and VC<sub>0.86</sub> in the temperature range of 10–300 K.<sup>65,67</sup>

| T, K | VC <sub>0.71</sub> |                            |                    | VC <sub>0.83</sub> |                            |                    | VC <sub>0.86</sub> |                            |                    |
|------|--------------------|----------------------------|--------------------|--------------------|----------------------------|--------------------|--------------------|----------------------------|--------------------|

| 150  | 9.839              | 561.0                      | 5.485              | 8.960              | 485.7                      | 4.522              | 8.834              | 473.1                      | 4.396              |
| 200  | 13.15              | 1138.8                     | 8.792              | 12.43              | 1025.8                     | 7.620              | 12.27              | 1004.8                     | 7.453              |
| 250  | 15.78              | 1863.1                     | 12.02              | 15.28              | 1720.8                     | 10.72              | 15.07              | 1691.5                     | 10.47              |
| 273  | 16.79              | 2269.2                     | 13.44              | 16.37              | 2085.0                     | 12.10              | 16.16              | 2051.5                     | 11.85              |
| 298  | 17.75              | 2671.2                     | 14.99              | 17.38              | 2507.9                     | 13.57              | 17.17              | 2466.0                     | 13.31              |
| 300  | 17.84              | 2704.7                     | 15.07              | 17.46              | 2512.1                     | 13.69              | 17.25              | 2503.7                     | 13.40              |

Taking into account the method used for the synthesis, the obtained carbides were, apparently, disordered. Nevertheless, with the reference to optical anisotropy of VC<sub>0.85</sub> observed in reflected white light, the authors of the study<sup>70</sup> hypothesised that this sample can contain the ordered V<sub>6</sub>C<sub>5</sub> phase.

According to the results of the investigation,<sup>65</sup> the entropies  $S_{298}^\circ$  of nonstoichiometric cubic carbides VC<sub>0.71</sub>, VC<sub>0.83</sub> and VC<sub>0.86</sub> are 14.99, 13.57 and 13.31 J g-atom<sup>-1</sup> K<sup>-1</sup> (see Tables 5 and 6) or 25.62, 24.83 and 24.76 J mol<sup>-1</sup> K<sup>-1</sup>, respectively. These values were used to calculate the dependence of the entropy (J mol<sup>-1</sup> K<sup>-1</sup>) on the composition of cubic vanadium carbide

$$S_{298}^\circ(y) = 40.21 - 32.77y + 17.22y^2. \quad (6)$$

The entropy  $S_{298}^\circ$  of hexagonal VC<sub>0.53</sub> is 16.87 J g-atom<sup>-1</sup> K<sup>-1</sup> (see Table 5) or 25.81 J mol<sup>-1</sup> K<sup>-1</sup>. Hence, the entropy of lower carbide V<sub>2</sub>C ( $\beta$ -V<sub>2</sub>C) of stoichiometric composition can be estimated at 51–52 J mol<sup>-1</sup> K<sup>-1</sup>. This entropy of hexagonal carbide  $\beta$ -V<sub>2</sub>C is, apparently, underestimated. In the study,<sup>71</sup> the change in the entropy upon the formation of  $\beta$ -V<sub>2</sub>C was evaluated at  $-4.2$  J mol<sup>-1</sup> K<sup>-1</sup>. Hence it follows that

$$S_{298}^\circ \text{V}_2\text{C} = 2S_{298}^\circ \text{V} + S_{298}^\circ \text{C} + \Delta S_{298}^\circ.$$

Taking into account the entropies of vanadium metal ( $S_{298}^\circ \text{V} = 28.67$  J mol<sup>-1</sup> K<sup>-1</sup>)<sup>72</sup> and carbon ( $S_{298}^\circ \text{C} = 5.39$  J mol<sup>-1</sup> K<sup>-1</sup>),<sup>73</sup>  $S_{298}^\circ \text{V}_2\text{C}$  for lower vanadium carbide is 58.53 J mol<sup>-1</sup> K<sup>-1</sup>.

#### e. Free energy

It was demonstrated<sup>28,74</sup> that the part of the free energy ( $F$ ) of the disordered MX<sub>y</sub> compound, which does not include components accounting for the contribution of the configurational entropy  $S_c(y,0)$ , is

$$F_0(T) + yF_1(T) + y^2F_2(T) = \Delta H_f^\circ(y) + (H_T^\circ - H_{298}^\circ)_{\text{MX}_y} - (7) \\ - T \left[ S_{298}^\circ(y) + \int_{298}^T \frac{1}{T} d(H_T^\circ - H_{298}^\circ)_{\text{MX}_y} \right].$$

The free energy (in kJ mol<sup>-1</sup>) of disordered vanadium carbide can be calculated with the use of dependences (1), (3) and (6) according to Eqn (7). The calculations carried out in the studies<sup>2,25–27</sup> demonstrated that the following dependence is valid for disordered cubic carbide VC<sub>y</sub>:

$$F_0(T) + yF_1(T) + y^2F_2(T) = (97.09 + 145.0 \times 10^{-3}T - 11.84 \times 10^{-6}T^2 - 208T^{-1} - 26.95 \times 10^{-3}T \ln T) + \\ + (-437.49 - 86.23 \times 10^{-3}T + 11.75 \times 10^{-6}T^2 + 932T^{-1} + 18.29 \times 10^{-3}T \ln T)y + \\ + (211.36 + 267.21 \times 10^{-3}T - 42.47 \times 10^{-3}T \ln T)y^2. \quad (8)$$

The energy parameters  $F_0(T)$ ,  $F_1(T)$  and  $F_2(T)$  of the free energy determined for disordered cubic carbide VC<sub>y</sub> are

applicable for the temperature range of 298–2000 K. Analogous calculations performed in these studies for hexagonal carbide  $\beta$ -V<sub>2</sub>C without consideration for its homogeneity region gave the following dependence of the free energy (in kJ mol<sup>-1</sup>) for the temperature range of 298–1600 K

$$F(T)_{V_2C} = -180.96 + 513.67 \times 10^{-3}T - 1.70 \times 10^{-6}T^2 + 1290T^{-1} - 83.12 \times 10^{-3}T \ln T. \quad (9)$$

With a knowledge of the parameters  $F_0(T)$ ,  $F_1(T)$  and  $F_2(T)$  and the free energy  $F(T)_{V_2C}$ , it is possible to perform thermodynamic calculations of phase equilibria involving hexagonal and cubic nonstoichiometric vanadium carbides.

### f. High-temperature vaporisation of vanadium carbide

In studies of the thermodynamic properties of nonstoichiometric carbides, vapour pressure measurements over a vaporising solid compound are used along with adiabatic, differential scanning and bomb calorimetry. From the viewpoint of determining the thermodynamic properties of nonstoichiometric carbides, congruent vaporisation (sublimation), *i.e.*, vaporisation, which occurs in equilibrium conditions without changes in the composition of the solid phase, is of most interest.

According to the kinetic theory of gases, the rate of vaporisation from the surface existing in equilibrium with vapour is equal to the condensation rate proportional to the equilibrium vapour pressure  $p$ . Under non-equilibrium conditions (for example, in the case of vacuum vaporisation from the open surface), the vaporisation rate is independent of the condensation rate but is equal to the equilibrium vaporisation rate at this temperature  $T$ .<sup>75</sup> This is true if the residual pressure in a vacuum chamber is no higher than 10 Pa ( $\sim 0.1$  mmHg). Therefore, the equilibrium parameter, *viz.*, the saturated vapour pressure, can be found from the rate of stationary vacuum vaporisation, after which many thermodynamic characteristics can be calculated. If the transition of the condensed phase into vapour is accompanied by its dissociation, the observed vaporisation rate and the partial pressures are smaller than the equilibrium values. This fact can be taken into account by introducing the vaporisation coefficient  $\alpha \leq 1.0$ .

The kinetic and thermodynamic conditions of congruent vaporisation of disordered nonstoichiometric interstitial compounds have been considered in detail in the monograph.<sup>1</sup> The thermodynamics of congruent vaporisation of nonstoichiometric compounds was investigated also in the studies.<sup>76,77</sup>

The vapour composition over the VC–C system in the temperature range of 2417–2603 K was studied by mass spectrometry.<sup>78</sup> Judging from the X-ray diffraction data and the lattice parameter, the authors used a sample containing carbide VC<sub>0.88</sub> along with free carbon. The vapour pressure was not measured and only data on the V : VC<sub>2</sub> ratio in the gas phase were reported.

The studies<sup>79,80</sup> were concerned with vaporisation of vanadium carbide by the Knudsen effusion method in the temperature range of 2346–2545 K. Taking into account the method of the synthesis, the composition of the resulting carbide is VC<sub>0.99</sub>. Hence, the study was, apparently, performed with the use of carbide VC<sub>0.88</sub> containing a large amount of free carbon. The vaporisation rate was determined from the mass change upon vaporisation. Vaporisation did not lead to a change in the composition of vanadium carbide, and the condensate consisted of pure vanadium. The temperature dependence of the vapour pressure of vanadium  $p_V$  (in atm) over the VC–C system is described by the equation

$$\log p_V = 7.63 - \frac{30\,700}{T}. \quad (10)$$

Investigation of the phase equilibria in the V–C system demonstrated<sup>10</sup> that heating of vanadium carbide of any composition *in vacuo* leads to the predominant loss of the metal. Vapor-

isation of vanadium carbide becomes noticeable at temperatures higher than 1800 K.

Storms<sup>11</sup> found the temperature dependence of the vapour pressure of vanadium (in atm) based on the thermochemical characteristics of dissociation of carbide VC<sub>0.88</sub> in equilibrium with carbon

$$\log p_V = 7.56 - \frac{31\,210}{T}. \quad (11)$$

Vaporisation of carbide VC<sub>0.84</sub> in the temperature range from 2073 to 2423 K under vacuum of 0.0013 Pa ( $1 \times 10^{-5}$  mmHg) was investigated<sup>81</sup> by the Langmuir method based on the determination of the vaporisation rate from the open surface of a sample heated *in vacuo*. The total time of vacuum vaporisation varied from 42 h at 2073 K to 12 h at 2423 K. During vaporisation, the crystal lattice parameter on the sample surface slightly increases. Taking into account the changes in the chemical composition and the lattice parameter, the vaporisation rate of vanadium atoms during vacuum heating of carbide VC<sub>0.84</sub> was initially larger than the vaporisation rate of carbon atoms, *i.e.*,  $V_V/V_C > 1/y$ . As a result, the samples were depleted in metal and enriched in carbon, and their compositions became close to the upper boundary of the homogeneity region of cubic carbide (VC<sub>0.88</sub>). Vacuum heating of vanadium carbide leads to vaporisation of not only vanadium but also of carbon, because elimination of free carbon was observed neither on the surface nor in the bulk of the samples. At 2000–2400 K, vaporisation of vanadium carbide occurs according to the reaction<sup>81</sup>

the composition of the congruently vaporising carbide varied from VC<sub>0.85</sub> to VC<sub>0.87</sub> and was shifted to the upper boundary of the homogeneity region with increasing temperature. A similar conclusion about the predominant loss of the metal and the shift of the composition of vanadium carbide to the upper boundary of the homogeneity region as a result of vaporisation has been drawn earlier in the study.<sup>10</sup>

An increase in the temperature from 2073 to 2423 K led to an increase in the total rate of vacuum vaporisation of vanadium carbides by a factor of almost 300, and the mass loss through vaporisation at 2423 K for one hour was 6%–7%. The experimental data on the vaporisation rate of vanadium carbide (in kg m<sup>-2</sup> s<sup>-1</sup>) at 2000–2500 K can be described by the equation<sup>81</sup>

$$\ln V = 25.117 - \frac{80\,900}{T} \pm 0.015. \quad (13)$$

The partial pressures of vanadium and carbon over congruently vaporising vanadium carbides were estimated from the measured vaporisation rate and assuming that the vaporisation coefficient of vanadium is 1.<sup>81</sup> At 2073, 2273 and 2423 K, congruent vaporisation of carbides VC<sub>0.85</sub>, VC<sub>0.86</sub> and VC<sub>0.87</sub>, respectively, was demonstrated to occur. The estimated partial pressures of vanadium and carbon were as follows:  $1.1 \times 10^{-3}$  and  $0.9 \times 10^{-3}$  Pa over carbide VC<sub>0.85</sub> at 2073 K; 0.035 and 0.030 Pa over carbide VC<sub>0.86</sub> at 2273 K; and 0.34 and 0.30 Pa over carbide VC<sub>0.87</sub> at 2423 K, respectively.

Vaporisation in the V–C system was thoroughly investigated<sup>50</sup> by mass spectrometry using a Knudsen effusion cell. The vapour was ionised and the ion current rather than its absolute pressure was measured. Several samples of vanadium metal and 18 samples of vanadium carbides of different compositions were used in measurements. The measurements for the samples of different compositions were carried out in the temperature ranges of 1445–1819, 1740–2226 and 1809–2173 K. The activity of vanadium ( $a_V$ ) was determined as the ratio of the ion currents of vanadium metal and vanadium carbide vaporised under comparable conditions. In these calculations, the heat of vaporisation of vanadium metal (532.1 kJ mol<sup>-1</sup>) was used as the basic value. The plots of  $\log a_V$  vs  $y$  for 1700 and 2000 K were constructed, and the carbon activity  $a_C$  was calculated by numerical integration

according to the Gibbs–Duhem equation. In the investigation,<sup>50</sup> the equation was not given in an explicit form. However, the carbon activity was, apparently, determined by integration of the following equation:

$$d \ln a_C = -\frac{1}{y} d \ln a_V. \quad (14)$$

The partial enthalpies of vaporisation of vanadium and carbon were calculated by the equation

$$\Delta \bar{H}_{V(C)} = \Delta H_{V(C)}^\circ - RT \ln a_{V(C)} \quad (15)$$

using the enthalpies of vaporisation of vanadium and carbon at 1650 K:  $\Delta H_V^\circ = 525.4$  and  $\Delta H_C^\circ = 713.8$  kJ mol<sup>−1</sup>.

The free energies of formation of vanadium carbides VC<sub>y</sub>, with different carbon contents at 1700 K were calculated<sup>50</sup> according to the formula

$$\Delta F_f(y, T) = RT(\ln a_V + y \ln a_C) + RT[y \ln y + (1-y) \ln(1-y)]. \quad (16)$$

At 1700 K,  $\Delta F_f(y, 1700)$  varied from  $-19.9$  for VC<sub>0.74</sub> to  $-21.3$  kJ mol<sup>−1</sup> for VC<sub>0.88</sub>. The enthalpy of formation  $\Delta H_f^\circ$  of carbide VC<sub>0.88</sub> is  $-104.6 \pm 1.8$  J mol<sup>−1</sup>. It should be noted that the results published in the study<sup>50</sup> were obtained for the temperature range higher than the temperature of the order–disorder transition VC<sub>y</sub>–V<sub>8</sub>C<sub>7</sub>, *i.e.*, for the disordered state of vanadium carbide.

### III. Ordered phases of nonstoichiometric vanadium carbides

Cubic vanadium carbide VC<sub>y</sub> is the first transition metal carbide, in which ordering was observed,<sup>12</sup> and is one of a few strongly nonstoichiometric carbides, in which atom–vacancy ordering was studied in detail. Let us consider the main concepts related to this ordering.

Atomic or atom–vacancy ordering is a synonym of a disorder–order structural phase transition (magnetic ordering in the case of magnetic phase transitions). Ordering as a phase transition is a result of atomic redistribution over sites of the crystal lattice of a substitutional solid solution. In the disordered state, components of the solid solution, which can replace each other, are randomly distributed over the sites of the crystal lattice and the probability of occupancy of a particular site by an atom of a particular type is equal to its concentration in solution. A decrease in the temperature leads to ordering, with the result that the crystal lattice sites of a disordered solution are divided into several sublattices. Sublattices of an ordered solution differ from each other in the probability of occupancy of the sites by atoms of a particular type. Ordered phases generated by dividing the lattice of a disordered crystal into several sublattices are called superstructures.

Ordering can also occur in interstitial solid solutions, if the number of interstitial sites is larger than the number of atoms occupying these sites. In the ordering process in interstitial solutions, vacancies and interstitial atoms serve as components of substitutional solutions, whereas solvent atoms form a stationary atomic framework, within which the interstitial atoms and vacancies are redistributed.

In disordered nonstoichiometric compounds, all sites of the non-metal sublattice are crystallographically equivalent. Ordering is accompanied by redistribution of interstitial atoms and structural vacancies over the non-metal sublattice sites. As a result, the crystal lattice sites of the disordered solution become non-equivalent and are divided into at least two sublattices, which differ in the probability of occupancy of the sites by atoms of one and the same type. From the above it is evident that nonstoichiometry is a prerequisite for ordering in imperfect interstitial compounds, because it is responsible for the fact that the number of interstitial

sites is larger than the number of atoms. Hence, the presence of structural vacancies in nonstoichiometric interstitial compounds leads, under certain conditions, to ordering. In the simplest case, ordering in a non-metal sublattice consists in dividing the system formed by octahedral interstitial sites of the metal sublattice into two new sublattices. All sites in the first superstructure sublattice are occupied by interstitial atoms, whereas the sites in the second sublattice are vacant. Hence, it is safe to assume that ordering in nonstoichiometric compounds gives rise to a vacancy sublattice.

Ordering in non-metal sublattices of nonstoichiometric compounds is accompanied by lowering of crystal symmetry. Actually, some symmetry transformations of a disordered non-metal sublattice, which relate the occupied sites to the vacancies, are not involved in the symmetry group of the ordered crystal, because these sites are crystallographically non-equivalent.

Over many years, the positions of interstitial atoms in lattices of nonstoichiometric compounds were determined primarily by X-ray diffraction methods. However, X-ray scattering amplitudes for interstitial atoms are small compared to those for metal atoms, due to which it is not always possible to determine the positions of interstitial atoms by analysing the intensities of diffraction lines. Hence, it is a wide spread opinion that interstitial atoms in non-metal sublattices of nonstoichiometric compounds are always randomly distributed.

The development of experimental techniques and, particularly, the use of neutron diffraction, made it possible to reveal that, under certain conditions, an ordered distribution of interstitial atoms can occur in nonstoichiometric compounds. The neutron diffraction technique is one of the most informative methods for studying nonstoichiometric interstitial compounds, because neutron scattering intensities of transition metal nuclei are comparable with those of light elements. Ordering of interstitial atoms in these compounds was detected also by other diffraction methods, such as electron diffraction, high-resolution X-ray diffraction and various physicochemical methods.

Ordering of interstitial atoms has been experimentally observed in most nonstoichiometric carbides of Group IV and V transition metals.

Vanadium carbides VC<sub>y</sub> and V<sub>2</sub>C<sub>y</sub> are rather convenient to study. Since the X-ray scattering amplitude for the vanadium atom differs not very much (by a factor of  $\sim 5$ ) from that for carbon, superstructure reflections can be observed in X-ray diffraction patterns. The neutron scattering amplitude for the vanadium atom is negative and small in magnitude compared to that for the carbon atom ( $-0.038 \times 10^{-12}$  and  $0.665 \times 10^{-12}$  cm, respectively).<sup>82</sup> For this reason, the ordered non-metal (carbon) sublattice makes the major contribution to neutron diffraction from vanadium carbide, and the most intense superstructure reflections are weaker than the structure reflections (111)<sub>B1</sub> and (200)<sub>B1</sub> by only a factor of 11–20, *i.e.*, these reflections are quite observable. Besides, vanadium carbide can be studied by NMR spectroscopy, because the <sup>51</sup>V nuclei have the nonzero spin  $I = 7/2$ . The structures of ordered phases of nonstoichiometric vanadium carbides VC<sub>y</sub> and V<sub>2</sub>C<sub>y</sub> were studied by X-ray, neutron and electron diffraction, NMR spectroscopy and electron and optical microscopy. However, in spite of the fact that ordering in vanadium carbides was studied more thoroughly compared to other transition metal carbides, many experimental data on the compositions and structures of ordered phases of carbide VC<sub>y</sub> were not confirmed in later studies. These phases are not mentioned in the present review.

#### 1. NMR spectroscopic studies of vanadium carbide

NMR spectroscopy provides information on the mutual arrangement of interstitial atoms and structural vacancies in non-metal sublattices of nonstoichiometric compounds, *i.e.*, information on the short-range order in such compounds. As a rule, no more than three–four types of the nearest environment of metal atoms formed by carbon atoms and vacancies are observed in ordered phases of nonstoichiometric carbides.<sup>3,4</sup> Hence data on the short-

range order in non-metal sublattices of carbides obtained by NMR spectroscopy provide indirect evidence for the presence of a particular ordered phase in samples.

The nearest environment of the vanadium atom in carbide  $VC_y$  with the  $B1$  structure involves three coordination spheres (see Fig. 4). The first coordination sphere is formed by six occupied or partially vacant sites of the non-metal sublattice. The second ordered coordination sphere consists of 12 metal atoms. The third coordination sphere is formed by eight sites of the non-metal sublattice occupying the vertices of the cubic unit cell. It is convenient to describe the environment of the metal atoms with the use of superscripts and subscripts indicating the numbers of vacancies in the first and third non-metal coordination spheres, respectively. For example, the vanadium position  $V_0^0$  signifies that the first coordination sphere of vanadium is complete (contains no vacancies), whereas the second non-metal coordination sphere has two vacancies.

Carbides  $VC_y$  with  $y = 0.66, 0.70, 0.80, 0.84$  and  $0.875$  were studied by NMR spectroscopy throughout the homogeneity region of the cubic phase.<sup>83</sup> The  $^{51}\text{V}$  NMR spectra of carbides  $VC_{0.875}$ ,  $VC_{0.84}$  and  $VC_{0.70}$  show several resonance lines, whose intensities depend on the composition of  $VC_y$ . The intensities of two lines rapidly decrease, whereas the intensity of the third line increases as the carbon content decreases. The spectrum of carbide  $VC_{0.70}$  shows an additional weak line. All observed lines and their satellites in the  $^{51}\text{V}$  NMR spectra of  $VC_y$  were compared with the positions of the vanadium atoms, whose first coordination spheres have different numbers of vacancies:  $V_0$  (without vacancies),  $V_1$  (with one vacancy),  $V_2$  and  $V_3$ . The following expression relating the jump in the Knight shift ( $K$ ) to the number of vacancies ( $n$ ) in the nearest environment of the vanadium atom was derived:

$$K_n - K_{n-1} \approx nK_0, \quad (17)$$

where  $K_0 \approx 0.07\% - 0.09\%$ , *i.e.*, the jump in the Knight shift is proportional to the number of vacancies in the first coordination sphere of the vanadium atom in  $VC_y$ .

To elucidate the character of distribution of vacancies in vanadium carbide, the experimental distribution of probabilities  $P(n)$  of vanadium sites was compared with the random distribution of probabilities calculated by the formula

$$P(n) = C_6^n (1 - y)^n y^{6-n}. \quad (18)$$

For all  $VC_y$  samples under consideration, the experimental distributions differed from the random distribution. For example, a decrease in the carbon content leads to a much more rapid decrease in the probability of existence of the  $V_0$  positions with the complete (without vacancies) environment in the first coordination sphere compared to the random distribution, and the  $V_3$  positions are observed much more rarely. A small number of the  $V_3$  positions and the absence of vanadium atom positions, whose first coordination spheres have four or more vacancies, were attributed to repulsion between the adjacent vacancies. Therefore, according to the results of the study,<sup>82</sup> cubic vanadium carbide has a short-range order.

The  $^{51}\text{V}$  NMR spectrum of carbide  $VC_{0.875}$  differs substantially from the spectra of other vanadium carbides. In particular, the intensity ratio of the lines corresponding to the  $V_0$  and  $V_1$  positions is 1 : 3. Assuming that the relative intensity of each line is proportional to the relative number of the corresponding positions, three-fourths of all vanadium atoms in carbide  $VC_{0.875}$  have one vacancy in the first coordination sphere, whereas the rest of the vanadium atoms have a complete environment. This distribution of vacancies is indicative of the presence of the  $V_8C_7$ -type superstructure with the space group  $P4_332$  or  $P4_132$ .<sup>12</sup> However, the authors of the publication<sup>83</sup> cast doubt that this model of distribution of vacancies is quite consistent with the real lattice. Actually, this superstructure characterised by a helicoidal arrangement of vacancies has only the  $V_0^1$  and  $V_1^1$  positions, whereas analysis of satellites in the NMR spectrum suggested the

existence of three types of positions  $V_1$ , which could not be resolved.

Interesting results were obtained in the study of an annealed single crystal of  $VC_{0.84}$ .<sup>13, 84</sup> The  $^{51}\text{V}$  NMR spectra of this carbide were resolved into lines corresponding to the  $V_0$  and  $V_1$  positions. Investigation of the satellites made it possible to resolve the intense band of  $V_1$  into lines corresponding to the  $V_1^0$ ,  $V_1^1$  and  $V_1^2$  positions which have no vacancies, one vacancy and two vacancies in the second coordination sphere, respectively. In the spectra, the intensity ratio of the  $V_1^1$  and  $V_1^2$  lines is 2 : 1. Hence, it is reasonable to assume that the number of the  $V_1^1$  positions in the carbide under study is twice as large as the number of the  $V_1^2$  positions. Taking into account high intensities of the lines, the corresponding  $V_1^1$  and  $V_1^2$  positions can be considered as positions of an ordered structure of vanadium carbide.

In the study of  $VC_{0.84}$  by electron diffraction,<sup>13</sup> the authors suggested the trigonal symmetry for the ordered phase  $V_6C_5$ . The available NMR data made it possible to describe the distribution of carbon atoms and vacancies in the trigonal unit cell, *i.e.*, to determine the structure of  $V_6C_5$ , taking into account the ratio of the number of the  $V_1^1$  positions to the number of the  $V_1^2$  positions. The trigonal superstructure of  $V_6C_5$  with the space group  $P3_1$  can be represented as helical chains composed of  $V_6C_5$  quasimolecules. The presence of weak lines corresponding to the  $V_0$  and  $V_1^0$  positions was attributed to the deviation of the composition of vanadium carbide  $VC_{0.84}$  from the ideal composition of the ordered phase  $V_6C_5$  ( $VC_{0.83}$ ). It should be noted that the presence of these lines can be associated also with the violation of the long-range order in the sample under investigation.

Attempts to obtain quantitative data on the short-range order in carbide  $VC_y$  by minimisation of the  $^{51}\text{V}$  NMR spectra were made in the studies.<sup>85, 86</sup> The experimental  $^{51}\text{V}$  NMR spectra of carbides  $VC_{0.75}$ ,  $VC_{0.84}$ ,  $VC_{0.85}$ ,  $VC_{0.86}$  and  $VC_{0.87}$  are analogous to the spectra described in the study<sup>83</sup> and have resonance lines corresponding to the  $V_0$ ,  $V_1$  and  $V_2$  vanadium atom positions. Assuming that the lines in the spectra are associated with the fact that the crystals contain nuclei in different local environments (different positions of metal atoms), and the intensity of the line is proportional to the number of positions of a particular type, the theoretical intensity of the line was represented as

$$I_{\text{theor}}(v) = \sum_i \lambda_i P_i I_i(v), \quad (19)$$

where  $P_i$  is the probability of existence of a cluster characterised by the  $i$ th configuration of the nearest environment of the resonating nucleus formed by non-metal atoms,  $\lambda_i$  is the multiplicity of the  $i$ th configuration; and  $I_i(v)$  is the mathematical model of the ideal spectral line for this configuration. (In the study,<sup>85</sup> the lines were described by the Gaussian distribution; the octahedron composed of six sites of the non-metal sublattice containing a metal atom in the centre was chosen as the basic cluster.) The probabilities  $P_i$  were represented as an expansion in series of pair and multi-particle correlation parameters, which were determined by minimisation of the functional  $\sum [I_{\text{theor}}(v) - I_{\text{exp}}(v)]^2$ . The spectra were best described taking into account pair and triple correlations. The consideration of higher-order correlation moments did not lead to a substantial change in the spectra.

According to the results of the studies,<sup>85, 86</sup> the pair correlations  $\varepsilon_{21}$  describing the distribution of carbon atoms (or vacancies) between two adjacent vertices of the octahedron, which are located relative to each other in the first coordination sphere, are negative throughout the homogeneity region of vanadium carbide. This fact indicates that the probability of finding vacancies in the nearest proximity to each other is lower than that in the case of random distribution throughout the homogeneity region of  $VC_y$ . The short-range order parameter  $\alpha_1$  for the first coordination sphere is approximately equal to  $-0.1$ . This parameter slowly increases in magnitude and passes through a minimum in the vicinity of the  $VC_{0.83}$  composition as the deviation from the stoichiometry increases.

The results of calculations<sup>85,86</sup> for the correlations and the short-range order parameter in vanadium carbide are on the whole consistent with the results of the publications.<sup>13,83,84</sup> The latter data provide evidence that there is the short-range order in carbide  $VC_y$  due to repulsions between vacancies. In the monograph,<sup>86</sup> the presence of ordered phases of vanadium carbide was erroneously attributed to a particular short-range order. In the studies,<sup>3,4,19,87,88</sup> it was demonstrated that the long-range order does not necessarily appear in nonstoichiometric compounds with the  $B1$  structure even in the presence of the highest short-range order in the first and second coordination spheres. Hence, the presence of the short-range order in strongly nonstoichiometric carbides is a necessary but not sufficient condition for the presence of the long-range order.

## 2. Diffuse electron scattering

Ordering in nonstoichiometric vanadium carbides was studied also by diffuse electron scattering. The short-order range parameters  $\alpha_{hkl}$  for eight nearest coordination spheres of non-metal sublattices were calculated<sup>89,90</sup> using experimental data<sup>45</sup> on the intensities of diffuse electron scattering by vanadium carbide  $VC_{0.75}$ . The vacancy was chosen as the centre of the coordination spheres. For nonstoichiometric carbide  $MC_y$ , the number of carbon atoms  $n_C$  and the number of vacancies  $n_{\square}$  in the  $j$ th sphere with coordination number  $z_j$  are

$$n_C = z_j(1 - \alpha_j)y, \quad (20)$$

$$n_{\square} = z_j[1 - (1 - \alpha_j)y].$$

With a knowledge of the short-range order parameter (including  $\alpha_j = 0$ ), the number of carbon atoms and the number of vacancies in the corresponding coordination sphere can be calculated by these equations.

The calculated parameters  $\alpha$  and the numbers  $n_C$  and  $n_{\square}$  in each coordination sphere are given in Table 7. For comparison, these values were calculated for the ordered phase  $V_6C_5$  with monoclinic (space group  $C2/m$  or  $C2$ ) or trigonal (space group  $P3_1$ ) superstructures (ideal  $M_6X_5$ -type superstructures do not differ in the short-range order) and disordered carbide  $VC_{0.75}$ .

As can be seen from Table 7, the distribution of carbon atoms and vacancies in the non-metal sublattice of carbide  $VC_{0.75}$  determined in the studies<sup>45,89,90</sup> differs substantially from the random distribution in disordered carbide  $VC_{0.75}$ . In the first two coordination spheres, the numbers of vacancies are much smaller than those observed for the random distribution. The parameter  $\alpha$  oscillates and decreases in magnitude with increasing radius of the coordination sphere. The data on the distribution of carbon atoms and vacancies were interpreted<sup>89,90</sup> as a consequence of mutual repulsion between the vacancies, and it was noted that an analogous short-range order should be observed in niobium and

tantalum carbides. A conclusion about the same type of short-range order in nonstoichiometric Group V transition metal monocarbides was drawn also in the study.<sup>91</sup> The authors of the cited paper believed that it is impossible to prepare completely disordered (without short-range order)  $VC_y$  samples with  $y > 0.78$ .

Diffuse electron scattering was also used to study the short-range order in lower hexagonal carbides  $V_2C_y$  and  $Nb_2C_y$ .<sup>92</sup> It was demonstrated that the short-range order and the long-range order in these carbides are associated with the distribution of carbon atoms and structural vacancies in regular  $C-\square-C-\square-\dots$  rows parallel to the  $c$  axis. A comparison of the experimental and calculated diffuse scattering intensities revealed the possible types of ordering in carbides  $V_2C$  and  $Nb_2C$ .

## 3. Crystal structures of ordered phases of nonstoichiometric vanadium carbides

Most precise and detailed information on the crystal structures of ordered phases of nonstoichiometric compounds can be obtained by diffraction methods. Principal structural characteristics of both experimentally observed and calculated ordered phases of nonstoichiometric lower hexagonal  $V_2C_y$  and cubic  $VC_y$  vanadium carbides are given in Table 8.

In disordered lower vanadium carbide  $V_2C_y$  ( $\beta$ - $V_2C$ ) with a hexagonal structure of the  $L'3$  ( $W_2C$ ) type, the hexagonal  $\varepsilon$ - $Fe_2N$ -type ordered phase  $\beta'$ - $V_2C$  ( $\beta_h$ - $V_2C$ ) initially appears due to ordering caused by lowering of the temperature. At temperatures lower than 1100 K, the orthorhombic  $\zeta$ - $Fe_2N$ -type ordered phase  $\beta_r$ - $V_2C$  ( $\alpha$ - $V_2C$ ) is formed. The existence of the hexagonal ordered phase  $\beta'$ - $V_2C$  ( $\beta_h$ - $V_2C$ ) was documented.<sup>37,44,47,93,94,105–109</sup> The orthorhombic ordered phase  $\beta_r$ - $V_2C$  ( $\alpha$ - $V_2C$ ) was found in the studies.<sup>44,46,93,94,105,108–113</sup> However, the refined data on the structures and crystal lattice parameters, the conditions of formation, concentrations and temperature ranges of existence of these phases obtained by different (and sometimes the same) research groups are not quite consistent with each other. Instability of the hexagonal  $\varepsilon$ - $Fe_2N$ -type ordered phase  $\beta'$ - $V_2C$  ( $\beta_r$ - $V_2C$ ) was noted in the investigation.<sup>107</sup> This high-temperature ordered phase was not observed in quenched samples of lower vanadium carbide.<sup>92,113</sup> However, the results of experimental studies<sup>108,109</sup> performed by high-temperature neutron diffraction demonstrated that the orthorhombic  $\zeta$ - $Fe_2N$ -type phase  $\beta_r$ - $V_2C$  ( $\alpha$ - $V_2C$ ) is a low-temperature ordered phase of lower vanadium carbide. An increase in the temperature leads to the transformation of the latter phase into the high-temperature ordered  $\varepsilon$ - $Fe_2N$ -type hexagonal phase  $\beta'$ - $V_2C$  ( $\beta_h$ - $V_2C$ ). The authors of these studies hypothesised that samples of lower vanadium carbide, whose composition differs from stoichiometric  $V_2C$ , undergo a polymorphic transformation

**Table 7.** Short-range order parameters ( $\alpha$ ), numbers of carbon atoms ( $n_C$ ) and vacancies ( $n_{\square}$ ) in the coordination spheres ( $hkl$ ) of carbide  $VC_{0.75}$ , the ideal ordered phase  $V_6C_5$  and disordered carbide  $VC_{0.75}$  (see Ref. 89).

<sup>a</sup> CS is the coordination sphere ( $hkl$ ) with the radius  $R_j = (a_{B1}/2)(h^2 + k^2 + l^2)^{1/2}$  ( $a_{B1}$  is the lattice parameter of disordered carbide  $VC_y$  with the  $B1$  structure; a vacancy is located in the centre of the coordination sphere). <sup>b</sup> CN is the coordination number of the sphere ( $hkl$ ).

**Table 8.** Ordered phases of strongly nonstoichiometric vanadium carbides.

in a two-phase region ( $\beta_r\text{-V}_2\text{C} + \beta_h\text{-V}_2\text{C}$ ). For example, only orthorhombic ordered  $\zeta\text{-Fe}_2\text{N}$ -type phase was observed<sup>108</sup> in neutron diffraction patterns of lower carbide  $\text{VC}_{0.47}$  at temperatures up to 1373 K inclusive. At 1393 K, the neutron diffraction pattern has reflections of the orthorhombic and hexagonal ordered phases. At 1413 K, the diffraction pattern shows superstructure reflections corresponding only to the high-temperature ordered  $\varepsilon\text{-Fe}_2\text{N}$ -type phase.

As can be seen from Table 8,  $\text{M}_3\text{C}_2$ -,  $\text{M}_6\text{C}_5$ - and  $\text{M}_8\text{C}_7$ -type ordered phases can exist in nonstoichiometric cubic vanadium carbide. In carbide  $\text{VC}_y$ , the first of these phases has not been experimentally detected. However, the possibility of its existence is supported by thermodynamic calculations. The phase  $\text{V}_8\text{C}_7$  was experimentally found only in vanadium carbide and was not observed in carbides of other transition metals. The existence of this phase is associated with the specific position of the upper boundary of the homogeneity region of vanadium monocarbide for  $\text{VC}_{0.875}$ .

As for the symmetry of the ordered phases, the trigonal (space group  $P3_1$ )<sup>13, 25, 69</sup> and monoclinic (space group  $C2$ )<sup>43, 45</sup>  $\text{V}_6\text{C}_5$ -type ordered phases and the cubic (space group  $P4_332$ ) ordered phase  $\text{V}_8\text{C}_7$  were found in  $\text{VC}_y$ .<sup>12, 46–49, 69, 103, 104</sup> It should be noted that  $\text{V}_8\text{C}_7$  (see Ref. 12) is the first ordered phase experimentally found in nonstoichiometric carbides. Hardening of high-vanadium cast iron was demonstrated<sup>98</sup> to be accompanied

by the formation of the disperse ordered carbide phases  $\text{V}_6\text{C}_5$  and  $\text{V}_8\text{C}_7$ . The phase  $\text{V}_6\text{C}_5$  is monoclinic (space group  $C2/m$ ) and is structurally similar to monoclinic ordered niobium carbide  $\text{Nb}_6\text{C}_5$  (space group  $C2/m$ ).<sup>99–102</sup> In high-carbon cast iron, monoclinic carbide  $\text{V}_6\text{C}_5$  is located in the centre of eutectic grains, whereas the cubic (space group  $P4_332$ ) ordered phase  $\text{V}_8\text{C}_7$  can occur in the outer layer of the grains.<sup>98</sup> The formation of the ordered phase  $\text{V}_6\text{C}_5$  was observed in the study<sup>114</sup> of vanadium-containing steel annealed at 1000 K for 50–150 h by transmission electron microscopy and electron diffraction. Data on the symmetry of the  $\text{V}_6\text{C}_5$  phase found in this study are lacking. Calculations demonstrated that the ordered phase  $\text{V}_3\text{C}_2$  can exist,<sup>25–27, 32</sup> and this phase can have orthorhombic (space group  $Immm$  or  $C222_1$ ) or monoclinic symmetry (space group  $P2$ ).

Investigations of the trigonal ordered phase  $\text{V}_6\text{C}_5$  by electron diffraction and electron microscopy<sup>13, 115</sup> showed that this phase is stable at temperatures close to the transition temperature to the disordered state, because this phase is disordered as a result of its heating with electron beam.<sup>115</sup> The monoclinic ordered phase  $\text{V}_6\text{C}_5$  is, apparently, formed at temperatures lower than the temperature of formation of the trigonal phase  $\text{V}_6\text{C}_5$ .<sup>43</sup> Actually, neutron diffraction studies demonstrated<sup>95–97</sup> that the monoclinic phase is stable in the temperature range of 1050–1370 K, and the trigonal phase exists in the range of 1140–1520 K. According to the average experimental estimates, the lower

boundary of the homogeneity region of the ordered phase  $V_6C_5$  corresponds to carbide  $VC_{0.75-0.77}$ , and the upper boundary corresponds to carbide  $VC_{0.82-0.86}$ . An ambiguity of the boundaries, particularly, of the upper boundary, is associated with the difference in the conditions of annealing of carbide  $VC_y$  used in different experiments. Annealed samples of carbide  $VC_y$  with  $y \geq 0.83$  contained already two ordered phases, *viz.*,  $V_6C_5$  and  $V_8C_7$ . The single-phase region of existence of the cubic superstructure of  $V_8C_7$  is very narrow (no broader than from  $VC_{0.863}$  to  $VC_{0.875}$ , *i.e.*, to the upper boundary of the homogeneity region of disordered  $VC_y$ ). The precise determination of the chemical composition of vanadium carbide, as well as of other refractory carbides, is a rather complicated problem. However, taking into account the errors in the determination of the composition, it can be assumed that vanadium carbides containing only the ordered phase  $V_8C_7$  have the composition  $VC_{0.870 \pm 0.005}$ . This may be evidence that the ordered phase  $V_8C_7$  has no homogeneity region and is formed only upon annealing of carbide  $VC_{0.875}$ . If the carbon content of carbide is smaller, the phase  $V_8C_7$  is present along with the ordered phase  $V_6C_5$ .

Therefore, several ordered  $M_6C_5$ -type phases of different symmetry and the ordered cubic  $M_8C_7$ -type phase were found in nonstoichiometric carbide  $VC_y$ . Let us consider their structures in more detail using such concepts as the disorder–order transition channel and the distribution function  $n(\mathbf{r})$  of atoms between the sites  $\mathbf{r}$  in an ordered crystal lattice. The distribution function  $n(\mathbf{r})$  has the symmetry of the ordered crystal lattice and reflects the probability of finding an atom of this type in the site  $\mathbf{r}$ . In a disordered crystal, the probabilities  $n(\mathbf{r})$  are equal for all sites and coincide with the fraction of lattice sites occupied by atoms of this type. For example, the distribution function  $n(\mathbf{r})$  of the atoms X in the disordered nonstoichiometric compound  $MX_y \square_{1-y}$  is equal to the fraction of lattice sites occupied by these atoms, *i.e.*,  $n(\mathbf{r}) = y$ .

The space-periodic modulation of the atom distribution (the deviation of the probability  $n(\mathbf{r})$  from its value for the random distribution) resulting in the formation of an ordered phase can be represented as a superposition of several plane concentration waves.<sup>116</sup> The wave vectors of the latter are the superstructure vectors  $\mathbf{k}_s^{(j)}$  of the reciprocal lattice in the first Brillouin zone of the disordered lattice. In the static concentration wave method,<sup>116</sup> the distribution function of atoms of this type is described through a fraction of sites occupied by these atoms and the superposition of the static concentration waves

$$n(\mathbf{r}) = y + \sum_s \sum_{j \in s} \Delta(\mathbf{k}_s^{(j)}, \mathbf{r}), \quad (21)$$

where  $\Delta(\mathbf{k}_s^{(j)}, \mathbf{r})$  is the standing plane static concentration wave generated by the superstructure vector  $\mathbf{k}_s^{(j)}$  of the star  $\{\mathbf{k}_s\}$ .<sup>†</sup> The equation for this wave takes the form

$$\Delta(\mathbf{k}_s^{(j)}, \mathbf{r}) = \frac{1}{2} \left[ Q(\mathbf{k}_s^{(j)}) \exp(i\mathbf{k}_s^{(j)} \mathbf{r}) + Q^*(\mathbf{k}_s^{(j)}) \exp(-i\mathbf{k}_s^{(j)} \mathbf{r}) \right], \quad (22)$$

where  $Q(\mathbf{k}_s^{(j)})$  is the concentration wave amplitude

$$Q(\mathbf{k}_s^{(j)}) = \eta_s \gamma(\mathbf{k}_s^{(j)}), \quad (23)$$

$\eta_s$  is the long-range order parameter and  $\gamma(\mathbf{k}_s^{(j)}) = \gamma_s \exp(i\varphi_s^{(j)})$  is the coefficient taking into account the crystal symmetry. The coefficient  $\gamma(\mathbf{k}_s^{(j)})$  is chosen so that the long-range order parameters equal to unity correspond to a completely ordered crystal of stoichiometric composition. Taking into account Eqn (23), the expression (22) can be represented as follows

<sup>†</sup> The wave vector star is a set of all nonequivalent vectors generated from the vector  $\mathbf{k}$  by rotation elements of the point symmetry group of the crystal. The wave vector star is denoted by  $\{\mathbf{k}\}$ , and the individual vectors involved in this set are called the arms of the star. The detailed definition of the wave vector star was given in publications.<sup>3,4</sup>

$$\Delta(\mathbf{k}_s^{(j)}, \mathbf{r}) = \frac{1}{2} \eta_s \left[ \gamma(\mathbf{k}_s^{(j)}) \exp(i\mathbf{k}_s^{(j)} \mathbf{r}) + \gamma^*(\mathbf{k}_s^{(j)}) \exp(-i\mathbf{k}_s^{(j)} \mathbf{r}) \right]. \quad (24)$$

From Eqns (21) and (24) it follows that the long-range order parameter  $\eta_s$  corresponds to each star of the wave vector  $\{\mathbf{k}_s\}$ . In the sites  $\mathbf{r}$  located in the crystallographically equivalent positions, the distribution function takes the same value because it is invariant with respect to rotation and reflection involved in the point symmetry group of an ordered crystal. The number of values assumed by the distribution function at the sites of an ordered lattice is one unit larger than the number of long-range order parameters.

Summation in Eqn (21) is carried out over all non-equivalent superstructure vectors of the first Brillouin zone of the disordered lattice, *i.e.*, over all superstructure vectors involved in the disorder–order phase transition channel.<sup>3,4,117</sup>

Analysis of the symmetry of the  $M_6C_5$ -type ( $M_6C_5 \square$ -type) superstructures formed in nonstoichiometric transition metal carbides was carried out in the studies.<sup>117,118</sup>

The unit cell of the monoclinic (space group  $C2/m$ ) superstructure of  $M_6C_5$  is shown in Fig. 9. The translation vectors of this unit cell and the coordinates of atoms and vacancies are given in Table 9.

The translation of all superstructure sites of the reciprocal lattice of the monoclinic ordered phase  $M_6C_5$  shows that the first

<sup>a</sup> Parameters of the monoclinic unit cell:

$$\mathbf{a}_m = \frac{1}{2} \langle 1\bar{1}2 \rangle_{B1}, \mathbf{b}_m = \frac{3}{2} \langle 110 \rangle_{B1}, \mathbf{c}_m = \frac{1}{2} \langle 1\bar{1}2 \rangle_{B1}.$$

**Figure 9.** Position of the monoclinic (space group  $C2/m$ ) unit cell of the superstructure  $M_6C_5$  in the lattice with the  $B1$  structure.

Brillouin zone of the disordered face-centred cubic (FCC) lattice contains five non-equivalent superstructure vectors belonging to three stars  $\{\mathbf{k}_9\}$ ,  $\{\mathbf{k}_4\}$  and  $\{\mathbf{k}_3\}$ .<sup>‡</sup> These five vectors are involved in the phase transition channel associated with the formation of the ordered phase  $\text{M}_6\text{C}_5$  (space group  $C2/m$ ).

Calculations demonstrated<sup>3, 4, 53, 117</sup> that the distribution function describing the superstructure of  $\text{M}_6\text{C}_5$  takes the form

$$n(x_1, y_1, z_1) = y - \frac{\eta_9}{6} \cos[\pi(x_1 - y_1 + z_1)] - \frac{\eta_4}{3} \cos \frac{4\pi(x_1 + y_1)}{3} - \frac{\eta_3}{3} \cos \frac{\pi(x_1 - 5y_1 - 3z_1)}{3}, \quad (25)$$

where  $x_1, y_1, z_1$  are the coordinates of the nodes of the ordered non-metal FCC sublattice,  $\mathbf{r} \equiv x_1, y_1, z_1$ .

The distribution function (25) at all sites of the basic non-metal FCC sublattice takes four values (see Table 9). This indicates that, in the case of the above ordering, the non-metal sublattice of disordered nonstoichiometric carbide  $\text{MC}_y$  is divided into four non-equivalent sublattices. The probability of occupancy of the sites of the first sublattice by interstitial atoms is  $n_1$ , the probability of occupancy of the sites of the second sublattice is  $n_2$ , etc. The resulting distribution function is a superposition of three concentration waves related to three long-range order parameters,  $\eta_9, \eta_4$  and  $\eta_3$ , respectively.

**Figure 10.** Position of the trigonal (space group  $P3_1$ ) unit cell of the superstructure  $\text{M}_6\text{C}_5$  in the lattice with the  $B1$  structure.

The trigonal (space group  $P3_1$ ) unit cell of the superstructure of  $\text{M}_6\text{C}_5$  is shown in Fig. 10. The translation vectors of this unit cell and the coordinates of atoms and vacancies in the ideal trigonal superstructure of  $\text{M}_6\text{C}_5$  are given in Table 10. The disorder – order phase transition channel giving rise to the trigonal superstructure of  $\text{M}_6\text{C}_5$  includes 13 arms belonging to three stars  $\{\mathbf{k}_9\}$ ,  $\{\mathbf{k}_4\}$  and  $\{\mathbf{k}_3\}$ . Hence, the distribution function, as in the above-considered case, depends on three long-range order parameters

<sup>‡</sup> Hereinafter, the numbering of the wave vector stars  $\{\mathbf{k}_s\}$  of the first Brillouin zone of the FCC crystal and the arms of the stars are given in accordance with the monographs<sup>3, 4</sup> where all  $\{\mathbf{k}_s\}$  stars were described in detail.

**Table 10.** Trigonal [space group  $P3_1 (C_3^2)$ ] superstructure of  $\text{M}_6\text{C}_5$  ( $\text{V}_6\text{C}_5$ ).

| M 2       | 3(a)                      | 4/9                                                        | 2/9               | 1/12              |                                            |
| M 3       | 3(a)                      | 7/9                                                        | 8/9               | 1/12              |                                            |
| M 4       | 3(a)                      | 1/9                                                        | 2/9               | 1/4               |                                            |
| M 5       | 3(a)                      | 4/9                                                        | 8/9               | 1/4               |                                            |
| M 6       | 3(a)                      | 7/9                                                        | 5/9               | 1/4               |                                            |

<sup>a</sup> Parameters of the trigonal unit cell:

$$\mathbf{a}_{\text{tr}} = \frac{1}{2} \langle 21\bar{1} \rangle_{B1}, \mathbf{b}_{\text{tr}} = \frac{1}{2} \langle \bar{1}12 \rangle_{B1}, \mathbf{c}_{\text{tr}} = 2 \langle 1\bar{1}1 \rangle_{B1}.$$

$$n(x_1, y_1, z_1) = y - \frac{\eta_9}{6} \cos[\pi(x_1 - y_1 + z_1)] - \frac{\eta_4}{6} \left[ \cos \frac{4\pi(x_1 + y_1)}{3} - \frac{\sqrt{3}}{3} \sin \frac{4\pi(x_1 + y_1)}{3} - \frac{2\sqrt{3}}{3} \sin \frac{4\pi(x_1 - z_1)}{3} + \cos \frac{4\pi(y_1 + z_1)}{3} + \frac{\sqrt{3}}{3} \sin \frac{4\pi(y_1 + z_1)}{3} \right] - \frac{\eta_3}{6} \left[ \cos \frac{\pi(x_1 - 5y_1 - 3z_1)}{3} - \frac{\sqrt{3}}{3} \sin \frac{\pi(x_1 - 5y_1 - 3z_1)}{3} + \frac{2\sqrt{3}}{3} \sin \frac{\pi(5x_1 + 5y_1 + z_1)}{3} + \cos \frac{\pi(3x_1 + y_1 - 5z_1)}{3} + \frac{\sqrt{3}}{3} \sin \frac{\pi(3x_1 + y_1 - 5z_1)}{3} \right]. \quad (26)$$

This distribution function describing the trigonal superstructure of  $\text{M}_6\text{C}_5$  takes the same four values,  $n_1, n_2, n_3$  and  $n_4$ , as the distribution function (25), which describes the monoclinic (space group  $C2/m$ ) superstructure of  $\text{M}_6\text{C}_5$ . However, the mutual arrangement of the sites of four sublattices in the trigonal ordered structure differs from that observed in the monoclinic superstructure. The values of the distribution function (26) are given in Table 10.

The unit cell of the monoclinic (space group  $C2$ ) superstructure of  $\text{M}_6\text{C}_5$  is shown in Fig. 11. The translation vectors of this unit cell and the coordinates of atoms and vacancies in the ideal monoclinic  $\text{M}_6\text{C}_5$ -type superstructure are given in Table 11. The monoclinic ordered phase of  $\text{M}_6\text{C}_5$  is formed through the transition channel involving nine superstructure vectors of the reciprocal lattice belonging to four stars  $\{\mathbf{k}_9\}$ ,  $\{\mathbf{k}_4\}$ ,  $\{\mathbf{k}_3\}$  and  $\{\mathbf{k}_0\}$ . Calculations demonstrated<sup>3, 4, 53, 117</sup> that this monoclinic superstructure of  $\text{M}_6\text{C}_5$  is described by the distribution function, which depends on four long-range order parameters

$$n(x_1, y_1, z_1) = y - \frac{\eta_9}{6} \cos[\pi(x_1 - y_1 + z_1)] - \frac{\eta_4}{12} \left[ \cos \frac{4\pi(x_1 + y_1)}{3} - \sqrt{3} \sin \frac{4\pi(x_1 + y_1)}{3} \right] - \frac{\eta_3}{12} \left[ \cos \frac{\pi(x_1 - 5y_1 - z_1)}{3} - \sqrt{3} \sin \frac{\pi(x_1 - 5y_1 - z_1)}{3} \right] - \quad (27)$$

**Figure 11.** Position of the monoclinic (space group  $C2$ ) unit cell of the superstructure  $M_6C_5$  in the lattice with the  $B1$  structure.

$$-\frac{\eta_0}{12} \left[ 3 \cos \frac{\pi(x_1 + 7y_1 + 9z_1)}{6} - \sqrt{3} \sin \frac{\pi(x_1 + 7y_1 + 9z_1)}{6} + 3 \cos \frac{\pi(7x_1 + y_1 - 9z_1)}{6} - \sqrt{3} \sin \frac{\pi(7x_1 + y_1 - 9z_1)}{6} \right].$$

At all sites of the basic non-metal FCC sublattice, the distribution function (27) takes five values (see Table 11). Hence, as a result of the above-described ordering, the non-metal sublattice of disordered nonstoichiometric carbide is divided

**Table 11.** Monoclinic [space group  $C2$  ( $C_2^3$ )] superstructure of  $M_6C_5$  ( $V_6C_5$ ).

| Atom | Position and multiplicity | Atomic coordinates in ideal ordered structure <sup>a</sup> |         |         | Distribution function $n(x_1, y_1, z_1)$                |

<sup>a</sup> Parameters of the monoclinic unit cell:

$$a_m = \frac{1}{2} \langle 1\bar{1}2 \rangle_{B1}, b_m = \frac{3}{2} \langle 110 \rangle_{B1}, c_m = \langle 1\bar{1}2 \rangle_{B1}.$$

into five non-equivalent sublattices, which differ in the probabilities of occupancy of their sites by interstitial atoms.

For all the completely ordered  $M_6C_5$ -type phases under consideration, the relative stoichiometric concentration of carbon atoms is  $y_{st} = 5/6$ . If only non-metal sublattices of these superstructures are considered, the complete atomic planes  $(1\bar{1}1)_{B1}$ , in which all sites are occupied by carbon atoms, alternate with the imperfect  $(1\bar{1}1)_{B1}$  planes, in which one-third of sites are vacant, along the  $[1\bar{1}1]_{B1}$  direction (see Figs 9–11). In the imperfect planes, one-third of all sites are vacant, and each vacancy is surrounded by interstitial atoms, which form a regular hexagon.

In the completely ordered monoclinic (space group  $C2/m$  and  $C2$ ) and trigonal (space group  $P3_1$ )  $M_6C_5$ -type carbide structures, the metal atoms are in the same environment formed by non-metal sublattice sites (see Table 6, which gives the short-range order parameters and the distributions of carbon atoms and vacancies from the first to the eighth coordination spheres in the non-metal sublattice for the ideal superstructures of  $V_6C_5$  crystallising in these space groups). If consideration is restricted to the first and second coordination spheres, these completely ordered structures have only two types of metal atom positions (Fig. 12),  $M_1^1$  or  $V_1^1$  (a metal atom with one vacancy in the first coordination sphere and one vacancy in the second coordination sphere) and  $M_1^2$  ( $V_1^2$ ) (a metal atom with one vacancy in the first coordination sphere and two vacancies in the second coordination sphere). In the ideal completely ordered structures of  $V_6C_5$  (space group  $C2/m$ ,  $P3_1$  and  $C2$ ), two-thirds of all vanadium atoms occupy the  $V_1^1$  positions and one-third of vanadium atoms occupy the  $V_1^2$  positions. Actually, the  $^{51}\text{V}$  NMR spectra of annealed single crystals of vanadium carbide  $\text{VC}_{0.84}$  show lines corresponding to the  $V_1^0$ ,  $V_1^1$  and  $V_1^2$  positions with the intensity ratio of the  $V_1^1$  and  $V_1^2$  lines equal to 2 : 1.<sup>13,84</sup> Taking into account high intensities of these lines,  $V_1^1$  and  $V_1^2$  were considered<sup>13,84</sup> as positions of an ordered structure of  $V_6C_5$  (see Section III.1).

The identity of the short-range order in three superstructures of  $V_6C_5$  does not allow one to distinguish them based on the NMR spectroscopic data. It is also difficult to distinguish these superstructures with the use of diffraction data. That is why the results obtained in different studies of the structures of ordered phases  $V_6C_5$  are so contradictory. In the study,<sup>117</sup> a procedure was developed for calculations of diffraction spectra of superstructures using the data on the disorder–order phase transition channel, and the diffraction spectra of all  $M_{2t}X_{2t-1}$ -type superstructures ( $X = \text{C, N, O}$ ;  $t = 1, 1.5, 2, 3, 4$ ), which can exist in strongly nonstoichiometric compounds, were calculated.

The calculated neutron diffraction spectra of the superstructures of  $V_6C_5$  are presented in Fig. 13. It can be seen that the theoretical diffraction patterns of the ideal monoclinic (space

**Figure 12.** The  $M_1^1$  (a) and  $M_1^2$  (b) sites occupied by metal atoms in ideal completely ordered  $M_6C_5$ -type structures (space group  $C2/m$ ,  $P3_1$  and  $C2$ ).

Two-thirds of all metal atoms occupy the  $M_1^1$  sites and one-third of metal atoms occupy the  $M_1^2$  sites.

**Figure 13.** Theoretical neutron diffraction spectra of the ideal superstructures  $V_6C_5$  (space group  $C2/m$  and  $P3_1$ ) (a) and  $V_6C_5$  (space group  $C2/m$ ) (b) constructed depending on the magnitude of the diffraction vector  $q = (2a_{B1}\sin\theta)/\lambda$ .

The intensities of reflections were calculated for the neutron scattering factors of vanadium and carbon atoms,  $f_V = -0.038 \times 10^{-12}$  and  $f_C = 0.665 \times 10^{-12}$  cm. The number of unit segments along the vertical lines representing the intensities of superstructure reflections is equal to the repetition factor of the corresponding reflection. For comparison, the intensities of the  $(111)_{B1}$  and  $(200)_{B1}$  structure reflections are 2.806 and 1.598 in units of the y axis, i.e., these intensities are 10–20 times higher than the intensities of the strongest superstructure reflections.

group  $C2/m$ ) superstructure of  $V_6C_5$  is identical to the trigonal (space group  $P3_1$ ) superstructure, which is reasonable taking into account that the disorder–order phase transition channel corresponding to each superstructure includes the arms of the same stars  $\{k_9\}$ ,  $\{k_4\}$  and  $\{k_3\}$ , and the parameters determining the length of the arms  $k_4^{(j)}$  and  $k_3^{(l)}$  are equal for both superstructures. If these superstructures are characterised by the equal long-range order parameters  $\eta_s$ , there are no differences in the intensity of the superstructure reflections determined by the same star  $\{k_s\}$ .<sup>4, 117</sup> Therefore, if the corresponding long-range order parameters are equal, the diffraction spectra of these ideal superstructures of  $V_6C_5$  (space group  $C2/m$  and  $P3_1$ ) have superstructure reflections identical in both position and intensity.

However, the intensities of superstructure diffraction reflections in the spectra of real ordered phases of  $V_6C_5$  (space group  $C2/m$  and  $P3_1$ ) will be different because the static atomic displacements differ in direction and magnitude. Analysis of diffraction spectra taking into account possible static atomic displacements allows one to determine whether ordered  $V_6C_5$ -type phases have monoclinic or trigonal symmetry.

The diffraction pattern of the monoclinic (space group  $C2$ ) superstructure of  $V_6C_5$  is more complex than those of the above two superstructures of  $V_6C_5$  (space group  $C2/m$  and  $P3_1$ ) (see Fig. 13), because the diffraction spectrum of this ordered phase has superstructure reflections associated with four stars  $\{k_9\}$ ,  $\{k_4\}$ ,  $\{k_3\}$  and  $\{k_0\}$ . Therefore, it is easier to distinguish the monoclinic (space group  $C2$ ) phase of  $V_6C_5$  in studies of ordered  $V_6C_5$  phases by diffraction methods.

The relation between three superstructures of  $V_6C_5$  is illustrated by Fig. 14.<sup>1, 4, 118</sup> If only the non-metal sublattice is considered, complete planes containing only carbon atoms alternate with partially imperfect planes containing carbon atoms and vacancies along the  $[1\bar{1}1]_{B1}$  direction in these superstructures. In the imperfect planes, vacancies occupy one-third of carbon sites. In the plane, the vacancies form regular hexagons. The mutual arrangement of the imperfect planes giving rise to three different

**Figure 14.** Models of related structures of the ordered carbide phases  $V_6C_5$  ( $M_6C_5$ ).<sup>1, 117</sup>

(a) the monoclinic (space group  $C2/m$ ) structure of  $V_6C_5$ , (b) the trigonal (space group  $P3_1$ ) structure of  $V_6C_5$ , (c) the monoclinic (space group  $C2$ ) structure of  $V_6C_5$ , (d) the position of the  $V_6C_5\square$  quasimolecule in  $B1$ -type lattice.

$M_6C_5$ -type structures is presented in Fig. 14. The successive threefold shift of the atoms with respect to the vacancies located in the equidistant imperfect planes along the  $\{1/2 - 1/2 1\}_{B1}$  direction gives rise to the monoclinic (space group  $C2/m$ ) structure of  $V_6C_5$  (see Fig. 14a). The successive helical shift along the  $\{1/2 - 1/2 1\}_{B1}$ ,  $\{1/2 - 1/2 1/2\}_{B1}$  and  $\{1 - 1/2 1/2\}_{B1}$  vectors gives rise to the trigonal (space group  $P3_1$ ) structure of  $V_6C_5$  (see Fig. 14b). Alternate shifts of the atoms and vacancies located in the imperfect planes along the  $\{1/2 - 1/2 1\}_{B1}$  and  $\{1/2 - 1/2 1/2\}_{B1}$  vectors (see Fig. 14c) give rise to the monoclinic (space group  $C2$ ) superstructure.

All superstructures of  $V_6C_5$  can be represented as a set of  $V_6C_5\square$  quasimolecules (see Fig. 14d) arranged in a certain order. These superstructures differ only in the mutual arrangement of partially imperfect planes. Since such superstructures are identical in character of the short-range order, they have similar energies of formation. This is responsible for mixing of the sequences of the mutual arrangement of partially imperfect planes typical of each structure. As a result, the regular alternation of the planes along the  $c$  axis can be distorted, resulting in weakening of particular superstructure reflections.

The cubic ordered phase  $V_8C_7$  with the space group  $P4_332$  is observed only in the vicinity of the upper boundary of the homogeneity region of carbide  $VC_y$  corresponding to  $VC_{0.875}$ . The translation vectors of the unit cell of this ordered phase (Fig. 15) are twice as large as those of the basic structure  $B1$ ,  $a_1 = \{2 0 0\}_{B1}$ ,  $a_2 = \{0 2 0\}_{B1}$  and  $a_3 = \{0 0 2\}_{B1}$ .

The cubic (space group  $P4_332$ ) superstructure of  $V_8C_7$  is formed through the transition channel including all arms belonging to three stars  $\{k_9\}$ ,  $\{k_8\}$  and  $\{k_4\}$ .<sup>117</sup> The corresponding

Figure 15. Position of the cubic (space group  $P4_332$ ) unit cell of the superstructure  $V_8C_7$  in the lattice with the  $B1$  structure.

distribution function depends on three long-range order parameters

$$n(x_1, y_1, z_1) = y - \frac{\eta_9}{16} [\cos \pi(x_1 + y_1 + z_1) - \cos \pi(x_1 - y_1 + z_1) - \cos \pi(x_1 + y_1 - z_1) - \cos \pi(-x_1 + y_1 + z_1)] - \frac{\eta_8}{8} [-\cos \pi(2x_1 + z_1) + \sin \pi(2x_1 + z_1) - \cos \pi(y_1 + 2z_1) + \sin \pi(y_1 + 2z_1) - \cos \pi(x_1 + 2y_1) + \sin \pi(x_1 + 2y_1)] - \frac{\eta_4}{8} [\cos \pi(x_1 + y_1) + \cos \pi(x_1 + z_1) + \cos \pi(y_1 + z_1) + \sin \pi(x_1 - y_1) - \sin \pi(x_1 - z_1) + \sin \pi(y_1 - z_1)]. \quad (28)$$

For this function,  $y_{st} = 7/8$ . In the case of the above-considered ordering, the non-metal sublattice of disordered nonstoichiometric carbide  $VC_y$  is divided into four non-equivalent sublattices. The probability of occupancy of the sites in these sublattices by carbon atoms [values of the distribution function (28)] are given in Table 12. In the ideal ordered cubic (space group  $P4_332$ ) phase  $V_8C_7$ , three-fourths of all metal atoms occupy the  $V_1^0$  positions, and the other atoms occupy the  $V_1^1$  positions.

The structures of ordered phases of carbide  $VC_y$  determined by X-ray diffraction<sup>49, 69</sup> were refined<sup>25, 26</sup> taking into account the

<sup>a</sup> Parameters of the cubic unit cell:  $a_1 = \langle 200 \rangle_{B1}$ ,  $a_2 = \langle 020 \rangle_{B1}$ ,  $a_3 = \langle 002 \rangle_{B1}$ .

data on disorder–order transition channels. In the latter studies, samples of nonstoichiometric carbide  $VC_y$  containing different amounts of carbon ( $y = 0.66, 0.79, 0.83$  and  $0.87$ ) were prepared by hot pressing of a mixture of powders of vanadium metal and carbide  $VC_{0.875}$  at  $\sim 2200$  K and a pressure of 35 MPa under an atmosphere of argon of special purity. Graphite foil was placed between the powder mixture and a graphite press-mould to avoid cracking. The hot-pressing time was 30 min. All samples had a porosity of  $< 3\%$ , were homogeneous and contained only one  $VC_y$  phase with the  $B1$  structure.

To prepare ordered carbides  $VC_y$ , compact samples synthesised as described above were annealed in evacuated sealed quartz tubes. Disordered carbide  $VC_{0.875}$  was prepared by water quenching of a sample, which was pre-annealed at 1450 K and sealed in a quartz tube. Free carbon in the  $VC_y$  samples was absent. The nitrogen content was no higher than 0.09 mass %, and the oxygen content was 0.1 mass %–0.3 mass %.

X-Ray diffraction studies ( $CuK\alpha_{1,2}$  radiation) were carried out in the angle range  $2\theta = 14–120^\circ$  in a step-scan mode with a step of  $0.02^\circ$ . The exposure time per step was 10 s. Metallographic studies were performed in reflected light using polished samples of sintered and annealed carbides. Before study, the surface of metallographic sections was subjected to etching.

X-Ray diffraction patterns of  $VC_{0.79}$ ,  $VC_{0.83}$  and  $VC_{0.87}$  samples prepared by annealing nonstoichiometric vanadium carbide had not only intense reflections but also additional peaks, whose intensities were no higher than 5% of the intensities of structure lines. The appearance of low-intensity additional reflections is indicative of the formation of ordered phases in thermally treated samples. In the X-ray pattern of carbide  $VC_{0.66}$  subjected to thermal treatment, no additional reflections were observed.

Figure 16 shows fragments of X-ray diffraction patterns of annealed samples of carbides  $VC_{0.79}$ ,  $VC_{0.83}$  and  $VC_{0.87}$ .<sup>25, 26</sup> The intense lines observed in all X-ray diffraction patterns in the angle ranges  $2\theta = 37.4^\circ$  and  $43.4^\circ$  are the  $(111)_{B1}$  and  $(200)_{B1}$  structure reflections. The X-ray diffraction patterns of all annealed carbides have diffuse peaks in the  $2\theta$  angle ranges of  $21.2–22.0^\circ$  and  $\sim 30.0–31.0^\circ$ . These peaks are absent in the X-ray diffraction

Figure 16. Fragments of X-ray diffraction patterns of annealed nonstoichiometric vanadium carbides  $VC_{0.87}$  (1),  $VC_{0.83}$  (2) and  $VC_{0.79}$  (3).<sup>25, 26</sup> The positions of superstructure reflections for the ordered  $V_6C_5$  and  $V_8C_7$  phases are indicated by arrows; for all reflections, the Miller indices corresponding to the space group of the ordered phase are given.

patterns of disordered carbides. They are parasitic reflections from radiation with the wavelength  $\lambda/2$  and correspond to the  $(200)_{B1}$  and  $(220)_{B1}$  structure reflections. The appearance of these peaks is associated with large accumulation of the signal during measurements of X-ray diffraction patterns of annealed carbides.

In the X-ray diffraction pattern of annealed carbide  $VC_{0.87}$ , the first superstructure reflection with the following diffraction vector

$$|q| = 2a_{B1} \frac{\sin \theta}{\lambda} \approx 0.710$$

is observed for the angle  $2\theta = 15.14^\circ$  (see Fig. 16). This reflection corresponds to the  $\{1/2 \ 1/2 \ 0\}$  superstructure vector with a length  $|q| \approx 0.707$  belonging to the star  $\{k_4\}$  with the running index  $\mu_4 = 1/4$ . The next reflection with  $|q| \approx 0.871$  is observed at  $2\theta = 18.55^\circ$  and corresponds to the  $\{1/2 \ 1/2 \ 1/2\}$  vector of the star  $\{k_9\}$ . The intensity of the third reflection ( $2\theta = 24.04^\circ$ ) corresponding to the  $\{1 \ 1/2 \ 0\}$  vector of the star  $\{k_8\}$  is the highest of all superstructure peaks. The next three superstructure reflections in the X-ray diffraction pattern of an annealed  $VC_{0.87}$  sample (see Fig. 16) are observed at the angles  $2\theta = 26.34, 39.14$  and  $46.34^\circ$  and correspond to the  $\{1 \ 1/2 \ 1/2\}$  vector of the star  $\{k_4\}$ , the  $\{3/2 \ 1 \ 0\}$  vector of the star  $\{k_8\}$  and the  $\{3/2 \ 3/2 \ 0\}$  vector of the star  $\{k_4\}$ . The X-ray diffraction spectrum of annealed carbide  $VC_{0.87}$  has 19 superstructure reflections corresponding to three stars  $\{k_9\}$ ,  $\{k_8\}$  and  $\{k_4\}$  in the  $2\theta$  angle range from  $14^\circ$  to  $110^\circ$ .

Analysis of the positions and intensities of the observed superstructure reflections demonstrated that thermal treatment of carbide  $VC_{0.87}$  afforded the cubic ordered phase  $V_8C_7$  (space group  $P4_332$ ). The disorder–order phase transition channel  $VC_{0.87} \rightarrow V_8C_7$  includes all arms of the Lifshitz stars  $\{k_9\}$  and  $\{k_8\}$  and the non-Lifshitz star  $\{k_4\}$  (at  $\mu_4 = 1/4$ ). The Landau group-theoretical criterion for the occurrence of the second-order phase transition is not fulfilled, because the transition channel involves arms of the non-Lifshitz star  $\{k_4\}$ , the sum  $(k_4^{(1)} + k_4^{(5)} + k_4^{(9)})$  being equal to the  $(111)$  structure vector of the reciprocal lattice. Even from symmetry considerations, it is evident that the formation of the ordered  $V_8C_7$  phase can occur only as the first-order phase transition. This is consistent with the conclusions drawn in the studies.<sup>4,117</sup>

Metallographic analysis of annealed carbide  $VC_{0.87}$  confirmed the presence of an ordered phase belonging to the cubic system. As a result of ordering, each grain of the basic disordered phase is divided into domains of an ordered phase of isometric shape (Fig. 17). In reflected polarised white light, the ordered domains give no interference, which indicates that the ordered  $V_8C_7$  phase is isotropic. Microstructural studies demonstrated also that the disorder–order phase transition in carbide  $VC_{0.87}$  starts at the grain boundaries of the disordered phase. In disordered carbide, grains of the basic phase have distinct straight boundaries (see Fig. 17a). After annealing, these boundaries become broken due to ordering (see Fig. 17b). The domains intergrow with grains of the basic phase from the boundaries to the centres of the grains and penetrate into crystallites with time. Due to small domain sizes and the same cubic symmetry of the disordered and ordered phases, the domain boundaries cannot be observed by optical microscopy.

Analysis of the X-ray diffraction pattern of annealed carbide  $VC_{0.83}$  (see Fig. 16) demonstrated that the sample contained two ordered phases. The X-ray pattern has superstructure reflections of the ordered phase  $V_8C_7$  along with lines of the phase  $V_6C_5$  with trigonal (space group  $P3_1$ ) or monoclinic (space group  $C2/m$ ) symmetry. In the X-ray pattern of annealed carbide  $VC_{0.83}$ , the ordered  $V_6C_5$  phase is characterised by the  $\{1/2 \ 1/2 \ 1/2\}$  superstructure reflection ( $2\theta = 18.54^\circ$ ), which belongs to the star  $\{k_9\}$  and whose position is identical to that of the analogous reflection for the cubic ordered phase  $V_8C_7$ , and the  $\{2/3 \ 2/3 \ 0\}$  ( $2\theta = 20.11^\circ$ ),  $\{1/6 \ -5/6 \ -1/2\}$  ( $2\theta = 21.14^\circ$ ),  $\{-1/3 \ -1/3 \ 1\}$  ( $2\theta = 23.74^\circ$ ) and  $\{7/6 \ 1/6 \ 1/2\}$  ( $2\theta = 27.34^\circ$ ) reflections belonging to the stars  $\{k_4\}$  (with  $\mu_4 = 1/3$ ) and  $\{k_3\}$  (with  $\mu_3 = 1/6$ ).

**Figure 17.** Changes in the microstructure of compact nonstoichiometric vanadium carbide  $VC_{0.87}$  upon ordering;

(a) in disordered carbide  $VC_{0.87}$ , grains have distinct linear boundaries, (b) in ordered carbide  $V_8C_7$  ( $VC_{0.87}$ ), the grain boundaries of the basic phase are corroded due to formation of domains of the ordered phase  $V_8C_7$ .

Therefore, the disorder–order phase transition channel associated with the formation of the superstructure of  $V_6C_5$  involves the arms of the Lifshitz star  $\{k_9\}$  and the non-Lifshitz stars  $\{k_4\}$  and  $\{k_3\}$ . From symmetry considerations, the formation of the ordered phase  $V_6C_5$  should occur as the first-order phase transition.

A set of the observed superstructure wave vectors giving rise to the transition channel  $VC_{0.83} \rightarrow V_6C_5$  can correspond to either trigonal (space group  $P3_1$ ) or monoclinic (space group  $C2/m$ ) superstructures of the  $V_6C_5$  type.

Investigation of the microstructure of annealed carbide  $VC_{0.83}$  in reflected polarised white light demonstrated that the sample contained domains of two ordered phases. One phase is composed predominantly of isometric grains and gives no interference, i.e., it is isotropic. Hence, this phase is apparently the cubic ordered phase  $V_8C_7$  and comprises 15%–20% of the sample. The second phase comprises 80%–85% of the sample. Domains of the second phase are of platelet-like and prismatic shape characteristic of crystals belonging to the monoclinic and trigonal systems and show an interference colour, i.e., they are anisotropic. In reflected polarised white light, the domains of the second phase are blue and yellow in colour. These facts suggest that the second phase is carbide  $V_6C_5$ . Therefore, the results of microstructural studies are consistent with the conclusions drawn from X-ray diffraction data.

The X-ray diffraction pattern of annealed carbide  $VC_{0.79}$  has superstructure reflections of only the ordered  $V_6C_5$ -type structure (see Fig. 16). Its microstructure contains domains of only an anisotropic ordered phase. Consequently, prolonged annealing of vanadium carbide  $VC_{0.79}$  afforded the only ordered  $V_6C_5$  phase.

The X-ray diffraction pattern of annealed carbide  $VC_{0.66}$  have reflections of only the basic cubic phase with the  $B1$  structure and

shows no additional reflections, although reflections of the rhombohedral (trigonal) phase  $\zeta\text{-V}_4\text{C}_{3-x}$  would be expected to appear. Carbides  $\zeta\text{-M}_4\text{C}_{3-x}$  ( $x \leq 0.33$ ) have an imperfect carbon sublattice and are formally (without consideration for the crystal structure) identical in composition to  $\text{M}_3\text{C}_2$  ( $\text{MC}_{0.67}$ ). Carbide  $\zeta\text{-V}_4\text{C}_{3-x}$  is not an ordered phase of cubic carbide  $\text{VC}_y$ , because it has the trigonal rather than the FCC metal sublattice.<sup>119</sup> According to the results of the study,<sup>52</sup> the rhombohedral phase  $\zeta\text{-V}_4\text{C}_{3-x}$  contains 37.9 at. % carbon, has a very narrow homogeneity region ( $\text{VC}_{0.605}\text{--VC}_{0.615}$ ), is generated by a peritectoid reaction at 2150 K and is observed up to 1540 K. The absence of the  $\zeta\text{-V}_4\text{C}_{3-x}$  phase in annealed carbide  $\text{VC}_{0.66}$  (see Refs 25 and 69) is, apparently, associated with the fact that annealing was carried out starting from a lower temperature (1200 K). It should be noted that the composition of carbide  $\text{VC}_{0.66}$  corresponds to the lower boundary of the homogeneity region of the  $\zeta\text{-V}_4\text{C}_{3-x}$  phase.

