based PC-palladacycles with phosphines having the *trans*(P,P)-configuration, the  $^2J_{\text{PP}}$  values vary in the range of 360–441 Hz. The  $^2J_{\text{PP}}$  values increase to 604–607 Hz when a phosphite phosphorus atom appears in either the palladacycle<sup>69</sup> or the auxiliary ligand<sup>94</sup> (see Supplement 1). In complexes having the *cis*(P,P)-geometry, this parameter decreases by more than an order of magnitude ( $^2J_{\text{PP}} = 19\text{--}56$  Hz). The legitimacy of this criterion is confirmed by the fact that in the mononuclear derivatives of PC-palladacycles with diphosphines, the coupling constants between the  $^{31}\text{P}$  nucleus of the metallacycle and diphosphine phosphorus nuclei located in the *trans* and *cis* positions vary approximately in the same ranges ( $^2J_{\text{PP}} = 333\text{--}540$  and  $30\text{--}52$  Hz, respectively).<sup>30,58,69,115</sup>

The  $^1\text{H}$  NMR spectra provide less unambiguous information on the geometric configuration of the coordination sphere of the PC-palladacycle adducts with P-donor ligands. The *trans*(P,P)-geometry of the phosphine adducts of the classical PC-palladacycles (with the phosphine donor atom) can be confirmed by shielding of the PC-palladacycle proton located most closely to the metallation site by the P-aryl groups of the auxiliary ligand.<sup>78,79,90</sup> For example, the  $^1\text{H}$  NMR spectra of the  $\text{PPh}_3$ -adducts **9b**<sup>79</sup> and **10b**<sup>78</sup> show the signal for the  $\text{H}^5$  proton of the palladated cyclopentadienyl fragment shifted upfield by  $\Delta\delta = 1.18$  and 0.92 ppm, respectively, with respect to its position in the spectra of the (*S*)-proline derivatives of the same palladacycles.<sup>90</sup> This effect is less pronounced in compounds with the  $\text{C(sp}^3\text{)}\text{--Pd}$  bond. For example, in the spectrum of adduct **7f**, the  $\Delta\delta$  value for the  $\text{PdCH}_2$ -protons in the *trans*(P,P)-isomer is only 0.33 ppm.<sup>117</sup>

R = H (**9b**), Me (**10b**)

The idea of using, for diagnostic purposes, the direct through-space coupling of the proton nearest to the metallation site with the phosphorus nucleus seems attractive at first glance. However, this criterion should be used with caution. In the case of PC-palladacycle derivatives, the situation is complicated by the presence of two  $^{31}\text{P}$  nuclei, whose effects are to be differentiated. For example, in the  $^1\text{H}$  NMR spectrum of the *trans*(P,P)-isomer of complex **7f**, the diastereotopic protons of the  $\text{Pd--CH}_2$  fragment are coupled with both the  $\text{PPh}_3$  ligand ( $^3J_{\text{HP}} = 11.0$  and 5.7 Hz) and the  $^{31}\text{P}$  nucleus of the phosphapalladacycle ( $^3J_{\text{HP}} = 3.7$  and 2.8 Hz).<sup>117</sup> Since both phosphorus atoms are separated from the  $\text{PdCH}_2$ -protons by three bonds, it seemed justified to assign the much greater spin–spin coupling constants of these protons with the phosphine  $\text{PPh}_3$  to an additional contribution of the through-space coupling of these nuclei. However, the use of this criterion is complicated, first, by the dependence of the coupling constant on the geometry and the nature of bonds separating the nuclei and, second, by the possibility of spin–spin coupling through rather long bond sequences. For example, the spectrum of the complex **9b** mentioned above was found to exhibit quite a detectable constant  $^5J_{\text{HP}} = 0.5$  Hz (through five bonds!) for the remote  $\text{H}^4$  proton of the palladated cyclopentadienyl fragment.<sup>79</sup>

The  $^1\text{H}$  NMR-based criteria proved inapplicable to phosphino-P-ylide analogues. Indeed, a comparison of the chemical shifts of the ylide CH proton in the spectra of the starting dichlorides **15a**, **16d** ( $\delta = 6.05\text{--}6.01$  ppm)<sup>129,134</sup> and their adducts with the phosphines  $\text{PCy}_3$  and  $\text{PPh}_3$ <sup>131,132</sup> shows that the upfield shift of this signal is more pronounced for complexes

with the aliphatic phosphine ( $\delta = 4.02\text{--}4.47$  ppm for **15i**, **16f**) than with the aromatic one ( $\delta = 4.54\text{--}4.90$  ppm for **15d**, **16e**).

Q = PPh<sub>3</sub> (**15d**, **16e**), PCy<sub>3</sub> (**15i**, **16f**).

The researchers cited assume that this shift is due to either shielding of the ylide proton by the phosphorus nucleus<sup>131</sup> or by the increase in the electron density on the metallic centre upon the introduction of phosphine ligands.<sup>132</sup> The latter version seems more likely in view of the much higher basicity of the aliphatic phosphine compared to the aromatic phosphine (for PCy<sub>3</sub> and PPh<sub>3</sub>,  $pK_a = 9.70$  and  $2.73$ , respectively<sup>101</sup>).

An example of low regioselectivity of coordination of non-symmetric bidentate ligands is provided by 2-acylphenolate derivatives of dimer **4a**, which are formed as mixtures of *cis*- and *trans*-isomers.<sup>118</sup> The researchers were able to increase the regioselectivity by varying the solvent. For example, complex **4p** exists as only the *trans*-isomer in a Bu<sup>t</sup>OH–MeOD mixture, whereas in CCl<sub>4</sub>, d<sub>8</sub>-toluene, C<sub>6</sub>D<sub>6</sub>, d<sub>6</sub>-DMSO and CDCl<sub>3</sub>, the *cis* : *trans* ratio varies from 1 : 2 to 1 : 9.<sup>118</sup>

In conclusion, we would like to note that the transphobia concept,<sup>111, 113, 152</sup> which describes rather adequately the behaviour of CN-palladacycles with respect to Lewis bases, is far from being always applicable to their PC-analogues as the reaction regiochemistry is strongly dependent on the electronic and steric factors. The predictive potential of this concept would be essentially increased by elucidation of detailed and correct *trans*-effect sequences for cyclopalladated compounds differentiated according to the types of P- and C-donors.

### 3. Bicyclic PCP-complexes

The derivatives of bicyclic PCP-systems are less diverse, because the possibility of their modification is usually restricted to one coordination site. Probably, the 'pincer' compound **36a** with the pyridine core, which can function as a metalloligand due to the pyridine nitrogen atom, is the only exception to this rule. For example, the reaction of this compound with palladium(II) benzonitrile complex affords trinuclear compound **36b** with two PCP fragments at the periphery.<sup>245</sup>

This method for aggregation of cyclometallated complexes may be useful for the design of multicentre polynuclear catalysts.

The standard initial form of PCP-complexes is a monomer with anionic ligand (Hal<sup>−</sup> or RCOO<sup>−</sup>). The exchange of these anions opens up the way to other derivatives. For example, chloride complex **37a**, prepared recently by direct cyclopalladation of non-symmetrical bis(phosphinite) HL<sup>37</sup> by [PdCl<sub>2</sub>(cod)] (cod is cyclo-octa-1,5-diene), was converted into iodide (**37b**) and acetate (**37c**) analogues.<sup>246</sup>

M = Na, Ag; X = I (**37b**), AcO (**37c**);

(a) NaI, Me<sub>2</sub>CO; (b) AgOAc, Et<sub>2</sub>O, ultrasound.

To replace chloride by the softer iodide, complex **37a** should be merely treated with NaI, whereas the replacement of the chloride by harder acetate requires dehalogenation of the initial chloride complex on treatment with AgOAc with ultrasonic activation.

The reactivity of PCP-complexes differs somewhat from that of their monocyclic PC-analogues. The formation of stable hydride derivatives (which are unknown for PC-structures) is the most interesting feature. The mononuclear hydrides, for example, **38a**<sup>247</sup> and **39a**,<sup>248</sup> are prepared by treating the chloride precursors with hydride reagents (NaBH<sub>4</sub> or LiAlH<sub>4</sub>), while the quantitative formation of binuclear hydride **40a** is attained by elimination of the chloride by the action of AgOTf followed by introduction of sodium formate.<sup>249, 250</sup>

Presumably,<sup>250</sup> the stability of the PCP-complexes with the Pd–H bond unusual for hydrides is determined by efficient shielding of this bond by bulky PBu<sub>2</sub><sup>t</sup> groups. This is consistent with both the higher stability of binuclear hydrides (in which the Pd–H–Pd fragment is not destroyed even under the action of CO or alkenes<sup>249</sup>) compared to the mononuclear ones and the lower stability of mononuclear CPC hydride derivatives based on sterically non-hindered diphosphines. For example, the formation of hydride **40b** from the PCP-complex with PPh<sub>2</sub> groups (through β-H elimination from the amide derivative) has been detected only by spectroscopy, whereas on attempted isolation, it was converted

into more stable binuclear complex **40a** with the bridging hydride ligand.<sup>251</sup> Conversely, mononuclear hydride **39a** with bulky Bu<sup>t</sup> substituents at the phosphorus atoms does not decompose even on heating above 100 °C.<sup>248</sup>

Probably, it is due to the low steric protection of the Pd–H bond in binuclear hydride **40a** that this hydride is easily converted into the chloride [Pd(η<sup>3</sup>-L<sup>40</sup>)Cl] (**40c**). This was the case, for example, on attempted crystallisation of complex **40a** as the BPh<sub>4</sub> salt from a solvent mixture including dichloromethane.<sup>252</sup>

Derivatives of PCP-complexes with molecular hydrogen like [(η<sup>3</sup>-L)Pd(η<sup>2</sup>-H<sub>2</sub>)]<sup>+</sup> might be of interest for the use in catalytic hydrogenation. However, attempts to generate such species by protonation of hydride **38a** with acids such as TfOH, HBF<sub>4</sub>·OEt<sub>2</sub> or [H(OEt)<sub>2</sub>]BAR<sub>4</sub> have not met with success.<sup>253</sup> Note for comparison that platinum analogues have been detected by spectroscopy at low temperatures.<sup>254</sup>

The replacement of the chloride in PCP-complexes by a methyl group on treatment with MeLi is a route to convenient catalyst precursors. Protolysis of these methyl derivatives<sup>255</sup> (for example, on treatment of complex **39b** with the salt [Me<sub>3</sub>NH]BF<sub>4</sub><sup>248</sup>) yields active coordinatively unsaturated species capable of functioning in a catalytic cycle by binding either the substrate or the reagent. These species can also be generated by dehalogenation of appropriate chloride PCP-complexes with AgBF<sub>4</sub> or TlPF<sub>6</sub>.<sup>256</sup> The coordination vacancy is usually occupied by a solvent molecule (THF, dioxane, acetone, CH<sub>2</sub>Cl<sub>2</sub>, CDCl<sub>3</sub>);<sup>256</sup> weak binding of the anion is also possible:<sup>248</sup>

When solvated, PCP-complexes are most convenient for the preparation or generation *in situ* of the adducts with weakly coordinated neutral monodentate ligands. The stability of these cationic adducts depends to a large extent on electronic and steric characteristics of both the PCP-template and the ligand entering the metal coordination sphere.

For example, the solvated derivative of PCP-template **39** with bulky PBu<sub>2</sub><sup>t</sup> groups generated *in situ* by the protolysis of Me-substituted complex **39b** proved incapable of forming adducts with secondary and tertiary amines (Et<sub>2</sub>NH, Me<sub>3</sub>N).<sup>248</sup> In particular, the reaction of compound **39b** with the ammonium salt [Et<sub>2</sub>NH<sub>2</sub>]BPh<sub>4</sub> (this reagent performed a dual function, being a protonating agent and a potential source of the amine ligand) in moist dichloromethane gave aqua complex **39c**, whose structure was confirmed by X-ray diffraction, instead of the expected adduct with the amine.<sup>248</sup>

The researchers attributed this outcome to blocking of the newly formed coordination vacancy by bulky PBu<sub>2</sub><sup>t</sup> donor groups of the PCP-template<sup>248</sup> (apparently, some contribution is made by relatively high steric requirements of the amines Et<sub>2</sub>NH and Me<sub>3</sub>N, for which θ = 125 and 132°, respectively<sup>257</sup>).

Conversely, complex **40c** with less bulky Ph<sub>2</sub>P donor groups forms an adduct with Me<sub>2</sub>NH,<sup>251, 258</sup> apparently, owing to the less pronounced steric restrictions from both the PCP-core and the amine. After deprotonation of the secondary amine incorporated in [Pd(η<sup>3</sup>-L<sup>40</sup>)(NHMe<sub>2</sub>)]OTf, the amide derivative [Pd(η<sup>3</sup>-L<sup>40</sup>)(NMe<sub>2</sub>)]<sup>+</sup>,<sup>251</sup> an analogue of an intermediate involved in palladium-catalysed amination, has been detected by spectroscopy.<sup>13</sup>

The coordination of the PCP template **40** with aniline is also facilitated by both factors: the lower steric requirements of the PCP-fragment and the relatively small size of the amine (aniline) (θ = 111°).<sup>257</sup> Complex **40d** was prepared in a high yield upon the substitution of aniline for norbornene (nb) in the intermediate

adduct [Pd(η<sup>3</sup>-L<sup>40</sup>)(η<sup>2</sup>-nb)]BF<sub>4</sub> (**40e**) generated *in situ* from chloride **40c**. The structure of complex **40d** was confirmed by X-ray diffraction.<sup>256</sup>

Within the framework of the same study devoted to the simulation of transformations like the Wacker process, hydroxy and some alkoxy derivatives of complex **40c** were synthesised and characterised by spectroscopy.<sup>256</sup> Thus dehalogenation of chloride **40c** with the subsequent introduction of sodium methoxide gave methoxide **40f**.<sup>256</sup>

Undoubtedly, a substantial contribution to weakening of the palladium bond with the incoming monodentate ligand is made by the strong *trans*-effect of the carbanionic centre of the PCP-template located opposite to this ligand. As an illustration, one can consider the protolytic displacement of the relatively small aliphatic phosphine PEt<sub>3</sub> (θ = 132°) from the complex [Pd(η<sup>3</sup>-L<sup>40</sup>)(PEt<sub>3</sub>)]BF<sub>4</sub> (**40g**) with the sterically non-hindered template. The structure of adduct **40g** was confirmed by X-ray diffraction.<sup>259</sup> The displacement of the phosphine from the coordination sphere is attained by mere treatment of complex **40g** with a 0.1 M solution of HBF<sub>4</sub> in MeCN. The initial CPC can be regenerated as the acetonitrile solvate. It is significant that the attempts to displace PEt<sub>3</sub> from its adducts with PNP-, PSP- and POP-templates containing the central heterodonor atom failed.

The possibility of the electronic control of the complexation of PCP-templates with additional ligands is illustrated by the results of a study dealing with norbornene binding to two complexes differing by the P-substituents. Adducts **40e** and **41b** have not been isolated due to the substantial weakening of alkene coordination, caused by the pronounced *trans*-effect of the carbanion centre of the PCP-template, but they have been identified by spectroscopy. Determination of the equilibrium constants between the starting solvates **40h**, **41a** and their norbornene adducts **40e**, **41b** showed

R = Ph (**40h,e**; K = 0.17), 4-Me<sub>2</sub>NC<sub>6</sub>H<sub>4</sub> (**41a,b**; K = 0.41).

that binding of the bicyclic alkene becomes stronger upon the introduction of the electron-donor  $\text{Me}_2\text{N}$  substituents into the benzene rings of the template  $\text{PPh}_2$  groups.<sup>256</sup>

The high stability of the alkene adduct **41b** is attributed to the increase in the electron density on the metal (the effect is transmitted from the heterodonor  $\text{PAr}_2$  groups), resulting in a greater contribution of the back  $d\text{-}\pi$ -backbonding of the metal to the alkene.<sup>256</sup>

The above examples clearly demonstrate the good prospects for the use of PCP-structures for stoichiometric simulation of the intermediates in the catalytic processes. This becomes possible due to the exceptionally high stability of this type of CPC, caused by the efficient steric shielding of the reaction centre. Using PCP-complex **40i** as the catalyst, the intermediates in the Stille coupling have been identified and the  $\text{Pd}^{\text{II}}/\text{Pd}^{\text{IV}}$  route of this catalytic reaction has been proved.<sup>260</sup>

The hetarylation product of catalyst **40i** with  $\alpha$ -stannylfuran, complex **40j**, has been not only isolated but also studied by X-ray diffraction. The intermediate with a  $\eta^2$ -coordinated organotin reagent existing as two isomers **A** and **B**, which directly precedes complex **40j** in the catalytic cycle, has been identified by low-temperature spectroscopy. The structure and stereochemistry of complexes **A** and **B** in solutions were convincingly proved by the whole set of advanced spectral methods ( $^1\text{H}$ ,  $^{31}\text{P}$ ,  $^{119}\text{Sn}$  NMR) including the NOE technique (Nuclear Overhauser Effect).