Additional analysis of the X-ray diffraction spectral patterns of ordered carbide  $\text{V}_8\text{C}_7$  (Fig. 18) led authors of the publication<sup>49</sup> to the conclusion that this superstructure is characterised by large static atomic displacements. The vanadium atoms, which form an octahedral environment of the structural non-metal vacancy, are shifted toward the vacancy by 0.003–0.006 nm. The carbon atoms are also shifted toward the vacancies, but these shifts are substantially larger (as large as 0.05 nm). In disordered carbide  $\text{VC}_{0.87}$  with the period  $a_{B1} = 0.4172$  nm, the V–V and V–C interatomic distances are 0.295 and 0.209 nm, respectively, whereas these distances in the vacant  $\square\text{V}_6$  octahedron in ordered carbide  $\text{V}_8\text{C}_7$  are smaller (0.282–0.293 and 0.180–0.209 nm), which is indicative of contraction of the octahedron. In the filled  $\text{CV}_6$  octahedron of ordered carbide  $\text{V}_8\text{C}_7$ , the V–V and V–C distances are 0.295–0.311 and 0.209–0.258 nm, respectively. Such large shifts of the metal atoms can give rise to additional reflections, which are absent in the X-ray diffraction pattern of the ideal (without consideration for atomic displacements) ordered  $\text{V}_8\text{C}_7$ -type cubic (space group  $P4_332$ ) phase.

**Figure 18.** Experimental (dotted line) and calculated (solid line) X-ray diffraction patterns ( $\text{Cu K}\alpha_{1,2}$  radiation) of the ordered phase  $\text{V}_8\text{C}_7$ .<sup>49</sup> The intensity differences between the experimental and calculated X-ray diffraction patterns are shown at the bottom of the figure.

#### IV. Nanocrystalline carbide $\text{V}_8\text{C}_7$ and molecular clusters $\text{V}_m\text{C}_n$

In the last 15–20 years, methods for the preparation of nanostructured substances and materials were extensively developed, and the influence of the particle (grain) size on the properties of nanocrystalline compounds was actively studied.<sup>120–126</sup> For example, vanadium carbide  $\text{VC}_{0.875}$  was prepared in the nano-

crystalline state by atom-vacancy ordering as a result of the disorder–order transformation  $\text{VC}_{0.875} \rightarrow \text{V}_8\text{C}_7$ .<sup>127–131</sup>

##### 1. Nanocrystalline vanadium carbide

A coarse-grained powder (with a particle size of 1–2  $\mu\text{m}$ ) of vanadium carbide  $\text{VC}_{0.875}$  was subjected to long-term ageing at an environmental temperature in a closed vessel (to avoid penetration of water vapour from air). An aged vanadium carbide powder appeared to be very hygroscopic. Immediately after withdrawal from the vessel, the powder contained no more than 0.2 mass % of physically adsorbed water. After storage under environmental conditions for several months, the water content reached 2.0 mass % and then remained unchanged. Generally, coarse-grained vanadium carbide powders do not possess such a high hygroscopicity.

Chemical analysis of an aged vanadium carbide powder demonstrated that it has the composition  $\text{VC}_{0.875}$  corresponding to the upper boundary of the homogeneity region of the cubic phase with the  $B1$  structure.

A vanadium carbide powder was studied by the microscopic method. Discrete irregularly shaped agglomerates with sizes of 5–50  $\mu\text{m}$  are observable under  $\sim 100$  magnification. These agglomerates consist of particles with sizes of  $\sim 1$   $\mu\text{m}$ . Under higher magnification, it is seen that these particles have a complex structure and are composed of a large number of very small, nanometre-size, particles (hereinafter, these particles will be referred to as nanoparticles or nanocrystallites). Figure 19 shows a photomicrograph taken with a high-resolution DSM 982 Gemini scanning electron microscope. Each particle with a size of  $\sim 1$   $\mu\text{m}$  looks like an opened rosebud or a loose head of cabbage and consists of nanocrystallites. Under 50 000 magnification it can be seen that the observed nanocrystallites appear as curved leaves, which, as a first approximation, can be modelled by disks with a diameter of  $\sim 400\text{--}600$  nm and a thickness of  $\sim 15\text{--}20$  nm. The volume of these disks corresponds to that of a rather large spherical particle with a diameter of 150–220 nm. However, due to the small thickness of the disk, the ratio of its surface area to the volume is  $0.107\text{--}0.143\text{ nm}^{-1}$ , which corresponds to the specific surface area of the powder of  $19\text{--}26\text{ m}^2\text{ g}^{-1}$ .

The crystal structure of vanadium carbide was studied by X-ray diffraction using  $\text{Cu K}\alpha_{1,2}$  radiation. The X-ray diffraction patterns of disordered carbide  $\text{VC}_{0.875}$ , annealed coarse-grained ordered carbide  $\text{VC}_{0.875}$  ( $\text{V}_8\text{C}_7$ ) and nanostructured carbide  $\text{VC}_{0.875}$  are shown in Fig. 20. The X-ray pattern of the  $\text{VC}_{0.875}$  nanopowder (see Fig. 20c) has structure reflections of the basic  $B1$  phase along with superstructure reflections corresponding to the cubic ordered phase  $\text{V}_8\text{C}_7$  with the space group  $P4_332$ . The

**Figure 19.** Microstructure of a powder of vanadium carbide  $\text{VC}_{0.875}$  subjected to long-term ageing at environmental temperature and under an environmental atmosphere (10 000 magnification).<sup>127, 131</sup>

**Figure 20.** Powder X-ray diffraction patterns of disordered carbide  $\text{VC}_{0.875}$  ( $a_{B1} = 0.41638$  nm) (a), ordered coarse-grained carbide  $\text{VC}_{0.875}$  ( $\text{V}_8\text{C}_7$ ) ( $a_{B1} = 0.41682$  nm) (b) and nanostructured carbide  $\text{VC}_{0.875}$  ( $a_{B1} = 0.41685$  nm) (c) (Cu  $K\alpha_{1,2}$  radiation).<sup>127, 130, 131</sup> Superstructure reflections observed in the X-ray diffraction patterns of b and c correspond to the cubic (space group  $P4_332$ ) ordered phase  $\text{V}_8\text{C}_7$ . High intensities of superstructure reflections for a  $\text{VC}_{0.875}$  nanopowder and an anomalous increase in their intensity in the region  $2\theta > 100^\circ$  can be a consequence of large static displacements of vanadium atoms.

lattice parameter of the ordered phase is  $0.8337 \pm 0.0001$  nm. The ideal cubic  $\text{M}_8\text{C}_7$ -type superstructure with the space group  $P4_332$  (see Fig. 15) has the doubled (compared to the disordered basic B1 phase) lattice parameter.<sup>17, 117</sup> Hence, the lattice parameter of the basic phase of the vanadium carbide under consideration is  $a_{B1} = 0.41685$  nm. This parameter is substantially (by  $0.00047$  nm) larger than the lattice parameter of disordered carbide  $\text{VC}_{0.875}$ . The authors speculated<sup>17, 25, 26, 55</sup> that this large difference in the lattice parameter of ordered and disordered carbides  $\text{VC}_{0.875}$  can be observed only in the case of the highest or near-highest degree of ordering.

The intensity ratio of the structure and superstructure reflections supports the conclusion that the degree of long-range order in vanadium carbide is close to the maximum value. Besides, this ratio indicates that the ordered phase occupies the whole volume of the substance, i.e., the latter is a single-phase powder.

The intensities of superstructure reflections of coarse-grained ordered carbide  $\text{VC}_{0.875}$  ( $I_{\text{super}}$ ) decrease with increasing diffraction angle  $2\theta$  (see Fig. 20b), whereas the intensities of superstructure reflections of a vanadium carbide nanopowder at  $2\theta > 100^\circ$  even increase (see Fig. 20c). This is probably attributable to large relaxation static displacements of vanadium atoms in the vicinity of carbon vacancies. These displacements were actually observed in ordered carbide  $\text{V}_8\text{C}_7$ .<sup>49</sup>

Defects in a nanostructured vanadium carbide powder were studied<sup>127, 130</sup> by positron lifetime measurements using a powder of carbide  $\text{VC}_{0.875}$ , which was precalcinated at  $400$  K to remove adsorbed water. For comparison, the positron lifetime in coarse-grained sintered vanadium carbide with the same composition

$\text{VC}_{0.875}$  was measured. The spectrum of coarse-grained vanadium carbide has only a short-lifetime component at  $157 \pm 2$  ps, which corresponds to positron annihilation at a structural vacancy of the carbon sublattice.<sup>132–134</sup> Quantitative analysis of the spectrum of the nanostructured powder demonstrated that this spectrum has a short-lifetime component along with a long-lifetime component at  $500$  ps with a relative intensity of  $7\%$  associated with positron annihilation at defects on the particle surface. The thickness of the surface layer in a vanadium carbide nanopowder was estimated<sup>127–131</sup> at  $0.5–0.7$  nm by comparing the relative intensities of the short- and long-lifetime components. Therefore, the results of positron lifetime measurements demonstrated that only non-metal structural vacancies are present in the interior of vanadium carbide nanocrystallites, whereas their surface layer contains vacancy agglomerates as defects.

The microhardness of a nanostructured powder of  $\text{VC}_{0.875}$ , which was cold pressed at  $10$  MPa and then sintered under vacuum ( $1 \times 10^{-3}$  Pa) with a rise in temperature from  $400$  to  $2000$  K, was measured under a load of  $200$  and  $500$  g. The microhardness was  $H_V = 60–80$  GPa, which is  $\sim 3$  times larger than that of macrocrystalline vanadium carbide ( $29$  GPa under a load of  $0.1$  and  $0.2$  kg) and approaches to the microhardness of diamond. The substantially higher microhardness of carbide  $\text{VC}_{0.875}$ , which was prepared by sintering a nanopowder, can be explained taking into account the Hall–Petch law, according to which  $H_V$  is proportional to  $d^{-1/2}$  ( $d$  is the grain size).

Based on the results of investigations of the structure and properties of vanadium carbide powders, the following model of the nanocrystallite structure was proposed.<sup>127, 129–131</sup> Nanocrystallites have a shape of strongly curved disks with a diameter of  $400–600$  nm and a thickness of  $15–20$  nm. Their interior consists of ordered carbide  $\text{V}_8\text{C}_7$  with a high degree of long-range order and contains a negligible amount of dissolved oxygen. The surface layer of nanocrystallites contains chemisorbed oxygen in an amount of  $3.1$  mass % and a substantial amount of vacancy agglomerates, which is indicative of its loose structure. The thickness of the surface phase is no larger than  $0.7$  nm or four atomic monolayers.

The observed morphology of the nanocrystalline vanadium carbide powder may be a consequence of grain cracking at the interface between disordered and ordered phases. Actually, a jump increase in the FCC-sublattice parameter by  $0.0004$  nm (as a result of the disorder–order phase transition  $\text{VC}_{0.875} \rightarrow \text{V}_8\text{C}_7$ ; the domain size of the ordered phase is  $\sim 20$  nm) was observed at  $1413 \pm 20$  K by high-temperature X-ray diffraction.<sup>48</sup> At  $300$  K, the parameter  $a_{B1}$  of the basic crystal lattice of quenched disordered carbide  $\text{VC}_{0.875}$  differs from that of ordered carbide with the same carbon content, but this difference (published data) is  $0.0002$  nm. The difference in the volumes of the disordered and ordered phases is responsible for strains followed by cracking.

Strains can occur also due to the mismatch between the atomic structures of antiphase domains in ordered vanadium carbide. In any case, the formation of a nanostructure of a powder of nonstoichiometric vanadium carbide  $\text{VC}_{0.875}$  is caused by the disorder–order phase transition  $\text{VC}_{0.875} \rightarrow \text{V}_8\text{C}_7$ .

## 2. Metallocarbohedrene $\text{V}_8\text{C}_{12}$

In 1992, the  $\text{V}_8\text{C}_{12}$  molecular cluster was detected in the V–C system by mass-spectrometric study of the products of the plasma-chemical gas-phase synthesis from hydrocarbons and vanadium vapour, which was prepared by laser heating of the metal. This cluster along with  $\text{Ti}_8\text{C}_{12}$  and analogous compounds belong to metallocarbohedrenes (metallocarbons, metcars)  $\text{M}_8\text{C}_{12}$ .<sup>35, 36</sup> In the synthesis, helium was used as an inert gas.

The molecular cluster of stoichiometric composition  $\text{V}_8\text{C}_{12}$  presumably has a pentagondodecahedral shape (Fig. 21a). In the ideal molecule, all atoms are located on the sphere, and its surface is formed by linking the adjacent atoms and consists of  $12$  regular pentagons. In this molecule, all vanadium and carbon atoms have

**Figure 21.** Dodecahedral structure of the molecular cluster  $V_8C_{12}$  ( $M_8C_{12}$ ) with symmetry  $T_h$  (a) and  $T_d$  (b).

identical (as in fullerene  $C_{60}$ ) coordination (the coordination number is three), occupy identical positions and are distributed between the vertices of the dodecahedron so that the vanadium atoms are bound only to the carbon atoms and six  $C_2$  fragments alternate with eight vanadium atoms. The dodecahedral structure of  $V_8C_{12}$  can be represented as a cube formed by vanadium atoms, the  $C_2$  fragment being bound to each face of the cube. The point symmetry group  $T_h$  of this ideal structure includes 24 symmetry elements (rotations and reflections).

The electronic structure of  $V_8C_{12}$  with symmetry  $T_h$  was calculated<sup>135</sup> with the use of the following bond lengths:

| Bond      | C–C   | V–C   | V–V   |
|-----------|-------|-------|-------|
| Length/nm | 0.144 | 0.189 | 0.285 |

The electronic energy spectrum of  $V_8C_{12}$  was demonstrated to be similar to the spectrum of  $Ti_8C_{12}$ , but it is slightly shifted to negative energies due to a larger electronegativity of vanadium compared to titanium. The populations of the atomic orbitals corresponding to M–C interactions involving vanadium are  $\sim 9\%$  lower than those involving titanium because the atomic orbitals of vanadium are more localised. The  $V_8C_{12}$  molecular cluster is chemically less stable than  $Ti_8C_{12}$ .

In another structure of the  $V_8C_{12}$  cluster with the point symmetry group  $T_d$  (see Fig. 21 b), the vanadium atoms occupy two types of positions, and the sites belonging to positions of each type form a tetrahedron. The smaller tetrahedron is rotated with respect to the larger tetrahedron by  $90^\circ$ . The vanadium atoms differ in the arrangement relative to the  $C_2$  dimers. Six  $C_2$  fragments are parallel to the edges of the larger tetrahedron formed by the V(1) atoms and perpendicular to the edge of the smaller tetrahedron formed by the V(2) atoms. The V(1) atoms are bound to three nearest carbon atoms, and the V(2) atoms are bound to six carbon atoms.

The question as to which of these two structures (with symmetry  $T_h$  or  $T_d$ ) actually exists remains open, because molecular crystals of metallocarbons are unavailable.

Initially, the plasma-chemical gas-phase synthesis of titanium, zirconium, hafnium and vanadium molecular clusters have afforded predominantly the  $M_8C_{12}$  and  $M_mC_n$  cluster particles with a ratio of C : M  $\approx 1.5$ – $2.0$ .<sup>35, 36, 136</sup> Nanoparticles of carbides TiC, ZrC, HfC and VC with a metal FCC sublattice were absent. At the same time, only monocarbide nanoparticles can be prepared by the conventional plasma-chemical synthesis (without laser heating of the plasma). More recently, particles with cubic ( $M_{14}C_{13}$ ) and dodecahedral ( $M_8C_{12}$ ) structures were simultaneously prepared by the plasma-chemical gas-phase synthesis in the V–C and Ti–C systems.<sup>137</sup> The synthesis with the use of low-power laser heating afforded a larger amount of ‘cubic’  $M_{14}C_{13}$  nanoparticles compared to  $M_8C_{12}$ . An increase in the power of laser radiation and an increase in the hydrocarbon concentration lead to the predominant formation of dodecahedral particles with

the metal-to-carbon ratio varying from 1 : 1.5 to 1 : 2, which was demonstrated in the study of the Nb–C and Zr–C systems.<sup>138, 139</sup> Therefore, a decrease in the carbon concentration in the plasma due to a decrease in the hydrocarbon concentration or a decrease in the power of laser radiation results in a relative carbon deficiency and the predominant formation of monocarbide nanoparticles, whereas an increase in the carbon concentration in the plasma makes it possible to synthesise the  $M_mC_n$  clusters varying from  $M_8C_{12}$  to  $M_{11}C_{21}$  and  $M_{13}C_{22}$ .<sup>138, 139</sup>

Such facts, as the synthesis of the  $V_8C_{12}$  molecular cluster in the V–C system and the formation of cubic  $V_{14}C_{13}$  nanoparticles in the plasma,<sup>137</sup> provide indirect evidence that it is possible to synthesise stoichiometric monocarbide  $VC_{1.0}$  with the B1 structure.

## V. Phase diagram for the V–C system with consideration for ordering of $VC_y$

Ordering of nonstoichiometric cubic vanadium carbide  $VC_y$  has been studied for many years. However, until recently, a reliable phase diagram of the V–C system, which takes into account the formation of ordered phases, has been lacking in the literature. The first attempt to construct a fragment of the phase diagram, where the ordered phases  $V_6C_5$  and  $V_8C_7$  co-exist, has been made in the publication.<sup>43</sup> Later on, an attempt was made<sup>48</sup> to take into account phase equilibria in  $VC_y$  in the narrow composition range  $0.84 \leq y \leq 0.93$  at  $1273 < T < 1473$  K. The main problem associated with the construction of the phase diagram of the V–C system is that  $VC_{0.875}$  rather than the  $MC_{1.0}$  compound of stoichiometric composition serves as the upper boundary of the homogeneity region of disordered cubic vanadium carbide  $VC_y$ , as opposed to other transition metal carbides. The unusual position of the upper boundary of the homogeneity region of carbide  $VC_y$  is responsible for the edge effect, which is manifested in the formation of the ordered phase  $V_8C_7$ , which is absent in other carbides.

As mentioned above, disordered vanadium carbide  $VC_y$  ( $VC_y \square_{1-y}$ ) has a rather extended homogeneity region, within which the carbon atoms and structural vacancies form a substitutional solution in the non-metal sublattice. Depending on the composition and the conditions of the synthesis and thermal treatment, carbide  $VC_y$  can exist in the disordered or ordered state. The disordered state is in thermodynamic equilibrium at temperatures higher than 1300–1400 K, whereas the ordered state is in thermodynamic equilibrium at  $T < 1300$  K. However, due to low diffusion mobility of atoms, the disordered state of nonstoichiometric vanadium carbide is easily retained upon quenching from  $T > 1400$  K to lower temperatures ( $\sim 300$  K) and exists as a metastable state at  $T < 1000$  K.

In the studies,<sup>27, 32</sup> the phase equilibria in the ordering region of nonstoichiometric cubic carbide  $VC_y$  were calculated by the order parameter functional method.<sup>1–4, 16, 53, 140–142</sup>

In the first version of calculations, it was assumed that the ordered phase  $V_8C_7$  has no homogeneity region. Actually, single-phase samples with the cubic superstructure  $V_8C_7$  are formed only in the case of carbide  $VC_{0.87-0.875}$ , whereas at lower carbon concentrations ( $0.83 < y < 0.87$ ), the phase  $V_6C_5$ , which has an extended homogeneity region,<sup>2</sup> is always present in samples containing the ordered phase  $V_8C_7$ .<sup>5, 47, 68, 69, 143</sup> In the studies,<sup>62, 144, 145</sup> the temperature of the  $V_8C_7 \rightleftharpoons VC_y$  transition was demonstrated to be virtually independent (within experimental error) of the composition of carbide  $VC_y$  (Fig. 22). To take into account the specific features of the ordered phase  $V_8C_7$  ( $VC_{0.875}$ ), where no homogeneity region was observed, its free energy was represented as follows

$$F_{V_8C_7(VC_{0.875})}(T) = F(T) - TS_c + \frac{\Delta H_{tr}}{T_{tr}}(T - T_{tr}), \quad (29)$$

where

**Figure 22.** Dependence of the temperature of the phase transitions  $V_6C_5 \rightleftharpoons VC_y$  (empty balls) and  $V_8C_7 \rightleftharpoons VC_y$  (solid balls) on the composition of vanadium carbide  $VC_y$ ; (1–5) the results of the studies,<sup>25, 62, 48, 144, 145</sup> respectively.

$$F(T) = F_0(T) + x F_1(T) + x^2 F_2(T)$$

at  $x = 0.875$  [ $F_0(T)$ ,  $F_1(T)$  and  $F_2(T)$  are the parameters of the free energy of disordered carbide  $VC_y$ , see Eqn (8)];  $S_c = 3.132 \cdot 10^{-3} \text{ kJ mol}^{-1} \text{ K}^{-1}$  is the configurational entropy of carbide  $VC_{0.875}$ ;  $\Delta H_{tr} = 3 \text{ kJ mol}^{-1}$  and  $T_{tr} = 1380 \text{ K}$  are the heat and temperature of the  $V_8C_7 \rightarrow VC_{0.875}$  transition estimated from experimental data.<sup>25, 62, 69, 143</sup>

The phase boundary between the homogeneity region of disordered carbide  $VC_y$  and the two-phase region ( $VC_y + V_8C_7$ ) was determined using<sup>27</sup> the equation

$$F_{V_8C_7}(VC_{0.875})(T) = F(y, 0, T) - (y - y_b) \frac{\partial F(y, 0, T)}{\partial y}, \quad (30)$$

where

$$F(y, 0, T) - (y - y_b) \frac{\partial F(y, 0, T)}{\partial y} = F_0(T) + y_b F_1(T) + y(2y_b - y)F_2(T) + kT \left[ \ln(1 - y) + y_b \ln \frac{y}{1 - y} \right], \quad (31)$$

$y_b = 0.875$ .

The position of the phase boundary between the homogeneity region of the ordered phase  $V_{2t}C_{2t-1}$  ( $V_6C_5$ ) and the two-phase region ( $V_{2t}C_{2t-1} + V_8C_7$ ) was specified analogously

$$F_{V_8C_7}(VC_{0.875})(T) = F(y, \eta, T) - (y - y_b) \frac{\partial F(y, \eta, T)}{\partial y}, \quad (32)$$

where

$$F(y, \eta, T) - (y - y_b) \frac{\partial F(y, \eta, T)}{\partial y} = F_0(T) + y_b F_1(T) + y(2y_b - y)F_2(T) + \frac{a^{(s)}}{4t^2} \eta_{eq}^2 F_2(T) + \frac{kT}{2t} \left\{ \ln \left[ n_1^{y_b} (1 - n_1)^{(1-y_b)} \right] + (2t - 1) \ln \left[ n_2^{y_b} (1 - n_2)^{(1-y_b)} \right] \right\}. \quad (33)$$

The parameters  $n_1$ ,  $n_2$ ,  $\eta_{eq}$ ,  $t$  and  $a^{(s)}$  (see below) refer to the phase  $V_{2t}C_{2t-1}$  ( $V_6C_5$ ).

In calculations of the phase equilibria involving lower disordered hexagonal carbide  $\beta\text{-}V_2C$  ( $V_2C_y$ ), its homogeneity region was not taken into account, and the composition of the lower carbide was interpreted as  $V_2C$  ( $VC_{0.50}$ ). Calculations were carried out according to the equation

$$0.5 F_{V_2C}(T) = F_0(T) + 0.5 F_1(T) + y(1 - y)F_2(T) + \quad (34)$$

$$+ \frac{a^{(s)}}{4t^2} \eta_{eq}^2 F_2(T) + \frac{kT}{4t} \left\{ \ln \left[ n_1(1 - n_1) \right] + (2t - 1) \ln \left[ n_2(1 - n_2) \right] \right\}_{\eta = \eta_{eq}},$$

where  $F_{V_2C}(T)$  is the free energy of lower hexagonal vanadium carbide  $\beta\text{-}V_2C$  described by Eqn (9).

Equations (33) and (34) include the parameters  $n_1$ ,  $n_2$ ,  $\eta_{eq}$ ,  $t$  and  $a^{(s)}$ . The numerical coefficients  $t$  and  $a^{(s)}$ , which characterise the possible  $M_{2t}C_{2t-1}$ -type superstructures of cubic carbides  $MC_y$ , are given in Table 13. The parameters  $n_1$  and  $n_2$  are the probabilities of finding a carbon atom in a site of the vacancy and carbon sublattices of the ordered phase  $M_{2t}C_{2t-1}$  (see Refs 3 and 4):

$$n_1 = y - \frac{\eta(2t - 1)}{2t}, \quad (35)$$

$$n_2 = y \frac{\eta}{2t}.$$

**Table 13.** Structural characteristics of possible ordered phases  $M_{2t}C_{2t-1}$  of strongly nonstoichiometric compounds  $MC_y$  with the B1 basic structure (NaCl).<sup>3, 4</sup>

The equilibrium long-range order parameter  $\eta_{eq}$  in the ordered phase  $M_{2t}C_{2t-1}$  at the temperature  $T$  satisfies the equation<sup>3, 4</sup>

$$\frac{1}{\eta_{eq}} \ln \left[ \frac{n_2(1 - n_1)}{n_1(1 - n_2)} \right]_{\eta = \eta_{eq}} = \frac{2a^{(s)}}{2t - 1} \frac{F_2(T)}{kT}. \quad (36)$$

The phase diagram of the V–C system published in the papers<sup>27, 32</sup> is shown in Fig. 23. Calculations demonstrated<sup>27</sup> that ordering of nonstoichiometric cubic carbide  $VC_y$  in different temperature and concentration ranges can give rise to three ordered phases, viz.,  $V_3C_2$ ,  $V_6C_5$  and  $V_8C_7$ .

The phase  $V_6C_5$  is the main ordered vanadium carbide phase. This phase appears at a temperature lower than 1485 K, and its homogeneity region extends from  $VC_{0.745}$  to  $VC_{0.831}$  at 1100 K. This phase can also be observed in two-phase regions, i.e., it exists almost throughout the homogeneity region of carbide  $VC_y$  (see Fig. 23). The ordered phase  $V_8C_7$  is formed at a lower temperature (1380 K). At 1330 K, it can be observed along with  $V_6C_5$  in the two-phase region extended from  $VC_{0.83}$  to  $VC_{0.875}$ , which is consistent with experimental data.<sup>47, 144, 146</sup> The  $V_6C_5 + V_8C_7$  two-phase region, where the ordered phase  $V_8C_7$  exists, becomes narrower with decreasing temperature. The ordered phases  $V_6C_5$  and  $V_8C_7$  form an eutectic with  $T_e = 1331 \text{ K}$  and  $y_e = 0.852$ . These parameters are close to the estimate obtained in the study:<sup>48</sup>  $T_e \approx 1300 \text{ K}$  and  $y_e \approx 0.852$ . The calculations also demonstrated that the ordered phase  $V_3C_2$ , which has a narrow homogeneity region (from  $VC_{0.667}$  to  $VC_{0.710}$  at 800 K), can be generated in

**Figure 23.** Phase diagram of the V–C equilibrium system, which was constructed taking into account the atomic ordering of nonstoichiometric cubic vanadium carbide  $VC_y$ .<sup>27, 32</sup>

The phase boundaries outside the ordering region are those published in the studies;<sup>41, 147</sup> the position of the phase  $\zeta$ - $V_4C_{3-x}$  is given according to the publication;<sup>52</sup>  $V_8C_7$ ,  $V_6C_5$  and  $V_3C_2$  are the ordered phases of cubic carbide  $VC_y$ ,  $\alpha$ - $V_2C$  is the ordered phase of lower hexagonal carbide  $V_2C_y$  ( $\beta$ - $V_2C$ ).

vanadium carbide at 1155 K (lower temperatures) under equilibrium conditions according to the peritectoid reaction

This phase has not been experimentally observed. According to the results of calculations,<sup>27</sup> the region of existence of the ordered phase  $V_3C_2$  is close to the concentration range, in which the rhombohedral (trigonal) phase  $\zeta$ - $V_4C_{3-x}$  is actually observed, but its existence was not taken into account in calculations of ordering of carbide  $VC_y$ , because the thermodynamic characteristics of this

phase are unknown. If the free energy of the  $\zeta$ -phase at  $T < 1150$  K is lower than that of the ordered phase  $V_3C_2$ , the phase  $V_3C_2$  cannot exist. Taking into consideration this fact, the region of existence of the ordered phase  $V_3C_2$  is shown hypothetically.

The position of the phase  $\zeta$ - $V_4C_{3-x}$  is given based on the results of the study.<sup>52</sup> The lowest temperature, at which it was detected after long-term annealing, is 1540 K. This temperature is close to the calculated maximum temperature of the disorder–order  $VC_y$ – $V_6C_5$  transition (1485 K) and is taken as the lower temperature boundary of existence of the phase  $\zeta$ - $V_4C_{3-x}$ .

In the homogeneity region of lower carbide  $V_2C_y$  ( $\beta$ - $V_2C$ ), the ordered orthorhombic phase  $\alpha$ - $V_2C$  ( $\beta$ - $V_2C$ ) is formed.<sup>108–113</sup> The precise temperature of ordering is unknown. According to the results of the studies,<sup>41, 147</sup> this temperature is lower than 1870 K. Magnetic susceptibility measurements of ordered carbide  $\alpha$ - $V_2C$  ( $\beta$ - $V_2C$ ) in the temperature range of 300–1300 K did not reveal the structural phase transition

up to 1300 K.<sup>148</sup> Taking into account this fact and the results of the investigation,<sup>147</sup> the temperature of the order–disorder phase transition in the phase diagram of the V–C system was assumed to be equal to  $\sim 1600$  K (see Fig. 23). The new  $V_8C_{12}$  compound, which was discovered in 1992,<sup>35</sup> was omitted in the phase diagram of the V–C system published in the papers,<sup>27, 32</sup> because it is outside the range of the compositions under consideration.

All disorder–order transitions in vanadium carbide  $VC_y$  belong to first-order phase transitions (see Fig. 23). The same conclusion was drawn in the publications,<sup>25, 69</sup> where the changes in the heat capacities of carbides  $VC_{0.79}$ ,  $VC_{0.83}$  and  $VC_{0.87}$  upon heating and cooling were considered.

The calculated<sup>27</sup> values of  $T_{tr}$ ,  $\Delta S_{tr}$  and  $\Delta H_{tr}$  for phase transitions associated with ordering of nonstoichiometric carbide  $VC_y$  are listed in Table 14, which gives also experimental  $T_{tr}$  and  $\Delta H_{tr}$  for comparison.<sup>25, 69</sup> For carbide  $VC_{0.79}$ , the calculated temperature  $T_{tr}$  and heat  $\Delta H_{tr}$  of the  $V_6C_5 \rightarrow VC_{0.79}$  transition are 1450 K and 2.84 kJ mol<sup>−1</sup>, respectively; the experimental  $\Delta H_{tr}$  value is somewhat lower, because a small amount of the

**Table 14.** Temperatures ( $T_{tr}$ /K), entropies ( $\Delta S_{tr}$ /J mol<sup>−1</sup> K<sup>−1</sup>) and heats ( $\Delta H_{tr}$ /kJ mol<sup>−1</sup>) of order–order and order–disorder phase transitions in nonstoichiometric vanadium carbide  $VC_y$ .

| 0.875 | —                                                       | —               | —               | —                             | —                            | —                                                | —                            | 1380                          | —                            | 2.17                                             | 3.00                         |

<sup>a</sup> In the study,<sup>69</sup> the total thermal effect  $\Delta H_{tr} = 2.11$  kJ mol<sup>−1</sup>, which includes the thermal effects of two transformations,  $VC_{0.83} \rightarrow V_6C_5$  ( $\Delta H_{tr} \approx 1.37$  kJ mol<sup>−1</sup>) and  $VC_{0.83} \rightarrow V_8C_7$  ( $\Delta H_{tr} \approx 0.75$  kJ mol<sup>−1</sup>), is given for the transformation occurring in carbide  $VC_{0.83}$  on cooling.

phase  $\zeta$ - $V_4C_{3-x}$  is present (which was demonstrated by calorimetric measurements<sup>69</sup>) in carbide  $VC_{0.79}$ .

Additional model calculations were carried out<sup>27</sup> to refine the phase diagram of the V–C system in the event that the phase  $V_8C_7$  has a small homogeneity region. In these calculations, the free energy of the ordered phase  $V_8C_7$  is represented as follows:

$$F_{V_8C_7(VC_{0.875})}(T) = F(T) - TS_c + \frac{\Delta H_{tr}(y)}{T_{tr}(y)} [T - T_{tr}^{\max}(a + by + cy^2)], \quad (37)$$

where  $F(T)$  and  $S_c$  are the same parameters as those in Eqn (29);

$$\frac{\Delta H_{tr}(y)}{T_{tr}(y)} \equiv \Delta S_{tr} = 2.174 \text{ J mol}^{-1} \text{ K}^{-1};$$

$T_{tr}^{\max} = 1380 \text{ K}$  is the maximum temperature of the  $V_8C_7 \rightarrow VC_y$  transition corresponding to  $VC_{0.875}$ ;  $a = 40.7455$ ,  $b = -93.367$  and  $c = 54.793$ .

If the phase  $V_8C_7$  has a homogeneity region, the boundaries of the  $VC_y + V_8C_7$  two-phase region were calculated according to the following equations:<sup>27</sup>

$$\begin{aligned} y_1^2 F_2(T) - kT \ln(1 - y_1) &= \\ &= y_2^2 F_2(T) - kT \ln(1 - y_2) - \Delta S_{tr} [T - (a - cy_2^2) T_{tr}^{\max}], \\ y_1(2 - y_1) F_2(T) + kT \ln y_1 &= \\ &= y_2(2 - y_2) F_2(T) + kT \ln y_2 + \\ &+ \Delta S_{tr} [T - (a + b + 2cy_2 - cy_2^2) T_{tr}^{\max}]. \end{aligned} \quad (38)$$

In the event that the phase  $V_8C_7$  has a homogeneity region, the phase boundaries of the  $V_6C_5 + V_8C_7$  two-phase region were determined analogously

$$\begin{aligned} y_1^2 F_2(T) - \frac{a^{(s)}}{4t^2} \eta_{eq}^2 F_2(T) - \\ - \frac{kT}{2t} [\ln(1 - n_1^{(d)}) + (2t - 1) \ln(1 - n_2^{(d)})]_{\eta=\eta_{eq}} &= \\ &= y_2^2 F_2(T) - kT \ln(1 - y_2) - \Delta S_{tr} [T - (a - cy_2^2) T_{tr}^{\max}], \\ y_1(2 - y_1) F_2(T) - \frac{a^{(s)}}{4t^2} \eta_{eq}^2 F_2(T) + \\ - \frac{kT}{2t} [\ln n_1^{(d)} + (2t - 1) \ln n_2^{(d)}]_{\eta=\eta_{eq}} &= \\ &= y_2(2 - y_2) F_2(T) - kT \ln y_2 + \\ &+ \Delta S_{tr} [T - (a + b + 2cy_2 - cy_2^2) T_{tr}^{\max}]. \end{aligned} \quad (39)$$

In Eqns (39), the parameters  $n_1$ ,  $n_2$ ,  $t$ ,  $\eta_{eq}$  and  $a^{(s)}$  refer to the ordered phase  $V_6C_5$ .

The fragment of the phase diagram of the V–C system calculated without considering the homogeneity region of the phase  $V_8C_7$  is shown in Fig. 24, and the corresponding fragment, which was calculated taking into account this region, is presented in Fig. 25. Calculations<sup>27</sup> demonstrated that the homogeneity region of the phase  $V_8C_7$  is very narrow (the maximum size is observed at 1340 K and corresponds to the composition range from  $VC_{0.852}$  to  $VC_{0.875}$ ). A decrease in the temperature from 1340 K leads to a further narrowing of the homogeneity region of the phase  $V_8C_7$ . At 1340 K, the phases  $V_6C_5$  and  $V_8C_7$  form an eutectic with  $y_e \approx 0.8476$ . The  $V_6C_5 + V_8C_7$  two-phase region existing at  $T < 1340 \text{ K}$  is almost half as wide as that observed in the first case. Otherwise the phase diagram of the V–C system remains unchanged. It is necessary to perform thorough exper-

**Figure 24.** Fragment of the ordering region near the upper boundary of the homogeneity region of carbide  $VC_y$  (see Fig. 23). Calculated on the assumption of the absence of the homogeneity region of the phase  $V_8C_7$ .

**Figure 25.** Fragment of the ordering region of carbide  $VC_y$  (see Fig. 23). Calculated on the assumption of the presence of a narrow homogeneity region of the phase  $V_8C_7$ .

imental investigations of the structure of vanadium carbide in the narrow composition range,  $VC_{0.85} - VC_{0.875}$ , to give an unambiguous answer to the question as to whether the phase  $V_8C_7$  has a homogeneity region.

On the whole, the calculations<sup>25–27, 32</sup> well reproduced the formation of the monoclinic (or trigonal) phase  $V_6C_5$  with the  $VC_{0.75} - VC_{0.83}$  homogeneity region (or 1100 K), the cubic phase  $V_8C_7$ , which can co-exist with  $V_6C_5$  in the two-phase region, and the ordered phase  $V_3C_2$ , which appears at  $T < 1150 \text{ K}$  and exhibits a very narrow homogeneity region, upon ordering of  $VC_y$ . The temperatures of the  $V_6C_5 \rightleftharpoons VC_y$  and  $V_8C_7 \rightleftharpoons VC_{0.875}$  transitions are 1400–1450 and 1360–1380 K, respectively.

## VI. Conclusion

Analysis of the results of investigations performed in the last 15 years demonstrated that a large number of compounds and phases are produced in the vanadium–carbon system. Their detection became possible due to the use of unconventional synthetic methods, studies of the phase equilibria in a low-temperature region and the use of highly sensitive diffraction and spectroscopic methods for analysing products of annealing and chemical reactions.

The phase  $V_6C_5$ , which can have monoclinic (space group  $C2/m$  and  $C2$ ) and trigonal (space group  $P3_1$ ) symmetry, and the cubic (space group  $P4_332$ ) phase  $V_8C_7$  are the most well-known ordered phases of vanadium carbide. The phase  $V_6C_5$  exists in the  $VC_{0.75-0.77}-C_{0.82-0.86}$  range. The phase  $V_8C_7$  was observed in vanadium carbide samples, whose compositions are close to the upper boundary of the homogeneity region of  $VC_y$  and was detected even in samples quenched from 1500 K.

Molecular clusters with compositions varying from  $V_{14}C_{13}$ , which, presumably, has a cubic structure, to  $V_8C_{12}$  with a dodecahedral structure and then to  $V_{11}C_{21}$  and  $V_{13}C_{22}$  were produced by the plasma-chemical synthesis using laser heating. Apparently, these compounds can be stabilised in the crystalline state in thin films by deposition of the molecular clusters onto supports.<sup>149</sup> A chemical modification of the support or thermal treatment of the deposited film provides additional possibilities of forming a particular structure of clusters.

X-Ray, neutron and electron diffraction techniques are the main experimental methods for the detection and investigation of new compounds and phases in the V–C system. The presence of model diffraction spectra for the phases under consideration in the V–C system substantially facilitates their identification and interpretation of experimental results.

Noteworthy is the applied aspect of investigations of non-stoichiometric carbides. Carbides of stoichiometric composition are generally used in the production of solid alloys with the aim of providing stability of their properties. However, interactions with matrix metal lead to complex chemical processes resulting in dissolution of matrix metal in carbide, depletion of the carbide phase in carbon and enrichment of matrix metal in metal from the carbide phase and (to a smaller degree) in carbon. Carbide grains in solid alloys have a ring structure with a non-uniform distribution of elements over the grain section. It is evident, even from this fact, that carbide phases in solid alloys are generally nonstoichiometric, and ordering and disordering processes can occur in these phases. Evidently, to provide stability of the properties of solid alloys during usage, i.e., at temperatures from 600 to 900 °C, it is necessary that the solid nonstoichiometric carbide phase be in a thermodynamically stable structural state and do not undergo transformations under these conditions. That is why ordering of nonstoichiometric carbides is of applied interest.

Investigations of high-alloy vanadium-containing steels performed in the last decades demonstrated that the resulting vanadium carbide phases are ordered  $V_6C_5$  phases and, more rarely,  $V_8C_7$  phases. An understanding of the conditions of formation and isolation of these phases requires a knowledge of the disorder–order transformations in nonstoichiometric carbides.

Finally, recent investigations showed that ordering of non-stoichiometric vanadium carbide can be used to form nanocrystalline structures. Apparently, disorder–order transformations can be used to construct other nanostructured nonstoichiometric compounds and solid solutions.

On the whole, investigations of ordering of vanadium carbides and properties of these compounds in different structural states contribute to fundamental knowledge of nonstoichiometry and provides the basis for their practical use.

I thank Professor A I Gusev, who encouraged me to write this review. This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 03-03-32031).

**Abstract.** Chemical methods for the preparation of oxide ferroelectric thin films from organometallic compounds published over the last 10–15 years are considered systematically and generalised. Layers of these films are promising for the creation of non-volatile memory elements and for use in nano- and microelectronic devices. The bibliography includes 318 references.

## I. Introduction

Progress in microelectronics requires novel materials for information storage and retrieval. Switches based on chalcogenide semiconductors containing transition metal oxides embedded into glassy matrices of phosphorus, barium, germanium and lead oxides are known. Memory elements based on them stand  $10^3$  recirculation cycles. However, these materials did not find further development.<sup>1</sup> Non-volatile memory elements that exist in two states corresponding to storage of either the logical zero or unity have been designed based on transistors with the structure metal–dielectric–floating gate semiconductor. Superlarge integrated circuits (SLIC) with high information capacities have been developed on their base.

In the course of intense investigations into the design of novel devices for information storage and processing it has been demonstrated that the effect of spontaneous polarisation in ferroelectrics (Fig. 1) can be exploited in the manufacture of non-volatile memory elements. In this case, the maximum number of recirculation cycles ( $Y$ ) reaches  $10^{10}$ – $10^{12}$ . A drawback of such materials consists of their fatigue, which is reflected in a decrease in the residual polarisation with an increase in the number of recirculation cycles. This fact impedes wide application of ferroelectrics in SLIC technology. With this regard, the search for novel materials with enhanced ferroelectric properties is urgently needed. In our opinion, the use of ferroelectrics in the form of thin films or layers with parameters approaching those of the bulk materials is highly promising. The energy consumption, levels of control, electrical and mechanical loads, and optical and acoustic

losses are relatively low for such films. Methods for the preparation of the films should be compatible with modern technology for the production of semiconducting microdevices. This issue has been the focus of several dedicated international symposia.<sup>2–6</sup> The relation between the structure of the films and their physical properties has been considered in monographs<sup>7,8</sup> and reviews.<sup>9–14</sup>

The methods for the preparation of ferroelectric thin films (FETF) can arbitrarily be classified into physical and chemical methods. For instance, thermal evaporation, high-vacuum sputtering induced by electron or ion beams, magnetron sputtering and laser ablation belong to the physical methods. Meanwhile, the sol–gel process, gas-phase deposition of layers from organometallic compounds [Metal-Organic Chemical Vapour Deposition (MOCVD)] or solid precursors (with or without the use of plasma), the hydrothermal method and the Langmuir–Blodgett method are classified as chemical methods. It is of note that the MOCVD method for the preparation of thin films is superior to other techniques for the following reasons:<sup>15</sup>

- it is compatible with the technology of SLIC production;
- it is applicable to the preparation of films in a wide range of thicknesses and areas;
- it yields films with high-quality surface morphologies suitable for further lithographic processing with the required spatial resolution.

**Figure 1.** Polarisation curve of a ferroelectric film.  $\pm P_r$  is the residual polarisation at  $E = 0$ ,  $\pm P_s$  is the spontaneous polarisation,  $\pm E_c$  is the coercive force.

The typical required thickness of ferroelectric thin films lies in the range from nanometers to a few hundred nanometers. Since nearly all ferroelectrics are complex oxides or solid solutions thereof, it is the partial pressure and chemical state of oxygen in the gas phase that play a crucial role in the vacuum deposition of films. The application of MOCVD to the synthesis of films can be stipulated, for instance, by the technology of capacitor manufacturing, where the multistage process of formation of ferroelectric layers and electrical electrodes above them is replaced by a single operation. Other chemical methods have their own advantages.

The authors of the present review aspired to survey the state-of-the-art advances in the field of preparation of FETF by chemical methods from various classes of organometallic precursors. Only selected types of films are concerned. Compounds manifesting piezoelectric properties, the potential of which has not been explored in sufficient detail so far, are left beyond the scope of this paper. These include complex oxides, such as  $(\text{Pb,Ba})_2\text{Nb}_5\text{O}_{15}$ ,  $\text{Bi}_7\text{Ti}_4\text{Nb}_4\text{O}_{21}$ ,  $\text{ACu}_3\text{Ti}_4\text{O}_{12}$  [ $\text{A} = \text{Bi}^{3+}$  or  $\text{Ln}^{3+}$  ( $\text{Y}$ ,  $\text{La}$ ,  $\text{Sm}$ ,  $\text{Dy}$ )],  $\text{MBi}_4\text{Ti}_4\text{O}_{15}$  ( $\text{M} = \text{Pb}$ ,  $\text{Ca}$ ,  $\text{Sr}$ ),  $(\text{Ba,Sr})\text{Nb}_2\text{O}_6$  and  $\text{Sr}_2(\text{Nb,Ta})_2\text{O}_7$ .

## II. Methods for thin film preparation

### 1. A MOCVD technology of film preparation

The technology of FETF preparation by chemical vapour deposition (CVD) has been reviewed in detail.<sup>16</sup> Film deposition from the vapour of organometallic compounds represents a particular case of this process based on the use of volatile organometallic compounds as the starting material. Presently, the major regularities relating the volatility of a compound to its composition and structure are reliably established, which facilitates the selection of a proper compound among the wide assortment of alkoxides,  $\beta$ -diketonates and mixed ligand–metal complexes. A precursor to be used in the synthesis of a complex oxide film by the chemical vapour deposition process should comply with several requirements: first, the metal should be in the form of its oxide that is deposited on a support; second, it is desirable that all the volatile starting compounds belong to the same class. This will exclude transesterification reactions in the gas phase and violations of the stoichiometry of the resultant films.

Considerable reduction of temperatures for film preparation can be achieved by either modifying the entire technological process (which is not always possible) or substituting one class of volatile starting compounds for other classes. Metal alkoxides possess the lowest evaporation temperatures among all suitable starting compounds. Alkoxide ligands efficiently screen the central metal atom, which favours a significant increase in the volatility. Meanwhile, alkoxides of alkaline-earth metals are characterised by a rather low thermal stability, they are prone to polymerisation and are moisture-sensitive. In contrast, metal  $\beta$ -diketonates are evaporated and condensed from the gas phase at temperatures up to 300 °C. This temperature can be substantially lowered (to 100–150 °C) if mixed ligand–metal complexes or their adducts are employed. Among metal  $\beta$ -diketonates, compounds based on dipivaloylmethane (DPM) are used most often, these afford high-purity films. Only in two studies,<sup>17,18</sup> strontium hexafluoroacetylacetonate in combination with tetraglyme was used to yield films with fairly good ferroelectric properties.

The nature of the metal atom is of particular importance in the synthesis of ferroelectrics. As a rule, it is heavy metals, such as barium, lead or bismuth, that are used. As the chemistry of volatile compounds of alkaline-earth metals, zirconium and titanium is being developed, an increasing number of publications appear that describe new compounds with a broad set of interesting properties. The prevailing part of these studies is devoted to adducts of metal (primarily, zirconium or titanium)  $\beta$ -diketonate complexes with oxygen-containing organic ligands. The probability of the preparation of FETF with desirable properties is enhanced if the starting compound contains oxygen in an amount

**Figure 2.** Unit cells of typical ferroelectric crystals.<sup>12</sup> (a) Cubic perovskite  $\text{Pb}(\text{Zr,Ti})\text{O}_3$ ; shifts of the  $\text{Zr}^{4+}$  or  $\text{Ti}^{4+}$  atoms upon polarisation are shown; vertical arrows to the left denote two states of the memory cell: the positive direction of polarisation is denoted as '1', the negative direction is denoted as '0'; (b) perovskite-like  $\text{SrBi}_2\text{Ta}_2\text{O}_9$  composed of alternating layers of perovskite and bismuth oxide.

sufficient for the formation of the target film with the perovskite stoichiometry (Fig. 2).<sup>12</sup> For this purpose, additional oxygen-containing ligands are often introduced into the adducts.

MOCVD has proven to be the method of choice for the synthesis of FETF from precursors belonging to these classes.

### 2. The sol–gel method for the preparation of films from solutions

The technology of the synthesis of films from solutions by the sol–gel method includes preparation of a sol followed by its conversion into a gel. In the first step, a highly disperse colloidal solution, *i.e.*, a sol, with a composition corresponding to that of the target film is formed. An increase in the concentration of the dispersed phase results in the formation of additional bonds between molecules in the solution, which favours gelation. Further increase in the volume concentration and surface area of the dispersed phase gradually changes the plastic properties of the gel. In order to deposit the compound in the form of a thin film, the gel is placed onto a rapidly spinning support for a few seconds. If a compound does not form a gel, its solution is just deposited on the support, which is further subject to annealing: first, to remove the solvent, then to decompose the organometallic starting compound, and finally to crystallise the target phase. Therefore, the method of decomposition of an organometallic precursor deposited from a solution (Metal–Organic Deposition, or MOD) represents a particular case of the sol–gel method as applied to thin film preparation.

In this method, metal hydroxides, salts of organic and inorganic acids and alkoxides are used as the starting compounds. Among salts of inorganic acids, chlorides are used most often. In the cases of metal alkoxides and carboxylates, the originally formed sol that is further annealed is highly homogeneous. It is advisable that hydrolysis of metal alkoxides and carboxylates be performed in aqueous and ethanolic solutions, respectively.

In a recently proposed method for the preparation of ferroelectric nanostructures with a crystallite size of 10 nm (see

Ref. 19), porous silicon produced by anodic etching in a 15% solution of HF in aqueous ethanol is used as a support. The porosity of the near-surface layer as high as 66% is reached at an etching rate of  $23 \text{ nm s}^{-1}$ . Wafers of porous silicon are immersed into a solution of starting compounds which enters the pores of the matrix. The material acquires ferroelectric properties after annealing.

### 3. Hydrothermal process

In the hydrothermal method, a support, starting compounds and a solvent are placed into an autoclave. The solubility of the starting compounds increases on heating under high pressures and a thin film of a metal oxide is deposited onto the support upon cooling of the mixture. It was shown that the resultant films possess poor ferroelectric properties, which limits the usage of this method.

Like in the sol–gel method, metal hydroxides, alkoxides and salts of inorganic and organic acids are used as the starting compounds in the hydrothermal method.

### 4. The Langmuir–Blodgett process

The Langmuir–Blodgett process includes three steps:

- creation of a monolayer of film-forming molecules on a water surface and formation of a compact floating film. The molecules within the film have a polar (or hydrophilic) group bound to a long hydrocarbon chain that is long enough to provide insolubility of the whole molecule in water (as in the case of, *e.g.*, stearic acid or octadecylaminomethyldehydrocarbotine,  $\text{n-C}_{18}\text{H}_{37}\text{NHCH}_2\text{C}_{26}\text{S}_2\text{H}_{11}$ );<sup>20</sup>
- formation of a layer of starting compounds (most often, salts of inorganic acids are used) on top of the monolayer film;
- transfer of the layer onto a support upon withdrawal of the latter from the solution.

The required thickness of the target film can be achieved by drying the film and repeating the procedure several times.

A distinctive feature of this method is the possibility to produce continuous films at extremely small thicknesses (tens of Å).

## III. Ferroelectric thin films for non-volatile memory elements

### 1. Tantalum pentaoxide films

Films of tantalum pentaoxide in the pure form are not used in non-volatile memory elements. A serious drawback of such films as compared to standard  $\text{SiO}_2$  films is larger leakage current. To correct for this, silicon supports are covered with a layer of silicon dioxide or silicon oxynitride prior to the deposition of a  $\text{Ta}_2\text{O}_5$  layer. The films can be produced using both sol–gel technology and the MOCVD method.<sup>21,22</sup> Metal alkoxides are used as the starting compounds in both cases (Table 1). The sol–gel technology is based on hydrolysis that is sometimes performed in the presence of an acidic catalyst, *e.g.*, HCl.<sup>30</sup> The sol is prepared at room temperature from a mixture of  $\text{Ta}(\text{OEt})_5$  and aqueous-ethanolic HCl. Titanium ethoxide  $\text{Ti}(\text{OEt})_4$  can be used as a dopant precursor in order to dope ferroelectric films of tantalum pentaoxide with titanium. The doping level is varied over the range from 8 mol.% to 46 mol.% with respect to  $\text{TiO}_2$ .<sup>30</sup> Following deposition, the film is annealed at 600–900 °C in an atmosphere of  $\text{N}_2\text{O}$ , which acts as an oxidant.

Typical conditions for the CVD deposition of  $\text{Ta}_2\text{O}_5$  films from organometallic precursors have been reported by Murawala *et al.*<sup>23</sup> by the example of tantalum pentaethoxide: the support temperature was 475 °C, the temperature of  $\text{Ta}(\text{OEt})_5$  deposition was 160–190 °C,  $\text{N}_2$  and  $\text{O}_2$  were used as a gas carrier and an oxidant, respectively, the rate of deposition was  $6.4 \text{ nm min}^{-1}$ . Rapid annealing at 700–900 °C afforded films with a specific electrical resistivity of  $10^{14}$ – $10^{15} \Omega \text{ cm}$ , a leakage current  $< 10^{-8} \text{ A cm}^{-2}$  at a voltage of 1.2 V and a break-down voltage not exceeding  $5 \text{ MV cm}^{-1}$ . These conditions allow preparation of films suitable for the manufacture of memory elements with a capacity of 256 MB.<sup>16,23,24</sup>

### 2. Films of yttrium–manganese double oxide ( $\text{YMnO}_3$ )

Films of  $\text{YMnO}_3$  can be synthesised both by the sol–gel and the CVD methods. In the former method, yttrium and manganese acetates were suggested as the most useful precursors.<sup>37–44</sup> Yttrium isopropoxide is also sometimes utilised. Ethanolic sol-

<sup>a</sup>  $\epsilon$  is permittivity,  $I$  is the leakage current density,  $n$  is the refraction index. <sup>b</sup> Amorphous state. <sup>c</sup> Crystal. <sup>d</sup> Dopants.

utions of diethanolamine and 2-ethoxyethanol are typically used as solvents. The increase in the coordination number of yttrium upon introduction of an additional ligand (*i.e.*, diethanolamine) into the coordination sphere of the metal atom increases the solubility of the starting compounds in organic solvents. The preparation of the films from polymerised salts of organic acids is accompanied by intense gas evolution during thermolysis. With this regard, the temperature is typically raised stepwise, first to 300–400 °C, and then higher.<sup>40,42</sup> Platinum is normally used as the material of the top layer of the supports.

In the case of the CVD synthesis of  $\text{YMnO}_3$ , DPM-based organometallic compounds are used as the starting compounds. The temperature modes of the process are nearly the same.

Parameters of the methods for the preparation of thin films of  $\text{YMnO}_3$  and the physical properties of the resultant films are summarised in Table 2.

### 3. Films of barium and strontium titanates ( $\text{BaTiO}_3$ , $\text{SrTiO}_3$ ) and of their solid solutions

Different starting compounds are used for the synthesis of ferroelectric films of  $\text{BaTiO}_3$ ,  $\text{SrTiO}_3$  and of their solid solutions, depending on the method selected. Metal hydroxides and salts of various inorganic acids, *e.g.*, chlorides,<sup>57</sup> are employed in solution methods (Table 3). This approach excludes side chemical reactions yielding products with uncontrolled compositions during the synthesis of FETF. However, combination of different technologies for the preparation of oxide films with desired properties implies simultaneous use of several classes of compounds in a single process. Zeng *et al.*<sup>64</sup> proposed a new method based on titanium alkoxides and barium carboxylates which combines the sol–gel and hydrothermal methods. The gel employed for the preparation of a  $\text{BaTiO}_3$  film was then subjected to hydrothermal treatment. A solution was applied onto a support followed by

**Table 2.** Conditions of synthesis and properties of ferroelectric thin films of  $\text{YMnO}_3$ .

<sup>a</sup> It is used to initiate polycondensation. <sup>b</sup> Here and in other tables, saturated aqueous solution of acids.

annealing for 30 min at 150 °C, then the support with a film was placed in a teflon container, an aqueous solution of barium hydroxide was added and the container was loaded into an autoclave. Hydrothermal treatment lasted for 1–6 h at 100–200 °C. Crystalline films with a good surface morphology have been prepared by this procedure at such low temperatures.<sup>64</sup>

McKinley and Sandler<sup>25</sup> prepared thin films of nanocrystalline barium titanate on silicon supports from solutions of barium and titanium alkoxides using the sol–gel method. Hydrolysis was effected by water, whereas the polymerisation was carried out in a monoglyme solution. The process of gel formation proceeded very slowly at 20–22 °C. After deposition of the film onto the support, its polarisation curve was obtained and the stability of its dielectric properties over a temperature range from –85 to +200 °C was established.

McCormick and Slamovich<sup>65</sup> used titanium ethoxide for the preparation of barium titanate films. A mixture of titanium ethoxide, barium acetate and tetramethylammonium hydroxide in an alkaline medium (pH > 13) was heated in an autoclave to 150 °C at a rate of 3 °C min<sup>–1</sup>, at which temperature the hydrothermal synthesis lasted for 2 h. However, in addition to the films, an appreciable amount of powder was formed, which negatively affected the properties of the films.

Films with good dielectric properties were obtained<sup>47, 52, 53, 58</sup> by dissolving  $\text{SrCO}_3$  and  $\text{Ti}(\text{OPr}^i)_4$  in a mixture of citric acid and ethylene glycol (see Table 3) and annealing at 550–1000 °C following the solution deposition onto a support.

Thin films of  $\text{BaTiO}_3$ ,  $\text{SrTiO}_3$  and  $(\text{Ba,Sr})\text{TiO}_3$  were also prepared from the respective metal carboxylates (Tables 4 and 5). They were grown on titanium supports using barium acetate solutions. Films with grain sizes of ~50–340 nm were obtained in the temperature range 120–200 °C and a solution flow rate of 1–50 cm<sup>3</sup> min<sup>–1</sup>. The design of the reactor made it possible to supply the solution in a cyclic manner, which facilitated control over the process.<sup>45</sup> Films of  $\text{BaTiO}_3$  with high permittivities were prepared from organometallic precursors by spin-coating with subsequent annealing. Xu *et al.*<sup>66</sup> employed titanium alkoxide-carboxylate  $(\text{MeO})_2\text{Ti}(\text{n-C}_9\text{H}_{19}\text{CO}_2)_2$  and barium carboxylate  $\text{Ba}(\text{n-C}_9\text{H}_{19}\text{CO}_2)_2$  and xylene as a solvent. First, a layer with a thickness of 350 nm was deposited onto a silicon support that was spinning with a velocity of 1500 rpm and the coated support was then annealed at 500–800 °C for 1 h. The thickness of the film was increased to 4–8 µm by repeating the procedure. The resultant films with grain sizes of 0.034, 0.1 and 0.2 µm manifested permittivities of 200, 500 and 1200, respectively. The spontaneous polarisation of the films with grain size of 0.2 µm was 3 µC cm<sup>–2</sup> and  $\tan \delta = 0.1$  (at 1 MHz).

An interesting new modification of the sol–gel–hydrothermal technique for the preparation of thin films of  $\text{BaTiO}_3$  on silicon supports developed by Zeng *et al.*<sup>64</sup> has already been mentioned above. The gel used for the preparation of the film served as a precursor that was subjected to hydrothermal treatment,  $\text{Ba}(\text{AcO})_2$  and  $\text{Ti}(\text{O}^n\text{Bu})_4$  being the starting compounds (see Table 4).

**Table 4.** Conditions of synthesis of ferroelectric thin films of BaTiO<sub>3</sub>, SrTiO<sub>3</sub> and (Ba,Sr)TiO<sub>3</sub> from salts of carboxylic acids and their properties.

Cole *et al.*<sup>87</sup> reported the following physical characteristics of the films prepared in this way:  $\epsilon = 205–450$ ,  $\tan \delta = 0.09–0.013$ ,  $I = 2 \times 10^{-11}–10^{-10}$  A cm<sup>−2</sup> (see Table 5).

Thin films of BaTiO<sub>3</sub> and SrTiO<sub>3</sub> can also be prepared from the gas phase.<sup>93,94</sup> In this case, volatile metal  $\beta$ -diketonates or adducts based on them are used as starting compounds. This approach is also applicable for solid solutions (Ba,Sr)TiO<sub>3</sub>. The starting compounds are evaporated and condensed onto a support at temperatures up to 300 °C. For the (Ba,Sr)TiO<sub>3</sub> films, the deposition temperature was significantly (by almost 100–150 °C) reduced, which did not deteriorate the properties of the resultant films (Table 6). The best results were achieved by Fitsilis *et al.*<sup>114</sup>

#### 4. Films of lead titanate (PbTiO<sub>3</sub>)

Films of PbTiO<sub>3</sub> with good ferroelectric properties were synthesised by solution methods from lead and titanium naphthenates (Table 7). The films grown on a TiSi<sub>2</sub> support possessed high electroconductivity, which made possible their use as bottom plate electrodes in capacitors.<sup>121</sup>

Preparation of PbTiO<sub>3</sub> from lead carboxylates using diols HOC<sub>n</sub>H<sub>2n</sub>OH ( $n = 3–5$ ), *i.e.*, propane-1,3-diol, butane-1,4-diol and pentane-1,5-diol, as solvents was reported by Pardo *et al.*<sup>123</sup> Exothermic effects at temperature ranges of 255–261 °C, 311–326 °C, 449–467 °C and 500–525 °C were detected by complex thermal analysis. These effects are due to oxidative

**Table 5.** Parameters of the solution synthesis and properties of ferroelectric thin films of (Ba,Sr)TiO<sub>3</sub>.

**Note.** The following notations are adopted: AmL is  $\text{MeCH}(\text{O})\text{CO}_2\text{NH}_4$ , EDTA is ethylenediaminetetraacetate.

processes and thermodestruction of the starting compounds. The films prepared from solutions in the diol with  $n = 3$  revealed a homogeneous microstructure, whereas those prepared from solutions in higher diols ( $n = 4$  and 5) were heterogeneous. With a decrease in the thickness of the  $\text{PbTiO}_3$  films, their ferroelectric properties degraded. This was related to the oxygen vacancies that diffuse from the film surface along the grain boundaries into the bulk. In order to compensate for this process, Iijma and Sanada<sup>124</sup> replaced part of titanium ions in  $\text{PbTiO}_3$  by aluminium. Films with the composition  $\text{Pb}(\text{Ti}_{0.85}\text{Al}_{0.15})\text{O}_{3-x}$  and a thickness of 0.14  $\mu\text{m}$  were prepared in air by the sol–gel method (the annealing temperature was  $\sim 700^{\circ}\text{C}$ ) from solutions of lead acetate trihydrate, titanium tetraisopropoxide and aluminium triisopropoxide in 2-methoxyethanol. The ferroelectric properties of the resultant films as a function of the annealing temperature were investigated.

Low temperature of the hydrothermal method for the synthesis of  $\text{PbTiO}_3$  films makes it attractive.<sup>138–140</sup> However, no high-quality films suitable for use in devices with non-volatile memory elements have been produced so far by this method. Sugai *et al.*<sup>129, 130</sup> have attempted to prepare ferroelectric ultrathin layers of  $\text{PbTiO}_3$  by the Langmuir–Blodgett method (see Table 7) using lead dichloride and titanium bis(ammonium lactate) or potassium titanium oxalate as starting compounds and a solution of stearic acid in chloroform as a solvent. Monolayer films were prepared,

which were irradiated with UV light and then annealed. As a result, a dense film with a thickness of 0.2 nm was obtained. Ferroelectric films with thicknesses of 30–50 nm possessing a perovskite-like structure dominantly exposing (111), (101) or (110) crystal faces were produced by repeating this procedure 250–300 times.

## 5. Films of solid solutions $\text{Pb}(\text{Zr},\text{Ti})\text{O}_3$ and $\text{Pb}(\text{Sr},\text{Ti})\text{O}_3$

Lead carboxylates are most commonly used as starting compounds in the preparation of FETF based on solid solutions  $\text{Pb}(\text{Zr},\text{Ti})\text{O}_3$  and  $\text{Pb}(\text{Sr},\text{Ti})\text{O}_3$  (also referred to as PZT and PST, respectively) by solution methods (Table 8). Lead carboxylates are well soluble in organic solvents, such as propan-2-ol or 2-methoxyethanol. Zirconium, titanium and strontium alkoxides are also soluble in these solvents, which favours the formation of high-quality films with uniform thicknesses. It should be taken into account that it is preferable to use starting compounds belonging to the same class, but this is not always possible (see Table 8).

More complex processes (as regards both the synthetic method and the starting compounds used) are also applied to prepare FETF of PZT solid solutions (Table 9). This may be exemplified by syntheses from metal alkoxides and chelate complexes as well as the hydrothermal synthesis envisaging two consecutive steps, *viz.*, generation of growth nuclei and film

**Table 8** Conditions of synthesis of ferroelectric thin films of  $\text{Pb}(\text{Zr,Ti})\text{O}_3$  and  $\text{Pb}(\text{Sr,Ti})\text{O}_3$  and their properties.

<sup>a</sup> A solid solution with a variable composition  $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$ , where  $x = 0-1$ , is formed on  $\text{Al}_2\text{O}_3$  supports.

growth. Properties of the resultant films strongly depend on the first step. The procedure for the hydrothermal synthesis of PZT films is as follows. A titanium support is immersed into an aqueous solution of lead nitrate, zirconium oxychloride and potassium hydroxide to initiate nucleation; the lead:zirconium ratio should be equal to 2.29 and the concentrations of lead nitrate and potassium hydroxide should be 0.33 and 8.0 mol litre<sup>-1</sup>, respectively. The solution and the support are slowly heated in an autoclave for 6–96 h. Heating at 120 °C for 48 h affords thin polycrystalline films.<sup>181</sup> However, this method is of low potential since it does not yield high-quality films.

A primary requirement of starting compounds to be used in the synthesis of complex oxide films by the CVD method is that the element is deposited as an oxide. Starting from the 1990s, lead, zirconium and titanium alkoxides have been commonly used for the preparation of films of  $\text{Pb}(\text{Zr,Ti})\text{O}_3$  solid solutions. The

evaporation temperatures of these compounds are very low (below 35 °C), which constitutes their major advantage over other classes of compounds. Parameters of the CVD method used to grow PZT films on various supports are summarised in Table 10. Among the alkoxides, zirconium derivatives are the least studied. Actually, the choice of suitable starting compounds is limited to two types, *viz.*, propoxy- and butoxy-derivatives (see below). Both types of compounds are employed for the preparation of  $\text{Pb}(\text{Zr,Ti})\text{O}_3$  thin films (doped with  $\text{La}^{3+}$ ,  $\text{Pb}^{3+}$ ,  $\text{Bi}^{3+}$  and  $\text{Nb}^{5+}$ ) from both solutions and the vapour phase. The first application of volatile complexes and adducts of metal  $\beta$ -diketonates dates back to the late 1980s.<sup>172, 194</sup> More recently, zirconium and titanium mixed-ligand complexes, such as metal alkoxy- $\beta$ -diketonates came in use (see Tables 6, 9 and 11).<sup>95</sup> Thin films of  $\text{Pb}(\text{Zr,Ti})\text{O}_3$  synthesised from mixed-ligand metal  $\beta$ -diketonates (see Tables 9 and 12) acquired the greatest practical importance

**Table 10.** Conditions of MOCVD synthesis of ferroelectric thin films of  $\text{Pb}(\text{Zr,Ti})\text{O}_3$  from metal alkoxides and their properties.

due to their high permittivities. As has been mentioned above, film structures play a crucial role in the preparation of ferroelectric layers. A film can undergo polarisation as a result of mutual shifts of atoms. The introduction of additional oxygen-containing ligands into metal  $\beta$ -diketonate complexes makes it possible to control the structure of the target films and, consequently, obtain films with the desired properties (see Tables 9 and 12).

FETF can be doped with various elements to improve their physical properties, in particular permittivity (see Table 12). As precursors of dopants enhancing the ferroelectric properties, either metal carboxylates (from 0 mol.% to 25 mol.%)<sup>216, 217</sup> or volatile thermally stable  $\beta$ -diketonates of alkaline-earth and rare-earth metals or of such metals as Nb, Al and Bi are used.<sup>212, 214, 218, 220, 222</sup>

## 6. Films based on strontium/bismuth/tantalum and strontium/bismuth/niobium complex oxides

Films of ternary oxides  $\text{SrBi}_2\text{Ta}_2\text{O}_9$  and  $\text{SrBi}_2\text{Nb}_2\text{O}_9$  (also referred to as SBT and SBN, respectively) can be prepared by both the MOCVD and solution methods. It is the hydrothermal technique that is most common among the solution methods. Published data on the preparation of films from bismuth and strontium carboxylates are summarised in Table 13. As for tantalum and niobium, the respective metal alkoxides are used most often. The sol–gel method is less common but it is also in use for the synthesis of SBT- and SBN-based FETF. Acetylacetone is sometimes added to the solution in the preparation of SBT films by the sol–gel method since it promotes growth of films oriented along the crystallographic  $c$  axis. The degree of the orientational ordering in

**Table 13.** Conditions of synthesis of ferroelectric thin films of  $\text{SrBi}_2\text{Ta}_2\text{O}_9$  and  $\text{SrBi}_2\text{Nb}_2\text{O}_9$  from metal carboxylates and their properties.

the films strongly affects the residual polarisation and the coercive field. Oriented films exhibit improved ferroelectric properties. In particular, for the films prepared in the absence of acetylacetone and annealed at 750 °C, the permittivity ( $\varepsilon$ ), residual polarisation ( $P_r$ ) and coercive field ( $E_c$ ) were equal to 119, 3.1  $\mu\text{C cm}^{-2}$  and 65.1  $\text{kV cm}^{-1}$ , respectively. For the similarly prepared film in the presence of acetylacetone, the following values of these parameters were obtained:<sup>252</sup>  $\varepsilon = 205$ ,  $P_r = 7.2 \mu\text{C cm}^{-2}$  and  $E_c = 53.3 \text{ kV cm}^{-1}$ .

Legrand *et al.*<sup>237</sup> prepared 30 nm-thick SBN films by the sol–gel method [deposition on a support of double oxide  $\text{SrTiO}_3(001)$ ]. The films often crystallise in the temperature range 500–700 °C. As a rule, this occurs at a lower temperature, between 500 °C and 550 °C. As a result, epitaxial layers (001)SBN/(001)SrTiO<sub>3</sub> and (100)SBN/(110)SrTiO<sub>3</sub> are formed.<sup>202</sup> The mechanism of crystallisation of the SBN films was studied in detail by Shimizu *et al.*<sup>184</sup>. However, SBN films with the composition 1:2:2:9 can hardly be applied in non-volatile memory elements.

In addition to metal carboxylates and  $\beta$ -diketonates, aryl derivatives and preformed bimetallic alkoxides are used in the preparation of SBT films by the MOCVD method (Table 14). Multilayer composites with the composition Pt/Ti/SiO<sub>2</sub>/Si are typically used as supports. The temperature of the process is typically varied from 300 to 800 °C and the residual pressure, from 1 to 10 Torr. Alkyl, aryl and dipivaloylmethane bismuth derivatives deposited at 500 °C,<sup>255</sup> 470 °C<sup>256</sup> and 330 °C, respectively. The use of aryl derivatives complicates the control over the

preparation of films with required compositions.<sup>256</sup> Final characteristics of the films are largely determined by the temperature regime of annealing; some of them are listed in Table 14.

## 7. Films of $\text{Bi}_4\text{Ti}_3\text{O}_{12}$

Films of  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$  (also referred to as BTO) are synthesised most often by the sol–gel and CVD methods (Tables 15 and 16). In the former method, metal alkoxides and carboxylates (primarily, acetates and naphthenates) are typically used. In the latter method, the available starting compounds are employed, *e.g.*, alkoxy or aryl derivatives or metal  $\beta$ -diketonates. Crackless films are produced from  $\text{Bi}(\text{NO}_3)_3$ ,  $\text{Ti}(\text{OPr}^i)_4$  and  $\text{Ti}(\text{OBu}^n)_4$  dissolved in glacial acetic acid or monoglyme. This was achieved by applying solutions of the starting compounds onto platinum-coated silicon or  $\text{SrTiO}_3(100)$  supports using spin-coating followed by annealing at 500 °C or 600 °C, respectively. This resulted in well-ordered films which consequently possessed good dielectric and ferroelectric properties. The films synthesised by the MOD method were additionally annealed at 700 °C and manifested the following characteristics: permittivity, 184 at a signal frequency of 100 kHz; dielectric loss tangent, 0.039; residual polarisation, 4.4  $\mu\text{C cm}^{-2}$ ; coercive force, 84  $\text{kV cm}^{-1}$ ; resistivity,  $10^8 \Omega \text{ cm}$  at room temperature; mean leakage current density,  $10^{-7} \text{ A cm}^{-2}$  at a film thickness of 0.5  $\mu\text{m}$  under an applied field of 100  $\text{kV cm}^{-1}$ . The hysteresis loop on the polarisation curve remained unchanged over  $10^{10}$  cycles of repolarisation.<sup>274</sup>

Jones *et al.*<sup>179</sup> accomplished deposition of films onto multi-layer composite supports Pt/Ti/SiO<sub>2</sub>/Si from vapour of organometallic precursors. The  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$  phase proved sensitive to pyrolysis and annealing due to diffusion of titanium into bismuth titanate to yield the  $\text{Bi}_2\text{Ti}_2\text{O}_7$  phase. Nevertheless, the ferroelectric properties of the resultant film were satisfactory: residual polarisation of  $8.2 \mu\text{C cm}^{-2}$  and coercive force of  $7 \text{ kV cm}^{-1}$ . Malik *et al.*<sup>275</sup> prepared thin films of BTO on Si(100) supports from vapour of  $\text{BiPh}_3$  and  $\text{Ti(OBu)}_4$  at  $550^\circ\text{C}$  and atmospheric pressure using  $\text{N}_2$  as a carrier gas and  $\text{O}_2$  as an oxidant. According to the X-ray diffraction study, the single-crystal films exclusively exposed (100) crystal faces. The residual polarisation and coercive force were  $38 \mu\text{C cm}^{-2}$  and  $45 \text{ kV cm}^{-1}$ , respectively. Desu *et al.*<sup>276</sup> also used  $\text{BiPh}_3$  and  $\text{Ti(OBu)}_4$  for the same purpose; they studied the film growth as a function of the oxidant concentration. The films were deposited at  $600^\circ\text{C}$  on composite supports Pt(111)/SiO<sub>2</sub>/Si(100) with buffer layers of  $\text{Bi}_2\text{Ti}_2\text{O}_7$ . The final films were characterised by a residual polarisation of  $1.3 \mu\text{C cm}^{-2}$ , coercive force of  $25 \text{ kV cm}^{-1}$ , permittivity of 130 and leakage current density of  $10^{-8} - 10^{-7} \text{ A cm}^{-2}$ .

The possibility of growing thin films of BTO from metal alkoxides by the MOCVD method at a temperature below  $400^\circ\text{C}$  has been demonstrated.<sup>268–270</sup> The films with a thickness of 100 nm manifested good surface morphology and good ferroelectric properties: residual polarisation of  $11 \mu\text{C cm}^{-2}$ , coercive force of  $90 \text{ kV cm}^{-1}$  and leakage current density of  $7 \times 10^{-9} \text{ A cm}^{-2}$  at 3 V. The ferroelectric properties of the films with a thickness of 50 nm were satisfactory:  $P = 9 \mu\text{C cm}^{-2}$  and  $E_c = 120 \text{ kV cm}^{-1}$ . No polarisation fatigue of the film was observed after  $10^{12}$  switches.

#### IV. Metal and metal oxide electrodes, prepared from organometallic precursors, for thin-film capacitors

Thin films of ferroelectrics can be used as electrode-separating dielectric layers in the manufacture of capacitors for the memory elements of SLIC. With this regard, the issue of polarisation fatigue of the capacitors due to ageing of the ferroelectric material becomes of key importance.