As a result, the sequence of reversible stages of this process was established and the thermodynamic parameters for substrate  $\eta^2$ -coordination and transmetalation were determined.<sup>260</sup>

### III. Transformations of phosphapalladacycles

We have discussed so far the reactions that involved the metallic centre but left the phosphapalladacycles intact, only the metal coordination environment being varied due to the introduction of auxiliary ligands. This Section deals with processes affecting the metal-containing rings. These can be divided into three types: (1) reactions at the  $\text{Pd}-\text{C}$  bond of the palladacycle, which allow regioselective introduction of substituents into the initial P-containing ligand (Section III.1); (2) structural modification of the phosphapalladacycle not affecting the  $\text{Pd}-\text{C}$  and  $\text{Pd}-\text{P}$  bonds (Section III.2); (3) dechelation and destruction of PC-palladacycles (Section III.3).

#### 1. Reactions of phosphapalladacycles involving the $\text{Pd}-\text{C}$ bond

The reactions of phosphapalladacycles involving the  $\text{Pd}-\text{C}$  bond are of considerable interest as a method for regioselective modification of the P-donor ligands. Unlike CN-palladacycles for which these reactions have been extensively studied within the framework of development of the routes of regioselective organic

synthesis,<sup>261–265</sup> studies of the transformations of PC-palladacycles are limited to a few examples. Of the few known publications, a brief communication dealing with the reactions of cyclopalladated phosphalkenes with some nucleophiles deserves attention.<sup>86</sup> Thus by treating the dimeric complex **20** with an organolithium reagent in the presence of triphenylphosphine, the *ortho*-methylated analogue of the initial ligand HL<sup>20</sup>, phosphalkene HL<sup>42</sup>, has been obtained.

When MeLi was replaced by  $\text{Bu}^n\text{Li}$  or PhLi, the product yield markedly decreased and alkylation with more bulky  $\text{Bu}^n\text{Li}$  proved impossible at all (apparently, due to steric restrictions). It should be noted that an attempt to obtain *ortho*-substituted phosphites failed: in this case, the reaction stopped after replacement of the chloride in the intermediate phosphine adduct  $[\text{Pd}(\eta^2\text{-L})(\text{PPh}_3)\text{Cl}]$  by the organic ligand R. For example, dimer **14b** is converted into mononuclear complex **14e** under these conditions.<sup>74</sup>

The carbonylation of the phosphalkene complex **20** at room temperature but at high CO pressure gave new ligand HL<sup>43</sup>, containing a methoxycarbonyl group in the *ortho*-position of one benzene ring, in an almost quantitative yield.<sup>86</sup>

Two other examples of reactions involving the  $\text{Pd}-\text{C}$  bond refer to transformations of strained four-membered PC-palladacycles. The oxidation of dimeric  $\text{Pd}(\text{I})$  complex **3q** with atmospheric oxygen affords binuclear  $\text{Pd}(\text{II})$  complex **3r** with a new phosphino-alcoholate ligand.<sup>176</sup>

In view of the ease of cyclopalladation of tris(*tert*-butyl)phosphine,<sup>12</sup> participation of a cyclopalladated intermediate in the oxidation of complex **3q** seems quite practicable, the more so, because a small amount of the dimeric CPC  $[(\eta^2\text{-L}^3)\text{Pd}(\mu\text{-Br})_2]$  (**3o**) has been isolated from the reaction mixture. Presumably, this process includes coordination of the oxygen molecule, cleavage of the metal-activated  $\text{O}=\text{O}$  bond, cyclopalladation of the phosphines and the subsequent formal insertion of oxygen into the resulting  $\text{Pd}-\text{C}$  bond. The structures of both the final product **3r** and intermediate dimer **3o** were proved by X-ray diffraction analysis.<sup>176</sup>

It is noteworthy that the  $\mu$ -iodide analogue of complex **3q** was absolutely inert with respect to atmospheric oxygen. The depend-

ence of the ability of compounds of this class to undergo oxidative addition on the nature of the halide ( $\text{Br} \gg \text{I}$ ) has also been noted for their reactions with other small molecules ( $\text{CO}$ ,  $\text{H}_2$ ,  $\text{RCN}$ ).<sup>176</sup>

A more practically interesting process has been discovered in a study of the behaviour of phosphine adduct **34c**, containing sterically strained four-membered PC-palladacycle, under photochemical activation.<sup>266</sup> A mixture of *cis*- and *trans*-isomers of this complex in the solid state is converted in the light at room temperature into coordination compound **44a** with *o*-phenylenediphosphine, formed upon the formal insertion of the  $\text{PPh}_2$  group into the  $\text{Pd}-\text{C}$  bond. The fact that the second phosphine fragment  $\text{PPh}_2$  is formed from the phosphine  $\text{PPh}_3$ , bound in the monodentate mode in the initial complex **34c**, was confirmed by experiments with deuterated ( $\text{Ar} = \text{C}_6\text{D}_5$ , complex **34d**) and structurally modified ( $\text{Ar} = \text{Tol-}p$ , complex **34e**) analogues of adduct **34c**. The structure of one product of this unusual reaction, complex **44a**, was proved by X-ray diffraction.

$\text{Ar} = \text{Ph}$  (**34c**, **44a**),  $\text{C}_6\text{D}_5$  (**34d**, **44b**),  $\text{Tol-}p$  (**34e**, **44c**).

Apparently, the formation of the  $\text{P}-\text{C}$  bond may be either an inter- or an intramolecular process. A study of the reactions of aryl halides with  $\text{Pd}(0)$  complex **45a** containing bulky phosphine ligands  $\text{HL}^{45}$  has shown the formation (in addition to the standard oxidative addition products **45b,c**) of a small amount ( $\sim 5\%$ ) of cyclic phosphonium salts.<sup>267</sup>

The structures of complex **45a** and two phosphonium salts with  $\text{X}^- = \text{Br}^-$  and  $\text{I}^-$  were confirmed by X-ray diffraction. When discussing the origin of these salts, the authors reasonably suggest that they result from metallation of the *ortho*-carbon atom in the remote benzene ring of the biphenylphosphine  $\text{HL}^{45}$  followed by reductive elimination of the  $\text{P}-\text{C}$  bond in the intermediate phosphapalladacycle.

$\text{X} = \text{Br}$  (**45b**),  $\text{I}$  (**45c**); TMEDA —  $\text{Me}_2\text{N}(\text{CH}_2)_2\text{NMe}_2$ .

This reaction route is supported by a number of considerations. First, a similar six-membered phosphapalladacycle **46** has been obtained recently in an almost quantitative yield under mild conditions.<sup>18</sup>

Second, X-ray diffraction and spectroscopic studies of the  $\text{Pd}(0)$ -containing starting complex **45a** has revealed  $\pi$ -coordination of the metal to the remote benzene ring of biphenylphosphine, which is usually considered as an initial step of cyclometallation.<sup>12</sup> Presumably, interactions of this type are also possible in com-

plexes **45b,c**, containing  $\text{Pd}(\text{II})$ . Finally, the presence of the  $\text{Ph}-\text{Pd}$  fragment in intermediate complexes **45b,c** should largely facilitate the cyclometallation.<sup>12</sup>

Note for comparison that the intermolecular formal insertion of the  $\text{PR}^1\text{R}^2$  fragments into the  $\text{Pd}-\text{C}$  bond of more stable five-membered  $\text{CN}$ -palladacycles has been carried out only using lithium phosphides  $\text{LiPR}^1\text{R}^2$  (Refs 268–270) or  $\text{PhPCl}_2$ .<sup>271</sup>

Studies of the reactivity of bis(chelate) *spiro*-PC-complexes of benzylphosphines have shown that their reactions with bromine result in the destruction of the phosphapalladacycle through the formal insertion of bromine into the  $\text{Pd}-\text{C}$  bond. This gave coordination complexes of palladium bromide with *ortho*-brominated phosphines in high yields.<sup>67</sup>

A practical significance of this process is problematic, because *o*-bromobenzylphosphines formed serve as the starting substrates for the synthesis of *ortho*-lithiated ligands (in particular,  $\text{LiL}^2$ ), necessary for the preparation of *spiro*-complexes. Note for comparison that analogous platinum(II) compounds undergo oxidative addition under these conditions with retention of the phosphametallacycle in the intermediate platinum(IV) complexes of the type  $[(\text{P}^{\text{C}})_2\text{PtBr}_2]$ .<sup>67, 71</sup>

Strange as it seems, reactions of phosphapalladacycles with alkynes have not yet been studied, although this line of research is being developed most extensively in the chemistry of  $\text{CN}$ -analogues.<sup>263, 264</sup> The possibility of these reactions for PC-complexes is supported by their implementation for nickel analogues like **2'b** under exceptionally mild conditions.<sup>272, 273</sup>

The structure of the products of formal insertion of alkyne into the  $\text{M}-\text{C}$  bond (complexes **47'**) was proved by various methods including X-ray diffraction analysis.<sup>272, 273</sup> Theoretical studies of insertion were carried out.<sup>274</sup>

If one takes into account the fact that the initial phosphanickelacycles are obtained by oxidative addition of *ortho*-bromosubstituted benzylphosphines to  $[\text{Ni}(\text{cod})_2]$ , while their palladium analogues are prepared by direct intramolecular activation of the  $\text{C}-\text{H}$  bond in unsubstituted phosphine,<sup>12, 54</sup> development of similar processes for phosphapalladacycles seems quite a promising path in the regioselective organic synthesis.

## 2. Modification of phosphapalladacycles with retention of the $\text{Pd}-\text{C}$ bond

The functionalisation of  $\text{P}$ -donor ligands activated by cyclometallation not involving the  $\text{Pd}-\text{C}$  bond is even less studied. Of certain practical value is the electronic and steric modification of the benzylphosphine ligands incorporated in bis(chelate) cyclopalladated complexes by lithiation<sup>†</sup> into the  $\alpha$ -position followed by 'quenching' of the carbanion formed with an appropriate electrophile.<sup>71, 275</sup>

<sup>†</sup> Note for comparison that reactions of  $\text{CN}$ -palladacycles with organolithium reagents involve the  $\text{Pd}-\text{C}$  bond.<sup>264</sup>

Using platinum analogues, it has been shown that this procedure ensures the introduction of not only alkyl groups but also silyl or phosphine groups ( $\text{Me}_3\text{Si}$ ,  $\text{Ph}_2\text{P}$ ) into the  $\alpha$ -position of the benzyl fragment.<sup>71, 275</sup> The reactions of cyclopalladated benzylphosphine ligands with salts of other metals, for example, with  $[\text{AuCl}(\text{PPh}_3)]$ , give heterobimetallic compounds with two different  $\text{M}-\text{C}$  bonds.<sup>275</sup> An advantage of this method for modification of benzylphosphines is the regioselectivity of metallation, which involves only the  $\alpha$ -benzyl position, whereas in the case of lithiation of free ligands, several routes are possible.<sup>12</sup>

One more example of modification of a phosphapalladacycle not affecting the  $\text{Pd}-\text{C}$  and  $\text{Pd}-\text{P}$  bonds is the deprotonation of the cationic derivatives of the cyclopalladated secondary phosphine  $\text{HPMe}_2$  (**23a** and **23b**) by treatment with the silylamides  $\text{M}'\text{N}(\text{SiMe}_3)_2$  ( $\text{M}' = \text{Li}$  or  $\text{Na}$ ) as bases.<sup>276</sup>

$\text{R} = \text{CH}_2\text{CH}_2$  (**23a,c**, 55%), *cis*- $\text{CH}=\text{CH}$  (**23b,d**, 82%).

The resulting neutral complexes **23c,d**, containing an unusual non-charged phosphapalladacycle with a covalent  $\text{Pd}-\text{P}$  bond (rather than the coordination  $\text{Pd} \leftarrow \text{P}$  bond, as all of the structures considered previously), are distinguished by high stability and do not tend to decompose through the reductive elimination of the  $\text{P}-\text{C}$  bond. In the case of analogues of complexes **23c,d** with a monodentate phosphite (for example,  $[(\text{dppe})\text{MePd}-\text{P}(\text{H}).\text{Mes}^*)]$ ), this process takes place even below room temperature. It is typical of organometallic complexes with a terminal phosphide ligand.<sup>276</sup>

In order to evaluate the activation routes of phosphite- and phosphinite-based cyclopalladated catalysts, the behaviour of triarylphosphite derivative **11a** has been studied under the conditions used normally to prepare biaryls by the Suzuki reaction.<sup>277</sup> Heating of dimer **11a** with phenylboronic acid hydrate in dimethylacetamide (DMA) in the presence of a base furnished unusual CPC dimer **48**, containing the central six-membered  $\{\text{Pd}_2\text{P}_2\text{O}_2\}$  ring (the structure of dimer **48** was established by X-ray diffraction).

$\text{Ar} = 2,4\text{-Bu}_2\text{C}_6\text{H}_3$ .

Dimer **48** is a cyclopalladated derivative of diarylphosphite  $(\text{ArO})_2\text{P}(\text{OH})$  ( $\text{H}_2\text{L}^{48}$ ), formed upon the hydrolytic elimination of an aryl group from the initial triarylphosphite  $\text{HL}^{11}$ . The bridging function in dimer **48** is performed by the oxygen atoms of the deprotonated hydroxy group of the diarylphosphite ligand. The hydrated reagent  $\text{PhB}(\text{OH})_2 \cdot \text{H}_2\text{O}$  is assumed to serve as the source of water needed for hydrolysis.

In the same reaction carried out in DMF, biphenol **49** was formed upon the oxidative coupling of two aryloxy fragments; its structure was confirmed by X-ray diffraction.<sup>277</sup>

$\text{Ar} = 2,4\text{-Bu}_2\text{C}_6\text{H}_3$ .

The true mechanism of this transformation is unknown. The researchers consider two possible routes: (1) coupling involving free phenol molecules, liberated upon hydrolysis of CPC **11a** (see above), assisted by the metal centre; (2) coupling between two aryloxy fragments incorporated into phosphite ligands (this route includes intramolecular reorganisation and reductive elimination).

It is reasonable to suggest that the ligands in cyclopalladated phosphites and phosphinites can undergo not only hydrolysis but also solvolysis under appropriate conditions. Unfortunately, no reliable information on this subject is available; it is only known<sup>277</sup> that an attempted *ortho*-palladation of aryldialkylphosphinite  $\text{HL}^{50}$  with  $\text{PdCl}_2$  on refluxing in 2-methoxyethanol (MET) (a) followed by recrystallisation from a  $\text{EtOH}-\text{CH}_2\text{Cl}_2$  mixture (b) gave, instead of the expected CPC **50**, coordination complex **51**, whose structure was proved by X-ray diffraction.

In the researchers' opinion, the new phosphinite  $\text{P}(\text{OEt})\text{Pr}_2^i$  ( $\text{HL}^{51}$ ) is the product of transesterification of the initial ligand  $\text{HL}^{50}$  with the solvent. However, the instant the solvolysis takes place remains unknown; this may occur either within the coordination intermediate  $[\text{Pd}(\text{HL}^{50})_2\text{Cl}_2]$  or in the intermediate CPC **50**, because no attempts to carry out solvolysis of dimer **50** have been

made. It is only known<sup>277</sup> that palladium complexes with less electron-enriched aryl diarylphosphinites  $\text{P}(\text{OAr})\text{Ar}_2$  and triaryl phosphites  $\text{P}(\text{OAr})_3$  are not susceptible to transesterification.

### 3. Dechelation and destruction of phosphapalladacycles

Three variants of cleavage of palladacycles without modification of the ligand structure are, in principle, possible: (1) transition to a monodentate coordination due to cleavage of the  $\text{Pd} \leftarrow \text{E}$  bond ( $\text{E}$  is the heteroatom); (2) the same due to cleavage of the  $\text{Pd} - \text{C}$  bond; (3) transformation of a chelating ligand into a bridging one. The first route is typical of  $\text{CN}^-$ ,<sup>111, 198, 278–280</sup> and  $\text{CO}$ -palladacycles<sup>281</sup> with hard heterodonor nitrogen and oxygen atoms, which are readily displaced from the metal coordination sphere by excess auxiliary ligand with a softer donor atom (most often, phosphine). This gives mononuclear complexes *trans*- $[(\eta^1\text{-E}^-\text{C})\text{PdX}(\text{PR}_3)_2]$  ( $\text{E} = \text{N}, \text{O}$ ) with the monodentate  $\eta^1\text{-C}$ -bonded ligand (the heterodonor  $\text{E}$  atom remains in the non-coordinated state). The other two variants are unlikely for systems with hard heterodonor atoms, as they are weakly coordinated to soft palladium. To our knowledge, only one structure with a bridging  $\text{CN}$ -ligand has been reported.<sup>282</sup>

#### a. Dechelation of phosphapalladacycles

In the case of phosphapalladacycles, decoordination of the heterodonor atom appears problematic due to the strong binding of the soft phosphorus atom to the soft palladium centre. We have not found any examples of dechelation of  $\text{PC}$ -structures according to this pattern. The cleavage of  $\text{PC}$ -palladacycles is accompanied most often by transition of the ligand from the  $\eta^2$ -binding to bridging position.