Both metals, such as platinum, gold, ruthenium, iridium and titanium, and highly conductive metal oxides, such as  $\text{RuO}_2$ ,  $\text{IrO}_2$ ,  $\text{SrRuO}_3$ ,  $\text{CaRuO}_3$ ,  $\text{LaNiO}_3$  and  $(\text{La,Sr})\text{CoO}_3$ , are used as

the electrode materials. These can be produced by vapour deposition from the following organometallic precursors:  $\text{Pt}(\text{acac})_2$ ,<sup>277, 278</sup>  $\text{MeCpPtMe}_3$ ,<sup>279–284</sup>  $\text{Au}(\text{HFA})\text{Me}_2$ ,<sup>285, 286</sup>  $\text{Me}_2\text{Au}(\text{TFA})$  (TFA is 1,1,1-trifluoropentane-2,4-dione),  $\text{Me}_2\text{Au}(\text{HFA})$ ,  $\text{Me}_2\text{Au}(\text{acac})$ ,<sup>287</sup>  $\text{AuR}(\text{CN})\text{R}'$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ , vinyl, prop-1-ynyl, 3,3-dimethylbutyl;  $\text{R}' = \text{Me}$ ,  $\text{Et}$ ,  $\text{Pr}^i$ ,  $\text{Bu}^i$ ,  $\text{Ph}$ ),<sup>288</sup>  $\text{Ru}(\text{EtCp})_2$ ,  $[\text{RuC}_5\text{H}_5(\text{CO})_2]_2$ ,<sup>289</sup>  $\text{Ru}_3(\text{CO})_{12}$ ,<sup>282</sup>  $\text{Ir}(\text{acac})_3$ ,  $\text{Ir}(\text{acac})\text{Cl}_2$ ,<sup>290</sup>  $(\text{EtCp})\text{Ir}(\text{COD})_2$  (COD is cyclooctadiene).<sup>291, 292</sup>

The starting compounds and selected technological parameters of the film deposition on supports are given in Table 17. For the preparation of  $\text{RuO}_2$  films,  $\text{RuCp}_2$ ,  $\text{Ru}(\text{DPM})_2$  and  $\text{Ru}(\text{EtCp})_2$  are most commonly utilised, whereas iridium cyclopentadienyl complexes and their derivatives are applied to the synthesis of  $\text{IrO}_2$ . Double oxides  $\text{SrRuO}_3$  and  $\text{LaNiO}_3$  can be prepared from  $\beta$ -diketonates of the respective metals, *e.g.*,  $\text{Sr}(\text{DPM})_2 \cdot (\text{C}_8\text{H}_{23}\text{N}_5)_x$ ,  $\text{La}(\text{DPM})_3$ ,  $\text{Ni}(\text{DPM})_2$  or  $\text{Ni}(\text{acac})_2$ . Films of  $\text{YBa}_2\text{Cu}_3\text{O}_7$  prepared from yttrium, barium and copper dipivaloylmethanates are sometimes employed.<sup>313, 314</sup>

\* \* \*

Studies conducted over the last 15 years have clearly demonstrated the possibility of using the effect of spontaneous polarisation in ferroelectric materials for the creation of the non-volatile memory elements. The requirements to such materials have been formulated.

Among chemical methods used for the preparation of ferroelectric thin films, the MOCVD method has become the most popular. Over the last few years, this method has been widely applied, in particular, for high-temperature coatings and superconductors.<sup>318</sup> Ferroelectric thin films manifesting the lowest polarisation fatigue have been synthesised, for which the maximum number of recirculation cycles reaches  $10^{11} - 10^{12}$ . Among the oxide films considered above, the following materials that are promising as ferroelectrics can be distinguished:  $\text{Ta}_2\text{O}_5$ ,  $\text{YMnO}_3$ ,  $\text{BaTiO}_3$ ,  $\text{SrTiO}_3$ ,  $(\text{Ba,Sr})\text{TiO}_3$ ,  $\text{PbTiO}_3$ ,  $\text{Pb}(\text{Zr,Ti})\text{O}_3$ ,  $\text{Pb}(\text{Sr,Ti})\text{O}_3$ ,  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ ,  $\text{SrBi}_2\text{Ta}_2\text{O}_9$ . An analysis of the temperature regimes of the preparation of oxide films shows that it is the annealing step that is of key importance. Control over this step can enable preparation of films with a layered perovskite-type structure. A systematic consideration of the methods for the synthesis of ferroelectric thin films with the emphasis placed on diverse chemical methods suggests the priority of the CVD

**Table 17.** Characteristics of oxides used as electrodes for ferroelectric thin films.

processes. Mixed-ligand complexes based on metal  $\beta$ -diketonates as are mainly used as the starting compounds. Metal and conductive oxide layers have been proposed for the manufacture of capacitors based on ferroelectric thin films and their effects on polarisation fatigue properties have been studied.

$M^1$  and  $M^2$  are metal cations,  $A$  is an anion.

Terpyridyl ligands are involved in the formation of inclusion compounds with transition metal cations and the  $PF_6^-$  anion, which occurs in the outer sphere. The reaction of polypyridyl-containing receptors with  $FeCl_2$ ,  $RuCl_3$  and  $CoAc_2$  in the presence of  $NH_4PF_6$  results in the isolation of stable hexafluorophosphates **4**,<sup>6,7</sup>

$R = Ph_2P, Ph_2PO$ .

The combination of pyridyl fragments and (thio)urea residues within one molecule enables the use of these compounds for the simultaneous binding of transition metal cations and dicarboxylic acid anions. In particular, upon the formation of a  $Ru(II)$  complex with two terpyridyl fragments, the urea residues are arranged in space in such a way that they can interact with dicarboxylic acids. For example, compound **5** (based on terpyridyl-substituted thio-

urea) selectively extracts the glutarate anion [ $K_{ass} = 8300 \text{ mol litre}^{-1}$  (see<sup>†</sup>)].

The replacement of the thiourea fragment by the urethane residue results in non-covalent binding of the acetate.<sup>8</sup> An interesting case of the construction of supramolecular structures with simultaneous complexation of  $Fe^{3+}$  and  $Cl^-$  ions has been discovered.<sup>9</sup> Ensemble **6** was obtained upon the template reaction between five tris(bipyridyl) ligands and  $FeCl_3$ .

Recently,<sup>10</sup> an ion pair receptor has been prepared on the basis of a pseudocrown ether modified by urea and a bipyridyl fragment. The resulting compound **7** is complexed with  $Cu(I)$  through bipyridyl groups to form closed structure **8**, whose cavity is suitable for the complexation of a potassium cation. Due to the presence of anion-binding sites, this compound can be used for the recognition of ion pairs, the receptor ability decreasing in the sequence  $Cl^- \gg Br^- > I^-$  (Scheme 1).

A few examples of heteroditopic receptors devoid of pyridyl and ureide fragments have been reported. It was shown that monodendate pyrazole and 3(5)-*tert*-butylpyrazole as solutions in methanol form stable complexes  $[ZnX(Het)_3]X$ , where  $X = Cl, Br, I$ , with zinc halides either in the solid state or as solutions in non-polar solvents.<sup>11</sup>

Compound **9** in the zwitter-ionic form is capable of the separate extraction of cations and anions.<sup>12,13</sup>

<sup>†</sup> Here and below, the binding constant is given in  $\text{mol litre}^{-1}$ .

Scheme 1

Crown ethers linked with Lewis acid fragments by covalent bonds represent another example of heteroditopic receptors. It was found that the oxygen atoms of the crown ether ring in compound **11** coordinate the potassium cation, the fluoride anion being bound simultaneously by the boron atom.

### III. The design of heteroditopic receptors based on crown ethers and calixarenes

Crown ethers and calixarenes are selective extractants for metals and therefore they are often used for the design of heteroditopic complexing agents as cation-binding sites.

#### 1. Crown-containing ligands

Crown ether **10**, containing a free hydroxy group, is among the first examples of heteroditopic receptors based on a macrocyclic matrix. This compound as a suspension in THF binds simultaneously a Li<sup>+</sup> cation and a thiocyanate anion.<sup>14</sup> The cation is retained by the macrocyclic cavity, while the thiocyanate anion is coordinated to the hydroxy group due to the formation of an intermolecular hydrogen bond.

However, in an attempt to trap KCl or KBr in the same way, compound **11** acts only as a cation acceptor.

Related compound **12**, prepared by the reaction of the corresponding alcohol with Me<sub>3</sub>Al, forms a complex with lithium chloride both in solution and in a suspension in THF.<sup>15–17</sup>

The introduction of urea fragments or amide groups, which tend to bind anions, into crown ether molecules allows one to use these compounds as bifunctional receptors.

A study of the binding of benzo-15-crown-5 ether, modified by a thiourea residue, to a series of anions has shown that upon the addition of two equivalents of  $\text{NaBPh}_4$ , ligand **13** captures the  $\text{NO}_3^-$  ( $K_{\text{ass}} = 66$ )  $\text{Br}^-$  ( $K_{\text{ass}} = 260$ ), and  $\text{I}^-$  ( $K_{\text{ass}} = 20$ ) anions.<sup>18</sup> Compound **14** forms complexes with the  $\text{Cl}^-$ ,  $\text{I}^-$  and  $\text{ReO}_4^-$  anions upon the introduction of one equivalent of sodium picrate.<sup>19</sup>

Nitrophenyl-substituted ureas are known to extract anions. Hence, one can expect that the introduction of such a residue into a benzocrown ether molecule would afford a heteroditopic receptor. However, it was found that for simultaneous binding of a cation and an anion, the molecule requires an additional modification with a fragment that would fix the complexation sites in space in an effective manner. Ferrocene proved to be the most appropriate spacer; this was used to synthesise the selective receptor for potassium fluoride **15**.<sup>20</sup>

Subsequently, examples of using hetaryl derivatives of crown ethers as bifunctional complexing agents have appeared in the literature. For example, a crown ether containing diaminopyridyl residues has been synthesised.<sup>21</sup> This molecule is capable of recognising monopotassium salts of dicarboxylic acids due to the formation of a hydrogen bond between the carboxyl group and the diaminopyridyl fragment, and the coordination of the potassium cation by the crown-ether oxygen atoms. 12-Crown-4 ether **16** modified with pyrido[1',2':1,2]imidazo[4,5-*b*]pyrazine exhibits complexing properties unusual for a compound with this size of molecular cavity. It was found by UV spectroscopy that compound **16** effectively reacts with  $\text{Ba}(\text{SCN})_2$  giving rise to a stable complex ( $\log K_{\text{ass}} = 3.98$ ).<sup>22</sup>

Recently, ditopic receptors **17** of a new class based on dipyrrolylquinoxaline have been prepared by the reaction of 1,2-diaminobenzocrown ethers with 1,2-dipyrrolylethane-1,2-dione.<sup>23</sup> Using NMR spectroscopy, it was shown that these compounds form complexes with the sodium cation and the fluoride anion.

X = O, NH;  $n = 0, 1$ .

Heteroditopic receptors are used not only for binding inorganic ions but also for complex formation with bipolar organic molecules. The combination, within one crown-ether host molecule, of a fragment capable of forming complexes with the  $\text{NH}_3^+$  group and an organophosphorus residue able to capture anions accounts for the use of compound **18** for dopamine transport.<sup>24</sup>

$\text{R} = n\text{-C}_{18}\text{H}_{37}$ .

Direct, metal-noncatalysed C–C coupling of 1,2,4-triazin-5-one and benzo-18-crown-6 ether has furnished triazine-containing benzocrown ethers **19a,b**,<sup>25</sup> which form complexes with amino acids. According to  $^1\text{H}$  NMR spectroscopy, compound **19b** selectively extracts  $\beta$ -phenylalanine due to binding of the  $\text{NH}_3^+$  group by the crown ether fragment and hydrogen bonding between the NH group of the triazine ring and the carboxyl group of the amino acid.

$\text{R} = \text{Me}$  (a),  $\text{CF}_3$  (b).

The formation of the complex is indicated by the upfield shift (by 0.07 ppm) of the  $^1\text{H}$  NMR signals of the methylene groups of the crown ether ring.<sup>26</sup>

Thiaazacrown compounds are the most vivid representatives of heteroditopic receptors. They are used most often to capture ion pairs formed from transition metal cations and anions of

various natures. Compounds such as macrocycle **20** selectively bind  $\text{PdCl}_2$ ,  $\text{CuCl}_2$  and  $\text{AgNO}_3$ .

When  $\text{AgNO}_3$  is added to a solution of ligand **20** in acetonitrile, the signals for the NH protons in the  $^1\text{H}$  NMR spectrum shift upfield by 0.4 ppm. This shift is due to rupturing of the intramolecular hydrogen bonds upon the complex formation with  $\text{Ag}(\text{I})$ . Further addition of silver nitrate induces the formation of an intermolecular hydrogen bond with the nitrate anion, which is manifested as a downfield shift of the NH-proton signals. Thus, binding of the anion can take place only after the initial interaction of the ligand with the silver cation, resulting in cleavage of the intramolecular hydrogen bond.<sup>27</sup>

When cryptands are used as heteroditopic ligands, their interaction with anionic substrates such as 1- and 2-naphthalenemonosulfonates and 1,5-, 2,6- and 2,7-naphthalenedisulfonates can be observed.<sup>28</sup>

The introduction of pyridyl fragments into an azacrown ether, both as additional ligand groups and as binding sites, results in new complexing centres in azacrown ether molecules, *i.e.*, the binding properties of the molecule change. Heteroditopic ruthenium(II)- and rhenium(I)-bipyridylbis(benzocrown ether) receptors **21** and **22** (see Ref. 29) selectively bind  $\text{KH}_2\text{PO}_4$  ( $K_{\text{ass}} = 205$ ) in the presence of chloride anions ( $K_{\text{ass}} = 55$ ).

## 2. Heteroditopic receptors on a calixarene matrix

The cation-binding properties of calixarenes are well-known. For the design of a heteroditopic ligand, it is necessary to introduce anion receptors into the calixarene structure.

Binding of  $\text{NaH}_2\text{PO}_4$  and  $\text{CsCl}$  by calixarene complexes containing  $\text{UO}_2$  has been described.<sup>30, 31</sup> In these cases, the cation

interacts either with the functional groups grafted to the lower rim (compound **23**) or with the crown-ether fragment which cross-links the lower rim of the calixarene matrix (compound **24**). In both examples, the anions are bound by the amide groups immobilised on the calixarene matrix.

Heteroditopic receptors based on calixarenes containing amide functional groups in both the upper and lower rims are known. In the former case (compound **25**), the anion and the cation are separated in space, *i.e.*, they are bound at the upper and lower rims, respectively. The latter case (compound **26**) is of interest for the fact that both the cation- and anion-binding sites are located in the lower rim of the calixarene matrix. A study of the receptor ability of these ligands was carried out by NMR titration. It was found that compound **25** in  $\text{CD}_3\text{COCD}_3$  is suitable for the selective binding of  $\text{NaBr}$  to give a complex with the stoichiometric ratio ligand:anion = 1:2 ( $K_{\text{ass}} = 738$ ). Compound **26** can selectively bind  $\text{NaHSO}_4$  ( $K_{\text{ass}} = 1197$ ).

Potassium acetate selectively reacts with the heteroditopic calixarene receptor **27**, existing in the 1,3-alternate conformation and containing two pentafluorophenylamide groups (for complex formation with the anion) and a crown-ether fragment (to capture the cation) (Scheme 2).<sup>32</sup>

Apart from compound **27**, rhenium and ruthenium complexes **28a,b** may be applicable for the simultaneous transfer of cations and anions through the membrane (Scheme 3).<sup>33</sup> These heteroditopic ligands, containing  $\text{Re(I)}$ - and  $\text{Ru(III)}$ -bipyridylamide fragments connected by a flexible spacer to the calixarene lower rim, proved to be specific for ion pairs containing  $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{Br}^-$  and  $\text{I}^-$  ions. NMR titration showed selective binding of lithium bromide ( $K_{\text{ass}} = 1260$ ).<sup>34</sup>

The introduction of  $\text{Re(I)}$ -bipyridyl fragments into the upper rim gives rise to selective receptor behaviour with respect to sodium iodide ( $K_{\text{ass}} = 392$ ),<sup>35</sup> while the calixarene modified with a  $\text{Ru(II)}$ -bipyridyl fragment at the upper rim can be used for binding  $\text{NaH}_2\text{PO}_4$ .<sup>36</sup>

It was found that the combination of urea fragments (as anion-binding sites) and ester groups grafted to the lower rim within the same calixarene molecule results in the formation of selective extractants for alkali metal halides.<sup>37–39</sup> This was confirmed by NMR data obtained for mixtures of the bifunctional ligands and alkali metal halides. The extraction of sodium halides with biureide-substituted calixarene involves non-selective binding of the cations and the anions. The attempt to prepare an inclusion compound with caesium salts did not lead to the desired outcome, which may be due to the mismatch between the size of the complexing cavity and the radius of the metal cation. However, this compound can be used for the selective binding of potassium iodide.<sup>40,41</sup> The introduction of four urea fragments into the upper rim (compound **29**) brings about complexing properties with respect to sodium chloride. This is due to a higher affinity of urea for chloride anions (compared to other halide anions) as a result of the formation of strong hydrogen bonds.<sup>42</sup>

Scheme 2

NMR titration has shown that calixarenes containing a crown ether substituent in the lower rim<sup>43,44</sup> and urea residues in the upper rim can be employed as heteroditopic receptors. The binding constant of the anion decreases in the order  $\text{H}_2\text{PO}_4^- \gg \text{Cl}^- > \text{Br}^- > \text{NO}_3^-$ . The complexation with  $\text{NaH}_2\text{PO}_4$  affords an ion pair.<sup>44</sup> Asymmetric thioureidocalixarenes **30** can be used for selective binding of sodium acetate ( $K_{\text{ass}} = 1200$ ) (Scheme 4).<sup>45</sup>

Linking two calixarenes by an ethylene bridge produces a molecular cavity suitable for the formation of complexes with cations. The modification of these calixarenes by urea fragments results in receptor **31**, which forms a complex with potassium

Scheme 3

Scheme 4

Scheme 5

chloride ( $K_{\text{ass}} > 730$ ), as confirmed by NMR titration data (Scheme 5).<sup>46</sup>

The heteroanalogue of calixarene, calixpyrrole **32**, is a promising heteroditopic ligand. In combination with benzocrown ether, this compound can selectively bind fluoride anions and metal cations.<sup>47</sup> Development of direct methods for the modification of calixpyrrole **32** by azine fragments<sup>48</sup> would pave the way to ligands of a heteroditopic nature (Scheme 6).

Scheme 6

### 3. Heteroditopic complexing agents based on other macrocycles

A method for the development of heteroditopic receptors based on cyclic peptides **33** has been proposed.<sup>49</sup>

These compounds can be used to bind ammonium iodide. In this case, the ligand adopts a conformation similar to the conical calixarene conformation and, similarly, it binds the cation through the interaction of the  $\pi$ -electrons of the carbonyl function, whereas the iodide anion is bound by hydrogen bonding with the NH groups of the peptide.

## IV. Conclusion

The review summarises the data on the synthesis of bifunctional ligands and their complexing properties. The publications devoted to the design of heteroditopic receptors for the recognition of ion pairs on the basis of known cation and anion acceptors are analysed. All the described syntheses have a strategy in common which implies the design of a host molecule containing complexing sites of different nature. The resulting systems can be used not only for simultaneous binding of cations and anions but also for the selective complexation of bipolar organic molecules (for example, amino acids).

**Abstract.** Methods of synthesis and properties of 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (also referred to as CL-20 or HNIW), a highly energetic polycyclic nitramine, are surveyed. The bibliography includes 49 references.

## I. Introduction

The progress in the defence technologies is naturally related to the development of novel more efficient components of mixed solid propellants, explosive compositions and gunpowders. A possible route to accomplish this task consists of the preparation of highly energetic compounds that provide the explosion power superior to any existing substance. According to the theoretical predictions on the physicochemical and explosion characteristics, polycyclic nitramines, in particular, hexanitrohexaazaisowurtzitane, 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**1**), HNIW, CL-20, a unique representative of this class of compounds, hold much promise in this respect.

An HNIW molecule possesses a compact structure, so that both the density<sup>†</sup> and energetic characteristics of **1** are exceptionally high (Table 1).<sup>1–3</sup>

Hexanitrohexaazaisowurtzitane was synthesised for the first time in 1987 at the Naval Air Warfare Center (USA).<sup>4</sup> Since then, intense investigations into optimisation of the methods for its synthesis as well as technologies of its production and preparation of explosives and propellants for diverse applications based on it are being conducted.

A pilot plant for the production of HNIW with a performance of 200 kg of the target product per load was designed in 1990 by the Thiokol corporation (USA).<sup>4</sup>

In the present review, the published data on the methods for the synthesis of polycyclic nitramine **1** and studies of its physicochemical properties are considered systematically. In all the documented methods for the synthesis of compound **1**, the overall process can be divided into two steps: first, construction of the hexanitrohexaazaisowurtzitane cage and, second, substitution of the nitro groups for functional groups at the nitrogen atoms.

## II. Construction of the hexanitrohexaazaisowurtzitane cage

The only available method for the construction of the hexanitrohexaazaisowurtzitane cage is based on the condensation of glyoxal<sup>‡</sup> with benzylamine or its derivatives.<sup>5,6</sup> A mechanism suggested for this reaction is shown in Scheme 1.

Two intermediates, *viz.*, diol **A** and diimine **B**, have been isolated and identified.<sup>5</sup> The reaction was carried out in aqueous

<sup>†</sup> The detonation pressure of an energetic compound is proportional to its density.

<sup>‡</sup> 2,3-Dihydroxy-1,4-dioxane can be used instead of glyoxal.

As can be judged from Table 2, the highest yield was obtained in the case of the condensation of glyoxal and unsubstituted benzylamine. The reaction product, 2,4,6,8,10,12-hexabenzyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**2a**), represents a white non-hygroscopic crystalline substance, which decomposes in acetic acid.<sup>5–7</sup> UV spectroscopic studies have shown that the decomposition of the hexabenzyl derivative **2a** in aqueous acetonitrile is catalysed by acids and probably involves protonation followed by decomposition of the isowurtzitane cage.<sup>6</sup>

The molecular structures of the condensation products **2b** (see Ref. 6), **2d** (see Ref. 5) and **2h** (see Ref. 7) have been confirmed by the data from IR and NMR spectroscopy and X-ray crystallography.

No compounds with the isowurtzitane cage could be synthesised upon condensation of glyoxal with *o*-aminobenzylamine, acetamide and *p*-carboxybenzylamine.<sup>7,11</sup>

### III. Preparation of hexaazaisowurtzitane derivatives to be used in the synthesis of hexanitrohexaazawurtzitane

No hexanitrohexaazaisowurtzitane was formed upon direct nitrolysis of the hexabenzyl derivative **2a** due to both competitive nitration of the benzene rings and instability of the intermediates. Therefore, the benzyl groups at the nitrogen atoms in **2a** should be first replaced by groups that are susceptible to nitrolysis, *e.g.*, AlkC(O), CHO, NO, *etc.*

Preparation of acylated hexaazaisowurtzitane is an especially promising direction for the synthesis of HNIW, since typically the acyl groups at the nitrogen atoms can easily be replaced by nitro groups. Direct acidolysis of **2a** with trimethylsilylpropionyl chloride is documented.<sup>12</sup>

Treatment of the hexabenzyl derivative **2a** with such acylation agents as acetic, chloroacetic and trifluoroacetic anhydrides results only in its extensive decomposition and resinification.<sup>11</sup>

Another approach to the synthesis of the hexaazaisowurtzitane *N*-acetyl derivative consists of the oxidation of **2a** to the respective *N*-oxide followed by the Polonovsky rearrangement.

The selection of a proper oxidant is a non-trivial problem, since oxidation of the hexabenzyl derivative **2a** often results in the decomposition of the polycyclic cage. For instance, it has been established experimentally that the C(1)–C(7) bond is cleaved upon oxidation of **2a** with copper(II) chloride in the presence of pyridine to yield 1,3,4,5,7,8-hexabenzyl-2,6-dioxo-*cis-cisoid-cis*-hexahydro-1*H*,5*H'*-diimidazo[4,5-*b*:4',5'-*e*]pyrazine.<sup>13</sup>

It is known that Cr(VI) species is the oxidant of choice for the benzylic C–H bonds. Therefore, Oiu *et al.*<sup>14</sup> tested various Cr(VI) compounds in the oxidation of the hexabenzyl derivative **2a**. In particular, the oxidation of **2a** with CrO<sub>3</sub> in acetone afforded the target product, *viz.*, hexabenzoylhexasaisowurtzitane,<sup>14</sup> whereas the oxidation with the system K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>–Ac<sub>2</sub>O–AcOH resulted in the cleavage of the C(1)–C(7) bond to yield diimidazolinopyrazinium chromate.

An analogous product was obtained in the oxidation of **2a** with butyl nitrite or ammonium cerium nitrate.<sup>15</sup>

The use of hydrogen peroxide or peroxy acids as oxidants does not result in the target product, defragmentation of the polycyclic cage occurs instead. *N,N'*-Dibenzylurea has been isolated as a product of the oxidative decomposition of the hexabenzyl derivative **2a**.<sup>11, 16</sup>

In principle, the benzyl groups at the nitrogen atoms can be removed by catalytic hydrogenolysis.

However, the reduction of **2a** with molecular hydrogen at an elevated pressure resulted in the decomposition of the polycyclic cage. The irreversible decomposition proceeds competitively in several directions to yield a mixture of products with both cyclic and linear structures.<sup>17</sup>

If the reduction is carried out in the presence of an acylation agent, it becomes possible to protect the secondary amino groups generated and thus to reduce the extent of decomposition of the polycyclic cage. As a result, the reductive debenzylation of **2a** can be successfully accomplished to afford the respective acyl derivative. If acetic anhydride is used as the acylation agent, the reaction proceeds stepwise and yields a mixture of various polyacetylpolymethyl derivatives.<sup>17–19</sup>

2,6,8,12-Tetraacetyl-4,10-dibenzyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0.3.11.0.5.9]dodecane (**3a**) is the main reaction product, which apparently suggests higher stability of the benzyl groups at the nitrogen atoms of the piperazine ring against debenzylation as compared to other benzyl groups that can be rather easily substituted.

A chromatographic analysis of the reaction mixture revealed at least four by-products, in particular, *N*-benzylacetamide. This implies that the hydrogenation is accompanied by partial decomposition of the polycyclic cage.<sup>18</sup>

*N*-Benzylacetamide is a catalyst poison and stops the hydrogenation reaction almost completely, which consequently results in a decrease in the yield of the dibenzyl derivative **3a**.<sup>18</sup>

The yield of **3a** also depends on the amount and activity of the hydrogenation catalyst utilised, concentration of acetic anhydride and the nature of the solvent. Typically, hydrogenation is performed in the presence of palladium catalysts supplemented with catalytic amounts of hydrohalide acids.<sup>1, 5, 19</sup>

The selectivity of the reaction can be substantially enhanced by choosing a proper solvent. For instance, the yield of **3a** was 50%–65% (with respect to the hexabenzyl derivative **2a**) in acetic anhydride<sup>19</sup> and increased to 75% in a mixture of ethylbenzene with *N*-acetoxysuccinimide and acetic anhydride (20 h, *p*H<sub>2</sub> = 9.8 kPa)<sup>18</sup> and further to 80% in DMF, *N*-methylpyrrolidone or 1,2-dimethoxyethane in the presence of a bromine source (*e.g.*, molecular bromine, bromobenzene or acetyl bromide) and acetic acid (20–50 °C, 6–12 h).<sup>20</sup> The role of the bromine source is to supply hydrobromic acid, which is necessary to activate the acetylating agent.<sup>20</sup>

According to the kinetic studies of the hydrogenation process, the activation energy is 48 kJ mol<sup>–1</sup> at a stirring velocity of 2.43 × 10<sup>6</sup> min<sup>–1</sup> and a temperature of 30 °C. The rate constant for the first-order reaction is 1.33 × 10<sup>–2</sup> min<sup>–1</sup> (see Ref. 21).

2,6,8,12-Tetraacetyl-4,10-diethyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0.3.11.0.5.9]dodecane was isolated as the main hydrogenation product of **2a** on a palladium catalyst at a hydrogen pressure of 2942–3923 kPa in acetic anhydride containing 10%–20% of acetic acid.<sup>17</sup>

Presumably, the reaction proceeds *via* a hexaazaisowurtzitane hexaacetyl derivative, but this mechanism has not been confirmed. A single reaction intermediate has been isolated by HPLC, most probably, 2,6,8,12-tetraacetyl-4-benzyl-10-ethyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0.3.11.0.5.9]dodecane.

Based on the experimental facts outlined above, one can conclude that debenzilation of **2a** should be carried out in two steps of which the first involves the formation of the dibenzyl derivative **3a** and its isolation from the reaction mixture and the second, removal of the remaining benzyl groups at the nitrogen atoms of the piperazine ring.

The reduction of the dibenzyl derivative **3a** in acetic acid at a hydrogen pressure of 4.53 kPa in the presence of  $\text{Pd}(\text{OAc})_2$  for 15 h affords 2,6,8,12-tetraacetyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**3b**) in a 73% yield.<sup>18</sup>

Hydroformates **3c** and **3d** are obtained in solutions of **3b** in formic acid.<sup>22</sup>

The reaction of the dihydro derivative **3b** with chloroacetyl chloride in DMF yields the respective bis(chloroacetate) **3e**.<sup>23</sup>

Compound **3b** and its mono(hydroformate) **3c** are converted into 2,4,6,8,12-pentaacetyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**3f**) in the presence of an acylation agent.<sup>24</sup> The synthesis of the hexaacetyl derivative has also been reported.<sup>22</sup> The reaction is performed in the presence of pyridine at 60 °C.

Formylation of the pentaacetyl derivative **3f** yields 2,6,8,10,12-pentaacetyl-4-formyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane.<sup>24</sup>

2,6,8,12-Tetraacetyl-4,10-diformyl-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**3g**) was synthesised by the reac-

tion of the bis(hydroformate) **3d** with acetic anhydride in the presence of pyridine or with acetyl chloride.<sup>22</sup> This dehydration reaction also occurs when the salt **3d** is boiled in benzene with azeotropic distillation of water.<sup>15</sup>

The diformyl derivative **3g** is also formed upon hydrogenation of the dibenzyl derivative **3a** in concentrated formic acid.<sup>18,22</sup> It was suggested that formic acid plays a prominent role in the process by converting the benzylamine fragment into benzylammonium formate, which undergoes the reduction more easily.

This suggestion on the involvement of protonation is supported by the isolation of the formates **3c** and **3d** from the reaction mixture and by the fact that the activity of the hydrogenation catalyst used for the removal of the two remaining benzyl groups is not critical. Therefore, the catalyst used in the first hydrogenation step (*i.e.*, in the conversion of **2a** into **3a**) can also be used for the preparation of the diformyl derivative **3g** without regeneration.<sup>20,22</sup> For the synthesis of **3g**, the use of formic acid with a concentration not lower than 88% is preferable. In dilute solutions, the dihydro derivative **3b** or its formates **3c,d** can be isolated.<sup>20</sup> The formation of the diformyl derivative **3g** proceeds at a lower rate than that of the dibenzyl derivative **3b** due to lower reactivity of the benzyl groups at the nitrogen atoms of the piperazine ring as compared to the benzyl groups in other positions. The yield of the diformyl derivative **3g** is as high as 86%.<sup>20</sup>

Nitrosation is an established method for the substitution of benzyl groups at nitrogen atoms of secondary amines. Wardle *et al.*<sup>4</sup> adapted this method to the nitrosation of the tertiary amine **3a** containing two benzyl groups and obtained 2,6,8,12-tetraacetyl-4,10-dinitroso-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**3h**).

Nitrosonium tetrafluoroborate was used as the nitrosation agent. The reaction was carried out in aqueous sulfolane. The overall process included two steps: first, oxidation of the benzyl groups (to form benzaldehyde) and subsequent nitrosation of the amino groups.<sup>4</sup> The yield of the dinitroso derivative **3h** was 55%. In acetonitrile as the solvent, the yield was lower (10%).<sup>25</sup>

Nitrosation of the dibenzyl derivative **3a** with excess of  $\text{N}_2\text{O}_4$  at 15–16 °C for 20 h afforded **3h** in 92% yield.<sup>25</sup>

In acetic acid, the reaction is more safe than in pure  $\text{N}_2\text{O}_4$ , but is slower.<sup>26</sup> TLC analysis of the reaction products confirmed the presence of an intermediate, 2,6,8,12-tetraacetyl-10-benzyl-4-nitroso-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane. Contamination of the dinitroso derivative **3h** with this intermediate can be avoided by increasing the reaction time and  $\text{N}_2\text{O}_4$

concentration, but 10%–12% of another admixture, *viz.*, 6,8,12-triacetyl-2,4,10-trinitroso-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane, is formed. The presence of this admixture substantially lowers the melting point of the product **3h** but does not prevent the next step, *i.e.*, nitrolysis.<sup>26</sup>

Nitrosation of the dihydro derivative **3b** with sodium nitrite in acetic acid affords the dinitroso derivative **3h** in a yield as high as 95%–100%.<sup>27</sup>

The tetraacetylhexaazaisowurtzitane derivatives described above are used as the starting materials in the synthesis of HNIW.

#### IV. Nitrolysis of tetraacetylhexaazaisowurtzitane derivatives

The final step in the synthesis of HNIW is the nitrolysis of tetraacetylhexaazaisowurtzitane derivatives. In general, this is a complex multi-step process, which yields an array of intermediate hexaazaisowurtzitane nitro derivatives, for instance, 2,6,8,12-tetraacetyl-4,10-dinitro-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**4a**), which is produced upon partial nitrolysis of **3h**.

Compound **4a** was synthesised by treating the nitrosation products of the dibenzyl derivative **3a** with nitronium tetrafluoroborate in acetonitrile at 45 °C. The yield of the product **4a** was 59%.<sup>28</sup> The reaction of the dinitroso derivative **3h** with nitric acid at room temperature afforded **4a** in 95% yield.<sup>29</sup>

The target hexanitro derivative can be obtained by nitrolysis of various tetraacetyl derivatives, *viz.*, compound **3b**, its mono- (**3c**) and bis(hydroformate) (**3d**), bis(chloroacetyl) (**3e**), diformyl (**3g**), dinitroso (**3h**) and dinitro (**4a**) derivatives.

Nitrolysis of **4a** with nitronium tetrafluoroborate in sulfolane afforded **1** in 90% yield. The yield decreased to 30% if the reaction was carried out in a mixture of sulfuric and nitric acids.<sup>18</sup>

Several authors reported consecutive nitrosation and nitrolysis of the dibenzyl derivative **3a** without isolation of the intermediate dinitroso derivative **3h**. Thus the nitrosation of compound **3a** with nitronium tetrafluoroborate in sulfolane followed by nitrolysis of the dinitroso derivative **3h** obtained with nitronium tetrafluoroborate afforded compound **1** in 93%–97% yield.<sup>4,8</sup> In another synthesis,<sup>25</sup> compound **3a** was nitrosated with N<sub>2</sub>O<sub>4</sub> and then nitrated with a mixture of sulfuric and nitric acids (20:80); the yield of HNIW was 97%. A major disadvantage of such one-pot syntheses is the higher explosion hazard due to the presence of benzaldehyde in the reaction mixture after nitrosation, which is nitrated to yield trinitrobenzoic acid.<sup>2</sup> Isolation of the nitrosation product **3h** from the reaction mixture significantly increases safety of the nitrolysis step. The isolated product **3h** is further nitrated with a mixture of sulfuric and nitric acids to give HNIW in 93% yield.<sup>26</sup> As has been established, the conversion of the dinitroso derivative **3h** into HNIW proceeds slowly even in 99% nitric acid and is accompanied by the formation of two by-products, *viz.*, 2,8-diacetyl-4,6,10,12-tetranitro- (**4b**) and 2-acetyl-4,6,8,10,12-pentanitro-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane (**4c**). Both intermediates have been isolated chromatographically and their structures have been confirmed by NMR and IR spectroscopy and elemental analysis.<sup>26,27</sup>

The addition of sulfuric acid (10%–15%) to the reaction mixture accelerates the reaction substantially. However, the higher rate of the nitrolysis does not guarantee the absence of admixtures in the final product, since sulfuric acid decreases solubility of the intermediates. This results in the co-crystallisation of the intermediates **4b** and **4c** with the target product **1**. If the modulus<sup>8</sup> is larger than 15, after 2 h the yield of HNIW at 70–75 °C is 99% (TLC).<sup>26</sup>

Yet another method for the nitrolysis of the diformyl derivative **3g** has been developed,<sup>28</sup> which makes it possible to prepare **1** in a virtually quantitative yield using 99% nitric acid (with the modulus of 4) in 4 h. Mixtures of sulfuric and nitric acids<sup>29</sup> or nitric acid and ammonium nitrate<sup>30–32</sup> can also be used as nitration agents. During the nitrolysis of **3g**, the temperature of the reaction mixture is gradually raised to 75–80 °C (*i.e.*, the temperature of the reaction onset). The upper temperature limit is determined by the boiling point of the reaction mixture.

The mechanism of the nitrolysis of the diformyl derivative **3g** has not been studied in detail so far. Presumably, concomitantly with consumption of nitric acid present in the nitration mixture water is accumulated, which can induce partial hydrolysis of the hexaazaisowurtzitane cage at an elevated temperature to yield oxatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane derivatives as by-products.<sup>28</sup>

Furthermore, products of incomplete nitrolysis of the diformyl derivative **3g**, *viz.*, diformyltetranitrohexaazawurtzitane (**4d**) and monoformylpentanitrohexaazawurtzitane (**4e**) derivatives are formed due to insufficiently drastic reaction conditions.<sup>29</sup> Both these products were isolated by preparative chromatography and their structures were confirmed by IR and NMR spectroscopy. The isolation of the intermediates **4d** and **4e** suggests that formyl groups in **3g** are substituted more slowly than the acetyl groups.

§ Hereinafter, the amount of the acid (in g) per 1 g of the substrate is meant.

The incomplete nitrolysis product, *viz.*, compound **4e**, is the major by-product in the synthesis of HNIW from the diformyl derivative **3g**.<sup>28, 29, 32–36</sup> This admixture cannot be efficiently removed by recrystallisation. The complete nitrolysis can only be achieved by prolonged (7–14 h) reaction at high temperature (115–120 °C) (Fig. 1).<sup>31, 32</sup> Such modes were realised if mixtures of sulfuric and nitric acids or nitric acid and ammonium nitrate with a modulus smaller than 10 were used as nitration agents. The role of ammonium nitrate consists of stabilisation of the nitration mixture and an increase in its boiling point, which makes it possible to achieve yields of the target product **1** as high as 98%–99% at a contamination level of 1.5%–0.5% (see Fig. 1).<sup>30, 32</sup>

Nitration of the dihydro derivative **3b** is faster than that of the diformyl derivative **3g**, but the yield of **1** is smaller in this case (90%).<sup>33</sup> Nitrolysis of **3b** is of interest since HNIW synthesised by this route is free of formyl admixtures, although other by-products can still be present (no intermediates have been isolated so far), which can affect the sensitivity of compound **1** to mechanical actions.<sup>33</sup> The nitrolysis of compound **3b** is a multi-step process. Probably, at the beginning of the reaction, the free amino groups of the substrate **3b** undergo protonation in the acidic solution. Then, the nitrolysis of the AcN fragments occurs, which gives rise to an increase in the concentration of acetic acid in the reaction mixture. Acetic acid reacts with nitric acid to yield acetyl nitrate. Presumably,<sup>33</sup> it is acetyl nitrate, which is the reagent of choice for the nitration of secondary amines, that is involved in the nitration of the  $\text{NH}_2^+$  fragments.

**Figure 1.** The fraction of hexanitrohexaazaisowurtzitane **1** in the nitrolysis products of the diformyl derivative **3g** as a function of the nitrolysis time and the type of nitration agent.

Nitration agents: a mixture of sulfuric and nitric acids (15:85) at a modulus of 5 (**1**); nitric acid–ammonium nitrate (25%) at a modulus of 6 (**2**); 98% nitric acid at a modulus of 5 (**3**).

This simplified scheme is complicated by the nature of the substrate subject to nitration. It is known that the basicity of the nitrogen atoms in polycyclic cage compounds are low. Therefore, unlike the nitration of standard amines that occurs rather smoothly, the nitration in this case is accompanied by partial decomposition of the cage. No oxides are evolved in this process and upon splitting of the acetyl groups in the nitrolysis of compound **3b** in contrast to the nitrolysis of the diformyl derivative **3g**, which is accompanied by the intense gas evolution, probably, owing to the decomposition of the formyl fragments. Thus, one can conclude that the decomposition products of **3b**, which can contain water and stable acidic fragments of the cage, do not undergo oxidation under the nitrolysis conditions.<sup>29</sup> Compound **3b** can be nitrated with an anhydrous mixture of nitric and sulfuric acids (85:15) at a modulus of 9 and 83 °C to afford HNIW in 91.8% yield.<sup>33</sup>

The product **1** obtained upon nitration of the chloroacetyl derivative **3e** is contaminated with 4-chloroacetyl-2,6,8,10,12-pentanitro-2,4,6,8,10,12-hexaazatetracyclo[5.5.0.0<sup>3,11</sup>.0<sup>5,9</sup>]dodecane.<sup>23</sup>

Thus, the methods based on the use of hexabenzylhexaazaisowurtzitane **2a** as a key compound and various tetraacetyl derivatives **3a–h** as intermediates have found the widest application among all methods for the synthesis of hexanitrohexaazaisowurtzitane reported in the literature.<sup>27, 29, 31, 32, 35</sup>

## V. Polymorphism of hexanitrohexaazawurtzitane and preparation of its $\epsilon$ -polymorph

Under normal conditions, HNIW has four stable polymorph modifications, *viz.*,  $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\epsilon$ .<sup>4, 37, 38</sup> which differ from each other in the spatial orientation of the nitro groups relative to the five- and six-membered rings of the cage, the type of the crystal packing and the number of molecules per unit cell (Table 3).<sup>37</sup>

The  $\beta$  polymorph isolated by recrystallisation of crude HNIW from benzene was the first crystalline modification discovered.<sup>4</sup> This modification is the least stable as regards polymorphic transformations: it readily converts into the  $\gamma$  polymorph at 185 °C.<sup>37</sup> The latter can be obtained by the nitrolysis of the diformyl derivative **3g** with nitric acid at a modulus no more than 4.5.<sup>28</sup> Heating of  $\gamma$  HNIW to 230 °C changes the crystal structure. According to data from IR spectroscopy, this is most likely due to a structural modification of the  $\gamma$  HNIW<sup>4</sup> rather than a phase transition into another polymorph form (*e.g.*,  $\delta$  polymorph, as was suggested earlier<sup>37</sup>). The conformations of the HNIW molecules in the  $\beta$  and  $\gamma$  polymorphs are identical, but their packing types are different, which results in different symmetries of their crystal structures [orthorhombic and monoclinic, respectively (see Table 3)].<sup>37</sup>

The  $\alpha$  polymorph is formed upon precipitation of HNIW with chloroform from its solutions in sulfolane.<sup>4</sup> Crystalline hemihydrate was obtained upon recrystallisation of this polymorph from 75% nitric acid. The crystal structure of the  $\alpha$  polymorph is stabilised by inclusion of water molecules in cavities at the inversion centres of the crystal lattice. The inclusion of a water molecule in each cavity gives rise to the hemihydrate whereas the quarterhydrate is formed if only 50% of all cavities are occupied (see Table 3).<sup>37</sup>

The  $\epsilon$  polymorph is characterised by the maximum density and thermal stability among all known crystalline modifications of HNIW. In addition to the modifications listed in Table 3, one more modification, *viz.*, the labile  $\delta$  form, is known. This form, which is stable only at elevated pressures, was detected during the equilibrium transformation of the  $\gamma$  phase. The crystal structure of the  $\delta$  polymorph and the conformation of the HNIW molecules therein have not been determined so far.<sup>37, 39</sup>

Theoretically, 24 conformers of the HNIW molecule with different orientations of six nitro groups relative to the molecular cage are possible. The number of most probable conformations is reduced to nine if steric hindrance is taken into consideration.

**Table 3.** Properties of the HNIW polymorphs.

| Property                                                              | Polymorph                  |                                    |                                     |                         |

| Decomposition temperature /°C                                         | 260                        | 260                                | 260                                 | 260                     |
| Polymorphic transition temperature (and type) /°C                     | —                          | 185 ( $\beta \rightarrow \gamma$ ) | 230 ( $\gamma \rightarrow \delta$ ) | —                       |
| Density /g cm <sup>-3</sup>                                           | 1.961 (2.001) <sup>a</sup> | 1.985                              | 1.916                               | 2.04                    |

<sup>a</sup> The value is given for the hemihydrate of the  $\alpha$  polymorph.

Presumably, the density of the most symmetrical structure is higher than that of the  $\epsilon$  polymorph. However, the high symmetry does not ensure necessarily the stability of the conformer: according to calculations, the  $\epsilon$  polymorph is more stable.<sup>37</sup>

Two groups of methods, *viz.*, precipitation and evaporation crystallisation, are used for the preparation of HNIW as the  $\epsilon$  polymorph.

The technology of precipitation methods implies that a crystallisation seed is first placed into a solution of HNIW in a suitable solvent and then a precipitant is gradually added to the solution.<sup>38,40</sup> The precipitate formed is filtered off and dried. The reverse sequence of steps, *i.e.*, addition of a HNIW solution to a precipitant with stirring, is also documented.<sup>41</sup>

Prior to crystallisation, crude HNIW is dissolved in ethyl acetate, and the solution is washed with water or 10% aqueous sodium carbonate (to remove acids) to neutral pH of the aqueous layer, then traces of water are removed by azeotropic distillation with the solvent or using a desiccant, such as anhydrous magnesium sulfate or sodium sulfate.<sup>42</sup>

The solvents for crystallisation where the solubility of HNIW is more than 20% include ethyl acetate or acetone,<sup>†</sup> whereas in precipitants the solubility of HNIW does not exceed 1% (aliphatic and aromatic hydrocarbons: heptane, hexane, benzene, toluene, xylenes, mineral oil or chloroform).<sup>38,42,43</sup> Hexanitrohexaazaisowurtzitane forms crystalline solvates with sulfolane and DMF.<sup>2,44</sup>

An original procedure of the preparation of solutions for the precipitation crystallisation of  $\epsilon$  HNIW was proposed by Bescond *et al.*<sup>25</sup> Pre-purified and dried HNIW is repeatedly heated and cooled in a mixture containing 27.5% of poly(glycidyl azide), 35% of trimethylolethane trinitrate, 35% of butane-1,2,4-triol trinitrate, 1.25% of 2-nitrodiphenylamine and 1.25% of *N*-methyl-*p*-nitroaniline. This procedure yields the  $\epsilon$  polymorph with a density of  $\sim 2.04$  g cm<sup>-3</sup>.

The technology of the evaporation crystallisation is based on the gradual distillation of the solvent from a mixture of HNIW – solvent – precipitant, which favours an increase in the concentration of HNIW and precipitation of the  $\epsilon$  polymorph. The solvent used has to be more volatile than the precipitant. Acetone, ethyl acetate, isopropyl acetate, methyl acetate, tetrahydrofuran, acetonitrile and ethyl methyl ketone are typically used as solvents, whereas toluene, dichloroethane or xylene are used as precipitants. Precipitation of the  $\epsilon$  polymorph with a certain particle size and granulometric composition can be achieved by adjusting temperature, stirring velocity and distillation rate.<sup>25</sup>

The thermal stabilities of different polymorphs of HNIW and possibilities of the phase transitions have been studied in detail by IR and optical spectroscopy, thermography and manometry.<sup>37,43,45–48</sup> It has been established that the thermal stability of

the polymorphs increases in the series  $\beta < \alpha < \alpha \cdot \text{H}_2\text{O} < \gamma < \epsilon$ .<sup>37</sup> The process of the thermal decomposition of HNIW in a solid phase follows first-order autocatalytical kinetics. The thermolysis of HNIW and its inflammation are accompanied by the formation of a solid residue.<sup>45</sup> Nitrogen constitutes a half of the gaseous products generated upon thermolysis.

According to tests, the explosion power of compositions based on HNIW is 14% higher than that of analogous octogen-based compositions.<sup>3</sup> Furthermore, the propelling performance (according to the faceplate acceleration tests) of hexanitrohexaazaisowurtzitane is superior to that of octogen. The energy density of HNIW is 8% higher than that of octogen.<sup>3</sup> This indicates that HNIW is currently the most powerful explosive and it will undoubtedly find wide applications in the armaments industry. More details on the sensitivity and thermal stability of HNIW as well as of compositions using its base can be found in a recent review by Nair *et al.*<sup>49</sup>

## VI. Conclusion

The analysis of published data indicates that there are several convenient methods for the synthesis of hexanitrohexaazaisowurtzitane. In all cases, hexabenzylhexaazaisowurtzitane **2a** is used as the starting material. The divergence of the synthetic routes begins from the step for the preparation of derivatives suitable for nitrolysis and the conditions of the nitrolysis. The best studied method for the synthesis of hexanitrohexaazaisowurtzitane implemented at the industrial scale is the two-step reductive debenzoylation of hexabenzylhexaazaisowurtzitane **2a** to yield the dihydro (**3b**) or diformyl (**3g**) derivatives, which are subsequently nitrated with nitric acid-based systems.

The establishment and development of industrial technologies for the production of HNIW will favour wider utilisation of this highly promising product.

**Abstract.** The published data on the complexation properties and abilities of porphyrins to recognise charged particles and neutral molecules are systematised. The bibliography includes 91 references.

## I. Introduction

The formation of supramolecular complexes is the groundwork of many biological processes and phenomena. Such processes as enzymatic catalysis, inhibition, immune response, reproduction of genetic information, bioregulation, drug effects, ion transport, *etc.* all include structural recognition in complexation. In molecular recognition, certain molecules ('host' or receptor molecules) select and bind other molecules ('guest' or substrate molecules) through intermolecular forces, resulting in the formation of systems with highly ordered structures. The existence of several binding sites is a prerequisite for attaining a high level of structural organisation of organic complexes, since the energy of a single intermolecular interaction is far too low in comparison with the energies of the covalent bonds.

Like crown ethers and calixarenes, porphyrin molecules are extremely interesting subjects as regards the design of 'host–guest'-type supramolecules. The rigid backbones of porphyrins make them ideal structural elements of 'host' molecules, the substituents in which are arranged in a definite order enabling specific interactions with 'guest' molecules. The presence, in the porphyrin molecule, of an extended conjugated  $\pi$ -system allows successful application of a variety of spectroscopic and analytical methods in the investigations of intermolecular interactions.

Publications on supramolecular porphyrin complexes containing no less than two binding sites appeared in the literature only 10–15 years ago. The aim of the present review is to generalise and analyse the published data on supramolecular porphyrin complexes and to track modern trends in the development of the supramolecular chemistry of porphyrins and its main achievements.

The ability of most porphyrin receptors to perform molecular recognition of various species is based on the possible axial coordination of ligands to the reaction centres of porphyrin metallocomplexes.<sup>1–4</sup> The overwhelming majority of metalloporphyrin receptors are represented by zinc–porphyrin complexes.

## II. Axial coordination of monodentate ligands to Zn-containing porphyrins

Axial coordination of ligands is inherent in many complexes with planar coordination centres ( $ML_4$ ), but is especially well-defined and peculiar for metalloporphyrins.<sup>1–5</sup> The structures, compositions and stabilities of axial metalloporphyrin–ligand complexes depend on the nature of the metal. The Zn(II) ion, which is prone to  $sp^3$ - or  $sp^2d^2$ -hybridisation, has to acquire an  $sp^2d$ -configuration in complexes with planar porphyrin molecules. This results in electron-deficient  $4p_z$ - and  $4d_{z^2}$ -orbitals, which enter into donor–acceptor interactions with electron-donor ligands.

Upon coordination of a ligand to a metalloporphyrin, the central metal atom exits the plane of the porphyrin macrocycle towards the axial ligand, which is accompanied by a bathochromic shift of the Soret and  $Q$ -bands in the electronic absorption spectra. The reason for such spectral changes is the weakening of the electronic  $\sigma$ -effects, which characterise the strengths of the M–N bonds and the positive charge on the metal cation.<sup>5</sup> A distinct correlation exists between the magnitude of the bathochromic shift of the adsorption bands and the basicity of the axial ligand.<sup>5,6</sup>

It is known that zinc–porphyrin complexes bind nitrogen bases easily, but coordinate oxygen- and sulfur-containing molecular ligands to a lesser degree. Nevertheless, the coordination of oxygen-containing molecules to zinc ions can also serve as a non-selective 'anchor' site in multisite recognition.<sup>7,8</sup> Monomeric Zn-containing porphyrins usually bind only one axial ligand to form pentacoordinate complexes.<sup>6</sup> In the case of weaker bases (*e.g.*, DMSO, DMF), zinc–porphyrin complexes bind two axial ligands, however, their bond strengths are different.<sup>9–12</sup>

Upon coordination of oxygen-, sulfur- or nitrogen-containing ligands to monomeric zinc–porphyrin complexes, the binding constants (also referred to as the association, extracoordination or stability constant,  $K_a$ ) strongly depend on the basicity of the ligand. In the general case, the greater the basicity of the ligand the stronger its coordination to the metalloporphyrin. The value of the binding constant for the zinc–tetraphenylporphyrine complex (I) in toluene increases by five orders of magnitude in the series: methanol < pyrrole < DMSO < pyridine < imidazole < piperidine.<sup>9</sup> Such a correlation is violated, if the lone electron pair of the ligand involved in the coordination is delocalised over the

adjacent substituents. The effects of the solvent, structure and position of the substituents in the porphyrin molecule on the axial coordination are less pronounced than the effect of the nature of the axial ligand (Table 1).<sup>13</sup>

<sup>a</sup> The data for 295 K are given. <sup>b</sup> The measurement temperature is not indicated. <sup>c</sup> The data for 303 K are given.

Axial coordination to metalloporphyrins is usually carried out in inert solvents (*e.g.*, benzene, toluene, dichloromethane). V'yugin *et al.*<sup>26,27</sup> studied the axial coordination of solvents to a vast variety of metalloporphyrins by calorimetry. The enthalpies of coordination of the aforementioned inert solvents to Zn-containing porphyrins were found to be close to zero. The values of the binding constants for the Zn–porphyrin–ligand complexes changed no more than fourfold on going from one inert solvent to another (see Table 1). The highest  $K_a$  values were observed in aromatic solvents, *viz.*, benzene and toluene.

The dependence of the binding constants on the structures of the substituents in porphyrins **1–12** was even less pronounced, since the electronic effects of the aryl and alkyl groups on the state of the central zinc ion were insignificant.

At the same time, the  $K_a$  values for the monodentate nitrogen bases changed by several orders of magnitude in the series of metalloporphyrins **13–29**, which differ in the degree of distortion of the tetrapyrrole macrocycle (Table 2). The major factors determining the axial coordination to these porphyrins are shielding of the reaction centre of the tetrapyrrole macrocycle (from one or both sides); changes in the electron densities on the nitrogen atoms of the porphyrin and in the charge on the Zn(II) cation due to distortion of the macrocycle structure; matching of the size of the cavity formed by the distorted porphyrin macrocycle to the size of the axial ligand and also complementary  $\pi$ – $\pi$ , CH– $\pi$ , *etc.*, interactions between the metalloporphyrin ('host') and ligand ('guest') molecules.

The coordination of axial ligands to 'picket-fence', 'strapped' and dimeric porphyrins has a number of specific features. The term 'picket-fence' is usually applied to porphyrins containing bulky peripheral substituents. In the majority of cases, these are tetraphenylporphine derivatives with *ortho*-substituents in each benzene ring. Depending on the orientation of the substituents relative to the plane of the tetrapyrrole macrocycle ( $\alpha$  on one side and  $\beta$  on the other side), there are four atropoisomers, *viz.*,  $\alpha,\alpha,\alpha,\alpha$ - ( $\alpha^4$ ),  $\alpha,\beta,\alpha,\alpha$ -,  $\alpha,\alpha,\beta,\beta$ - (*cis*- $\alpha^2$ ) and  $\alpha,\beta,\alpha,\beta$ - (*trans*- $\alpha^2$ ).

The axial coordination of pyridine, piperidine and quinoline to 'picket-fence' metalloporphyrins **13** and **14** in toluene and other non-coordinating solvents has been studied.<sup>28</sup> The results obtained suggest that the affinities of *trans*- $\alpha^2$ -atropoisomers for pyridine and quinoline are higher than those of  $\alpha^4$ -atropoisomers.

Both sides of the metalloporphyrin reaction centre of the *trans*- $\alpha^2$ -atropoisomer **14** are equally accessible for coordination. In this case, the enhanced affinities for pyridine and quinoline are due to weak CH– $\pi$  interactions between the bulky alkyl groups of the *ortho*-substituents and the  $\pi$ -electron systems of the ligand. In the case of the  $\alpha^4$ -atropoisomer **13**, both sides of the reaction centre of the metalloporphyrin are non-equivalent. The reaction centre is virtually completely shielded by four *ortho*-substituents, and the ligands are coordinated to the zinc cation only from the 'open' side of the porphyrin macrocycle and do not enter into any

**Table 2.** Binding constants of sterically hindered monomeric and dimeric Zn-containing porphyrins with monodentate ligands at 298 K.

| Porphyrin | Ligand                        | Solvent                         | $K_a$ /litre mol <sup>-1</sup> | Reference porphyrin | $K_a/K_{comp}$ | Ref. |

additional interactions with the *ortho*-substituents in the benzene rings.

‘Strapped’ porphyrins are compounds with different types of bridges that link peripheral positions of the macrocycle.<sup>33</sup> Synthesis of such porphyrins was aimed at the construction of complexes that mimic natural enzymatic systems. The binding constants of ‘strapped’ porphyrins with the ligands are determined primarily by the shielding of the porphyrin cores and matching of the size of their intramolecular cavity to the size of the coordinated ligand. If the reaction centre is not shielded by bulky substituents, as is the case for porphyrin **15**, the  $K_a$  value is virtually the same as that of the non-distorted porphyrin (see Table 2).<sup>20</sup>

In the case of a unilateral shielding of the reaction centre by a bulky substituent, the binding constant depends first of all on the matching of the size of the intramolecular cavity of the metalloporphyrin to the size of the coordinated ligand. In the case of mismatch, the coordination of the ligand takes place exclusively to the 'open' side of the macrocycle. In this case, the binding constants of 'strapped' metalloporphyrins with different ligands are smaller than those of porphyrins devoid of steric shielding of the reaction centres, *e.g.*, compounds **16–21** (see Table 2).<sup>14, 17, 29, 34</sup>

Metalloporphyrins **16, 17, 20** and **21** contain aromatic fragments in their bridges that are involved in  $\pi$ – $\pi$  interactions with the porphyrin macrocycles.<sup>29</sup> This results in a decrease of charge on the Zn(II) cation of the reaction centre, which we consider as a

major reason for the decrease in the  $K_a$  values of complexes **16, 17, 20** and **21** in comparison with metalloporphyrins devoid of shielding substituents.

The value of  $K_a$  increases substantially if the size of the ligand matches the diameter of the intramolecular cavity of the sterically shielded porphyrin, which enables its incorporation into the cavity.

Interesting results were obtained in studies on the coordination of various imidazole derivatives to the porphyrin receptor **22**.<sup>30</sup>

In this case, not only does the diameter of the intramolecular cavity of the porphyrin match the ligand size. Also, additional binding sites between the receptor and the ligand appear due to the nitrogen atoms of the 'strap'. The binding constants of such complexes are of the order of  $10^6$ – $10^8$  litre mol<sup>–1</sup> (see Table 2).

High values of binding constants are characteristic of porphyrins **23–26** containing a calix[4]arene molecule as the ‘strap’ fragment.<sup>19</sup> The receptor **25** with the smallest distance between the porphyrin and calixarene fragments and four bridges that stabilise the molecular structure and confer a strictly specific shape on the hydrophobic cavity forms the most stable complexes. The binding patterns of large and small ‘guest’ molecules differ significantly from one another. Larger molecules (*e.g.*, nicotine and 4-phenylpyridine) bind on the outer side of the receptor; their  $K_a$  values are equal to, or a little smaller than, the corresponding value for tetraphenylporphyrine **1**. Binding of smaller molecules (*e.g.*, pyridine,  $\alpha$ - and  $\gamma$ -picolines) occurs in the inner cavity and depends critically on the electron density on the donor nitrogen atom.<sup>19</sup>

The phenyl fragments in the ‘basket-handle’ porphyrins **27–29** are linked by bridges on both sides of the porphyrin macrocycle. The complexation properties of the derivative **29** do not disappear completely despite shielding of the coordination centre of the metalloporphyrin and the geometrical mismatch of the size of the intramolecular cavity of the receptor to that of the ligand, they are only twice as weak as those of the sterically non-shielded porphyrin **2**. This suggests the incomplete shielding of the coordination centre of the porphyrin by the cyclophane ligands. If the size of the intramolecular cavity of the ‘host’ matches the size of the ‘guest’, as in the case of porphyrins **27** and **28**, their  $K_a$  values exceed that of compound **1**.<sup>8, 31</sup>

Each monomeric porphyrin fragment in the cyclophane dimers **30–42** is shielded on one side by another porphyrin fragment, as a result of which the  $K_a$  values of the dimers **30**, **31**, **33**, **36** and **42** are smaller than those of their monomeric analogues. Contrariwise, the coordination of monodentate ligands to the dimers **32**, **34**, **35** and **39–41**, which results in the formation of 1:1 complexes, is characterised by higher binding constants in comparison with the monomeric porphyrins. For example, in the coordination of pyridine the  $K_a$  value increases 1.5–3-fold. Some authors suggest<sup>17, 34</sup> that in addition to the formation of a donor–acceptor  $\sigma$ -bond  $Zn-N$ , pyridine interacts with the metal by a  $\pi$ -type mechanism with a transfer of the electron density from the  $d_{xz}$ -,  $d_{yz}$ -orbitals

In the coordination of a bifunctional ligand to a dimeric cyclophane porphyrin, formation of complexes on both the inner [ $K_{a(in)}$ ] and outer [ $K_{a(out)}$ ] sides of the dimeric molecule is possible. The most stable complexes are formed where the bifunctional ligand is coordinated inside the dimer cavity. In the general case, the binding energy of such a complex is not equivalent to the double energy of formation of the monomeric complex due to a number of factors such as the chelating effect, interactions between different reaction centres of the bidentate ligand, conformational changes and new interactions that appear in the system. These contributions to the total binding energy of the dimeric porphyrin–bidentate ligand complex depend on the nature and the conformations of the bridges in the dimeric porphyrin and can be rather significant.

Sanders *et al.*<sup>21,29</sup> have developed formulae for calculating the concentration ratios of dimeric and trimeric complexes of a dimeric porphyrin with DABCO as a function of biporphyrin concentration,  $\alpha$ ,  $K_{a(in)}$  and  $K_{a(out)}$

$$\frac{[\text{ZnP}_2 - \text{DABCO} - \text{ZnP}_2]}{[\text{ZnP}_2 - 1 - \text{DABCO}]} = \frac{\alpha K_{a(out)}^2 [\text{ZnP}_2]}{4K_{a(in)}}, \quad (2)$$

and for calculating energies of different effects associated with the coordination of bidentate ligands to a dimer and forming a part of the general equation:

$$\begin{aligned} \Delta G_{a(in)} = & 2\Delta G_{a(m)} + \Delta G_{a(z)} + \\ & + \Delta G_{a(chel)} + \Delta G_{a(conf)} + \Delta G_{a(new)}, \end{aligned} \quad (3)$$

where  $\Delta G_{a(in)}$  is the energy of formation of a complex of the bidentate ligand with the inner cavity of the dimer;  $\Delta G_{a(m)}$  is the energy of formation of a complex of the same ligand and the monomeric porphyrin;  $\Delta G_{a(z)}$  is the energy of the interaction between the reaction centres of the bidentate ligand;  $\Delta G_{a(chel)}$  is the energy of the chelating effect;  $\Delta G_{a(conf)}$  is the energy of conformational changes and  $\Delta G_{a(new)}$  is the energy of new interactions in the system.

Depending on the nature of the bridges, the binding constant of a dimeric porphyrin to a bidentate ligand according to a bidentate scheme is 3–5000 times higher than the  $K_a$  for a monomeric analogue (Table 3).

The coordination of bidentate ligands to linear dimeric porphyrins depends on their flexibilities.

Thus the porphyrin fragments in the dimer **43** with a rigid aromatic bridge are at a large distance from one another; their interactions with DABCO in  $\text{CH}_2\text{Cl}_2$  yield 1:2 complexes with  $K_a \approx 10^5 \text{ litre mol}^{-1}$  where each metalloporphyrin fragment of the dimer binds one molecule of the bidentate ligand.<sup>36</sup> The interaction of the dimer **44** with a more flexible bridge with DABCO yields a 1:1 ‘internal’ complex ( $K_a \approx 10^7 \text{ litre mol}^{-1}$ ) where two metalloporphyrin fragments of the dimer bind one molecule of the bidentate ligand. The dimer **45** forms similar ‘internal’ complexes with DABCO ( $K_a = 6 \times 10^6 \text{ litre mol}^{-1}$ ).<sup>24</sup>

Dimeric porphyrins containing calixarene and crown-ether fragments possessing multifunctional recognising abilities present special interest. The calixarene and crown-ether fragments of these molecules form stable complexes with metal cations; porphyrin fragments coordinate nitrogen bases, whereas the bridges between the calixarene and porphyrin fragments can bind anions.

**Table 3.** Binding constants of 1 : 1 complexes of Zn-containing porphyrins with bidentate ligands.

| Porphyrin                                                                       | Ligand            | Solvent                         | $K_a$ /litre mol <sup>-1</sup> | Reference porphyrin | $K_a/K_{comp.}$ | Ref.   |

Interesting results were obtained for the dimer **46** with a crown-ether bridge binding  $\text{Ba}^{2+}$  ions (see Ref. 37). On the one hand, this dimer manifested high affinity for diamines in the presence of barium perchlorate. On the other hand, the presence of diamines in the reaction system and their coordination to the porphyrin fragments of the dimer **46** increased the extraction coefficients of the barium salts from the aqueous phase to the organic phase.

The ability of supramolecular metallocomplexes containing crown-substituted porphyrins to recognise metal cations is considered in detail in a review by Tsivadze.<sup>38</sup>

The ability of calixarenes to recognise metal cations has been studied extensively over the past two decades.<sup>39–41</sup> The addition of porphyrin chromophores to calixarene molecules has made it possible to apply conventional spectrophotometric methods of porphyrin chemistry to ion binding studies. Some papers<sup>42, 43</sup> describe the use of calixarene–porphyrin receptors for the recognition of anions based on the formation of hydrogen bonds with the NH groups of bridges.

An analysis of the binding constants ( $K_a$ ) of  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$  and  $\text{NO}_3^-$  with calixarene–porphyrins **47–51** (Table 4) has shown that compound **50**, which contains an additional complex-forming cavity formed by four ethyl acetate groups in the lower rim of the calixarene base, manifested the highest recognising capacity.<sup>43</sup>

Smaller anions ( $\text{Cl}^-$  and  $\text{Br}^-$ ) are characterised by higher  $K_a$  values than larger anions  $\text{I}^-$  and  $\text{NO}_3^-$ , which points to the existence of specific steric requirements for the complexation process.

$\text{R}^1 = \text{R}^2 = \text{OPr}^n$ ;  $\text{R}^3 = \text{R}^4 = \text{R}^5 = \text{H}$  (**47**),  $\text{R}^3 = \text{R}^5 = \text{H}$ ,  $\text{R}^4 = \text{Y}$  (**48**),  $\text{R}^3 = \text{Y}$ ,  $\text{R}^4 = \text{R}^5 = \text{H}$  (**49**);  $\text{R}^1 = \text{R}^2 = \text{OCH}_2\text{CO}_2\text{Et}$ ,  $\text{R}^3 = \text{Y}$ ,  $\text{R}^4 = \text{R}^5 = \text{H}$  (**50**);  $\text{R}^1 = \text{H}$ ,  $\text{R}^2 = \text{R}^4 = \text{R}^5 = \text{OPr}^n$ ,  $\text{R}^3 = \text{Y}$  (**51**),

**Table 4.** Binding constants of anions to calixarene–porphyrins **47–51** in  $\text{CH}_2\text{Cl}_2$  at 24 °C obtained by spectrophotometric titration.<sup>43</sup>

The ability of the calixarene–porphyrin conjugates **52–56** to recognise bidentate ligands including DABCO has been studied.<sup>44, 45</sup> Compounds **53**, **55** and **56** formed 1 : 1 complexes where DABCO was coordinated to both porphyrin fragments ( $K_a \sim 10^7$  litre mol<sup>−1</sup>), whereas the derivatives **52** and **54** coordinated DABCO only on the outer side.

$\text{X} = \text{CH}_2$  (**52**),  $\text{S}$  (**53**).

A detailed study of the binding of oligopyridyl ligands to di-, tri- and tetrameric porphyrins has been carried out.<sup>24, 46–50</sup> A good geometrical matching of the size of the porphyrin cavity to the ligand was observed for the dimeric porphyrin **35** with bipy ( $K_a = 6 \times 10^6$  litre mol<sup>-1</sup>), for the trimeric porphyrins **57** and **58** with Py<sub>3</sub>P ( $K_a = 9 \times 10^9$  and  $4 \times 10^{10}$  litre mol<sup>-1</sup>, respectively) and for the cyclic porphyrin **59** and the linear tetrameric porphyrin **60** with H<sub>2</sub>PPy<sub>4</sub> ( $K_a = 2 \times 10^{10}$  and  $7 \times 10^9$  litre mol<sup>-1</sup>, respectively).<sup>24</sup>

The distance between the porphyrin fragments in the dimer **36** is ~1.5 nm, which makes it a ‘host’ for the matching ‘guest’, viz., bis(4-pyridyl)acetylene (Py<sub>2</sub>C<sub>2</sub>) ( $K_a = 7 \times 10^6$  litre mol<sup>-1</sup>). The diameter of the spacious intramolecular cavity of the trimer **61** matches the size of the ligand Py<sub>3</sub>C<sub>12</sub>H<sub>3</sub> ( $K_a = 2 \times 10^8$  litre mol<sup>-1</sup>).<sup>47</sup>

R = (CH<sub>2</sub>)<sub>2</sub>CO<sub>2</sub>Me.

R = (CH<sub>2</sub>)<sub>2</sub>CO<sub>2</sub>Me.

Some porphyrin-based derivatives of cholic acid, *e.g.*, the conjugate **62**, form the so-called 'calix', which can be used for the recognition of enantiomers of different bases, of morphine in particular.<sup>51, 52</sup> The interaction between the nitrogen atom of the ligand and the zinc atom of the 'calix' is the main driving force for this process. Moreover, the ligand can form hydrogen bonds with the 'calix'. For example, morphine forms two strong hydrogen bonds with the 'calix'; the  $K_a$  values for the morphine (+)- and (–)-enantiomers differ 43-fold.

The synthesis and complex-forming properties of porphyrin dendrimers built of nine covalently linked monomeric porphyrins have been documented.<sup>36, 53</sup> The complex-forming properties of the dendrimers, like those of the dimers **43** and **44**, depend on the flexibilities of the bridges between the porphyrin fragments. Dendrimers coordinate DABCO either to two parallel porphyrin fragments<sup>36</sup> or through one-point binding of each metalloporphyrin fragment of the nanomer to one molecule of the bidentate ligand.<sup>53</sup>

Among porphyrin–metal complexes, Ni- and Ru-containing porphyrins are especially popular as receptors. The strength of binding of nitrogen bases to the central metal atom decreases in the following order: Ru  $\gg$  Zn  $\gg$  Ni.<sup>54–57</sup> Supramolecular compounds containing 5, 7 or 9 porphyrins, *e.g.*, complex **63**, were prepared based on Ru–porphyrin complexes.<sup>55</sup>

#### IV. Recognition of amino acids, purine bases, sugars and quinones by porphyrins

In addition to axial coordination of ligands to metalloporphyrins, other interactions, such as the formation of hydrogen bonds, van der Waals and dispersion interactions in molecular complexes, are also important. It is these interactions that are crucial for the molecular recognition of amino acids, sugars, quinones, purine bases, *etc.*, by the porphyrins.

The recognition of amino acids in aqueous media has been studied using tetrakis(*N*-methylpyridyl)porphine **64** and its zinc and cobalt complexes as examples.<sup>58, 59</sup> Axial coordination of the amino group of the amino acid to the central metal atom is the main driving force in the recognition of amino acids by metalloporphyrins. If the amino acid contains several electron-donating groups, the contribution of each of these groups to the binding to the coordination centre of the metalloporphyrin is determined by the pH of the medium. For methionine, the coordination involves the sulfur atom at low (3.8) and the amino group at high (9.8) pH values. The coordination of lysine involves predominantly the  $\alpha$ -NH<sub>2</sub> group at low and both the  $\alpha$ - and  $\epsilon$ -NH<sub>2</sub> groups at high (10.3) pH values.

In addition to the axial coordination, dispersion interactions between the carboxylate anions of the 'guest' and the pyridine cation of the 'host' play a prominent role in the recognition of amino acids by porphyrins. The strength of such interactions is pH-dependent and increases with pH.<sup>59</sup> In the case of amino acids

containing aromatic substituents, phenylalanine and tryptophan, the interaction with the porphyrin molecule occurs according to the  $\pi$ - $\pi$  mechanism, which stabilises the complex<sup>60</sup> and appreciably increases  $K_a$  (from 60 litre mol<sup>-1</sup> for glycine to 1200 litre mol<sup>-1</sup> for tryptophan).<sup>58</sup>

M = 2 H, Zn, Co.

In organic solvents, the recognition of amino acids by porphyrin complexes is achieved through coordination to the metal cation and is accompanied by the formation of hydrogen bonds on the periphery of the macrocycle.<sup>61-66</sup>

The complex-forming properties of metalloporphyrins **65-67** with respect to some methyl esters of  $\alpha$ -amino acids have been studied.<sup>63</sup> Porphyrin **66** manifested the highest binding constants. The complex **68** is stabilised through coordination of the amino group to the central zinc atom and formation of a hydrogen bond with the peripheral OH group.

**65-67**

R = H (**65**), OH (**66**), OMe (**67**).

**68**

A comparison of the recognising abilities of metalloporphyrins **65-67** has made it possible to estimate the contributions of different energy components, viz., the axial coordination energy ( $\Delta G_{\text{coord}}^\circ$ ) and the energy of hydrogen bond formation ( $\Delta G_{\text{H-bond}}^\circ$ ), to the total energy of the complex formation ( $\Delta G_{\text{total}}^\circ$ ). If  $\Delta G_{\text{coord}}^\circ$  for complex **66** in CH<sub>2</sub>Cl<sub>2</sub> is 15 kJ mol<sup>-1</sup>,  $\Delta G_{\text{H-bond}}^\circ$  varies from -1 to -6 kJ mol<sup>-1</sup> depending on the amino acid. As regards aliphatic amino esters, those containing bulky side groups bind preferentially to the porphyrin: the absolute value of  $\Delta G_{\text{H-bond}}^\circ$  is the highest for L-leucine (-6.2 kJ mol<sup>-1</sup>) and the lowest for glycine (-0.8 kJ mol<sup>-1</sup>).<sup>61, 63</sup> Although the  $K_a$  values of aliphatic

and aromatic amino acids (phenylalanine and tryptophan) to metalloporphyrin **66** are commensurable, higher  $K_a$  values of the latter are due to additional  $\pi$ - $\pi$  interactions rather than to the formation of hydrogen bonds.

The relationship between the position of the hydroxy groups in the benzene rings and the ability of arylporphyrins to recognise L-leucine methyl ester has been studied.<sup>65</sup> A comparison of arylporphyrins with hydroxy groups in the *ortho*-, *meta*- and *para*-positions of the benzene rings has shown that only porphyrins containing hydroxy groups in the *ortho*-positions form hydrogen bonds with this amino acid ( $\Delta G^\circ$  = from -1 to -1.4 kJ mol<sup>-1</sup>).

The hydroxy groups in the porphyrin receptor **69** are arranged on both sides of the macrocycle plane.<sup>66</sup>

**69**

Dimethyl aspartate has the highest  $K_a$  value ( $6.9 \times 10^4$  litre mol<sup>-1</sup>) (two CO<sub>2</sub>Me groups form hydrogen bonds with the OH groups on the periphery of the macrocycle); the value of the binding constant for the leucine methyl ester is four times as low ( $1.8 \times 10^4$  litre mol<sup>-1</sup>).

'Host-guest'<sup>67</sup> interactions are widely used for the chiral recognition of optically active amino acids. In addition to two binding points, porphyrin receptors responsible for the chiral recognition of amino acids should create steric hindrance against interaction of certain groups of the receptor with the side substituents of the ligands. Such steric hindrance results from the limitation of rotational freedom upon 'bicentred' binding. The energy of chiral recognition,  $\Delta\Delta G_{\text{DL}}^\circ$ , is defined as the difference between the binding energies of the L- and D-enantiomers:  $\Delta\Delta G_{\text{DL}}^\circ = \Delta G_{\text{D}}^\circ - \Delta G_{\text{L}}^\circ$ . An exhaustive description of porphyrins capable of chiral recognition of amino acids is given in a review.<sup>3</sup> The chiral recognition energies of the porphyrin receptors **70-73** are listed in Table 5.

In the case of porphyrin **70**, steric hindrance is created by methyl acetate groups at positions 2 and 6 of the benzene ring. If at least one ester or hydroxy group is missing, the receptor loses the ability for chiral recognition.<sup>73, 74</sup>

**70**

In the 'strapped' porphyrin **71**, steric hindrance is created by the nitrophenyl groups present in the bridges.<sup>69, 75</sup> Porphyrin **71** manifests intrinsic chirality due to its C<sub>2</sub> molecular symmetry and can therefore distinguish optically active amino acids. The leucine methyl ester enantiomers manifest the highest values of  $\Delta\Delta G_{\text{DL}}^\circ = -5.28$  kJ mol<sup>-1</sup> in CH<sub>2</sub>Cl<sub>2</sub>.

**Table 5.** Energies of chiral recognition of amino acids by porphyrin receptors.

<sup>a</sup> The data were obtained by spectrophotometric titration.

The paper by Konishi *et al.*<sup>70</sup> is devoted to the recognition of *N*-benzyloxycarbonyl-substituted amino acids by the *N*-methylporphyrin receptor **72**. The role of three binding elements responsible for chiral recognition is played by the coordination of the carboxylate anion to the Zn(II) cation, the hydrogen bond between the amide group of the porphyrin and the substituted amino group of the amino acid and the steric interactions between the side substituents of the amino acid molecule and the ‘strapping’ ligand of the porphyrin.

This receptor **72** also possesses high energy in the chiral recognition of polyglutamic acid<sup>71</sup> due to the interaction between the Zn(II) cation and the  $\gamma$ -carboxy group of the ligand.

The enantioselective recognition of histidine esters by the bisporphyrin receptor **73** possessing a chiral cavity with a rigid structure, occurs due to the binding of two central zinc atoms to two basic nitrogen atoms of the amino acid and the steric interactions between the cavity walls and the side group of the

amino acid. The difference between the free binding energies for the two diastereomeric complexes ( $\Delta\Delta G_{\text{DL}}^{\circ} = -6.4 \text{ kJ mol}^{-1}$ ) exceeds the corresponding values for the complexes of the porphyrin receptors **70** and **71** with neutral amino acid derivatives. At the same time, the formation of less stable complexes between lysine benzyl ester and the dimeric porphyrin **73** and lesser enantioselectivities of recognition are due to the greater flexibility of the side chain linking two nitrogen atoms in the ligand molecule.

Chiral recognition of amino acid esters was the subject of an investigation<sup>76</sup> in which porphyrin **19** was used as a receptor. The  $\Delta\Delta G_{\text{DL}}^{\circ}$  values for serine and threonine derivatives in CD<sub>2</sub>Cl<sub>2</sub> were equal to 6.3 and 8.2 kJ mol<sup>−1</sup>, respectively.

The ability of porphyrin receptors to recognise purine bases was studied using porphyrin complexes with Rh(III) and Zn(II) as examples. Porphyrin complexes with Rh(III) possessed very high affinities for heterocyclic bases, especially for adenine. For example, Rh(III) *meso*-tetraphenylporphinate binds 9-ethyladenine in CH<sub>2</sub>Cl<sub>2</sub> with  $K_a \sim 10^6 \text{ litre mol}^{-1}$ , which suggests that the binding was irreversible.<sup>77</sup> 9-Ethyladenine is coordinated to the Rh(III) ion of the metalloporphyrin through the N(1)-atom as can be judged from X-ray spectroscopic data.<sup>62</sup> Unlike the case of Rh(III)-containing porphyrins, the coordination of heterocyclic bases to Zn(II)–porphyrin complexes is reversible. The  $K_a$  values for the Zn(II)–porphyrin–purine base complexes (1 : 1) lie in the range  $10^2$ – $10^4 \text{ litre mol}^{-1}$  (see Ref. 78).

Porphyrins containing two hydroxy groups on one side of the macrocycle form complexes **74** with adenine. In these complexes,

one adenine molecule is coordinated to the central metal cation of the tetrapyrrolic fragment, while the second one binds to the hydroxy groups of the naphthalene substituents.

Such porphyrins are usually referred to as ‘bidentate’ complexes; their  $K_a$  values are several orders of magnitude higher.<sup>78</sup>

In complexes of Zn-containing porphyrins **19**, **69** and **75** with carbohydrates, the hydroxy groups of the sugars bind to the zinc cation of the coordination centre of the porphyrin and to heteroatoms of the peripheral substituents.<sup>79–84</sup> The  $K_a$  values of some carbohydrate–porphyrin complexes are presented in Table. 6.

In addition to zinc complexes, the ability to recognise sugars is also inherent in some free porphyrin bases. Thus Král *et al.*,<sup>85–87</sup> demonstrated that porphyrin receptors containing 1,1-binaphthol

substituents **76** and cyclic cryptand–porphyrin conjugates **77** are especially efficient in aqueous media.

R = Me (a), H (b).

X = (CH<sub>2</sub>)<sub>6</sub>, Y = CO(CH<sub>2</sub>)<sub>4</sub>CO.

The keen interest of investigators in donor–pigment–acceptor ternary systems as valuable tools for the study of individual photosynthetic steps has culminated in the appearance of a large

**Table 6.** Binding constants of various sugars by porphyrin receptors.

Chemical reaction scheme showing the synthesis of Zn complex 78. The starting material is a macrocyclic ligand with four methyl-substituted pyrrole rings, two phenyl rings, and a phthalate ester group. It reacts with  $\text{Zn}(\text{OAc})_2$  to form the Zn complex 78, where the zinc ion is coordinated by the four nitrogen atoms of the pyrrole rings in a square planar geometry.

**Abstract.** The principal achievements and the modern trends in the development of the chemistry of elemental phosphorus are analysed, described systematically and generalised. The possibilities and advantages of the preparation of organophosphorus compounds directly from white phosphorus are demonstrated. Attention is focused on the activation and transformation of elemental phosphorus in the coordination sphere of transition metal complexes. The mechanisms of the reactions of white phosphorus with nucleophilic and electrophilic reagents are discussed. Electrochemical approaches to the synthesis of organic phosphorus derivatives based on white phosphorus are considered. The bibliography includes 251 references.

## I. Introduction

The extensive use of organic derivatives of phosphorus in various branches of industry imposes certain requirements on the methods of their preparation. Until recently, phosphorus chlorides and their derivatives (oxy- and thiochlorides) have served as the main starting reagents for the synthesis of compounds containing an organic substituent at a phosphorus atom. Industrial methods for the production of organophosphorus compounds (OPC) by direct chlorination of white phosphorus and by substitution of organic ligands for the chlorine atoms suffer from a number of serious drawbacks. The first one is evolution of large amounts of hazardous and corrosive wastes (hydrogen chloride, alkyl halides, *etc.*), which damage the process equipment and are harmful for the environment. Modern requirements for environmental safety of industrial plants dictate the need to develop OPC production processes free from the chlorination stage. This has attracted attention to the chemistry of elemental phosphorus.

The search for highly efficient methods for the synthesis of OPC from elemental phosphorus, long carried out in scientific centres of the world, has resulted in the discovery of a large

number of new reactions. The chemical behaviour of phosphorus with respect to reagents of different nature was investigated.

Elemental phosphorus has two allotropes, white and red phosphorus. The white phosphorus molecule is a P<sub>4</sub> tetrahedron with a P–P bond length of 2.21 Å. The ring strain and the presence of vacant p orbitals and a lone pair at each P atom account for its high reactivity. Red phosphorus has a planar layered polymeric structure; therefore, it is chemically more inert than white phosphorus.

In many cases, reactions involving white and red phosphorus are of the same type, although they differ in their rates and conditions of conduction. For this reason, we consider them in the same review. It should be noted, however, that irregularities in the polymeric structure of red phosphorus hamper investigation of the mechanisms of its reactions and identification of intermediates, whereas the molecular structure of white phosphorus unambiguously indicates that its reactions would require cleavage of the P<sub>4</sub> tetrahedron. This permits one to predict the structures of intermediates and to control the process.

In the last 15 years, phosphorus chemistry has undergone a qualitative change. The line of research dealing with methods for activating white phosphorus in the coordination sphere of transition metal complexes has been developed most appreciably. Meanwhile, the existing reviews dealing with the chemistry of elemental phosphorus<sup>1–12</sup> consider only particular aspects and give no general view of the new trends in this field of chemistry. We have attempted to generalise and analyse the information on the chemistry of elemental phosphorus published in recent years from modern standpoint.

This review considers the reactions of elemental phosphorus that take place under relatively mild conditions. In these reactions, intermediates can be detected and, in some cases, even isolated, which provides information on the reaction mechanisms. Attention is concentrated on the chemical behaviour of white phosphorus towards organic transition metal complexes. This is one of the most convenient and promising approaches to investigating the transformation routes of the P<sub>4</sub> molecule. Determination of the structures of the intermediates underlies the development of new catalytic processes for the preparation of organophosphorus compounds directly from white phosphorus. This study considers the reactions of white phosphorus with organic and organometallic compounds from a unified standpoint, which clearly demonstrates the relationship between various fields of chemistry. A special section is devoted to reactions of white phosphorus with organic substrates under electrochemical activation, which is a promising method for the preparation of organophosphorus compounds from elemental phosphorus under mild conditions.

## II. Activation and transformations of a white phosphorus molecule in a metal coordination sphere

Despite certain progress in the study of the mechanisms of OPC formation from white phosphorus, these reactions have not been fully investigated as yet. The search for and the development of new methods for the preparation of phosphorus-containing derivatives are based on the elucidation of the rules of cleavage of the  $P_4$  molecule and the factors governing the formation of new compounds (including the structures and transformation pathways of the intermediates). This task is complicated by the high reactivity of white phosphorus and the instability of intermediates formed. In addition, the transformations of  $P_4$  into the target products require fairly drastic conditions.

For the correct interpretation of data on the structures and chemical properties of phosphorus intermediates, one can use the isolobal analogy principle,<sup>13</sup> which is the key link<sup>14</sup> and a sort of 'bridge between organic and inorganic chemistry and, hence, supports the continuity of chemistry as a whole'.<sup>15</sup> According to this principle, 'two fragments are isolobal if the number, symmetry properties, approximate energy and shape of the frontier orbitals, and the number of electrons in them are similar — not identical but similar'.<sup>13</sup> Thus, the phosphorus atom is isolobal to the CH fragment, which allows one to draw analogies between the usual organic compounds and the phosphorus fragments formed upon transformation of a white phosphorus molecule.

Study of the behaviour of the white phosphorus molecule in the coordination sphere of transition metal complexes is a promising approach that allows one to clarify the complex processes of opening of the initial  $P_4$  molecule and OPC formation. The transition metal atom acts as a sort of stabiliser for all phosphorus intermediates, ranging from the simple phosphide anion to complex phosphorus oligomers  $P_n$  containing up to 14 phosphorus atoms. The reactions of these complexes with other transition metal derivatives and with organic compounds may underlie the design of production processes of organic and organoelement phosphorus compounds directly from elemental phosphorus.<sup>7,8</sup>

Researchers who try to classify the reactions of white phosphorus with transition metal complexes are faced with the problem of identification of the diverse products formed in this seemingly simple reaction. Here we try to avoid the classifications used previously. Cleavage of the  $P_4$  tetrahedron is considered from the standpoint of a relationship between the structures of the initial complex (the electronic structure of the metal, the presence of vacant and latent coordination sites, and the ligand nature and stereochemistry) and the phosphorus intermediates stabilised in the metal coordination sphere. In our opinion, by using this approach, one can consider more comprehensively the activation of white phosphorus in the metal coordination sphere and identify the factors that determine the structure of the phosphorus fragment in the metal complex formed.

### 1. Derivatives of Group IVB metals (Ti, Zr, Hf)

The chemical behaviour of white phosphorus towards Group IVB metal derivatives has been little studied. A probable reason for this is the low stability of the complexes formed, which can be attributed, from the standpoint of the hard and soft acid–base (HSAB) theory,<sup>16</sup> to the low affinity of the phosphorus atom (soft base) for Group IVB metal atoms (soft acids).

The reaction of white phosphorus with zirconium or hafnium bis(cyclopentadienyl)dicarbonyl complexes occurs *via* elimination of two carbonyl ligands, giving rise to bicyclo[1.1.0]tetraphosphabutane **1** stabilised in the metal coordination sphere.<sup>17</sup> The yields of complexes **1** are nearly quantitative.

$M = \text{Zr, Hf}; R = \text{Bu}^t, 1,3\text{-Bu}_2^t.$

In the case of the bis(pentamethylcyclopentadienyl) titanium derivative, the reaction requires more drastic conditions.<sup>18</sup> Elimination of not only the CO groups but also one pentamethylcyclopentadienyl ring takes place. This gives a triple-decker compound of titanium **2** containing a  $\mu, \eta^3, \eta^3$ -distorted hexaphosphacyclohexane in the chair conformation (yield 19%). Note that the change in the structure of the phosphorus ligand is directly related to the change in the titanium coordination number.

$\text{Cp}^*$  is pentamethylcyclopentadienyl.

The structure of the phosphorus fragment also depends on the coordination environment of the metal. The replacement of the carbonyl groups in the zirconium dicyclopentadienyl complex by phosphide groups switches the route of reactions with white phosphorus, which now give under mild conditions, instead of complexes **1**, metal complexes **3** with basically different phosphorus ligands.<sup>19</sup> The reaction pathway considered by the authors includes the activation of white phosphorus *via* complexation to a coordinatively unsaturated zirconium atom and the subsequent double intramolecular rearrangement.

An X-ray diffraction study has shown that the P–P bond length in the cyclo- $P_3$ -fragment of complex **3**, equal to 2.213 Å, differs little from the bond length in the  $P_4$  molecule.

Thus, it can be seen from the above examples that in the reactions of white phosphorus with transition metal complexes, the nature of the ligands has a substantial influence on the structure of the phosphorus fragment formed.

### 2. Derivatives of Group VB metals (V, Nb, Ta)

The outcome of the reactions of white phosphorus with (cyclopentadienyl)carbonyl derivatives of vanadium group metals is a vivid example demonstrating the dependence of the structure of the polyphosphorus fragments stabilised in the metal coordination sphere on the process conditions.<sup>20–22</sup> For example, photochemical substitution of the carbonyl groups in compounds **4a–c**

by a white phosphorus molecule yielded a product mixture which was separated by column chromatography to give organometallic tetraphosphacyclobutane derivatives **5a–c**. In the case of vanadium, the reaction did not stop at this stage but proceeded to give binuclear complex **6a**. It is of interest that the reaction of  $P_4$  with tantalum 1,3-di-*tert*-butylcyclopentadienyl complex followed a more complicated route, resulting in a polynuclear complex  $[(Cp''Ta)_3(\mu_3-P_4)(\mu_3-P_2)]$  ( $Cp''$ , 1,3-di-*tert*-butylcyclopentadienyl).<sup>22</sup>

According to X-ray diffraction, the phosphorus atom in niobium complex **5b** is slightly disordered; this should be considered as the initial stage of decomposition of the  $P_4$ -ring into  $P_3$ - and  $P_1$ -fragments.

The same reactions carried out under thermolysis conditions (refluxing in xylene, 16 h) result in a different structure of the phosphorus ligands formed. The triple-decker compounds **7a,b** containing cyclo- $P_6$ , isolobal to benzene, as the central fragment were formed as the major products in the reaction of complexes **4a,b** with white phosphorus.<sup>15, 17, 20, 23</sup>

The  $^{51}V$  NMR spectrum of vanadium derivative **7a** exhibits a septet with the spin–spin coupling constant  $^1J(^{51}V^{31}P) = 56$  Hz, which confirms the structure of the complex.

### 3. Derivatives of Group VIB metals (Cr, Mo, W)

The reactions of cyclopentadienylcarbonyl complexes formed by chromium group metals with white phosphorus are most studied. A number of research groups have detected various phosphorus intermediates stabilised in the metal coordination sphere. For example, the reaction of organometallic compounds **8** with white phosphorus yields a mixture of transition metal complexes **9** and **10**, containing  $\mu, \eta^2$ -diphosphorus and  $\mu^3$ -triposphacyclopentane ligands, respectively.<sup>23–25</sup>

According to the isolobal analogy theory, both compounds represent a  $P_4$  molecule in which one or two phosphorus atoms

have been replaced by a 15-electron organometallic fragment  $[P \leftrightarrow M(CO)_3]$ . The tungsten alkoxide complex **11**, containing a  $\mu, \eta^2$ -coordinated diphosphine as an additional ligand, was prepared using diphosphine transfer from cobalt derivative **12**. The reaction takes place under mild conditions to give the target product in a high yield.<sup>26</sup>

However, the direct introduction of white phosphorus into the reaction with tungsten alkoxide results in metal complex **13**, containing a  $\eta^3$ -triposphacyclopentane fragment.<sup>27, 28</sup>

The change in the electronic state of tungsten on passing from cationic to neutral complexes and the appearance of bulky ligands both influence the structure of the phosphorus fragment formed. At low temperatures, coordinatively unsaturated tungsten and molybdenum complexes **14** form derivatives **15** containing an intact molecule of white phosphorus.<sup>29</sup>

$M = W$ ;  $R = cyclo-C_6H_{11}$  (Cy),  $Pr^i$ ;  $M = Mo$ ;  $R = Cy$ .

The structure of complexes **15** has only been proved<sup>29</sup> by  $^{31}P$  NMR spectroscopy as these compounds are stable only in toluene at a temperature below  $-40^\circ C$ .

Thermolysis of white phosphorus in the presence of bis(cyclopentadienyl)dicarbonyldichromium **16a** affords a 27-electron triple-decker paramagnetic ( $\mu = 2.07 \mu_B$ ) chromium complex **17**, containing a  $\mu, \eta^5$ -pentaphosphacyclopentadienyl ligand.<sup>30</sup>

$R_n = Me_5, Bu^t$ .

A cyclic voltammetry study of the electrochemical properties of compounds **17** has shown that they can be either reversibly reduced ( $E_{red} = -0.97$  V) or reversibly oxidised ( $E_{ox} = 0.07$  V). For preparative purposes, ferrocenium derivatives  $[Cp_2Fe]^+$  have been proposed as the oxidants.<sup>31</sup>

Thermolysis of white phosphorus in the presence of similar molybdenum and tungsten derivatives **16b,c** is also accompanied by the elimination of all carbonyl groups, and gives 28-electron triple-decker complexes **18**, containing hexaphosphabenzene as a ligand.<sup>23, 32–34</sup>

According to quantum-chemical data obtained for the model compound  $[\text{CpMoP}_6\text{MoCp}]$ ,<sup>35</sup> the optimal number of valence electrons for this complex is 28. For this reason, complexes **18** are distinguished by high thermal stability and resistance against oxidation by air oxygen.

Scheer *et al.*<sup>36</sup> have proposed a method for investigation of the mechanism of  $P_4$  cleavage. The method consists of conducting the reactions with organometallic compounds in the presence of labile metal complexes [as a rule,  $\text{Cr}(\text{CO})_5(\text{THF})$ ]. This method was successfully used to study the reactions of white phosphorus with the molybdenum dimer  $[\text{Cp}^R\text{Mo}(\text{CO})_3]_2$  (**16c**) (hereinafter  $\text{Cp}^R$  designates a cyclopentadienyl fragment containing an R substituent).<sup>36</sup> Heating a mixture of reactants in THF affords polynuclear complex **19a**, containing a distorted tetraphosphacyclobutane fragment. It is noteworthy that this complex and similar tungsten derivative **19b** were prepared previously by the photolysis of a mixture of white phosphorus and metal hexacarbonyl (of chromium or tungsten, respectively).<sup>37, 38</sup>

The photochemical reaction of dimer **16c** with white phosphorus in the presence of  $\text{Cr}(\text{CO})_5(\text{THF})$  (UV irradiation) yielded compound **20**, containing a  $P_2$  fragment, and unusual complex **21**. The formation of the P–H bond in the latter compound was interpreted<sup>36</sup> as being due to hydrolysis of the Mo–P bond by traces of water. The modelling of the last-mentioned reaction for a white phosphorus molecule and chromium compound **16a** (R = H) in the absence of other chromium derivatives resulted in the formation of two tetrahedral chromium complexes, **22** (with the composition  $[\{\text{CpCr}(\text{CO})_2\}_2(\mu, \eta^{2:2}\text{-P}_2)]$  similar to molybdenum derivative **20**) and **23**  $[\{\text{CpCr}(\text{CO})_2(\eta^3\text{-P}_3)]$  with the cyclo- $P_3$  fragment as the ligand), and polynuclear phosphorus-containing complex **24**.<sup>24, 39</sup>

Thermolysis of this mixture furnished a triple-decker chromium complex **17** (R = H), containing a pentaphosphacyclopentadienyl ligand.<sup>30</sup> This reaction clearly demonstrates the ability of the phosphorus atom to form complex oligomers. Also noteworthy are the difficulties that arise in the studies of multi-component reaction mixtures formed in the reactions of white phosphorus with transition metal derivatives.

#### 4. Derivatives of group VIIB metals (Mn, Re)

The chemical transformations of white phosphorus under the action of manganese group metal derivatives have been little studied. Only two examples have been described in the literature.<sup>40, 41</sup> The rhenium carbonyl complex **25** with a bulky 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) ligand reacts with white phosphorus under mild conditions to give charged rhenium compound **26**, containing an intact  $P_4$  molecule as a ligand. The properties of the molecule are typical of trivalent phosphorus derivatives.<sup>40</sup> The  $P_4$  ligand in complex **26** is coordinated by rhenium and ruthenium derivatives under mild conditions, giving rise to homo- and heterobinuclear complexes **27a–c**,<sup>41</sup> which also contain a  $P_4$  ligand.

The formation of binuclear complexes **27** was demonstrated by  $^{31}\text{P}$  NMR spectroscopy. Indeed, without additional splitting from NMR-active phosphorus or metal nuclei, complexes with a  $P_4$  ligand exhibit a well-resolved  $AB_3$ -system. The signal of the  $P_\alpha$  atom shifts by 200–250 ppm, whereas the position of the signal from  $P_\beta$  almost coincides with that for the free white phosphorus molecule.

[M] = (triphos)Re(CO)<sub>2</sub>(OTf) (**a**), Cp\*Re(CO)<sub>2</sub> (**b**), Cp\*Ru(PEt<sub>3</sub>)<sub>2</sub>(OTf) (**c**).

It has been suggested<sup>42</sup> that transition metal complexes containing an intact  $P_4$  molecule as a ligand are stable only when bulky ligands are present near the metal atom. The change in the ligand environment of rhenium changes the structure of the final reaction products. The reaction of white phosphorus with the 16-electron intermediate  $Cp^*Re(CO)_2$ , generated from the corresponding dimer **28**, gives a mixture of rhenium complexes **29** and **30**, differing in coordination number and, hence, in the type of coordination of the  $P_2$  ligand.<sup>43,44</sup>

Thus, these examples demonstrate the important role of steric factors for realising of a particular route of transformation of white phosphorus in the presence of transition metal complexes.

## 5. Derivatives of Group VIIIB metals

Published data on the reactions of white phosphorus with group VIIIB metal derivatives are very abundant. The ready availability of the initial compounds, the ease of processing and the stability of the final products are the factors that lead to success in these studies. Almost all types of phosphorus intermediates resulting from cleavage of the  $P_4$  tetrahedron followed by aggregation of the phosphorus species have been stabilised in the coordination sphere of Group VIIIB metals. These complexes were isolated and characterised by various physicochemical methods. In addition, Group VIIIB metals allowed researchers to demonstrate the relationship between the structure of the starting metal complexes (the presence of vacant coordination sites, steric and electronic characteristics of the ligands) and the structure of the metal-coordinated phosphorus fragments.

### a. Iron group metal derivatives

As noted above, the  $P_4$  molecule can act as a  $\eta^1$ -ligand when bulky ligands are present in the metal atom environment.<sup>41</sup> The first binuclear complex **31**, containing a  $\eta^1$ - $P_4$  ligand, has been prepared<sup>45</sup> in a study of the hydrogenation of white phosphorus in the presence of a homogeneous catalyst, bis(triphenylphosphine)ruthenium(II) chloride.

The poor solubility and the low stability of compound **31** precluded<sup>45</sup> its full characterisation; only its  $^{31}P$  NMR spectrum was reported.

Thermolysis of a mixture of white phosphorus and iron carbonyl  $Fe_2(CO)_9$  results in partial decarbonylation. Four phosphorus–phosphorus bonds are cleaved during the reaction. This gives cluster **32** containing two separated  $P_2$  fragments.<sup>46</sup>

The most important and interesting results were obtained for the reactions of white phosphorus with cyclopentadienylcarbonyl complexes of iron group metals. The study by Scherer *et al.*<sup>47</sup> made a significant contribution to investigations of the activation of white phosphorus in the coordination sphere of transition metals and the mechanism of  $P_4$  cleavage. This study is devoted to the transformations of white phosphorus under the action of binuclear (cyclopentadienyl)carbonyliron complexes  $[Cp^RFe(CO)_2]_2$ , which contain sterically crowded ligands. It was shown that photolysis of  $[Cp''Fe(CO)_2]_2$  ( $Cp''$  is 1,3-di-*tert*-butylcyclopentadienyl) yields two 17-electron  $Cp''Fe(CO)_2$  fragments, and one  $P-P$  bond in the  $P_4$  molecule is cleaved to give complex **33a** with the composition  $[Cp''Fe(CO)_2]_2(\mu, \eta^{4,1}-P_4)$ . This complex loses one carbonyl group under the reaction conditions, being converted into the binuclear adduct **34a**, whose formula is  $\{Cp''Fe(CO)_2\}[\{Cp''Fe(CO)\}(\mu, \eta^{1,2}-P_4)]$  and in which the geometry of the  $P_4$  ligand is essentially preserved. The subsequent photochemical elimination of CO affords a 13-electron iron complex **35a**, in which the metal atom is easily inserted into the phosphorus–phosphorus bond to give a sandwich type complex **36a** with an almost planar five-membered  $P_4Fe$  ring. The elimination of a CO ligand from complex **36a** induces an intramolecular rearrangement of the  $FeP_4$  ring into triple-decker complex **37a**,  $[\{Cp''Fe\}_2(\mu, \eta^{4,4}-P_4)]$ , in which the tetraphosphabutane fragment is connected to two equivalent  $\{Cp''Fe\}$  residues.

(a) *hν*; (b) toluene, 110 °C, 2 min; R = 1,3- $Bu_2^t$  (a), 1,2,4- $Bu_3^t$  (b).

The structure of the binuclear complex **33**, containing bicyclo[1.1.0]tetraphosphabutane as the ligand and first proposed on the basis of spectroscopic data,<sup>47–49</sup> was recently proved by the X-ray diffraction of **33b** ( $R_n = 1,2,4\text{-Bu}_3^1$ ). It has been shown<sup>50</sup> that the process considered above can be terminated after the formation of compound **33** by introducing one more *tert*-butyl substituent into the cyclopentadienyl ring of the initial complex. In this case, the reaction with white phosphorus proceeds in toluene on heating to 110 °C over a period of 2 min. The resulting binuclear complex **33b** can react with excess white phosphorus at 190 °C to give 1,2,4-tri-*tert*-butylpentaphosphaferrocene **38b**.<sup>51</sup> Under these conditions, compound **33b** and diphenylacetylene form sandwich iron complex **39**, in which one ligand is 4,5-diphenyl-1,2,3-triphenylphosphacyclopentadiene, an isolobal analogue of the cyclo-P<sub>5</sub> ligand. In the last-mentioned reaction, polynuclear phosphorus-containing complex **40** was also isolated as a side product.

The introduction of five methyl substituents instead of the *tert*-butyl groups into the cyclopentadienyl ring of the initial Fe complex changes crucially the process route. Thermolysis of a mixture of white phosphorus and bis(pentamethylcyclopentadienyl)dicarbonyliron [ $\text{Cp}^*\text{Fe}(\text{CO})_2$ ]<sub>2</sub> in xylene affords pentamethylpentaphosphaferrocene  $\text{Cp}^*\text{FeP}_5$  in ~15% yield. This reaction has become an important stage of development of the organometallic chemistry of highly reactive phosphorus intermediates.<sup>52, 53</sup>

Raising the reaction temperature to 190 °C increased the yield of the target product **38c** to 80%.<sup>54</sup> The ruthenium and osmium sandwich compounds containing a pentaphosphacyclopentadienyl fragment were obtained in moderate yields on heating complex **38c** with bis(pentamethylcyclopentadienyl)dicarbonylmetals [ $\text{Cp}^*\text{M}(\text{CO})_2$ ]<sub>2</sub> ( $M = \text{Ru, Os}$ ) at 220–250 °C.<sup>55</sup>

## b. Derivatives of cobalt group metals

As shown above, transition metal complexes containing an intact P<sub>4</sub> molecule are stable only in the presence of bulky ligands at the metal atom.<sup>42</sup> Derivatives of cobalt and rhodium hydrides with the tris[2-(diphenylphosphino)ethyl]phosphine ligand are convenient starting compounds for the preparation of complexes containing a P<sub>4</sub> molecule. The reductive elimination of the hydride ion on treatment with methyltrifluoromethanesulfonate (MeOTf) affords a coordinatively unsaturated intermediate, which coordinates white phosphorus under mild conditions giving rise to cationic complexes **41a,b**, containing an intact P<sub>4</sub> molecule.<sup>56, 57</sup>

Like W and Mo derivatives, complexes **41a,b** are stable only at low temperatures (< –40 °C).

The use of transition metal complexes containing other phosphines as ligands in reactions with white phosphorus results in the generation of diverse phosphorus fragments which can be stabilised in a metal coordination sphere. For example, in the presence of bis(diphenylphosphino)methane, the aqua complexes of  $\text{Co}(\text{BF}_4)_2$  are converted into mononuclear complex **42**, containing an unusual P<sub>6</sub> ligand formed by four phosphorus atoms of the P<sub>4</sub> molecule and two phosphorus atoms of the phosphine.<sup>58</sup>

An X-ray diffraction study of complex **42** has shown that all atoms of the P<sub>4</sub> fragment are coordinated to cobalt. The phosphorus–phosphorus bond lengths are 2.17–2.19 Å, *i.e.*, they are shorter than the bond length in P<sub>4</sub> (2.21 Å).

The introduction of 1,1,1-tris(diphenylphosphinomethyl)ethane into this reaction results in cobalt compounds **43**, containing a cyclo-P<sub>3</sub> fragment.<sup>59</sup>

Cobalt complexes containing similar phosphorus ligands are also formed on treatment of white phosphorus with dicobalt octacarbonyl.<sup>60, 61</sup>

Using complex **43**, it has been demonstrated that a phosphorus–carbon bond can be formed in these systems by treatment with trimethylxonium tetrafluoroborate, resulting in the methylation of one phosphorus atom; the structure of the triphosphacyclopentane fragment remains unchanged.<sup>62</sup>

A scheme for the formation of the cyclo- $P_3$  fragment upon the destruction of  $P_4$  has been proposed after an investigation of the reaction of white phosphorus with rhodium and cobalt compounds.<sup>63,64</sup> It was shown that on treatment with rhodium complexes **44a,b** under mild conditions, the  $P_4$  tetrahedron is converted into an unusual  $\eta^{2:1}\text{-}P_4R$  ligand, which is stabilised in the coordination sphere of the metal. A similar Rh complex **45c** has been obtained from hydride derivative **44c**. The same transformations are known for iridium.

$R^1 = R^2 = \text{Me}$  (**a**),  $\text{Ph}$  (**b**);  $R^1 = \text{H}$ ,  $R^2 = \text{Et}$  (**c**).

These reactions are among the first examples of the formation of compounds with  $P\text{--}C$  bonds from white phosphorus by the participation of a metal complex; they also represent the first examples of metal-mediated direct transfer of an organic fragment to phosphorus coordinated as a tetrahedron. Hydrogenation of **45** yields alkylphosphine  $\text{PH}_2R$  and a stable non-reactive compound **46** containing the cyclo- $P_3$  ligand.<sup>42</sup>

$M = \text{Rh, Ir}$ ;  $L = \text{H}_2$ ,  $R = \text{H}$ ;  $L = \text{C}_2\text{H}_4$ ;  $R = \text{H, Me, Et, Ph}$ .

The generation of a highly reactive bicyclo[1.1.0]tetraphosphabutane and its subsequent stabilisation in a metal coordination sphere is observed in the reaction of  $P_4$  with Wilkinson's catalyst or other square planar  $\text{Rh(I)}$  or  $\text{Ir(I)}$  complexes.<sup>65,66</sup> At low temperatures, one triphenylphosphine molecule is eliminated to give rhodium complex **47** containing a  $\eta^2\text{-}P_4$  fragment.

This reaction can formally be considered as an oxidative addition of a white phosphorus molecule with a simultaneous increase in the rhodium coordination number.

The structure of (bicyclo[1.1.0]tetraphosphabutane)bis(triphenylphosphine)rhodium **47** was proved by X-ray diffraction. The  $\eta^2$ -coordination of the  $P_4$  fragment results in an increase in the  $P_\alpha\text{--}P_\alpha$  bond length to 2.4616 Å. This type of coordination was previously predicted theoretically by Albright *et al.*<sup>67</sup> for the model complex  $[(\text{PH}_3)_2\text{ClRhP}_4]$ , in which the  $\eta^2$ -coordination of

the  $P_4$  fragment proved to be 15 kcal mol<sup>-1</sup> more favourable than the  $\eta^1$ -coordination.<sup>67</sup> However, the computation data do not provide an unambiguous answer to the question of whether or not the structure of the white phosphorus molecule is retained or whether the oxidative addition takes place due to cleavage of the phosphorus–phosphorus bond.

On the basis of experimental data, one can conclude that the initial formation of bicyclo[1.1.0]tetraphosphabutane fragment is a general step in the opening of the white phosphorus molecule on treatment with transition metal derivatives. The formation of metal complexes is the result of the subsequent transformation of this intermediate and depends on the reaction conditions (first of all, on the reactant ratio). The  $\eta^2$ -coordination of the  $P_4$  fragment, arising from the cleavage of one  $P\text{--}P$  bond in the  $P_4$  tetrahedron of metal complex **48**, is observed upon reaction of the white phosphorus with (pentamethylcyclopentadienyl)carbonylcobalt  $[\text{Cp}^*(\text{CO})_2](\text{Co}=\text{Co})$ .<sup>68</sup> This reaction may also involve the simultaneous cleavage of two  $P\text{--}P$  bonds, giving rise to complex **49** with a bridging  $\mu, \eta^{2:2}$ -tetraphosphacyclobutane ligand. Note that complex **49** was obtained in 30% yield on treatment of compound **48** with an excess of the initial metal complex.<sup>68</sup>

On introduction of a similar mononuclear cobalt complex into the reaction with  $P_4$ , complete decarbonylation of the metal atom takes place, ultimately giving a series of compounds. The reaction affords both the complexes **50–53**, with highly reactive phosphorus ligands, and products of their further transformations containing  $P_8$ ,  $P_{10}$  and  $P_{12}$  type polyphosphorus fragments as ligands, compounds **54**, **55** and **56**, respectively (Scheme 1).<sup>69,70</sup> The latter were isolated from the reaction mixture in low yields (< 5%).

A similar chemical behaviour for white phosphorus was found in its joint thermolysis with rhodium and iridium complexes  $[\{\text{Cp}^*\text{M}(\text{CO})_n\}_m]$  ( $m + n = 3$ ;  $M = \text{Rh, Ir}$ ).<sup>17,68,71–76</sup>

A study of the reaction of  $P_4$  with rhodium derivatives has provided one more step towards understanding the cleavage of  $P\text{--}P$  bonds in metal coordination spheres and elucidating the relationship between the structures of the resulting phosphorus ligands and the initial metal complexes.<sup>17</sup> The thermolysis of white phosphorus in the presence of (tetramethylethylcyclopentadienyl)dibondylrhodium was found to give complex **57**, containing two non-equivalent rhodium atoms. The long-term heating of compound **57** induces the loss of CO, resulting in binuclear complex **58**, in which the  $P_4$  fragment splits into two  $P_2$  fragments stabilised by two rhodium atoms.

Scheme 1

$R_n = 1,3\text{-Bu}_2^1, 1,2,4\text{-Bu}_3^1, \text{Me}_3\text{Si}.$

Fuller information on the pathways of cleavage of the  $P_4$  molecule, resulting in one or another phosphorus ligand, has been gained from a study of the reaction of the cyclopentadienylcar-

bonyl complexes of cobalt group metals with white phosphorus in the presence of  $\text{Cr}(\text{CO})_5(\text{THF})$ . It has been found<sup>74, 77, 78</sup> that the process starts with the generation of bicyclo[1.1.0]tetraphosphabutane, which forms heteropolynuclear complexes of type **59a,b** with transition metal compounds. Analogous cobalt complexes have also been isolated in the absence of  $\text{Cr}(\text{CO})_5(\text{THF})$ .<sup>68</sup>

The decarbonylation of polynuclear complexes **59a,b** gives four types of coordination compound with a planar tetraphosphacyclobutane fragment, which has not been observed previously for cobalt group metals (Scheme 2). The product of the coordination of four  $\text{Cr}(\text{CO})_5$  molecules is the predominant product.

In complex **59a**, the bicyclo[1.1.0]tetraphosphabutane fragment is a 10-electron-donor ligand, which is its maximum value. In the case of iridium derivatives, in addition to complex **60**, the product of inserting the carbonyl group into the metal–phosphorus bond, compound **61**, was isolated quite unexpectedly (yield 58%).<sup>79</sup>

$R_n = \text{Me}_5, \text{Bu}^1, 1,3\text{-Bu}_2^1; \text{M} = \text{Co}, \text{Rh}, \text{Ir}.$

### c. Derivatives of nickel group metals (Ni, Pd, Pt)

Derivatives of nickel group metals containing a white phosphorus molecule as a ligand were the first representatives of metal complexes of this class.<sup>6, 7, 15, 80–85</sup> The  $[(\text{NR}_3)\text{M}(\eta^1\text{-P}_4)]$  complexes, where  $\text{NR}_3$  is tris(2-diphenylphosphinoethyl)amine,  $\text{M} = \text{Ni}$  (**62a**)<sup>86</sup> or  $\text{Pd}$  (**62b**),<sup>87</sup> were obtained in the late 1970s by Sacconi and co-workers, who studied the reactions of white phosphorus with nickel and palladium derivatives,  $[(\text{NR}_3)\text{M}]$ , which are strong Lewis acids.

The structure of nickel complex **62a**, relatively insensitive to oxidation in the solid state, was proved by X-ray diffraction,<sup>86</sup> which confirmed the presence of  $\eta^1$ -coordination of a phosphorus molecule to the metal. Due to coordination of only one phosphorus atom, the  $\text{P}_4$  tetrahedron is converted into a trigonal pyramid, which shows itself as a change in the  $\text{P}_\alpha\text{-P}_\beta$  and  $\text{P}_\beta\text{-P}_\gamma$  bond lengths (see below).

Changes in the steric and electronic parameters of ligands surrounding the nickel atom influence the route of the reaction between nickel complexes and white phosphorus. The reaction of  $\text{P}_4$  with nickel tetrafluoroborate in the presence of 1,1,1-tris(diphenylphosphinomethyl)ethane results in a cationic complex containing a cyclo- $\text{P}_3$  ligand.<sup>59</sup>

The transformation of a  $\text{P}_4$  molecule in the coordination sphere of a metal with a 15-electron configuration has been studied in relation to nickel (cyclopentadienyl)carbonyl complexes. Thermal activation of white phosphorus under the action of (cyclopentadienyl)carbonylnickel dimer results in the formation of a mixture of products containing sandwich-type 18-electron complex **63**, binuclear complex **64** with an open-chain  $\text{P}_4$  fragment, and two organometallic 'cubanes': **65** with separated  $\text{P}_4$  and  $\text{P}_1$  fragments and **66** with four  $\text{P}_1$  fragments.<sup>88, 89</sup> Complex **65** is the major product of this reaction (yield 58%).

In order to elucidate the mechanism of complexation of  $[\text{Cp}^R\text{Ni}(\text{CO})_2]$ , this reaction was investigated in the presence of a pentacarbonyl chromium complex. Exposure of the reaction mixture to the UV light afforded complex **67**, containing the tetraphosphacyclobutane ligand in an unusual distorted square conformation (Scheme 3).<sup>90, 91</sup> Owing to the additional stabilisation by bulky  $\text{Cr}(\text{CO})_5$  fragments, intermediate **67** was isolated and studied.<sup>90</sup>

It was found that further photolysis of complex **67** was accompanied by elimination of chromium hexacarbonyl and the simultaneous rupture of one  $\text{P-P}$  bond of the tetraphosphacyclobutane fragment, giving rise to complex **68** with an open-chain  $\text{P}_4$  substituent. Heteropolynuclear nickel complexes **69** and **70**, containing cyclo- $\text{P}_3$  and  $\text{P}_2$  ligands, respectively, were isolated as

Scheme 3

the minor products. The formation of complex **70** was attributed<sup>90</sup> to the dimerisation of the highly reactive intermediate  $[\text{Cp}^*\text{Ni}\equiv\text{P}\rightarrow\text{Cr}(\text{CO})_5]$ .

Thermolysis of complex **67** can also yield compound **68**. This rearranges at high temperature to cubane **71** with separated  $\mu_3\text{-P}$  and tridentate  $\text{P}_4$  ligands.<sup>90</sup>

It has been noted above that the stabilisation of  $\text{P}_3$  or  $\text{P}_4$  fragments in the coordination sphere of transition metals is possible only in the presence of bulky ligands (*e.g.*, triphos) at the metal atom. The stabilising role of the  $\text{Cr}(\text{CO})_5$  group has also been found for platinum derivatives containing a  $\text{P}_4$  ligand in the coordination sphere.

The oxidative addition of white phosphorus to platinum(0) complexes in the presence of  $\text{Cr}(\text{CO})_5(\text{THF})$  allowed the preparation of compound **72**, in which the bicyclo[1.1.0]tetraphosphabutane fragment acts as a  $\text{P}_4^{2-}$  ligand, stabilised *via* coordination to two  $[\text{Cr}(\text{CO})_5]$  groups.<sup>92</sup>

Thus, the route of cleavage of the  $\text{P}_4$  tetrahedron has been elucidated as a result of studies into the transformations of a white phosphorus molecule under the action of transition metal complexes, and into the structures of phosphorus intermediates thus generated and stabilised in metal coordination spheres (Table 1). In addition, factors responsible for the formation of particular types of phosphorus species were revealed.

In summary, one can represent the general scheme of cleavage and subsequent transformation of the white phosphorus molecule in the coordination sphere of a transition metal. The presence of four lone electron pairs (LEP) in the initial molecule accounts for the formation of complexes containing a  $\text{P}_4$  fragment at the metal atom. When additional bulky ligands (for example, triphos) are present, these complexes can be isolated in a pure state. A small steric bulk of ligands and additional vacant coordination sites at the metal atom dictate the pathway of  $\text{P}-\text{P}$  bond cleavage in  $\text{P}_4$  during its coordination to transition metal complexes, accompanied by the formation of bicyclo[1.1.0]tetraphosphabutane stabilised in the metal coordination sphere. The cleavage of the  $\text{P}-\text{P}$  bond in this product furnishes two types of phosphorus species, tetraphosphacyclobutadiene and triphosphacyclop propane. The rupture of  $\text{P}-\text{P}$  bonds in these intermediates yield a series of highly reactive phosphorus-containing fragments, many of which have also been stabilised in a metal coordination sphere. This pathway is simplified, as it does not include the aggregation processes of phosphorus intermediates. These processes afford complex polyphosphorus ligands  $\text{P}_n$  ( $n < 14$ ), which can also be isolated as complexes with transition metals.

The reactions of organic compounds with transition metal complexes containing  $\text{P}_n$  species ( $n \leq 4$ ) with unsubstituted phosphorus atoms as ligands have been barely studied as yet. These reactions result in  $\text{P}-\text{C}$  and  $\text{P}-\text{E}$  bonds (where  $\text{E} = \text{O}, \text{S}, \text{N}$ , *etc.*). This is undoubtedly a topical problem. The fact is that all complexes described in this Section are relatively stable. The use of these compounds as efficient catalysts of the reactions of white phosphorus with organic substrates implies the presence of coordinative or electronic unsaturation of the metal atom. Hence, less stable transition metal complexes with phosphorus intermediates should become objects of investigation. These complexes are expected to be highly reactive towards organic and organoelement substrates used for the synthesis of organophosphorus compounds directly from white phosphorus.

**Table 1.** Types of phosphorus species formed from the  $\text{P}_4$  tetrahedron and stabilised in a metal coordination sphere.

| Type of species | Examples of metal complexes |
|-----------------|-----------------------------|
|                 |                             |
|                 |                             |
|                 |                             |

|                 |                             |
|                 |                             |
|                 |                             |

### III. Reactions of white phosphorus with nucleophilic and electrophilic reagents

The reactions of elemental phosphorus with nucleophilic reagents have been studied in the most detail. Relying on abundant experimental data, Brown and Hudson<sup>93-97</sup> considered some theoretical aspects and rules for these processes. The phosphorus atoms in the  $\text{P}_4$  tetrahedron are known to exhibit weak nucleophilic properties, as was confirmed by quantum-chemical calculations.<sup>98</sup> This is attributable to the fact that the electron pair of each phosphorus atom is localised, in the first approximation, in the  $3s$  orbital, *i.e.*, it is arranged as a sphere around the nucleus. In the partially opened  $\text{P}_4$  structure, the phosphorus atoms become more nucleophilic. However, due to ring strain and the instability of the  $\text{P}-\text{P}$  bond, the atoms possess strong electrophilic properties. Attack at the  $\text{P}_4$  molecule by a nucleophilic reagent ( $\text{Nu}^-$ ) yields the phosphide anion **73**, which is both a strong nucleophile and strong base:<sup>93</sup>

In the absence of electrophilic reagents, the equilibrium of this reaction is shifted towards the starting compounds for almost all types of nucleophiles, except for the very strong ones, such as carbanions. Due to its basic properties ( $\text{p}K_{\text{a}}$  of the corresponding acid is about 29), the phosphide anion **73** is rapidly protonated in a proton-donating medium, giving rise to an unstable intermediate. For example, if a hydroxide or alkoxide anion is used as the nucleophile, this intermediate spontaneously decomposes with evolution of hydrogen, phosphine, hypophosphite anions and phosphite anions.<sup>99</sup> In order to eliminate this undesirable process, it is necessary to use an electrophilic reagent capable of competing with the proton. This was attained in the reactions of  $\text{P}_4$  with organometallic compounds in the presence of alkyl halides;<sup>100</sup> with the hydroxide ion in the presence of aldehydes;<sup>101</sup> with acrylonitrile and other  $\alpha,\beta$ -unsaturated compounds;<sup>102</sup> with disulfides;<sup>103</sup> and with alkoxide ions in a mixture of an alcohol and tetrachloromethane.<sup>93–96, 104</sup> Repeated nucleophilic attack followed by the capture of the phosphide anion by an electrophilic reagent allows one to obtain diverse products under mild conditions.

It is noteworthy that in the vast majority of cases, the rupture of the P–P bonds in  $\text{P}_4$  proceeds by a pattern much more complicated than merely the successive addition of nucleophilic and electrophilic reagents (the latter may be represented by the white phosphorus itself). It was shown<sup>105, 106</sup> that the formation of oligomeric phosphides is a general process accompanying the cleavage of the  $\text{P}_4$  molecule. The negative charge on the phosphorus atom, which results from rupture of the first P–P bond on treatment with a nucleophilic reagent, can be stabilised due to fast interaction with the second  $\text{P}_4$  molecule, *etc.* The formation of dark solid precipitates with a high content of phosphorus has been observed in the reaction of  $\text{P}_4$  with disulfides,<sup>103</sup> phenyllithium and other reagents.<sup>102, 107</sup>

The earliest attempts<sup>100</sup> to determine the structure of the intermediate phosphorus oligomers resulting from the attack by carbanions on  $\text{P}_4$  suggest that these polyphosphides have a cross-linked structure. More recent studies attest to even more complex reaction pathways, involving opening of the  $\text{P}_4$  molecule under the action of nucleophilic reagents<sup>108</sup> followed by disproportionation and elimination of polyphosphide residues.

where  $m > n > p$ .

These transformations have been studied, taking reactions of  $\text{P}_4$  with the  $\text{CN}^-$  and  $\text{Ph}_2\text{P}^-$  anions and other nucleophiles as examples, in order to elucidate the factors that would suppress disproportionation.<sup>108</sup> The selection of the optimal conditions ensures, in some cases, the selective formation of the target products from the intermediate phosphorus oligomers.

### 1. Reactions of white phosphorus with alkali metals and magnesium

Studies of the reactions between white phosphorus and alkali metals and magnesium clearly demonstrated the difficulties faced when conducting these seemingly simple reactions. As in the case of transition metal complexes, the product structure is determined by a number of factors, first of all, reactant ratio.

Thus heating a mixture of white phosphorus and sodium (atomic ratio 3 : 1) in THF or dimethoxyethane in the presence of a

phase transfer catalyst, 18-crown-6 ether, resulted in a mixture of compounds, from which disodium hexadecaphosphide  $\text{Na}_2\text{P}_{16}$  was isolated by partial crystallisation.<sup>105</sup> A detailed investigation of the reaction mixture showed the formation of an isolobal analogue of sodium cyclopentadienide ( $\text{NaCp}$ ), namely, sodium pentaphosphacyclopentadienide  $\text{NaP}_5$ ,<sup>109</sup> stable only in solution. An alternative method for the preparation of alkali metal pentaphosphacyclopentadienides  $\text{MP}_5$  consists of the reaction of white or red phosphorus with alkali metal dihydrophosphides  $\text{MPH}_2$  (in 5 : 1 molar ratio).<sup>110, 111</sup> The reaction of white phosphorus with sodium in the presence of catalytic amounts of dibenzo-18-crown-6 ether is a convenient method for the synthesis of  $\text{NaP}_5$ .<sup>112</sup> Note that the pentaphosphacyclopentadienide anion  $\text{P}_5^-$  is a new and promising ligand in organometallic chemistry,<sup>109, 113</sup> as has been mentioned in a previous subsection.

The formation of a series of polyphosphides in the reactions of white phosphorus with alkali metals is a general process and depends on many factors, in particular, the boiling point of the solvent. The use of solvents with boiling points lower than the melting point of the alkali metal facilitates the formation of polyphosphides.<sup>114</sup> In particular, the fraction of polyphosphides can be reduced and, hence, the yields of the target products increased by using a Na–K alloy, the melting point of which is lower than the melting points of the pure metals.

For example, white phosphorus reacts with the Na–K alloy (1 : 3) or with Li metal in the presence of naphthalene to give bicyclo[1.1.0]tetraphosphine salts **74**.<sup>106</sup>

Phosphine **75**, having a nortricyclane structure, has been isolated<sup>115</sup> in a study of the reaction of  $\text{P}_4$  with a Na–K alloy in the presence of 1,3-dibromo-2-bromomethyl-2-methylpropane  $\text{MeC}(\text{CH}_2\text{Br})_3$ . Note that phosphine **75** reacts with metal carbonyls  $\text{M}(\text{CO})_5(\text{THF})$  ( $\text{M} = \text{Cr}, \text{W}$ ) under mild conditions to form metal complexes in which the metal is coordinated to one, two, or three phosphorus atoms  $\text{MeC}(\text{CH}_2\text{P})_3[\text{M}(\text{CO})_5]_n$  ( $n = 1, 2, 3$ ).

The reaction of white phosphorus with a Na–K alloy has been successfully used to prepare silylphosphines, which are basic reagents for the preparation of diverse derivatives of trivalent phosphorus. Thus treatment of the reaction mixture with chlorotrimethylsilane resulted in the isolation of tris(trimethylsilyl)phosphine, which is widely used in the chemistry of low-coordinate phosphorus compounds.<sup>116</sup> The replacement of chlorotrimethylsilane in this reaction by dichlorodimethylsilane allowed the preparation of silylphosphine  $(\text{Me}_2\text{Si})_3\text{P}_4$  (yield ~1%) with a nortricyclane structure. Optimisation of the reaction conditions, first of all, changing the reactant ratio, markedly increased the yield of the target silylphosphine. The introduction of a Na–K alloy into the reaction with white phosphorus in a 1 : 3 atomic ratio and subsequent treatment of the reaction mixture with  $\text{R}^1\text{R}^2\text{SiCl}_2$  at  $-78^\circ\text{C}$  opened up the way to the synthesis of silylphosphines having the adamantane structure  $(\text{R}^1\text{R}^2\text{Si})_6\text{P}_4$  (see Ref. 117).

$\text{X} = \text{R}^1\text{R}^2\text{Si}$  ( $\text{R}^1, \text{R}^2 = \text{Me}, \text{Et}, \text{Ph}$ ).

This method was successfully used for the preparation of both the silicon analogues of adamantane, such as  $[\text{R}(\text{Me})\text{Si}]_6\text{P}_4$ , containing diverse functional groups (for example,  $\text{R} = \text{CH}_2 = \text{CH}$ ), mixed silylphosphines  $(\text{MeHSi})(\text{Et}_2\text{Si})_5\text{P}_4$ .<sup>118</sup>

However, due to steric and electronic factors, this approach cannot be applied to the synthesis of silaphosphaadamantanes containing *tert*-butyl and phenyl groups at the silicon atom.<sup>118</sup>

The reactions of white phosphorus with sodium tris(*tert*-butyl)silicide ( $\text{Bu}_3^t\text{SiNa}$ ) and hexakis(*tert*-butyl)disilane have been proposed<sup>119</sup> as an alternative pathway to silylphosphines containing a bulky *tert*-butyl group. These reactions furnish a number of silylphosphines containing a tris(*tert*-butyl)silyl group:  $\text{Na}_2\text{P}_4(\text{SiBu}_3)_2$ ,  $\text{NaP}_3(\text{SiBu}_3)_2$ ,  $\text{Na}_2\text{P}_5(\text{SiBu}_3)_2$  (compound **76**,  $\text{R} = \text{Bu}^t$ ) and  $\text{Na}_2\text{P}_7\text{SiBu}_3$ .

The reaction of  $\text{P}_4$  with hexakis(*tert*-butyl)disilane presumably proceeds by a free-radical mechanism. The  $\text{Bu}_3^t\text{Si}^\cdot$  radical is generated on thermal decomposition of  $(\text{Bu}_3^t\text{Si})_2$  ( $T > 100^\circ\text{C}$ ) and reacts with white phosphorus, giving rise to silylphosphines  $(\text{Bu}_3^t\text{Si})_2\text{P}_4$  and  $(\text{Bu}_3^t\text{Si})_3\text{P}_7$  (compounds **77** and **78**, respectively).<sup>119</sup> Heptaphosphine **78** has a nortricyclane structure and is distinguished by a high thermal stability. The steric crowding of the  $\text{Bu}_3^t\text{Si}$  groups results in an increase in the exocyclic angles at the equatorial phosphorus atoms but scarcely influences the structure of the phosphorus  $\text{P}_7$ -skeleton of the molecule. On treatment with chlorine or bromine at  $70^\circ\text{C}$ , heptaphosphine **78** decomposes to give phosphorus trihalides and halosilanes.<sup>119</sup>

$\text{X} = \text{Cl}, \text{Br}$ .

Yet another method for decreasing the fraction of polyphosphides in the reaction products and increasing the yield of the target compounds in the reaction of white phosphorus with alkali metals is to conduct the process in liquid ammonia.<sup>120</sup> A good solubility of both reactants in liquid ammonia is favourable for high product yields. It was shown<sup>121</sup> that the reaction of white phosphorus with sodium metal in liquid ammonia yields the previously unknown 1,3-diaminotriphosphine  $\text{H}_2\text{NPH}$ .  $\text{PHPHNH}_2$ , which is stable only in solution. Of the three possible diastereomers, only the *erythro,erythro*-isomer, with the transoid arrangement of the  $\text{NH}_2$  groups, was isolated. The reduction of white phosphorus with lithium metal in liquid ammonia results in a complex mixture of polyphosphides. On treatment of red phosphorus with lithium under these conditions, phosphide anion **79** is generated *in situ*. This anion is a convenient reagent for the synthesis of diverse compounds of trivalent phosphorus.<sup>122</sup>

$\text{R}^1 = n\text{-C}_9\text{H}_{19}, \text{PhCH}_2, \text{cyclo-C}_5\text{H}_9; \text{X} = \text{CH}, \text{N}$ .

When the phosphide anion **79** reacts with alkyl halides, primary phosphines are formed in high yields,<sup>123</sup> while the reaction with alkyl fluorides gives symmetric triarylphosphines (yields 36%–60%).<sup>124</sup> Note that the latter can contain functional

substituents, including phosphonodiimide, sulfonamide, 2-oxazole and nitrile groups.

Phosphine  $\text{HOCH}_2\text{CH}_2\text{PH}_2$  was isolated in 27% yield from the reaction of the phosphide anion **79** with oxirane at  $-33^\circ\text{C}$ .<sup>125</sup> With a sterically crowded oxirane, 7-oxabicyclo[4.1.0]heptane, a good yield of the target phosphinoethanol (60%) was attained when the reaction was carried out at high temperature ( $40^\circ\text{C}$ ).<sup>126</sup>

An interesting version of the activation of elemental phosphorus has been reported by Bornancini *et al.*<sup>127</sup> They proposed using radiation for initiating the reactions of sodium phosphides and aryl halides. A series of symmetrical and asymmetrical triarylphosphines were prepared in good yields using this approach.

The development of methods for the synthesis of polycyclic organophosphines<sup>128,129</sup> has resulted in the synthesis of the first representative of this class of compound, tetraisopropyltetradecaphosphine  $\text{P}_{14}\text{Pr}_4^i$ . It is formed in the reaction of white phosphorus with magnesium metal in the presence of  $\text{Pr}^i\text{PCl}_2$ .<sup>130</sup> The first stage of the process affords a mixture of polyphosphines  $\text{P}_9\text{Pr}_5^i$  and  $\text{P}_7\text{Pr}_5^i$ , and isopropylphosphines with high phosphorus contents. Further thermolysis of the reaction mixture gives, in addition to  $\text{P}_9\text{Pr}_5^i$  and  $\text{P}_7\text{Pr}_5^i$ , a substantial amount of less alkylated phosphorus derivatives containing more than 9 phosphorus atoms in each molecule (including  $\text{P}_{14}\text{Pr}_4^i$ ). As a result of systematic research, both stages were optimised. This unusual synthetic approach has been successfully used for the synthesis of a number of polycyclic organophosphines such as  $\text{P}_{11}\text{Pr}_3^i$  (see Ref. 131),  $\text{P}_{11}\text{Pr}_5^i$  (see Refs 132, 133),  $\text{P}_{12}\text{Pr}_4^i$  (see Refs 134, 135),  $\text{P}_{13}\text{Pr}_5^i$  (see Ref. 136),  $\text{P}_{18}\text{Pr}_6^i$  (see Ref. 137),  $\text{P}_{18}\text{Pr}_4^i$  (see Ref. 138),  $\text{P}_{20}\text{Pr}_6^i$  (see Ref. 139) and  $\text{P}_{14}\text{Pr}_4^i$  (see Ref. 131). The reaction of  $\text{PET}_5$  with  $\text{PCl}_3$  in the presence of magnesium metal can be used as an alternative method for the preparation of compounds of this class.<sup>140</sup>

Thus, the reaction of white phosphorus with alkali metals, magnesium and C-electrophiles can be used to prepare OPCs with different oxidation states of phosphorus. However, the scope of this method is limited due to oxidative elimination processes. Metal phosphides formed upon interaction of white or red phosphorus with alkali metals react with alkyl (or aryl) halides to give not only compounds with the  $\text{P}-\text{C}$  bonds, but also polyphosphines, which reduces the yield of the target product.

The oxidative elimination and formation of polyphosphines can be suppressed by using organic derivatives of alkali and alkaline earth metals as nucleophilic agents.

## 2. The reactions of white phosphorus with organolithium and organomagnesium compounds

The use of organolithium compounds ensured the first synthesis of organophosphorus derivatives with  $\text{P}-\text{C}$  bonds directly from white phosphorus.<sup>100</sup> It was suggested that the reaction yields a mixture of alkali metal phosphides and triphenylphosphine:

However, only traces of triphenylphosphine  $\text{Ph}_3\text{P}$  and diphenylphosphine were isolated after hydrolysis of the reaction mixture, unsubstituted phosphine was not even detected, while phenylphosphine was formed as the major product. The yields of primary phosphines in the reaction of  $\text{P}_4$  with  $\text{Bu}^n\text{Li}$  and  $\text{PhLi}$  were 9% and 40%, respectively, while those for reactions with  $\text{Bu}^n\text{MgBr}$  and  $\text{PhMgBr}$  were 5%–7%.<sup>100</sup>

The use of a combination of reactants — carbanions generated from organometallic compounds and electrophiles (for example, alkyl halides) — increased the overall yield of organophosphorus compounds to 70%–80%.<sup>100</sup> The reaction of white phosphorus with phenyllithium in the presence of alkyl halides affords, after hydrolysis, a mixture of tertiary phosphines and their oxides.

This reaction gives organopolyposphines as intermediates; most likely, these are cross-linked polymeric phosphorus fragments. Their composition is determined by the reactant ratio. Hydrolysis of these polyphosphines proceeds much more readily than the decomposition of lithium phenyl polyphosphide; therefore, the total yield of OPCs does not depend on the nature of the alkali metal. On changing the reactant ratio (increasing in the proportion of phosphorus), the reaction gives tetrabutylcyclotetraphosphine, resulting from the rupture of two P–P bonds in the  $P_4$  tetrahedron<sup>100</sup>

The introduction of sterically hindered 2,4,6-tri-*tert*-butylphenyllithium and 2-bromo-1,3,5-tri-*tert*-butylbenzene into the reaction with phosphorus affords a mixture of bis(2,4,6-tri-*tert*-butylphenyl)bicyclotetraphosphine (**80**) and bis(2,4,6-tri-*tert*-butylphenyl)diphosphene (**81**) in moderate yields.<sup>107</sup>

Compound **80** is unstable in air and decomposes in chlorinated hydrocarbons. Attempts to convert it into stable compounds of four-coordinate phosphorus by treatment with elemental sulfur or trimethylsilyl azide failed.

It was found<sup>141, 142</sup> that the but-1-ynylphosphide and di(but-1-ynyl)phosphide anions were generated in the reaction of white phosphorus with but-1-ynyllithium in liquid ammonia; these anions reacted with alkyl halides  $\text{RHal}$  ( $\text{R} = \text{Et}, \text{Pr}^n$ ) to give mixtures of approximately equal amounts of but-1-ynyldialkylphosphines  $\text{EtC}\equiv\text{CPR}_2$  and alkyldi(but-1-ynyl)phosphines  $(\text{EtC}\equiv\text{C})_2\text{PR}$ .<sup>141, 142</sup> The overall yield of phosphines was 15%–20%.

The discovery of pentaphosphaferrocenes<sup>83</sup> and the development of methods for the preparation of the pentaphosphacyclopentadienide ion<sup>109, 111</sup> have stimulated research into the transformation processes of white phosphorus aimed at the construction of new ligands containing several phosphorus atoms in the molecule. It was suggested that the carbene anion  $\text{RC}^-$  can be inserted into a  $\text{P}_4$  molecule, yielding directly the  $[\text{RCP}_4]^-$  ion, owing to stabilisation of the aromatic phosphorus-containing heterocycle.<sup>143</sup> This was confirmed in a study of the reaction of white phosphorus with lithium (trimethylsilyl)diazomethanide. The salt with the previously unknown 1,2,3,4-diazaphospholide anion **82a**, formed during the formal [3+2]-cycloaddition of the  $\text{P}\equiv\text{P}$  fragment to the diazomethyl anion, was isolated as the only reaction product.

The protonation of lithium salt **82a** with trifluoroacetic acid at low temperature produces stable 2*H*-1,2,3,4-diazadiphosphole **83**, which was converted into Na salt **82b**.<sup>143</sup>

The use of dialkylamines as nucleophilic reagents in the reaction of white phosphorus with  $\text{Bu}^n\text{Li}$  results in a mixture of equimolar amounts of lithium dialkylaminophosphide and dilithioalkylaminophosphide.<sup>144</sup>

In this case, amine is probably first deprotonated to the amide anion, which then attacks the white phosphorus molecule. The formation of a mixture of two products is attributable to different extents of nucleophilic attack.

### 3. The reactions of white phosphorus with electrophilic reagents in the presence of hydroxide ions

The reactions of elemental phosphorus with electrophiles in the presence of the hydroxide anion are well studied processes. The simple procedures, mild conditions, ready availability of the initial reactants and the easy isolation and identification of products are the reasons for the fast progress in this field of chemistry of elemental phosphorus.

As shown above, the first stage in the cleavage of the  $\text{P}_4$  molecule under the action of nucleophilic reagents gives bicyclo[1.1.0]tetraphosphabutane derivatives; in the absence of electrophiles, the equilibrium is shifted towards the starting compounds. In the presence of the hydroxide ion, this equilibrium can be represented as follows:

In our opinion, the prototropic tautomerism inherent in the  $\text{P}(\text{III})$  intermediates generated *in situ* predetermines the formation of four-coordinate phosphorus compounds in this process. Simultaneously, the tautomeric equilibrium is favourable for the stabilisation of bicyclo[1.1.0]tetraphosphabutane derivatives, which makes it possible to accomplish the reactions of white phosphorus with nucleophilic reagents in the presence of electrophiles under relatively mild conditions.

The combined action of nucleophilic and electrophilic reagents on white phosphorus often allows one to accomplish the consecutive rupture of all P–P bonds and to obtain the target product. However, nucleophilic cleavage of the  $\text{P}_4$  tetrahedron in the absence of electrophiles specially added to the reaction mixture is also of interest in itself, and deserves special consideration. These reactions may underlie the synthesis of unknown polyphosphorus structures thus providing new information on the reactivity of white phosphorus.

The nucleophilic cleavage of white phosphorus on treatment with NaOH in water (or in a high-molecular-weight alcohol with surfactant additives) results in the formation of high-purity phosphine  $\text{PH}_3$ .<sup>145–147</sup>

The reaction of white phosphorus with  $\text{H}_2\text{O}$  in the presence of HI proceeds with  $\text{PH}_3$  evolution to give phosphorous acid  $\text{H}_3\text{PO}_3$ .<sup>148</sup> Recall that disproportionation of phosphorous acid to phosphine  $\text{PH}_3$  and phosphoric acid is a well-known reaction.<sup>149</sup>

The reaction of elemental phosphorus with electrophilic agents in the presence of strong alkalis (so-called superbasic media) is a convenient way for the preparation of OPCs.<sup>1, 150–160</sup> The most important work on the arylation and alkylation of elemental phosphorus was carried out by Trofimov and co-workers.<sup>150–159</sup> As a rule, these reactions are carried out in the presence of alkali metal hydroxides in aprotic solvents (HMPTA, DMSO) or under phase transfer catalysis conditions. Tertiary phosphines

and phosphine oxides are formed as major products in total yields of 40%. Note that trialkylphosphines cannot be isolated, even when the process is conducted under conditions that absolutely rule out contact with atmospheric oxygen.

R = Et, Pr<sup>n</sup>, Bu<sup>n</sup>, n-C<sub>5</sub>H<sub>11</sub>, n-C<sub>8</sub>H<sub>17</sub>; X = Cl, Br, I.

On heating a suspension of red phosphorus in the KOH–DMSO (or HMPTA) system in the presence of benzyl chloride to 70–80 °C, tribenzylphosphine oxide is formed as the major product (yield 65%). Small amounts of tribenzylphosphine and tetrabenzylphosphonium chloride were also isolated.<sup>151</sup> Since the phosphonium salt and toluene were detected in the reaction mixture, the known decomposition of phosphonium hydroxide could form an alternative route to phosphine oxide.<sup>151</sup>

Allyl halides react with red phosphorus at elevated temperatures in a similar way, resulting in tris(prop-1-enyl)phosphine oxide and tris(prop-2-enyl)phosphine oxide in 35% and 30% yields, respectively.<sup>152, 153</sup>

The simultaneous phosphorylation of alkyl bromides and benzyl chloride with red phosphorus was carried out in the development of a one-step method for the synthesis of asymmetrical tertiary phosphine oxides, which are difficult to obtain by other methods. The yield of these products was found to depend, first of all, on the ratio of the initial organyl halides.<sup>161</sup>

R = Alk.

Since alkyl bromides are subject to side dehydrobromination and hydrolysis under these conditions, and are less reactive than benzyl chloride, the use of a two- to three-fold excess of RBr has been proposed for increasing the yield of asymmetric tertiary phosphine oxides.

In superbasic media KOH–HMPTA(DMSO), unsaturated compounds, namely acrylonitrile, acrylamide, ethyl acrylate, vinylphosphonate, styrene, 4-vinylpyridine and acetylene derivatives, can be used as electrophilic reagents (Refs 125, 141, 144, 155–159, 162–164). For example, the reaction of phosphorus with styrene gave tris(2-phenylethyl)phosphine oxide (yield 60%) with bis(2-phenylethyl)phosphinous acid as the minor product.<sup>155</sup>

In the case of phenylacetylene, in conformity with the rule for addition of nucleophiles to alkynes,<sup>165</sup> tris[(Z)-styryl]phosphine is formed stereoselectively in 55% yield.<sup>156–158</sup> Tris[(Z)-styryl]phosphine oxide was obtained as a by-product.

To increase the yield of the target products, it has been proposed to carry out additional activation of elemental phosphorus by using ionising radiation (X-ray or γ electromagnetic radiation); the degree of conversion of red phosphorus reached 97%.<sup>166, 167</sup> The researchers believe that on irradiation, non-paramagnetic cationic and anionic defects appear in the P<sub>red</sub> layered polymeric structure; these are converted into radical paramagnetic defects,<sup>168</sup> which are responsible for the high activity of elemental phosphorus.

The introduction of 2-vinylnaphthalene into the reaction with elemental phosphorus allows one to synthesise previously unknown phosphines and phosphine oxides with bulky radicals that are promising ligands for metal complex catalysts. In the case of red phosphorus, the reaction takes place on heating of the reactants to 90–96 °C in a superbasic medium, KOH–DMSO. The reaction yields a mixture of compounds: primary and secondary phosphines, phosphinic acid and phosphine oxide, in a total yield of up to 40%.<sup>169</sup>

Naph is 2-naphthyl.

The degree of conversion of white phosphorus in this reaction is twice as high as the degree of conversion of P<sub>red</sub>. In addition, an increase in the content of 2-vinylnaphthalene in the initial mixture results in a higher reaction selectivity, and in the formation of tertiary phosphine **84** and phosphine oxide **85** in a 1 : 5 ratio as the major products (total yield 63%). After treatment of the reaction mixture with atmospheric oxygen, phosphine oxide **85** was isolated in 58% yield.<sup>169</sup>

A convenient method for the preparation of phosphinous acids has been developed on the basis of reactions of red phosphorus with arylalkenes in aprotic solvents in the presence of strong bases.<sup>162</sup> This reaction with styrenes affords tris- and bis(2-phenylethyl)phosphine oxides in yields of up to 20%.

R = H, Me.

Under similar conditions, tris(2,2-dialkoxyethyl)phosphine oxides [(RO)<sub>2</sub>CHCH<sub>2</sub>]<sub>3</sub>PO were obtained from red phosphorus and 1,1-dialkoxy-2-bromoethanes (RO)<sub>2</sub>CHCH<sub>2</sub>Br (R = Et, Bu<sup>n</sup>), the product yields being moderate (15% and 8%, respectively).<sup>163</sup>

The use of formaldehyde as an electrophilic reagent in the reaction with white phosphorus results in a mixture of bis(hydroxymethyl)phosphinic (**86**), hydroxymethylphosphonic (**87**) and methyl(hydroxymethyl)phosphinic (**88**) acids.<sup>101, 144</sup>

A method for the preparation of methylphosphonic acids, which have found wide use as fire retardants, has been developed on the basis of the reaction of white phosphorus with methyl chloride in the presence of KOH. Phosphonium salts were employed as phase transfer catalysts.<sup>170</sup>

By using organic bases (first of all, primary and secondary amines), one can prepare a series of organic phosphorus derivatives under mild conditions. For instance, white phosphorus reacts with formaldehyde in the presence of piperidine, giving rise to a mixture of tris(piperidinomethyl)phosphine oxide (**89**), bis(piperidinomethyl)phosphinic acid (**90**) and piperidinomethylphosphonic acid (**91**).<sup>171, 172</sup>

When linear amines, for example,  $\text{Me}_2\text{NH}$  and  $\text{Et}_2\text{NH}$ , are used, the reaction affords also tertiary phosphine.<sup>102</sup> The product yields depend on the starting reactant ratio, the nature of the solvent and the pH of the medium. It was found<sup>102</sup> that  $\text{P}_4$  reacts with *N*-hydroxymethyldialkylamine, formed in the primary reaction between amine and aldehyde. The process starts with nucleophilic attack by the  $\text{R}_2\text{NCH}_2\text{O}$  on the white phosphorus molecule, and is accelerated by the presence of basic catalysts.

This hypothesis has been confirmed in a study of the chemical behaviour of white phosphorus towards alcohol-oxirane mixtures in the presence of inorganic and organic bases.<sup>173–176</sup> The reactions of oxiranes (in particular, ethylene oxide) with *N,N*-dimethylethanamine were found to afford betaine **92**, which can react with white phosphorus.

$\beta$ -Hydroxyethyltrimethylammonium hydroxide (choline) was used as the model compound in the reaction with  $\text{P}_4$ ; this gave  $\beta$ -hydroxyethyltrimethylammonium hypophosphite.<sup>177</sup>

If ethylene oxide and trimethylamine are added consecutively to white phosphorus, the same products are formed as in the reaction with choline.<sup>177</sup>

#### 4. Reactions of white phosphorus with alkyl halides

Since elemental phosphorus has weak nucleophilic properties, the reaction of both of its allotropes with organic halides usually take place under drastic conditions.

White phosphorus reacts with alkyl or aryl halides at a temperature of  $>250^\circ\text{C}$  to give phosphorus halides and phosphonium salts.<sup>178</sup>

$\text{X} = \text{Cl}, \text{Br}$ .

The introduction of alkyl iodides into this reaction, or conducting the process in the presence of elemental iodine, increases the yield of the target products.

Heating red phosphorus and lower alkyl iodides  $\text{RI}$  ( $\text{R} = \text{Me}, \text{Et}, \text{Bu}^n$ ) in an autoclave at  $200^\circ\text{C}$  in the presence of traces of iodine or diphosphorus tetraiodide, followed by treatment of the reaction mixture with dilute nitric acid, affords tertiary phosphine oxides:  $\text{Me}_3\text{PO}$  (yield 54%),  $\text{Et}_3\text{PO}$  (56%) and  $\text{Bu}_3\text{PO}$  (66%).<sup>179–181</sup> The separation of this process into two steps, that is, heating of catalytic amounts of alkyl iodide with red phosphorus in the presence of  $\text{I}_2$  or the salt  $[\text{IR}_3\text{PP}^+\text{R}_3]\text{I}_5^-$  to  $180\text{--}230^\circ\text{C}$  and the subsequent addition of excess alkyl iodide, increases the yield of trialkylphosphine oxides.<sup>179</sup> For example, the yield of triethylphosphine oxide reaches 88%. The researchers believe that the process follows an ionic mechanism as no free radicals were detected during the reaction and UV irradiation or the addition of benzoyl peroxide did not influence the reaction rate.

$\text{R} = \text{Me}, \text{Et}, \text{Bu}^n$ .

Alcohols are suitable as alkylating agents for red phosphorus. The reaction occurs in the presence of iodine under drastic conditions. After treatment of the reaction mixture with an aqueous solution of sodium sulfite, the yield of phosphine oxide reaches 80%.<sup>182</sup>

$\text{R} = \text{Alk}$ .

Under alternative conditions, for example, refluxing the reaction mixture in aqueous alkali, phosphinic and phosphonic acids are formed together with phosphine oxides.<sup>183</sup>

$\text{R} = \text{Alk}$ .

A similar reaction carried out using unsaturated compounds (fluorinated acetylene and ethylene derivatives) as the alkylating agents affords tertiary phosphines — diphosphabicyclooctatrienes (yields  $<30\%$ ).<sup>183</sup>

In the presence of catalysts (aluminium halides), the reactions between alkyl halides and white phosphorus can be carried out under mild conditions.<sup>184</sup> For example, white phosphorus dissolved in carbon disulfide reacts with *tert*-butyl chloride in the presence of Lewis acids, even at  $-10^\circ\text{C}$ . After hydrolysis of the reaction mixture, di(*tert*-butyl)phosphine oxide and di(*tert*-butyl)phosphinic acid chloride were isolated.