As an illustration, one can consider the dechelation of cyclopalladated triphenylphosphine.<sup>241</sup> The steric strain of the four-membered phosphapalladacycle with the  $\text{Pd}-\text{C}(\text{sp}^2)$  bond accounts for its easy opening to give the tetramer  $[\{\text{Pd}(\mu\text{-L}^{34})(\mu\text{-X})\}_4]$  (**34f**) with bridging  $\text{P}, \text{C}$ -bound ligands  $(\text{L}^{34})^-$ , which combine four metallic centres to form a macrocycle. The mononuclear species with this  $\text{PC}$ -palladacycle really exist in solutions only in the presence of excess auxiliary phosphine ligand, the equilibrium between complexes with ligands of two types —  $\mu\text{-L}^{34}$  and  $\eta^2\text{-L}^{34}$  — being displaced towards the cyclopalladated structure (for example, **34g**) with an increase in the steric requirements of the auxiliary ligand (when  $\theta > 150^\circ$ ).<sup>241</sup>

It is noteworthy that structures with the bridging  $\text{PC}$ -ligands like  $(\text{R}_2\text{PC}_6\text{H}_4)^-$  are frequently encountered in dirhodium complexes,<sup>283–288</sup> in which they form the five-membered rings  $\{\text{RhPCCRh}\}$  involving the  $\text{Rh}_2$  fragment.

At first glance, this type of dechelation with transition from  $\eta^2$ - to  $\mu$ -binding of the  $\text{PC}$ -ligand may seem impracticable for non-strained and rather stable five-membered phosphapalladacycles. Nevertheless, transformations of this type are still possible under certain conditions. For example, the reaction of xanthate (**4l**) and dithiocarbamate (**4k**) derivatives of cyclopalladated tris(*o*-tolyl)-phosphine with mercury bromide gave binuclear heterobimetallic

compounds **4q,r** with the bridging anionic ligand  $(\mu\text{-L}^4)^-$  (see Ref. 53).

The dechelation giving analogous binuclear compounds **4s,t** has also been observed in the reaction of complex **4k** with mercury dicarboxylates.<sup>122</sup>

$\text{R} = \text{Me}$  (**4s**, 79%),  $\text{CF}_3$  (**4t**, 60%).

The structures of complexes **4q**<sup>53</sup> and **4s**<sup>122</sup> were proved by X-ray diffraction. In both cases, the bridging ligand  $(\text{L}^4)^-$  remains  $\text{P}$ -coordinated to palladium, the carbanionic centre being lent to mercury. As was to be expected, compounds of this type are relatively unstable. For example, halide complexes **4q,r** dissociate in solutions at room temperature with recovery of the starting  $\text{CPCs}$  **4l,k**; this process can be 'frozen' by lowering the temperature to  $-55^\circ\text{C}$  only in the case of dithiocarbamate derivative **4k**.<sup>53</sup>

A number of unusual features of these processes deserve attention. First, fairly unexpected is the cleavage of the  $\text{Pd}-\text{C}$  covalent bond rather than the  $\text{Pd} \leftarrow \text{P}$  coordination bond. In principle, this result can be attributed to stronger binding of palladium(II) to phosphorus than to the carbanionic fragment of the  $\text{PC}$  ligand (see Section II.2.c). However, the reason may also be in the reaction mechanism. The transmetalation is assumed<sup>122</sup> to occur *via* an electrophilic attack by the mercury salt on the  $\text{Pd}-\text{C}(\text{sp}^3)$  bond rather than on the  $\text{Pd}(\text{II})$  centre or, the more so, the phosphorus atom.

The second unusual fact is that mercury(II), having high affinity to  $\text{S}$ -donor atoms, remains indifferent towards the dithiocarboxylate ligands. Note for comparison that an X-ray diffraction study of the structure of the binuclear compound  $[\text{Pt}(\eta^2\text{-L}^4)(\kappa^2\text{-}\mu\text{-S}_2\text{CNMe}_2)\{\text{Ag}(\text{PPh}_3)\}]$ , isolated upon the reaction of the platinum analogue of complex **4k** with  $[\text{Ag}(\text{OCIO}_3)(\text{PPh}_3)]$ , revealed the interaction of the silver ion with one sulfur atom of the dithiocarbamate ligand.<sup>123</sup>

The third unusual fact is the strong influence of not only the nature of the metal incorporated into the  $\text{PC}$ -metallacycle but also the auxiliary ligand and the anion in the mercury salt on the reaction pathway. For example, in the reaction of dithiocarbamate **4k** with  $\text{HgI}_2$  carried out under mild conditions, the  $\text{PC}$ -palladacycle is retained, the reaction yielding the tetranuclear complex with a dative  $\text{Pd} \rightarrow \text{Hg}$  bond.<sup>53</sup>

However, a close analogue of this complex — xanthate derivative **4l** of the same palladacycle — does not react with mercury iodide even on refluxing.<sup>53</sup> The reactions of the acetylacetonate derivative **4v** with mercury bromide and carboxylate were found to result in the recovery of the starting  $\mu$ -bromide (**4w**) or  $\mu$ -carboxylate dimeric CPCs (**4a** or **4x**). In the latter case, the  $\beta$ -diketonate ligand is displaced from the palladium(II) coordination sphere by mercury in the  $\gamma$ -C-bound state, as the compound  $[\text{Ac}_2\text{C}(\text{HgO}_2\text{CR})_2]$  ( $\text{R} = \text{Me}, \text{CF}_3$ ).<sup>121</sup>

$\text{R} = \text{Me}$  (**4a**),  $\text{CF}_3$  (**4x**).

The behaviour of the platinum analogues in the reactions with mercury salts differs appreciably from the behaviour of PC-palladacycles such as **4**. For platinum systems, the formation of donor–acceptor  $\text{Pt} \rightarrow \text{Hg}$  bonds is most typical;<sup>53, 121, 289</sup> the oxidative addition of  $\text{HgX}_2$  to give  $\text{Pt}(\text{IV})$  compounds is also possible.<sup>122</sup> However, no examples of dechelation of PC-platinacycles have been found so far.

Note that dechelation induced by mercuriation has also been observed for a five-membered PC-palladacycle with a  $\text{C}(\text{sp}^2) - \text{Pd}$  bond incorporated in *spiro*-complex **2c** when it has been made to react with mercury bromide.<sup>71</sup> In this case, mercury also attacks the carbon end of the palladacycle to give coordination complex **2l** with the monodentate P-coordinated *ortho*-mercurated phosphine.

An absolutely different principle underlies the cleavage of the phosphapalladacycle in *spiro*-complex **31a**. The thermolysis of this complex is accompanied by almost quantitative isomerisation of the PC-palladacycle into PO-chelating phosphinoenolate to give complex **31c**. This process also involves rupture of the  $\text{Pd} - \text{C}$  bond (but not the  $\text{Pd} \leftarrow \text{P}$  bond) followed by 1,3-migration of hydrogen from the carbon atom adjacent to phosphorus to the metallated alkenyl carbon atom.<sup>237, 239</sup>

The structure of complex **31c** and the retention of the *E*-configuration of the exocyclic alkene fragment were confirmed by X-ray diffraction.<sup>239</sup> The researchers assume the tendency for the formation of a system of conjugated double bonds in the new  $\beta$ -phosphinoenolate ligand to be the driving force of the process.<sup>237</sup> However, if one estimates the relative stability of complexes **31a** and **31c** from the standpoint of the transphobia concept, the higher stability of the latter may be due to the replacement of the unfavourable *trans*-arrangement of two carbanionic centres ( $\text{C} - \text{Pd} - \text{C}$ ) with the highest *trans*-effect in one axis by a more favourable combination of the softest and the hardest donor atoms on one diagonal ( $\text{C} - \text{Pd} - \text{O}$ ). This also accounts for more preferred binding, unexpected at first glance, of the soft palladium to the hard enolate oxygen atom rather than to the soft carbanionic atom.

## b. Destruction of phosphapalladacycles

A fundamentally different pattern of cleavage of phosphapalladacycles is induced by treatment with reducing agents or acids. In this case, the reaction involves the  $\text{Pd} - \text{C}$  bond and results in the recovery of the ligand HL. However, unlike these processes for CN-systems, in this case, the liberated ligand remains bound to palladium through the heteroatom to form a coordination compound. These reactions carried out with deuterated reagents ( $\text{DCl}$  or  $\text{LiAlD}_4$ ) can be used, in principle, for regioselective introduction of an isotope label into the ligand molecule or to confirm cyclometallation and establish its path (for example, using mass spectrometry<sup>290</sup>).

The reduction of PC complexes can be used to prepare phosphine compounds of zerovalent palladium. For instance, treatment of dimer **3b** or its mononuclear adduct **3e** with the same phosphine HL<sup>3</sup> with sodium tetrahydroborate in ethanol results in the synthesis of the bis(phosphine) complex  $[\text{Pd}^0(\text{PBu}_3)_2]$  (**3s**).<sup>88, 102</sup>

The classical PC-type complexes are not highly prone to protolysis. Treatment of mononuclear PC-palladacycles with a dilute aqueous solution of hydrochloric acid in a biphasic system with an organic solvent is often used to remove the auxiliary ligand (amine or amino acid) from these complexes (for example, in the optical resolution of the PC-palladacycles<sup>79, 117, 125</sup>). This procedure virtually does not affect the starting palladacycle, which can be recovered as the  $\mu$ -chloride dimer (for example, **7a**<sup>117</sup>) in an almost quantitative yield.

It is reasonable to suggest that the protolytic destruction of the PC-palladacycles can take place under more drastic conditions, for example, upon an increase in the strength and concentration of the acid and the reaction temperature and time and also on passing to homogeneous media. More evidence is provided by the fact that scalemic CN-palladacycle with the Pd–C\* bond is fully racemised on long-term storage of its (*S*)-leucinate derivative in a solution of HCl in aqueous methanol.<sup>291</sup> When a weaker acid is used (AcOH in methanol), the enantiomeric composition changes insignificantly.<sup>292</sup>

Useful information on the course of acidolysis was gained from a spectroscopic (<sup>31</sup>P NMR) study of the reactions of cyclopalladated phosphite **11a** with a stoichiometric amount of anhydrous hydrogen chloride in the organic medium.<sup>69</sup>

Ar = 2,4-Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>.

The order in which the signals corresponding to the species shown in the scheme appear in the spectrum implies the initial destruction of only one of the two PC-palladacycles to give binuclear complex **11g** (as a ~4.8:1 mixture of *cis*- and *trans*-isomers). The subsequent cleavage of the second palladacycle yields binuclear coordination complex **11i** with monodentate ligands HL<sup>11</sup>, which is partially converted into mononuclear analogue **11h**. Three hours later, the ratio of the initial complex to the complexes formed upon protolysis, **11a**:**11g**:**11i**:**11h**, was 8.5:37.5:52:2, indicating rather high stability of the PC-palladacycles of this type against protolysis: almost a half of the phosphite ligand retains the cyclopalladated structure.

The susceptibility of phosphapalladacycles to protolysis markedly increases when they are incorporated into *spiro*-structures. The reactions of these complexes with hydrogen chloride are exothermal; they are carried out at reduced temperatures.<sup>71</sup> The reactions give mono- or binuclear coordination compounds of palladium(II) with *ortho*-unsubstituted benzylphosphines.<sup>71–73</sup> The geometry of the mononuclear products like [Pd(HL)<sub>2</sub>Cl<sub>2</sub>] depends on the steric situation at the P-donor atom: the coordination compounds of sterically less hindered phosphines PhCH<sub>2</sub>PR<sub>2</sub> (R = Me, Ph) are formed as mixtures of *cis*- and *trans*-isomers, whereas for more bulky di(*tert*-butyl)benzylphosphine, this process is selective and gives only the *cis*-isomer.<sup>71</sup>

The practical use of these transformations appears problematic in view of the multistage character of the synthesis of *spiro*-PC-complexes *via* *ortho*-bromo-substituted benzylphosphines.<sup>12</sup>

These reactions may be of some practical value as applied to heteroligand *spiro*-structures, which are converted upon protolysis into mixed-ligand coordination compounds. For example, the reaction of complex **2g** with a stoichiometric amount of hydrogen chloride gave arsino-phosphine coordination complex **2m** in a high yield.<sup>72, 73</sup>

It should be noted that the protolytic stability of phosphapalladacycles in *spiro*-structures is higher than the stability of their N- and As-analogues. Spectroscopic studies of the behaviour of mixed-ligand *spiro*-complexes **2g** and *cis*-[(η<sup>2</sup>-L<sup>2</sup>)Pd(η<sup>2</sup>-C<sub>6</sub>H<sub>4</sub>CH<sub>2</sub>NMe<sub>2</sub>)] (**2e**) in relatively weak acetic acid have shown that in both cases, protolysis takes place for the less stable AsC- or CN-metallacycle, whereas the PC-palladacycle is retained as dimeric CPC **2b** with acetate bridges.<sup>293</sup> Note that in a stronger acid (HCl), both palladacycles of complex **2g** are destroyed, benzylamine is removed as the ammonium salt, while benzylphosphine HL<sup>2</sup> remains in the metal coordination sphere in the resulting binuclear complex [(Pd(κ<sup>1</sup>-HL<sup>2</sup>)Cl(μ-Cl))<sub>2</sub>].<sup>72</sup>

The phosphino-P-ylide palladacycles are also destroyed under the action of acids to give coordination complexes with the monodentate P-bonded cationic phosphonio-phosphine.<sup>133</sup> However, unlike the reactions of *spiro*-complexes considered above, the protonation of phosphino-P-ylide CPC is reversible, and the phosphapalladacycle can be regenerated by deprotonation of phosphonium ligands in coordination species. Thus complex **16g**, formed upon the protolysis of complex **16h**, can be recovered in the initial state on treatment with sodium hydride in THF.<sup>133</sup>

The information presented in this Section demonstrates that the data on the reactivity of phosphapalladacycles are scarce, which calls for further systematic research along this line.

## IV. Conclusion

The future development of the chemistry of phosphapalladacycles is of interest not only from the fundamental standpoint; its topicality is determined first of all by the demands of homogeneous catalysis, which has entered a new phase after PC- and PCP-complexes have been included in the range of available (pre)catalysts. Several promising lines of research can be distinguished.

First, one should expect the solution of the mechanistic problem related to the true role of phosphapalladacycles in the catalysis: whether they function as such in the catalytic cycle or serve only as convenient sources of zerovalent palladium? This point is still debated. With rare exceptions,<sup>294</sup> the possibility of the Pd<sup>II</sup>/Pd<sup>IV</sup> interconversion in a catalytic cycle<sup>2, 3, 6, 295</sup> is considered together with classical Pd<sup>II</sup>/Pd<sup>0</sup> schemes;<sup>2, 5, 294</sup> it has also been suggested that a PC-palladacycle can be retained as an anionic Pd<sup>0</sup>-containing intermediate.<sup>296</sup> Elucidation of the behaviour of phosphapalladacycles in catalytic processes requires conducting the reactions under stoichiometric conditions with isolation or spectroscopic identification of possible intermediates. Therefore, knowledge of the reactivity of phosphapalladacycles becomes especially important.

Realisation of the fact that the efficiency of many classical catalytic systems containing palladium(0) and bulky monodentate phosphines may be determined by the *in situ* generation of PC-species can also stimulate further, more extensive development of the chemistry of phosphapalladacycles. Indeed, the unique efficiency of these catalytic systems in the cross-coupling and the formation of carbon–heteroatom bonds is known. It is also evident that under conditions standard for the reactions of this type (80–160 °C, the presence of a base), the formation of PC-palladacycles with ligands such as  $\text{P}(\text{Bu}^t)_3$ ,<sup>297–299</sup>  $\text{P}(\text{Tol-}o)_3$ ,<sup>297, 300, 301</sup>  $\text{P}(\text{OAr})_3$ <sup>302</sup> and 2-phosphinobiaryls<sup>303, 304</sup> is inevitable.

Even if the role of PC- or PCP-complexes in some reactions would be restricted only to the supply of palladium(0) into the catalytic cycle, the unique thermal and hydrolytic stability of these compounds makes them fairly promising as (pre)catalysts. Many phosphapalladacycles withstand long-term heating (up to 300 h, 140–320 °C) without any signs of decomposition,<sup>295, 305–307</sup> which allows one to avoid the precipitation of palladium black during the process.<sup>302</sup> Therefore, more extensive involvement of not only standard (usually dimeric) PC-palladacycles but also their various derivatives into catalytic processes should be expected. The results obtained to date<sup>14–19, 22</sup> demonstrate that modification of the environment of the metallic centre in these complexes can serve as a potent method for increasing their catalytic activity.

## V. Supplements

<sup>a</sup> The complexes studied by X-ray diffraction are asterisked. <sup>b</sup> Here and below, the digits designate different methods for the preparation of a complex, while letters mark the preparation stages. <sup>c</sup> The isolated yield is given; the yield determined from spectroscopic data is indicated in parentheses. <sup>d</sup> The synthesis was carried out under conditions described <sup>310</sup> for the Pt-analogue. <sup>e</sup> The complex exists in solution as a mixture of *cis*- and *trans*-isomers. <sup>f</sup> The complex was generated *in situ* and identified by spectroscopy. <sup>g</sup> The complex represents a mixture of two diastereomers (1 : 1), each existing as geometric *cis*- and *trans*-isomers (<sup>31</sup>P NMR). <sup>h</sup> The complex was prepared similarly to the chloride analogue. <sup>i</sup> The adduct is unstable and dissociates in solutions. <sup>j</sup> The complex consists of two diastereomers. <sup>k</sup> For the adduct with P(Tol-*o*)<sub>3</sub>, the constant <sup>2</sup>J<sub>PP</sub> = 54 Hz is given.<sup>242</sup> <sup>l</sup> A mixture of two diastereomeric racemates. <sup>m</sup> Mixed with a small amount of tetranuclear species with a bridged phosphine.

## Supplement 2. Derivatives of phosphino-P-ylide PC-palladacycles.

<sup>a</sup> The complexes studied by X-ray diffraction are asterisked. <sup>b</sup> The formula or the number of the starting complex is given. <sup>c</sup> The yield based on spectroscopic data is given in parentheses. <sup>d</sup> The complex was identified on the basis of spectroscopic data. <sup>e</sup> The synthesis of  $[(\eta^3\text{-L}^{40})\text{Pd}(\text{HNMe}_2)]\text{OTf}$  has been reported.<sup>258</sup> <sup>f</sup> The complex is unstable and decomposes in solutions to give Pd(0). <sup>g</sup> nb is norbornene.

\* \* \*

During the preparation of this manuscript for publication (2004–2005), a number of new studies dealing with this subject have appeared. A series of reviews on the chemistry of palladacycles<sup>315</sup> and their use in catalysis<sup>316–320</sup> published during this period demonstrates the persistent interest in this field of knowledge. Studies on the activation of C–H bonds,<sup>321</sup> estimation of the phosphine basicity<sup>322</sup> and coordination properties<sup>323</sup> have con-

tinued; new data on the STE of coordination<sup>324</sup> and organometallic<sup>325</sup> palladium compounds have appeared.

As regards the design of new phosphapalladacyclic structures, attention has been focused on pincer PCP-complexes. Methods for the synthesis of new CPCs of this type have been developed;<sup>326–332</sup> in particular, the first complexes with the ferrocenyl core<sup>330,331</sup> and non-symmetric PCP'-structures with two different palladacycles were obtained.<sup>332</sup> The linear and branched bi- and trinuclear compounds with two or three PCP fragments<sup>333</sup> have been synthesised (for platinum, a tetra-PCP complex with the

porphyrin core has been prepared<sup>334</sup>). The unsuccessful attempt at cyclopalladation of diphosphine with the *m*-terphenyl core<sup>335</sup> emphasises once again the lack of stability for systems with two annelated seven-membered palladacycles.

The range of monocyclic PC-structures has been barely extended.<sup>336,337</sup> The development of a new method for the synthesis of mixed-ligand *spiro*-complexes<sup>338</sup> and the study of the rotation isomerism of PC-palladacycles<sup>339</sup> deserve attention.

The works dealing with reactions of phosphapalladacycles remain scarce. Of obvious interest are the results obtained in a study of the transformations of PCP-complexes under the action of reducing agents.<sup>340</sup> Further development of the chemistry of CPCs would be facilitated by the use of mass spectrometry. The potential of this method has recently been demonstrated in relation to the reactions of PCP-complexes with compounds of other metals (Pt, Au, Hg).<sup>326</sup> New derivatives of both known and new CPCs of the PC<sup>336,341</sup> and PCP types<sup>326,331,342,343</sup> have been synthesised, in particular, unusual dimers with a bridging anion (Cl<sup>−</sup>, CN<sup>−</sup>, COO<sup>2−</sup>) or a diphosphine linking two PCP-fragments.<sup>326,331,342,343</sup> A derivative of the ferrocenyl PCP-complex with a monodentate borohydride ligand has been isolated and studied by X-ray diffraction. This compound is unusual not only for a CPC but also for the coordination chemistry of palladium as a whole.<sup>331,342</sup> Study of the electrochemical behaviour of ferrocenyl PCP-complexes has shown oxidation of the ferrocenyl fragment.<sup>331</sup> The carbonylation of the hydroxy derivatives of PCP-complexes results in CO insertion into the Pd–O bond to give  $\mu$ -COO dimers.<sup>343</sup> The main impetus for the development of the chemistry of phosphapalladacycles is still the design of new efficient homogeneous (pre)catalysts based on the PC-<sup>336,337,344,345</sup> and PCP-type<sup>333,346–351</sup> CPCs. Recently, a soluble PC-palladacycle immobilised on polystyrene has been obtained.<sup>345</sup>

In conclusion, note the synthesis of new phosphapalladacyclic structures containing a carbene carbon atom instead of the carbanionic atom present in the classical CPCs.<sup>352</sup> The first imidazol-2-ylidene ligand functionalised by a phosphine fragment was synthesised in 2002.<sup>353</sup> A dozen palladium complexes with chelating carbene P $\curvearrowright$ C:-ligands have now been reported,<sup>354–357</sup> at least three pincer complexes with tridentate carbenes of the P $\curvearrowright$ C:P type have been obtained.<sup>357–359</sup> In all cases, the chelate carbene complexes were meant for being tested in catalysis; the brilliant future of this line of research is beyond doubt.

The authors are grateful to Prof. I P Smolyakova (USA, The University of North Dakota) and to Dr. M Yu Rubina (USA, The University of Illinois of Chicago) for valuable assistance in working on the manuscript and also wish to thank NATO (grant PST.CLG.979757), the Russian Foundation for Basic Research (Project No. 04-03-32986) and the Foundation for the Support of Russian Science (O N Gorunova) for partial financial support of the work.

**Abstract.** The published data on the methods for the synthesis, properties and applications of benzo[*b*]naphthyridines are analysed and generalised. The main attention is focused on biologically active compounds of the benzo[*p*]naphthyridine series. The bibliography includes 140 references.

## I. Introduction

Benzo[*b*]naphthyridines **1–4** can be regarded as aza derivatives of acridines. By virtue of their planar linear structures, benzo[*b*]naphthyridines attract keen attention of investigators as promising antitumour agents, *viz.*, intercalators.<sup>†</sup> The number of publications devoted to the synthesis and analysis of biochemical and pharmacological properties of representatives of this class of heterocycles is steadily increasing. However, no reviews specially devoted to benzo[*b*]naphthyridines exist so far. Several papers published before 1986 were considered in a review.<sup>1</sup> Some novel data on benzonaphthyridines were included into more recent reviews<sup>2–4</sup> devoted to naphthyridines. In this study, we made an attempt to generalise and systematise all published data on the methods for the synthesis and properties of benzo[*b*]naphthyridines (hereinafter referred to for the sake of brevity as benzonaphthyridines). The review encompasses the literature published in the period from 1980 to 2004. Wherever necessary, some earlier papers are included for a more logical and consistent presentation of the material. Special attention is given to the description of methods for the synthesis of benzonaphthyridine derivatives which present interest for medicinal chemistry with due regard to the state-of-the-art and trends.

The structural formulas of all the four isomeric benzo[*b*]naphthyridines **1–4** containing 1,5-, 1,6-, 1,7- or 1,8-naphthyridine skeletons are given below.

## II. Physicochemical properties

Relative nucleophilicities of the nitrogen atoms in the peripheral pyridine ring of 6-methylbenzo[*b*]naphthyridines **5–8** upon their interactions with MeI in DMSO have been studied.<sup>5</sup> To this end, the relative methylation rates of compounds **5–8** with respect to pyridine ( $k_1/k_{Py}$ ) were measured by the competitive reaction method (Table 1). The presence of a methyl group in the benzene ring near the nitrogen atom in the central ring in the compounds under study prevents the reaction from occurring at the acridine nitrogen atom; the reactivities of compounds **5–8** decrease in the following order: 1,8-naphthyridine > 1,6 > 1,7 > 1,5 (see<sup>‡</sup>).<sup>5,6</sup> High reactivity of benzo[*b*][1,8]naphthyridine (**5**) is attributed<sup>5</sup> to the proximity of the lone pairs of the N(1) and N(10) atoms involved in transition state **9** upon quaternisation of N(1). However, in the case of the benzo[*b*][1,5]-isomer **8** the reaction at N(1) is hindered by the H(10) atom in the *peri*-position.<sup>6,7</sup>

Such an interpretation seems to be reasonable enough, but it fails to provide an explicit answer to the question why the methylation rates of all benzonaphthyridines fit in the above-mentioned series. In our opinion, this problem requires an analysis of all initial and hypothetical transition states realised in the processes under consideration. For compound **5**, stabilised hypothetical transition state **9** is rather plausible despite certain instability of the initial state resulting from the interaction of the electron pairs at N(4) and N(5). A combination of these two factors leads to a general decrease in the free activation energy and

Received 2 March 2005

Uspekhi Khimii 74 (10) 1001–1024 (2004); translated by R L Birnova

<sup>†</sup> Intercalation entails insertion of compounds between base pairs of DNA; the complex formed is stabilised by van der Waals forces. Intercalation prevents unwinding of DNA chains and, as a consequence, their normal functioning.

<sup>‡</sup> Hereinafter, the isomers bear the numbers corresponding to those used to denote naphthyridines.

**Table 1.** Relative methylation rates of compounds **5–8** in comparison with pyridine.

| Compound | Isomer | $k_1/k_{Py}$ | Compound | Isomer | $k_1/k_{Py}$ |
|----------|--------|--------------|----------|--------|--------------|
|          | 1,8    | 0.325        |          | 1,6    | 0.265        |
|          | 1,7    | 0.169        |          | 1,5    | 0.010        |

thus determines the highest methylation rate of this particular isomer.

The methylation rate of the 1,6-isomer **7** is comparable with that of the isomer **5**.

The absence of conjugation between the electron-withdrawing double bond C(4a)=N(5) and the nitrogen atom at position 2 of compound **7** favours the electrophilic attack at this nitrogen atom in comparison with other benzonaphthyrindines (except for compound **5**). Neither stabilisation of the initial state nor destabilisation of the transition state take place in this case. The methylation rate of the 1,7-isomer **6** is even lower, since the conjugation between two double bonds C=N results in stabilisation of the initial state and destabilisation of the transition state.

This finding provides a rationale for the decrease in the methylation rate of compound **6** in comparison with other isomers considered above. Methylation of the tricycle **8** is controlled by the same factors. There exists yet another factor responsible for the lowering of the reactivity of 1,5-naphthyrindine (**8**) in comparison with the isomer **6**. The transition state of compound **8** can be presented as follows:

Apart from destabilisation induced by the electron-withdrawing effect (conjugation) of the C(4a)=N(5) bond, the stability of

the transition state is adversely affected by yet another factor, *viz.*, the nonbonding interaction between the N(1)⋯Me and C(10)–H bonds in *peri*-positions. It is this contributing evidence that sheds additional light on the lower (in comparison with the isomeric compound **6**) methylation rate of the tricycle **8**.

The electroreduction of 3-substituted 4-cyanobenzo[*b*][1,6]-naphthyrindine derivatives **10** in DMF was studied by polarography.<sup>8</sup> It was found that the first step of this reaction includes transfer of one electron to position 10 (analogously to reduction of acridine), which is consistent with the appearance of one-electron waves on the polarograms. It was found also that an increase in the electron-donor properties of the substituents at position 3 causes a shift of polarographic half-wave reduction potentials to negative values, *i.e.*, hinders reduction of the tricycles **10**.

X = NR<sup>1</sup>R<sup>2</sup>, SR<sup>1</sup>; R<sup>1</sup>, R<sup>2</sup> = Alk, Ar.

### III. Methods for synthesis

The most general approaches to the synthesis of benzonaphthyrindines are based on the methods used for the closure of the pyridine ring in the course of quinoline synthesis. The use of the Friedlander and Pfitzinger reactions and the synthesis based on arylaminopyridines enable the preparation of derivatives with functional groups at different positions of the tricyclic system.

#### 1. Friedlander reaction and its modifications

The Friedlander reaction is the most general and well-developed approach to the synthesis of various benzo[*b*]naphthyrindines. It is based on the reaction of *o*-aminoaryl(hetaryl)carbonyl compounds with methylene ketones.<sup>9</sup>

The Niementowski (R<sup>1</sup> = OH) and Pfitzinger (R<sup>1</sup> = CO<sub>2</sub>H) reactions are essentially very similar to the Friedlander reaction (the Pfitzinger reaction is more extensively used for the preparation of benzo[*b*][1,6]naphthyrindines).

The classical variant of the Friedlander reaction makes use of *o*-aminobenzaldehydes and basic catalysts (KOH, NaOH, piperidine, *etc.*), but this reaction can also be carried out in the absence of these catalysts. However, attempts to synthesise quinolines from less reactive *o*-aminobenzophenones under alkaline conditions are not always successful. In this case, the carbonyl group is activated by acids [HCl, H<sub>2</sub>SO<sub>4</sub>, TsOH, polyphosphoric acid (PPA), *etc.*]. Very often, the reaction is carried out by refluxing in AcOH in the presence of catalytic amounts of H<sub>2</sub>SO<sub>4</sub> (the so-called Fehnel modification<sup>10</sup>).

The formation of a pyridine ring in this reaction enables the synthesis of tricyclic benzonaphthyrindines. This can be accompanied by the closure of both the central (routes *a* and *b*) and peripheral pyridine rings (routes *c* and *d*).

Substituted 2-amino-3-formylpyridines **12a,b** are involved in the Friedlander reaction with cyclohexane-1,3-dione and cyclohexanone under conditions of basic catalysis giving rise to the 1,8-naphthyridine derivatives **13a,b** and **14**. Cyclisation of cyclohexane-1,3-dione occurs much more smoothly due to higher CH-acidity of the methylene fragment.<sup>11, 12</sup>

If *o*-aminoaldehyde is used in excess, the reaction with cyclohexane-1,3-dione does not stop at the formation of benzonaphthyridine **14**, but proceeds further eventually resulting in the pentacyclic product **15**.<sup>12</sup>

Shiozawa *et al.*<sup>13</sup> used 4-piperidones as ketone components in the synthesis of 2-benzyl-1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridine (**16**).

The reaction of 2-amino-3-formylpyridine with 2-methylcyclohexanone in the presence of 1,3,3-trimethyl-6-azabicyclo[3.2.1]octane (TABO) as the basic catalyst produced tetrahydrobenzo[*b*][1,8]naphthyridine **17**.<sup>14</sup> In earlier studies,<sup>15</sup> such conversion has been achieved by heating the reactants with sodium *tert*-butoxide in *tert*-butyl alcohol; the yield of naphthyridine **17** was 84%. Apparently, TABO is the catalyst of choice for the Friedlander reaction both by virtue of its high catalytic activity and optimum selectivity. This circumstance is of special importance in those cases where unsymmetrical ketones are used.<sup>14</sup>

idine **17** was 84%. Apparently, TABO is the catalyst of choice for the Friedlander reaction both by virtue of its high catalytic activity and optimum selectivity. This circumstance is of special importance in those cases where unsymmetrical ketones are used.<sup>14</sup>

The Friedlander synthesis based on aminoformylquinolines was successfully used for the preparation of benzo[*b*][1,5]naphthyridines and benzo[*b*][1,8]naphthyridines.<sup>16</sup> Thus 2-amino-3-formylquinoline **18** was introduced into base-catalysed cyclocondensation with diethyl malonate and aryl methyl ketones to give the corresponding benzo[*b*][1,8]naphthyridines **19** and **20** in good yields. The reaction with ethyl cyanoacetate gave a mixture of naphthyridines **21** and **22**.

Pip is piperidine.

3-Aminoquinoline-2-carbaldehyde (**23**) reacts with acetylacetone in the presence of piperidine to give 3-acetyl-2-methylbenzo[*b*][1,5]naphthyridine (**24**). The condensation of compound **23** with ethyl acetoacetate under identical conditions involves only the ketone carbonyl group, 3-ethoxycarbonyl-2-methylbenzo[*b*][1,5]naphthyridine (**25**) being the only reaction product.<sup>16</sup>

R = Me (**24**, 74%), OEt (**25**, 70%).

2-Aminobenzophenone reacts with quinuclidin-3-one under basic catalysis to give the benzo[*b*][1,5]naphthyridine derivative **26**.<sup>17</sup>

The Borsche modification of the Friedlander synthesis<sup>18</sup>, *i.e.*, the replacement of the aldehyde group with the azomethine fragment, enables the reaction to occur without complications due to low stability of substituted 2-aminobenzaldehydes at elevated temperatures. This reaction was used in the synthesis of benzonaphthyridine **27**.<sup>19</sup>

PMB is  $\text{CH}_2\text{C}_6\text{H}_4\text{OMe-4}$ .

The reactions of *vic*-aminobenzoylpyridines or *vic*-(pivaloyl-amino)benzoylpyridines with cyclohexanone were used in the synthesis of the corresponding tricyclic derivatives of 1,6- (**28**), 1,7- (**29**) and 1,8-naphthyridine (**30**) (70%–99% yields).<sup>20–22</sup>

R = H,  $\text{Bu}^t\text{CO}$ .

The Pfitzinger reaction<sup>23</sup> involves condensation of isatine and its derivatives with methylene ketones in the presence of bases (KOH, NaOH, *etc.*), which convert isatine into isatinates. The latter, being *o*-aminocarbonyl compounds, react further with ketones according to the Friedlander reaction.