Other alkyl chlorides have also been used in this reaction. It has been suggested<sup>184</sup> that aluminium chloride polarises the  $\text{C}-\text{Cl}$  bond leading to the formation of a carbocation. The addition of the carbocation to a white phosphorus molecule results in a new cation, in which the phosphorus–phosphorus

A more efficient procedure for the preparation of phosphorus derivatives with P–heteroatom bonds has been proposed by Lemann<sup>194</sup> and by Brown and Hudson.<sup>93–96</sup> It is based on the assumption that the reaction of white phosphorus with disulfides can be considered as a redox process. Since the forward reaction of white phosphorus with disulfides takes place only under drastic conditions, the reaction is carried out in CCl<sub>4</sub> in the presence of strong nucleophiles. Tetrachloromethane is known to form charge transfer complexes (CTC) with nucleophiles. White phosphorus possesses weak nucleophilic properties; therefore, before introduction into the reaction with CCl<sub>4</sub>, it was converted into a rather stronger nucleophile<sup>194</sup> by treatment with, for example, alkoxide anions. The bicycletetraphosphide type anion **73**, formed during this process, forms a CTC with CCl<sub>4</sub>. On treatment with protic reagents, this complex decomposes to give chloroform and bicycletetraphosphine.

By repeating this process several times, consecutive rupture of all P–P bonds in the P<sub>4</sub> tetrahedron can be attained to give trivalent phosphorus derivatives.

If the PNu<sub>3</sub> derivatives are relatively strong nucleophiles, they can be oxidised by CCl<sub>4</sub> in the presence of protic reagents to give four-coordinate phosphorus compounds.<sup>194</sup>

The side reactions in the synthesis of trialkyl phosphites or trialkyl trithiophosphites can be suppressed by using a two-fold excess of alkoxide or thiolate ion with respect to the stoichiometric amount. The use of an equivalent amount of alkoxide decreases the yields of trialkyl phosphite due to the formation of dialkyl phosphite (RO)<sub>2</sub>PHO. The formation of dialkyl phosphite can be attributed to either protonation of the initial phosphide anion or cleavage of trialkyl phosphite to dialkyl phosphite and alkyl halide on treatment with acids.<sup>96</sup> The optimal reaction conditions are as follows: a large excess of CCl<sub>4</sub>, a two-fold amount of the alkoxide, room temperature, vigorous stirring and a short residence time.

X = O: R = Me (82%), Et (76%), Bu<sup>n</sup> (58%) (see<sup>101</sup>);

X = S: R = Alk (<90%) (see<sup>94</sup>).

The key problem faced by this procedure is related to the purification of trialkyl phosphites, which form stable azeotropic mixtures with excess alcohol and CCl<sub>4</sub>. On repeated distillation of these mixtures, products of decomposition of trialkyl phosphites are formed.

An increase in the residence time results in the formation of trialkyl phosphate *via* the reaction of phosphite and CCl<sub>4</sub> in alcohol.<sup>96</sup>

Under similar conditions, P<sub>4</sub> does not react with phenoxide and thiophenoxide ions. Relying on this fact, Brown *et al.*<sup>93–96</sup> made an unreasonable assumption that transformations of white phosphorus could be induced only by highly basic nucleophiles. Lemann and co-workers<sup>194</sup> demonstrated that it is nucleophilicity of the PhO<sup>-</sup> and PhS<sup>-</sup> anions rather than their basicity that plays the crucial role, the variation in the anion concentration having

only a minor influence on the reaction rate. The use of bipolar aprotic solvents and a base (for example, Et<sub>3</sub>N) to increase the nucleophilicity of these anions allowed the researchers to synthesise triphenyl phosphite (yield <50%) and triphenyl trithiophosphite (<80%).<sup>194</sup>

Despite the formal resemblance of the reactions giving trialkyl phosphite and its thio analogue in the P<sub>4</sub>–CCl<sub>4</sub>–RXH–NEt<sub>3</sub> system (X = O, S), these reactions were found to be quite different,<sup>194,195</sup> the rate of reaction of P<sub>4</sub> with thiols proving to be much higher. The difference between the reaction mechanisms is due to the fact that thiol can be rapidly oxidised to form disulfide. This species is not nucleophilic enough to cleave the P–P bond but it can be involved in the acid–base reaction with triethylamine to generate thiolate ions, which initiate the decomposition of P<sub>4</sub>.

The method based on the reaction of white phosphorus with proton-containing compounds in the presence of CCl<sub>4</sub> and a nucleophilic reagent has been successfully used to prepare triaminophosphines. A secondary amine functions as both a proton-donating reagent and a base.<sup>194</sup>

The target product, tris(dialkylamino)phosphine, is a strong base and can form stable quasi-phosphonium salts with [(R<sub>2</sub>N)<sub>3</sub>PCl]<sup>+</sup> and [(R<sub>2</sub>N)<sub>3</sub>PCCl<sub>3</sub>]<sup>+</sup> cations.

Phosphoramidates were prepared by the reaction of white phosphorus with a mixture of dialkylamine and alcohol.<sup>194</sup>

Due to the formation of by-products (R<sub>2</sub>N)<sub>2</sub>P(O)(OR), (RO)<sub>3</sub>PO and (R<sub>2</sub>N)<sub>3</sub>PO, the yield of the target phosphoramidates did not exceed 50%.<sup>194</sup>

An original method has been proposed for the preparation of phosphorus derivatives with P–X bonds (X = S, O and N) using transition metal, first of all copper(II), salts as oxidants.<sup>196–206</sup>

As shown above (see Section II), the white phosphorus molecule can be either a η<sup>1</sup>- or η<sup>2</sup> ligand. In the former case, the P<sub>4</sub> tetrahedron is converted into a trigonal pyramid arranged with its vertex towards the metal atom, which is manifested by an increase in the P<sub>α</sub>–P<sub>β</sub> bond length to 2.20 Å compared to the P<sub>β</sub>–P<sub>β</sub> bond lengths (2.09 Å). In the latter case, the length of the P–P bond that is coordinated to the metal atom (2.46 Å) increases to a greater extent than the bond length in the free phosphorus molecule, thus providing more appreciable loosening of the orbitals of the P<sub>4</sub> molecule. It has been suggested<sup>2</sup> that coordinatively saturated Cu(II) compounds containing donor ligands such as Cl<sup>-</sup>, Br<sup>-</sup>, SO<sub>4</sub><sup>2-</sup> and RCO<sub>2</sub><sup>-</sup>, incapable of the η<sup>2</sup>-coordination of tetrachlorophosphorus, possess lower catalytic activities than the coordinatively unsaturated complexes that display η<sup>1</sup>- and η<sup>2</sup>-binding modes.<sup>196–199</sup> This hypothesis is confirmed by the fact that the addition of pyridine to the former compounds sharply increases the reaction rate.

It was found<sup>196–199</sup> that the reaction of white phosphorus with alcohols proceeds selectively. The reaction takes place in the presence of copper(II) salts on moderate heating of the reactants dissolved in an aromatic hydrocarbon under an O<sub>2</sub> atmosphere.

R<sup>1</sup> = Me, Et, Pr<sup>n</sup>, Bu<sup>n</sup>, Bu<sup>i</sup>, n-C<sub>5</sub>H<sub>11</sub>, iso-C<sub>5</sub>H<sub>11</sub>, Ph, *p*-Tol.

(a) [Cu] = CuCl<sub>2</sub>, CuBr<sub>2</sub>; (b) [Cu] = CuSO<sub>4</sub>, Cu(O<sub>2</sub>CR<sup>2</sup>)<sub>2</sub>

(R<sup>2</sup> = Me, Pr<sup>n</sup>, n-C<sub>17</sub>H<sub>35</sub>, Ar).

The reaction products depend on the copper(II) salt used. In the case of halides, phosphates and dialkyl (or diaryl) phosphites are mainly formed, while in the case of sulfates or carboxylates, the reaction gives trialkyl (or triaryl) phosphites.<sup>200</sup>

Under an inert atmosphere, copper(II) compounds react with white phosphorus in arene–alcohol solutions and are reduced to copper(I) salts or copper metal, which, in turn, can be oxidised by air oxygen to divalent copper.

Copper(II) complexes exhibit high catalytic activities in the oxidative coupling of  $P_4$  with primary and secondary amines<sup>201,202</sup> to give phosphazeno compounds. Amines react with  $P_4$  one or two orders of magnitude faster than alcohols. Under an argon atmosphere, white phosphorus reduces Cu(II) to Cu(0).

$R^1 = H$ ;  $R^2 = Et, Cy, PhCH_2$ ;  $R^1 = R^2 = Et, Cy, PhCH_2$ .

The reactions of red phosphorus with alcohols in the presence of copper(II) salts afford trialkyl phosphates and dialkyl phosphates.<sup>202–205</sup> The process is carried out either under an inert gas or in the presence of atmospheric oxygen. In the latter case, oxygen and red phosphorus are consumed only by the formation of organic phosphates, whose yields based on the reactants are ~100%. The oxidative P–O coupling of red phosphorus with glycols in dioxane results in linear and cyclic alkylene phosphates.

Subsequently, other procedures for oxidative alkoxylation of white phosphorus have been proposed.<sup>206</sup> In these reactions, a co-oxidant and a catalyst are used in addition to the oxidant (oxygen or  $NaBrO_3$ ).

$[O] = O_2, NaBrO_3 + \text{co-oxidant} (CuCl_2, NaNO_2, FeCl_3, C_6H_4O_2)$ ;  
Cat =  $PdCl_2, Ru(OH)Cl_3, RuCl_3 \cdot 6 H_2O$ .

The oxidation of elemental phosphorus with oxygen in the presence of organic compounds yields a number of derivatives. In a study of the oxidation mechanism of white phosphorus in the presence of phenol in water, 17 reaction products have been detected, phosphonic acids being the major components.<sup>206,207</sup> In some cases, the researchers were able to attain selectivity in the formation of particular compounds. For example, white phosphorus is rapidly and selectively oxidised by air oxygen to give trialkyl phosphate from benzene–alcohol mixtures in the presence of iodine and sodium nitrite at 20–60 °C.<sup>208</sup>

Slow oxidation of white phosphorus with oxygen in ethylenediamine results in ethylenediammonium monophosphate  $[H_3NCH_2CH_2NH_3]^+[PHO_3]^-$  (see Ref. 209).

Benzoquinones can be used as oxidants in the synthesis of phosphoranes. For example, phosphoranes  $P(O_2C_6R)_2X$  ( $R = Cl_4, Br_4, Bu^t_2H_2$ ;  $X = Br, SePh$ ) were formed as the major products in the reaction of white phosphorus with *o*-benzoquinones, performed in the presence of bromine or diphenyl diselenide.<sup>210</sup> Studies of these reactions by EPR spectroscopy showed the presence of *o*-semiquinone radicals. Exposure to UV radiation

or thermolysis of a mixture of white phosphorus and substituted *o*-benzoquinone in the presence of catechol derivatives also yielded phosphoranes.<sup>211</sup>

$R_n = H, 3,5-Bu^t_2, 3,6-Bu^t_2, 3,4,5,6-Cl_4, 4-Ph_3C$ .

The addition of anhydrous copper(II) chloride substantially accelerates this reaction and increases the yield of phosphoranes to 40%–60%; copper(II) being reduced to copper(I).

#### IV. Electrochemical methods for the synthesis of organophosphorus compounds from elemental phosphorus

Studies of the electrochemical behaviour of white phosphorus and the scope of applicability of electrochemistry for the synthesis of OPCs are in their infancy; therefore, the number of relevant papers is relatively small. The major contribution to the development of this line of chemistry was made by the Russian scientific groups headed by A P Tomilov and Yu M Kargin.

It has been shown<sup>212</sup> that electrochemical reduction of white phosphorus in an aprotic medium at a mercury dropping electrode is irreversible (half-wave potential  $E_{1/2} = -1.55$  V vs. mercury pool in DMF). The calculated number of accepted electrons depends on the concentration of  $P_4$ . It was suggested that the first stage of reduction is a one-electron transfer to give a radical anion:

In the presence of active proton donors, which rapidly protonate the intermediate anions, all P–P bonds in the white phosphorus molecule are cleaved to give phosphine.

In alcohol solutions, white phosphorus is reduced *via* the intermediate chemisorbed product  $P_4/(Hg)_x$ .<sup>213</sup>

The electrochemical hydrogenation of white phosphorus is of practical interest as a method for the synthesis of phosphine. This process has been studied in detail using a lead cathode.<sup>214,215</sup> The results of the study initiated an important field of OPC electro-synthesis, namely reduction of white phosphorus in a proton-donating medium at a cathode with high hydrogen overvoltage (a mercury or lead cathode). The process consists of a number of successive steps giving highly reactive phosphorus hydrides of type  $(PH)_x$  (see Ref. 214). The final phosphine and intermediate phosphorus hydrides can react with various compounds that have been added to the electrolyte and are electrochemically inactive in the potential region of the working electrodes; these include alkenes,<sup>216</sup> carbonyl compounds,<sup>217,218</sup> alkyl halides<sup>219</sup> and so on. These reactions yield mixtures of phosphines or individual phosphine oxides. Lower alkyl halides react with  $P_4$  to give quaternary phosphonium salts.

The electrolysis of an emulsion of  $P_4$  in DMF in the presence of *n*-butyl bromide<sup>220</sup> furnishes a complex mixture of organic phosphines and phosphine oxides with an overall yield of 29%. At the cathode, hydrogen is apparently evolved and phosphorus and  $Bu^+Br$  are reduced.

In the above reactions, a substantial portion of elemental phosphorus polymerises and alkylation proceeds only partially (by 20%–50%). The low yields and the complex compositions of the mixtures hamper the separation and purification of the products.

Electrochemical reduction of red phosphorus in alkaline solutions has been proposed for the synthesis of phosphine. It was found<sup>221</sup> that 15%–25% solutions of NaOH and a temperature range of 70–100 °C were the conditions of choice for the synthesis of  $PH_3$ . In more concentrated solutions, phosphorous and hypophosphorous acids were mainly formed. When a lead cathode was used, the yield of phosphine varied from 60% to 83%.<sup>221</sup>

The electrochemical oxidation of white phosphorus supported on porous conductive substrates in neutral or acidic media results in phosphoric and phosphorous acids.<sup>222</sup> It has been suggested that the reaction is accompanied by oxidation of phosphine formed upon disproportionation of white phosphorus.

In aqueous solutions of hydrogen halides<sup>223, 224</sup> (in some cases, with the addition of the organic solvents, benzene or chloroform<sup>224</sup>), indirect electrochemical oxidation of white phosphorus to phosphorous acid takes place. Apparently, in the first stage, phosphorus is oxidised by the elemental halogen evolved at the anode; this gives phosphorus halides, which are hydrolysed to give  $H_3PO_3$ .

The synthesis of phosphorous and hypophosphorous acids was performed by electrolysis of a suspension of red phosphorus in the presence of organic bases, ethylenediamine and triethylamine.<sup>224</sup> The influence of a number of parameters on the yield and product ratio, which depend on the amount of electricity passed, was studied. The process was intensive only at a temperature of > 70 °C, the degree of conversion of phosphorus being 40%–45%.

Of interest from both theoretical and practical standpoints was a study of the anodic oxidation of a suspension of red phosphorus in alcohols in the presence of hydrogen chloride.<sup>225</sup> In these experiments, electrolysis was carried out in an undivided cell; hydrogen being evolved at the cathode, and trialkyl phosphate and alkyl chloride at the anode. The process can be represented as follows:

Chlorine evolved at the anode reacts with phosphorus and alcohol, giving the final products in 40%–70% yields. This

method is applicable only to primary aliphatic alcohols in an excess of hydrogen chloride; in other cases, the anodic process appears to yield compounds that cannot be isolated or identified.

An electrochemical procedure for the synthesis of OPCs from white phosphorus in an undivided cell was developed in the USA.<sup>226, 227</sup> The process is carried out in solutions of alcohols, phenols or mercaptans in the presence of nitrates, bicarbonates, *etc.* as the supporting electrolytes, and using either a mercury<sup>226</sup> or ferrophosphorus anode.<sup>227</sup> Hydrogen is evolved at the cathode, and the metal cation formed upon anode dissolution serves as the oxidant. However, the yields of triorganyl phosphates are relatively low (45%–50%). In addition, this method is environmentally unsafe due to its use of large amounts of mercury. No data on the mechanism of formation of the products have been reported in the publications cited.

In recent years, new approaches to the synthesis of OPCs have been developed. They combine the advantages of conventional (homogeneous) chemistry in solution with electrochemistry, in which the reagents are generated at the electrodes directly in the reaction system.<sup>228–241</sup>

The following processes occur in an undivided cell: the formation of nucleophiles (alkoxide, hydroxide, phenoxide, amide or other anion) at the cathode and oxidation of halide ions (*e.g.*, iodide to iodine) at the anode.<sup>228–238, 240–243</sup> The halogen, together with the nucleophile, reacts with the  $P_4$  molecule to give various phosphorus compounds depending on the conditions of electrolysis. The general pattern of electrosynthesis of trialkyl phosphate from white phosphorus in anhydrous alcohol is as follows:

In the presence of water, optimal conditions are ensured and the yield of trialkyl phosphate becomes nearly quantitative.<sup>231, 233, 235–238</sup>

The proposed method for the electrosynthesis of trialkyl phosphates is almost waste-free. By varying the electrolysis conditions, the process can be directed towards the formation of other products, for example, tetraalkyl pyrophosphates.<sup>230, 232, 236–238</sup> The yield of these products depends on the structure of the aliphatic alcohol and the reactant ratio. In the case of linear aliphatic alcohols, a mixture of trialkyl phosphate and tetraalkyl pyrophosphate in ~2:3 ratio is formed, while the use of branched alcohols results in a similar mixture, but in a 1:9 ratio.

These studies provided an understanding of the mechanism of transformation of white phosphorus during the electrolysis of its solutions in aqueous alcohols in the presence of  $Et_4NI$ , and also made it possible to control this complex process. In the systems in question, cathodically generated nucleophile initiates the opening of the phosphorus rings, while halogen resulting from oxidation of the halide ion facilitates the replacement of the proton of the P–H bond. The halogen is regenerated during the electrolysis, and thus the cycle is completed. Owing to the high selectivity and rate of

these processes, phosphorus can be transformed into organophosphorus compounds with a high degree of conversion. Varying of the pH of the alcohol- and water-containing electrolyte can result in a substantial change in the composition of the cathodically generated species and, hence, in the routes of transformation of white phosphorus into target products.<sup>236, 237</sup> For example, in acidic solutions, hydrogen ions are reduced at the cathode instead of alcohol; therefore, no opening of the phosphorus rings induced by nucleophiles (alkoxide ions) takes place. In addition, dealkylation of the esters of trivalent phosphorus acids readily occurs under these conditions. Indeed, electrolysis of aqueous alcohol solutions of HBr (or HI) over a broad concentration range in the presence of an emulsion of white phosphorus gives dialkyl phosphite as the major product (yield 70%).

It was found that anodically generated phenothiazine and triarylamine radical cations can be used to cleave P<sub>4</sub> in alcohol solutions.<sup>234</sup>

Thus, using the simple phosphorus–alcohol–water system as an example, a number of essential advantages of electrochemical methods over classical approaches of organic chemistry have been demonstrated. The use of electrochemistry allows one to synthesise OPCs from white phosphorus in high yields under mild conditions. This opens up the way to almost waste-free environmentally safe processes, allowing one to design a controlled chemical system in which the desired products can be obtained specifically by varying the conditions.

The oxidation of Cu(I) catalyst to Cu(II) during the preparation of trialkyl phosphates from white phosphorus,<sup>196–206</sup> considered above, can be carried out by an electrochemical process,<sup>239</sup> which would eliminate the explosion-prone oxidant O<sub>2</sub>. The important advantages of the electrochemical regeneration of the catalyst include a decrease in the number of components to the reaction system, the elimination of side reactions and an increase in the yield of the target products. Studies of the Cu–ROH–P<sub>4</sub> ternary system revealed an analogy with the behaviour of white phosphorus in the coordination sphere of copper or nickel. The redox properties of copper catalysts were found to change in the presence of white phosphorus: the Cu<sup>I</sup>/Cu<sup>0</sup> reduction wave shifting towards more positive potentials. The Cu<sup>I</sup>–P<sub>4</sub> complex is characterised by a smaller electrochemical gap, *i.e.*, it is more polarisable and reactive than the initial Cu(I) compound. The possibility of electrosynthesis of phosphorus-containing acid derivatives from P<sub>4</sub> and alcohol, promoted by copper(II) compounds which serve as charge transferring catalysts, was also demonstrated.

The use of electrochemical methods has extended the range of compounds that can be prepared directly from white phosphorus. For example, aromatic esters of phosphorus acids have been synthesised in good yields.<sup>237–242</sup> By varying the conditions of electrolysis, one can obtain either triaryl phosphites (by adding pyridine to the electrolyte) or triaryl phosphates in nearly quantitative yields.

A study<sup>237, 240</sup> of the decomposition routes of white phosphorus during the electrolysis of phenol solutions of Et<sub>4</sub>Ni has confirmed the general rules of behaviour of P<sub>4</sub> molecule in alcohol media. Characteristic features of the subsequent transformations of the organophosphorus intermediates were also elucidated. It was found that rupture of all the P–P bonds in phosphorus oligomers produced the phosphite (PhO)<sub>3</sub>P. It was the first product formed in the reaction of white phosphorus with nucleophilic and electrophilic reagents generated at the electrodes.

It was shown experimentally for the first time<sup>237, 240</sup> that pentaphenoxyphosphorane formed at intermediate stages of the process undergoes cathodic reduction to triphenyl phosphite. This accounts for the quantitative transformation of triphenyl phosphite into the corresponding phosphate.

This accumulated experience has been used to develop a procedure for the electrosynthesis of phosphorotriamidates and thiophosphorotriamidates from white phosphorus under the action of amide anions R<sub>2</sub>N<sup>−</sup>, generated by the reduction of amines at the cathode with a low hydrogen overvoltage.<sup>237, 242, 243</sup> The electrolysis of amine in the presence of an emulsion of white phosphorus gave the corresponding phosphorotriamidate; the yields in DMF (62%) were substantially higher than those in acetonitrile (12%). Presumably, phosphorotriamidate is formed by hydrolysis of the intermediate triamidoiodophosphoranes.<sup>237, 243</sup>

R = Alk.

Yet another route of transformation of (R<sub>2</sub>N)<sub>3</sub>P formed initially has been accomplished by conducting the electrolysis in the presence of carbon disulfide. This compound acts as a sulfur donor, the reaction yielding thiophosphorotriamidate (R<sub>2</sub>N)<sub>3</sub>P=S (major product) and thioformamide (minor product).<sup>237, 243</sup>

The methods described above are based on the combined treatment of white phosphorus with nucleophilic and electrophilic reagents in an undivided cell. In these reactions, one can obtain only esters or amides of phosphorus acids but not compounds with P–C bonds.

In recent years, a new efficient method for the selective electrosynthesis of compounds with P–C bonds from white phosphorus, using metal complexes as catalysts, has been developed.<sup>244–249</sup> The activation of white phosphorus followed by rupturing of the P–P bonds takes place in a system that ensures cyclic regeneration of the catalyst at an electrode. It was shown that by treatment with organic halides in the presence of electrochemically generated catalysts, namely Ni(0) complexes with 2,2'-bipyridine (bipy) ligands, white phosphorus can be converted into organic phosphines and phosphine oxides. The process scheme is as follows:<sup>246–249</sup>

*n* = 2, 3; M = Mg, Zn, Al; L = bipy, Ph<sub>3</sub>P.

The electrocatalytic arylation of white phosphorus has been studied using preparative electrolysis and cyclic voltammetry.<sup>246–248</sup> Some stages of the catalytic cycle were simulated and studied separately. Cathodically generated Ni(0) complexes were found to react with organic halides to give nickel organyl-σ-complexes, which are involved in the functionalisation of white phosphorus. The reaction of organonickel compound, RNi<sup>II</sup>XL<sub>*m*</sub> with white phosphorus is the key step of the process.

The reaction route and the yields of the final products of the electrochemical phosphorylation of organic halides with white phosphorus are considerably affected by the sacrificial anode material. The use of a zinc anode results in the synthesis of three-coordinate phosphorus compounds, triorganylphosphines, an aluminium anode stipulates the formation of triorganylphosphine oxides, and the presence of Mg(II) ions in the reaction mixture ensures the transformation of P<sub>4</sub> into cyclic polyphosphines (PhP)<sub>5</sub>.

To elucidate the pathways leading to the formation of P—C bonds, an attempt has been made to cleave the white phosphorus molecule directly using Ni(II) and Ni(0) complexes.<sup>246–248</sup> Metal-coordinated white phosphorus becomes a stronger electron acceptor and is more readily reduced on treatment with Ni(0) complexes. A voltammetric study of the behaviour of Ni(II) complexes with bipyridine in the presence of white phosphorus has shown that the latter forms a more stable complex with Ni(0) than with Ni(II). The process irreversibility and the shift of the potential from the equilibrium value to less negative values are due to the subsequent fast chemical reduction of the P<sub>4</sub> molecule with the Ni<sup>0</sup> complex.

It was found that Ni<sup>0</sup>(bipy) reacts with white phosphorus to give a binuclear complex with a cyclo-P<sub>3</sub> fragment. The arylation of the phosphorus fragment with aromatic halides results in a mononuclear complex with Ph<sub>3</sub>P<sub>3</sub> ligand.

Among the numerous catalysts of OPC electrosynthesis, primary attention is attracted by samarium(II) derivatives, which possess strong reducing properties.<sup>243</sup> Electrochemical generation of these compounds from stable samarium(III) salts, in the presence of an emulsion containing a mixture of white phosphorus and iodobenzene, gives rise to products containing phosphorus—carbon bonds. If the hydrate SmCl<sub>3</sub> · 5 H<sub>2</sub>O is used, a mixture of phosphines, PhPH<sub>2</sub>, Ph<sub>2</sub>PH and Ph<sub>3</sub>P, is formed predominantly, together with the phosphonium salt Ph<sub>4</sub>PI. The anhydrous salt SmCl<sub>3</sub> catalyses the predominant formation of PhPI<sub>2</sub>; some Ph<sub>4</sub>PI

was also isolated as a minor product.<sup>244</sup> The following scheme for the catalytic process was proposed:

Different routes for the activation of white phosphorus in the coordination sphere of nickel complexes, depending on the nature of the ligands, have been considered.<sup>250</sup> The first route is based on coordination of the P<sub>4</sub> molecule to the metal, resulting in a deformation of the tetrahedron without its destruction. This is the case with the NiX<sub>2</sub>L complexes [where X = BF<sub>4</sub>, Br, Cl; L = bipy (the solvents are DMF, MeCN, acetone); L = 2,9-dimethyl-1,10-phenanthroline (phen) or PPh<sub>3</sub> (the solvents are DMF or acetone)], which are reduced at the most negative potentials, |E<sub>red</sub>| > -0.9 V. To cleave the P—P bonds in the complex formed, its electrochemical reduction is required.

The second route is oxidation of white phosphorus in the coordination sphere of a Ni(II) complex. This method is used when the NiX<sub>2</sub>L complex exhibits relatively strong oxidative properties and is reduced readily (|E<sub>red</sub>| < -0.9 V). When X = BF<sub>4</sub> and L = triphos, the reaction is carried out in acetone; for L = 1,1',5,5'-bis[methylenedi(*p*-phenylene)]di(3,7-diphenyl-1,5-diaza-3,7-diphosphacyclooctane) (n<sup>2</sup>p<sup>2</sup>), the reaction is carried out in DMF; for L = phen or PPh<sub>3</sub>, the process is conducted in MeCN. In these cases, cleavage of the P<sub>4</sub> molecule affords a new Ni(I) complex, containing a P<sub>3</sub> fragment, for example, [(triphos)-Ni(P<sub>3</sub>)Ni(triphos)](BF<sub>4</sub>)<sub>2</sub>.

The reduction of white phosphorus in the coordination sphere of the electrochemically produced nickel(0) complex with a σ-donor ligand results in previously unknown nickel phosphides.

L = bipy, phen.

A relatively high reactivity of these complexes, compared to the known nickel phosphides, has been demonstrated.<sup>251</sup>

To conclude this Section, it should be noted that electrochemical methods can be successfully used to synthesise a wide range of compounds containing P—O, P—N, P—C and P—S bonds from white phosphorus. These reactions usually proceed under mild conditions, at high rates and with high selectivities, providing a good base for consideration at an industrial level.

\* \* \*

The information on the chemical properties of elemental phosphorus considered in this review is indicative of the keen attention given by researchers to this line of investigation, situated at the junction of different fields of chemistry. This is reflected in numerous publications on the subject. An important reason for this interest is the demand for new highly effective industrial processes for the production, direct from white phosphorus, of organophosphorus compounds which possess diverse useful properties. These compounds have found extensive use in various fields of human activity. Study of the chemical behaviour of white phosphorus with respect to transition metal complexes is the most convenient technique for investigation of the mechanisms of cleavage of the P<sub>4</sub> molecule and the stabilisation of the phosphorus-containing intermediates thus formed.

**Abstract.** The published data on the synthesis of organomagnesium compounds assisted by metal complex catalysts are generalised and described systematically for the first time. Hydro-, carbo- and cyclomagnesiation reactions of unsaturated compounds with  $R^1MgR^2$  ( $R^1 = \text{Alk, Ar; } R^2 = \text{H, Hal; } R^1 = R^2 = \text{Alk}$ ) catalysed by Ti, Zr and other transition metal salts and complexes are considered. Selected examples of applications of organomagnesium reagents to organic synthesis are given. The bibliography includes 206 references.

## I. Introduction

The first organomagnesium compounds (hereinafter, OMC) were synthesised by Grignard<sup>1</sup> in 1900 by a reaction of organic halides with metallic magnesium. This simple and efficient method for the synthesis of OMC is still widely employed in synthetic practice. The Grignard reagents are used to create new C–C bonds for the syntheses of various classes of organic compounds. The preparation of OMC by this method and their applications have been subjects of numerous publications. The results reported have been summarised in a number of monographs.<sup>2–10</sup> It is evident that further progress regarding this classical method for the synthesis of OMC should primarily rely on the involvement of more complex halide-containing systems in the reaction with metallic magnesium.

The elaboration of a novel non-traditional approach to the synthesis of organomagnesium reagents from unsaturated compounds and ordinary Grignard reagents under conditions of metal complex catalysis is a sound achievement of modern organometallic chemistry. These include catalytic hydro-, carbo- and cyclomagnesiation with  $R^1MgR^2$  ( $R^1 = \text{Alk, Ar; } R^2 = \text{H, Hal; } R^1 = R^2 = \text{Alk}$ ). Owing to the high reactivity and availability of

starting magnesium-containing reagents, the applicability to the synthesis of organomagnesium compounds with diverse structures and the mild conditions of these catalytic reactions, they hold much promise in organic and organometallic synthesis.

Presently, a large body of information on the formation of OMC in the presence of metal complex catalysts and various types of promoters has been collected (for instance, see reviews<sup>11–15</sup>). The authors of the present review have also contributed to the emergence and maturation of the chemistry of organometallic compounds. The aim of the present review is to summarise the published results concerning catalytic synthesis of OMC and analyse the most promising avenues in the further development of this field of research. Applications of OMC to organic synthesis are illustrated with selected examples only. Furthermore, numerous publications on the use of organomagnesium derivatives as co-catalysts in the oligo- and polymerisation of unsaturated compounds are also beyond the scope of the review.

## II. Hydromagnesiation of $\alpha$ -alkenes

The interaction of magnesium hydrides or alkylmagnesium halides with unsaturated compounds (alkenes, dienes or alkynes) catalysed by Ti, Zr and other transition metal salts and complexes is a convenient synthetic route to diverse OMC. The diversity of unsaturated compounds and the availability of starting reagents make it possible to prepare various uncommon OMC, which can be hard to synthesise by the traditional Grignard method.

Catalytic hydromagnesiation of  $\alpha$ -alkenes with  $Pr^nMgBr$  in the presence of titanium compounds was first reported by Finkbeiner and Cooper in 1961.<sup>16</sup> They found that different terminal alkenes could be converted into the respective organomagnesium derivatives **1** in the presence of 3 mol.%  $TiCl_4$  in yields of 20%–50% with evolution of an equimolar amount of propylene. The latter is indirect evidence of the generation, under the reaction conditions, of titanium hydrides, which are responsible for the subsequent hydrometallation of the starting alkenes.

The thus prepared organomagnesium compounds **1** react with aldehydes or carbon dioxide to yield the respective alcohols **2** or carboxylic acids **3**.

$R^1 = \text{Alk, cyclo-C}_6\text{H}_{11} \text{ (Cy), Bn; } R^2 = \text{H, Me.}$

In addition to  $TiCl_4$ , such compounds as  $Ti(OPr^i)_4$ ,  $Cp_2TiCl_2$  ( $Cp$  is cyclopentadienyl),  $ZrCl_4$ ,  $VCl_4$  (see Refs 17, 18) can also be used as catalysts for this reaction. In contrast to Ti-containing catalytic systems, nickel complexes are less selective in the reaction of  $\alpha$ -alkenes with  $RMgX$ . In particular, both primary (compounds **1**) and secondary (compounds **4**) OMC are formed in the presence of a catalytic amount of  $NiCl_2$ , their ratio being dependent on the structures of the starting alkenes and the nature of the hydrometallation agents.<sup>19, 20</sup>

$R = \text{Alk; } X = \text{Br, Cl.}$

Meanwhile,  $NiCl_2$ -catalysed hydromagnesiation of allylic alcohols with *n*-propylmagnesium bromide yields the primary products selectively. An organomagnesium compound **5** prepared by this method further reacted with  $CO_2$  and acetone.<sup>21</sup>

Presumably, the generation of nickel hydride complexes **6**, responsible for the hydrometallation of the starting allylic alcohols, is the key step in the synthesis of the OMC **5**. The catalytic cycle can be represented as follows.

$Cp_2TiCl_2$ -catalysed hydromagnesiation reactions of  $\alpha$ -alkenes were studied<sup>22</sup> using a variety of organomagnesium reagents ( $EtMgCl$ ,  $EtMgBr$ ,  $Pr^nMgCl$ ,  $Pr^iMgBr$ ,  $Bu^nMgCl$ ,  $Bu^iMgCl$ ,  $Bu^iMgBr$ ,  $Bu^iMgI$ ,  $Et_2Mg$ ,  $Pr_2^iMg$ ,  $Pr_2^iMg$ ,  $Bu_2^iMg$ ,  $Bu_2^iMg$ ,  $Bu_2^iMg$ ). Higher homologues of the OMC were obtained in satisfactory yields.

In addition to alkenes,<sup>22</sup> hydrometallation of imines was accomplished under the action of  $Bu^nMgCl$  (1.2 equiv.) and a catalytic amount of  $Cp_2TiCl_2$  under mild conditions ( $Et_2O$ ,  $25^\circ C$ , 15 h). Magnesium amides are formed in this reaction, and their subsequent hydrolysis yielded the corresponding secondary amines **7**.<sup>23</sup>

$R^1 = \text{H, Me, Et, Pr}^i; R^2 = \text{Et, Pr}^i, \text{Ph; } R^3 = \text{Pr}^n, \text{Pr}^i, \text{Bu}^i, \text{Bn.}$

An efficient method for the hydrogenation of alkenes with hydrogen ( $p = 1 \text{ atm}$ ) using a two-component catalyst  $Cp_2TiCl_2-Pr^iMgBr$  ( $[Ti]:[Mg]:[alkene] = 1:6:50$ ,  $20^\circ C$ , 5 h), which afforded the corresponding alkanes in a nearly quantitative yield, was proposed.<sup>24</sup>

Organomagnesium hydrides  $RMgH$  ( $R = \text{H, Hal, Alk}$ ) are employed in the hydromagnesiation of alkenes. Magnesium hydride generated *in situ* from  $Mg$  and  $H_2$  adds to ethylene, isobutylene and oct-1-ene to afford the corresponding dialkylmagnesium compounds in yields 4%–13%. Meanwhile, the reaction of terminal and 1,1(or 1,2)-disubstituted alkenes with  $MgH_2$  in the presence of a catalytic amount of  $Cp_2TiCl_2$  in THF at a molar ratio alkene: $MgH_2$ : $[Ti]$  of 2:1:0.05 under mild conditions (from 20 to  $60^\circ C$ ) affords the alkylmagnesium derivatives in high yields.<sup>25</sup> A system  $CrCl_3-[Mg-\text{anthracene}]$  (1:1) in THF has been recommended as a promoter for the synthesis of magnesium hydride complexes ( $HMgCl \cdot MgH_2$  or  $2HMgCl \cdot MgH_2$ ).<sup>26, 27</sup> Organomagnesium compounds **8** are prepared in nearly quantitative yield upon hydromagnesiation of  $\alpha$ -alkenes with  $EtMgH$  in the presence of Ni- or Zr-containing catalysts.<sup>28</sup>

$R = \text{Alk; } [M] = NiCl_2, Cp_2ZrCl_2.$

Bogdanović *et al.*<sup>29–31</sup> have employed catalysts based on Zr, Ti, Hf, Cr and Fe halides for the hydromagnesiation of alkenes with magnesium hydride. The OMC obtained were further converted into the corresponding ketones and carboxylic acids.

R<sup>1</sup> = H, Alk, cyclo-Alkenyl; [M] = ZrI<sub>4</sub>, ZrCl<sub>4</sub>, ZrBr<sub>4</sub>, TiCl<sub>4</sub>, Cp<sub>2</sub>TiCl<sub>2</sub>, HfCl<sub>4</sub>, CrCl<sub>3</sub>, FeCl<sub>2</sub>; R<sup>2</sup> = Alk.

Hydromagnesiation of ω-N(or O)-substituted α-alkenes with MgH<sub>2</sub> in the presence of ZrCl<sub>4</sub> yields magnesium-containing compounds **9** and **10** stabilised by intramolecular coordination of the nitrogen or oxygen atoms to the central magnesium atoms.<sup>32</sup>

R<sup>1</sup>, R<sup>2</sup>, R<sup>3</sup> = Alk.

Catalytic hydromagnesiation of α-alkenes followed by functionalisation of the resulting OMC involving the reactive Mg–C bond has been successfully used in the synthesis of steroids,<sup>33</sup> alcohols,<sup>16, 18, 21</sup> γ- and δ-lactones,<sup>34</sup> ketones, carboxylic acids<sup>16, 31</sup> and other classes of organic compounds. Selected examples of these reactions are given below.

R<sup>1</sup>, R<sup>2</sup> = Alk; R<sup>1</sup>–R<sup>2</sup> = cyclo-Alk; n = 1, 2; [Ti] = Cp<sub>2</sub>TiCl<sub>2</sub>.

R<sup>1</sup> = H, Alk, Alkenyl; R<sup>2</sup> = Alk; [M] = TiCl<sub>4</sub>, ZrCl<sub>4</sub>, ZrI<sub>4</sub>.

### III. Hydromagnesiation of 1,3-dienes

Hydromagnesiation of 1,3-dienes with magnesium hydrides is an efficient method for the synthesis of unsaturated OMC.<sup>35, 36</sup> As in the case of alkenes, Ti-containing catalysts, *viz.*, Cp<sub>2</sub>TiCl<sub>2</sub> and TiCl<sub>4</sub>, demonstrated the highest catalytic activities in this reac-

tion. With these catalysts, the conversion of the starting dienes is typically ~75%. On the other hand, the conversion of the diene did not exceed 30% and the process proceeded non-selectively with Cp<sub>2</sub>ZrCl<sub>2</sub>, ZrCl<sub>4</sub>, HfCl<sub>4</sub> and CrCl<sub>3</sub> as catalysts. This can be illustrated by catalytic reactions of isoprene with magnesium hydride, which can follow four alternative reaction pathways: 1,4-addition to form either the Mg–C(1) (path *a*) or Mg–C(4) (path *b*) bond, 1,2-addition to form either the Mg–C(1) (path *c*) or Mg–C(4) (path *d*) bond. The hydromagnesiation in the presence of Cp<sub>2</sub>TiCl<sub>2</sub>, Cp<sub>2</sub>ZrCl<sub>2</sub>, TiCl<sub>4</sub> or ZrCl<sub>4</sub> proceeds as the 1,4-addition of magnesium hydride to isoprene.<sup>35</sup>

[M] = Cp<sub>2</sub>TiCl<sub>2</sub>, Cp<sub>2</sub>ZrCl<sub>2</sub>, TiCl<sub>4</sub>, ZrCl<sub>4</sub>.

Hydromagnesiation of 1,3-dienes (butadiene, isoprene or myrcene) or styrene with Pr<sup>n</sup>MgBr in the presence of a catalytic amount of Cp<sub>2</sub>TiCl<sub>2</sub> is the simplest and the most convenient method for the synthesis of unsaturated OMC.<sup>37</sup> These studies were preceded by investigations into the hydromagnesiation of α-alkenes with propylmagnesium bromide in the presence of TiCl<sub>4</sub>.<sup>16–18</sup> The attempted use of TiCl<sub>4</sub> as a catalyst for the hydromagnesiation of 1,3-dienes failed, whereas, in the presence of Cp<sub>2</sub>TiCl<sub>2</sub>, regioisomeric allylic OMC **11a,b** were successfully prepared from 2-substituted 1,3-dienes.<sup>37</sup> It is of note that such a reaction is unknown for 1-substituted 1,3-dienes.

R = H, Me, (CH<sub>2</sub>)<sub>2</sub>CH = CMe<sub>2</sub>.

Sato *et al.* proposed<sup>37</sup> a mechanism of catalytic hydromagnesiation of 1,3-dienes, which implies that it is titanium organic hydrides **12** generated as a result of the reaction of Cp<sub>2</sub>TiCl<sub>2</sub> with Pr<sup>n</sup>MgBr that act as active hydrometallation intermediates in these reactions. They add to 1,3-dienes giving rise to allylic bis(cyclopentadienyl)titanium complexes **13**.<sup>38</sup> The latter undergo transmetalation by an excess of Pr<sup>n</sup>MgBr and are converted into regioisomeric allylmagnesium bromides **11a,b** with regeneration of catalytically active n-propyltitanium complexes **14**.

The hydromagnesiation pathway depends on both the nature of the catalyst and the structure of the starting 1,3-dienes. For instance, butadiene reacts with Pr<sup>n</sup>MgBr in the presence of a catalytic amount of Ni(PPh<sub>3</sub>)<sub>2</sub>Cl<sub>2</sub> to form octa-2,7-dienylmagne-

sium bromide (**15**), which undergoes intramolecular cyclisation into an organomagnesium compound **16**.<sup>39</sup> Isoprene reacts with  $\text{Pr}^n\text{MgBr}$  (an ethereal solution) to yield 3,7-dimethylocta-2,7-dienylmagnesium bromide (**17**).<sup>40</sup>

$[\text{Ni}] = \text{Ni}(\text{PPh}_3)_2\text{Cl}_2$ .

Hydromagnesiation of 2-alkyl-1,3-dienes (isoprene, myrcene, 2-isopropylbuta-1,3-diene, 2-*tert*-butylbuta-1,3-diene) with  $\text{RMgX}$  ( $\text{R} = \text{Et}, \text{Pr}^n, \text{Pr}^i, \text{Bu}^i, \text{Bu}^s$ ;  $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) in the presence of nickel catalysts with phosphine oxide or nitrogen-containing ligands is less selective.<sup>41,42</sup> In this case, allylic-type isomers of monomeric organomagnesium compounds (**20** and **21**) are formed in addition to the regioisomeric dimeric hydromagnesiation products **18** and **19**.

$[\text{Ni}] = \text{NiPy}_4\text{Cl}_2$ .

The use of pyridine nickel complexes as catalysts enabled the hydromagnesiation of 2-alkoxy- (see Ref. 43), 1-alkylbuta-1,3-dienes<sup>44,45</sup> and of di- and poly-alkylbuta-1,3-dienes,<sup>46</sup> which could not be effected using  $\text{Cp}_2\text{TiCl}_2$ .<sup>37</sup>

$[\text{Ni}] = \text{NiPy}_4\text{Cl}_2$ .

An efficient method for the synthesis of isoprenoid carboxylic acids **22** using Grignard reagents was developed.<sup>46–48</sup> It is based on the reaction of allylic OMC, generated *in situ* by the hydromagnesiation of substituted 1,3-dienes, with  $\text{CO}_2$ . If carbonyl compounds are used instead of carbon dioxide, the corresponding isoprenoid alcohols are formed.<sup>46–48</sup>

$[\text{Ni}] = \text{NiPy}_4\text{Cl}_2$ .

Hydrometallation of 2-alkylbutadienes with  $\text{Pr}^i\text{MgCl}$  catalysed by a chiral indenyl titanium complex afforded allylic

titanium complexes; their treatment with  $\text{CO}_2$  or aldehydes represents a convenient method for the synthesis of optically active  $\beta, \gamma$ -unsaturated carboxylic acids **23** or *threo*-homoallylic alcohols **24** with high enantiomeric purity (96%).<sup>49</sup>

$\text{R}^1 = n\text{-C}_9\text{H}_{19}$ ,  $\text{Me}_2\text{C} = \text{CH}(\text{CH}_2)_3$ ;  $\text{R}^2 = \text{Et}, \text{Pr}^i, \text{Bu}^i, \text{Ph}$ ;

Cross-coupling of N-, O- and S-functionalised allylic compounds with dienyilmagnesium reagents catalysed by transition metal complexes results in unsaturated hydrocarbons with the isoprenoid structure in high yields.<sup>50</sup>

$\text{X} = \text{OAlk}, \text{OAr}, \text{OAc}, \text{SAlk}, \text{SO}_2\text{Alk}, \text{Alk}_3\text{N}^+\text{Hal}^-$ .

An analogous scheme was used for the synthesis of polyene sulfides **25** and **26**.<sup>51</sup> In this case, a sulfur atom (from the  $\text{S}_8$  molecule) is inserted at the  $\text{Mg}-\text{C}$  bond simultaneously with the interaction of the 'isoprenemagnesium' reagent with the allylic electrophiles.

$\text{R}^1 = \text{Me}, \text{Et}, \text{Ph}$ ;  $\text{R}^2 = \text{Me}, \text{Et}$ .

The corresponding thioesters are formed if  $\text{CS}_2$  is used in this reaction.<sup>51</sup>

Synthesis and transformations of such OMC of the non-Grignard type prepared from 1,3-dienes and highly active metallic Mg are reviewed in more detail elsewhere.<sup>13</sup>

#### IV. Hydromagnesiation of alkynes

The catalytic hydromagnesiation of alkynes with magnesium hydrides or alkylmagnesium halides in the presence of Ti complexes affords vinylic organomagnesium compounds. The direction and selectivity of this reaction depend on the nature of the

catalyst, the structure of the starting alkyne and the hydromagnesiation reagent used. Hydromagnesiation of symmetrical disubstituted acetylenes with  $\text{MgH}_2$ ,<sup>25</sup>  $\text{MgH}_2 \cdot \text{CuI}$ ,  $\text{MgH}_2 \cdot \text{CuOBu}^t$  (see Ref. 52) or  $\text{Bu}^i\text{MgHal}$  ( $\text{Hal} = \text{Cl}, \text{Br}$ )<sup>11,53</sup> in the presence of a catalytic amount of  $\text{Cp}_2\text{TiCl}_2$  yields alkenylmagnesium compounds **27** or **28** with *E*-double bonds.

$\text{R} = \text{Alk}, \text{Ph}$ ;  $[\text{Ti}] = \text{Cp}_2\text{TiCl}_2$ .

Hydromagnesiation of non-symmetrical dialkylacetylenes affords two regioisomeric alkenylmagnesium halides in nearly equal proportions. The hydromagnesiation of alkylarylacetylenes<sup>53</sup> and alkyl(trimethylsilyl)acetylenes<sup>54–59</sup> is more selective. In ether at 20 °C, the magnesium atom is preferably (>95%) attached to the carbon atom bearing the phenyl or silyl substituents.<sup>60</sup>

Hydromagnesiation of 3-trimethylsilylprop-2-yn-1-ol with  $\text{Bu}^i\text{MgCl}$  in the presence of  $\text{Cp}_2\text{TiCl}_2$  (the ratio  $[\text{alkyne}]:[\text{Mg}]:[\text{Ti}] = 1:2.4:0.08$ ; 25 °C, 6 h) followed by hydrolysis of the reaction mixture affords stereoisomeric alcohols **29** in a total yield of 98%, *E*:*Z* = 95:5.<sup>61</sup>

$[\text{Ti}] = \text{Cp}_2\text{TiCl}_2$ .

$\text{Cp}_2\text{TiCl}_2$ -catalysed hydromagnesiation of disubstituted acetylenes with organomagnesium compounds of the type  $\text{R}^1\text{MgR}^2$  was studied by Dzhemilev *et al.*<sup>62</sup> It was shown that reagents containing cyclic and allylic substituents are less reactive than  $\text{Alk}_2\text{Mg}$ , whereas OMC with tertiary and vinylic substituents are virtually inert in this reaction.

The mechanism of the hydromagnesiation of disubstituted acetylenes with Grignard reagents in the presence of Ti complexes implies the generation of reactive titanium hydrides **12** under the reaction conditions. These intermediates hydrometallate the starting alkynes to form alkenyltitanium complexes **30**. This step determines the regio- and stereoselectivities of the formation of the target products: in the case of symmetrical alkynes, the transmetalation of complexes **30** with  $\text{AlkMgX}$  yields *E*-alkenylmagnesium halides **31**.<sup>60</sup> The regioselectivity of the addition of the titanium hydride complex **12** to non-symmetrical disubstituted acetylenes is governed by the nature of substituents that determine the electron density on the carbon atoms of the  $\text{C}\equiv\text{C}$  bond.

Vinylic organomagnesium compounds synthesised by the hydromagnesiation of disubstituted acetylenes are used in the selective synthesis of *Z*- (see Refs 25, 62, 63) and *E*-alkenes,<sup>64</sup> terpenoids,<sup>65</sup> *E*-allylic alcohols,<sup>66</sup> *Z*- $\alpha,\beta$ -unsaturated ketones,<sup>67</sup> substituted furans,<sup>68,69</sup> different biologically active compounds and fragrances.<sup>55,70–73</sup> Selected examples of the use of this reaction for the preparation of compounds with valuable properties are given below.

$\text{R}^1 = \text{H}, \text{Pr}^n; \text{R}^2 = \text{Me}, \text{Et}, \text{Pr}^i, \text{Ph}$ .

Cross-coupling of vinylic OMC with allylic ethers, sulfones, sulfides and quaternary ammonium salts catalysed by Pd, Ni and Cu complexes yields 1,4-dienes **32** with a trisubstituted double bond in the *E* configuration.<sup>74</sup>

$\text{R}^1 = \text{Et}, \text{Pr}^n; \text{R}^2 = \text{Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{Bu}^i; \text{R}^3 = \text{H}, (\text{CH}_2)_3\text{CH} = \text{CH}_2$ ;  
 $\text{X} = \text{OR}^4, \text{SR}^4, \text{SO}_2\text{R}^4$  ( $\text{R}^4 = \text{Et}, \text{Alk}, \text{Ph}$ ),  $\text{Et}_3\text{N}^+$ ;  $[\text{M}] = \text{Pd}, \text{Ni}, \text{Cu}$ .

Hydromagnesiation of alkynylsilanes with  $\text{Bu}^i\text{MgBr}$  catalysed by  $\text{Cp}_2\text{TiCl}_2$  (5 mol.%) followed by cross-coupling of the vinylic organomagnesium compounds **33** generated *in situ* with vinyl-, aryltellurenyl or trialkylstannyl halides represents a method for the stereoselective synthesis of 1,3-dienylsilanes,<sup>75</sup> (*E*)- $\alpha$ -aryltellurenylvinylsilanes,<sup>76</sup> (*E*)- $\alpha$ -silylvinylstannanes<sup>77</sup> and (*E*)-1,2-disubstituted vinylstannanes.<sup>78</sup>

$\text{R}^1, \text{R}^2 = \text{Alk}$ ;  $\text{X} = \text{Br}, \text{I}$ ;  $\text{Ar} = \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4$ ;  
 $[\text{Ti}] = \text{Cp}_2\text{TiCl}_2$ ,  $[\text{Pd}] = \text{Pd}(\text{PPh}_3)_4$ ;  $[\text{Ni}] = \text{Ni}(\text{PPh}_3)_2\text{Cl}_2$ .

Diynes with the triple bonds separated by hydrocarbon bridges react with  $\text{Bu}^i\text{MgBr}$  with high regio- and stereoselectivities to yield *Z*-alkenes **34**.<sup>79</sup>

$\text{R}^1, \text{R}^2 = \text{Alk}$ ;  $n = 1-4$ .

A mixed reagent  $\text{Bu}^i\text{MgBr} \cdot \text{Bu}_3^i\text{Al}$  also provides highly stereoselective hydromagnesiation of alkynes.<sup>79</sup>

$\text{R}^1, \text{R}^2 = \text{Alk}$ .

Thus, the hydromagnesiation of disubstituted acetylenes with magnesium hydrides and alkylmagnesium halides catalysed by titanium complexes represents an efficient method for the stereoselective conversion of alkynes into *Z*-alkenes.

## V. Carbomagnesiation of alkenes

In 1978, Negishi *et al.*<sup>80</sup> suggested the term 'carbometallation' for the reaction of 1,2-addition of organometallic reagents to unsaturated compounds; later on, this term became commonly adopted.<sup>81-84</sup>

It is known<sup>81,85,86</sup> that only alkenes with activated double bonds, such as bicyclo[2.2.1]hept-5-en-2-ol or (*E*)-3-phenylallylamine, can be involved in the reaction of thermal carbomagnesiation with allylmagnesium halides.

Catalysts based on titanium and other transition metal chlorides ( $\text{NiCl}_2$  or  $\text{CoCl}_2$ ) enabled catalytic carbomagnesiation of  $\alpha$ -alkenes devoid of activated double bonds with Grignard reagents.<sup>19,20,87</sup> However, due to low regio- and stereoselectivities, these catalysts have not found wide application.

In 1983, the authors of the present review accomplished for the first time regioselective carbomagnesiation of  $\alpha$ -alkenes with non-activated double bonds. High yields of products were obtained with  $\text{Et}_2\text{Mg}$  or  $\text{EtMgBr}$  in the presence of a catalytic amount of  $\text{Cp}_2\text{ZrCl}_2$ .<sup>88</sup> This reaction, referred to as 'catalytic ethylmagnesiation', is applicable to diverse alkenes.<sup>88-91</sup>

In particular, bicyclo[2.2.1]hept-2-ene reacts with an equimolar amount of  $\text{Et}_2\text{Mg}$  in the presence of a catalytic amount of  $\text{Cp}_2\text{ZrCl}_2$  ( $\text{Et}_2\text{O}$ , 20 °C, 4 h) to form compound **35**, which was further hydrolysed to yield 2-*exo*-ethylbicyclo[2.2.1]heptane.

$[\text{Zr}] = \text{Cp}_2\text{ZrCl}_2$ .

The reaction of  $\text{Et}_2\text{Mg}$  with *endo*-tricyclo[5.2.1.0<sup>2,6</sup>]deca-3,8-diene ( $\text{Et}_2\text{O}$ , 20 °C,  $\text{Cp}_2\text{ZrCl}_2$  as a catalyst) affords a mixture of regioisomeric OMC **36a,b** differing in the position of the ethyl group relative to the double bond in a total yield 60%, the ratio of the isomers being ~1 : 1. Under the same conditions, the organomagnesium compound **37** is obtained from bicyclo[2.2.1]hepta-2,5-diene and  $\text{Et}_2\text{Mg}$ , and its hydrolysis resulted in 3-ethylnor-tricyclene.<sup>90</sup>

$[\text{Zr}] = \text{Cp}_2\text{ZrCl}_2$ .

A tentative mechanism of the ethylmagnesiation reaction of alkenes with  $\text{EtMgBr}$  in the presence of  $\text{Cp}_2\text{ZrCl}_2$  as a catalyst proposed by Negishi and Takahashi implies consecutive forma-

tion of a zirconacyclopentadiene intermediate **38** and a bimetallic complex **39**, which is finally converted into the target OMC **40**.<sup>92–95</sup>

Various N-, O- and S-containing alkenes served as the substrates in the ethylmagnesiation reaction.<sup>91,96–121</sup> Ethylmagnesiation of octa-2,7-dienyl ethers and octa-2,7-dienylamines with EtMgR (R = Br, Et) catalysed by Cp<sub>2</sub>ZrCl<sub>2</sub> involves the terminal double bond to yield the corresponding O- and N-functionalised OMC **41**.

R<sup>1</sup> = Br, Et; X = OR<sup>2</sup>, SR<sup>2</sup> (R<sup>2</sup> = Me, Et, Bu<sup>n</sup>), NEt<sub>2</sub>; [Zr] = Cp<sub>2</sub>ZrCl<sub>2</sub>.

Reagents of the type EtMgOR, EtMgSR, EtMgOC(O)R, and EtMgC≡CR (R = Alk) appeared inert in ethylmagnesiation of α-alkenes catalysed by Cp<sub>2</sub>ZrCl<sub>2</sub>.<sup>91</sup>

Ethylmagnesiation of allylic and homoallylic alcohols and ethers with an excess of EtMgCl in the presence of Cp<sub>2</sub>ZrCl<sub>2</sub> has been studied by Hoveyda *et al.*<sup>96–99</sup> This reaction was highly stereoselective and afforded β-ethyl-substituted organomagnesium compounds in high yields. The structures of these OMC were established by an analysis of their oxidation products, **42** and **43**. Presumably, the high stereoselectivity of ethylmagnesiation is due to the coordination of the heteroatom of the starting unsaturated compound to the central metal atom of the catalyst.

(a) EtMgCl (4 equiv.), Cp<sub>2</sub>ZrCl<sub>2</sub> (5%), Et<sub>2</sub>O, 25 °C, 12 h;  
(b) B(OMe)<sub>3</sub>, H<sub>2</sub>O<sub>2</sub>, –78 °C.

| R  | The ratio <i>anti</i> : <i>syn</i> |           | Yield (%) |           |
|----|------------------------------------|-----------|-----------|-----------|
|    | <b>42</b>                          | <b>43</b> | <b>42</b> | <b>43</b> |
| H  | 5 : 95                             | > 99 : 1  | 70        | 75        |
| Me | 89 : 11                            | 97 : 3    | 80        | 65        |

Asymmetric ethylmagnesiation of α-alkenes, non-cyclic and cyclic allylic alcohols, ethers and amines<sup>100–117</sup> in the presence of Zr-containing catalysts is highly diastereo- and enantioselective. The enantioselective formation of C–C bonds catalysed by chiral Zr and Ti complexes has been reviewed elsewhere.<sup>110–113</sup> Selected representative examples of such asymmetric syntheses are given below.

[Zr] is ethylene-1,2-bis(η<sup>5</sup>-4,5,6,7-tetrahydro-1-indenyl)zirconium dichloride.

A tentative mechanism of the catalytic reaction of EtMgCl with cyclic allylic ethers and amines involves the enantioselective addition of the starting unsaturated compound to the complex **44** to form a zirconacyclopentadiene intermediate **45**.<sup>104</sup> The regio-controlled opening of the zirconacyclopentadiene fragment with EtMgCl results in a sterically less hindered complex **46**, intramolecular rearrangement of which results in a γ-ethyl-substituted α-alkene **47**.

X = O, NC<sub>9</sub>H<sub>19–n</sub>; L is 1,2-bis(η<sup>5</sup>-4,5,6,7-tetrahydro-1-indenyl)ethylene.

The enantioselective alkylation of cyclic allylic ethers or acyclic homoallylic alcohols (or ethers) with Pr<sup>n</sup>MgCl or Bu<sup>n</sup>MgCl in the presence of a catalytic amount of Cp<sub>2</sub>ZrCl<sub>2</sub> affords γ-substituted terminal alkenes as isomers with primary (compounds **48**) and secondary (compounds **49**) alkyl groups. The regioselectivity of the reaction depends on the structure of the starting reagents and temperature.<sup>121,122</sup> Typically, ether is used as a solvent, since tetrahydrofuran provides lower selectivities and yields of the products.

[Zr] = Cp<sub>2</sub>ZrCl<sub>2</sub>.

| <i>n</i> | R <sup>1</sup>  | R <sup>2</sup> | Temperature / °C | Ratio<br><b>49:48</b> | <i>ee</i> (%) |

In analogy with ethylmagnesiation,<sup>88</sup>  $\alpha$ -alkenes were successfully ethylzincated<sup>123</sup> with Et<sub>2</sub>Zn catalysed by Et<sub>2</sub>ZrCp<sub>2</sub>. The latter was generated from Cp<sub>2</sub>ZrCl<sub>2</sub> and EtMgBr. As a result, a series of organozinc compounds **50** have been obtained.

R = Alk.

Ethylmagnesiation reaction of alkenes catalysed by Zr complexes is widely applied in the synthesis of biologically active compounds,<sup>109, 118–120, 124</sup> such as the natural antibiotic fluviricin B<sub>1</sub> (see Ref. 118).

## VI. Cyclomagnesiation of alkenes and allenes

Based on the results of investigations<sup>125, 126</sup> into the catalytic cycloaluminum of alkenes with trialkyl- or alkylhaloalanes to give aluminacyclopentanes, the first cyclomagnesiation of alkenes with R<sub>2</sub>Mg and Cp<sub>2</sub>ZrCl<sub>2</sub> as a catalyst was accomplished in 1989.<sup>127</sup> It was found that the reaction of styrene with Alk<sub>2</sub>Mg (Alk = Pr<sup>n</sup>, Bu<sup>n</sup>, n-C<sub>6</sub>H<sub>13</sub>) in the presence of a catalytic amount of Cp<sub>2</sub>ZrCl<sub>2</sub> in a mixture THF–Et<sub>2</sub>O afforded a mixture of 2,4-disubstituted magnesacyclopentanes **51a** and **52a** in a ratio ~ 1:3 (the total yield is ~ 80%<sup>†</sup>).<sup>127, 128</sup>

<sup>†</sup> Hereinafter, the yields of OMC are calculated based on the hydrolysis products of the reaction mixture.

R = Me, Et, Bu<sup>n</sup>; [Zr] = Cp<sub>2</sub>ZrCl<sub>2</sub>.

Ring-substituted styrenes (2-, 3- and 4-methyl-, 3-*tert*-butyl-) can also be cyclomagnesiated with R<sub>2</sub>Mg catalysed by Cp<sub>2</sub>ZrCl<sub>2</sub> to magnesacyclopentanes **51b–e** and **52b–e** (in a ratio of ~ 1:1) in yields of > 70%.<sup>129–131</sup>

R<sup>1</sup> = Me, R<sup>2</sup> = R<sup>3</sup> = H (**b**); R<sup>2</sup> = Me, R<sup>1</sup> = R<sup>3</sup> = H (**c**);

R<sup>3</sup> = Me, R<sup>1</sup> = R<sup>2</sup> = H (**d**); R<sup>3</sup> = Bu<sup>t</sup>, R<sup>1</sup> = R<sup>2</sup> = H (**e**); R<sup>4</sup> = Me, Et.

Cyclomagnesiation of a mixture of styrene and hex-1-ene with Pr<sub>2</sub><sup>n</sup>Mg in the presence of Cp<sub>2</sub>ZrCl<sub>2</sub> as a catalyst in a mixture THF–Et<sub>2</sub>O resulted in 2,4-disubstituted magnesacyclopentanes **53:50a:54** in a ratio of ~ 35:35:30 in a total yield of 85%.<sup>132</sup>

Based on the results obtained, a tentative mechanism of cyclomagnesiation of alkenes with di(n-propyl)magnesium catalysed by Cp<sub>2</sub>ZrCl<sub>2</sub> has been proposed.<sup>131</sup> It involved alkylation of Cp<sub>2</sub>ZrCl<sub>2</sub> to di(n-propyl)zirconocene **55**, intramolecular  $\beta$ -hydride transfer<sup>133</sup> with elimination of propane and formation

of a propylene–zirconocene intermediate **56**. The latter reacts with a mixture of alkenes affording 2,4-disubstituted zirconacyclopentanes **57–59**,<sup>134</sup> which react with the starting reagent ( $\text{Pr}_2^{\text{n}}\text{Mg}$ ) to give the corresponding 2,4-disubstituted magnesacyclopentanes **50a**, **53** and **54**.

Cyclomagnesiation of norbornenes with  $\text{Pr}_2^{\text{n}}\text{Mg}$  or  $\text{Bu}_2^{\text{n}}\text{Mg}$  catalysed by  $\text{Cp}_2\text{ZrCl}_2$  (3 mol.%) in THF– $\text{Et}_2\text{O}$  resulted in mixtures of polycyclic OMC in yields of 80%–95%.<sup>135</sup>

R = Me, Et.

Aliphatic  $\alpha$ -alkenes react with  $\text{Alk}_2\text{Mg}$  (Alk =  $\text{Pr}^{\text{n}}$ ,  $\text{n-C}_6\text{H}_{13}$ ,  $\text{n-C}_8\text{H}_{17}$ ) in the presence of  $\text{Cp}_2\text{ZrCl}_2$  to give predominantly acyclic unsaturated organomagnesium compounds.<sup>131, 136</sup> Presumably, intermediate 2,4-dialkyl-substituted zirconacyclopentanes **60** and **61** are formed under the reaction conditions, which undergo intramolecular  $\beta$ -hydride transfer under the action of the starting magnesium reagent and are converted into the isomeric acyclic unsaturated OMC **62** and **63**. It is of note that 2-arylzirconacyclopentanes **57–59** have no hydrogen atoms at the  $\beta$ -carbon atom and thus no transformations of this type with opening of the metallacycle take place.

$\text{R}^1 = \text{H}, \text{Pr}^{\text{n}}, \text{n-C}_5\text{H}_{11}$ ;  $\text{R}^2 = \text{Alk}$ .

Unlike  $\text{Alk}_2\text{Mg}$  (Alk =  $\text{Pr}^{\text{n}}$ ,  $\text{Bu}^{\text{n}}$ ,  $\text{n-C}_6\text{H}_{13}$  or  $\text{n-C}_8\text{H}_{17}$ ), such magnesium reagents as  $\text{EtMgX}$  (X = Cl, Br) or  $\text{Et}_2\text{Mg}$  react with  $\alpha$ -alkenes in the presence of a catalytic amount of  $\text{Cp}_2\text{ZrCl}_2$  to yield ethylmagnesiation (**64**) or cyclomagnesiation products **65** and/or **66**, respectively (Scheme 1). The reaction pathway depends on the reaction conditions, *viz.*, the nature of the solvent, the temperature and the ratio of the starting reagents. For instance, ethylmagnesiation products are formed with high selectivity [the ratio **64**:(**65** + **66**) is 95:5] in THF (2 equiv. of  $\text{EtMgHal}$ ,  $\sim 20^\circ\text{C}$ , 16 h), whereas 1,4-dimagnesium compounds are predominantly formed [the ratio **64**:(**65** + **66**) is 15:85] in  $\text{Et}_2\text{O}$  with 4 equiv. of  $\text{Et}_2\text{Mg}$  ( $0^\circ\text{C}$ , 16 h).<sup>137</sup>

R =  $\text{n-C}_5\text{H}_{11}$  (70%),  $\text{C}_5\text{H}_9\text{N}$  (65%),  $\text{C}_5\text{H}_8\text{NCH}_2$  (75%),  $\text{C}_4\text{H}_3\text{N}_2$  (65%),  $\text{C}_4\text{H}_2\text{N}_2\text{NCH}_2$  (75%), BnO (54%),  $\text{BnOCH}_2$  (56%),  $\text{BnO}(\text{CH}_2)_2$  (65%),  $\text{Bu}^{\text{t}}\text{Me}_2\text{SiO}(\text{CH}_2)_2$  (70%), PhS (80%),  $\text{Me}_3\text{Si}$  (63%); X = Cl, Et.

Scheme 1

A tentative mechanism was proposed in order to rationalise the experimental results, which is shown in Scheme 1. In the first step, diethylmagnesium alkylates  $\text{Cp}_2\text{ZrCl}_2$  to yield zirconacyclopentane intermediates **67**. Depending on the reaction conditions, the latter react with  $\text{Et}_2\text{Mg}$  to give either ethylmagnesium (64) or cyclomagnesium (65, 66) products.<sup>137, 138</sup>

The reactions of non-conjugated  $\alpha,\omega$ -dienes with  $\text{Bu}^n\text{MgX}$  or  $\text{Bu}_2\text{Mg}$  catalysed by  $\text{Cp}_2\text{ZrCl}_2$  (1 mol.%–10 mol.%) in ether-type solvents afford 1,2-bis(magnesiomethyl)carbocycles **68** or 1-(magnesiomethyl)-2-methylcarbocycles **69**<sup>139–142</sup> via zirconacyclopentane intermediates that are formed under these conditions.<sup>143, 144</sup> The rates of formation and yields of the target products, the selectivity and stereochemistry of the process depend on the structure of the starting  $\alpha,\omega$ -diene (this can be hepta-1,6-diene, octa-1,7-diene or 9,9-diallylfluorene), the organomagnesium compound used (e.g.,  $\text{Bu}^n\text{MgHal}$  or  $\text{Bu}_2\text{Mg}$ ), reaction temperature (from 0 to 120 °C), solvent ( $\text{Et}_2\text{O}$ , THF,  $\text{Pr}_2\text{O}$ ,  $\text{Bu}_2\text{O}$ ) and the ratio of the reagents. For instance, with  $\text{Bu}_2\text{Mg}$  in  $\text{Et}_2\text{O}$  at 20 °C, 1,2-bis(n-butylmagnesiomethyl)cycloalkanes **68** are predominantly formed. In contrast, the reaction of  $\alpha,\omega$ -dialkenes with  $\text{Bu}^n\text{MgHal}$  in THF yields mainly 1-(halomagnesiomethyl)-2-methylcarbocycles **69**. It is of note that the total yield of organomagnesium compounds **68** and **69** in  $\text{Et}_2\text{O}$  is higher than that in THF. The ratio between *trans* and *cis* isomers in the products **68** and **69** increases with an increase in temperature. The transmetalation of bimetallic complexes **70** with the starting organomagnesium reagents is the key step of the catalytic cycle, which determines the overall chemoselectivity of the reaction.<sup>141, 142</sup>

Negishi *et al.*<sup>145</sup> investigated the reactions of  $\text{Bu}^n\text{MgCl}$  and  $\text{Bu}_2\text{Mg}$  with 3-bis( $\eta^5$ -cyclopentadienyl)zirconabicyclo[3.3.0]octane **71** (R =  $\text{CH}_2$ ) in two solvents, *viz.*, THF and  $\text{Et}_2\text{O}$  (Scheme 2) to get an insight into the mechanism of the above transformations. The complex **71** (R =  $\text{CH}_2$ ) is a possible intermediate in the reaction of hepta-1,6-diene with  $\text{Bu}^n\text{MgX}$  (X = Cl,  $\text{Bu}^n$ ) catalysed by  $\text{Cp}_2\text{ZrCl}_2$ .

It was found that the monomagnesium derivative **72** is formed only in the case of  $\text{Bu}^n\text{MgCl}$  in THF. In all other cases ( $\text{Bu}^n\text{MgCl}$  in  $\text{Et}_2\text{O}$  and  $\text{Bu}_2\text{Mg}$  in any of the two solvents), the 1,4-dimagnesium derivative **73** was the major product. This fact can be explained as follows. It is known that the Grignard reagents  $\text{AlkMgHal}$  exist as monomers in tetrahydrofuran and as dimers in diethyl ether.<sup>146</sup> In the case of dimeric structures ( $\text{Bu}^n\text{MgCl}$  in  $\text{Et}_2\text{O}$  or  $\text{Bu}_2\text{Mg}$ ), an intramolecular transfer of the butyl group from the magnesium to the zirconium atom occurs in the complexes **74** and **75** resulting in the 1,4-dimagnesium compound **73**. No similar process is possible for monomeric structures ( $\text{Bu}^n\text{MgCl}$  in THF) or at a molar ratio complex **71**: $\text{Bu}_2\text{Mg}$  other than 1:1 or 1:2. If the reaction is performed with  $\text{Bu}_2\text{Mg}$ , the magnesium-containing bicyclic compound **76** is formed in addition to **73** in both solvents.

Unsaturated monomagnesium compounds **77** are obtained only in the reaction of  $\text{Bu}^n\text{MgCl}$  with hepta-1,6-diene in THF or  $\text{Et}_2\text{O}$  in the presence of a catalytic amount of  $\text{Cp}_2\text{ZrCl}_2$  in a yield of ~10%. This conclusion was drawn from the analysis of subsequent iodination products, **78–80**.

| Solvent               | Yield (%) |    |        |
|-----------------------|-----------|----|--------|
|                       | 78        | 79 | 80     |
| THF                   | 45        | 10 | traces |
| $\text{Et}_2\text{O}$ | 10        | 10 | 40     |

The stereochemistry of the carbomagnesium and cyclo-magnesium of  $\alpha$ -alkenes or non-conjugated dienes with  $\text{Alk}_2\text{Mg}$  or  $\text{AlkMgHal}$  catalysed by chiral zirconium complexes was discussed elsewhere.<sup>147–149</sup> Under the reaction conditions, intermediate *cis*- (**81**) and *trans*-zirconacyclopentanes **82** are selectively formed, which are further converted into the corresponding *cis*- and *trans*-dimagnesium compounds **83** and **84** (Scheme 3).<sup>149</sup>

Carbocyclisation of unsaturated compounds using OMC and Zr-containing catalysts is applied to the synthesis of hydrogenated indane derivatives, including optically active ones.<sup>150–160</sup> The

Scheme 2

(a)  $\text{Bu}^n\text{MgCl}$ , THF; (b)  $\text{Bu}^n\text{MgCl}$ ,  $\text{Et}_2\text{O}$ ; (c)  $\text{Bu}_2\text{Mg}$ ,  $\text{Et}_2\text{O}$  (THF);  $n = 1$  or  $2$ ; X = Cl (for b) and  $\text{Bu}^n$  (for c).

Scheme 3

$\text{X} = (\text{CH}_2)_n$  ( $n = 1, 2$ ),  $\text{NBu}^t$ ,  $\text{SiMe}_2$ ;  $\text{R} = \text{Bu}^n$ ,  $\text{Cl}$ ;  $\text{Cp}_2^*\text{ZrCl}_2$  is 2,2'-biphenyl-bis(3,4-dimethylcyclopentadienyl)zirconium dichloride.

multistep synthesis shown below has been accomplished by Mori *et al.*<sup>153</sup>

$\text{R} = \text{H}$ ,  $\text{Bu}^t\text{Me}_2\text{Si}$ ;

Allenes react with  $\text{Et}_2\text{Mg}$  in the presence of  $\text{Cp}_2\text{ZrCl}_2$ . Depending on the conditions, either carbomagnesiation (**85**–**87**) or cyclomagnesiation products **88**–**90** can be obtained.<sup>161</sup>

$\text{R} = n\text{-C}_5\text{H}_{11}$ ,  $n\text{-C}_7\text{H}_{15}$ ,  $\text{Bn}$ .

2,5-Dialkylidenemagnesacyclopentanes **91** and 1,4-dimagnesium compounds **92** (in a ratio of  $\sim 1:1$ ) were obtained<sup>161</sup> by  $\text{Cp}_2\text{TiCl}_2$ -catalysed cyclomagnesiation of substituted allenes with  $\text{EtMgX}$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ) and activated magnesium (see also Ref. 162).

$\text{R} = n\text{-C}_5\text{H}_{11}$ ,  $n\text{-C}_7\text{H}_{15}$ ,  $\text{Bn}$ .

The formal reduction of  $\text{Cp}_2\text{TiCl}_2$  to ' $\text{Cp}_2\text{Ti}$ ', selective formation of intermediate 2,5-dialkylidenetitanacyclopentanes **93** followed by their transmetalation with  $\text{EtMgX}$  are the most probable intermediate steps, which explain the formation of the unsaturated OMC **91** and **92**.

$\text{X} = \text{Cl}$ ,  $\text{Br}$ .

Intermolecular cyclomagnesiation of  $\alpha,\omega$ -diallenes with  $\text{EtMgX}$  and activated magnesium catalysed by  $\text{Cp}_2\text{TiCl}_2$  (10 mol.%) has led to  $\text{Mg}$ -containing macrocycles **94** under mild conditions and in high yields ( $> 90\%$ ).<sup>161</sup> Subsequent treatment of the OMC **94** with a deuterated acid affords macrocyclic compound **95** with alternating *cis*-double bonds.

The idea of generation of zirconacyclopentane intermediates in the reaction of allylic ethers with EtMgBr in the presence of a catalytic amount of  $\text{Cp}_2\text{ZrCl}_2$  is exploited in an efficient method for the formation of C–C bonds. In contrast to the cyclo- and carbomagnesiation reactions (see Section V), it is unsaturated compounds rather than organomagnesium compounds that are the target products of these reactions. In particular, the reaction of allylic ethers containing a disubstituted double bond with EtMgBr catalysed by  $\text{Cp}_2\text{ZrCl}_2$  (THF, 20  $^\circ\text{C}$ , 6 h) results in the regioselective formation of a C–C bond involving the  $\gamma$ -carbon atom of the allylic ether, *i.e.*, affords an unsaturated compound **96**.<sup>163</sup> The high regioselectivity of the reaction is due to the formation of zirconium alkoxide **97** from regioisomeric<sup>164</sup> zirconacyclopentane intermediates **98** and **99**.

In addition to  $\text{Cp}_2\text{ZrCl}_2$ ,  $\text{Cp}_2\text{HfCl}_2$  can be used as a catalyst for these reactions. However, in this case, a satisfactory yield can be obtained only for a longer reaction time (65 h). No target products **96** are formed if MeMgBr devoid of the  $\beta$ -hydrogen atoms is used instead of EtMgBr.