Thus the use of 4-piperidone derivatives as a carbonyl component in the Pfitzinger reaction enables the one-pot synthesis of 1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridines in good yields. For example, refluxing of 7-methylisatine with 1-benzylpiperidin-4-one in ethanolic KOH affords 1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridine-10-carboxylic acid (**31**).<sup>24</sup>

The synthesis of benzo[*b*][1,6]naphthyridine derivatives containing an amide group at position 10 by the Pfitzinger reaction is carried out in the presence of ammonia or ammonium salts. Thus derivatives of 2-benzyl-1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridine-10-carboxamide (**32**) and 1,2,3,4-tetrahydro-2-ethoxycarbonylbenzo[*b*][1,6]naphthyridine-10-carboxamide (**33**) were prepared by passing ammonia through the reaction mixture containing 5-substituted isatines and 1-benzylpiperidin-4-one or 1-ethoxycarbonylpiperidin-4-one, respectively, in ethylene glycol at 150–160 °C.<sup>25</sup> The reaction of isatine with 1-*tert*-butoxycarbonylpiperidin-4-one proceeds in a similar fashion: heating in DMF with ammonium acetate affords 2-*tert*-butoxycarbonyl-1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridine-10-carboxamide (**34**) in 50% yield.<sup>26</sup>

R<sup>1</sup> = H, Cl, F, OMe; R<sup>2</sup> = Bn (**32**), CO<sub>2</sub>Et (**33**), CO<sub>2</sub>Bu<sup>t</sup> (**34**).

The approach employed in the synthesis of benzonaphthyridines, *i.e.*, reactions of substituted anthranilic acids and *o*-aminonitriles with cyclic ketones, is very similar to that underlying the Friedlander reaction. It is noteworthy that cyclisation reactions involving nitrile groups produce various amino derivatives of benzonaphthyridines (*i.e.*, aza analogues of 9-aminoacridines) that present substantial interest for biological investigations.

Heating of substituted anthranilic acids with *N*-alkyl- and *N*-arylpiperidin-4-ones in POCl<sub>3</sub> gave 2-substituted 10-chloro-1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridines **35**.<sup>27–30</sup>

R<sup>1</sup> = H, Alk, NO<sub>2</sub>, Hal; R<sup>2</sup> = Alk, Ar.

Analogously, heating of 2-aminonicotinic acid with cyclohexanone and POCl<sub>3</sub> affords 5-chloro-6,7,8,9-tetrahydrobenzo[*b*][1,8]naphthyridine (**36**).<sup>31–33</sup>

The synthesis of aminobenzonaphthyridines by reactions of *vic*-aminonitriles with cyclic ketones is of importance because it provides an approach to tetrahydro derivatives of 9-aminoacridine (aza analogues of the pharmaceutical tacrine). Heating of the reactants with Lewis acids (ZnCl<sub>2</sub>, AlCl<sub>3</sub>, TiCl<sub>4</sub>) affords complexes, which are decomposed by treatment with bases (NH<sub>4</sub>OH, aqueous NaOH). Thus reactions of 3-amino-4-cyanopyridine and 2-amino-3-cyanopyridine with cyclohexanone and TiCl<sub>4</sub> in dichloroethane give the corresponding 5-amino-6,7,8,9-tetrahydrobenzo[*b*]naphthyridines **37** and **38**. The tetracyclic 1,7- and 1,8-naphthyridine derivatives **39** and **40** were successfully synthesised,

although in lower yields, by the reactions of these compounds with norcamphor, which has a more rigid (in comparison with cyclohexanone) carbon skeleton.<sup>34</sup>

Pyrans **41** derived from ethyl acetoacetate and arylmethylidenemalononitriles underwent recyclisation under the action of ammonium acetate in acetic acid to yield the pyridine derivatives **42**. The resulting compounds containing cyano and amino groups in *vic* positions are involved in cyclocondensation with cyclohexanone in refluxing dichloroethane in the presence of  $\text{AlCl}_3$  to give the tricyclic 1,8-naphthyridine derivatives **43**.<sup>35,36</sup>

R = Ph,  $\text{C}_6\text{H}_4\text{OMe-4}$ ,  $\text{C}_6\text{H}_4\text{OMe-3}$ ,  $\text{C}_6\text{H}_3(\text{OMe})_2\text{-3,4}$ ,  
 $\text{C}_6\text{H}_4\text{F-4}$ ,  $\text{C}_6\text{H}_4\text{Cl-4}$ ,  $\text{C}_6\text{H}_4\text{NO}_2\text{-3}$ .

Cyclocondensation of 2-amino-4,6-diaryl nicotinonitriles with cyclohexanone in the presence of  $\text{ZnCl}_2$  gave 10-amino-1,3-diaryl-6,7,8,9-tetrahydrobenzo[*b*][1,8]naphthyridines in 57%–65% yields.<sup>37</sup>

In the presence of  $\text{ZnCl}_2$ , anthranilonitrile reacts with cyclic ketones, such as 1-*tert*-butoxycarbonylpiperidin-4-one and pseudopelletierine hydrochloride (**44**), to give the corresponding 1,6-naphthyridine derivatives **45** and **46**.<sup>26,30</sup>

Boc =  $\text{CO}_2\text{Bu}^t$ .

## 2. Cyclisation of arylaminopyridines

An efficient approach to the design of the benzonaphthyridine system is based on the synthesis involving arylaminopyridines whose aryl rings (less frequently, the pyridine ring) contain a group capable of providing intramolecular cyclisation. Arylaminopyridines are usually prepared by the replacement of good leaving groups in pyridine derivatives with arylamines as well as by the Ullman reaction.

### a. Cyclisation involving carbonyl groups of aldehydes, ketones and esters

*N,N*-Dimethylformamide dimethyl acetal (DMFDMA) reacts with *N*-aryleneamines **47** involving both the amide and reactive methyl groups to give mixtures of dieneamidines **48** and 1-arylpyrimidinones **49**.<sup>38</sup> Because of low stability of dieneamidines **48**, the resulting mixtures are subjected to acid hydrolysis in aqueous AcOH without separation; this resulted in mixtures of the corresponding formylpyridones **50** and pyridones **51**. The former can be easily isolated due to their lower solubility. Special studies have demonstrated that formylpyridones can be produced only from dieneamidines **48**, whereas hydrolysis of pyrimidinones **49** yields exclusively pyridones **51**.

Cyclisation of 4-arylamino-3-cyano-5-formylpyridones **50a,b** under the action of  $\text{POCl}_3$  in the presence of  $\text{Et}_3\text{N} \cdot \text{HCl}$  afforded 3-chloro derivatives of benzo[*b*][1,6]naphthyridine **52a,b**.<sup>38,39</sup>

The reactions of arylamines with pyridones **53** give the corresponding 4-arylaminopyridones **54**. These reactions can be performed in the presence of the corresponding arylamine hydrochloride.<sup>40,41</sup> Compounds **54** undergo regioselective formylation at position 3 activated by the arylamino group followed by cyclisation to give the corresponding benzo[*b*][1,6]naphthyridines **55** substituted in the benzene ring and at position 3.<sup>40,42</sup>

$R^1 = \text{H, 3-Cl, 3-OMe, 2,5-Me}_2$ ;  $R^2 = \text{H, Me}$ .

4-(2-Aminophenoxy)-3-benzoylpyridine (**56**) is unstable in both the solid state and in solution and is gradually isomerised into anilinyridine **57** as a result of the  $\text{O} \rightarrow \text{N}$ -Smiles rearrangement.<sup>43</sup> Heating of compound **56** in PPA leads to the rearrangement and subsequent cyclisation to give 6-hydroxy-10-phenylbenzo[*b*][1,6]naphthyridine (**58**).<sup>44</sup>

Heating of compounds **59** in diphenyl ether leads to its cyclisation to form benzo[*b*][1,7]naphthyridines **60**.<sup>45</sup>

$R = 2\text{-Cl (59), 4-OMe (59); 6-Cl (60), 8-OMe (60)}$ .

#### b. Cyclisation involving the carboxy group

The Ullman reaction was used in the synthesis of 2-(3,5-dimethoxyphenyl)aminonicotinic acid (**61**), which underwent cyclisation to form benzo[*b*][1,8]naphthyridinone **62** as a result of heating in PPA.<sup>46</sup>

Other benzo[*b*][1,8]naphthyridinone derivatives were prepared analogously from arylaminonicotinic acids.<sup>47,48</sup>

#### c. Cyclisation involving the nitrile group

Heating of starting compounds with strong acids is one of the most efficient procedures for the closure of the pyridine ring involving the nitrile group. Thus PPA can add to the nitrile group to give compounds **63**.<sup>49</sup> The latter can exist in equilibrium with iminocarbenium ions **64**, which are much more electrophilic than the starting imidoyl polyphosphates **63**.<sup>50</sup>

Concentrated  $\text{H}_2\text{SO}_4$  and  $\text{H}_3\text{PO}_4$  capable of activating the nitrile group through protonation can be used instead of PPA. However, the disadvantage of the use of PPA and  $\text{H}_2\text{SO}_4$  is that protonated amino derivatives produced upon cyclisation often undergo hydrolysis to give the corresponding oxo derivatives. Thus the reaction of substituted 2-chloro-3-cyanopyridine **65** with arylamines gives the corresponding 2-arylmino-3-cyanopyridines **66**. Heating of the latter in PPA leads to their cyclisation to form benzo[*b*][1,8]naphthyridinones **67**.<sup>51</sup>

$R^1 = \text{H, Me; } R^2 = \text{H, Me, Et}$ .

#### d. Cyclisation involving carbocations

5,10-Dihydro-5,5-dimethylbenzo[*b*][1,8]naphthyridine derivatives (**68**) were prepared by intramolecular cyclisation of the carbocations **69** generated *in situ* from alcohols **70** under the action of PPA.<sup>52</sup>

$R^1 = \text{H, Hal, OMe, OEt}; R^2 = \text{H, Cl, Me}.$

### 3. Annulation of the pyridine ring to the quinoline system

Annulation of the pyridine ring to substituted quinolines can be used as an alternative approach to the design of the benzonaphthyridine system.

Benzonaphthyridines can be prepared by the Skraup synthesis.<sup>53</sup> Thus annulated benzonaphthyridine **72** was synthesised starting from 2-aminobenzo[*f*]quinoline **71**. This reaction was carried out in the presence of an oxidant (nitrobenzenesulfonic acid) formed *in situ* upon the reaction of nitrobenzene with oleum.<sup>54</sup>

*N*-Arylamides (**73**) and nitriles (**74**) of 2-methylquinoline-3-carboxylic acid reacted with aromatic aldehydes on heating in *p*-xylene in the presence of piperidine as a base.<sup>55,56</sup> The  $\beta$ -aryl-vinyl derivatives **75** and **76** formed upon heating in PPA underwent cyclisation to form 3-phenyl-1-oxo-1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridines **77**.<sup>55,56</sup>

$R = \text{Ar, H}.$

Analogous cyclisation of 8-benzylidene-2-styryl-5,6,7,8-tetrahydroquinoline-3-carboxanilide giving rise to 6-benzylidene-2,3-diphenyl-1-oxo-1,2,3,4,6,7,8,9-octahydrobenzo[*b*][1,6]naphthyridine was performed by heating in PPA (80%–84%  $\text{P}_2\text{O}_5$ ) at 135 °C.<sup>57</sup>

Acylation of 2-amino-3-cyano-6,7,8,9-tetrahydroquinoline (**78**) with chloroacetyl chloride followed by the reaction with morpholine affords the morpholinoacetyl derivative **79**. Cyclisation of the latter under the action of sodium *tert*-butoxide yields benzo[*b*][1,8]naphthyridinone **80**.<sup>58</sup>

The piperidine-catalysed reaction of morpholinomethylene-cyclohexanone with the malononitrile dimer **81** and subsequent heating of the product in concentrated  $\text{H}_2\text{SO}_4$  gave the benzo[*b*][1,6]naphthyridine derivative **82**.<sup>59</sup>

Dimethoxyquinolines **83** containing the *vic*-amino and methoxycarbonyl groups were transformed into benzo[*b*][1,5]- and benzo[*b*][1,8]naphthyridinone derivatives **84** in two steps. The reactions of quinolines **83** with the DMF acetal gave amidines whose reactions with acetonitrile and *n*-butyllithium include nucleophilic substitution of the dimethylamino group for the acetonitrile anion and the Thorpe–Ziegler cyclisation. Butyllithium acted as a base abstracting the proton from the reactive methylene group and thus providing the closure of the pyridine ring.<sup>60</sup>

Condensation of 2-chloro-3-formylquinolines **85** with substituted acetonitriles in MeOH in the presence of MeONa yields the 2-chloro-3-cyanovinyl derivatives **86**.<sup>61</sup> The latter react with

secondary amines resulting in smooth cyclisation giving rise to the 2-aminobenzo[*b*][1,8]naphthyridine derivatives **87**.

$R^1 = R^2 = \text{H, OMe}$ ;  $R^3 = \text{C}_6\text{H}_4\text{Cl-4, SC}_6\text{H}_4\text{Cl-4}$ ;

$X = -\text{N}(\text{CH}_2)_2\text{CH}_2\text{CH}_2\text{N}-, -\text{N}(\text{CH}_2)_2\text{CH}_2\text{CH}_2\text{N}(\text{Me})-$

2-Chloro-3-cyanoquinoline (**88**) and trimethylsilylacetylene are involved in the Sonogashira reaction catalysed by  $\text{Pd}^0$  that is generated from  $\text{PdCl}_2(\text{PPh}_3)_2$  during the reaction. Subsequent elimination of the trimethylsilyl group in an alkaline medium gives rise to 3-cyano-2-ethynylquinoline **89**. The addition of (*S*)-phenylalaninol to the latter compounds and subsequent reduction of the double bond yield the amine **90**, whose refluxing in aqueous ethanol results in intramolecular cyclisation at the nitrile group and hydrolysis to give lactam **91** (the yield over two steps is 52%).<sup>62</sup>

$R = \text{CH}(\text{CH}_2\text{OH})\text{CH}_2\text{Ph}$ .

3-Formylchromone (**92**) containing three electrophilic centres, *viz.*, C(2), C(4) and CHO, reacts with 2-amino-1*H*-quinolin-4-one to give benzo[*b*][1,8]naphthyridinone **93**.<sup>63</sup> It is suggested<sup>63</sup> that 2-aminoquinolin-4-one in which position 3 is activated by the electron-donating amino group similarly to the  $\beta$ -position in enamines can undergo condensation at both the aldehyde group (which seems to be a more preferable route) and the C(2) atom of chromone **92** to give the intermediates **94** or **95**, respectively. In both cases, cyclisation of the addition products **94** and **95** gives benzonaphthyridinone **93**.<sup>63</sup>

Condensation of compound **96** with di-*tert*-butyl succinate in the presence of  $\text{Bu}^n\text{Li}$  yields a mixture of the corresponding diastereomeric alcohols **97** in 59% yield. Refluxing of these alcohols with HCl in dioxane leads to elimination of the protective *tert*-butoxycarbonyl group and cyclisation to form 3-carboxymethylbenzonaphthyridine **98**.<sup>64</sup>

Condensation of compounds **99** with dimethylformamide dimethyl acetal gave enamine. Transamination of the latter with methylamine resulted in the replacement of chlorine at position 2 of the quinoline ring and cyclisation to form the benzo[*b*][1,8]-naphthyridine derivative **100**.<sup>65–67</sup>

#### 4. Syntheses involving *ortho*-quinomethane intermediates

Syntheses of heterocycles involving intermediates having *o*-quinomethane or *o*-quinomethane imide structures (hereinafter referred to as quinomethanes) offer an original approach to the design of the benzonaphthyridine system. The literature term azaxylenes is, in our opinion, inappropriate as a synonym for *o*-quinomethane imides.

Amidine **101**, which was prepared by the reaction of 2-trifluoromethylaniline and the *N*-methylpiperidin-2-one complex with POCl<sub>3</sub>, reacted with sodium hexamethyldisilazide (NaHMDS) to give the tricyclic product **102**.<sup>68</sup>

In terms of the cyclisation mechanism proposed in,<sup>68</sup> the anion formed as a result of proton abstraction from amidine **101** under the action of a base loses the fluoride anion to give quinomethane **103**. Its cyclisation giving rise to the target tricyclic product **102** can occur by two different pathways: (a) through the electrocyclic reaction with subsequent nucleophilic substitution of fluorine for the amino group followed by aromatisation and elimination of HF; (b) through the addition of the Z<sup>−</sup> anion and elimination of the fluoride anion to give the target product **102**.

Hemiacetals **104** derived from the corresponding 4-hydroxypyridin-2-ones can be used as a source of quinomethanes.<sup>69, 70</sup> Heating of hemiacetals **104** leads to elimination of acetone to form quinomethane intermediates **105**, which react with aniline to give the tricyclic products **106**.

Tetracyclic derivatives of 1,6-naphthyridine were synthesised with the use of hemiacetals derived from 3-hydroxyquinolones as a source of quinomethanes. Elimination of acetone in this reaction was confirmed by the formation of the corresponding 2,4-dinitrophenylhydrazone.

Directed *ortho*-lithiation of 4-*tert*-butoxycarbonylamino-pyridine (**107**) and subsequent reactions of the lithium derivative with aldehydes yield alcohol **108**, which is further transformed into the benzo[*b*][1,6]naphthyridine derivative **109** by flash vacuum pyrolysis (FVP). Apparently, quinomethane intermediate **110** is involved in the formation of tricyclic product **109**.<sup>71</sup>

#### 5. Domino reactions

Domino reactions involve two or more transformations giving rise to new bonds (as a rule, C–C bonds). These reactions proceed under identical conditions without the addition of supplementary reagents or catalysts. Noteworthy, each subsequent reaction is triggered by a functional group generated in the previous step.<sup>72</sup> Only a few examples of the synthesis of benzonaphthyridines by domino reactions are known. Thus the piperidine-catalysed reaction of 2-aminobenzaldehyde with the malononitrile dimer **81** gives 1,3-diamino-2-cyanobenzo[*b*][1,8]naphthyridine (**110**).<sup>73</sup>

4-Amino-3-cyano-2-methylthioquinoline (**111**) reacts with two molecules of dimethyl acetylenedicarboxylate (DMAD) in the presence of K<sub>2</sub>CO<sub>3</sub> or K<sub>3</sub>PO<sub>4</sub>·H<sub>2</sub>O to give tetramethyl 1*H*-quinolino[2,3,4-*de*][1,6]naphthyridine-2,3,5,6-tetracarboxylate (**112**).<sup>74</sup> The mechanism of this reaction can be presented as follows: the addition of DMAD to the amino group, proton abstraction from the activated methylene group under the action of a base and, finally, cyclisation involving the nitrile group. The addition of the second DMAD molecule to the amino group of the naphthyridine derivative thus formed is followed by cyclisation involving the activated methylene group and the replacement of the good leaving group MeS.

## 6. Other transformations of heterocycles producing benzo[b]naphthyridines

The synthesis of benzonaphthyridine derivatives by recyclisation of other heterocyclic systems is an efficient approach to the synthesis of compounds many of which are otherwise inaccessible.

The ability of  $8\pi$ -electron systems containing divalent sulfur to be transformed into more stable aromatic compounds in the course of thermal rearrangement accompanied by the removal of sulfur from the ring is well known.<sup>75</sup> This principle underlies the synthesis of benzo[b][1,5]naphthyridine derivatives generated *in situ* from the corresponding fused 1,4-thiazepines. Thus the reaction of 3-amino-2-chloropyridine with cyclohexanone diethyl ketal gives imine **113**. Lithiation of the latter with lithium diisopropylamide (LDA) and subsequent treatment with  $\text{ArC(S)OEt}$  afford 10-aryl-6,7,8,9-tetrahydrobenzo[b][1,5]naphthyridines **114**. In all probability, this reaction entails sequential addition of the lithiated imine to  $\text{ArC(S)OEt}$ , closure of the 1,4-

$\text{Ar} = 4\text{-XC}_6\text{H}_4$  ( $\text{X} = \text{Cl}, \text{MeO}, \text{Me}$ );

thiazepine ring and extrusion of sulfur from the  $8\pi$ -electron system of the intermediate **115** giving finally benzonaphthyridines **114**.<sup>76</sup> Apparently, this approach can be used in the synthesis of both 1,5-naphthyridines and other isomers.

The reaction of *N*-(4-methoxybenzyl)anthranilamide (**116**) with *N*-methylpiperidin-4-one yielded spiro[piperidine-4,2'-(1',2',3',4'-tetrahydroquinazolinone)] (**117**), whose refluxing with acetic anhydride and pyridine in xylene led to recyclisation to form benzonaphthyridine **118**.<sup>77</sup>

Earlier study has shown<sup>78</sup> that *N*(3)-substituted and *N*(1),*N*(3)-disubstituted spiro compounds that are structurally similar to quinazoline **117** do not react under these conditions. At the same time, the spiro compound in which both atoms in the quinazoline ring are devoid of substituents was transformed into quinazolinone. The benzonaphthyridine structure was prepared exclusively from *N*(1)-substituted compounds.<sup>78</sup> Based on these findings, a mechanism for the rearrangement of compounds **117** into **118** has been proposed. Its first step involves acylation of the lactam NH group.

Heating of diazepine **119** in 40% HBr leads to demethylation along with recyclisation to give benzo[b][1,6]naphthyridinone **120**. It may be assumed that hydrolytic cleavage of the diazepine ring in acidic media affords the intermediate **121** which contains an  $\alpha,\beta$ -

Scheme 1

unsaturated ketone fragment. This compound is transformed into the *trans*-isomer **120** through the intramolecular Michael addition involving the NH group and the  $\beta$ -carbon atom of the acryloyl fragment.<sup>79</sup>

Arylmethylidenemalononitriles **122a,b** react with dimedone to give Michael addition products which undergo spontaneous cyclisation to form 4*H*-pyrans **123a,b**. Reactions of the latter with benzylidenemalononitrile in the presence of catalytic amounts of piperidine at 160 °C afforded benzonaphthyridines **124a,b**.<sup>80</sup> In the authors' opinion, this reaction proceeds *via* the intermediate formation of compounds **125a,b** and **126a,b**. An analogous rearrangement concomitant with the formation of 1,6-naphthyridine derivatives has been reported.<sup>81</sup> It is noteworthy that this reaction is accompanied by aromatisation of the 1,4-dihydropyridine fragment (Scheme 1).

Ethyl (3-carboxy-8-methylquinolin-2-yl)acetate (**127**) undergoes cyclisation to form 4-dimethylaminomethylidene-6-methyl-4*H*-pyrano[4,3-*b*]quinoline-1,3-dione (**128**) by the Vilsmeier reaction. Heating of the latter with POCl<sub>3</sub> results in its transformation into 1,2-dihydro-2,6-dimethyl-1-oxo-benzo[*b*][1,6]naphthyridine-4-carboxylic acid (**129**).<sup>82</sup>

An analogous POCl<sub>3</sub>-induced transformation has been described for homophthalic acid and its methyl ester.<sup>83</sup> Based on these data, the following reaction mechanism for the synthesis of benzonaphthyridine **129** can be proposed. Cyclisation of dicarboxylic acid **127** into anhydride **130** is followed by electrophilic addition of the Vilsmeier reagent to form enamino anhydride **128**. *o*-Acylation of the latter with POCl<sub>3</sub> and cleavage of the C–O bond yield the acylium cation **131**, which can undergo cyclisation involving the dimethylamino group to give the intermediate **132**. Subsequent elimination of MeCl and hydrolysis afford benzonaphthyridine **129**.

## 7. Other methods

The reaction of the *N*-methylpiperidin-2-one–POCl<sub>3</sub> complex (**133**) with the methyl 4-nitroanthranilate (**134**) gives amidine **135**. Heating of the latter in the presence of TsOH results in cyclisation to form benzonaphthyridinone **136**. Analogous cyclisation takes place in the Friedlander reaction.<sup>84</sup>

The addition of *N,N*-dimethyldichloromethyleneimmonium chloride to *N*-methylpiperidin-2-one gives the salt **137**. The reaction of the latter with aniline proceeds selectively and is

accompanied by the replacement of chlorine at the C(2) atom followed by cyclisation to form benzonaphthyridine **138**.<sup>85, 86</sup>

A procedure for the synthesis of benzonaphthyridines based on cycloaddition of arynes to 1,4-dipolar compounds was developed. The *N*-lithium derivative of methyl 2-(trimethylsilylamino)-nicotinate **139** reacts with dehydrobenzene, which is generated *in situ* from bromobenzene in the presence of a base, under mild conditions to give benzo[*b*][1,8]naphthyridinone **140**. 6-Methoxybenzonaphthyridinone **141** was isolated as the only product from 3-methoxydehydrobenzene derived from 3-bromoanisole.<sup>87</sup> High regioselectivity of this reaction testifies that the process occurs by a concerted mechanism.<sup>88</sup>

Ar = Ph, MeOC<sub>6</sub>H<sub>4</sub>Br-3.

The conversion of 3-(*N,N*-diallylamino)quinoline into the benzo[*b*][1,5]naphthyridine derivative **142** was carried out under a CO atmosphere using Co<sub>2</sub>(CO)<sub>8</sub> as a catalyst. Analogously, *N,N*-diallylaniline is transformed under the action of CO and Co<sub>2</sub>(CO)<sub>8</sub>, the mechanism of transfer of the allylic groups between the substrate molecules being confirmed for this process.<sup>89</sup>

The reaction of *N*-alkylisatin anhydrides **143** with the lithium derivative of enamine **144** was used for the preparation of benzo[*b*][1,8]naphthyridinones **145**.<sup>90</sup> Presumably, the addition of enamine **144** to the C(4)-carbonyl group of isatin anhydride derivatives gives the intermediates **146**, which can be further transformed into the tricyclic derivatives **147** with elimination of the CO<sub>2</sub> molecule. After elimination of MeSH, these compounds are transformed into benzonaphthyridinones **145**.<sup>90</sup>

R<sup>1</sup> = Me, Bn; R<sup>2</sup> = H, Cl; R<sup>3</sup> = H, Me.

1,2,3,4,6,7,8,9-Octahydrobenzo[*b*][1,6]naphthyridine (**148**) was synthesised starting from 2-aminomethylidenecyclohexanone, 1-benzylpiperidin-4-one and ammonium acetate.<sup>13</sup>

A procedure was proposed for the synthesis of dibenzo[*b,h*]-[1,6]naphthyridines based on the BiCl<sub>3</sub>-catalysed hetero-Diels–Alder reaction involving the aryl ring as a component of the diene system.<sup>91</sup> Cyclisation of aldimines generated *in situ* from anilines **149a–h** and the *N*-allylic derivative of *o*-aminobenzaldehyde **150** affords a mixture of the diastereomers **151a–h** and **152a–h** in a 1 : 1 ratio in 90%–96% yields.<sup>92</sup>

R<sup>1</sup> = R<sup>2</sup> = H (**a**); R<sup>1</sup> = Me, R<sup>2</sup> = H (**b**); R<sup>1</sup> = Br, R<sup>2</sup> = Me (**c**);  
R<sup>1</sup> = H: R<sup>2</sup> = OMe (**d**), Cl (**e**), F (**f**), Me (**g**);  
R<sup>1</sup> = OH, R<sup>2</sup> = H (**h**).

Cyclisation of (*S*)-*N*-(1-(4-methylpent-3-enyl)pyrrolidin-2-yl)methylidene)toluidine (**153**), which is catalysed by Lewis and Brønsted acids (FeCl<sub>3</sub>, SnCl<sub>4</sub>, BF<sub>3</sub>·Et<sub>2</sub>O, TsOH, CF<sub>3</sub>CO<sub>2</sub>H, SnCl<sub>4</sub>, AlCl<sub>3</sub>, EtAlCl<sub>2</sub>, Et<sub>2</sub>AlCl, MeAlCl<sub>2</sub>, Me<sub>2</sub>AlCl), yields tetracyclic decahydro-7,7,4-trimethylindolizino[3,4-*b*]quinolines **154a,b** (79%–84% total yields). Only two out of four possible

isomers are formed under these conditions. The ratios of the isomeric products depend on the coordination number of the acidic catalyst. Monodentate Brønsted and Lewis acids as well as octahedral bidentate Lewis acids yield predominantly the *trans,trans*-product **154b**, whereas tetrahedral aluminium Lewis acids give the *cis,cis*-product **154a**.<sup>93</sup>

A stepwise mechanism involving the imino group was proposed for cyclisation of compound **153**. Within the framework of this mechanism, complete inversion of the configuration occurs due to the presence of the nitrogen atom in the pyrrolidine ring capable of complex formation.<sup>93</sup>

Reduction of 2-fluoro-3-(2-nitrobenzoyl)pyridine (**155**) by hydrogen over Pd/C yields the amino derivative **156**, which undergoes spontaneous cyclisation to give benzonaphthyridinone **157**.<sup>22</sup>

Addition of 2-chloronicotinoyl chloride to morpholinocyclohexene yields enamino ketone **158**, which is involved in the reactions with arylamines accompanied by cyclisation to form the 1,8-naphthyridine derivatives **159**.<sup>94</sup> It is of note that this process occurs both through transamination of the enamino ketone **158** with arylamine followed by cyclisation and replacement of chlorine at position 2 of the pyridine ring and through the primary replacement of chlorine by the arylamine fragment with subsequent intramolecular transamination and elimination of morpholine.

Mor is ; Ar = XC<sub>6</sub>H<sub>4</sub> (X = 3-MeO, 3-Cl, 2-Cl, 3-NO<sub>2</sub>), 3-Py.

Moderate yields of the target products **159** are partly due to hydrolysis of enamines and a side process involving cyclisation of enamino ketone **158** to give the spiro intermediate **160**. Treatment of the latter with nucleophilic reagents eventually results in its conversion into the acridine derivatives **161** containing an *N*-alkyl substituent.<sup>94</sup>

#### IV. Chemical properties

The chemical properties manifested by benzonaphthyridines are equally characteristic of acridine derivatives and the corresponding naphthyridines.

## 1. Oxidation and dehydrogenation

This section contains information concerning oxidation of benzonaphthyridines and their di- and tetrahydro derivatives that yields fully aromatic tricycles.

Four isomeric 6-methylbenzo[*b*]naphthyridines **5–8** were treated with a basic solution of silver oxide at 20 °C for 30 min. The structures of the reaction products were established by <sup>1</sup>H NMR spectroscopy. The processes associated with such

oxidation were found to depend on the structures of isomeric substrates. The methyl group can be oxidised to the formyl group (compound **8**) or the carboxy group (for all isomers).

The abilities of compounds **5–8** to be oxidised can be compared using oxidation at position 10 as a criterion. The reactivities of the isomeric compounds change in the following order: **7** (1.6) > **5** (1.8) > **6** (1.7) > **8** (1.5).<sup>5</sup> The difference in stability of the radical cations **A–D** generated upon oxidation of the isomeric compounds **5–8** can in principle be regarded as the determining factor.

However, this experimental material is insufficient for adequate interpretation of the available data.<sup>5</sup> Therefore, in this review we simply cite the results of investigations.

5,10-Dihydrobenzo[*b*][1,8]naphthyridine (**162**) is rapidly oxidised under the action of a chromic mixture to give benzo[*b*][1,8]-naphthyridine (**4**).<sup>24</sup>

Debenzylation, decarboxylation and dehydrogenation of benzonaphthyridine **31** were successfully combined by refluxing with 10% Pd over activated carbon in diphenyl ether.<sup>24</sup>

However, an attempt to perform dehydrogenation of 6,7,8,9-tetrahydrobenzo[*b*][1,8]naphthyridine (**163**) by heating over 20% Pd/C gave a mixture of compounds **164** and **162**. The product **162** was obtained as the major one at higher temperatures.<sup>95</sup>

Dehydrogenation of 6-methyl-6,7,8,9-tetrahydrobenzo[*b*]-[1,5]naphthyridine achieved by heating with 10% Pd/C in biphenyl afforded a fully aromatic tricycle in 76% yield.<sup>15</sup>

Potassium ferricyanide or bispyridine silver(I) permanganate (BPSP) was used as an oxidant for the transformation of 5,10-dihydrobenzo[*b*][1,6]naphthyridine **165** into the corresponding aromatic heterocycle **166**.<sup>96</sup>

Oxidation of 6-methyl-9-nitrobenzo[*b*][1,6]naphthyridine (**167**) by a chromic mixture occurred at the methyl group without affecting position 10 and yields 9-nitrobenzo[*b*][1,6]naphthyridine-6-carboxylic acid (**168**). The latter was oxidised with sodium chlorite at 20 °C for 4 days to give the 10-oxo derivative **169**.<sup>24</sup>

Oxidation of benzonaphthyridines by peroxy acids is often accompanied by transformations of the heterocyclic system. Thus oxidation of benzo[*b*][1,8]naphthyridine (**4**) with peracetic acid occurred at the nitrogen atom of the peripheral pyridine ring to yield *N*-oxide **170**.<sup>93</sup> This was concomitant with competitive reactions yielding the oxazepine derivatives **171** and **172** and aldehyde **173**. The latter seems to be formed as a result of opening of the oxazepine ring in the compound **171**.<sup>93</sup> The reactions of 1,8-naphthyridine<sup>97</sup> and acridine<sup>98</sup> with peroxy acids were not accompanied by expansion of the pyridine ring to the oxazepine ring. However, oxidation of acridine by perbenzoic and *m*-chloroperbenzoic (MCPBA) acids yielded a mixture of acridine *N*-oxide and 2-(2-hydroxyanilino)benzaldehyde analogous to compound **173**.

Oxidation of benzo[*b*][1,8]naphthyridine (**4**) by MCPBA gives a mixture of the products **174** and **175**; their ratio depends on the reaction temperature.

R = C<sub>6</sub>H<sub>4</sub>Cl-3.

Benzonaphthyridinone **176** is oxidised by MCPBA in non-aqueous media to give dioxo lactam **177** or, in the presence of water, hydroxyoxo lactam **178**.<sup>99</sup>

A mechanism for oxidative cleavage of benzonaphthyridinone **176** has been proposed that involves the formation of lactams **177** and **178** in the presence and absence of water.<sup>99</sup>

Ar = C<sub>6</sub>H<sub>4</sub>Cl-3.