$\text{R}^1 = \text{Pr}^n; \text{R}^2 = \text{Me, Bn, Ph}.$

2-Bromo- $\alpha,\omega$ -diene,<sup>165</sup> dienic ethers and amines with allylic double bonds<sup>166,167</sup> cyclised into unsaturated carbo- and heterocyclic compounds **100** with high selectivities using  $\text{Bu}^n\text{MgCl}$  and  $\text{Cp}_2\text{ZrCl}_2$  as a catalyst. The formation of zirconacyclopentane intermediates **101** is the key step of this reaction. Subsequent intramolecular rearrangement proceeds through zirconium alkoxide complexes **102**, which are further transmetalated with the starting reagent  $\text{Bu}^n\text{MgCl}$ . The catalytic cycle is closed by elimination of the unsaturated cyclic product **100**.

$\text{X} = \text{CH}_2, \text{NPr}^n, \text{NPh}; \text{Y} = \text{OMe, OPh}.$

Electrophilic alkylation of alkenes, indenes and chromenes with alkyl *p*-toluenesulfonates, sulfates or bromides has been realised<sup>168–170</sup> *via* intermediate zirconamagnesium complexes of the type **103** (see Ref. 168).

$\text{R}^1, \text{R}^2 = \text{Alk}.$

## VII. Carbomagnesiation of 1,3-dienes

Thermal carbomagnesiation of conjugated dienes can only be performed with allylic OMC.<sup>171,172</sup> Alkyl- and arylmagnesium halides do not react with 1,3-dienes under these conditions.

It was demonstrated<sup>173</sup> that isoprene undergoes carbomagnesiation with geranylmagnesium halides under relatively mild conditions in the presence of Ti-containing catalysts. The OMC **104** and **105** synthesised in this way were further converted into the corresponding isoprenoid alcohols.

$[\text{Ti}] = \text{Ph}_2\text{TiCl}_2, (\text{RO})_2\text{TiCl}_2 (\text{R} = \text{Alk, Ar}).$

Carbomagnesiation of isoprene with allylic OMC catalysed by  $\text{Cp}_2\text{TiCl}_2$  proceeds in THF with heating.<sup>174, 175</sup> The OMC **106** formed can be converted into the corresponding alcohols or carboxylic acids **107** by oxidation or reaction with  $\text{CO}_2$ .

$\text{R}^1 = \text{Me}$ ,  $\text{R}^2 = \text{R}^3 = \text{H}$  (25%);  $\text{R}^1 = \text{R}^2 = \text{Me}$ ,  $\text{R}^3 = \text{H}$  (20%);  
 $[\text{Ti}] = \text{Cp}_2\text{TiCl}_2$

The addition of  $\text{PhMgBr}$  to butadiene in the presence of low-valent nickel complexes activated by  $\text{P}(\text{O}Ph)_3$ <sup>176</sup> is the earliest example of carbomagnesiation of dienes with arylmagnesium halides. The formation of intermediate bis- $\pi$ -allyl nickel complexes **108** is the key step of this reaction. This is followed by the oxidative addition of  $\text{PhMgBr}$  to this intermediate and reductive elimination of  $\text{Ni}^0$ , which yields (*E,E*)-octa-2,7-dienylmagnesium bromide **109** selectively.

$\text{L}_n = \text{P}(\text{O}Ph)_3$ .

Phosphines and acetylacetonate can be used as ligands in the nickel complexes. The activity of the Ni-containing catalysts in the reaction of arylmagnesium halides with butadiene decreases in the series:  $\text{Ni}(\text{PPh}_3)_2\text{Cl}_2 > \text{Ni}(\text{Ph}_2\text{PCH}_2\text{CH}_2\text{PPh}_2)\text{Cl}_2 > \text{Ni}(\text{Ph}_2\text{PCH}_2\text{CH}_2\text{PPh}_2)(\text{acac})_2 > \text{Ni}(\text{acac})_2$ .<sup>177</sup> In the case of phenylmagnesium bromide, a number of salts and complexes of various transition metals, including Pd, Cu, Rh, Ni, Co, Cr and Fe, in different oxidation states with different types of metal atom coordination, ligands and counterions were assayed as catalysts. In the presence of Fe(III) salts and complexes, the reactions of alka-1,3-dienes with arylmagnesium halides yield 1-aryllalka-1,3-dienes. This reaction catalysed by phosphine Ni(II) complexes affords telomeric 1-aryllalka-2,7- and 1-aryllalka-2,6-dienes.<sup>178, 179</sup>

In contrast to arylmagnesium halides,  $\text{Bu}^t\text{MgCl}$  reacts with 1,3-dienes in the presence of nickel complexes yielding 1,4-addition products **110** and **111**.<sup>40, 46</sup>

By analogy with the carbomagnesiation reaction, silylmagnesiation of 1,3-dienes leading to unsaturated Si-containing OMC **112** in the presence of manganese catalysts was carried out.<sup>180</sup>

Carbomagnesiation of 1,3-dienes with alkyl-, aryl- and allyl-type OMC catalysed by metal complexes affords unsaturated organomagnesium reagents that are difficult to obtain by conventional methods.

## VIII. Carbomagnesiation of alkynes

Regio- and stereoselective carbomagnesiation of alkynes is used in synthetic practice for the preparation of substituted alkenes with *Z*-configuration of the double bond.<sup>181</sup>

As a rule, non-catalytic carbomagnesiation of alkynes requires drastic conditions and long reaction time.<sup>182</sup> The use of metal complex catalysts makes it possible to decrease the temperature, reduce the duration and increase the yields of the target products. For instance, carbomagnesiation of acetylene with Grignard reagents in the presence of Cu(I) compounds takes 1–2 h at low temperature to give organomagnesium compounds **113** containing *Z*-double bonds.<sup>183</sup>

$\text{R} = \text{Alk}$ ;  $\text{X} = \text{Cl}, \text{Br}$ ;  $[\text{Cu}] = \text{CuBr}, \text{CuCN}, \text{PhSCu}, \text{Bu}^t\text{OCu}, \text{MeCu}$ .

Carbomagnesiation of monosubstituted alkynes in the presence of copper salts involves the addition of the magnesium atom to the non-substituted  $\alpha$ -carbon atom of the original alkyne. Subsequent functionalisation of the OMC formed with chlorosilanes is of interest as a method for the synthesis of unsaturated silanes of the type **114** with a *Z*(or *E*)-trisubstituted double bond.<sup>184</sup>

(a)  $\text{EtMgCl}$ ,  $\text{CuI}$ ,  $\text{LiBr}$ , THF,  $-60^\circ\text{C}$ , 14 h;  
 (b)  $\text{Me}_3\text{SiCl}$ , HMPA,  $-60$  to  $20^\circ\text{C}$ , 5 h.

Carbomagnesiation of disubstituted acetylenes results in OMC containing *E*- and *Z*-double bonds. In particular, prolonged boiling of diphenylacetylene in ether with a twofold excess of  $\text{MeMgBr}$  in the presence of  $\text{Ni}(\text{PPh}_3)_2\text{Cl}_2$  (10 mol.%) yields the unsaturated OMC **115**, which is hydrolysed to the individual trisubstituted alkene **116** with *cis*-arrangement of the phenyl substituents.<sup>185</sup> The reaction of hex-3-yne with  $\text{PhMgBr}$  under similar conditions affords *cis*- (**117**) and *trans*-isomers (**118**) in a ratio of 9:1. Duboudin *et al.*<sup>185</sup> proposed that the *cis*–*trans*-isomerisation of organomagnesium compounds in the latter case

$[\text{Ni}] = \text{Ni}(\text{PPh}_3)_2\text{Cl}_2$ .

is due to the formation of intermediate  $\pi$ -allyl nickel complexes.<sup>186, 187</sup>

Diacetylenes undergo carbomagnesiation in the presence of  $\text{NiCl}_2$ , which results in OMC **119** with an enyne fragment.<sup>188</sup> Functionalised alkadiynes, such as alkyl(alkylthio)diacetylenes, have also been carbomagnesiated in the presence of Ni-containing catalysts.<sup>189</sup>

R = Me, Bu<sup>t</sup>.

Carbomagnesiation of conjugated enynes yields alkadienylmagnesium halides, and their hydrolysis offers a convenient route to 1,3-dienic hydrocarbons.<sup>190</sup> Pd, Fe, Ni and Co complexes can be used as catalysts in the carbomagnesiation of 1-en-4-yne with arylmagnesium bromides to a mixture of *Z*- and *E*-isomers of aryl-substituted 1,3-dienes **120**.<sup>191</sup>

R = Me, Et; Ar = Ph, 2-MeC<sub>6</sub>H<sub>4</sub>, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>, 4-Me<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>; [M] = Pd, Fe, Ni, Co.

A proposed mechanism of carbomagnesiation of alkynes with the Grignard reagents in the presence of Ni-containing catalysts involves the oxidative addition of  $\text{RMgHal}$  to the low-valent nickel complex **121** to form the alkenylmagnesium complex **122**, which induces carbomagnesiation of the original alkyne to give the alkenylmagnesium complex **123**.<sup>192</sup> Subsequent reductive elimination of a low-valent Ni complex yields the target alkenyl OMC **124**.

Carbomagnesiation of silylacetylenes with a fourfold excess of  $\text{MeMgBr}$  in the presence of a two-component catalyst  $\text{Ni}(\text{acac})_2-\text{Me}_3\text{Al}$  (1:1) is rather highly regioselective. The Grignard reagent adds predominantly (~90%) to the carbon atom bearing the silyl group.<sup>193</sup> The use of  $\text{EtMgBr}$  and a system  $\text{Ni}(\text{acac})_2-\text{Bu}_3\text{AlH}$  as a catalyst affords alkenyl- (~50%) and alkadienylmagnesium bromides (~30%). The latter are formed upon carbomagnesiation of the original alkyne with alkenylmagnesium halide generated *in situ*.<sup>194</sup>

Cu(I) salts are more active catalysts in the carbomagnesiation of propargylic and allenic alcohols in contrast to the corresponding reactions with alkyl-, aryl- and silylacetylenes.<sup>195–197</sup>

R<sup>1</sup> = Me, Et, Pr<sup>i</sup>, Bu<sup>t</sup>, All, Bn, Ph; R<sup>2</sup> = H, Me, Ph, Bu<sup>n</sup>, Me<sub>3</sub>Si; X = Cl, Br.

Propargylic ethers readily react with Grignard reagents (~20 °C, ether, 10 mol.% of CuBr) to afford carbomagnesiation products in 70%–80% yields.<sup>198</sup> In the presence of  $\text{MnCl}_2$  as a catalyst, carbomagnesiation<sup>199</sup> as well as silylmagnesiation<sup>180</sup> of disubstituted acetylenes, including those containing functional groups, can successfully be carried out.

X = OH, OMe, OBn, NEt<sub>2</sub>.

Stannylmagnesiation of terminal alkynes, like carbomagnesiation, is performed in the presence of CuCN. This reaction with various electrophilic reagents yields vinylstannanes **125** with high regio- and stereoselectivities.<sup>200</sup>

R = Alk, cyclo-Alk, Ph, BnO(CH<sub>2</sub>)<sub>2</sub>; E = H, D, Me, Et, All, PhCH(OH).

Carbomagnesiation of alkynes with the Grignard reagents is widely applied to the synthesis of unsaturated halides,<sup>201</sup>  $\Delta^{\alpha,\beta}$ -butenolides, alk-2-ene-1,4-diols,<sup>202</sup> cyclopentenones,<sup>203</sup> vinyl sulfones<sup>204</sup> and various biologically active compounds.<sup>205</sup> Furthermore, it is useful in the cross-coupling reactions.<sup>206</sup>

In particular, Duboudin and Jousseau<sup>202</sup> reported the synthesis of a number of unsaturated diols and lactones exploiting organomagnesium compounds **126** prepared from the respective alkyne.

(a) R<sup>2</sup>MgBr, CuI (10%); R<sup>1</sup>, R<sup>2</sup> = H, Me, Et, Ph, Bz, All; R<sup>3</sup>C(O)R<sup>4</sup> = EtCH(O), Me<sub>2</sub>C(O), PhC(O)Me, (CH<sub>2</sub>)<sub>5</sub>C(O).

The above results demonstrate that the carbomagnesiation of alkynes with Grignard reagents in the presence of transition metal-based catalysts represents a convenient method for the synthesis of alkenylic, alkadienylic and enynic organomagnesium compounds. Functionalisation of such derivatives offers new potential in synthetic practice.

## IX. Conclusion

The application of metal complex catalysis to the chemistry of OMC has led to the discovery of new reactions, development of efficient methods of synthesis of various types of compounds and development of novel highly reactive reagents to meet the needs of modern organic and organometallic chemistry. Non-traditional 'non-Grignard' organomagnesium compounds with different structures that became available due to advances in the metal complex catalysis, have solidly taken their places in the arsenal of common reagents. Investigations into hydro- and carbomagnesiation of alkenes, dienes and alkynes with magnesium hydride and alkylmagnesium compounds in the presence of transition metal-based catalysts are currently in progress, which unveils new avenues in the preparation of non-trivial magnesium-containing systems. Catalytic cyclomagnesiation of unsaturated compounds with  $\text{AlkMgHal}$  (or  $\text{Alk}_2\text{Mg}$ ) has led to new classes of cyclic OMC.

According to the above analysis of the published data, one can expect, in the very near future, further progress in several promising directions, in particular, selective functionalisation of unsaturated compounds through the intermediate formation of  $\text{Mg}-\text{C}$  bonds; chiral synthesis of organomagnesium reagents and their conversion into optically active compounds. Hopefully, the catalytic hydro-, carbo- and cyclomagnesiation of  $\alpha,\omega$ -dialkenes, diallenes or dialkynes will be demanded by chemists for the synthesis of metal-containing and polyfunctional macrocycles required for the preparation of new reagents and materials.

**Abstract.** Three methods used in the kinetics of liquid-phase radical reactions for estimating the dissociation energies of individual bonds in polyatomic molecules are described. The first approach is based on the study of the equilibrium in radical abstraction reactions involving stable radicals and measurements of the equilibrium constants. The second method is based on the study of the kinetics of homolytic decomposition of molecules. Measuring the activation energy of these reactions makes it possible to estimate the dissociation energies of the weakest bonds, *e.g.*, the O–O bonds in various peroxides. The essence of the third approach developed in the framework of the model of intersecting parabolas is calculations of the bond dissociation energy from the activation energy of a radical reaction involving the molecules under consideration. This method allowed the dissociation energies of the C–H, N–H, O–H and S–H bonds in a large number of organic compounds to be estimated. The scope and the specific features of application of each method are discussed and the bond dissociation energies determined by these methods are given. The bibliography includes 78 references.

## I. Introduction

The dissociation energies of individual bonds in a molecule and the enthalpies of formation of a molecule or radical are the most important energy characteristics of such species, which are widely used in science and technology. Every year brings tens of studies presenting the results of measurements of these parameters. The first review summarising data on the bond dissociation energies in molecules was reported five decades ago.<sup>1</sup> In the USSR, collec-

tion, systematisation and publication of such data were initiated by academician V N Kondrat'ev.<sup>2,3</sup> Publication of a multivolume handbook of the thermal properties of molecules and atoms<sup>4</sup> became a great scientific event. A recently published handbook<sup>5</sup> by Luo contains a considerable body of information on the bond dissociation energies in polyatomic molecules.

A broad spectrum of physicochemical methods developed for measuring the bond dissociation energies comprises low-pressure pyrolysis, kinetic studies of gas-phase bromination and iodination of hydrocarbons, spectral methods (these are used for estimating the bond energy in diatomic molecules), electron impact mass spectrometry, photoelectron spectroscopy, electrochemical methods and recently elaborated photoacoustic calorimetry. Each method has its own field of application, specific features and limitations.<sup>6–15</sup>

The last two decades have been characterised by the widespread use of kinetic methods for studying and analysing liquid-phase radical reactions. Such methods allow one to estimate the strengths of individual bonds in polyatomic molecules and considerably extend the range of compounds with known bond strengths. They include:

(1) studies of equilibrium bimolecular reactions involving stable free radicals;

(2) investigations on the kinetics of monomolecular decomposition of compounds involving homolysis of one (the weakest) bond;

(3) measurements of the absolute or relative rate constants for radical abstraction reactions or the activation energies of such reactions followed by calculations of the dissociation energy of a particular bond involved in the rearrangement.

The aim of this review is to consider these methods and the values of the strengths of individual bonds in various organic compounds obtained using these approaches. The methods mentioned above made it possible to significantly extend the range of complex polyatomic molecules for which the bond dissociation energies were determined from experimental data.

## II. Chemical equilibrium $X^\bullet + HY \rightleftharpoons HX + Y^\bullet$

The chemical equilibrium

where  $X^\bullet$  and  $Y^\bullet$  are reactive free radicals, cannot be achieved in solution owing to very fast recombination or disproportionation of these species. Such an equilibrium can be attained only when both radicals ( $X^\bullet$  and  $Y^\bullet$ ) are stable and do not enter the recombination reaction. In this case the equilibrium concentrations of both radicals can be determined by EPR spectroscopy or spectrophotometrically. The equilibrium constant ( $K$ ) is calculated from the ratio of the equilibrium concentrations of the molecules and radicals:

$$K = \frac{[Y^\bullet]_\infty [XH]_\infty}{[X^\bullet]_\infty [YH]_\infty}, \quad (1)$$

and the equilibrium enthalpy ( $\Delta H$ ) is calculated from the temperature dependence of  $\ln K$ . On the other hand, the equilibrium enthalpy of this reaction is equal to the difference between the dissociation energies ( $D$ ) of the bonds involved in the reaction

$$\Delta H = D_{Y-H} - D_{X-H} \quad (2)$$

provided that solvation of reactants makes an insignificant contribution to the equilibrium. This can be attained by carrying out experiments in non-polar solvents.

The approach was employed in a number of studies<sup>16–18</sup> for estimating the dissociation energies of the O–H bonds in phenols. Belyakov *et al.*<sup>16</sup> measured the equilibrium of the type

with galvinoxyl as the reference phenoxyl radical  $Ar^1O^\bullet$  and *para*-substituted 2,6-di-*tert*-butylphenols as the second reactants  $Ar^1OH$ . Changes in the galvinoxyl and phenoxyl  $Ar^1O^\bullet$  concentrations were monitored by EPR spectroscopy (benzene, 298 K). Calculations of the equilibrium constant

$$K = \frac{[Ar^1O^\bullet][Ar^1OH]}{[Ar^1O^\bullet][Ar^1OH]}, \quad (3)$$

from the reactant concentration ratio were followed by calculations of the Gibbs free energy of equilibrium ( $\Delta G$ ):

$$\Delta G = -RT \ln K. \quad (4)$$

The equilibrium enthalpy was determined using the temperature dependence of the equilibrium constant. Experience showed that in such reactions one has  $\Delta H \approx \Delta G$  within the limits of error in measurements. An analogous conclusion was also drawn by authors of other studies.<sup>17,18</sup> The dissociation energies of the O–H bonds in phenols thus measured are listed in Table 1.

It was found that this approach can also be used in studies of the systems characterised by recombination of phenoxyl radicals formed. Here, the reaction conditions are chosen in such a fashion that an equilibrium between reactants is attained and the phenols are consumed slowly, so it is possible to monitor each reactant and calculate the equilibrium constant.<sup>17,18</sup> This allowed the range of phenols with known O–H bond dissociation energies to be extended.

Having determined the equilibrium constant, it is possible to estimate the O–H bond strength difference between two phenols. To calculate the absolute value of  $D_{O-H}$ , one must know the  $D_{O-H}$  value for one phenol. For 2,4,6-tri-*tert*-butylphenol,  $D_{O-H} = 339.7 \text{ kJ mol}^{-1}$  (see Ref. 19), which is in good agreement with the  $D$  value for unsubstituted phenol ( $D_{O-H} = 369.0 \text{ kJ mol}^{-1}$ ).<sup>5,21</sup> Both these phenols were used as reference compounds for calculating the absolute values of  $D_{O-H}$  of some other phenols (see Table 1). The error in estimating  $\Delta H$  values is only  $\pm 1.1 \text{ kJ mol}^{-1}$  (see Ref. 17).

In order to evaluate the dissociation energies of O–H bonds in various phenols, Mahoney and DaRooge<sup>22</sup> measured the equilibrium constant  $K = k_1/k_{-1}$  for the reactions

To this end, 9,10-dihydroanthracene (RH) was oxidised with oxygen in the presence of corresponding hydroperoxide (ROOH) and phenol (ArOH) in chlorobenzene at 333 K with 2,2,3,3-tetraphenylbutane as initiator. The experimental conditions were chosen in such a manner that the equilibrium (see above) was established in the system and the chain termination step was limited by the recombination of  $ArO^\bullet$  and  $ROO^\bullet$  radicals. In this case the rate, ( $v_v$ ), of the chain oxidation process is satisfactorily described by the following equation<sup>21</sup>

$$v_v = k_p[RH] \sqrt{\frac{k_{-1}v_i[ROOH]}{2k_1k_t[ArOH]}}, \quad (5)$$

where  $k_p$  and  $k_t$  are the rate constants for the reactions of  $ROO^\bullet$  with RH and  $ROO^\bullet$  with  $ArO^\bullet$ , respectively, and  $v_i$  is the initiation rate.<sup>21</sup> The dependence of the chain oxidation rate  $v_v = v - v_i$  ( $v$  is the overall reaction rate) on the ROOH and ArOH concentrations was used to determine the  $k_p^2/(2Kk_t)$  ratio and then the equilibrium constant  $K = k_1/k_{-1}$  was calculated using known values of  $k_p$  and  $2k_t$ . The  $\Delta H = D_{ArO-H} - D_{ROO-H}$  values were determined assuming that  $\Delta H = \Delta G = -RT \ln K$ . The  $D_{ArO-H}$  calculated relative to the O–H bond dissociation energy in PhOH ( $369.0 \text{ kJ mol}^{-1}$ ) are listed in Table 1. Analysis of the data from Table 1 shows that differences between  $D_{O-H}$  values for the same phenol, reported by different authors, are small, being on average  $1.2 \pm 0.7 \text{ kJ mol}^{-1}$ .

The equilibrium

was studied by pulse radiolysis.<sup>20</sup> Here, the equilibrium constant was used to calculate the redox potential ( $E_0$ ) of the aroxyl radical in aqueous solution. The Gibbs energy ( $\Delta G^\circ$ , in  $\text{kJ mol}^{-1}$ ) of the reaction

was calculated as follows

$$\Delta G^\circ = 96.5 E_0 + 5.70 pK_a \quad (6)$$

( $pK_a$  characterises acid dissociation of phenol) and used for calculating the O–H bond dissociation energy of phenol in water. This energy was estimated to be  $12 \pm 4 \text{ kJ mol}^{-1}$  higher than in the gas phase due to solvation.<sup>20</sup> Table 1 lists the O–H bond dissociation energies for monosubstituted phenols (corrected for solvation effects in water), obtained based on the  $D_{O-H} = 369.0 \text{ kJ mol}^{-1}$  value for phenol.

Reactions of aminyl radicals with phenols are extremely fast. The reverse reactions of phenoxyl radicals with amines also proceed at a high rate.<sup>23–25</sup> The interaction of a stable phenoxyl radical  $ArO^\bullet$  with amine (AmH) in the presence of phenol (ArOH) can be considered as a two-step process:<sup>23</sup>

with the total rate given by

$$v_v = k[Am^\bullet]^2 = kK^2 \left( \frac{[ArO^\bullet][AmH]}{[ArOH]} \right)^2. \quad (7)$$

The kinetics of the reactions of 2,4,6-tri-*tert*-butylphenoxyl radical with eleven amines (AmH) were studied<sup>23</sup> under the conditions

**Table 1.** Dissociation energies of O–H bonds in phenols calculated from the equilibrium constants.

**Note.** Hereinafter the attacked bonds are shown.

of fast establishment of the equilibrium between the (ArO $\cdot$ ) radical involved in the reaction and the forming (Am $\cdot$ ) radical. The equilibrium constants  $K$  (in CCl $_4$  at 298–340 K) were calculated from the reagent concentration ratio [see Eqn (7)]. The equilibrium enthalpies were determined from the temperature dependence of  $K$

$$\Delta H = -R \frac{d \ln K}{d(1/T)}. \quad (8)$$

As mentioned above, the entropy of equilibrium in exchange radical reactions varies only slightly and can be set to zero; in these cases, one has  $\Delta H = \Delta G$ . Then the enthalpy of reaction can be determined from the equilibrium constant [see Eqn (4)].

The  $D_{N-H}$  values were calculated using two procedures:<sup>23</sup> (1) from the equilibrium constant measured at the same temperature (298 K),

$$D_{N-H} = 339.7 - RT \ln K \text{ (kJ mol}^{-1}\text{)}; \quad (9)$$

and (2) from the equilibrium enthalpy determined using expression (8). In this case the N–H bond strength was calculated as follows:

$$D_{N-H} = 339.7 + \Delta H \text{ (kJ mol}^{-1}\text{)}. \quad (10)$$

The first term in Eqns (9) and (10) is the dissociation energy of the O–H bond in the newly forming phenol. The dissociation energies of the N–H bonds in amines thus obtained are listed in Table 2. These  $D_{N-H}$  values are in agreement with the  $D_{O-H}$  values for phenols (see Table 1).

Jonsson *et al.*<sup>26,27</sup> reported a flash radiolysis study of two equilibrium reactions involving a number of substituted anilines

each of them being followed by the equilibrium deprotonation reaction

The equilibrium constant of one reaction was used to calculate the redox potential  $E_0$  of aminyl radical in aqueous solution. The N–H bond strength (in kJ mol $^{-1}$ ) in aniline was calculated as follows:

$$D_{N-H} = 96.48 E_0 + 5.70 \text{ p}K_a + 238.5. \quad (11)$$

The  $D_{N-H}$  values thus obtained for eighteen anilines studied are listed in Table 2 along with the dissociation energies of the N–H bonds in substituted anilines determined using the recommended<sup>5</sup> value  $D_{N-H}(\text{PhNH}_2) = 375.3 \text{ kJ mol}^{-1}$ .

The composition of radicals produced upon photolysis of di-*tert*-butylperoxide in a benzene solution in the presence of phenol and amine was studied by EPR spectroscopy.<sup>28</sup> The radical ratio established in the system after fast exchange reaction is characteristic of the equilibrium (a).

The phenoxyl-to-aminyl radical concentration ratio was determined by EPR spectroscopy and the equilibrium constant of this reaction,

$$K = \frac{[\text{Am}^{\cdot}][\text{ArOH}]}{[\text{ArO}^{\cdot}][\text{AmH}]}. \quad (12)$$

was calculated. 2,6-Di-*tert*-butyl-4-methoxyphenol was used as the reference phenol. The  $D_{N-H}$  thus obtained for ten amines are listed in Table 2.

A number of EPR studies on the equilibrium between stable iminoxyl radicals and various hydroxylamines and oximes are available.<sup>29–32</sup> A calorimetric study of the reactions of such radicals with 1,2-diphenylhydrazine<sup>29</sup>

made it possible to determine their enthalpies of formation and use this parameter for calculating the O–H bond strengths in the corresponding hydroxylamines and oximes (Table 3).

The  $D_{O-H}$  value for 2,4,6-*tert*-butylphenol was determined analogously.<sup>19</sup> Thus, it was found that the equilibrium-based  $D_{O-H}$  scale for hydroxylamines is consistent with the  $D_{O-H}$  scale for phenols and  $D_{N-H}$  scale for amines (see Tables 1 and 2). The  $D_{O-H}$  for various hydroxylamines calculated from the equilibrium constants of the following reactions

are listed in Table 3.

Determination of the dissociation energy of the attacked bond in various semiquinone radicals is a rather complicated task. For instance, a radical attack on *p*-hydroxydiphenylamine produces two radicals, namely, *p*-hydroxyphenylaminyl radical **1** and *p*-(phenylamino)phenoxyl radical **2**:

The strengths of the O–H bond in radical **1** and the N–H bond in radical **2** were estimated by Varlamov<sup>33</sup> in a recent detailed study of a reversible exchange reaction between *N*-phenyl-1,4-benzoquinoneimine (**3**) and 2,5-di-*tert*-butylhydroquinone (**4**). As was shown earlier, this reaction proceeds by a chain mechanism,<sup>34</sup> the chain initiation following two pathways:

The chain propagation step involves four very fast reactions of radicals **A–C** with quinoneimine **3** and quinone **5**.

**Table 2.** N–H bond dissociation energies in aromatic amines calculated from the equilibrium constants.

The chain termination step involves six disproportionation reactions of the three radicals involved in the chain reaction. In order to obtain an additional chain initiation, an amine (AmH), namely, di-*p*-tolylamine or 4-methoxyphenyl-*p*-tolylamine was introduced into the system. The amine reacted with quinoneimine, which accelerated the process.<sup>35</sup>

The overall rate of the additional initiation was measured from the dependence of the initial reaction rate of quinoneimine reduction on the initiation rate (with tetraphenylhydrazine as initiator, mixed initiation technique). Based on the kinetic data, the overall initiation rate constants were calculated for the reactions involving amines. Experiments were carried out at different temperatures. The  $D_{O-H}$  and  $D_{N-H}$  values for the radicals mentioned above were calculated using the intersecting parabolas method (see Section V). These parameters were also calculated from experimental values of the activation energies for these reactions. The O–H and N–H bond strengths in *p*-hydroxydiphenylamine were estimated using the Hammett correlation equations. Their values (in kJ mol<sup>-1</sup>) are listed below<sup>35</sup> (for comparison, we also present the  $D_{O-H}$  values in hydroquinone and in semiquinone radical<sup>21</sup>):

| Compound (radical) | $D_{O-H}$ | $D_{N-H}$ |

### III. The kinetics of homolytic decomposition of molecules

Consider decomposition of a molecule into two radicals involving cleavage of a single bond, *e.g.*, the O–O bond in a peroxide

The activation energy ( $E_a$ ) for this reaction is very similar to the dissociation energy of the bond being cleaved. In the framework of the Rice–Ramsperger–Kassel–Marcus (RRKM) theory in accord with the harmonic model the activation energy for the decomposition of a molecule differs from the dissociation energy by only  $0.5RT$ .<sup>36</sup>

$$D_{O-O} = E_a - 0.5RT. \quad (13)$$

This holds for gas-phase decomposition of substances at high pressures and, apparently, for liquid-phase decomposition (in solution) in non-polar solvents.

The rate constant for decomposition:

$$k = -\frac{d \ln[R^1OOR^2]}{dt}, \quad (14)$$

is determined from the kinetics of decomposition of the initial compound and the activation energy:

$$E_a = -\frac{R d \ln k}{d(T^{-1})}, \quad (15)$$

is found from the temperature dependence of  $k$  in a series of experiments carried out at different temperatures.

The rate constants for decomposition of various peroxides can be found in the literature;<sup>37</sup> they were used<sup>38,39</sup> for estimating the  $D_{O-O}$  values. Analysis of experimental data on the kinetics of peroxide decomposition revealed a large error in measuring the activation energies for the decomposition of these compounds.<sup>37</sup> To improve the accuracy in determining this characteristic, the following procedure was employed. Experimental data for the structurally similar group in peroxides were used to calculate the average pre-exponent  $A$

$$\ln A = \frac{1}{n} \sum_i \ln A_i$$

and then the activation energy was calculated from the rate constant for the reaction at each temperature using the Arrhenius relation:

$$E_a = RT \ln \left( \frac{A}{k} \right). \quad (16)$$

Listed below are the average  $A$  values for various peroxides:<sup>38,39</sup>

| Peroxide              | ROOR | PhR <sup>1</sup> R <sup>2</sup> COOCR <sup>1</sup> R <sup>2</sup> Ph | RC(O)OOC(O)R |
|-----------------------|------|----------------------------------------------------------------------|--------------|
| $10^{-15} A / s^{-1}$ | 2.4  | 1.4                                                                  | 0.63         |

Knowing the O–O bond dissociation energy and the enthalpy of formation of the initial ROOR molecule, it is possible to calculate the standard enthalpy of formation of RO<sup>•</sup> radical:

$$2\Delta H_f^\circ(RO^\bullet) = \Delta H_f^\circ(ROOR) - D_{O-O}. \quad (17)$$

Such calculations were performed using the experimental values of the standard enthalpies of formation of peroxides and the enthalpies of vaporisation or sublimation of these compounds (see Ref. 37). In turn, the enthalpy of formation of the RO<sup>•</sup> radical allows the dissociation energies of the RO–H, RO–Alk, RO–Acyl bonds, *etc.* to be calculated. This was done for a series of alkoxy and acyloxy radicals using the kinetic characteristics of decomposition of corresponding peroxides.<sup>38,39</sup> The results of calculations of  $D_{O-H}$  values for alcohols and organic acids are presented in Table 4.

† Hereafter R (R<sup>1</sup>, R<sup>2</sup>) denotes alkyls.

In addition to the  $D_{O-H}$  values calculated from the peroxide decomposition kinetics, Table 4 lists the published<sup>5</sup>  $D_{O-H}$  values for a number of alcohols and acids (figures in parentheses). The differences between them lie within the range of scatter for similar values. Usually, the  $D_{O-H}$  values calculated using the procedure mentioned above are smaller than those obtained by other methods.

Aliphatic acids  $C_nH_{2n+1}COOH$  are characterised by similar O–H bond strengths, the average  $D_{O-H}$  value being equal to  $441.0 \pm 3.3 \text{ kJ mol}^{-1}$ . The  $D_{O-H}$  values (in  $\text{kJ mol}^{-1}$ ) for alicyclic carboxylic acids  $\text{cyclo-}C_nH_{2n-1}COOH$  depend on the ring strain energy,  $E_{rsc}(n)$

$$D_{O-H} = (441.9 \pm 1.0) + (5.0 \pm 1.2) \cdot 10^{-2} E_{rsc}(n), \quad (18)$$

where  $n$  is the number of carbon atoms in the ring (Fig. 1).<sup>38</sup>

Figure 1. O–H bond dissociation energies ( $D_{O-H}$ ) in cyclocarboxylic acids  $C_nH_{2n-1}C(O)OH$  plotted vs. ring strain energy ( $E_{rsc}$ ).

Limitations of the method for estimating the O–O bond strength ( $D_{O-O}$ ) are as follows.

1. The technique is applicable only to the compounds which decompose *via* homolysis of a single (the weakest) bond. If the decomposition occurs as concerted cleavage of two bonds, the activation energy for the process does not characterise the cleavage of the single bond. This is the case for, *e.g.*, the decomposition of many peracid esters.<sup>37</sup> For instance, the decomposition of the peroxy ester  $\text{PhCH}_2\text{C(O)OOBu}^t$  involves simultaneous cleavage of two bonds:

Experiments showed that in this case one has  $E_a < D_{O-O}$  and, at the same time,  $E_a > \Delta H(r)$  [ $\Delta H(r)$  is the enthalpy of reaction].

2. Radicals produced from solvent molecules and capable of attacking the initial peroxide molecule must not initiate an additional decomposition of the peroxide by the chain mechanism. For instance, the decomposition of dibenzoyl peroxide in alcohol ( $\text{RCH}_2\text{OH}$ ) is described by the following chain reaction:<sup>37</sup>

As a result, the rate of peroxide consumption becomes much higher than the peroxide homolysis rate and the activation energy for the decomposition no longer characterises the homolysis reaction. To exclude the chain decomposition of peroxide, an acceptor of free radicals, which does not react with the initial peroxide, is introduced into the solvent.

**Table 4.** O–H bond dissociation energies in alcohols and acids calculated from kinetic data on peroxide decompositions.<sup>38, 39</sup>

**Note.** Data taken from handbook<sup>5</sup> are given in parentheses.

3. The decomposition of a molecule must follow a homolytic pathway only. The introduction of radical acceptor excludes a concurrent heterolytic decomposition of the peroxide. If only homolysis occurs, the rate of consumption of the radical acceptor equals the rate of peroxide decomposition within the accuracy to the escape probability ( $e$ ) of radicals from the cage to the bulk ( $e \approx 0.3-0.8$  for conventional solvents<sup>37</sup>).

#### IV. Linear correlations

Evans and Polanyi<sup>40</sup> were the first who found an empirical linear correlation between the activation energy and the enthalpy of reaction taking the reactions

as examples.

Semenov<sup>41</sup> extended this correlation to abstraction reaction involving various molecules and radicals and obtained the following averaged expression for such reactions:

$$E_a = A' + \alpha' \Delta H, \quad (19)$$

where  $\alpha' = 0.25$  and  $A' = 48 \text{ kJ mol}^{-1}$ . More recently, it was shown that this correlation equation correctly describes 'narrow' reaction series with the same reaction centre for each series characterised by its own coefficients  $\alpha'$  and  $A'$ . Listed below are the X–H bond dissociation energies<sup>5</sup> and the  $\alpha'$  and  $A'$  coefficients for a number of reaction series of  $X^{\cdot}$  radical (X atom) reacting with the C–H bonds of paraffin hydrocarbons:<sup>42</sup>

| $X^{\cdot}$ (X)               | $D_{X-H} / \text{kJ mol}^{-1}$ | $\alpha'$ | $A' / \text{kJ mol}^{-1}$ |
|-------------------------------|--------------------------------|-----------|---------------------------|
| HO $^{\cdot}$                 | 499.1                          | 0.25      | 31.6                      |

| H <sub>3</sub> C $^{\cdot}$   | 440                            | 0.52      | 62.0                      |
| MeO $^{\cdot}$                | 436.2                          | 0.59      | 49.0                      |
| F <sub>3</sub> C $^{\cdot}$   | 449.4                          | 0.66      | 60.0                      |
| MeC $^{\cdot}$ H <sub>2</sub> | 422                            | 0.70      | 53.0                      |
| Cl <sub>3</sub> C $^{\cdot}$  | 392.5                          | 0.94      | 67.0                      |
| Br $^{\cdot}$                 | 366.3                          | 0.86      | 16.0                      |
| I $^{\cdot}$                  | 298.4                          | 0.97      | 9.7                       |

In these ten reaction series the  $\alpha'$  coefficient varies from 0.25 to 0.97. The  $\alpha'$  and  $D_{X-H}$  values vary in antiparallel fashion, namely, the higher the  $D_{X-H}$  value, the smaller the  $\alpha'$  coefficient. The enthalpies of the investigated reactions of hydroxyl radical ( $D_{X-H} = 499.1 \text{ kJ mol}^{-1}$ ) vary in the range from  $-60$  to  $-100 \text{ kJ mol}^{-1}$  at  $\alpha' = 0.25$ . In contrast, similar reactions of iodine atoms ( $D_{I-H} = 298.4 \text{ kJ mol}^{-1}$ ) are highly endothermic ( $\Delta H \approx 100-140 \text{ kJ mol}^{-1}$ ) and the  $\alpha'$  coefficient approaches unity. Naturally, one can assume that the  $E_a$ -vs.- $\Delta H$  dependence is nonlinear and therefore the  $\alpha' = dE_a/d(\Delta H)$  parameter depends on the range of changes in  $\Delta H$  in each reaction series. This issue was considered in a review.<sup>43</sup>

Linear dependence (19) is often used for estimating the bond dissociation energy. To this end, it is written as follows:

$$D_i = D_1 + \frac{E_{ai} - E_{a1}}{\alpha'} \quad (20)$$

or

$$D_i = D_1 + \frac{RT}{\alpha'} \ln \left( \frac{n_i k_1}{n_1 k_i} \right), \quad (21)$$

where  $k_1$ ,  $E_{a1}$  and  $D_1$  are respectively the rate constant for, the activation energy for and the bond strength corresponding to the reaction of the  $X^{\cdot}$  radical with the compound  $R^1H$  with known strength of the X–H bond being formed,  $n_1$  is the number of

equally reactive bonds in the  $R^1H$  molecule involved in the reaction; and  $k_i$ ,  $n_i$ ,  $E_{ai}$  and  $D_i$  are the corresponding parameters of the reaction between the  $X^{\cdot}$  radical and  $R^1H$  compound. Calculations give  $\Delta D_i = \pm 2/\alpha' \text{ kJ mol}^{-1}$  provided that the error in determination of the activation energy is  $2 \text{ kJ mol}^{-1}$ . The accuracy of calculations can be improved by considering the partial rate constant,  $k$ , for the reaction per equally reactive C–H bond involved in the reaction of the  $X^{\cdot}$  radical with  $R^1H$  rather than the activation energy. The method is applicable to any reaction which belongs to the same series characterised by the  $\alpha'$  coefficient and lies within the difference  $\Delta H_{\min} - \Delta H_{\max}$  for this reaction series.

The kinetics of heterolytic reactions widely uses linear correlations based on linear relations for the free energy.<sup>44,45</sup> Correlations of the type

$$\log k_i = \log k_0 + \rho \sigma, \quad (22)$$

where  $\rho$  is the correlation coefficient,  $\sigma$  is the Hammett constant [or analogous Brown constants ( $\sigma^+$ ) and Taft constants ( $\sigma^*$ )] are also used in radical chemistry.<sup>46,47</sup> Equation (22) can be reduced to the Polanyi–Semenov equation (19) at a constant pre-exponent for a given reaction series. Seemingly, Eqn (22) can also be employed for estimating the bond strength from the kinetic data for corresponding series of compounds using the following transformation:

$$D_i = D_0 + \rho \sigma, \quad (23)$$

where  $D_i = D_0$  for the compound characterised by  $\sigma = 0$ . However, special care must be taken when using such correlations. Figure 2 shows the O–H bond strengths in monosubstituted phenols (the data for twenty-seven phenols were taken from handbook<sup>21</sup>) plotted vs. Hammett constants. Although we do observe a trend towards an increase in the  $D_{O-H}$  values as the  $\sigma$  constant increases, the correlation is very poor, because the correlation coefficient is only 0.75. The correlation equation of the straight line shown in Fig. 2 has the form

$$D_{O-H} (\text{kJ mol}^{-1}) = (364.8 \pm 1.4) + (19.22 \pm 3.44) \sigma. \quad (24)$$

For eight phenols the  $D_{O-H}$  values differ from the predicted results by more than  $10 \text{ kJ mol}^{-1}$ . Apparently, the reasons for poor correlation consist in fundamentally different stabilising effects of certain substituents Y on the acid anion  $YC_6H_4CO_2^-$  and the aroxyl radical  $YC_6H_4O^{\cdot}$  and in an additional solvation effect of the polar solvent on the benzoic acid anion, whereas the phenoxyl radical is generated in the non-polar solvent characterised by weaker solvation of reactants and transition state. Clearly, this type of correlation cannot serve as a reliable procedure for evaluating the bond strengths in molecules.

Figure 2. O–H bond dissociation energies ( $D_{O-H}$ ) in phenols 4- $YC_6H_4OH$  plotted vs. Hammett constants ( $\sigma$ ).

## V. Parabolic model for radical reactions

In the framework of the intersecting parabolas (IP) model the transition state of a radical reaction

is treated as a result of intersection of two potential energy curves.<sup>21, 37, 43, 45, 48</sup> One of them characterises the potential energy of the stretching vibration of the attacked R–H bond ( $U_{R-H}$ ) as a function of the vibration amplitude while the other characterises the potential energy of the vibration of the X–H bond being formed ( $U_{X-H}$ ). The stretching vibrations of the bonds are considered harmonic:

$$U_{R-H}^{1/2} = b\Delta r_{R-H},$$

$$U_{X-H}^{1/2} = b_f\Delta r_{X-H},$$

where  $\Delta r_{R-H}$  and  $\Delta r_{X-H}$  are the corresponding bond elongations in the transition state;  $b$  and  $b_f$  are the coefficients of proportionality ( $2b^2$  and  $2b_f^2$  are the force constants of the bond being cleaved and the bond being formed, respectively):

$$b = 2\pi\nu_{R-H}\mu_{R-H}^{1/2},$$

$$b_f = 2\pi\nu_{X-H}\mu_{X-H}^{1/2},$$

$\nu_{R-H}$  and  $\nu_{X-H}$  are the corresponding vibrational frequencies and  $\mu_{R-H}$  and  $\mu_{X-H}$  are the reduced masses of the atoms involved in the C–H and X–H bonds. Figure 3 presents the transition state diagram of the  $ROO^\bullet + RH$  reaction in the framework of the intersecting parabolas model.

A radical abstraction reaction is characterised by the following parameters:

- (1) enthalpy  $\Delta H_e$ , which includes the zero-point vibrational energy difference between the bond being cleaved and the bond being formed;
- (2) classical potential activation barrier  $E_e$ , which includes the zero-point vibrational energy of the bond being cleaved;
- (3) parameter  $r_e$  equal to the total elongation of the bond being cleaved and the bond being formed in the transition state;
- (4) coefficient  $b$ ;
- (5) parameter  $\alpha$  ( $\alpha^2$  is the force constant ratio of the bond being cleaved to the bond being formed);
- (6) pre-exponent  $A_0$  per equally reactive bond (in the molecule) involved in the reaction.

The parameters listed above are interrelated as follows:<sup>48</sup>

**Figure 3.** ‘Bond stretch – potential energy’ diagram for the  $ROO^\bullet + RH$  reaction in the framework of the intersecting parabolas model.

$$\Delta H_e = D_{R-H} - D_{X-H} + 0.5hN_A(\nu_{R-H} - \nu_{X-H}), \quad (25a)$$

$$br_e = \alpha\sqrt{E_e - \Delta H_e} + \sqrt{E_e}. \quad (25b)$$

Knowing the parameter  $br_e$ , one can calculate the classical potential barrier  $E_{e0}$  to a thermally neutral reaction characterised by  $\Delta H_e = 0$ :

$$E_{e0} = \frac{(br_e)^2}{(1 + \alpha)^2}. \quad (26)$$

The rate constant for the reaction is related to the activation energy,  $E_a$ , and the pre-exponent,  $A_0$ , by the Arrhenius relation:

$$k = nA_0 \exp\left(-\frac{E_a}{RT}\right), \quad (27)$$

where  $n$  is the number of equally reactive bonds in the reactant molecule.

The IP method allows the variety of radical reactions to be divided into classes using experimental data. Each class is characterised by the same set of parameters:  $\alpha$ ,  $br_e$ ,  $0.5hN_A\nu_{RH}$  ( $h$  is the Planck constant,  $N_A$  is the Avogadro constant) and  $A_0$  and an individual reaction belonging to a certain class is characterised by the enthalpy,  $\Delta H_e$ , and activation energy,  $E_e$ .

A method for estimating the bond strengths from the kinetic data, developed in the framework of the IP model, involves a number of versions.<sup>43, 49–51</sup>

1. With the measured rate constants  $k_i$  or the  $k_i/k_1$  ratios for a reaction class of the type  $X^\bullet + R^iH$  it is possible to estimate the bond strengths between the  $R^i-H$  and  $R^1-H$  compounds. The rate constant ratio,  $k_i/k_1$ , allows the activation energy difference,  $\Delta E_{ei}$ , between these reactions to be calculated:

$$\Delta E_{ei} = E_{ei} - E_{e1} = RT \ln \left( \frac{n_i k_i}{n_1 k_1} \right), \quad (28)$$

where  $n_1$  and  $n_i$  are respectively the numbers of equally reactive bonds in the  $R^1H$  and  $R^iH$  molecules attacked by the  $X^\bullet$  radical. From Eqns (25b) and (28) it follows that the relation between the  $\Delta E_{ei}$  value and the enthalpy difference  $\Delta(\Delta H_i)$  between these reactions has the form:<sup>49</sup>

$$\Delta(\Delta H_i) = 2br_e\alpha^{-2}(\sqrt{E_{ei}} - \sqrt{E_{e1}}) - (\alpha^{-2} - 1)\Delta E_{ei}. \quad (29)$$

On the other hand the enthalpy difference  $\Delta(\Delta H_i) = D_i - D_1$  and the energy of the  $R^i-H$  bond can be calculated using the equation

$$D_i = D_1 + 2br_e\alpha^{-2}(\sqrt{E_{ei}} - \sqrt{E_{e1}}) - (\alpha^{-2} - 1)\Delta E_{ei}. \quad (30)$$

Thus, calculations of the  $D_i$  values require knowledge of the  $D_1$ ,  $E_{e1}$ ,  $k_1/k_i$  ratio and the parameters characterising a given reaction class ( $br_e$  and  $\alpha$ ). Experience showed that the error in  $\Delta D$  measurements is 2–3 kJ mol<sup>−1</sup> (see Ref. 49). At low  $\Delta E_{ei}$  values ( $\Delta E_{ei} \ll E_{e1}$ ), Eqn (30) can be simplified:<sup>43</sup>

$$D_i = D_1 + \frac{1 + \alpha}{\alpha^2} \left( \sqrt{\frac{E_{e0}}{E_{e1}}} - 1 + \alpha \right) \Delta E_{ei}. \quad (31)$$

This approach was used for estimating  $D_{C-H}$  values in hydrocarbons,<sup>49, 50, 52</sup> oxygen-containing compounds,<sup>51, 53–55</sup> amines and amides,<sup>56, 57</sup> nitriles and nitro compounds;<sup>58</sup>  $D_{O-H}$  values in phenols<sup>59, 60</sup> and hydroxylamines;<sup>61</sup>  $D_{N-H}$  values in aromatic amines;<sup>62</sup>  $D_{S-H}$  values in thiophenols<sup>63, 64</sup> and  $D_{Si-H}$  values in silanes.<sup>65</sup>

2. Using different radicals  $X^\bullet$  (e.g.,  $X^i = R^iOO^\bullet$ ) in a series of radical reactions  $X^\bullet + RH$  belonging to the same class allows the approach to be employed for evaluating the  $X^i-H$  bond strengths. In this case Eqn (30) takes the form:

$$D_i = D_1 + 2br_e\alpha^{-2}(\sqrt{E_{e1}} - \sqrt{E_{ei}}) + (\alpha^{-2} - 1)\Delta E_{ei}. \quad (32)$$

This version of the technique was used in estimating the  $D_{O-H}$  values in hydroperoxides,<sup>66</sup> alcohols and acids.<sup>67</sup>

3. The  $D_i$  value for a reaction  $X^\bullet + R^iH$  can also be evaluated from the absolute value of the rate constant  $k_i$ . Since, according to the Arrhenius relation,

$$k_i = n_i A_0 \exp\left(-\frac{E_{ai}}{RT}\right),$$

the energy  $E_{ei}$  is calculated using the following equation

$$E_{ei} = RT \ln\left(\frac{A_0 n_i}{k_i}\right) + 0.5hN_A \nu_{R-H} - 0.5RT, \quad (33)$$

and  $\Delta H_e$  is calculated using the equation

$$\Delta H_e = E_{ei} - \alpha^{-2}(br_e - \sqrt{E_{ei}})^2, \quad (34)$$

from which after substituting expression (34) in Eqn (25a) we get:

$$D_i = D_{H-X} + E_{ei} - \alpha^{-2}(br_e - \sqrt{E_{ei}})^2 - 0.5hN_A(\nu_{R-H} - \nu_{X-H}). \quad (35)$$

In this case the error in the determination of  $D_i$  is usually higher than in the estimation using Eqn (32).

The parameters used for evaluating the  $D_i$  values in the radical abstraction reactions are listed in Table 5.

The limitation imposed on the method is associated with the enthalpy of reaction,  $\Delta H_e$  (see Refs 43 and 49). The case in point is that Eqn (26) is valid for reactions belonging to the same reaction class and characterised by enthalpies lying in the interval  $\Delta H_{e\min} < \Delta H_e < \Delta H_{e\max}$ . The activation energy for a highly exothermic reaction ( $\Delta H_e < \Delta H_{e\min}$ ) is nearly zero (more correctly,  $E = 0.5RT$ ) and independent of  $\Delta H$ . Therefore, the enthalpies,  $\Delta H_e$ , of such reactions cannot be estimated from the  $E_e$  values. The  $\Delta H_{e\min}$  value depends on the  $br_e$  and  $\alpha$  parameters and on the zero-point vibrational energy of the  $R-H$  bond being cleaved:

$$\alpha^2 \Delta H_{e\min} = -(br_e)^2 + 2br_e \sqrt{0.5hN_A \nu_{R-H}} + 0.5hN_A \nu_{R-H}(\alpha^2 - 1). \quad (36)$$

The activation energies of highly endothermic reactions ( $\Delta H_e > \Delta H_{e\max}$ ) approximately equal  $\Delta H_e$ , also being independent of the  $br_e$  and  $\alpha$  parameters:

$$E_e = \Delta H_e + 0.5RT. \quad (37)$$

The threshold value,  $\Delta H_{e\max}$ , depends on the  $\alpha$  and  $br_e$  parameters and on the zero-point vibrational energy of the bond being formed

$$\Delta H_{e\max} = (br_e)^2 - 2br_e \sqrt{0.5hN_A \nu_{X-H}} + 0.5hN_A \nu_{X-H}(\alpha^2 - 1). \quad (38)$$

An analogous method for evaluating the  $\Delta D$  values for two reactants from kinetic data ( $\Delta E$ ) was elaborated in the framework of the reaction model using two intersecting Morse curves.<sup>68, 69</sup> The results obtained by this technique and using the IP model are very similar.

**Table 5.** Parameters of the intersecting parabolas model used for calculating  $\Delta D$  values from experimental data.<sup>21, 37, 43, 48</sup>

Note. In this Table,  $R^1H$ ,  $R^2H$  and  $R^3H$  denote paraffin, olefinic and alkylaromatic hydrocarbons, respectively.

## VI. Structure of molecular fragments and the C—H bond dissociation energies

The dissociation energies of the C—H bonds in hydrocarbon molecules were estimated from the experimental rate constants for abstraction reactions of the following radicals (the bond strengths were taken from Ref. 12):  $H_3C'$  ( $D_{C-H} = 440 \text{ kJ mol}^{-1}$ ),  $RC'H_2$  ( $D_{C-H} = 422 \text{ kJ mol}^{-1}$ ),  $Me_3C'$  ( $D_{C-H} = 400 \text{ kJ mol}^{-1}$ ),  $Ph'$  ( $D_{C-H} = 474 \text{ kJ mol}^{-1}$ ),  $PhC'H_2$  ( $D_{C-H} = 375 \text{ kJ mol}^{-1}$ ),  $RO'_2$  ( $D_{O-H} = 365.5 \text{ kJ mol}^{-1}$  for the secondary and  $D_{O-H} = 358.6 \text{ kJ mol}^{-1}$  for the tertiary alkylperoxy radicals).<sup>21</sup> The parameters for calculating the bond dissociation energies using the IP model are listed in Table 5 and the results of  $D_{C-H}$  calculations are presented in Tables 6–8.

The results obtained by this technique make it possible to significantly increase the number of hydrocarbons with known strengths of individual bonds.<sup>5</sup>

Attempts at evaluating the  $D_{C-H}$  values for various oxygen-containing compounds were found to be successful. In this case the limitation imposed on the IP method is as follows. All oxygen-containing molecules are polar and the reaction of a polar radical with a polar molecule leads to manifestation of the polar effect, which affects the activation energy.<sup>70–74</sup> Therefore, the C—H bond strengths in such compounds can be estimated only from the rate constants for reactions of non-polar alkyl radicals and hydrogen atom. The experimental  $D_{C-H}$  values for various alcohols, ketones and other oxygen-containing compounds are listed in Table 9.

Table 6. Dissociation energies (in  $\text{kJ mol}^{-1}$ ) of C—H bonds in linear and cyclic alkanes calculated using the intersecting parabolas model.<sup>37,49,50</sup>

<sup>a</sup> The bond dissociation energies were taken from Ref. 12.

In Table 10 we compare the  $D_{C-H}$  values obtained using the IP method with the published data. By and large, the results obtained are in reasonable agreement with one another, the differences between them lying within the scatter of the data that are also characteristic of other methods. Comparison of the two lists of compounds given in Tables 10 and 9 shows how the IP method made it possible to increase the number of compounds with known  $D_{C-H}$  values.

The strengths of the most reactive C–H bonds in aliphatic amines, nitriles, nitro compounds and sulfides (information on these parameters is scarce) were determined analogously. The results of calculations are listed in Table 11.

Empirical analysis of the effect of the structure of molecular fragments on the  $D_{C-H}$  values using the C–H bond strengths in various molecules (see Tables 6–11) makes it possible to draw some conclusions.

1. The presence of  $\alpha$ -C=C bonds causes the  $D_{C-H}$  value to decrease. Owing to stabilisation of the allyl radical the  $\alpha$ -C–H

bonds in olefins are much weaker than in paraffins. The effect of the neighbouring methyl groups on the allyl C–H bond is illustrated below (see also Table 7; the  $D$  values are given in  $\text{kJ mol}^{-1}$ ).

| Compound                                              | $D_{C-H}$ | $\Delta D$ |
|-------------------------------------------------------|-----------|------------|
| $\text{MeCH}_2(\text{C}-\text{H})\text{H}_2$          | 422       | 0          |
| $\text{CH}_2=\text{CH}(\text{C}-\text{H})\text{H}_2$  | 368       | –54.0      |
| $\text{CH}_2=\text{CH}(\text{C}-\text{H})\text{HMe}$  | 349.8     | –72.2      |
| $\text{CH}_2=\text{CH}(\text{C}-\text{H})\text{Me}_2$ | 339.6     | –82.4      |

As can be seen, not only the double bond but also the neighbouring methyl groups strongly affect the strength of the C–H bond in the  $\alpha$ -position with respect to the double bond. Replacement of a hydrogen atom at the carbon atom involved in the double bond by a methyl group also leads to reduction of  $D_{C-H}$  values, although to a somewhat lesser extent (see Table 4; the  $D_{C-H}$  values are given in  $\text{kJ mol}^{-1}$ ).

**Table 9.** Dissociation energies of C–H bonds in oxygen-containing compounds calculated using the intersecting parabolas model.<sup>51, 53–55</sup>

| $(CH_2=CH)_2(C-H)Me$   | 321.1     | -46.9            |

|                                                                                     |       |        |
|-------------------------------------------------------------------------------------|-------|--------|
|    | 408.4 | 0      |
|    | 342.5 | -65.9  |
|    | 329.3 | -79.1  |
|    | 288.8 | -119.6 |
|    | 408.8 | 0      |
|   | 341.5 | -67.3  |
|  | 330.9 | -77.9  |
|  | 312.6 | -96.2  |
|  | 338.9 | -69.9  |

2. The benzene ring has a similar effect on the  $\alpha$ -C-H bond (see Table 8; the  $D_{C-H}$  values are given in  $\text{kJ mol}^{-1}$ ).

| Compound      | $D_{C-H}$ | $\Delta D_{C-H}$ |
|---------------|-----------|------------------|
| $Me(C-H)H_2$  | 422       | 0                |
| $Ph(C-H)H_2$  | 375.0     | -47.0            |
| $Ph(C-H)HMe$  | 364.1     | -57.9            |
| $Ph(C-H)Me_2$ | 354.2     | -67.8            |
| $Ph_2(C-H)H$  | 356.8     | -65.2            |

3. The C-H bond weakens if a nitrogen-containing functional group X-NH<sub>2</sub>, NH<sub>2</sub> or CN is in the  $\alpha$ -position with respect to this bond (see Table 11; the  $D_{C-H}$  values are given in  $\text{kJ mol}^{-1}$ ).

| Compound    | X               | $D_{C-H}$ | $\Delta D_{C-H}$ |
|-------------|-----------------|-----------|------------------|
| $X(C-H)H_2$ | Me              | 422.0     | 0                |
|             | NH <sub>2</sub> | 400.0     | -22.0            |
|             | NHR             | 398.0     | -33.0            |
|             | CN              | 401.7     | -20.3            |
|             | NO <sub>2</sub> | 415.4     | -6.6             |
| $X(C-H)HMe$ | Me              | 412.0     | 0                |
|             | NH <sub>2</sub> | 389.6     | -22.4            |
|             | NHR             | 384.6     | -27.4            |
|             | CN              | 387.2     | -24.8            |
|             | NO <sub>2</sub> | 402.4     | -9.6             |

| Compound     | X               | $D_{C-H}$ | $\Delta D_{C-H}$ |
|--------------|-----------------|-----------|------------------|
| $X(C-H)Me_2$ | Me              | 400.0     | 0                |
|              | NH <sub>2</sub> | 379.5     | -20.5            |
|              | NHR             | 375.0     | -25.0            |
|              | CN              | 372.2     | -27.8            |
|              | NO <sub>2</sub> | 394.9     | -5.1             |

This is due to stabilisation of free valence caused by the neighbouring group containing p- or  $\pi$ -electrons. With respect to their ability to stabilise the free valence on the neighbouring carbon atom the groups considered are in the same order: NO<sub>2</sub> < CN < NH<sub>2</sub> < NHR. Replacement of a hydrogen atom by a methyl group in the X(C-H)H<sub>2</sub> fragment reduces the  $D_{C-H}$  value by  $10.5 \pm 3.4 \text{ kJ mol}^{-1}$  (cf.  $19.2 \pm 2.6 \text{ kJ mol}^{-1}$  for replacement of two molecules).

4. Oxygen-containing groups X have a similar effect on the  $\alpha$ -C-H bond (see Table 9; the  $D_{C-H}$  values are given in  $\text{kJ mol}^{-1}$ ).

| Compound     | X      | $D_{C-H}$ | $\Delta D_{C-H}$ |
|--------------|--------|-----------|------------------|
| $X(C-H)H_2$  | Me     | 422.0     | 0                |
|              | OH     | 411.0     | -11.0            |
|              | OR     | 411.9     | -10.1            |
|              | C=O    | 411.8     | -10.2            |
|              | C(O)OH | 414.1     | -7.9             |
| $X(C-H)HMe$  | Me     | 412.0     | 0                |
|              | OH     | 399.8     | -12.2            |
|              | OR     | 399.5     | -12.5            |
|              | C=O    | 397.2     | -14.8            |
|              | C(O)OH | 398.9     | -13.1            |
| $X(C-H)Me_2$ | Me     | 400.0     | 0                |
|              | OH     | 390.5     | -9.5             |
|              | OR     | 390.8     | -9.2             |
|              | C=O    | 387.6     | -12.4            |
|              | C(O)OH | 388.3     | -11.7            |

With respect to their ability to stabilise the free valence the oxygen-containing groups can be ordered as follows: OH > OR > C=O > CO<sub>2</sub>H. The increments characterising the effect of one and two methyl groups on the  $D_{C-H}$  value are similar to those of hydrocarbons and N-containing groups:

$$D_{C-H}(XC-H)H_2 - D_{C-H}(XMeC-H)H = 13.3 \pm 1.6 \text{ kJ mol}^{-1};$$

$$D_{C-H}(XC-H)H_2 - D_{C-H}(XMeC-H)H = 15.9 \pm 3.0 \text{ kJ mol}^{-1}.$$

5. The C-H bond strengths in cyclic acetals are affected by the ring strain energy. Table 9 shows that the smaller the  $E_{\text{rsc}}$  (see Ref. 55) the larger the  $D_{C-H}$  value.

| Cyclic acetal                                                                       | $D_{C-H}/\text{kJ mol}^{-1}$ | $E_{\text{rsc}}/\text{kJ mol}^{-1}$<br>(see Refs 6, 7) |
|-------------------------------------------------------------------------------------|------------------------------|--------------------------------------------------------|
|  | 381.2                        | 29.16                                                  |
|  | 385.5                        | 25.52                                                  |
|  | 388.0                        | 13.09                                                  |

The C-H bond dissociation energies in 1,3-dioxolane, 1,3-dioxane and 1,3-dioxepane are related to the ring strain energy  $E_{\text{rsc}}$  (in  $\text{kJ mol}^{-1}$ ) by the following correlation equation:

$$D_{C-H} = 393.17 - 0.37 E_{rsc}. \quad (39)$$

The C–H bond strength difference between 1,3-dioxane and diethoxymethane is  $-2.4 \text{ kJ mol}^{-1}$ , *i.e.*, at minimum ring strain energy the C–H bond strength in 1,3-dioxane is similar to that of acyclic acetals ( $390.4 \text{ kJ mol}^{-1}$ ).

6. In the text below the C–H bond dissociation energies in SCHR (R = H, Me, Pr<sup>i</sup>) fragments are compared with the C–H bond strengths in similar hydrocarbons<sup>12</sup> (the  $D_{C-H}$  values are given in  $\text{kJ mol}^{-1}$ ).

| Compound                | (EtX) <sub>2</sub> (C–H)H | (EtX) <sub>2</sub> (C–H)Pr <sup>i</sup> | (EtX) <sub>2</sub> (C–H)Me |
|-------------------------|---------------------------|-----------------------------------------|----------------------------|
| $D_{C-H}$               | 390                       | 389                                     | 376                        |
| for X = S               |                           |                                         |                            |
| $D_{C-H}$               | 412                       | 400                                     | 396                        |
| for X = CH <sub>2</sub> |                           |                                         |                            |
| $\Delta D$              | –22                       | –11                                     | –20                        |

As can be seen, the sulfur atoms lead to an appreciable (by  $11\text{--}22 \text{ kJ mol}^{-1}$ ) decrease in the strength of the neighbouring C–H bond.

## VII. Dissociation energies of O–H bonds in alcohols, acids, hydroperoxides, hydroxylamines and phenols

The O–H bond strengths in various hydroperoxides were first calculated<sup>66</sup> from experimental data (parameters of co-oxidation). The estimates of the  $\Delta D_{O-H}$  values were obtained using the

ratio of the rate constants for reactions of two different peroxy radicals with the same hydrocarbon. The parameters of the IP model used in the  $\Delta D_{O-H}$  calculations are listed in Table 5. Dimethylethyl hydroperoxide ( $D_{O-H} = 358.6 \text{ kJ mol}^{-1}$ )<sup>76</sup> was used as a reference hydroperoxide. The results of calculations are presented in Table 12.

As can be seen from the data in Table 12, the  $D_{O-H}$  values vary over a wide range from 360 to  $413 \text{ kJ mol}^{-1}$  depending on the hydroperoxide structure. The hydroperoxides studied can be ordered as follows with respect to the O–H bond strength ( $D_{O-H}$ , in  $\text{kJ mol}^{-1}$ ):  $R_2CHOC(OO-H)R_2$  (358.4) <  $RPhC(O-H)OO-H$  (359.8) < 1-hydroxycyclohexyl 1-hydroperoxide (362.1) <  $ROCH(OO-H)R$  (367.3) < 2-hydroperoxytetrahydrofuran (367.6) <  $\alpha$ -ketocyclohexyl peroxide (369.8) <  $ROCH(OO-H)Ph$  (374.8) <  $\alpha$ -RC(O)OCH(OO-H)Ph (376.4) < cyclohexylperacid (376.9),  $R_3CC(O)(OO-H)$  (376.9) <  $RC(O)(OO-H)$  (387.1) <  $PhC(O)(OO-H)$  (403.9) <  $Cl_2CH.CCl_2(OO-H)$  (411.6) <  $Cl_3CCCl_2(OO-H)$  (413.1). The highest  $D_{O-H}$  values were obtained for peracids and chlorine-containing hydroperoxides.

The  $D_{O-H}$  values in alcohols (dimethylethoxyl radical with  $D_{O-H} = 439.4 \text{ kJ mol}^{-1}$  was used as a reference alkoxyl radical)<sup>38</sup> and acids (benzoyloxy radical with  $D_{O-H} = 439.3 \text{ kJ mol}^{-1}$  was used as a reference radical)<sup>5</sup> were estimated in a similar fashion.<sup>67</sup> The results of evaluation of the O–H bond strength are given in Table 12. As can be seen, the  $D_{O-H}$  values vary only slightly on going from one alcohol to another. As was mentioned above, the O–H bond strengths of various acids are also similar (see Table 4). The EtX compounds form the following sequence with respect to the O–H bond dissociation energy (in

**Table 12.** Dissociation energies of O–H bonds in hydroperoxides, alcohols and acids calculated from experimental data using the intersecting parabolas model.

| Compound                                                                                                    | $D_{O-H} / \text{kJ mol}^{-1}$ | Compound                                                                             | $D_{O-H} / \text{kJ mol}^{-1}$ |
|-------------------------------------------------------------------------------------------------------------|--------------------------------|--------------------------------------------------------------------------------------|--------------------------------|

$\text{kJ mol}^{-1}$ ):  $\text{EtOO-H}$  (365.5) <  $\text{EtO-H}$  (432.4) <  $\text{EtC(O)O-H}$  (439.3). It was found that the O–H bond strengths in *para*-substituted benzoic acids  $4\text{-YC}_6\text{H}_4\text{CO}_2\text{H}$  are independent of the substituent Y and only at Y = Cl is the  $D_{\text{O-H}}$  value  $7 \text{ kJ mol}^{-1}$  lower than in unsubstituted benzoic acid.

| Y   | $\sigma$ | $D_{\text{O-H}}/\text{kJ mol}^{-1}$ |
|-----|----------|-------------------------------------|
| MeO | –0.268   | 438.5                               |
| Me  | –0.170   | 437.0                               |
| H   | 0.0      | 439.3                               |
| Cl  | 0.227    | 432.2                               |

Tables 13 and 14 list the  $D_{\text{O-H}}$  values for phenols, calculated from experimental data in the framework of the IP model. The  $\Delta D_{\text{O-H}}$  values were estimated from the rate constant ratio for the reactions of the same peroxy radical with two phenols. The reference compounds were unsubstituted phenol ( $D_{\text{O-H}} = 369.0 \text{ kJ mol}^{-1}$ ) and 2,4,6-tri-*tert*-butylphenol ( $D_{\text{O-H}} = 339.7 \text{ kJ mol}^{-1}$ ).<sup>19</sup> The parameters of the IP model used in calculations are given in Table 5.

Comparison shows that in most cases the O–H bond strengths thus obtained are in good agreement with the  $D_{\text{O-H}}$  values found from the chemical equilibrium (see Table 1). The

$D_{\text{O-H}}$  values (in  $\text{kJ mol}^{-1}$ ) for phenols  $4\text{-YC}_6\text{H}_4\text{OH}$ , calculated from the equilibrium constants and from the kinetic data using the IP model are listed below.

| Y               | $D_{\text{O-H}}$ (equilibrium) | $D_{\text{O-H}}$ (IP model) |
|-----------------|--------------------------------|-----------------------------|
| MeO             | 346.3                          | 347.5                       |
| Me              | 360.5                          | 362.2                       |
| H               | 369.2                          | 369.0                       |
| Bu <sup>t</sup> | 356.7                          | 360.1                       |

An analogous picture is also observed for *para*-substituted 4-Y-2,6-di-*tert*-butylphenols ( $D_{\text{O-H}}$  values are given in  $\text{kJ mol}^{-1}$ ).<sup>21</sup>

The O–H bond strengths in hydroxylamines were calculated using the IP model from the characteristics of reactions of various iminoxyl radicals with 1,2-diphenylhydrazine<sup>61</sup> using 1-hydroxy-2,2,6,6-tetramethylpiperidin-4-one ( $D_{O-H} = 300.4 \text{ kJ mol}^{-1}$ ) as the reference hydroxylamine. The results of calculations are listed in Table 15. They are in good agreement with the data presented in Table 3 and obtained from the equilibrium constants ( $D_{O-H}$  values are given in  $\text{kJ mol}^{-1}$ ).

| Hydroxylamine                                                                       | $D_{O-H} \text{ (equilibrium)}$ | $D_{O-H} \text{ (IP model)}$ |

295.1

Comparison of the  $D_{O-H}$  values in alcohols, phenols, hydroperoxides and hydroxylamines indicates that the O–H bond strength is strongly affected by conjugation of free valence of the oxygen atom with adjacent  $\pi$ -bonds and p electrons of heteroatoms (N, O).

## VIII. Dissociation energies of N–H bonds in amines and S–H bonds in thiols

The dissociation energies of the N–H bonds in aromatic amines are listed in Table 16. They were calculated using the IP method from experimental rate constants for the reactions of peroxy radicals with amines<sup>62</sup> with diphenylamine ( $D_{\text{N-H}} = 364.7 \text{ kJ mol}^{-1}$ )<sup>21</sup> as the reference amine. The parameters used in calculations are given in Table 5.

The  $D_{\text{N-H}}$  value calculated for 1-naphthylphenylamine using the IP model ( $352.5 \text{ kJ mol}^{-1}$ ) is nearly the same as the value obtained by the chemical equilibrium method ( $352.8 \text{ kJ mol}^{-1}$ , see Table 2).

The dissociation energies of the S–H bonds in aliphatic and aromatic thiols are presented in Table 17. They were calculated in the framework of the IP model using the experimental rate constants for reactions between alkyl radicals and the S–H bonds of the corresponding compounds.<sup>63,64</sup> As can be seen, the structure of the hydrocarbon fragment in thiols has little effect on the  $D_{\text{S-H}}$  value.

## IX. Dissociation energies of Si–H, Ge–H, Sn–H, Se–H and P–H bonds

The Y–H bond dissociation energies in organoelement compounds using the IP model were estimated<sup>77</sup> from the experimen-

tal rate constants for the reactions of hydrogen abstraction by the following radicals (the  $D_{\text{C-H}}$  values in  $\text{kJ mol}^{-1}$  taken from Ref. 12 are given in parentheses):  $\text{RC}\cdot\text{H}_2$  (422),  $\text{Me}_3\text{C}\cdot$  (400),  $\text{PhC}\cdot\text{H}_2$  (375),  $\text{PhC}\cdot\text{HR}$  (364.1), *tert*- $\text{RO}_2\cdot$  (356.8),  $\text{Bu}^t\text{O}\cdot$  (439.4). The parameters used for calculating  $D_{\text{C-H}}$  values are listed in Table 5. The reference compounds with known Y–H bond strengths were  $\text{Et}_3\text{Si-H}$  (398.0),  $\text{Bu}_3^t\text{Ge-H}$  (347.3),  $\text{Bu}_3^t\text{Sn-H}$  (309.6),  $\text{n-C}_8\text{H}_{17}\text{PH}_2$  (375.3) ( $D_{\text{Y-H}}$  in  $\text{kJ mol}^{-1}$  are given in parentheses). The results of calculations are presented in Table 18.

Comparison shows that the weaker the Y–H bond, the longer is this bond and the lower is the corresponding stretching vibration frequency ( $\nu_{\text{Y-H}}$ ).

## X. Dissociation energies of $\text{C}-\text{Hal}$ bonds

The dissociation energies of the  $\text{C}-\text{halogen}$  ( $\text{Hal}$ ) bonds in halogen-containing compounds were estimated<sup>78</sup> by the IP method from the experimental rate constants for the reactions of halogen abstraction by hydrogen atom and by  $\text{Ph}^\cdot$  and  $\text{Me}^\cdot$  radicals ( $D_{\text{C}-\text{H}} = 474$  and  $440 \text{ kJ mol}^{-1}$ , respectively).<sup>12,13</sup> The  $\text{S}-\text{Cl}$  bond dissociation energy was also estimated for two compounds. The following halides were used as reference compounds with known  $\text{C}-\text{Hal}$  and  $\text{S}-\text{Cl}$  bond strengths (the  $D_{\text{C}-\text{Hal}}$  and  $D_{\text{S}-\text{Cl}} / \text{kJ mol}^{-1}$  values are given in parentheses):  $\text{BrCH}_2\text{CO}_2\text{H}$  (270.9),  $\text{MeBr}$  (290.0),  $\text{MeCl}$  (354.0),  $\text{MeI}$  (240.0),  $\text{PhI}$  (281.0),  $\text{PhCH}_2\text{Cl}$  (309.7),  $\text{PhCH}_2\text{Br}$  (252.9),  $\text{MeSO}_2\text{Cl}$  (292.9).<sup>5</sup> The parameters used for the IP model calculations are given in Table 5. The results of calculations are listed in Table 19.

Analysis of the data from Table 19 shows the following (on the average) decreasing order of the bond strengths:  $D_{\text{C}-\text{Cl}} > D_{\text{C}-\text{Br}} > D_{\text{C}-\text{I}}$ .

## XI. Conclusion

Thus, the use of kinetic methods for estimating the  $\text{Y}-\text{H}$  ( $\text{Y} = \text{C, O, N, P, Si, Ge, Sn}$ ) bond strengths makes it possible to considerably extend the range of compounds with known values of this important characteristic. Indeed, earlier only two hydroperoxides, namely,  $\text{H}_2\text{O}_2$  and *tert*- $\text{ROOH}$  were characterised by  $D_{\text{O}-\text{H}}$  values. Carrying out calculations based on experimental data on co-oxidation of organic compounds made it possible to determine the  $\text{O}-\text{H}$  bond strength values for nineteen different hydroperoxides (see Table 12). The number of alcohols and acids for which the  $D_{\text{O}-\text{H}}$  values were calculated (see Tables 4 and 12), and the number of oxygen-containing compounds with known  $D_{\text{C}-\text{H}}$

**Table 19.** Dissociation energies (in kJ mol<sup>-1</sup>) of C–Hal (Hal = Cl, Br, I) and S–Cl bonds calculated from experimental data using the intersecting parabolas model.<sup>78</sup>

|  | 304.4    |                                                                                   |          |                                                                                   |          |                                                                                     |          |
|  | 292.4    |                                                                                   |          |                                                                                   |          |                                                                                     |          |

values (see Table 9) increased similarly. A salient feature of the methods considered above is that they are applicable to various organic compounds of complex structure. This opens up prospects for estimating the bond dissociation energies in fragments constituting polymers and biopolymers. This review shows that the results obtained using various kinetic methods are in good agreement with one another.