Oxidation of 3-chloro-4-cyanobenzo[*b*][1,6]naphthyridine (**179**) by hydrogen peroxide in acetic or propionic acid afforded the corresponding ethers **180a,b** and a small amount of the 10-oxo derivative **181**.<sup>100</sup> Oxidation of the compound **179** by MCPBA in aqueous AcOH at 20 °C gave the acyloxy derivative **182** and trace amounts of the products **180a** and **181**. This reaction performed in

R<sup>1</sup> = Me (**a**), Et (**b**); R<sup>2</sup> = C<sub>6</sub>H<sub>4</sub>Cl-3.

refluxing acetone gave the 10-oxo derivative **181** as the only product.<sup>96</sup>

Most probably, the transformation of the starting compound **179** into the acyloxy derivatives **180a,b** and **182** under the action of MCPBA occurs *via* N(5)-oxidation (oxidation of the nitrogen atom in the peripheral pyridine ring is hindered due to the presence of electron-withdrawing substituents). The resulting N(5)-oxide intermediate readily add acyloxy anions and water to give the products **180a,b**, **181** and **182**.

The mechanisms of action of NADH-containing coenzymes in stereospecific biochemical reactions formed the basis of the biomimetic approach to the design of novel chiral NADH mimetic agents of the benzo[*b*][1,6]naphthyridine series. The derivatives **183a–f** (Table 2) were used for stereoselective reduction of the oxo groups of methyl mandelate and 2-benzoylpyridine.<sup>101</sup>

**Table 2.** Reduction of the oxo groups of methyl mandelate and 2-benzoylpyridine by compounds **183a–f**.<sup>101</sup>

The data listed in Table 2 suggest that the compounds **183f** (*ee* 87%) and **183c** (*ee* 84%) are stereoselective reagents of choice for reduction of methyl mandelate and 2-benzoylpyridine, respectively. Both reactions were carried out in the presence of Mg(ClO<sub>4</sub>)<sub>2</sub>, which is thought to be involved in the formation of the triple **183a–f**–Mg<sup>2+</sup>–substrate complexes (**A** and **B**).<sup>101</sup>

## 2. Reduction and hydrogenation

Treatment of 6-methylbenzo[*b*][1,6]naphthyridine (**7**) with hydrochloric acid in the presence of Pd/C is accompanied by reduction of the central ring to form the derivative **184**.<sup>24</sup>

As expected, reduction of benzonaphthyridinium salts occurs more smoothly than reduction of the corresponding bases. Sodium dithionite was used for reduction of the benzonaphthyridinium salts **185a,b** at 20 °C.<sup>62, 101</sup>

$\text{R} = \text{H}$  (**a**),  $\text{Me}$  (**b**).

### 3. Substitution reactions

Data on the electrophilic substitution in benzonaphthyridines are scarce. It is known that nitration of benzonaphthyridines by a  $\text{HNO}_3$ – $\text{H}_2\text{SO}_4$  mixture occurs exclusively in the benzene ring. Thus nitration of 6-methyl-(**7**) and 6-carboxybenzo[*b*][1,6]naphthyridines (**186**) gives the corresponding 9-nitro (**187**, 78%) and 8-nitro derivatives (**188**, 82%).<sup>24</sup>

Nitration of 9-methylbenzo[*b*][1,8]naphthyridine (**5**) and 6-methylbenzo[*b*][1,5]naphthyridine (**8**) occurs analogously. In these reactions, the nitro group is also attached to the benzene ring in the *para* position with respect to the methyl substituent.<sup>15</sup>

Nitration of 5,10-dihydro-9-carboxy-5-oxobenzo[*b*][1,8]naphthyridine by a nitrating mixture at 20 °C gave the 7-nitro derivative **189**.<sup>102</sup>

At the same time, isomeric 6-methylbenzo[*b*]naphthyridines **5–8** are brominated at the peripheral pyridine ring in the  $\beta$ -position with respect to the nitrogen atom (rather than at the benzene ring).<sup>5</sup>

This reaction pathway cannot be explained in terms of the electrophilic substitution mechanism [aromatic  $\text{S}_\text{E}(\text{AE})$ ]. In this case, the behaviour of benzonaphthyridines **5–8** is similar to that of quinoline and isoquinoline. Bromination of the latter in weakly acidic media also occurs at the pyridine ring in the  $\beta$ -position with respect to the nitrogen atom rather than at the benzene ring. The mechanism for bromination of these compounds, which entails nucleophilic addition–elimination [ $\text{S}_\text{N}(\text{AE})$ ], was proposed.<sup>103</sup>

Nucleophilic substitution of hydrogen ( $\text{S}_\text{N}^\text{H}$ ) is widely used in the synthesis of heterocycles and for the introduction of various substituents into  $\pi$ -electron-deficient heterocycles.<sup>104–107</sup> The  $\text{S}_\text{N}^\text{H}$  reactions were well studied for benzo[*b*][1,6]naphthyridine derivatives in which position 10 is depleted of electrons as a result of the unidirectional electron-withdrawing effect of both nitrogen atoms. The latter created a prerequisite for the nucleophilic addition at this position.

In the absence of bases, 3-chloro-4-cyanobenzo[*b*][1,6]naphthyridine (**179**) adds thiols at position 10 to give stable products **190a–c** even at 20 °C. The reaction of the compound **179** with thiols in the presence of a basic catalyst ( $\text{AcONa}$ ) yields sulfides **191a–c**.<sup>100</sup> Reversibility of the addition of thiols to the tricyclic compound **179** can be illustrated by the following experiment. Heating of compound **190b** with sodium acetate as a base in isopropyl alcohol resulted in its conversion into sulfide **191b**.

$\text{R} = \text{Ph}$  (**a**),  $\text{CH}_2\text{CO}_2\text{Et}$  (**b**),  $\text{CH}_2\text{CONHPh}$  (**c**).

Evidently, the reaction involves abstraction of the NH proton and elimination of the thiolate anion under the action of a base followed by slower, albeit irreversible substitution of chlorine at position 3 for the thiol residue.<sup>100</sup>

The reaction of benzonaphthyridine **179** with various C-nucleophiles yielded the addition products **192a–d** at position 10. Compounds with strong C–H-acidic properties, such as malononitrile and dimedone, and electron-rich aromatic compounds,

such as indole and *N,N*-diethylaniline, were used as C-nucleophiles.

The reaction of benzonaphthyridine **179** with aniline gave a mixture of C–C- (**193**) and C–N-addition (**194**) products. Thus aniline manifested dual reactivity by reacting with the substrate both as a C- and N-nucleophile.

At the same time, reactions of compound **179** with more basic arylamines, *e.g.*, *p*-toluidine and *p*-anisidine, and aliphatic alkyl- and dialkylamines were accompanied by the replacement of chlorine at position 3.<sup>8, 100</sup>

Dimethylacetamide acetals, which can act as C-nucleophiles due to equilibrium between amidoacetals **195**, their ionised forms **196** and  $\alpha$ -alkoxy enamines **197**, were studied as nucleophilic reagents in a reaction with the tricyclic compound **179**.

R = Me, Et.

However, the reactions of compound **179** with acetals **195** gave the 3-dimethylamino derivative **198** as the only product.<sup>96</sup> The latter was also synthesised by the reaction of the chloro derivative **179** with dimethylformamide dimethyl acetal, which excludes its involvement in the reactions with  $\alpha$ -alkoxy enamine **197**. Evidently, the latter reaction involves hetarylation of amidoacetals by the compound **179**. The reaction of enamine **197** with DMF diethyl acetal results in elimination of ethyl acetate (identified by GLC) due to dealkylation of the diethoxycarbenium ion A, which is produced upon arylation and then easily splits the corresponding alkyl halide.

R<sup>1</sup> = H, Me; R<sup>2</sup> = Me, Et.

2,6-Dimethylbenzo[*b*][1,6]naphthyridinium iodide (**199**) in DMSO is easily dimerised to form compound **200**. The structure

of the latter was established by X-ray diffraction analysis. Dimerisation is markedly accelerated in the presence of water. Apparently, water can add to the cation **199** to give pseudobase **201**. The latter can be deprotonated to give the intermediate **202**. The dimer is formed through the addition of the intermediate **202** at electron-deficient position 10 of the cation **199**. Subsequent elimination of water and oxidation afford the dication **200**.<sup>5</sup>

#### 4. Deacylation and dealkylation

Considering that many synthetic processes produce benzonaphthyridines containing alkyl or acyl substituents at the pyridine nitrogen atom, it is necessary to get a better insight into the mechanism of their elimination. Thus the acyl group of tetrahydrobenzo[*b*][1,6]naphthyridines is easily eliminated under conditions of acid or alkaline hydrolysis to give deacylation products in nearly quantitative yields.<sup>30</sup> The protective 4-methoxybenzyl group in compounds **203** can smoothly be removed under oxidative conditions; this affords debenzilation products **204** in good yields.<sup>19</sup>

R = H (72%), Me (67%).

The benzyl group in compounds **205** and **206** is not activated by electron-donating substituents and it was removed by hydrogenation over Pd/C. This approach was used for the preparation of the debenzylated tetrahydro derivatives of benzo[*b*][1,7]-(**207**) (see Ref. 45) and benzo[*b*][1,6]naphthyridines **208**.<sup>30</sup>

R = 7-F, 7-OMe, 8-F, 8-OMe.

### 5. Synthesis of bis(benzo[b]naphthyridines)

Biological (mostly antitumour and antiacetylcholinesterase) properties of dimeric derivatives of acridine and its aza analogues, *viz.*, benzo[b]naphthyridines, have been studied extensively in the past decade. Reactions of the corresponding 10(5)-chlorobenzonaphthyridines with alkylenediamines or reactions of alkylene dihalides with the corresponding 10(5)-aminobenzonaphthyridines are used in the synthesis of bis(aminobenzonaphthyridines). However, the yields of the target products are rather low.

The tricyclic compounds **209** and **210** were used as the starting reagents in the synthesis of *N,N'*-bis(benzo[b][1,8]naphthyridin-5-yl)- $\alpha,\omega$ -alkylenediamines **211** and  $\alpha,\omega$ -bis(5,10-dihydro-5-oxo-benzo[b][1,8]naphthyridin-10-yl)alkanes **212**. These reactions were carried out under phase-transfer catalysis conditions using tetrabutylammonium bromide (TBAB) as a catalyst.<sup>108</sup>

$n = 3, 6, 8, 10$ .

$n = 3, 6, 8, 10$ .

The synthesis of a series of *N,N'*-bis(6,7,8,9-tetrahydrobenzo[b][1,8]naphthyridin-5-yl)- $\alpha,\omega$ -alkylenediamines containing polymethylene chains of different length was also documented.<sup>31–33</sup>

Dimeric benzo[b][1,5]naphthyridines **214a–d** were synthesised by the reactions of 7,10-dichlorobenzonaphthyridine **213** with di- and polyamines.<sup>109</sup>

X = CH<sub>2</sub>CH(OH)CH<sub>2</sub> (**a**), (CH<sub>2</sub>)<sub>3</sub>NH(CH<sub>2</sub>)<sub>3</sub> (**b**), (CH<sub>2</sub>)<sub>4</sub>NH(CH<sub>2</sub>)<sub>3</sub> (**c**), (CH<sub>2</sub>)<sub>3</sub>NH(CH<sub>2</sub>)<sub>4</sub>NH(CH<sub>2</sub>)<sub>3</sub> (**d**).

Aminobenzonaphthyridines linked to other heterocycles through a flexible chain are synthesised in a similar way.<sup>26, 110</sup>

## V. Biological activity

### 1. Antimicrobial activity

The Chinese antimalarial drug pyronaridine (**215**) is related to the class of benzo[b][1,5]naphthyridine derivatives. Its preclinical trials demonstrated its safety and high activity against *Plasmodium falciparum* and *P. vivax*.<sup>111, 112</sup> The clinical efficiency of pyronaridine against the chloroquine (**216**) resistant strain of *P. falciparum*, *P. ovale* and *P. malariae* was established in studies with human volunteers from Thailand and Cameroon.<sup>113–115</sup> The antimalarial activities of pyronaridine and other drugs were compared in *vitro* studies on clinically isolated malarial strains obtained from Cameroon, Gabon and Senegal.<sup>116–120</sup> An HPLC procedure for measuring pyronaridine levels in human blood plasma samples and in different drug forms has been developed.<sup>121</sup> *In vitro* studies demonstrated synergism between pyronaridine **215** and primaquine **217**.<sup>116</sup>

A more long-lasting pharmacological effect of pyronaridine in comparison with amodiaquine (**218**), tebuquine (**219**) and other antimalarial drugs related to the group of Mannich monobases

can be attributed to its higher lipophilicity and, as a consequence, higher ability to be accumulated in tissues.<sup>122</sup>

| Drug         | Distribution coefficient<br>in octanol–water (log <i>P</i> ) |        |
|--------------|--------------------------------------------------------------|--------|
|              | pH 5.0                                                       | pH 7.4 |
| Pyronaridine | −0.88                                                        | 0.34   |
| Amodiaquine  | −1.16                                                        | 0.93   |
| Tebuquine    | 0.99                                                         | 1.08   |

A series of benzo[*b*][1,8]naphthyridine-based antimicrobial agents highly active against multiresistant Gram-positive pathogens, including *Staphylococcus aureus* (MRSA), have been synthesised. These substances did not exhibit cross-resistance against the major classes of antimicrobial drugs (quinolones,  $\beta$ -lactams, *etc.*). The 50% inhibitory concentration ( $IC_{50} = 0.25–2$  mg litre<sup>−1</sup>) was established *in vitro* for the most reactive compound, RP60556A (**220**); its *in vivo* activity upon topical use in a model of skin infection (*Staphylococcus aureus*) in guinea pigs was found to be similar to that of mupirocin (**221**).<sup>65</sup>

## 2. Anticholinesterase activity

The use of drugs related to the class of acetylcholinesterase inhibitors (tacrine, amiridine) is chronologically the earliest and most well-developed approach to the use of adjuncts to control an attack of neurodegenerative diseases (*e.g.*, Alzheimer's disease).<sup>123, 124</sup> The disadvantage of this class of medicinal drugs is that they are low selective acetylcholinesterase (AChE) inhibitors (compared to butyrylcholinesterase (BChE) inhibition), which evokes undesirable side effects. A series of investigations are devoted to the synthesis of tricyclic aza analogues of tacrine (**222**) and analysis of their anticholinesterase properties. 1,7-Naphthyridine **223**,<sup>34, 45, 125</sup> 1,6-naphthyridine **224** (see Ref. 25) and 1,8-naphthyridine **225** derivatives were synthesised and studied.<sup>35</sup> The  $IC_{50}$  values of compounds **223** lie in the range 0.06 ( $R = 8\text{-Cl}$ )–0.5 ( $R = 8\text{-OMe}$ ) mM, the tacrine activity being 0.19 mM. The presence of a substituent at position 8 (corresponding to position 6 of tacrine) improves the inhibiting properties.<sup>45</sup> 1,6-Naphthyridines **224** have much lower affinity for the enzyme in comparison with tacrine. The  $IC_{50}$  of the most efficient of those, *viz.*, ( $R = H$ ), was = 0.86 mM, *i.e.*, about four times lower in comparison with tacrine.<sup>25</sup> Naphthyridine **225** approached tacrine in terms of anti-AChE activity, but strongly exceeded it in selectivity (AChE/BChE).<sup>35, 36</sup> Compounds of the type **225** also manifested the properties of L-type calcium channel blockers.<sup>36</sup>

Compounds exhibiting a higher AChE inhibition level *in vitro* and higher [in comparison with tacrine (**222**)] anti-AChE selectivity with respect to butyrylcholinesterase (BChE) were identified among other dimeric tetrahydroacridine derivatives (tacrine analogues) and 5,7,8,9-tetrahydrobenzo[*b*][1,8]naphthyridine derivatives. The optimum length of the polymethylene bridge was 7 methylene units.<sup>31</sup>

## 3. Antitumour activity

Antitumour activity of 9-aminoacridine derivatives is closely connected with the intercalation characteristic of many planar ionisable systems. The drug amsacrine (**226**) (see Ref. 126) is an example.

A series of compounds the acridine system in which was modified by the insertion of an additional nitrogen atom into the benzene ring have been synthesised in an attempt to search for novel promising medicinal drugs endowed with antitumour activities. The same approach was used in the synthesis of amsacrine aza analogues **227**.<sup>127</sup>

The antitumour properties of benzonaphthyridines have also been studied. Some of these compounds manifested antitumour properties *in vitro*<sup>32, 47, 102, 109, 127</sup> and *in vivo*.<sup>102</sup> Dimeric intercalators based on *N,N'*-bis(benzonaphthyridine)- $\alpha,\omega$ -alkylenediamines manifested higher (in comparison with mono-intercalators) DNA binding constants.<sup>108, 109</sup> If the chains contained 7–10 methylene fragments, double intercalation took place.

The benzo[*b*][1,8]naphthyridine derivatives **228** were studied as modulators of multidrug resistance (MDR). These compounds were tested *in vitro* on mouse T-lymphoma cells after transfection (artificial transfer of genetic information) of the MDR1 gene into eukaryotic cells with the help of purified DNA. The effects of compounds **228** were compared to those of 6-methyl-5-oxobenzo[*a*]phenolthiazine (**229**) and 9-[2-(diethylamino)ethylamino]-2,7-dimethoxyacridine (**230**). The majority of the tested substances killed MDR tumor cells more effectively than the reference compounds **229** and **230**.<sup>128</sup>

$X = O, NH$ ;  $R^1 = OMe$ ;  
 $R^2 = R^3N(CH_2)_n$  ( $R^3 = Alk, Ar$ ;  $n = 2, 3$ ).