**Abstract.** The review summarises structures, activities and selectivity of NO-synthase (NOS) inhibitors belonging to various classes of chemical compounds. Linear, cyclic and heterocyclic structures containing guanidine, amidine and/or isothioureia fragments are considered. The structure–activity relationships for these inhibitors were analysed in relation to their action on the inducible NOS isoform. This analysis can provide the basis for the synthesis of new more efficient compounds. The bibliography includes 115 references.

## I. Introduction

The fact that nitrogen(II) oxide is an endothelium-derived relaxing factor (EDRF) and the enzymatic origin of nitric oxide were both established more than 15 years ago.<sup>1,2</sup> Since then, it has been found that the NO<sup>•</sup> radical has unique functions in the functioning of organisms both in normal and various pathophysiological states (ischemic, inflammatory and degenerative processes, cancerogenesis).<sup>3–6</sup> These findings have stimulated a search for and the synthesis of new compounds capable of regulating the activity and NO<sup>•</sup> levels in animal and human organisms with the aim of using these compounds in therapy of many widespread diseases.<sup>7,8</sup>

Since some diseases are characterised by increased NO<sup>•</sup> production (arthritis, diabetes, sepsis, myocardial ischemia), a decrease in NO<sup>•</sup> levels is of importance in the treatment of these diseases. The available inhibitors of nitric oxide synthase (NOS) isoforms (synthase is an enzyme that catalyses the NO<sup>•</sup> synthesis)

are insufficiently active and selective and cannot be localised in various tissues and cell organelles. Hence the search for new chemical NOS inhibitors is a topical problem.<sup>9,10</sup>

Taking into account that L-arginine is virtually the only endogenous substrate, whose guanidine group provides a nitrogen source for the NO<sup>•</sup> synthesis in enzymatic oxidation, certain analogues of this amino acid would be expected to serve as highly specific substrates for NOS enzymes. Hence, the synthesis of compounds containing groups isosteric to the guanidine group of L-arginine attracts the most attention. In the present review, we analyse the data on the relationships between the chemical structures and biochemical activities of inhibitors that bind specifically to the catalytic site of the enzyme, where L-arginine is accepted and oxidised. The data published in 1997–2003 are summarised. The properties of inhibitors are considered in relation to the inducible NOS (iNOS) isoform, which not only plays a key role in the regulation of nonspecific immunity<sup>4</sup> but also can suppress defence mechanisms in pathogenesis of certain diseases by synthesising excess NO<sup>•</sup>.<sup>8,11,12</sup>

## II. L-Arginine-dependent NO<sup>•</sup> synthesis

In living organisms, NO<sup>•</sup> is produced primarily by enzymatic oxidation of L-arginine,<sup>13,14</sup> although there are other sources of this radical.<sup>15</sup> The following three forms of the enzymes synthesising NO<sup>•</sup> are distinguished: two constitutive forms and one inducible form, which is expressed by anti-inflammatory cytokines and bacterial products. The isoforms are encoded by distinct genes and are named for their predominant localisation: neuronal NOS (NOS-1, nNOS), inducible NOS (NOS-2, iNOS) and endothelial NOS (NOS-3, eNOS).

### 1. Substrates and cofactors

The following three substrates are involved in the NO<sup>•</sup> synthesis performed by the homodimeric enzyme: L-arginine (R = NH), oxygen and nicotinamide adenine dinucleotide phosphate (NADPH) as the electron source. Two-step oxidation of the amino acid occurs through the intermediate formation of N<sup>ω</sup>-hydroxy-L-arginine (R = NOH) followed by the formation of L-citrulline (R = O) and NO<sup>•</sup> in equimolar amounts.<sup>13</sup>

*Uspekhi Khimii* 74 (9) 939–952 (2005); translated by T N Safonova

The activity of NOS is mediated by several cofactors and prosthetic groups. Some of them, for example, FAD, FMN, a haem with pentacoordinate  $\text{Fe}^{2+}$ , the  $\text{Ca}^{2+}$ -binding protein (calmoduline, CaM) and  $\text{Zn}^{2+}$ , are involved in each subunit. There is certain evidence that cofactors other than (6*R*)-5,6,7,8-tetrahydro-L-biopterin ( $\text{BH}_4$ ) can be absent in the dimer.<sup>14</sup> Flavins involved in the reductase domain transfer electrons from NADPH to the oxidase domain containing the haem (oxidation site),  $\text{BH}_4$ - and L-arginine-binding regions and a zinc ion.<sup>16</sup>

## 2. Dimerisation and proteolysis of NOS

Nitric oxide synthase oxidises L-arginine and synthesises  $\text{NO}'$  only in the form of the homodimeric complex, L-arginine,  $\text{BH}_4$  and the haem being altogether involved in the formation of the active form of the enzyme. Hence, the replacement of the substrate with the inhibitor not only inhibits the  $\text{NO}'$  synthesis but also often hinders the formation of the active tertiary structure of NOS.<sup>14, 16, 17</sup> In intact cells, ~50% of NOS polypeptides exist as dimers.<sup>18</sup> The involvement of the haem in an NOS polypeptide is apparently the first necessary step of dimerisation for all isoforms.<sup>19</sup> However, the role of  $\text{BH}_4$  and L-arginine is more differentiated. In particular, the substrate is more efficient in association of nNOS subunits than  $\text{BH}_4$ . However, this dependence for iNOS is inverse. On the whole, in the presence of the above-mentioned cofactors and the substrate, resistance of the dimer to dissociation and proteolysis decreases in the following series of NOS isoforms: eNOS  $\gg$  nNOS  $>$  iNOS.<sup>20</sup> However, noteworthy is the unexpected fact of the possible binding of L-arginine to the  $\text{BH}_4$ -binding site of eNOS.<sup>21</sup>

## 3. Structure of the oxidase domain of NOS

The oxidase domain of NOS contains four important structure fragments of the enzyme: the oxidation site containing the haem with pentacoordinate iron, the L-arginine-binding region, the  $\text{BH}_4$ -accepting pocket, and the  $\text{Zn}^{2+}$  thiolate complex. Two conservative amino acids play the central role in L-arginine binding. A proton of one of the amino groups (from the guanidine structure) of L-arginine is accepted by the carbonyl group of tryptophan in the haem proximal pocket. In the distal pocket, the carbonyl group of glutamic acid binds the second proton of the same amino group and the proton attached to the N(5) atom.<sup>21</sup> L-Arginine is apparently involved in the accepting pocket of the oxidase domain in the extended *E* conformation.<sup>22</sup> Figure 1 shows the arrangement of one of NOS inhibitors, *viz.*,  $N^{\omega}$ -*n*-propyl-L-arginine (PLA), in the guanidine-binding pocket of NOS<sup>23, 24</sup> and indicates two main amino acids of the accepting pocket, Glu and Trp. Substrate-like inhibitors can interact with the oxidation pocket containing the haem with the penta- or hexacoordinate iron ion, resulting in either the displacement of the sixth ligand (without the bond formation) or the formation of the sixth coordination bond with the haem iron ion (for example, L-thiocitrulline). The carbonyl groups of Trp and Glu are involved in PLA

**Figure 1.** Scheme of assumed interactions of  $N^{\omega}$ -*n*-propyl-L-arginine (a substrate-like NOS inhibitor) with the catalytic site of NO synthase, where binding and oxidation of the substrate (L-arginine) occurs.

binding analogously to L-arginine binding. One of the axial bonds of penta- or hexacoordinate  $\text{Fe}^{2+}$  is formed by the cysteine residue from the NOS polypeptide, whereas another bond can be formed with an inhibitor, which substantially affects its efficiency.

Analysis of the relationships between the sizes of the substituents in L-arginine-like inhibitors and stability of inhibitor–NOS complexes (inhibitor analysis) and investigation of the spectroscopic characteristics of nNOS, iNOS and eNOS demonstrated that the size of the substrate pocket of the isoforms increases in the following series: nNOS  $>$  iNOS  $>$  eNOS.<sup>25, 26</sup> In addition, the discriminative topological features of the distal and proximal pockets accepting guanidine amino groups were revealed. The binding region for the amino group (which serves as the nitrogen source for  $\text{NO}'$ ) can interact with fragments substantially bulkier than the  $\text{NH}_2$  or  $=\text{NOH}$  groups. In contrast, the binding site of the distal nitrogen cannot accommodate such groups. These topological features of the substrate-binding pocket are also retained for the isoforms. Thus, iNOS reacts only weakly with *N*-alkyl groups larger than the ethyl group in the vicinity of the haem and cannot accept the SR group in the distal guanidine-binding pocket. At the same time, inhibitors containing larger SAlk or NAlk groups are more strongly bound to the catalytic site of nNOS and, consequently, more strongly and selectively inhibit nNOS than iNOS.<sup>24</sup>

It should be noted that, in spite of the structural features of the catalytic sites of the NOS isoforms, peptide regions located in the haem access channel play apparently a more essential role in selective inhibitor binding to the enzyme. It is these regions that accept  $\text{BH}_4$  and determine dimerisation of monomers, their covalent modification and localisation of the protein in cells. These structural features, which remain unstudied by X-ray diffraction analysis, hold promise for the design of highly selective and active NOS inhibitors.

## III. Structures and activity of nitric oxide synthase inhibitors

Since the discovery of the enzymatic origin of  $\text{NO}'$ , hundreds of compounds have been studied as NOS inhibitors using the isolated enzyme with different degrees of purity. However, these necessary and useful data were obtained in the absence of commonly accepted standards for the analysis of the species origin of the enzymes, procedures for their isolation, reaction conditions, *etc.* In addition, estimates for the inhibiting activity of compounds on isolated enzymes ruled out a number of important mechanisms, which can determine the efficiency of inhibitor at the cell level. Among them are, for example, modifications of the enzyme stability to proteolysis, the metabolism rate of inhibitors, the cell membrane permeability, *etc.*

The activity of nitric oxide synthase inhibitors is generally characterised by the stability of an inhibitor–enzyme complex using the  $K_i$  (see  $\dagger$ ) and  $IC_{50}$  parameters $\ddagger$  determined from the kinetic data. The compounds are classified into four groups according to the activity. For these groups,  $K_i$  ( $IC_{50}$ ) vary in the ranges  $>100$ ,  $10$ – $100$ ,  $<10$  and  $<1$   $\mu\text{M}$ , respectively. For example, the Michaelis–Menten constant of NOS for arginine  $K_M^{\text{Arg}} = 1$ – $10$   $\mu\text{M}$ ,<sup>27</sup> whereas the corresponding constant for L-homoarginine is approximately 10 times larger. The data on selective inhibition of a particular NOS isoform are represented as the  $K_i^{\text{eNOS}}/K_i^{\text{iNOS}}$  (e/i) and  $K_i^{\text{nNOS}}/K_i^{\text{iNOS}}$  (n/i) ratios (or as the corresponding  $IC_{50}$  ratios). The inhibitors are also divided into four groups according to the numerical values of the ‘selectivity’

$\dagger$  The inhibition constants  $K_i$  (assuming that the reaction is competitive and stationary) are calculated by the equation  $1/v = 1/V_{\text{max}} + (K_M^{\text{Arg}}/V_{\text{max}}[\text{Arg}]) \times (1 + [I]/K_i)$ , where  $[I]$  and  $[\text{Arg}]$  are the concentrations of the inhibitor and arginine, respectively;  $K_M^{\text{Arg}}$  is the Michaelis–Menten constant.

$\ddagger$   $IC_{50}$  is the inhibitor concentration at which the NOS activity is suppressed by 50% at a given arginine concentration.

parameter:  $e/i$  and  $n/i < 1$  or  $> 1$ ;  $e/i$  and  $n/i < 0.1$  or  $> 10$ ;  $e/i$  and  $n/i < 0.01$  or  $> 100$ ; and  $e/i$  and  $n/i < 0.001$  or  $> 1000$ . Except for the abbreviated names of NOS inhibitors proposed by the International Union of Pharmacology Nomenclature,<sup>28</sup> other abbreviated names and notations correspond to those reported in original works.

### 1. Guanidine and L-arginine derivatives

Aminoguanidine is one of the structurally simple and most well-known NOS inhibitors. This compound inhibits all NOS isoforms and exhibits certain selectivity for iNOS. The *in vivo* action of this inhibitor is difficult to interpret because of the presence of alternative biochemical targets (see comments to the paper<sup>13</sup>). Aminoguanidine (**1a**), like other guanidine derivatives, irreversibly inactivates all NOS isoforms (Table 1).

The replacement of the amino group in compound **1a** with the methyl group noticeably decreases the inhibiting activity of *N*-methylguanidine (**1b**) ( $IC_{50}^{iNOS} \approx 100 \mu M$ ).<sup>31</sup> Of 1-substituted

guanidines, *N*-ethylguanidine (**1c**) proved to be the strongest iNOS inhibitor. Compound **1c**, unlike compound **1a**, appeared to be more selective for this isoform.

The known pharmaceutical vasorelaxant agent, an  $\alpha_2$ -adrenoreceptor agonist, *viz.*, 1-(2,6-dichlorobenzylideneamino)guanidine (**1e**), was found to inhibit NOS.<sup>35</sup> In the initial period, this agent reversibly inhibits the enzyme in HEK 293 cell cytosol ( $K_i^{nNOS} = 1 \mu M$ ), but later on, irreversible inactivation of nNOS occurs. In the presence of compound **1e**, the lifetime of nNOS in the cell culture decreased from 20 to 10 h.<sup>36</sup>

L-Arginine derivatives (**2a–i**) containing the substituted guanidine group were the first, which proved to be NOS inhibitors. It should be emphasised that their D isomers have no effect on the enzymatic activity of NOS.<sup>24</sup> According to the iNOS-inhibiting activity of *N*<sup>ω</sup>-nitro-L-arginine (**2a**), the latter can be assigned to strong inhibitors ( $K_i < 10 \mu M$ , see Table 1). The activity of nNOS and eNOS is suppressed to a greater degree compared to iNOS due to the difference in the mechanisms of binding to the enzyme isoforms. Binding to iNOS, as well as the replacement with L-arginine, occur rapidly. Binding of the inhibitor to constitutive NOS occurs slowly, and the inhibitor is even more slowly separated from the enzymes in the presence of a substrate.<sup>37, 38</sup> The amino derivative of arginine **2b** also inhibits NOS both *in vitro* and *in vivo* through either irreversible removal of the haem from the polypeptide or covalent binding of the haem to the polypeptide.<sup>39</sup>

Active compounds were also found among monoalkyl-arginines. *N*<sup>ω</sup>-Methyl-L-arginine (**2c**), like nitro derivative **2a**, serves as an efficient inhibitor of all NOS isoforms without pronounced selectivity. The mechanism of action of compound **2c** as an inhibitor involves inactivation of the enzyme, compound **2** being hydroxylated as a pseudosubstrate with NOS analogously to L-arginine. However, products formed in the next step ( $MeNO^+$ ,  $CH_2O$ , *etc.*), covalently modify the enzyme, which is apparently accompanied by removal of the haem.<sup>40–42</sup> It should be noted that *N*<sup>ω</sup>-methyl-L-arginine (**2c**) and *N*<sup>ω</sup>,*N*<sup>ω</sup>-dimethyl-L-arginine (**2i**) (asymmetric dimethylarginine) are endogenous NOS inhibitors formed in living organisms. Derivatives **2c,i** have approximately equal activity ( $K_i^{nNOS} \approx 0.5$  and  $0.7 \mu M$ , respectively),<sup>43</sup> which is attributed to the fact that one of the amino groups of the guanidine fragment of L-arginine is not bound to the substrate-binding region (see Fig. 1). By contrast, symmetric *N*<sup>ω</sup>,*N*<sup>ω</sup>-dimethyl-L-arginine (**3**) is a very weak inhibitor.

In a series of L-arginine derivatives containing aliphatic substituents in the *N*<sup>ω</sup> position, the iNOS-inhibiting activity of the compounds decreases substantially as the substituent size increases [ $> 4000 \mu M$  for *N*<sup>ω</sup>-*n*-butyl-L-arginine (**2e**)], but the nNOS-inhibiting activity increases.<sup>24</sup> For example, *N*<sup>ω</sup>-*n*-propyl-arginine (**2d**), being a weak iNOS inhibitor ( $IC_{50}^{iNOS} \approx 950 \mu M$ ), exhibited high selectivity for nNOS ( $n/i < 0.001$ )<sup>31</sup> and moderate selectivity for eNOS ( $e/i < 0.1$ ). *N*<sup>ω</sup>-Cyclopropyl-L-arginine (**2f**) appeared to be a strong m-iNOS inhibitor ( $K_i^{iNOS} \approx 8 \mu M$ ).<sup>42</sup>

The appearance of a multiple bond in the alkyl substituent of arginine [in *N*<sup>ω</sup>-allyl-L-arginine (**2g**) and *N*<sup>ω</sup>-propargyl-L-arginine (**2h**)] is accompanied by a decrease in their nNOS-inhibiting activity and an increase in the iNOS- and eNOS-inhibiting activity. Apparently, this is associated with inactivation of iNOS under the action of inhibitors with a multiple bond.<sup>44</sup>

The amino acid of plant origin, L-canavanine (**4**), in which the  $\delta$ -methylene group of L-arginine is replaced with the oxygen atom, weakly and non-selectively inhibits the  $NO^{\bullet}$  synthesis ( $IC_{50}^{nNOS} \approx 130 \mu M$ ). This is apparently attributed to the fact that a hydrogen bond involving the hydrogen atom at the N(5) atom cannot exist, because the labile hydrogen is absent in the favourable tautomeric form of L-canavanine.<sup>24</sup> However, physiological experiments provided evidence for specific activity of this amino acid against iNOS. In particular, the hypertensive effect of the inhibitor on animals treated with lipopolysaccharide (with the iNOS inducer) was substantially higher than that on the intact

**Table 1.** Inhibiting activity of guanidine and L-arginine derivatives.

**Note.** Hereinafter, the averaged data are given, which can be used for comparative analysis only within the scope of the present review.

<sup>a</sup> In the cases noted, the constants  $K_i$  were calculated from the data reported in the corresponding studies according to the equation  $IC_{50} = K_i(1 + [Arg])/K_M^{Arg}$ . <sup>b</sup> The selectivity (predominant inhibition of one NOS isoform compared to another isoform) is expressed as the ratio of the values characterising the activity of the inhibitor,  $IC_{50}$  or  $K_i$  ( $n/i = IC_{50}^{nNOS}/IC_{50}^{iNOS}$ ,  $e/i = IC_{50}^{eNOS}/IC_{50}^{iNOS}$ ). <sup>c</sup> h-NOS,  $IK_{50}$ ;  $[Arg] = 30 \mu M$  (the species origin of NOS: m, r, b, h are mouse, rat, bovine and human, respectively). <sup>d</sup>  $K_i$  was calculated from the data published in the study.<sup>24, 29, 30</sup> <sup>e</sup> m-i NOS, r-nNOS, b-eNOS. <sup>f</sup> h-NOS. <sup>g</sup> m-i NOS, b-nNOS, b-eNOS,  $IK_{50}$ ;  $[Arg] = 120 \mu M$ .

animals, in which the vascular tone is regulated by NO<sup>•</sup> produced by eNOS.<sup>45</sup>

The NO-inhibiting properties of derivatives **5–7**, which are structurally similar to L-arginine, contain a substituent in the amino acid moiety and are characterised by the same structure of the guanidine group, were studied.<sup>46</sup>

It appeared that, of the conformational isomers of (±)-*trans*-3(2-guanidino)cyclopropylalanine (**5**), *syn,trans*-guanidinocyclopropylalanine is a poor substrate, whereas the *anti* isomer is a weak NOS inhibitor. Amino acid **6**, in which the ornithine fragment of L-arginine is replaced with L-proline, is also a weak NOS inhibitor.<sup>47</sup> The absence of the amino acid moiety does not hinder the formation of a complex of the inhibitor with the guanidine-binding region, as evidenced by abundant data. However, the amino acid fragment limits the number of isomers (generally, of the L form), which can bind to the catalytic site of the enzyme.

Studies of 1-amino-4-guanidinobutane [agmatine (**7**)], which is one of the products of L-arginine metabolism, revealed new NOS-inhibiting properties. Agmatine (**7**) enhances oxidation of NADPH and facilitates the formation of H<sub>2</sub>O<sub>2</sub> by the isomer of nNOS, the latter being inactivated. In the reversible initial inhibition step, the affinity of agmatine (**7**) for nNOS was characterised by  $K_i^{\text{nNOS}} \approx 30 \mu\text{M}$ .<sup>48</sup>

Considering the satisfactory inhibiting activity of compound **2a**, *N*<sup>ω</sup>-nitro-L(D)-arginine derivatives as dipeptides containing D and L isomers of phenylalanine were synthesised and characterised. The inhibition constants ( $K_i^{\text{iNOS}} > 10 \mu\text{M}$ ) show that these compounds can be considered as weak inhibitors. Of these compounds, *N*<sup>ω</sup>-nitro-L-arginyl-L-phenylalanine benzyl ester, which is conditionally selective for iNOS, is most active against iNOS ( $K_i^{\text{iNOS}} = 18 \mu\text{M}$ , *n/i* and *e/i* > 1).

At the same time, compounds with unique selectivity for nNOS and eNOS were found among inefficient iNOS inhibitors ( $K_i^{\text{iNOS}} > 1000 \mu\text{M}$ ) belonging to this series. In particular, D-phenylalanyl-*N*<sup>ω</sup>-nitro-D-arginine methyl ester selectively inhibits nNOS and eNOS compared to iNOS ( $K_i^{\text{iNOS}} = 3600 \mu\text{M}$ , *n/i* < 0.001, *e/i* < 0.01). It should be noted that dipeptides containing the nitro-D-arginine (D-NA) and D/L-phenylalanine (D/L-Phe) fragments proved to be iNOS inhibitors uncompetitive with L-arginine, but they are competitive nNOS and eNOS inhibitors.<sup>49, 50</sup> These data suggest that there are specific binding sites in iNOS outside the guanidine-binding pocket, which can accept amino acid fragments with an unnatural geometry.

More active and selective inhibitors were prepared by the replacement of the carboxy group with the amide group in dipeptides. Amides of *N*<sup>ω</sup>-nitro-L-arginyl-D-asparagine ( $K_i^{\text{iNOS}} = 9 \mu\text{M}$ , *n/i* < 0.1, *e/i* > 10) and *N*<sup>ω</sup>-nitro-L-arginyl-D-2,4-diaminobutanoic acid ( $K_i^{\text{iNOS}} = 25 \mu\text{M}$ , *n/i* < 0.01, *e/i* > 1) exhibited exclusive selectivity for nNOS compared to eNOS. One of the least active iNOS inhibitors, *viz.*, L-lysyl-*N*<sup>ω</sup>-nitro-D-arginine amide, exhibited selectivity for all three isoforms ( $K_i^{\text{iNOS}} = 4700 \mu\text{M}$ , *n/i* < 0.001, *e/i* > 0.1).

Reduction of the amide group to the amine group in this class of stereoselective compounds afforded peptidomimetic agent **8**, which has moderate iNOS-inhibiting activity ( $K_i^{\text{iNOS}} > 10 \mu\text{M}$ ) and exhibits even higher selectivity for nNOS (*n/i* < 0.01 and *n/e* < 0.001).<sup>51</sup> With the aim of increasing the lipophilicity of such compounds, their analogues were synthesised. One of them (compound **9**) also has exclusive activity and selectivity for nNOS ( $K_i^{\text{iNOS}} = 3.5 \mu\text{M}$ , *n/i* ≈ 0.01 and *n/e* < 0.001).<sup>52</sup>

Yet another class of NOS inhibitors, which contain no carboxamide groups and are structurally similar to arginine **2a**, was found among compounds **10a–c**. 5-Methylphenyl-2-nitro-*N*(5)-L-ornithine (**10b**) appeared to be the most active of these compounds and exhibited moderate selectivity for nNOS ( $K_i^{\text{nNOS}} = 1.4 \mu\text{M}$ , *n/i* < 1, *e/i* < 1). Stereoselectivity of this compound, unlike that of arginine derivatives, was not pronounced. The stereoisomer of D-ornithine **10c** inhibited nNOS 30 times weaker compared to the L form of **10b**.<sup>53</sup>

R = H (**a**), Me (L-form) (**b**); Me (D-form) (**c**).

Therefore, efficient NOS inhibitors were found among compounds containing the high-basicity guanidine group. However, the degree of binding to the enzymes is substantially affected by another fragment of the inhibitor molecule, which is responsible for its selectivity for NOS isoforms.

## 2. Inhibitors containing the carboxamidine group

The theoretical model<sup>24</sup> of the L-arginine-binding pocket of NOS suggests that the oxidised amino group of the guanidine fragment is not involved in complexation of L-arginine (or a substrate-like inhibitor) with the corresponding amino acids of the catalytic site. Hence, modifications or the complete replacement of the amino group oxidised to NO<sup>•</sup> should not influence substantially the interaction of a substrate-like inhibitor with the enzyme (see Fig. 1).

In a series of *N*<sup>ω</sup>-(1-iminoalkyl)-L-ornithines **11a,b** and L-lysines (**11c,d**), *N*(5)-(1-iminoethyl)-L-ornithine (**11a**) is the most active iNOS inhibitor, which exhibits low selectivity for nNOS and eNOS (Table 2). An increase in the length of the alkyl substituent leads to a decrease in the activity of inhibitors of all NOS isoforms, unlike *N*<sup>ω</sup>-alkyl-L-arginines **2**, whose affinity for nNOS increases.<sup>24</sup>

**Table 2.** Inhibiting activity of amino acid derivatives containing the amidine fragment.

| Compound   | $K_i^{\text{iNOS}} / \mu\text{M}$ | Selectivity |            | Ref. |
|------------|-----------------------------------|-------------|------------|------|
|            |                                   | <i>n/i</i>  | <i>e/i</i> |      |
| <b>11a</b> | 5 <sup>a</sup>                    | < 1         | < 1        | 24   |

| <b>12b</b> | 8 <sup>b,c</sup>                  | 80          | 100        | 57   |
| <b>12c</b> | 1.4 <sup>b</sup>                  | 300         | 100        | 57   |
| <b>12d</b> | 1 <sup>a</sup>                    | 60          | 130        | 58   |

<sup>a</sup> IC<sub>50</sub>. <sup>b</sup>  $K_i$  was calculated from the data published in the study<sup>31</sup>.

<sup>c</sup> h-NOS [Arg] = 30 μM.

The influence of the allyl substituent on the behaviour of the L-ornithine molecule was demonstrated using *N*(5)-(1-iminobut-3-enyl)-L-ornithine (**11b**) as an example. The latter also exhibited high selectivity for nNOS. Apparently (as in the above-described cases), this is associated with an inactivation mechanism of the reaction of compound **11b** with the enzyme.

The replacement of ornithine with lysine gives rise to *N*(6)-(1-iminioethyl)-L-lysine (**11c**) having the highest iNOS-inhibiting activity. Unlike L-ornithine derivatives, the lysine derivative exhibits moderate selectivity for iNOS (see Table 2). The replacement of the ethyl substituent with the allyl group in *N*(6)-(1-iminobut-3-enyl)-L-lysine has virtually no effect on the activity and selectivity. Therefore, the aliphatic substituent at the carboxamidine group has the same effect on the iNOS-inhibiting activity of compounds **11a–d** as the aliphatic substituent at the guanidine group. However, the selectivity of inhibitors belonging to the amino-acid class depends substantially on the modification of such substituents (the insertion of an unsaturated bond) and the nature of the amino acid residue (lysine instead of ornithine).

An original series of stereospecific NOS inhibitors **12a–f** analogous to compounds **11c** was designed (see Table 2).

The influence of the carboxy group on the efficiency of inhibition was studied for compound **11c** and *N*-[(5*S*)-amino-(6*R*),7-dihydroxyheptyl]acetamidine (**12a**), which, although being less active against iNOS, appeared to be highly selective for this isoform (compared to eNOS).

In a series of derivatives in which the carbon atom is replaced with the S atom and the SO<sub>2</sub> group (**12b,c**), the iNOS-inhibiting activity of the L isomers is higher (*IC*<sub>50</sub> = 0.7–1.6 μM) than that of the corresponding D isomers. Three compounds of this series, viz., *S*-{2-[(1-iminioethyl)amino]ethyl}-4,4-dioxo-L-cysteine (**12b**), *S*-{2-[(1-iminioethyl)amino]ethyl}-L-homocysteine (**12c**) and *S*-{2-[(1-iminioethyl)amino]isopropyl}-L-cysteine (**12d**), exhibited high selectivity for iNOS.

Fluorination of lysine at position 4 afforded the following iNOS inhibitors: *N*(5)-(1-iminioethyl)-4,4-difluoro-L-lysine (**12e**) and *N*(5)-(1-iminioethyl)-4-fluoro-L-lysine (**12f**).<sup>59</sup>

The presence of an amino acid residue is not necessary for inhibitors containing the carboxamidine group,<sup>60</sup> as well as for compounds containing the guanidine group.

Of non-amino acid inhibitors containing the amidine group, *N*-[3-(aminomethyl)benzyl]acetamidine (**13a**) proved to be iNOS-selective. Apparently, the activity and specificity are governed by the two-step chemical reaction of the inhibitor with the inducible enzyme. Unlike the fast and reversible reaction of arylamidine **13a** with constitutive NOS, the second step of the reaction of this inhibitor with iNOS occurs slowly and virtually irreversibly<sup>61</sup> (Table 3).

| Compound <b>13</b> | R                  | <i>n</i> | Compound <b>13</b> | R                 | <i>n</i> |
|--------------------|--------------------|----------|--------------------|-------------------|----------|
| <b>a</b>           | Me                 | 1        | <b>d</b>           | CH <sub>2</sub> F | 0        |
| <b>b</b>           | Me                 | 0        | <b>e</b>           | 2-thienyl         | 0        |
| <b>c</b>           | MeSCH <sub>2</sub> | 0        | <b>f</b>           | 2-furyl           | 0        |

Of other analogues of structure **13a**, nNOS-selective inhibitors, in particular, *N*-[3-(aminomethyl)phenyl]acetamidine (**13b**), were found. These inhibitors differ from compound **13a** by one methylene group. In this class of compounds, the inclusion of the thiomethyl group into the acetamidine fragment in *N*-[3-(aminomethyl)phenyl]methylthioacetamidine (**13c**) gives rise to the most active inhibitor of both iNOS and nNOS. Compound **13d** containing the fluoromethyl substituent in the acetamidine group is also a highly efficient nNOS inhibitor. Analogously, the replacement of the acetamidine group with the hetarylamidine group (**13e,f**) increases the nNOS-inhibiting activity of the resulting compounds (*K*<sub>i</sub><sup>nNOS</sup> = 6 and 9 nM, respectively). Of other thiophene-2-carboxamidines, *N*-{4-[2-[(3-chlorophenyl)methyl]-amino]ethyl]phenyl}thiophene-2-carboxamidine **13g** is a highly efficient iNOS inhibitor (see Table 3), in which the thiophene fragment proved itself as a promising pharmacophore.<sup>15</sup>

The presence of the thiophenecarboxamidine group and the active site of the vitamin E in one molecule made it possible to prepare highly selective nNOS inhibitor **14** (*K*<sub>i</sub><sup>r-nNOS</sup> ≈ 0.9, *K*<sub>i</sub><sup>b-eNOS</sup> ≈ 110, *K*<sub>i</sub><sup>m-iNOS</sup> > 300 μM) and the antioxidant BN80933 exhibiting the anti-ischemic activity.<sup>31, 62</sup>

Among syntheses of compounds biologically active *in vivo*, noteworthy is the synthesis of drugs, i.e., substances with useful pharmacological properties (necessary lipophilicity, solubility, etc.), which undergo metabolism with elimination of an NOS inhibitor in living organisms. For example, *N*(6)-(1-iminioethyl)-L-lysine *N*-tetrazol-5-ylamide **11c** showed efficiency comparable with that of compound **11a** in a model of endotoxin shock and arthritis.<sup>63</sup>

**Table 3.** Inhibiting activity of non-amino acid compounds containing the amidine group.

| Compound <b>13</b> | <i>K</i> <sub>i</sub> <sup>iNOS</sup> /μM | Selectivity |        | Ref. |
|--------------------|-------------------------------------------|-------------|--------|------|
|                    |                                           | n/i         | e/i    |      |
| <b>a</b>           | 0.14                                      | > 10        | ≈ 500  | 29   |
|                    | 0.2 <sup>a, b</sup>                       | > 10        | > 1000 | 14   |

<sup>a</sup> *IC*<sub>50</sub>. <sup>b</sup> h-NOS, [Arg] = 30 μM. <sup>c</sup> h-NOS. <sup>d</sup> m-iNOS, r-nNOS, h-eNOS.

The above data demonstrate that a decrease in the basicity of the guanidine-like group (which determines binding of the inhibitor to the enzyme) as a result of the complete replacement of one amino group does not decrease the inhibiting activity. Moreover, more active compounds **13a,c,g** were prepared by modifications of the carboxamidine residue with aryl and hetaryl fragments.

### 3. L-Thiocitrulline and its isothiocarbamide analogues

L-Citrulline and its analogues **15–17** belong to a vast class of compounds in which one nitrogen atom of the guanidine group is replaced by the oxygen or sulfur atom. L-Citrulline, which is one of the products of enzymatic oxidation of L-arginine, is a very weak NOS inhibitor.<sup>24</sup> However, L-thiocitrulline (**15a**) proved to be a strong inhibitor, nNOS being inhibited ~50 times stronger than iNOS (Table 4).

One of the mechanisms determining the strength of affinity of compound **15a** to the neuronal isoform of the enzyme involves binding between the Fe atom of the haem and the thiol group of the inhibitor. This fact was observed spectrophotometrically (a type-II differential spectrum of the haem recorded upon binding of compounds as the sixth ligand of the hexacoordinate Fe atom).

The introduction of the methyl substituent into the thiol group of L-thiocitrulline **15a** giving rise to S-methyl-L-thiocitrulline (**15b**) substantially strengthens binding to the enzyme and simultaneously decreases selectivity. A further increase in the size of the aliphatic substituent leads to a decrease in the inhibiting activity by a factor of *ca.* 50. Unlike binding of L-thiocitrulline **15a**, binding of its aliphatic derivatives to the enzyme was characterised by a type I spectral shift (*i.e.*, by the differential spectrum analogous to the spectrum of the haem upon the formation of the L-arginine–enzyme complex). This reflects the displacement of the sixth ligand from the hexacoordinate haem iron without bonding with the latter.<sup>64</sup> By contrast to *N*<sup>ω</sup>-alkyl-L-arginines, stereoselectivity was not absolutely necessary for binding this

group of inhibitors to the enzyme. S-Methyl-D-thiocitrulline (**15c**) inhibits, although weakly, iNOS and nNOS ( $IC_{50} \approx 470$  and  $160 \mu\text{M}$ , respectively). S-Methyl-L-thiocitrullinyl-L-phenylalanine appeared to be a strong and selective iNOS inhibitor ( $IC_{50} = 0.65 \mu\text{M}$ ,  $n/i \approx 60$ ).<sup>67</sup>

The replacement of the second amino group in L-citrulline or L-thiocitrulline with the alkyl group leads to a virtually complete loss (a decrease by two orders of magnitude) of the inhibiting activity of these compounds. For *N*(5)-acyl-L-ornithines **16** and *N*(5)-thioacyl-L-ornithines **17**,  $IC_{50} \geq 1000 \mu\text{M}$ . This is indicative of a weak affinity of the sulfur and oxygen heteroatoms for the catalytic site, if the alkyl group is at position 6 of the molecule. Therefore, for a strong complex with the enzyme to be formed, it is necessary that the inhibitor should contain the second NH group that forms the carboxamidine fragment.<sup>24</sup>

In compounds containing the isothiocarbamide group, as in guanidines and carboxamides, the amino acid moiety is not a necessary component for the design of efficient inhibitors. Exceptions are thiocarbamide, in which the nitrogen atom bears the terminal L-thiocitrulline residue ( $K_i > 2500 \mu\text{M}$ ), and its N-methyl derivatives. Their inhibiting activity is substantially lower (by > 500 times) than that of the corresponding S-alkyl derivatives. Ethyl- (**18b**) and isopropylisothiocarbamides (**18c**) are weakly selective for this isoform and proved to be the most active iNOS inhibitors (see Table 4).

|              | Compound <b>18</b> | R <sup>1</sup>                                                      | R <sup>2</sup> |
|--------------|--------------------|---------------------------------------------------------------------|----------------|
| <b>18a–e</b> |                    |                                                                     |                |
| <b>a</b>     |                    | (CH <sub>2</sub> ) <sub>2</sub> NH <sub>2</sub>                     | H              |
| <b>b</b>     |                    | Et                                                                  | H              |
| <b>c</b>     |                    | Pr <sup>i</sup>                                                     | H              |
| <b>d</b>     |                    | (CH <sub>2</sub> ) <sub>2</sub> C <sub>6</sub> H <sub>4</sub> OMe-3 | H              |
| <b>e</b>     |                    | H                                                                   | Ph             |

All S-alkylisothiocarbamides are competitive reversible inhibitors; they are simultaneously substrates for the haem.<sup>34,65,66</sup> S-Ethylisothiocarbamide promotes dimerisation of iNOS to a greater degree even compared to L-arginine.<sup>68</sup> S-(2-Aminoethyl)-isothiocarbamide (**18a**), like aminoguanidine **1a**, inhibits expression of iNOS in mouse macrophages and rat lungs.<sup>69</sup> In aqueous solutions (pH 7), S-aminoalkylisothiocarbamides are rearranged into the corresponding mercaptoalkylguanidines,<sup>70</sup> which are also iNOS inhibitors.<sup>71</sup>

Among S-phenylalkyl derivatives of isothiocarbamides, only compound **18d** exhibited selectivity, which was manifested in weaker inhibition (by a factor of 20) of b-eNOS compared to m-iNOS.<sup>72</sup>

N-Phenyl derivatives more actively inhibit nNOS. At the same time, N-phenylisothiocarbamide (**18e**) exhibited weak selectivity ( $K_i^{\text{iNOS}} \approx 0.9 \mu\text{M}$ ,  $n/i \approx 0.1$  and  $e/i \approx 0.5$ ). It should be noted that S-ethyl-N-phenylisothiocarbamide derivatives are less active against iNOS compared to nNOS. The values of  $K_i$ ,  $n/i$  and  $e/i$  for 2- and 4-trifluoromethylphenyl derivatives **19a,b** are, respectively,  $K_i \approx 20$  and  $40 \mu\text{M}$ ;  $n/i \approx 0.06$  and  $0.01$ ;  $e/i \approx 1$  and  $0.3$ .

<sup>a</sup> r-NOS. <sup>b</sup> r-NOS. <sup>c</sup>  $K_i$  was calculated from the data published in the study.<sup>31</sup> <sup>d</sup> h-NOS. <sup>e</sup> m-iNOS, r-nNOS, b-eNOS.

Compound **19b** did not inhibit nNOS in a tissue culture (see Table 4).<sup>73</sup>

Amidine **13a** and its analogue **13b** are known as unique inhibitors. Hence, isothiocarbamide derivatives were constructed on the basis of the above compounds.<sup>74</sup> However, compounds **20a,b** did not exhibit the expected inhibiting activity. *N*-(3-Amino-methylphenyl)isothiocarbamide (**20a**) was the most active inhibitor ( $IC_{50}^{iNOS} = 23 \mu M$  without pronounced selectivity). However, it appeared that the benzyl derivatives of isothiocarbamides (in particular, compound **20b**) serve as h-iNOS stimulators when added simultaneously with <sup>14</sup>C-arginine without preincubation with the enzyme.

The introduction of the *N*-amino group into isothiocarbamides (by analogy with aminoguanidine) did not give rise to strong and selective inhibitors. These compounds were many times (> 100) less active than the corresponding *S*-alkylisothiocarbamides. Like aminoguanidine, these compounds inactivate NOS and accelerate autoinactivation of nNOS in the absence of a substrate.<sup>31</sup>

Compounds **21a,b** containing two isothiocarbamide groups proved to be active. *S,S'*-[1,4-Phenylene(bisethyle)diisothiocarbamide (**21a**) inhibited iNOS even at a nanomolar concentration. A change in the position of the substituents from *para* to *meta* led to the appearance of selectivity, because a substantial decrease in activity of *S,S'*-[1,3-phenylene(bisethyle)diisothiocarbamide (**21b**) toward eNOS was observed ( $IC_{50}^{iNOS} \approx 0.05 \mu M$ , *n/i*  $\approx 5$ , *e/i*  $\approx 200$ ).

Crystallographic study of complexes of *S*-alkylisothiocarbamides (and their selenium analogues) with eNOS demonstrated that not only hydrogen bonds of the conservative amino acids Trp and Glu, which are acceptors of substrates for all isoforms, but also nonpolar interactions in the catalytic pocket of the enzyme play a role in binding to the substrate pocket of the enzyme.<sup>75</sup> Study of the eNOS-inhibiting activity of compounds **19** and **21a,b** revealed the topological factors responsible for the affinity of the inhibitors for this constitutive enzyme, which are partially determined by interaction of the second ureide group with the propionate of the pyrrole ring D of the haem.

An increase in the length of the hydrocarbon fragment, which binds two isothiocarbamide residues, to C<sub>12–14</sub> results in the formation of active NOS inhibitors. Apparently, this is associated with the involvement of new peptide bonds outside the catalytic site and the substrate access channel in a contact with the inhibitor, because bis(isothiocarbamides) (unlike simple *S*-alkylisothiocarbamides) inhibit electron transfer in the reduction domain of NOS.<sup>62</sup> Unfortunately, this class of compounds is of limited pharmacological utility because of toxicity and poor cell membrane permeability.<sup>66</sup>

On the whole, both the inhibiting activity of the above-described compounds and their selectivity are determined by the mechanism of the enzyme–inhibitor interaction. The strongest and most selective inhibitors are characterised by either a slow rate of binding to the enzyme or the ability to inactivate the enzyme (suicide inhibitors). The latter (arginine **2b**, ornithine **11a** and isothiocarbamide **18a**) enhance proteolysis of NOS, whereas reversible inhibitors, such as compounds **2a** and **18b**, promote stability of the NOS dimer.<sup>36, 76</sup>

#### IV. Cyclic analogues of substrate-like inhibitors

The involvement of a guanidine-like group in a cyclic structure opens considerable possibilities for the chemical design of NOS inhibitors recognised by a target enzyme on the principle of similarity with L-arginine. These compounds containing one or two amidine nitrogen atoms in the ring differ somewhat in the mechanism of action.

##### 1. 1*H*-Pyrazole-1-carboxamidines

1*H*-Pyrazole-1-carboxamidines represent a small group of competitive NOS inhibitors containing one of the nitrogen atoms of

the guanidine fragment in the heterocycle.<sup>77, 78</sup> 1*H*-Pyrazole-1-carboxamidine (**22a**), which is a very strong but nonselective NOS inhibitor, is a parent compound (Table 5).

R = H (**a**), CH(NH<sub>2</sub>)CH<sub>2</sub>NH<sub>2</sub> (**b**),  
HNC<sub>6</sub>H<sub>4</sub>(CH<sub>2</sub>)<sub>2</sub>NH<sub>2</sub>-3 (**c**).

<sup>a</sup> m-iNOS, r-nNOS, b-eNOS. <sup>b</sup>  $K_i$  was calculated from the data published in the study<sup>31</sup>.

The introduction of the methyl group at position 3 or 4 of the pyrazole ring decreases the inhibiting activity by an order of magnitude. On the whole, this class of compounds inhibit nNOS to a greater degree and inhibit eNOS to a smaller degree. *N*<sup>G</sup>-Substituted derivatives, viz., *N*-(1,2-diaminoethyl)-1*H*-pyrazole-1-carboxamidine (**22b**) and *N*-(3-aminoethylamino)-1*H*-pyrazole-1-carboxamidine (**22c**), were found to exhibit high selectivity (*n/i*  $\approx 0.1$ , *e/i*  $\approx 10$ ).

##### 2. Cyclic amidines

Amidine-containing compounds, primarily, heterocyclic imines and imidazoles, belong to the most well-studied class of cyclic NOS inhibitors. The introduction of aliphatic substituents at positions 4 and 5 of the pyrrolidine ring leads to a substantial increase in the activity and selectivity of new compounds, particularly, of 4-methyl-2-iminopyrrolidine (**23b**) and *trans*-5-ethyl-4-methyl-2-iminopyrrolidine **23c** (see Table 5).

R<sup>1</sup> = R<sup>2</sup> = R<sup>3</sup> = H (**a**);  
R<sup>1</sup> = R<sup>3</sup> = H, R<sup>2</sup> = Me (**b**);  
R<sup>1</sup> = *trans*-Et, R<sup>2</sup> = Me, R<sup>3</sup> = H (**c**);  
R<sup>1</sup> = *cis*-n-C<sub>5</sub>H<sub>11</sub>, R<sup>2</sup> = (+)-Me, R<sup>3</sup> = H (**d**);  
R<sup>1</sup> = *cis*-n-C<sub>5</sub>H<sub>11</sub>, R<sup>2</sup> = (+)-CF<sub>3</sub>, R<sup>3</sup> = H (**e**);  
R<sup>1</sup> = (*R*)-n-C<sub>5</sub>H<sub>11</sub>, R<sup>2</sup> = (*S*)-Me,  
R<sup>3</sup> = (*S*)-OH (**f**).

The iNOS-inhibiting activity of pyrrolidine derivatives **23b** and **23c** is two orders of magnitude higher than that of the starting compound **23a** ( $K_i^{iNOS} < 1 \mu M$ ). The resolution of racemic mixtures of (+)-4-methyl-*cis*-5-n-pentyl-2-iminopyrrolidine (**23d**) and 4-trifluoromethyl-*cis*-5-n-pentyl-2-iminopyrrolidine (**23e**) into stereoisomers demonstrated that the (+)-*cis* isomers are almost an order of magnitude more selective for iNOS than for eNOS ( $K_i \approx 0.1 \mu M$ , *n/i*  $\approx 10$ , *e/i* > 100).<sup>79</sup> This is evidence that new stereospecific acceptors were revealed in iNOS. The recently characterised iNOS inhibitor, viz., (3*S*,4*S*,5*R*)-3-hydroxy-4-methyl-5-n-pentyl-2-iminopyrrolidine (**23f**), exhibited selectivity (*e/i*) three times higher than that of compound **23d**. This fact confirmed once again that a search for stereoselective iNOS inhibitors in the class of iminopyrrolidines holds promise.

Highly active competitive iNOS inhibitors with  $K_i < 1 \mu M$  were found in a series of heterocyclic imines containing from five to nine carbon atoms in the ring (Table 6). However, these

**Table 6.** Inhibiting activity of 2-imino-N-containing heterocyclic derivatives.

| <b>26g</b> | 0.4                             | >1          | 200 | 83   |

<sup>a</sup>  $K_i$  was calculated from the data published in the study<sup>31</sup>. <sup>b</sup> h-iNOS. <sup>c</sup> The experimental value of  $K_i$  = 0.09  $\mu\text{M}$ .

inhibitors do not exhibit pronounced selectivity. The activity of 2-iminopyrrolidine (**23a**) is *ca.* 25 times lower than that of the six-membered amidine 2-iminopiperidine **24a**. A further increase in the size of the inhibitor molecule leads to a decrease in activity (see Table 6).

Fused six-membered amidines were found to have the unique inhibiting properties. In this series, the bicyclic amidine (1*S*,5*S*,6*R*,7*R*)-7-chloro-3-imino-5-methyl-2-azabicyclo[4.1.0]heptane (**25a**) proved to be most active against h-iNOS (see Table 6). Certain fused and spirocyclic derivatives of 2-iminopiperidine were found to be highly active iNOS inhibitors ( $IC_{50} < 0.1 \mu\text{M}$ ,  $e/i > 1$ ).<sup>84</sup> DL-(1*R*,5*S*,6*R*)-3-Imino-5-methyl-2-azabicyclo[4.1.0]heptane hydrochloride (**25b**) has *in vitro* and *in vivo* very high inhibiting activity ( $IC_{50}^{\text{h-iNOS}} = 0.09$ ,  $IC_{50}^{\text{m-iNOS}} = 0.007 \mu\text{M}$ , respectively). In experiments on mice treated with lipopolysaccharides, the dose of the agent necessary to decrease the concentration of nitrite anions (the product of  $\text{NO}^*$  metabolism) in blood plasma was  $0.013 \text{ mg kg}^{-1}$ , which is almost 1500 times lower than the maximum tolerable level for animals.

The introduction of side substituents and modifications of the ring in hexahydro-2-iminoazepine (**24b**) gave rise to iNOS-selective inhibitors. For example, hexahydro-7-(but-2-enyl)-2-iminoazepine (**26a**) containing the alkenyl substituent at position 7 inhibits iNOS *ca.* 100 times more strongly than eNOS. Due to the presence of the oxygen atom at position 5, the selectivity of hexahydro-7-n-butyl-2-imino-5-oxazepine (**26b**) for iNOS is almost two times higher than that for eNOS, the nNOS-inhibiting activity varying only slightly.<sup>56</sup> The iNOS-inhibiting activity of hexahydro-2-imino-7-(2-nitroethyl)azepine (**26c**) containing the polar nitroethyl group is almost an order of magnitude higher, although the selectivity of this compound is low.

Alkylation at position 7 in hexahydro-2-iminoazepines (see Table 6) results in an increase in activity and selectivity of such

inhibitors as hexahydro-7-n-butyl-2-imino-5-oxazepine (**26d**), hexahydro-2-imino-7-propenylazepine (**26e**), hexahydro-7-n-butyl-2-iminoazepine (**26f**) and hexahydro-7-(2-ethyl-2-n-butyl)-2-iminoazepine (**26g**) ( $K_i < 1 \mu\text{M}$ ,  $e/i > 100$ ).<sup>83</sup>

The synthesis of analogues of iminopiperidines, *viz.*, aminopyridines **27a–d**, is a natural continuation of a search for NOS inhibitors among heterocyclic imines.

Later on, one of the first inhibitors belonging to this class, *viz.*, 2-amino-4-methylpyridine (**27a**)<sup>85</sup> ( $K_i$  are 55, 65 and  $98 \mu\text{M}$  for h-iNOS, h-nNOS and h-eNOS, respectively), has been used as a competitive radioligand to estimate the affinity and selectivity of other NOS inhibitors.<sup>31</sup> However, neither compound **27a** nor other mono- and disubstituted alkyl derivatives of 2-aminopyridine exhibited pronounced selectivity for the inducible enzyme ( $n/i > 1$ ,  $e/i > 1$ ). Of these compounds, 2-amino-6-*tert*-butyl-4-methylpyridine (**27b**) is the strongest iNOS inhibitor ( $IC_{50} < 1 \mu\text{M}$ ). 2-Amino-6-(4-substituted)phenylpyridines (for example, **27c**) did not have iNOS-inhibiting activity. However, arylidenepiperazine-bridged compound **27d** appeared to be an h-nNOS strong inhibitor ( $IC_{50} < 1 \mu\text{M}$ ), the selectivity being low ( $e/n > 1$ ). Compound **27d** exhibited the highest selectivity and inhibited h-nNOS six times more strongly than h-eNOS ( $IC_{50}^{\text{h-nNOS}} = 0.14 \mu\text{M}$ ).<sup>86</sup> 2-Aminopyridines fused with five- or six-membered saturated and unsaturated rings are active iNOS inhibitors ( $IC_{50} < 10 \mu\text{M}$ ) without pronounced selectivity, compounds containing unsaturated rings being more active. 2-Aminoquinoline **28** is the most active iNOS inhibitor ( $IC_{50} \approx 2 \mu\text{M}$ ).<sup>87</sup>

### 3. Imidazoles and nitroindazoles

Imidazole derivatives can be considered as cyclic analogues of carboxamidines containing both amidine nitrogen atoms in the heterocycle. Their reactions with the enzyme are targeted primarily to the haem. Imidazoles bind to the enzyme as the sixth ligand of the hexacoordinate iron atom in the haem, *i.e.*, analogously to  $\text{CO}$ ,  $\text{NO}^*$ ,  $\text{O}_2$  and  $\text{CN}^-$ . This property was well studied for cytochrome P-450, which is closely similar to NOS.<sup>88</sup>

Inhibition of NOS by imidazoles occurs reversibly. However, depending on the nature of the substituents and the NOS source, imidazoles compete with  $\text{BH}_4$  and/or L-arginine for binding to the catalytic site. For example, 1-phenylimidazole (**29a**) ( $IC_{50}^{\text{h-iNOS}} \approx 40 \mu\text{M}$ ), which is one of the strongest iNOS inhibitors, noncompetitively (with respect to L-arginine) binds to m-iNOS and competitively binds to b-eNOS (Table 7).

These differences in the inhibition mechanisms makes it difficult to interpret the inhibition constants determined by spectroscopic or kinetic methods.

Modifications of the substituent at the nitrogen atom afford inhibitors active against nNOS. However, frequently used 1-(2-

**Table 7.** Inhibiting activity of imidazole and 7-nitroindazole derivatives.

| Compound   | $K_i^{\text{iNOS}}/\mu\text{M}$ | Selectivity |      | Ref.   |
|------------|---------------------------------|-------------|------|--------|

| <b>33</b>  | 1.6 <sup>a, f</sup>             | 0.1         | 0.5  | 94     |

<sup>a</sup>  $IK_{50}$ . <sup>b</sup> r-iNOS, m-nNOS, b-eNOS. <sup>c</sup> r-nNOS, e-hNOS. <sup>d</sup> r-iNOS, r-nNOS, h-eNOS. <sup>e</sup> h-iNOS, crude cell lysate. <sup>f</sup> m-iNOS, b-nNOS, b-eNOS.

trifluoromethylphenyl)imidazole (**29b**) did not exhibit considerable activity and selectivity in *in vitro* experiments (see Table 7), although it caused a decrease in pain sensitivity of animals to formalin, which reflects its nNOS-inhibiting ability. Since imidazole derivatives containing substituents at positions 2 and 4 have lower inhibiting activity ( $IC_{50} > 1000 \mu\text{M}$ ),<sup>95</sup> attempts to design highly efficient inhibitors belonging to the class of 1,2-disubstituted imidazoles failed. It is believed that compounds with this structure may be useful tools for revealing the characteristic features of the guanidine–oxygen- and  $\text{BH}_4$ -binding regions of NOS.<sup>96</sup>

An increase in the length of the aliphatic bridge between the imidazole and the amino acid group made it possible to prepare active compounds.<sup>92</sup> Inhibitors **29e** containing an odd number of methylene groups are more selective for nNOS ( $K_i^{\text{nNOS}} = 2 \mu\text{M}$  for both compounds). Compounds containing an even number of methylene groups are less active.

Crystallographic studies demonstrated that two imidazole molecules can simultaneously bind to the oxidative domain of the m-iNOS monomer: one molecule is located in the catalytic site as the sixth ligand of the haem iron atom, and another molecule is located in the guanidine-binding pocket with Glu371.<sup>22</sup> In this connection, guanidine-substituted imidazoles were synthesised. However, most agents appeared to be poorly active, if at all. Among these compounds, imidazole derivative **29d** is the strongest inhibitor (against iNOS;  $IC_{50} \approx 140 \mu\text{M}$ ).<sup>97</sup>

Attempts were made to enhance the inhibiting activity of imidazoles by including an amino acid residue into molecules of these inhibitors. 2-Amino-5-(imidazol-1-yl)pentanoic acid (**29c**) has the highest activity (see Table 7).

Antifungal clotrimazole (**30a**) and miconazole (**30b**), which inhibit nNOS competitively with CaM, belong to imidazoles containing bulky substituents.<sup>98</sup>

In addition, these drugs *in vitro* inhibit dimerisation of the oxidative domain of iNOS. In RAW264.7 cells, clotrimazole (50  $\mu\text{M}$ ) also blocks the formation of dimeric iNOS,<sup>99</sup> unlike substrate-like inhibitors, in the presence of which the fraction of dimeric iNOS increases from 50% to 90%.<sup>18, 69</sup>

Powerful inhibitors with bulky substituents were found by screening 8649 compounds prepared by combinatorial chemistry based on nitrogen-containing heterocycles.<sup>93</sup> Of 53 compounds

inhibiting iNOS by 60% at 200  $\mu\text{M}$ , three compounds, **31a–c**, which have  $IC_{50}^{\text{iNOS}} < 1 \mu\text{M}$  in a cell test system, were chosen.

R = H, X = Cl (**a**); R =  $\text{CO}_2\text{Me}$ , X = H (**b**);  
R =  $\text{CO}_2\text{Et}$ , X = H (**c**).

R<sup>1</sup> = 7- $\text{NO}_2$ ; R<sup>2</sup> = H (**a**), Br (**b**);  
R<sup>1</sup> = 6- $\text{NO}_2$ , R<sup>2</sup> = H (**c**);  
R<sup>1</sup> = R<sup>2</sup> = H (**d**);  
R<sup>1</sup> = 5- $\text{NO}_2$ , R<sup>2</sup> = H (**e**).

Compound **31b** was a highly efficient nNOS inhibitor not only in a cell culture,<sup>100</sup> but also in animals treated with a lipopolysaccharide ( $ID_{50} = 1.2 \text{ mg kg}^{-1}$ )<sup>8</sup> (based on the criterion of a decrease in the nitrite level in rat blood plasma). Crystallographic analysis of the complex of the oxidative domain of iNOS with compound **31b** demonstrated that free nitrogen of the imidazole group is coordinated to the haem iron atom in the sixth axial position, and the structure of the guanidine-binding sequence involving Glu371 is destroyed under the action of the adjacent imidazole, pyrimidine and piperazine rings. Inhibitors belonging to this series of compounds do not suppress activity of dimeric NOS. However, inhibitors were found among imidazole-containing compounds.

3-(2,4-Difluorophenyl)-6-{2-[4-(1*H*-imidazol-1-ylmethyl)phenoxy]ethoxy}-2-phenylpyridine (**32**) inhibits the  $\text{NO}^{\bullet}$  synthesis in activated macrophages with  $IC_{50} = 0.08 \mu\text{M}$  and have the therapeutic effect in experimental arthritis models.<sup>101</sup>

The inhibition mechanism involving the interaction with the haem was observed for compounds of the nitroindazole series. The most well-known agent, *viz.*, 7-nitroindazole **33a**, is a competitive inhibitor of iNOS (against L-arginine and  $\text{BH}_4$ ) and eNOS (against  $\text{BH}_4$ ). This is associated with the fact that compound **33a**, like its analogue, *viz.*, 3-bromo-7-nitroindazole (**33b**) ( $IC_{50}^{\text{r-iNOS}} = 0.29 \mu\text{M}$ , n/I < 1, e/I > 1),<sup>102</sup> contacts with one of the propionate groups of the haem, thus suppressing its interaction with  $\text{BH}_4$ .<sup>62</sup>

Nitroindazoles **33c** ( $K_i^{\text{b-nNOS}} = 40 \mu\text{M}$ ) and **33a** were the strongest b-nNOS inhibitors, whereas the inhibiting activities of indazole (**33d**) and 5-nitroindazole (**33e**) were very weak ( $IC_{50} > 1000 \mu\text{M}$ ).<sup>103</sup> However, according to the results of the study,<sup>104</sup> compounds **33c,e** are virtually identical in the r-nNOS-inhibiting activity. The selectivity of 7-nitroindazole **33a** for nNOS, which is manifested *in vivo*, is apparently associated with its cell membrane permeability and metabolism.<sup>14</sup>

#### 4. Cyclic analogues of isothioureas

Cyclisation of *S*-aminoalkylisothioureas affords the corresponding *S,N*-heterocycles with structures isosteric with the guanidine group of L-arginine.<sup>105, 106</sup> Although thiazole **34a** is a very weak inhibitor of all NOS isoforms ( $K_i > 200 \mu\text{M}$ ), the introduction of an amino group giving rise to 2-aminothiazole (**34b**) increases the inhibiting activity against iNOS by a factor of *ca.* 5 (Table 8).

$\%ID_{50}$  is the dose at which the rate of the  $\text{NO}^{\bullet}$  synthesis is half that observed for an intact sample.

$R^1 = R^2 = H$  (**a**);  
 $R^1 = NH_2$ ,  $R^2 = H$  (**b**), Me (**c**);  
 $R^1 = NH(CH_2)_3Cl$ ,  $R^2 = H$  (**d**).

$R = H$  (**a**);  
 $(CH_2)_3Ala$  (**b**).

$R = H$  (**a**);  
 Me (**b**).

$R = CH_2-N$  (morpholine ring).

**Table 8.** Inhibiting activity of cyclic analogues of isothioureas.

| <b>42</b>  | 0.8 <sup>g</sup>       | > 1         | > 1  | 109  |

<sup>a</sup> h-NOS. <sup>b</sup>  $IC_{50}$ . <sup>c</sup> r-iNOS, r-nNOS, h-eNOS. <sup>d</sup>  $K_i$  was calculated from the data published in the study.<sup>31</sup> <sup>e</sup> m-iNOS, r-nNOS, b-eNOS. <sup>f</sup> [Arg] = 5  $\mu M$ , m-iNOS, m-nNOS, b-eNOS. <sup>g</sup> h-NOS.

2-Amino-5-methylthiazole (**34c**) ( $IC_{50} \approx 12 \mu M$ ) is even more active.<sup>61</sup> However, these inhibitors exhibited selectivity for none of the NOS isoforms. *N*(5)-(Thiazolin-2-yl)-L-ornithine (**35b**) prepared by modifying the amino group in 2-amino-2-thiazoline (**35a**) is an active eNOS inhibitor ( $IC_{50} \approx 1 \mu M$ ). At the same time, *N*(5)-(thiazol-2-yl)-L-ornithine (**34d**) is a weak inhibitor.<sup>107</sup>

The activity and selectivity of 2-amino-5,6-dihydro-4*H*-1,3-thiazine (**36a**) synthesised by cyclisation of *S*-aminopropylisothiourea exhibits are similar to those of compound **35a** (see Table 8). The replacement at position 6 leads to a substantial increase in activity and selectivity of the derivatives (as in the case of N-containing heterocyclic imines) (see Table 6). For example, 2-amino-6-methyl-5,6-dihydro-4*H*-1,3-thiazine (**36b**) inhibits iNOS almost 150 times more strongly than thiazine **36a**.

## 5. Other inhibitors

The NOS-inhibiting activity was found in a series of antithyroid agents belonging to thiouracils. 6-Methyl- (**37a**) and 6-*n*-propyl-2-thiouracils (**37b**) exhibited selectivity for r-nNOS inhibition. At a concentration of 500  $\mu M$ , compound **37a** inhibited the synthesis of L-citrulline by the enzyme isoforms m-iNOS, r-nNOS and b-eNOS by  $\approx 20\%$ , 80% and 40%, respectively.<sup>110</sup> The inhibition occurred competitively and reversibly, suppression of  $BH_4$ -dependent dimerisation of nNOS playing a certain role in this effect.<sup>111</sup>

$R = Me$  (**a**),  $Pr^n$  (**b**).

$R = H$  (**a**), OH (**b**).

The introduction of the nitro group in dopamine and nor-adrenaline gave rise to the corresponding nitro derivatives, *viz.*, 4-(2-aminoethyl)-5-nitromethylpyrocatechol (**38a**) and 4-(2-aminoethyl-1-hydroxy)-5-nitromethylpyrocatechol (**38b**). These compounds inhibited NOS two orders of magnitude more strongly ( $K_i \approx 50 \mu M$ ) than the starting catecholamines. The inhibition occurred reversibly and competitively with L-arginine and  $BH_4$ ; in addition, slight selectivity for r-nNOS, was observed, which may be attributed to suppression of enzyme dimerisation.<sup>112</sup> These results suggest that the nitro group plays a great role in inhibitor–NOS complexation.

Screening of a chemical library revealed a series of promising bicyclic NOS inhibitors. Thus,  $IC_{50}^{m-iNOS}$  for 5-chloro-1,3-dihydro-2*H*-benzimidazol-2-one (**39**), (2*H*,4*H*)-isoquinoline-1,3-dione (**40**) and 5-chloro-(1*H*,3*H*)-quinazolin-2,4-dione (**41**) were < 10  $\mu M$ . The selectivity of compounds **39** and **41** for r-nNOS and b-eNOS (n/i) is > 10 and > 1, respectively. In a series of benzoxazolones, 6-chloro-*N*-morpholinomethylbenzoxazolone (**42**) appeared to be an active h-iNOS inhibitor, which, however, did not exhibit noticeable selectivity (see Table 8).

It is known<sup>113</sup> that substituted 2-aminobenzimidazoles **43a–d** have NOS-inhibiting activity. 2-Aminobenzimidazole (**43a**) competitively inhibited iNOS, the selectivity for eNOS being very low ( $IC_{50}^{h-iNOS} = 25 \mu M$ , n/i  $\approx 3$ , e/i > 5). 2-Amino-1-aminomethylbenzimidazole (**43b**) is more selective for h-nNOS ( $IC_{50}^{h-nNOS} \approx 6 \mu M$ , n/i < 0.1, n/e < 0.1). 1-Ethyl- (**43d**) and 2-amino-1-isopropylaminobenzimidazoles (**43c**) are inactive.<sup>113</sup>

$R = H$  (**a**),  $CH_2NH_2$  (**b**),  
 $Pr^iNH$  (**c**), Et (**d**).

Recently, compounds belonging to the class of 1,2-dihydroquinazolineamines and their spirocyclic derivatives were found to have inhibiting activity against iNOS.<sup>114</sup> For example, 1-(6-cyano-3-pyridylcarbonyl)-5',8'-difluorospiro[piperidine-4,2'(1'*H*)-quinazoline]-4'-amine hydrochloride (**44**) showed high efficiency both *in vitro* and *in vivo* ( $IC_{50}^{h-iNOS} = 0.04 \mu M$ , n/i > 10, e/i > 1000).

## V. Conclusion

Based on the above data, the following physicochemical features responsible for the efficiency of NOS inhibitors, which interact with the catalytic site of the enzyme, can be noted.

1. The guanidine, carboxamide or isothiocarbamide groups in linear or cyclic structures

provide hydrogen bonding with Glu and/or the formation of a coordination bond with the haem Fe atom.

2. Small hydrophobic substituents at the guanidine-like group (alkyl, phenyl or thienyl), which can form additional bonds with haem-proximal peptide regions, should be present.

3. The chemical activity of a guanidine-like group as a pseudosubstrate can have a determining effect on both the selectivity and inhibiting activity of substrate-like compounds.

4. In addition to these factors, such properties of compounds as suppression of superoxide synthase activity of the enzyme, regulation of NOS dimerisation and inactivation of active oxygen forms produced by NOS can facilitate efficiency of *in vivo* NOS inhibition.<sup>115</sup>

One would expect that the next step in the chemical synthesis and design of pharmacological agents modifying the enzymatic NO<sup>•</sup> production will be aimed at preparing compounds that combine the following functions: specificity for NOS isoforms, antioxidant activity and specificity for accumulation in subcellular targets (caveoles, synapses, mitochondria, *etc.*).

We thank Prof. T M Roshchina, Prof. F A Tpopimov and Dr. V Yu Kovtun for helpful discussion and valuable advice. We also acknowledge the designers of the molbiol.ru site for the information support.

**Abstract.** Some aspects of the reactivity of cyclopalladated complexes with phosphorus donor atoms are discussed, in particular, the routes of modification of the metal coordination environment in phosphapalladacycles by means of diverse auxiliary ligands; the transformations of phosphapalladacycles involving the Pd–C bond; the modification of phosphapalladacycles with retention of the Pd–C bond; and dechelation and destruction of phosphapalladacycles. The regiochemistry of ligand coordination to PC-palladacycles is considered from the standpoint of the *trans*-effect of the P- and C-donor atoms of the palladacycle. The bibliography includes 359 references.

## I. Introduction

The development of modern chemistry of phosphapalladacycles is mainly determined by the increased demands of the homogeneous metal complex catalysis for compounds of this class, as they proved to be remarkably efficient and practically convenient catalysts or precatalysts.<sup>1–11</sup> There are two approaches to the optimisation of the structures of phosphapalladacycles to meet the requirements of a particular chemical process and a particular substrate: (1) modification of electronic and steric characteristics of the phosphapalladacycle and (2) variation of the nature of auxiliary ligands in the coordination environment of palladium.

The first approach (usually, fairly labour consuming) involves targeted design of P-donor ligands and the selection of optimal methods for their cyclopalladation. The relevant information can be found in a review,<sup>12</sup> which gives a detailed analysis of the known methods for the synthesis of the PC- and PCP-type cyclopalladated complexes (CPCs). An alternative solution to this problem is chemical modification of the phosphapalladacycle prepared beforehand. The influence of the structure of phosphapalladacycles on their catalytic activity can be followed from a

series of reviews on homogeneous catalysis, which are devoted to either particular types of reactions<sup>2, 3, 6, 13</sup> or particular classes of cyclopalladated (pre)catalysts of the PC<sup>5, 7, 8</sup> or PCP type.<sup>4, 5, 7, 9–11</sup>

The second approach appears less labour consuming, as it implies only the variation of the coordination environment of the metal in the pre-formed phosphapalladacycles. Its efficiency can be illustrated by the substantial increase in the activity of the PC-type (pre)catalysts in the Suzuki and Stille reactions and in amination attained on passing from standard dimeric complexes to monomeric analogues (mononuclear palladium complexes) with monodentate phosphines.<sup>14–18</sup>

Conversely, in other processes (for example, in the Heck reaction), the activity of the monomeric phosphine derivatives proved to be lower than the activity of the dimers.<sup>19, 20</sup> The activity of the cyclopalladated catalysts can be substantially enhanced by selecting an appropriate bridging anion in the CPC dimers ( $\text{Cl}^- < \text{AcO}^- < \text{CF}_3\text{COO}^-$ )<sup>21</sup> or by converting dimers into monomeric  $\beta$ -diketonate derivatives.<sup>22</sup> Similar effects have been found for the use of CN-palladacycles whose catalytic activity in various processes can either increase<sup>23–28</sup> or, conversely, decrease<sup>29</sup> on passing from dimers to monomers. For example, the cationic mononuclear adducts of the CN-palladacycles efficiently catalyse CO copolymerisation with ethylene,<sup>30</sup> while in the Heck reaction they show no activity.<sup>29</sup> These facts demonstrate the necessity of individual approach to the coordination environment of palladium in the palladacycle chosen for catalysis.

The implementation of the second approach requires the knowledge of synthetic routes to various derivatives of a palladacycle and of their behaviour in chemical transformations. The only published review on the cyclometallation of phosphorus-containing ligands (separately<sup>31</sup> and in the monograph<sup>32</sup>) covers the literature only up to 1985 and does not describe the behaviour of phosphapalladacycles in various reactions or the modification routes of the coordination environment of palladium.

The purpose of this review is to analyse the properties and the reactivity of phosphapalladacyclic compounds based on publica-

Received 30 July 2004

Uspekhi Khimii 74 (10) 955–1000 (2005); translated by Z P Bobkova

<sup>†</sup> This review naturally continues the review by the same authors 'Phosphapalladacycles: preparation routes' published previously [Russ. Chem. Rev. 73 309 (2004)].

tions that appeared up to 2003. Two different types of reactions are considered:

1. Modification of the coordination environment of the metal in phosphapalladacycles by introducing auxiliary ligands without affecting the proper metallacyclic fragment (Section II).

2. Transformations of phosphapalladacycles (Section III): reactions involving the Pd–C bond and processes resulting in palladacycle modification with retention of the cyclic structure. This Section also covers dechelation and destruction of palladacycles.

The investigation objects include mono- (**A**) and bicyclic (**B**, **C**) compounds in which palladium is directly linked to one or two atoms of trivalent phosphorus and to, at least, one carbanionic centre incorporated in the same anionic bi- or tridentate chelated ligand.

E is heteroatom.

The structures of type **D–G**

are beyond the scope of this review as their properties differ significantly from the properties of phosphapalladacycles **A–C**.<sup>‡</sup>

However, PC-chelated derivatives of phosphino-phosphorus ylides are included in the consideration, despite the formally neutral nature of ligands of this class (really, the zwitterionic nature), because the C-donor atom in them exhibits pronounced carbanion properties.

An idea of the diversity of derivatives possible for CPC bearing P-donor atoms can be gained from Supplements 1–3, which present data on the methods of synthesis of phosphapalladacycle derivatives classified according to structural features: PC-type compounds (**A**, Supplement 1), their bicyclic (pincer) PCP-analogues (**B**, Supplement 3) and PC-coordinated phosphino-phosphorus ylides (Supplement 2). Within each Table, phosphapalladacycles are grouped according to the type of hybridisation of the metal-bonded carbon atom ( $sp^3$  or  $sp^2$ ) and the size of the chelate ring (six-, five-, four-, and three-membered). In addition, derivatives of each palladacycle are classified according to types of complexes, either neutral or cationic, with either mono- or bidentate auxiliary ligands. The complexes whose structures were reliably confirmed by X-ray diffraction are asterisked.

## II. Forms of existence of phosphapalladacycles

This Section describes phosphapalladacycle derivatives of PC- and PCP types and their interconversion routes.

### 1. Monocyclic PC-complexes

#### a. Dimers

The direct intramolecular cyclopalladation of monodentate P-donor ligands usually gives, as the primary products, dimeric complexes with halide or carboxylate bridges, most often, chloride or acetate ones (depending on the nature of the palladating agent used).<sup>12</sup> Modification of bridging anions is required in those cases where it is necessary (1) to increase the dimer solubility (most

often, the solubility of  $\mu$ -halide dimers is lower than that of  $\mu$ -carboxylate analogues); (2) to remove the complications caused by the dynamic behaviour of complexes (most typical of  $\mu$ -carboxylate dimers<sup>2, 22, 51</sup>); (3) to increase the thermal stability of complexes;<sup>8</sup> (4) to optimise the structure of a dimeric PC-type (pre)catalyst.<sup>21</sup>

The transformation of  $\mu$ -acetate PC-dimers into  $\mu$ -chloride or  $\mu$ -bromide analogues is easily accomplished by simple replacement of  $\mu$ -OAc by a 'softer' halide at room temperature (see Supplement 1). The reactions with LiCl are carried out in a mixture of methanol with dichloromethane<sup>53</sup> or in aqueous acetone,<sup>54</sup> while those with ammonium salts (for example, with  $[Bu_4N]Cl$  or  $[Bu_4N]Br$ ) are carried out in dichloromethane. An example of anion exchange in dimer **1a** is presented below<sup>¶</sup> (see Ref. 51).

The  $\mu$ -chloride PC-dimers are usually transformed into  $\mu$ -bromide or  $\mu$ -iodide analogues (with softer anions) by means of simple metal halide salts KBr,<sup>55, 56</sup> LiBr,<sup>57</sup> KI<sup>55, 57</sup> and NaI.<sup>58, 59</sup> The reactions are carried out in acetone at room temperature.

However, the reverse replacement of relatively soft bridging halide anions in dimers by harder anions (for example, the **2a**  $\rightarrow$  **2b** transition) requires dehalogenation of the substrate with an appropriate  $RCO_2Ag$  salt ( $R = Me, Ph$ ).<sup>54, 60</sup>

Of the few non-standard forms of dimeric CPC with monoatomic bridges, we would like to mention the non-symmetrical  $\mu$ -methoxy- $\mu$ -chloride complex **3a**, which is prepared by methoxylation of  $\mu$ -chloride dimer **3b** with methanol in an alkaline medium.<sup>61</sup>

As was to be expected, the reaction of non-symmetrical dimer **3a** with phosphine affords a mixture of two mononuclear derivatives with different anions.

One more type of dimeric CPCs with diatomic bridges includes phosphapalladacycles with azolate bridges, namely, pyrazolate (pz),<sup>62–64</sup> 4-methyl- (4-mpz) and 3,5-dimethyl-substituted (3,5-dmpz) pyrazolate bridges.<sup>63, 64</sup> These binuclear com-

<sup>‡</sup> Examples of structures **D–G** have been reported.<sup>33–50</sup>

<sup>§</sup> For PC-palladacycles, these studies have not been carried out, but the stability of benzylamine CN-dimers is known<sup>52</sup> to increase, depending on the nature of the bridging anions, in the series  $CN^- < NCO^- < Cl^- < SCN^-$ .

<sup>¶</sup> In the designations of complexes, the Arabic numeral corresponds to the superscript in the designation of the cyclopalladated ligand  $HL^n$ , while the letters are used to number particular derivatives of a particular phosphapalladacycle (see the designations in the previous review<sup>12</sup>).

plexes are prepared by treatment of the  $\mu$ -acetate<sup>63,64</sup> or  $\mu$ -chloride<sup>62</sup> dimer with pyrazole. In the former case, the reaction is carried out in the presence of  $\text{Et}_3\text{N}$  in methanol on heating, while in the latter case, in the presence of  $\text{NaOH}$  at room temperature. In both cases, the yields are relatively high (80%–97%). The scheme of transformation of dimer **4a** into pyrazolate analogues **4b–d** is shown below.

In the  $\mu$ -pyrazolate dimers, the central six-membered ring  $\{\text{Pd}_2\text{N}_4\}$  involves two nitrogen atoms from each bridging ligand. This determines the structural diversity of dimers **4b–d**. Since the tetraazadipalladacycle exists as the boat conformation, the complexes acquire the shape of a ‘half-open book’ (a typical shape of  $\mu$ -carboxylate dimers). The same conformation is typical of simple coordination compounds of palladium with bridging pyrazolate ligands.<sup>65,66</sup>

With this orientation of two flat pyrazolate ligands, a  $\pi$ -electron-enriched gap convenient for incorporation of a cation of another metal is formed between them. The reaction of bridging 3,5-dimethylpyrazolate ligands in dimer **4d** with  $\text{AgClO}_4$  provides an example of secondary complexation.<sup>63,64</sup>

The structure of hexanuclear complex **4e** was confirmed by X-ray diffraction analysis.<sup>63</sup> The structural parameters of this complex were interpreted as being indicative of  $\eta^1$ -binding of the silver ion to the unsubstituted carbon atoms of the two bridging pyrazolate ligands, which are arranged at a  $44.8^\circ$  angle with respect to each other.

The synthesis of dimeric CPCs from *spiro*-complexes is important from the practical standpoint. The easy cleavage of the bridges, which allows one to modify the coordination environment of the metal by introducing auxiliary ligands (see Section II.1.b) is a valuable advantage of dimers with bridging anions compared to *spiro*-PC-structures. The *spiro*-complex can be converted into the dimer in two ways: on treatment with mercury(II) bromide or acetate or on treatment with an appropriate palladium(II) halide.<sup>67</sup>

The drawbacks of the former method include the formation of mercury metal in the reaction and the requirement to strictly maintain the 1 : 1 reactant ratio, as an excess of a mercury salt (for example,  $\text{HgBr}_2$ ) promotes full cleavage of the  $\text{Pd} - \text{C}$  bond to give a coordination complex of palladium(II) bromide with *ortho*-mercured phosphine<sup>67</sup> (see Section III.3.a).

The latter method based on the use of a stoichiometric amount of the  $[\text{PdCl}_2(\text{SEt}_2)_2]$  complex is more convenient and usually gives binuclear  $\mu$ -halide compounds in high yields. For example,  $\mu$ -chloride dimer **5a** was synthesised from *spiro*-complex **5b** in a quantitative yield.<sup>67</sup>

At first glance, it seems attractive to prepare  $\mu$ -chloride dimers by this method using two different phosphapalladacycles. An attempt to implement this idea has been reported.<sup>67</sup>

However, due to the relatively low yield of product **5d** and the known dynamic behaviour of dimeric complexes,<sup>51,68,69</sup> which opens the way for easy migration of palladacycles between mixed-ligand dimer molecules, one can hardly expect reactions of this type to be selective.

Polymeric palladium chloride can also be used for this purpose instead of  $[\text{PdCl}_2(\text{SEt}_2)_2]$ , but this is less efficient and requires more drastic conditions (refluxing in xylene for many hours). In addition, the process can be complicated by the side formation of the palladium(II) complex with *ortho*-chlorinated phosphine.<sup>67</sup> The possibility of using hydrogen chloride in ether for converting the *spiro*-complex into the corresponding  $\mu$ -chloride dimer was shown for the platinum analogues. Under these conditions, the formation of the  $[\{\text{Pt}(\eta^2\text{-L}^5)(\mu\text{-Cl})\}_2]$  dimer from the mononuclear *cis*- $[\text{Pt}(\eta^2\text{-L}^5)_2]$  complex has been detected by spectroscopy.<sup>70</sup>

The transformation of  $\mu$ -halide dimers into *spiro*-complexes is possible only when *ortho*-lithiated derivatives, for example, *o*- $\text{LiC}_6\text{H}_4\text{CH}_2\text{XR}_2$  ( $\text{X} = \text{N}, \text{P}, \text{As}$ ;  $\text{R} = \text{Alk}, \text{Ar}$ ) (see Supplement 1), are used as auxiliary ligands.<sup>71–73</sup> The reactions of this type proceed under mild conditions ( $\text{Et}_2\text{O}$ ,  $-20^\circ\text{C}$ ) usually giving the corresponding *spiro*-complexes in high yields (61%–89%). This method allows the preparation of mixed-ligand (heteroleptic) complexes including those with different heterodonor atoms in two palladacycles (for example, complex **2e**).

Note that other routes for the transformation of  $\mu$ -halide dimers into *spiro*-complexes are also known in the chemistry of the CN analogues. For example, one can use organotin derivatives of

the incoming ligand.<sup>74,75</sup> This type of transformation has been observed during the CPC carbonylation.<sup>76</sup> Using cycloplatinated complexes as examples, it was demonstrated that a non-functionalised ligand (azobenzene) can be involved in this process with assistance by silver ions.<sup>77</sup> However, it remains obscure whether these methods can be adapted to PC-systems.

$\mu$ -Halide dimeric CPCs usually exist as mixtures of geometric isomers (*syn*- and *anti*-isomers). When the molecule contains stereocentres or other chirality elements, the number of isomers increases to at least six (four of these are spectrally discernible) due to the existence of *syn*- and *anti*-isomers as the *meso*-form (*R,S*-D) and the racemate (*S,S*-D and *R,R*-D).<sup>78,79</sup>

The *syn*:*anti* isomer ratio depends on the structure of the phosphapalladacycle<sup>12,17,69</sup> and on the nature of the solvent, but usually the *anti*-isomer is thermodynamically more favourable.<sup>80</sup> The fact that the dimeric cyclopalladated derivatives of trimesitylphosphine (HL<sup>1</sup>) exist only as the *anti*-isomers<sup>55</sup> is attributable to the tendency for avoiding unfavourable through-space interactions between two bulky PMes<sub>2</sub> groups in the *syn*-isomer.

The drawbacks of the dimeric CPCs include also their dynamic behaviour, which often hampers recording the <sup>1</sup>H NMR spectra at room temperature. The  $\mu$ -acetate PC-dimers having a half-open book conformation are the most fluxional.<sup>2,22,51,59,68</sup> The spectroscopic studies of the CN analogues have shown that the dynamic behaviour of these structures stems from the inversion of acetate bridges.<sup>81,82</sup> In the  $\mu$ -halide PC-dimers, the central four-membered ring {Pd<sub>2</sub>Hal<sub>2</sub>} is usually planar (according to X-ray diffraction);<sup>83–85</sup> some folding of the ring is observed only in sterically hindered complexes.<sup>79,86</sup> Nevertheless, in these dimers, too, exchange processes may take place due to the lability of the halide bridges. The fluxional behaviour of the  $\mu$ -chloride CN-analogues was confirmed unambiguously using stereochemical criteria.<sup>87</sup>

The complications arising in the measurement of the NMR spectra of dimeric complexes caused by isomerism can be illustrated in relation to complex **6**. The pronounced signal broadening in its <sup>1</sup>H and <sup>31</sup>P NMR spectra recorded at 25 °C has been suggested<sup>69</sup> to be due to the interconversions of *syn*/*anti*-isomers and the atropoisomers of the eight-membered ring **A**.

This is confirmed by splitting of the <sup>31</sup>P NMR signals into eight peaks on lowering the temperature to –90 °C due to freezing out of the exchange processes. Previously, it has been suggested<sup>58</sup> that *syn* to *anti* transitions of the dimeric complexes are intramolecular. The presence of a signal close in position to that of the free HL<sup>6</sup> ligand in the low-temperature spectrum of dimer **6** may imply decoordination of the P-donor atom of one palladacycle, which opens up the way for the subsequent rotation around the Pd–C bond.<sup>69</sup>

In the case of dimeric complexes **4b–d** with pyrazolate bridges, *anti*-isomers also tend to predominate in solutions.<sup>64</sup> However, the isomeric composition of these complexes depends on the degree of substitution of the bridging azolate heterocycle. Dimer **4d** with disubstituted 3,5-dmpz ligands exists as the *anti*-isomer both at room temperature and in the cold (–60 °C), whereas its analogues with unsubstituted (pz) and monosubstituted (4-mpz) pyrazolate bridges (**4b** and **4c**) exist as mixtures of *syn*- and *anti*-isomers in solutions at low temperature (<sup>31</sup>P NMR data). The redistribution of isomers in favour of the latter (which

is the only form at 20 °C) attests to the dynamic behaviour of the dimers. Presumably, the interconversion of geometric isomers in these structures takes place through the formation of mononuclear species with monodentate N-bonded pyrazolate.<sup>64</sup>

The combination of the properties of dimeric PC-complexes including poor solubility, isomerism and dynamic mobility makes them inconvenient for practical use and structural studies. The corresponding mononuclear derivatives are free from these drawbacks.

## b. Mononuclear derivatives of PC-palladacycles

The mononuclear CPCs are used first of all for obtaining spectroscopic evidence for the structures of phosphapalladacycles. In addition, they are used in catalysis; some of them proved to be more efficient catalysts than the corresponding dimers.<sup>14–18</sup>

The structures of mononuclear PC-palladacycles are diverse: they depend on the nature of the auxiliary ligands incorporated in the molecule (the denticity, the charge and the nature of the heterodonor atoms) and on the steric crowding of this ligand and the PC-palladacycle. Depending on the charge of the auxiliary ligand, either neutral (**A**, **B**) or cationic (**C**, **D**) complexes containing monodentate (**A**, **C**) or bidentate (**B**, **D**) auxiliary ligands are formed.

The mononuclear complexes of type **A** are the simplest derivatives of phosphapalladacycles; under certain conditions, they can even be the primary cyclopalladation products.<sup>12</sup> In the general case, these complexes are produced by cleavage of halide bridges in the dimers by monodentate auxiliary ligands. The possibility of such dimer monomerisation is largely determined by the steric requirements of the PC-palladacycle and the incoming ligand, the basicity of this ligand and the preferred geometric configuration of the resulting mononuclear adduct. Type **A** complexes are synthesised most often using phosphines and pyridine or its derivatives as auxiliary ligands. The reactions of PC-dimers with pyridine are usually carried out at room temperature.<sup>54,60,88,89</sup> The complete *in situ* conversion of the dimer into the monomer on treatment with a moderate excess of pyridine-d<sub>5</sub> in CDCl<sub>3</sub> opens up an easy way for obtaining spectroscopic (<sup>1</sup>H NMR) characteristics of phosphapalladacycles.<sup>90</sup>

The influence of the basicity of the auxiliary ligand on the monomerisation of the PC-dimers has been elucidated in a spectroscopic study of the reaction of  $\mu$ -chloride dimer **1c**<sup>55,91</sup> with pyridine derivatives. It was shown that this dimer readily reacts with highly basic 4-dimethylaminopyridine (pK<sub>a</sub> = 9.61) to give mononuclear adduct **1d** but does not react (even on heating)

with analogous compounds containing electron-withdrawing 3-CN or 4-CO<sub>2</sub>Me groups ( $pK_a = 1.35$  and  $3.51$ , respectively).<sup>92</sup>

For the same reason, only the primary highly basic  $\alpha$ -methylbenzylamine ( $\alpha$ -MBA) was able to cleave the chloride bridges of dimer **7a** under mild conditions to give mononuclear derivative **7b**.<sup>60</sup>

No adducts of PC-palladacycles with less basic monodentate tertiary amines are known. Attempts to introduce an amine of this type into the coordination sphere of a CN-palladacycle have failed.<sup>93</sup>

The nature of the donor atom of the auxiliary ligand is an important factor governing its affinity to palladium. This determines not only the ease but the mere possibility of its coordination to the PC-palladacycle. Thus a study of monomerisation of dimer **3b** under the action of related ligands like  $\text{EPh}_3$  ( $\text{E} = \text{P}, \text{As}, \text{Sb}$ ) has shown that only with triphenylphosphine does the reaction proceed readily under mild conditions to give mononuclear complex **3c**, whereas with  $\text{AsPh}_3$  the reaction does not go to completion (complex **3d** largely dissociates in solutions due to the weaker  $\text{Pd} \leftarrow \text{As}$  bond), and in the case of  $\text{SbPh}_3$ , no reaction takes place for **3b**.<sup>88, 94</sup>

$\text{E} = \text{P}$  (**3c**),  $\text{As}$  (**3d**).

The transformation of dimeric CPCs into monomers for structural studies is often accomplished using phosphines, the most popular of which is triphenylphosphine, a ligand with moderate steric requirements (the Tolman cone angle  $\theta = 145^\circ$ ).<sup>†</sup> The reactions of the PC-dimers (for example, dimer **8a**) with  $\text{PPh}_3$  are usually carried out at room temperature in benzene<sup>78, 79, 88, 90</sup> or dichloromethane,<sup>58, 69, 96</sup> or more rarely, acetone.<sup>56</sup> In some cases, due to the low solubility of the starting dimers or steric hindrance,<sup>94</sup> heating is required.<sup>60, 94, 97–99</sup>

A similar procedure is used to prepare adducts with other phosphines with relatively small molecules, for instance,  $\text{PPh}_2\text{Me}$ <sup>88</sup> and  $\text{PMe}_2\text{Ph}$ ,<sup>96</sup> ( $\theta = 127$  and  $136^\circ$ , respectively), with phosphites  $\text{P}(\text{OMe})_3$ ,<sup>58, 69, 74</sup>  $\text{P}(\text{OEt})_3$ ,<sup>69</sup> and  $\text{P}(\text{OPh})_3$ ,<sup>58, 69, 74, 94</sup> ( $\theta = 107$ ,  $109$  and  $128^\circ$ , respectively)<sup>95, 100</sup> and with 5-phenyldibenzophosphole (DBP)<sup>94</sup> (see Supplement 1).

In the reactions of dimeric CPCs with P-donor substrates, the steric factors become crucial, while the basicity of the auxiliary ligand is less significant. As a consequence, even in the reaction with phosphines containing a donor phosphorus atom optimal for

the coordination to palladium, the formation of mononuclear adducts can be prevented by steric restrictions. For example, a spectroscopic study ( $^1\text{H}$  and  $^{31}\text{P}$  NMR) of the complexation of dimer **3b** with monodentate phosphines has shown that the strength of their binding with the PC-palladacycle decreases in the sequence given below:<sup>88</sup>

|               |                |                              |                     |                    |                  |                                |                    |
|---------------|----------------|------------------------------|---------------------|--------------------|------------------|--------------------------------|--------------------|
| $\text{ER}_3$ | $\text{PEt}_3$ | $\sim \text{PPh}_2\text{Me}$ | $\sim \text{PPh}_3$ | $> \text{PPR}_3^i$ | $> \text{PCy}_3$ | $\sim \text{PBu}_2^i\text{Me}$ | $> \text{PBu}_3^i$ |
| $\theta$      | 132            | 127                          | 145                 | 160                | 170              | 161                            | 182                |
| $pK_a$        | 8.69           | 4.57                         | 2.73                | —                  | 9.70             | —                              | 11.40              |

A comparison of the Tolman cone angles  $\theta$  and the  $pK_a$  constants<sup>101</sup> demonstrates that this sequence is correlated with the increase in the ligand bulk but by no means with the basicity. The adducts with  $\text{PEt}_3$ ,  $\text{PPh}_2\text{Me}$ ,  $\text{PPh}_3$  and  $\text{PPR}_3^i$  ( $\theta = 127–160^\circ$ ) are stable in the solid state and in solutions; complexes with more bulky phosphines,  $\text{PCy}_3$  and  $\text{PBu}_2^i\text{Me}$  ( $\theta = 170$  and  $161^\circ$ , respectively), were prepared but they partly dissociate in solutions to give the starting dimer. In the case of sterically overcrowded adduct **3e** with the  $\text{PBu}_3^i$  phosphine ligand ( $\theta = 182^\circ$ ), the monomer  $\rightleftharpoons$  dimer equilibrium is shifted to the right almost completely, as indicated by the lack of spin–spin coupling between the two  $^{31}\text{P}$  nuclei.<sup>88, 102</sup>

Moreover, an attempted recrystallisation of the isolated complex **3e** gave the starting dimer **3b**.<sup>88, 102, 103</sup> When bulky phosphines such as  $\text{PBu}_2^i\text{Tol-}o$  ( $\theta = 186^\circ$ ) and  $\text{PBu}^i(\text{Tol-}o)_2$  ( $\theta = 190^\circ$ ) are made to react with PC-palladacycles, for example, with dimer **5a**, mononuclear derivatives are not formed for steric reasons.<sup>57</sup>

It is reasonable to assume that the steric crowding of the PC-palladacycle should also influence the efficiency of the reaction with phosphines. For example, the transformation of dimeric CPCs **9a** and **10a** with an unwieldy ferrocenyl core into the mononuclear derivatives **9b**, **10b**, containing even a small auxiliary ligand,  $\text{PPh}_3$  ( $\theta = 145^\circ$ ), does not proceed to completion when a strictly stoichiometric amount of the phosphine is used.<sup>78, 79</sup> According to the  $^1\text{H}$  and  $^{31}\text{P}$  NMR spectra, the reaction mixture contains mononuclear adducts **9b**, **10b** together with the starting dimers **9a**, **10a** and the unreacted phosphine  $\text{PPh}_3$ .

$\text{R} = \text{H}$  (**9a,b**),  $\text{Me}$  (**10a,b**).

The equilibrium between the dimeric and monomeric complexes can be shifted towards the latter by using a slight (10%–15%) excess of the auxiliary ligand.<sup>78, 79</sup> This method is also used in synthetic work<sup>60, 97, 98</sup> (see Supplement 1).

The steric obstacles are especially obvious in the monomerisation of cyclopalladated bulky phosphites. An attempt to monomerise the sterically overcrowded dimer **11a** by treating it with bulky tris(*o*-tolyl)phosphine ( $\theta = 194^\circ$ ) has not met with success, whereas the small-size phosphite  $\text{P}(\text{OMe})_3$  ( $\theta = 107^\circ$ ) readily reacts with dimer **11a** at room temperature to give adduct **11b**.<sup>69</sup>

<sup>†</sup> Here and below, the Tolman cone angles  $\theta$  were taken from Ref. 95

Ar = C<sub>6</sub>H<sub>3</sub>Bu<sup>t</sup><sub>2</sub>-2,4.

Extra complications arise in the monomerisation of dimeric CPCs based on phosphites due to the forced (electronic requirements, see Section II.2.b) *cis*(P,P)-configuration of the resulting adduct. In this case, a bulky auxiliary ligand should be inserted into the Pd coordination sphere near the bulky P(OC<sub>6</sub>H<sub>3</sub>Bu<sup>t</sup><sub>2</sub>-2,4)<sub>2</sub> fragment of the phosphite palladacycle. Note for comparison that dimeric CPCs based on phosphines (for example, dimer **3b**) react with bulky phosphines such as PBu<sub>2</sub>Me, PCy<sub>3</sub> and P(Tol-*o*)<sub>3</sub> under mild conditions (20 °C) to give the *trans*(P,P)-complex.<sup>88</sup> In this case, the auxiliary ligand is inserted into the Pd coordination sphere near the methylene group (the least steric requirements) of the phosphine palladacycle.

It is pertinent to mention a modified method for the synthesis of mononuclear phosphine derivatives of PC-palladacycles consisting of the use of the phosphine adduct with carbon disulfide instead of the free phosphine. Since the electron-enriched aliphatic phosphines (unlike aromatic phosphines) form rather stable adducts of the Alk<sub>3</sub>P·CS<sub>2</sub> type,<sup>104</sup> these adducts are destroyed only on heating. Only using this technique, was dimer **11a** completely converted into mononuclear adduct **11c** (this reaction with free phosphine does not proceed to completion).<sup>69</sup>

Ar = C<sub>6</sub>H<sub>3</sub>Bu<sup>t</sup><sub>2</sub>-2,4.

Although the true role of carbon disulfide in this reaction is not discussed in the study cited,<sup>69</sup> one cannot rule out the intermediate formation of species with the ylide phosphonium-dithiocarboxylate ligand R<sub>3</sub>P<sup>+</sup>—CSS<sup>−</sup> (see Ref. 104).

The cationic complexes of type **C** belong to the least studied class of phosphapalladacycle derivatives. The introduction of two monodentate neutral ligands into the reaction with the PC-palladacycle requires the preliminary removal of chloride ions from the dimeric precursor on treatment with silver salts. The reaction is carried out in a solvent capable of coordination, for example, in acetonitrile. A cationic bis(acetonitrile) adduct is formed intermediately and can be used for the subsequent introduction of other auxiliary ligands, including those with low coordinating capacity. The synthesis of bis(iminophosphorane) derivative **4f** from cyclopalladated tris(*o*-tolyl)phosphine **4g** through acetonitrile intermediate **4h** can serve as an example of using this approach.<sup>105</sup>

Cationic complexes of type **D** are formed upon coordination of non-charged bidentate ligands to a phosphapalladacycle. Under the optimal conditions, these derivatives can be obtained directly from μ-chloride dimeric CPCs. In most cases, the reaction is carried out at room temperature. The direct reaction of the μ-chloride dimer with a neutral chelating reagent gives rise to ionic complex **D** with the outer-sphere chloride.<sup>58, 60, 69</sup> The introduction of the [NH<sub>4</sub>]PF<sub>6</sub>, KPF<sub>6</sub> or NaClO<sub>4</sub> salts either directly or in the second stage of the reaction (after chelation of the auxiliary ligand) allows these adducts to be isolated as hexafluoro-phosphates<sup>90</sup> or perchlorates<sup>56</sup> (see Supplement 1). This technique was used to prepare ionic complexes **4i** or then **4j** from dimer **4g**.<sup>30</sup>

dppp is Ph<sub>2</sub>P(CH<sub>2</sub>)<sub>3</sub>PPh<sub>2</sub>.

The obvious gain in entropy caused by binding of bidentate ligands compared to monodentate ligands is partially counterbalanced by the necessity of replacement of two halide ligands in the initial dimer (instead of mere cleavage of halide bridges). As a consequence, the rules for complexation of phosphapalladacycles with mono- and bidentate ligands become similar in many respects.

Detailed studies of the complexation of μ-chloride dimer **3b** with a number of potentially bidentate ligands<sup>106</sup> have shown that the ligand structure has a pronounced effect on the course of the reaction. Under unfavourable conditions, type **E** and **F** complexes with bridging or monodentate ligands, respectively, are formed instead of the expected κ<sup>2</sup>-chelation (complex **D**).

As was to be expected, the chelating properties of the ligand depend, first of all, on the nature of the donor atoms (P > As > N); this is most important for their reactions with μ-halide dimers. As opposed to the easy chelation attained with diphosphines, dppe [bis(diphenylphosphino)ethane]<sup>58, 69</sup> and dppp,<sup>30</sup> the As,As- (diars) and N,N-donor (bipy) ligands behave as monodentate in the reaction with dimer **3b**. Even with a twofold excess of the ligand (for diars) or on raising the temperature (for bipy), only neutral adducts **3f**, **3g** are formed.<sup>106</sup>

A similar reaction of complex **3b** with a P,As-donor ligand (ape) also gave mononuclear derivative **3h** of type **F**; however, according to  $^{31}\text{P}$  NMR spectroscopy, it is equilibrated in solutions with cationic complex **3i** of type **D**:

ape is  $\text{Ph}_2\text{P}(\text{CH}_2)_2\text{AsPh}_2$ .

The coordination mode of the potentially bidentate ligands also depends on the length of the fragment that separates the donor atoms and determines the size of the chelate ring. Methylene-diphosphines are known<sup>107–109</sup> to possess low susceptibility for chelation (in particular, in the reactions with palladacycles<sup>110–113</sup>) due to the strain in the four-membered  $\{\text{MP}_2\text{C}\}$  ring thus formed. Therefore, it is not surprising that bis(diphenylphosphino)methane (dppm) reacts with  $\mu$ -chloride dimer **3b** as a bridging ligand to give non-charged dimer **3j** of type **E**, despite the presence of two optimal donor atoms of phosphorus:<sup>106</sup>

Probably, the chelation of dppm with PC-palladacycles could be accomplished by dehalogenating the starting  $\mu$ -Cl-dimers, because the efficiency of this approach for CN-analogues is well known.<sup>110, 111, 113, 114</sup>

The chelation properties of N,N-donor ligands are enhanced with an increase in their basicity and a decrease in the steric requirements. Thus  $(R,R)$ -1,2-diamino-1,2-diphenylethane (stien), containing two primary amino groups, directly reacts with  $\mu$ -chloride dimer **7a** under mild conditions to give cationic complex **7c** in a high yield, despite the steric crowding of the phosphine ligand.<sup>60</sup>

This reaction can be carried out *in situ*, which is especially important for solving some stereochemical problems.<sup>90</sup>

The success of chelation using potentially bidentate ligands with dimeric PC-palladacycles is also determined by the ability of bridging anions to compete for the metal. The situation is simplified upon the replacement of bridging halide ligands by harder anions. For example, binuclear derivative **12b** is formed as the major product when tetranuclear complex **12a**, containing trifluoroacetate bridges, reacts with diphosphine dppe.<sup>115</sup>

The researchers noted the formation of a minor amount of a compound with bridging diphosphine ligands, probably having a tetranuclear structure similar to the structure established by X-ray diffraction for the starting complex **12a**.<sup>‡</sup>

This side process might be due to steric restrictions between the neighbouring  $\text{PPh}_2$  groups of two diphosphines dppe chelated to the metal atoms of the doubly cyclopalladated bis(phosphinite)  $\text{H}_2\text{L}$ <sup>12</sup>.

An efficient solution to the problem of anion competition in the formation of type **D** complexes is the removal of chloride ions from the metal coordination sphere in the starting dimer on treatment with an appropriate silver salt, for example, triflate<sup>69</sup> or hexafluorophosphate.<sup>106</sup> The reaction with  $\text{AgOTf}$  is usually carried out in acetonitrile in two steps with intermediate generation of the reactive bis(acetonitrile) adduct of the PC-palladacycle, which is then made to react with an auxiliary ligand. Using this method, successful chelation of 1,1'-bis(diphenylphosphino)-ferrocene (dppf) with the phosphite palladacycle of dimer **11a** was accomplished.<sup>69</sup>

Ar =  $\text{C}_6\text{H}_3\text{Bu}^t\text{-2,4}$ .

‡ The synthesis of the complex **12a** is the first example of double cyclopalladation of P-donor substrates at the same benzene ring.

It should be noted that an attempt to prepare complex **11d** by direct reaction of  $\mu$ -chloride dimer **11a** with diphosphine dpfp ( $\text{CH}_2\text{Cl}_2$ , 20 °C, 30 min) has not met with success, a complex mixture of products being formed under these conditions.<sup>69</sup>

The dehalogenation of  $\mu$ -chloride dimers under the action of  $\text{AgPF}_6$  is carried out in a mixture of dichloromethane with methanol;  $\text{AgCl}$  is removed before the addition of the auxiliary ligand to the solution of the intermediate solvated PC-palladacycle. The cationic complexes **3k**, **3l** and **3m** with the ape, diars and bipy ligands having low coordinating abilities have been obtained by this method in quite acceptable yields.<sup>106</sup>

The neutral complexes of type **B** are formed upon chelation of PC-palladacycles by anionic ligands. Although the ionic type of these ligands (which are used as Na, K or Tl salts) essentially eliminates the possibility of competition of the bridging halides of the starting CPC dimer for the metal, some synthetic problems still remain. As auxiliary ligands in the synthesis of type **B** complexes,  $\beta$ -diketonates,<sup>54, 57, 60, 97</sup> dithiocarboxylates,<sup>53, 69</sup> pyrazolylborates,<sup>116</sup> prolinates<sup>79, 117</sup> and 2-acylphenolates<sup>118</sup> have been used (see Supplement 1).

For the spectral investigations of PC-palladacycles, complexes with the symmetric acetylacetonate (acac) ligand are most convenient. The acetylacetonate complexes possess a number of advantages: first, the  $^1\text{H}$  NMR spectrum of the acetylacetonate ligand is 'transparent' (the ligand gives rise to only three additional singlets); second, the volatility of the neutral complexes allows the use of mass spectrometry in the studies of PC-palladacycles.<sup>54, 119</sup> For the synthesis of acetylacetonate complexes from  $\mu$ -chloride dimers, fairly toxic thallium salt  $\text{Tl}(\text{acac})$  is normally used; with rare exceptions,<sup>57</sup> the yields are relatively low (40%–70%)

$\text{R} = \text{Ph (2a,f), Bu}^t \text{ (5a,e)}.$

The replacement of  $\text{Tl}(\text{acac})$  by  $\text{K}(\text{acac})$  was of low utility. Acetylacetonate derivative **10c** has been prepared from dimer **10a** in only a 28% yield,<sup>90</sup> although the yields of the corresponding complexes in the reactions of  $\text{K}(\text{acac})$  with CN-palladacycles reach 97%.<sup>120</sup> It is worth noting that transition from dimeric PC-complexes to the mononuclear type **B**  $\beta$ -diketonate derivatives and the subsequent modification of auxiliary ligands (for example, the replacement of the methyl groups in the acetylacetonate ligand by trifluoromethyl groups) may markedly enhance the catalytic activity of phosphapalladacycles.<sup>22</sup>

The dithiocarboxylate and bis(pyrazolyl)borate ligands are also symmetric. The dithiocarbamate (**4k**) and xanthate (**4l**) derivatives of the PC-palladacycles have found application in the synthesis of bi- and polynuclear heterometallic compounds.

Thus the reactions of dithiocarboxylate complexes with Lewis acids such as  $\text{HgX}_2$ ,<sup>53, 121, 122</sup>  $\text{AgClO}_4$  and  $[\text{M}(\text{OClO}_3)(\text{PPh}_3)]$  ( $\text{M} = \text{Ag, Au}$ ),<sup>123</sup> have resulted in bimetallic Pd,M complexes in which the metal atoms are connected by bridging sulfur atoms.

The modification of dimer **4a** with poly(pyrazol-1-yl)boronates to give complexes **4m,n** has been designed to facilitate the oxidative addition of electrophiles ( $\text{MeI}$ ,  $\text{ArBr}$ , etc.) to the metal and to stabilise the Pd(IV) centre in the resulting cyclopalladated complex through increasing the nucleophilicity of the Pd(II) centre.<sup>116</sup> Unfortunately, these attempts have failed.

Cyclopentadienyl derivatives of phosphapalladacycles occupy a special position among mononuclear complexes of type **B**, because the auxiliary ligand is  $\eta^5$ -coordinated instead of being  $\kappa^2$ -bound through two heteroatoms. These complexes are synthesised by treatment of the corresponding  $\mu$ -chloride dimers (for example, **3b** or **13a**) with  $\text{TiCp}$  or  $\text{LiCp}^*$  ( $\text{Cp}^*$  is pentamethylcyclopentadienyl) in benzene<sup>124</sup> or THF<sup>58, 59</sup> at room temperature. Complexes with the  $\text{Cp}^-$  ligand have been obtained in quite satisfactory yields (67% for  $\text{R} = \text{Ph}$  and 77% for  $\text{R} = \text{Bu}^t$ ), whereas the yields of complexes with the bulky  $\text{Cp}^*$ - ligand are much lower (39% for  $\text{R} = \text{Ph}$  and 60% for  $\text{R} = \text{Bu}^t$ ).<sup>124</sup>

$\text{R} = \text{Bu}^t \text{ (3b,n), Ph (13a,b)}.$

The number of complexes in which the PC-palladacycle is bound to the  $\eta^5$ - $\text{Cp}$ <sup>58, 59, 124</sup> or  $\eta^5$ - $\text{Cp}^*$  ligand<sup>124</sup> is limited to derivatives of two cyclopalladated phosphines ( $\text{P}(\text{Bu}^t)_3$  and  $\text{P}(\text{PhBu}^t)_2$ )<sup>124</sup> and two phosphites,  $[\text{P}(\text{OPh})_3]$ <sup>58</sup> and  $[\text{P}(\text{OTol-}o)_3]$ <sup>59</sup> (see Supplement 1). The  $\eta^5$ -coordination of the auxiliary ligand in complex **14a** was confirmed by X-ray diffraction; however, the ligand is bound to the metal non-symmetrically, the  $\text{Pd}-\text{C}(\text{Cp})$  bond lengths varying in the range of 2.284(7)–2.347(9) Å.<sup>58</sup>

To conclude this Section, let us consider the possibility of back monomer  $\rightarrow$  dimer transformation. The success of this transformation is determined, first of all, by the nature of the donor atoms of the auxiliary ligand and its denticity. The removal of the mono- or bidentate ligands with relatively rigid N- and O-donor atoms from the coordination sphere of the palladacycle is attained by mere protonation of the auxiliary ligand (for example, with dilute  $\text{HCl}$ ).<sup>79, 90, 117, 125</sup> The situation becomes much more complicated on passing to adducts with phosphine ligands due to stronger binding of the soft P-donor atom with the soft Pd(II) centre. Nevertheless, the monodentate phosphines can be

removed using a method elaborated for CN systems,<sup>126</sup> namely, by treatment of the adduct with an excess of a cheap bidentate ligand, ethylenediamine (en), in a biphasic system (for example, in the dichloromethane–water system).<sup>90, 127, 128</sup>

### c. Phosphino-P-ylide complexes

Due to the formal neutrality of zwitter-ionic phosphino-P-ylide ligands, the forms of existence of the metallacycles they form (A–C) differ from those for classical PC-systems. Chelation with these ligands yields mononuclear compounds of type **A** with five-<sup>129–133</sup> or six-membered<sup>129–137</sup> PC-palladacycles or bis(chelate) *spiro*-complexes.<sup>138</sup> Binuclear compounds with phosphino-P-ylide ligands have not been reported as yet. The ways for modification of the metal coordination environment in these systems are reduced to variation of the nature of the anions in type **A** complexes and the introduction of one or two neutral monodentate ligands, resulting in mono- (**B**) or dication (**C**) derivatives, respectively. In both cases, halide replacement takes place.

This constitutes the key difference between the reactions of phosphino-P-ylide PC-complexes and those typical of classical dimeric PC-systems in which labile halide bridges are cleaved.

Perhaps, for this reason, the replacement of two chloride ions in type **A** complexes by softer halides ( $\text{Br}^-$ ,  $\text{I}^-$ ) or by a pseudohalide ( $\text{SCN}^-$ ) on treatment with simple salts, NaBr, NaI or KSCN, under mild conditions ( $\text{MeOH}-\text{CH}_2\text{Cl}_2$ , 20 °C) gives the target products in moderate yields (24%–59%).<sup>130, 131</sup> This can be illustrated by the transformation of dichloride **15a** into isothiocyanate derivative **15b** in 26% yield. It is worth noting that two isomers, **15b** and **15c** (1 : 2) containing N- and S-bound anions, respectively, exist in solutions (IR data).<sup>130</sup>

The metathesis of anions in monoarylated complexes  $[\text{ArPd}(\eta^2\text{-L})\text{Cl}]$  requires long-term heating of the chloride precursor with KBr, KI or KSCN in acetone, but the yields of modified complexes (for example, **16b**) increase in this case to 62%–73%.<sup>133</sup>

A monodentate neutral auxiliary ligand can be attached to a phosphino-P-ylide palladacycle only after dehalogenation of the dichloride precursor, for example, on treatment with sodium tetraphenylborate.<sup>131, 132, 136</sup> Reactions of this type are usually carried out under mild conditions, irrespective of the coordinating ability of the incoming ligand, which can be represented by phosphines, phosphites, arsines, or stibines or N-donor ligands (see Supplement 2).

E = P (**15d**, 39%), As (**15e**, 41%), Sb (**15f**, 37%).

Using this method, it is even possible to introduce two auxiliary neutral ligands into the coordination to a phosphino-P-ylide palladacycle, which is indicative of the efficiency of this approach. The substitution of N-donor ligands for the two halides in the dichloride precursor **15a** (bis-adducts **15g**) can be attained by using a four-fold excess of 4-methylpyridine; the reaction with an equimolar amount of the auxiliary ligand yields monoadduct **15h**.<sup>132</sup>

Although dicationic complex **15g** has been isolated in a low yield, this reaction is of interest, because structures of this type are rather seldom encountered among both classical PC-palladacycle derivatives<sup>105</sup> and their CN-analogues.<sup>5, 47, 111</sup>

The cationic phosphino-P-ylide complexes, formed in the reactions with neutral monodentate ligands (see Supplement 2), are less stable<sup>132, 136</sup> than neutral dichloride precursors such as  $[\text{Pd}(\eta^2\text{-L})\text{Cl}_2]$ , which are resistant against oxidants and heating.

Apparently, attempts at direct substitution of monodentate ligands for the chloride in type **A** precursor are impracticable due to the lower stability of phosphino-P-ylide palladacycles compared to the classical PC-analogues. For example, partial decomposition of dichloride complexes of type **A** with evolution of free ligands  $\text{L}''$  has been detected by IR spectroscopy on refluxing in pyridine.<sup>130</sup> Analysis of the dependence of the degree of destruction on the structure of the complexes showed that the stability of phosphapalladacycles of this type depends on their size (five-membered rings are more stable than six-membered rings) and on the electronic effects of substituents at the carbonyl group ( $\text{Ph} > \text{Me} > \text{MeO}$ ).<sup>130</sup>

## 2. Regioselectivity of ligand coordination to phosphapalladacycles

The problem of determining the geometric configuration of complexes formed upon the coordination of additional ligands to palladacycles arises necessarily in relation to structural studies or practical use. For example, when palladacycles are used as catalysts, it is pertinent to have an idea of the regiochemistry of particular stages of the catalytic cycle. The regiochemistry of the coordination of additional ligands to palladacycles is one more feature which distinguishes PC-palladacycles from their CN-analogues.

### a. General views on the regiochemistry of coordination to palladacycles

Palladium complexes are usually classified as labile. It is known that their reactions in solutions are many orders of magnitude faster than the reactions of platinum analogues.<sup>139</sup> Therefore, it is natural to assume that the regiochemistry of the reactions of palladacycles with auxiliary ligands is determined by thermodynamics rather than the kinetics of these processes. This accounts for the fact, surprising at first glance, that the monodentate auxiliary ligand is inserted predominantly (in some cases, exclusively) into the *trans*-position to the heterodonor atom of the palladacycle in the dimeric CPC rather than to the carbon atom, which has a higher capacity for labilisation of the *trans*-located Pd–Hal bond.

A distinctive feature of CN-systems is the high regioselectivity of monomerisation of the dimeric complexes by auxiliary ligands. In the vast majority of cases, the monodentate N- and P-donor ligands are inserted into the coordination sphere of the CN-palladacycle in the *trans*-position to nitrogen.<sup>140–144</sup> Exceptions to this rule are few<sup>145–147</sup> and refer only to pyridine adducts, whereas the formation of monophosphine derivatives with the *trans*(P,C)-geometry is either impossible,<sup>111</sup> or these complexes are highly unstable and highly reactive.<sup>148</sup> The introduction of phosphine into the *trans*-position to the carbon atom becomes possible only after removal of the halide and blocking of the *cis*-position. For example, bis(phosphine) derivatives [Pd(C<sup>⋈</sup>N)(PAr<sub>3</sub>)<sub>2</sub>]<sup>+</sup> have been prepared in this way.<sup>149</sup>

This high selectivity is usually attributable to the anti-symbiosis phenomenon according to which the *trans*-coordination of two soft ligands to a transition metal destabilises the system.<sup>150,151</sup> Recently, more expressive terms, ‘transphobia’<sup>111,113,152,153</sup> and ‘*trans* choice’,<sup>154</sup> have been proposed for interpreting the regioselectivity of reactions of CPC with Lewis bases within the framework of the same antisymbiosis concept. All three concepts can be substantiated in terms of the Maximum Hardness Principle (MHP) proposed by Pearson.<sup>155,156</sup> According to this principle, structures (or systems) with the maximum energy difference between the occupied and vacant orbitals possess the highest thermodynamic stability. A softer molecule has a more diffuse electron shell and is more reactive.

The ‘*trans* choice’ principle is underlain by the concept of stabilisation of square planar complexes with *trans*-arrangement of the ‘softest’ and the ‘hardest’ ligands in the coordination sphere.<sup>154</sup> To predict the regiochemistry of the reactions of palladacycles using this concept, one needs quantitative characteristics of the ‘softness’ or ‘hardness’ of the donor atoms in the palladacycle and the additional ligands present in the coordination sphere. Since such information is unavailable without calculations, the use of this concept is limited to qualitative analysis.

The ‘transphobia’ concept<sup>113,152</sup> appears more attractive, as it opens the way for some quantitative considerations. In this case, analysis of the differences in the stability of different geometric configurations is based on comparison of the *trans*-effects of two pairs of ligands on the diagonals of the square planar complex. The essence of this concept is the assumption that the degree of destabilisation of complexes increases with an increase in the *trans*-effect of both partners. If only donor atoms (X, Y, C) of the ligands bound to the metal are taken into account, then, in the most general form, the transphobia (which has been proposed to be designated by the letter T<sup>152</sup>) sequence for pairs of donors located on one diagonal is as follows:<sup>111,113,152</sup>

$$X/Y \text{ (X, Y = Hal, N, P)} \approx C/X \text{ (X = Hal, N)} < C/P < C/C.$$

Among the rules found for the coordination properties of CN-palladacycles, the following deserves attention: (1) greater *trans*-

effect of  $\sigma$ -bonded aryl groups compared to phosphines entails an increase in the transphobia in ligand pairs in the sequence  $PR_3/PR_3 < Ar/PR_3 < Ar/Ar$ ;<sup>111</sup> (2) the antisymbiotic effect for triarylphosphines is higher<sup>§</sup> than for trialkylphosphines ( $PAlk_3 < PAr_3$ );<sup>111,113</sup> (3) the transphobia for any ligand pair increases on passing from platinum to palladium.<sup>111,113,152</sup> The transphobia concept predicts high reactivity for the complexes in which ligands with high *trans*-effects are located on the same diagonal.<sup>113,148,149,152</sup>

The applicability of the transphobia concept to CN-systems has been confirmed by vast experimental data.<sup>111,113,148,149,152,153,161,162</sup> However, in the general case, this concept does not fully explain the significant difference between the PC-palladacycles and CN-systems, namely, the lower (in some cases, inverted) regioselectivity of binding of monodentate and non-symmetrical bidentate ligands. Apart from the expected dependence on the behaviour of the incoming ligand, the regioselectivity of the phosphapalladacycle coordination with additional ligands depends, to a considerable extent, on the features of the PC-palladacycle. The nature of the P-donor atom (phosphine, phosphinite or phosphite) is most important, first of all, due to different relationships between the  $\sigma$ -donor and  $\pi$ -acceptor properties. The hybridisation of the C-donor atom ( $sp^2$  or  $sp^3$ ) and steric effects may also be significant. Depending on the combination of these factors, mononuclear derivatives of PC-palladacycles can form as *cis*- or *trans*-isomers or an isomer mixture.

### b. The *trans*-effect in palladacycles

The ligand *trans*-effect discovered by Chernyaev in the beginning of the 20th century has been studied in detail both experimentally and theoretically.<sup>158,163–166</sup> The terminology used in this field has been markedly changed through the years. Originally, the terms ‘*trans*-influence’ and ‘*trans*-effect’ have been used in the literature to refer to the static (ground state) and dynamic (kinetic, transition state) aspects of the phenomenon. In our opinion, these terms do not reflect the key difference between these two variables. The terms ‘structural *trans*-effect’ (STE) and ‘kinetic *trans*-effect’ (KTE) used more recently are much more informative.<sup>166</sup>

Due to the known lability of palladium compounds,<sup>139</sup> consideration of the regiochemistry of reactions of palladacycles may be limited to the use of static (thermodynamic) parameters describing the structural *trans*-effect (STE). Unfortunately, despite the long-standing history of development of the views on the *trans*-effect, the main bulk of studies concerning the quantitative *trans*-effect refers to platinum compounds.<sup>158,163–166</sup> The information on palladium complexes,<sup>160,167</sup> the more so, organopalladium compounds,<sup>168,169</sup> in particular, cyclometallated ones,<sup>161,170</sup> is extremely scarce. Although it is believed<sup>159</sup> that derivatives of metals with similar electron configurations do not differ much in properties, the transfer of general rules from one metal to another may bring about distortions.

The few known data on the *trans*-effect of ligands in organopalladium compounds demonstrate that only general trends are retained on passing from platinum to palladium. For instance, on the basis of comparison of the chemical shifts of metallated  $sp^2$ -hybridised carbon atoms in the <sup>13</sup>C NMR spectra of a series of CPCs of the type [PdX(C<sup>⋈</sup>N)(PPh<sub>3</sub>)], the following STE sequence for the X<sup>–</sup> anions was established:  $CN^- < SCN^- < Cl^- < Br^- < I^-$ .<sup>170</sup> This sequence is consistent with the general views on the halide STE in platinum coordination compounds ( $F^- < Cl^- < Br^- < I^-$ ).<sup>139,159,165</sup> A similar (but not identical) order of variation of the halide STE has been found by analysis of

§ This conclusion contradicts the results of quantitative estimates of the *trans*-effect of various phosphines in platinum complexes obtained by X-ray diffraction<sup>157</sup> and IR<sup>158,159</sup> and NMR spectroscopy,<sup>157,159,160</sup> according to which it decreases in the sequence  $PEt_3 \approx PBu_3 > PMe_2Ph > PPh_3$ .

X-ray diffraction data for the *trans*-[PhPdX(PPh<sub>3</sub>)<sub>2</sub>] complexes (X = F, Cl, Br, I): F<sup>−</sup> < Cl<sup>−</sup>; Br<sup>−</sup> < I<sup>−</sup>; but Cl<sup>−</sup> ≥ Br<sup>−</sup>.<sup>169</sup> However, the positions of the cyanide and the thiocyanate ions in the series of STE found for CPCs<sup>170</sup> differ from those typical of coordination compounds of platinum (Cl<sup>−</sup> < I<sup>−</sup> ≈ SCN<sup>−</sup> < CN<sup>−</sup>;<sup>139, 158, 159</sup>). These deviations may be due to different contributions of the σ- and π-constituents of the M–L bond (L is the ligand) located in the *trans*-position. In the case of platinum, the order of anions changes on passing from σ-STE (SCN<sup>−</sup> < CN<sup>−</sup> > Br<sup>−</sup> ≈ Cl<sup>−</sup><sup>164</sup>) to π-STE (CN<sup>−</sup> < SCN<sup>−</sup><sup>164</sup>). The STE for carboxylate anions in palladium compounds has not been estimated; however, it can be assumed (by analogy with platinum compounds<sup>159, 160, 163</sup>) that the effect of these O-donor anions should be least pronounced. For example, according to IR data (ν<sub>Pt–H</sub>), the STE of anions increases in the sequence NO<sub>3</sub><sup>−</sup> < CF<sub>3</sub>COO<sup>−</sup> < ArCOO<sup>−</sup> < NCO<sup>−</sup> ≈ NCS<sup>−</sup> ≈ Cl<sup>−</sup> ≈ Br<sup>−</sup> < I<sup>−</sup> ≈ SCN<sup>−</sup> < CN<sup>−</sup>.<sup>158, 159</sup>

X-Ray diffraction data for a large series of iminoacyl palladium complexes including CO-type CPCs were used to determine the relative STE values for C- and N-donor ligands and for iodide in these complexes: bipy < I<sup>−</sup> < σ-C(sp<sup>2</sup>)<sup>−</sup> (see Ref. 161). This sequence is consistent with the STE series for platinum complexes derived from IR spectroscopy data (ν<sub>Pt–H</sub>): Py ≈ MeNH<sub>2</sub> < I<sup>−</sup> < PhC≡C<sup>−</sup>.<sup>58, 159</sup> However, the NMR spectra (J<sub>Pt–P</sub>) give a somewhat different sequence: I<sup>−</sup> < Py < Et<sub>2</sub>NH < Me<sup>−</sup> < Ph<sup>−</sup>.<sup>158–160</sup>

The results of studies of the STE of heterodonor ligands in palladium compounds<sup>168</sup> imply that this effect is most pronounced in P-containing ligands. For example, it was found that in the palladium coordination complexes [Pd(X<sup>∧</sup>Y)Cl<sub>2</sub>] with the bidentate ligands X<sup>∧</sup>Y, the STE decreases in the sequence Ph<sub>2</sub>P<sup>∧</sup>PPh<sub>2</sub> > Ph<sub>2</sub>P<sup>∧</sup>SMe > Ph<sub>2</sub>As<sup>∧</sup>SMe.<sup>167</sup> For the allyl complexes [Pd(η<sup>3</sup>-All\*)(O<sup>∧</sup>X)]BF<sub>4</sub> (All\* = 2-methylallyl; O<sup>∧</sup>X = XCH<sub>2</sub>COOEt, where X = PPh<sub>2</sub>, NPh<sub>2</sub>, OPh, SPh, NC<sub>5</sub>H<sub>5</sub>), a similar dependence has been found: PPh<sub>2</sub> ≫ NPh<sub>2</sub> ≈ OPh > SPh > NC<sub>5</sub>H<sub>5</sub>.<sup>168</sup> These sequences are mainly in line with the STE scale established for platinum coordination complexes using X-ray diffraction data (from comparison of the Pt–Cl bond lengths): PPh<sub>3</sub> > AsPh<sub>3</sub> > Me<sub>2</sub>S ≈ Ph<sub>2</sub>S > NH<sub>3</sub>.<sup>157</sup>

### c. Estimation of the *trans*-effect of P- and C-donor atoms in phosphapalladacycles

It can be seen from the foregoing that the studies on the structural *trans*-effect of ligands in palladium(II) complexes and, the more so, in organometallic types of complexes are few. The total lack of any information on the STE in phosphapalladacyclic structures and the inconsistency of some conclusions, drawn using different criteria, concerning the ligand *trans*-effect in platinum(II) coordination compounds promote the search for more legitimate ways for estimating the STE in PC-palladacycles of various types. To interpret and/or predict the regiochemistry of the coordination of palladacycles with an additional ligand, it is necessary first to compare the STEs of a carbon and a heterodonor atom of the palladacycle.

Since a large number of publications deal with the X-ray diffraction analysis of the PC- (Table 1) and especially CN-palladacycles (Table 2), we used X-ray diffraction data to tackle this problem. The PC-palladacycles in which the metal is bound either to two identical anions [dimeric CPCs with chloride (**1c**, **3b**, **6**, **9a**, **11a**, **17–21**), bromide (**3o**, **22**), iodide (**4o**) and carboxylate (**4a**, **7d**, **12b**) bridges] or with bidentate symmetrical auxiliary ligands [mononuclear derivatives of PC-palladacycles (**11e**, **23a**), their phosphino-P-ylide analogues (**16c**) and the dichlorides of the latter (**15a**, **24**)] were used as models. Comparison of the lengths of bonds formed by the metal with two identical atoms that occupy *trans*-positions relative to the carbanionic and heterodonor centres, provides the most correct view on the relative STEs of the two 'ends' of the ligand enclosed in a palladacycle.

Table 1 presents the lengths of two Pd–X bonds (X = Cl, Br, I, O, S or P) that occupy the *trans*-positions with respect to C- and P-donor atoms of phosphapalladacycles and the difference

**Table 1.** *trans*-Effect of P- and C-donor atoms in PC-palladacycles.

<sup>a</sup> Code in the Cambridge Structural Database.

between them ( $\Delta l$ ), which characterises the difference between the STEs of these atoms.

In order to compare the regiochemistry of coordination of additional ligands to palladacycles containing P- and N-hetero-donor atoms, the corresponding parameters for CN-systems are given in Table 2 (taking the five-membered CN-palladacycles containing amine, imine or heterocyclic nitrogen atom as examples).

The  $\Delta l$  parameters given in Tables 1 and 2 indicate that PC- and CN-palladacycles are essentially different. In the case of CN-dimers with various C- and N-donors (see Table 2), the  $\Delta l_{av}$  parameters averaged for each group vary in the ranges of 0.115–0.180 and 0.094–0.103 Å for  $\mu$ -halide and  $\mu$ -carboxylate dimers, respectively, thus demonstrating a substantial difference between the STE values of C- and N-donor atoms of the palladacycle. These values imply a high degree of selectivity in the

**Table 2.** *trans*-Effect of N- and C-donor atoms in five-membered CN-palladacycles (on the basis of structural parameters of dimeric CPCs).

<sup>a</sup> The ligand fragment to which this donor atom belongs is given in braces. <sup>b</sup> *R,R*-*cis*-Isomer. <sup>c</sup> *R,S*-*trans*-Isomer. <sup>d</sup> The parameters for the μ-fluoroacetate dimer are given. <sup>e</sup> Here and below pin is pinan-3-yl. <sup>f</sup> mmp is 2-(methoxymethyl)pyrrolidine. <sup>g</sup> An is anisyl. <sup>h</sup> Here and below, ox is oxazoline. <sup>i</sup> *R<sub>C</sub>,S<sub>Pl</sub>*-Diastereomer. <sup>j</sup> *S<sub>C</sub>,R<sub>Pl</sub>*-Diastereomer.

coordination of additional ligands to CN-palladacycles and account for the almost complete regioselectivity of these processes. Conversely, in the structures of dimeric CPC of the PC-type (see Table 1), the difference between the lengths of the two Pd–X bonds (X = Hal, RCOO) largely disappears: here the  $\Delta l_{av}$  values vary in the ranges of 0.010–0.058 and 0.007–0.037 Å for μ-halide and μ-carboxylate dimers, respectively. Moreover, for some complexes, the parameter  $\Delta l$  decreases to negligibly low values (0.002 Å for dimer **21**<sup>17</sup>) or even changes the sign (–0.007 Å for dimer **18**<sup>173</sup>).

More evidence supporting the similarity of STE values of C- and P-donor atoms of phosphapalladacycles comes from the structural parameters of mononuclear derivatives of PC-palladacycles with symmetric ligands. In the cationic adduct **23a**<sup>179</sup> with the diphosphine ligand dppe, the lengths of two Pd–P bonds

located in the *trans*-positions relative to the phosphapalladacycle C- and P-donor atoms differ only slightly ( $\Delta l$  = 0.034 Å), and in the dithiocarbamate derivative **11e**,<sup>69</sup> the difference between the lengths of two Pd–S bonds does not exceed the experimental error ( $\Delta l$  = 0.002 Å).

Analysis of these parameters entails quite a reasonable conclusion: the difference between the STEs of C- and P-donor atoms of phosphapalladacycles is too low to induce a satisfactory regioselectivity of their coordination to additional ligands. In most cases, one should expect a mixture of geometric isomers; the selective formation of one of these can rather be considered as an exception to the general rule.

Comparative analysis of the dependence of the Pd–Hal bond length located in the *trans*-position relative to the PC-palladacycle carbon atom on the hybridisation of the C-donor atom leads to the conclusion that the *trans*-effect of the aliphatic carbon atom is higher than that for the aromatic atom. For example, in the structures of μ-chloride dimers of the PC type (see Table 1), the Pd–Cl bond lengths on the C(sp<sup>2</sup>)–Pd–Cl and C(sp<sup>3</sup>)–Pd–Cl diagonals vary in non-overlapping ranges 2.408–2.446 and 2.455–2.487 Å, respectively (the averaged  $l_{av}$  values are 2.429 and 2.472 Å, respectively, over 14 and 6 palladacycles). This trend is also retained in the structures of μ-bromide PC-dimers, although the available information is limited to only two structures. The Pd–Br bond lengths on the C(sp<sup>2</sup>)–Pd–Br and C(sp<sup>3</sup>)–Pd–Br diagonals in complexes **22**<sup>177</sup> and **30**<sup>176</sup> are equal to 2.560 and 2.592 Å, respectively.

As was to be expected, the P-ylide carbon atom has the minimum STE. Indeed, in complexes **24**<sup>180</sup> and **15a**,<sup>137</sup> belonging to the common structural type [Pd(η<sup>2</sup>-L)Cl<sub>2</sub>], the Pd–Cl bonds located in the *trans*-position to the ylide carbon atom are 2.394 and 2.340 Å long, respectively, *i.e.*, they are substantially shorter than the average Pd–Cl bond lengths for the C(sp<sup>2</sup>)–Pd–Cl and C(sp<sup>3</sup>)–Pd–Cl diagonals in the classical μ-chloride PC-dimers (2.429 and 2.472 Å, respectively) and are below the lower limits of

the ranges for these values (2.408–2.446 and 2.455–2.487 Å, respectively, see Table 1).

This result appears quite a natural consequence of the substantial delocalisation of the carbanion charge over both the phosphonium fragment and the electron-withdrawing substituents. Therefore, STE values of the C- and P-donor atoms in P-ylide complexes become comparable: the  $\Delta I$  value for two Pd–Cl bonds on the C–Pd–Cl and P–Pd–Cl diagonals is only 0.016 Å in complex **24** and becomes negative ( $\Delta I = -0.050$  Å) in complex **15a**. The last-mentioned value shows that the STE of the P-donor substantially exceeds that for a  $\sigma$ -bonded carbon. This trend is retained for the bis(ylide) compound **16c**,<sup>138</sup> for which the parameter  $\Delta I(\text{Pd} - \text{C}) = -0.016$  Å attests to a greater *trans*-effect of the PPh<sub>2</sub> group compared to the P-ylide carbon.

Thus, using X-ray diffraction data, the C-donor phosphapalladacycles can be arranged in the following series in terms of increasing structural *trans*-effect: C(P-ylides)  $\ll$  C(sp<sup>2</sup>)<sup>–</sup> < C(sp<sup>3</sup>)<sup>–</sup>.

Unfortunately, the P-donor groups of various types cannot be classified legitimately in terms of their *trans*-effect relying on the Pd–X bond lengths available from X-ray diffraction data for dimeric complexes, due to both the scarcity of these data and too slight variations of this parameter (0.1–0.2 Å, see Table 1). As a preliminary estimate, one can consider the sequence of increasing STE for P-donors, which was derived from the averaged lengths of the Pd–Cl bond located in the *trans*-position to the P-donor atom of the phosphapalladacycle in  $\mu$ -chloride dimers:

|                                       |       |                      |                   |                    |                    |
|---------------------------------------|-------|----------------------|-------------------|--------------------|--------------------|
| P-donor                               | C=P   | OP(OAr) <sub>2</sub> | CPAr <sub>2</sub> | CPAlk <sub>2</sub> | OPAlk <sub>2</sub> |
| $I(\text{Pd} - \text{Cl})/\text{\AA}$ | 2.389 | 2.399                | 2.413             | 2.424              | 2.431              |

A greater *trans*-effect of the phosphinite phosphorus atom in OPR<sub>2</sub> compared to the phosphine atom is indicated by the decrease in the Pd–O bond length in  $\mu$ -acetate dimers (see Table 1)

|                                      |                   |                   |
|--------------------------------------|-------------------|-------------------|
| P-donor                              | CPAr <sub>2</sub> | OPAr <sub>2</sub> |
| $I(\text{Pd} - \text{O})/\text{\AA}$ | 2.117             | 2.143             |

Nevertheless, the need to elucidate more correctly the dependence of the STE of P-donors on both their chemical nature and the steric features of their environment is obvious. This requires detailed analysis of X-ray diffraction data for a broader range of phosphapalladacycle derivatives. At the current stage of research, it can only be stated that in most classical PC-palladacycles, the carbanionic centre exhibits a greater *trans*-effect, than the P-donor centre, no matter what is the carbon hybridisation (sp<sup>2</sup> or sp<sup>3</sup>). However, in some classical PC-structures and in cyclopalladated derivatives of phosphino-P-ylides, the STE values of C- and P-donor atoms of a phosphapalladacycle are comparable, which implies a low regioselectivity of their reactions with auxiliary ligands.

#### d. Manifestation of the transphobia in phosphapalladacycles

Analysis of the available data on the geometric configurations of various derivatives of PC-palladacycles largely confirms the above conclusions and demonstrates an essential difference between the PC- and CN-palladacycles.

**spiro-Complexes.** In conformity with much more pronounced *trans*-effect of the carbanionic C-donor centres compared to hard N-donor centres, the vast majority of palladium<sup>218–221</sup> and

platinum<sup>221–227</sup> bis(chelate) *spiro*-complexes with CN-type metallacycles exist as the *cis*(C,C)-configuration. Exceptions to this rule are scarce. The *trans*(C,C)-geometry of these complexes becomes possible only due to a sharp decrease in the difference between the STEs of the C- and N-donor atoms of the palladacycle. As an example, one can consider complex **25**,<sup>228</sup> in which the *trans*-effect of the carbanionic centre is sharply reduced due to the presence of two electron-withdrawing nitro groups, whereas the STE of the primary amino group is essentially higher than that of tertiary amino groups in analogous compounds (for example, in complex **26**<sup>221</sup>). As a consequence, the former complex exists as the *trans*(C,C)-isomer and the latter one has the standard *cis*(C,C)-geometry (the structures and configurations of both complexes were confirmed by X-ray diffraction).

At first glance, an increase in the transphobia in the order C/P < C/C<sup>111</sup> would be sufficient for predicting the regiochemistry of formation of bis(chelate) *spiro*-complexes involving phosphapalladacycles. Indeed, two standard PC-palladacycles are usually combined into the *spiro*-structure in the *cis*(C,C)-configuration. This geometry exists both with the sp<sup>3</sup>-hybridised carbanionic centre (for example, in complex **27**<sup>229, 230</sup>) and with the sp<sup>2</sup>-hybridised carbanionic centre [for example, in complexes **2c**<sup>†</sup> (see Ref. 71), **5b**,<sup>71</sup> **5e**,<sup>71, 231–233</sup> **5c**,<sup>71, 233</sup> **28**,<sup>71</sup>]. The regiochemistry also does not depend on the nature of the substituent at the phosphorus atom, which may be either aromatic or aliphatic. Note that the *cis*(C,C)-configuration has been confirmed unambiguously by X-ray diffraction analysis, for platinum *spiro*-complexes **5b**,<sup>234</sup> **2c**<sup>235</sup> and **29**.<sup>222</sup>

M = Pd: R<sup>1</sup> = R<sup>2</sup> = Ph (**2c**), Bu<sup>t</sup> (**5b**), Me (**28**);

R<sup>1</sup> = Bu<sup>t</sup>; R<sup>2</sup> = Ph (**5e**), Me (**5c**);

M = Pt: R<sup>1</sup> = R<sup>2</sup> = Ph (**2'c**), Bu<sup>t</sup> (**5'b**), Bn (**29'**).

However, analysis of the geometry of modified phosphapalladacyclic *spiro*-structures and conditions for their synthesis demonstrate that prohibition of the *trans*(C,C)-configuration is not very strict. For example, it does not apply to mixed-ligand *spiro*-complexes containing PC- and CN-palladacycles. Complex **30** with an alkyl<sup>236</sup> and complexes **31a**<sup>237</sup> and **32**<sup>236</sup> with an alkenyl C-donor in the phosphapalladacycle exist in solutions as *trans*(C,C)-isomers (the configuration of the former complex was determined by X-ray diffraction<sup>236</sup>).

R = Ph (**31a**), OEt (**32**)

<sup>†</sup> Early studies<sup>232</sup> assumed the formation of a mixture of *cis*- and *trans*-isomers of this complex.

The *trans*-configuration appears abnormal only from the standpoint of the classical view of the maximum STE for any carbanionic centre. However, the *trans*-effects of C(sp<sup>3</sup>) in complex **30** and C(sp<sup>2</sup>) in compounds **31a** and **32** are substantially reduced due to the presence of strong electron-acceptor nitrile or methoxycarbonyl groups. Under these conditions, the *trans*-effect of the phosphine PPh<sub>2</sub> fragment becomes more significant; as a result, the *cis*-localisation of this fragment relative to the phenyl carbon atom of the benzylamine CN-palladacycle becomes quite justified from the standpoint of the transphobia concept.

Yet another example of violation of classical rules is demonstrated by mixed-ligand complex **2e**, which is formed as a mixture of *cis*(C,C)- and *trans*(C,C)-isomers.<sup>72,73</sup> The structure of the predominant *cis*(C,C)-isomer has been confirmed by X-ray diffraction.<sup>238</sup> Probably, the dependence of the ratio of geometric isomers on the order in which the two palladacycles are closed is the most intriguing feature of this complex. Thus the formation of the CN-palladacycle on the PC-template (path *a*) results almost exclusively in the *cis*(C,C)-isomer, whereas the closure of the PC-palladacycle on the CN-template (path *b*) yields a mixture of *cis*(C,C)- and *trans*(C,C)-isomers, the former being the predominant product (~70%).<sup>72,73</sup>

*cis* : *trans* = 100 : 0 (*a*), 70 : 30 (*b*).

The formation of *trans*(C,C)-**2e** under conditions *b* was attributed to the possibility of system stabilisation due to a decrease in the electron density of the N-ligand (possessing strong  $\sigma$ -donor properties) by the *trans*-arranged P-donor atom. This explanation can hardly be accepted, because it implies the thermodynamic control of the process. Meanwhile, the differences between the two paths leading to the same complex are, most likely, due to changes in the reaction kinetics.

The dependence of the regiochemistry of the formation of *spiro*-complexes on the nature of the substituents in the hetero-donor fragments has not been actually studied. One can only mention the results obtained in the synthesis of two mixed-ligand complexes containing simultaneously phospho- and arsenapalladacycles.<sup>72</sup> Closure of an AsC-palladacycle on a PC-template affords only the *cis*(C,C)-isomer if R = Ar (compound **2g**) or a mixture of *cis*- and *trans*-isomers (*spiro*-complex **2h**) if R = Alk (the isomer ratio has not been reported).

R = Ph (*cis*-**2g**), Me (*cis*/*trans*-**2h**).

The reasons for the difference between the regiochemistry of these two reactions have not been discussed in the study cited.<sup>72</sup> Since one can hardly expect a sharp increase in the STE upon the replacement of the AsPh<sub>2</sub> group by the more electron-enriched AsMe<sub>2</sub> fragment, it can only be assumed that either the geometry

of the complexes is subject to the kinetic control or these systems do not obey the transphobia principle.

The behaviour of the alkenyl *spiro*-PC-complex **31b** should also be considered abnormal (from the standpoint of the transphobia concept).<sup>237,239</sup> This complex was obtained as the *cis*(C,C)-isomer (kinetically controlled product) under mild temperature conditions. However, the subsequent thermolysis of one diastereomer, *cis*(*R,S*)-**31b**, resulted in its quantitative conversion into the *trans*(C,C)-form (thermodynamically controlled product).

The structure and the configuration of both isomers, *cis*(*R,S*)-**31b**<sup>239</sup> and *trans*(C,C)-**31b**,<sup>237</sup> were confirmed by X-ray diffraction. These results provide a rare opportunity for estimating the relative STE of the P- and C-donor atoms in identical palladacycles. Similar Pd–P and Pd–C bond lengths in the two isomers prompted the conclusion<sup>237</sup> that the STEs of the phosphine and alkenyl groups are comparable. However, analysis of the variation dynamics of the bond lengths on passing from the P–Pd–C diagonal in the *cis*-isomer to the P–Pd–P and C–Pd–C diagonals in the *trans*-isomer shows that upon replacement of the *trans*-arranged vinylic carbon by a P-donor, the Pd–P bonds are elongated [ $\Delta l = 0.009(2)$  Å], whereas the reverse replacement resulted in shorter Pd–C bonds [ $\Delta l = -0.014(9)$  and  $-0.036(9)$  Å], the  $\Delta l$  values exceeding the experimental errors. These effects can be attributed to the greater STE of P-donor groups compared to the STE of the alkenyl carbon. However, the thermodynamic preference for the *trans*(C,C)-isomer cannot be explained in terms of the transphobia concept. Probably, in this case, steric effects make a significant contribution to the relative stability of the isomers.

Thus, even in the *spiro*-PC-complexes with two carbanionic C-donors (formally, possessing the highest *trans*-effect), the transphobia is not absolute, due to the insignificant difference between the STEs of the palladacycle C- and P-donor atoms.

**Adducts with N-donors.** In the coordination of the phosphine PC-palladacycles with N-donor ligands, the degree of transphobia should be nearly the same for any geometry of the complex (C/Hal ~ C/N<sup>153</sup>); therefore, in this case, an isomer mixture is expected to form. The reaction of benzylphosphine dimer **2a** with 3,5-lutidine affords a 85 : 15 mixture of *trans*(N,P)- and *cis*(N,P)-isomers of adduct **2i**, which undergo fast (on the NMR time scale) interconversion in solutions at room temperature.<sup>54</sup>

Assuming that the STE of four ligands in complex **2i** varies in a sequence similar to that for platinum compounds

[Ph<sup>−</sup> > PPh<sub>3</sub> > Py > Cl<sup>−</sup>; NMR data ( $J_{\text{Pt-P}}$  158–160)], it is possible to explain the predominance of the *trans*(N,P)-isomer of adduct **2i** in which the softest (Ph<sup>−</sup>) and the hardest (Cl<sup>−</sup>) ligands are arranged on one diagonal.

It has been assumed<sup>88, 103</sup> that the pyridine adduct **3p** with a four-membered PC-palladacycle exists only in the *trans*(N,P)-geometry.<sup>88, 103</sup> This assumption was based on the low frequency  $\nu_{\text{Pd-Cl}} \approx 280 \text{ cm}^{-1}$  in the IR spectra and on the presence of only one signal in the <sup>31</sup>P spectrum and one set of signals in the <sup>1</sup>H NMR spectrum.

At a qualitative level, this is consistent with the STE scale. However, taking into account the change in the hybridisation of the carbon atom ( $\text{sp}^2 \rightarrow \text{sp}^3$ ) and the increase in the basicity of the P atom, one could expect that the STE values for C- and P-donors would approach each other. Indeed, according to NMR data for platinum compounds ( $J_{\text{Pt-P}}$ ), the following STE sequence was elucidated: Ph<sup>−</sup> > Me<sup>−</sup> ≥ PBu<sub>3</sub> > PPh<sub>3</sub> > Py > Cl.<sup>158–160</sup> Therefore, in this case, the existence of two geometric isomers should rather be expected in solutions. The deviation of the experimental data from those predicted in terms of the transphobia principle may be due to a fast equilibrium between the isomers, because the Pd ← N bond in both isomers should be substantially weakened due to the σ-bonded carbon atom or the PAlk<sub>2</sub> group arranged on the same diagonal. The dynamic behaviour of the N-donor ligands is typical of PC-complexes. Their dissociation can be partly suppressed by introducing an excess of the incoming ligand.<sup>60, 90</sup> The spectra of these systems are more informative when recorded at low temperatures.<sup>54</sup>

The regiochemistry predicted in terms of the STE is supported by the spectroscopic detection of comparable amounts of *trans*(N,P)- and *cis*(N,P)-isomers (in 1 : 2 ratio) of the d<sub>5</sub>-pyridine adduct **7e**, which belongs to the structural type characterised by the maximum STE for σ-C(sp<sup>3</sup>)- and PAlk<sub>2</sub>-donors.<sup>90</sup>

A reliable criterion for determining the geometry of these mononuclear adducts is provided by the opposite directions of shift of <sup>1</sup>H NMR signals for protons located most closely to the metallation site and belonging to P-substituents, caused by their moving towards the pyridine ring (shielding) or towards the halide ligand (deshielding). For example, in the spectrum of the *trans*-(N,P)-isomer of complex **7e**, the signal for the PdCH<sub>2</sub> methylene protons is shifted upfield ( $\Delta\delta = -0.42 \text{ ppm}$ ) with respect to its position in the spectrum of the *cis*(N,P)-isomer, whereas the signal for the PBu<sup>t</sup>-group protons moves downfield ( $\Delta\delta = +0.324 \text{ ppm}$ ).<sup>90</sup> Under the optimal conditions, the difference between the chemical shifts of the same proton in the spectra of the two geometric isomers may reach 2 ppm.<sup>145</sup>

**Adducts with P-donors.** According to the transphobia concept,<sup>152</sup> monodentate phosphines should be more prone to *trans*-coordination relative to the P-donor atom of the phosphine PC-palladacycle (see Supplement 1) than N-donor ligands due to the pronounced destabilisation of the *trans*(P,C)-geometry. Indeed, the coordination of the sterically overcrowded phosphines, phosphites and phospholes to palladacycle **1c** based on trimesitylphosphine yields only *trans*(P,P)-isomers.<sup>94</sup> This is the only form for

the triphenylphosphine adducts of cyclopalladated α-ferrocenyl-alkylphosphines **9b** and **10b**.<sup>78, 79</sup>

However, as opposed to CN-systems, the coordination of phosphines to phosphapalladacycles is not absolutely *trans*(P,P)-selective. The phosphine adducts formed by sterically non-hindered palladacycles are often formed as mixtures of *cis*- and *trans*-isomers with pronounced predominance of the latter. The recent repeated investigation of cyclopalladated di(*o*-tolyl)-*tert*-butylphosphine (HL<sup>7</sup>) has shown that its triphenylphosphine adduct exists as a mixture of *trans*- and *cis*-isomers (12 : 1).<sup>117</sup> The fact that only the *trans*-isomer was previously identified for this complex by spectroscopy<sup>60</sup> suggests that other non-selective systems of this type may also exist.

The essential deviations of the configuration of complexes from those predicted on the basis of the transphobia concept arise upon modification of the nature of the C- or P-donor centres of the palladacycle or its size. For example, the phosphine adducts of the *ortho*-palladated triphenylphosphine with a strained four-membered palladacycle are formed as mixtures of geometric isomers whose ratio varies over a broad range depending on the structure of the phosphine used.<sup>240, 241</sup>

Q = PPh<sub>2</sub>(C<sub>6</sub>H<sub>4</sub>Cl-*o*) (**34a**), P(Tol-*p*)<sub>3</sub> (**34b**);  
*cis* : *trans* = 93 : 7 (**a**), 20 : 80 (**b**).

The regiochemistry of coordination of P-donor ligands to cyclopalladated derivatives of substrates having enhanced π-acidity depends on the electronic characteristics of the ligands and on the steric situation in the coordination sphere. Most triaryl phosphite-<sup>58, 69, 74, 242</sup> and arylphosphinite-based<sup>115</sup> CPCs bind monodentate phosphines and phosphites, preferably in the *cis*(P,P)-geometry (for example, complexes **14c,d**, see Supplement 1). This unusual fact may be explained by the clearly pronounced π-acceptor nature of the phosphorus atom in the phosphite palladacycle,<sup>101</sup> which accounts for system destabilisation upon *trans*-coordination of monodentate π-acceptor phosphites or phosphines.

R = Ph (**14c**, 96%), MeO (**14d**, 89%).

However, in the case of sterically crowded dimer **11a**, the *cis*(P,P)-regiospecificity is retained only in reactions with monodentate phosphites P(OR)<sub>3</sub> (R = Me, Et, Ph),<sup>69</sup> while on passing to phosphine auxiliary ligands, the formation of the *trans*(P,P)-isomer also becomes possible. For example dimer **11a** reacts with PPh<sub>3</sub> to give a mixture of *cis*(P,P)- and *trans*(P,P)-isomers **11f**, the latter being the major product (ratio 1 : 2.4).<sup>69</sup>

Ar = C<sub>6</sub>H<sub>3</sub>Bu<sub>2</sub>-2,4.

The formation of an isomer mixture has also been detected in reactions of dimer **11a** with  $\text{PCy}_3$  (under certain conditions).<sup>69</sup> In this case, the tendency for the formation of *trans*(P,P)-isomers of the phosphine (but not phosphite) adducts may be due to steric effects. Indeed, phosphines  $\text{PR}_3$  have a greater bulk than phosphites  $\text{P(OR)}_3$  with the same groups. For example, the Tolman cone angles  $\theta$  for the phosphines  $\text{PPh}_3$  and  $\text{PCy}_3$  are 145 and 179°, while for the similar phosphites  $\text{P(OPh)}_3$  and  $\text{P(OPr}^i)_3$ , these angles amount to 121 and 114°, respectively.<sup>95,243</sup> Therefore, the coordination of phosphines in the *cis*-position relative to the bulky  $\text{P(OAr)}_2$  fragment of dimer **11a** should be sterically hampered.

One more example of abnormal regioselectivity is the formation of phosphine derivatives of phosphino-P-ylide palladacycles. The replacement of the carbanion C-centre in cyclopalladated phosphines by an ylide centre (*i.e.*, bearing only a partial negative charge) results in a decrease in its *trans*-effect compared to the STE of the P-donor atom (see Section II.2.c). Under these conditions, one should expect an inverted regiochemistry of the coordination of auxiliary ligands. Indeed, the reaction of dichloride **35a** with phosphine  $\text{PMePh}_2$  yields a mixture of *trans*(P,P)- and *cis*(P,P)-isomers of cationic complex **35b**, the latter being the predominant product.<sup>136</sup>

The preference of the *trans*-coordination of phosphine  $\text{PMePh}_2$  relative to the ylide carbon atom is even more pronounced in its reaction with similar dichloride **15a**; in this case, the *trans*(P,P)- and *cis*(P,P)-isomer ratio for the cationic complex  $[\text{Pd}(\eta^2\text{-L}^{15})\text{Cl}(\text{PMePh}_2)]\text{BPh}_4$  (**15i**) increases to 1:7.<sup>132</sup>

The reduced STE of the ylide carbon can also be illustrated by the preferred formation of the *trans*-(C,C)-isomers of monoarylated derivatives of phosphino-P-ylide palladacycles (this contradicts the formal prediction based on the transphobia concept<sup>111,113,152</sup>). In structures of this type (for example, in complex **16a**), the *trans*-(C,C)- to *cis*-(C,C)-isomer ratio varies over a rather broad range. In chloride complexes, it varies from 3:1 to 10:1. The content of the *cis*-(C,C)-isomer increases when the chloride in complex **16a** is replaced by softer iodide (complex **16b**).<sup>133</sup>

The magnitudes of the spin–spin coupling of two phosphorus nuclei may serve as a reliable criterion for estimating the geometric configuration of the adducts of various PC-palladacycles with P-donor ligands.<sup>244</sup> In the adducts of phosphine- and phosphinite-