#### 4. Anti-inflammatory activity

10-Substituted 1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridines manifested remarkable activities as interleukin-1 inhibitors and were patented as anti-inflammatory drugs.<sup>28, 29</sup>

Several neurokinin A antagonists, which represent 1,2,3,4-tetrahydrobenzo[*b*][1,6]naphthyridine derivatives, were patented as remedies against diseases associated with tachykinin receptors and as preventives.<sup>30</sup>

3-Amino derivatives of 4-cyanobenzo[*b*][1,6]naphthyridine relieved the spasmogenic effect of bradykinin in experiments with isolated segments of guinea pig ileum; however, these compounds manifested significantly lower activities when the experiments were carried out on whole animals.<sup>129</sup>

#### 5. Other biological characteristics

In some papers devoted to the study of the cofactor properties of modified flavins, benzo[*b*][1,6]naphthyridine derivatives were considered as 1,5-dideaza analogues of alloxazine and isalloxazine. Bio-isomers of flavins, such as compound **231**, were used to simulate the activities of flavin-dependent enzymes and to elucidate the structural properties essential for the manifestation of cofactor effects.<sup>130, 131</sup>

Flavin mononucleotide (FMP)

**231**

6-[ω-(4-Aryl-1-piperazinyl)alkyl]-1,2,3,4,6,7,8,9-octahydrobenzo[*b*][1,6]naphthyridines **232** manifested high antivertigo and anti-emetic activities.<sup>132–135</sup> A close QSAR – activity relationship was established for *ortho*-substituted arylpiperazine derivatives.<sup>135</sup> Compound **232** (NK 422; difumarate) was chosen as a promising antivertigo drug<sup>134</sup> and manifested a stronger (in comparison with diphenidol<sup>136</sup> and chlorpromazine<sup>137</sup>) anti-emetic effect.

**233** (diphenidol)

**234** (chlorpromazine)

A series of acridines and their aza derivatives (in total, 71 compounds) were tested as  $\text{Ca}^{2+}$ -dependent inhibitors of protein kinase from wheat embryos. Benzo[*b*][1,5]naphthyridine derivatives containing basic and neutral substituents at position 4 manifested the highest activity.<sup>138</sup>

The ability of the 10-aminobenzo[*b*][1,5]naphthyridine compounds, fragments in which are linked together through flexible chains, to inhibit replication of the prions  $\text{PrP}^{\text{Sc}}$  was studied.<sup>§</sup>

However, the activities of such bisbenzonaphthyridines appeared to be lower than those of the corresponding bisacridines.<sup>140</sup>

#### VI. Conclusion

This review is a generalisation of the published data on the synthesis and properties of benzo[*b*]naphthyridines. The data reviewed suggest that a search for novel compounds endowed with unique biological properties is the main trend of research in this area. Indeed, some experimental findings corroborate the conclusion that such a search can be both successful and constructive. The discovery of pyronaridine, the first representative of this class of compounds manifesting high clinical efficiency, is the first step in this direction. In-depth studies into antitumour activities of some benzo[*b*]naphthyridine derivatives, their ability to inhibit acetylcholinesterase and to suppress replication of prions are currently of paramount importance. The search for novel biologically active substances among compounds of the benzo[*b*]naphthyridine series demands additional experiments aimed at the functionalisation of this type of tricyclic compound through the insertion of various pharmacophores able to enhance their biological properties.

**Abstract.** The experimental data and theoretical views on the relations between the relaxation properties and structure of polymers are generalised. The attention is focused on the topological structural level, in particular, characteristics including the molecular mass, the molecular mass distribution, the degree of branching, and the covalent and equilibrium network parameters. In relation to the discussion of the relaxation spectrometry concept, the physical meaning of the kinetic parameters of local transitions and the nature of  $\beta$ -relaxation are considered. Methods of calculation of the continuous and discrete relaxation spectra from the results of relaxation and rheological experiments are described. Data establishing the relation between the relaxation spectrum and the topological structure of a polymer are analysed. The bibliography includes 282 references.

## I. Introduction

The relaxation properties of polymeric materials determine the possibility of using them in practice.<sup>1,2</sup> Of course, the nature and character of relaxation processes depend on the polymer structure. However, the concept of polymer structure requires a clear definition.

A feature of high-molecular-mass compounds is that their complex structure cannot be described in a certain single fashion. Conditionally, it is possible to consider three interrelated structural levels, namely, a molecular, a topological and a supra-molecular level.<sup>3</sup> Characterisation of each level requires the use of a specific approach.

The molecular level covers the chemical and isomeric structure, *i.e.*, all aspects that can be described by structural formulae accepted in chemistry. On this level polymers are not basically different from low-molecular-mass compounds (of course, if we are dealing with rather complex molecules). While on the subject of chemical structure, the case in point is mainly the local organisation of compounds (at least on the length scale of a unit). At the same time introduction of the notion of sequences (blocks) comprising units of different chemical structure (including isomeric states) (copolymers) is due to the chain nature of

high-molecular-mass compounds. Besides, chain molecules (in contrast to the molecules of low-molecular-mass compounds) can have stereoisomers, *i.e.*, include isotactic and syndiotactic groups and correspondingly, blocks comprised of them. Therefore, characterisation of the molecular structure of a polymer requires the use of not only 'chemical language' but also complex concepts, which provide a quantitative description of sequences comprising different types of units.

The second, topological, level is immediately related to the concept of polymer chains. Here, we abstract from particular chemical meaning and consider polymers as sets of chains. Chains can have different lengths and different molecular mass distributions (MMDs), be linear or branched or have a complex cyclic structure (including chemically nonbonded molecules, *e.g.*, catenanes); they can also form a continuous three-dimensional network. It is the topological structure that is responsible for many physical properties of polymeric materials.<sup>1,3–5</sup> The concept of local structural organisation of molecules is insufficient for an understanding of the polymer structure on the topological level. Apparently, the chemical notation is inappropriate for the description of the topological structure, which has a particular geometrical meaning. The topological structure is characterised by graphs which include such elements as vertices (branching points), edges (chains), *etc.* The graph theory ignores the edge length, but the chain length and the chain length distribution are quite important for the topological structure of polymers.

The topological structural level 'abstracts' from the spatial arrangement of macromolecules, which characterises the supra-molecular structure of the polymer. In essence, this is a macroscopic level; nevertheless, the local structural organisation is an important factor. For instance, the local density strongly depends on the energy of intermolecular interaction (chemical nature of the polymer units). The topology also plays a significant role; for instance, the degree of polymer crystallinity is very responsive to the degree of chain branching, *i.e.*, to the structural level in question.

The chemical level of the polymer structure is basic (eventually, chain formation involves formation of chemical bonds; the possibility or impossibility of ring formation or branching in macromolecules is essentially a chemical problem). However, when considering the relations between the structure and properties of a polymer, it is convenient to discuss the effect of each level separately.

V I Irzhak Institute of Problems of Chemical Physics, Russian Academy of Sciences, 142432 Chernogolovka, Moscow Region, Russian Federation. Fax (7-496) 515 32 44, tel. (7-496) 522 21 63, e-mail: irzhak@icp.ac.ru

The relaxation properties characterise the ability of a compound disturbed from the equilibrium state to return to the equilibrium state. They are determined by the sum of all types of motions of molecular groups, chain fragments and macromolecules, that is, rotational, vibrational and translational motions. Representation of a relaxation process by the sum of such motions makes it possible to obtain an idea of a spectral characteristic of the compound.

If a process can be expressed by the sum of  $n$  independent elementary relaxation transitions, the kinetics of the process can formally be expressed as follows:

$$g(t) = \sum_{i=1}^n h_i e^{-t/\lambda_i},$$

where  $g(t)$  is the kinetic modulus,  $t$  is the running time,  $h_i$  is the relaxation spectrum and  $\lambda_i$  is the relaxation time.

In the continuous case one has

$$g(t) = \int_0^{\infty} h(\lambda) e^{-t/\lambda} d\lambda. \quad (1)$$

Sometimes the relaxation spectrum  $h_i$  or  $h(\lambda)$ , as a function of the relaxation time  $\lambda_i$  (or  $\lambda$ ), is denoted as  $H(\lambda) = \lambda h(\lambda)$ . A very broad range of relaxation times can be described in a more compact form, namely, in the logarithmic scale

$$g(t) = \int_{-\infty}^{\infty} H(\lambda) e^{-t/\lambda} d \ln \lambda. \quad (1a)$$

The frequency dependence of a relaxation process is represented by a Fourier transform of expression (1), namely

$$G^*(\omega) = i\omega \int_0^{\infty} g(t) e^{-i\omega t} dt, \quad (2)$$

where  $G^*(\omega)$  is the complex frequency modulus and  $\omega$  is the frequency.

As can be seen, there is a one-to-one correspondence between  $G^*(\omega)$  and  $g(t)$ , *i.e.*, knowledge of one parameter permits determination of the other. Since expression (1) is an integral Laplace transform of the spectrum  $h(\lambda)$ ,<sup>‡</sup> there is also a one-to-one correspondence between these quantities. A difficulty consists in that the experimentally measured  $G^*(\omega)$  and  $g(t)$  values (i) usually include random (noise) or systematic errors and (ii) are obtained within limited time and frequency intervals. The integral operator on the right side of equality (1) is a smoothing operator, *i.e.*, intensive perturbations in the  $h(\lambda)$  function are considerably smoothed in the  $g(t)$  function. But this also means that minor disturbances (*e.g.*, errors) in experimental data can introduce a large uncertainty into solution of the problem of determination of the relaxation spectrum  $h(\lambda)$ . Cutting off the integration limits due to limitations imposed by experimental techniques can also be a source of errors introduced into the results of the inverse Laplace transform and Fourier transform.

The complex frequency modulus  $G^*(\omega)$  is usually expressed through its real and imaginary components

$$G^*(\omega) = G'(\omega) + iG''(\omega), \quad (3)$$

$$G'(\omega) = \int_0^{\infty} h(\lambda) \frac{\omega^2 \lambda^2}{1 + \omega^2 \lambda^2} d\lambda,$$

$$G''(\omega) = \int_0^{\infty} h(\lambda) \frac{\omega \lambda}{1 + \omega^2 \lambda^2} d\lambda,$$

<sup>‡</sup> Strictly speaking, the Laplace integral transform of the function  $h(1/s)/s^2$ , where  $s = \lambda^{-1}$ .

Their ratio, called the (mechanical, dielectric, *etc.*) loss factor and given by

$$\tan \delta = \frac{G''(\omega)}{G'(\omega)}, \quad (4)$$

is often used for the determination of individual relaxation transitions. In this case the amplitude (intensity) of a peak in the  $\tan \delta$ -vs.-temperature ( $T$ ) or in the  $\tan \delta$ -vs.-frequency plots is usually related to the content of the relaxing element (relaxer).

## II. Relaxation spectrometry

In order to describe and classify local relaxation transitions, G M Bartenev put forward a concept of relaxation spectrometry.<sup>1,2,5</sup> As it was written in a monograph<sup>1</sup> that 'relaxation spectrometry itself, as a specific kind of kinetic spectroscopy,... is in the early stage of its development and at present not all principles of relaxation spectrometry can be considered rigorously substantiated'.<sup>§</sup>

In fact, local character of relaxation processes means that each process occurs (and, correspondingly, can be considered) independently. Parameters of each process (in particular, the relaxation times) are determined by the local polymer structure, which in turn can be characterised by these parameters. This is a distinctive feature of relaxation spectrometry as a method for studying the polymer structure.

A more or less broad spectrum of local relaxation times is due to the fact that even in the simplest macromolecules (such as polyethylene, polyethylene oxide and polystyrene molecules) one can select a set of relaxers. Torsional motions of atoms and side groups and crankshaft rotations of various intrachain atomic groups are characterised by different relaxation times. Complication of the molecular structure leads to broadening of the relaxation spectrum.

Structural description of local relaxation transitions is usually performed by relating the position of the maximum in the temperature dependence of loss factor, at a given frequency or temperature scan rate, to the presence of particular molecular groups in the polymer chain. At the point of maximum, the condition  $\omega\lambda = 1$  or  $W(T)\lambda = 1$  is met, where  $W(T)$  is the temperature scan rate. This makes it possible to determine the relaxation time  $\lambda$ .

According to Bartenev,<sup>2</sup> a relaxation transition can be represented by a jump of a relaxer through an activation barrier, *i.e.*, the temperature dependence of relaxation time obeys an Arrhenius equation

$$\lambda = B \exp \frac{E}{RT}.$$

The barrier height is governed by the activation energy  $E$  while the pre-exponent  $B$  characterises the volume of the relaxing element (relaxer)

$$B = \frac{v^{5/6}}{(6kT/\rho)^{1/2}}, \quad (5)$$

where  $v$  is the volume and  $\rho$  is the relaxer density.

Processes due to motions of small molecular groups (group size is much less than the size of a chain segment) belong to the smallest-scale  $\gamma$ -processes. Typical values of the kinetic parameters characteristic of this type of motion are as follows:  $B \approx 10^{-9} - 10^{-12}$  s and  $E_\gamma = 10 - 20$  kJ mol<sup>-1</sup>.

Larger-scale  $\beta$ -relaxation is characterised by  $B$  values of the order of  $2 \times 10^{-13}$  s and  $E_\beta$  values lying between 30 and 70 kJ mol<sup>-1</sup>.  $\alpha$ -Relaxation also belongs to local processes. Usually, the temperature dependence of the  $\alpha$ -relaxation time does not obey the Arrhenius equation. However, in a limited temperature

<sup>§</sup> See page 297 in Ref. 1.

interval it is characterised by the parameters  $B \sim 5 \times 10^{-12}$  s and  $E_\alpha = 50-70$  kJ mol $^{-1}$ .

It should be noted that almost all local transitions can be detected by both high-frequency (NMR, EPR, acoustic, dielectric and various mechanical dynamical methods) and low-frequency [the same mechanical dynamical methods in the low-frequency range, thermomechanical analysis (TMA), differential scanning calorimetry (DSC), *etc.*] methods.<sup>1,2,6</sup> For instance, knowledge of the temperature dependence of the damping constant or of the mechanical loss factor at a frequency of about 1 Hz (or fractions of a Hertz) makes it possible to find out all these transitions.<sup>2,5</sup>

As a rule, local relaxation transitions correspond to structural transitions. For instance, it was shown<sup>7</sup> that the thermal expansion coefficients of the polymers listed below change stepwise at the following temperatures (°C):

|                             |                   |
|-----------------------------|-------------------|
| poly(methyl methacrylate)   | 15, 100           |
| poly(methacrylate)          | -115, -15, 25, 60 |
| poly(n-propyl methacrylate) | -85, -35, 15, 30  |
| poly(n-butyl methacrylate)  | -95, -55, -25, 20 |

The last-mentioned temperatures correspond to  $\alpha$ -transitions and the lower temperatures correspond to small-scale local transitions.

### 1. Model of coupled rotators

The Frenkel–Eyring discrete model of activated diffusion provides the basis for relaxation spectrometry. According to this model, a diffusion act involves three consecutive stages. These are (i) reorganisation of the environment of the diffusing species involving formation of a ‘hole’ of comparable volume, (ii) the jump of the particle through the activation barrier to the ‘hole’ formed and (iii) reorganisation of the environment to remove the ‘hole’.

According to modern concepts of the diffusion mechanism (see, *e.g.*, Ref. 2), the motion of a particle occurs simultaneously with local reorganisation of the environment. The particle moves gradually by ‘elbowing’ particles of the environment rather than by hopping over distances of the order of the particle size. According to this continuous model, the particle executes a number of steps during the hopping time and thus travels a distance comparable with the particle size. Thus, formally both models lead to the same results. However, the kinetic parameters of the process (‘hole’ volume, energy of ‘hole’ formation, activation energy for hopping) and, correspondingly, the parameters  $B$  [see Eqn (5)] and  $E$  in the Arrhenius equation have a different physical meaning.<sup>8-10</sup>

The model of elastically coupled rotators<sup>11,12</sup> was first proposed by Mansfield.<sup>13</sup> It is based on the physically more substantiated mechanism of local relaxation.

Rotators (asterisked) execute torsional motions near the equilibrium positions in the plane normal to the axis. The character of motion is determined by the local (torsional) friction coefficient  $\zeta_i$  and by the rigidity,  $K_i$ , of the bond being twisted (rotators are enumerated from the left, so the bonds are enumerated from zero to  $n$ ). The two outermost bonds can have a zero rigidity (free chain) or a finite rigidity (chain is embedded into a framework, *e.g.*, a network).

The equations describing relaxation of this system, have the form

$$\begin{aligned}\dot{x}_1 &= -K_0x_1 - K_1(x_1 - x_2) - \tau_1^{-1}x_1 = \\ &= -x_1(K_0 + K_1 + \tau_1^{-1}) + K_1x_2, \\ \dot{x}_2 &= K_1(x_1 - x_2) - K_2(x_2 - x_3) - \tau_2^{-1}x_2 = \\ &= K_1x_1 - x_2(K_1 + K_2 + \tau_2^{-1}) + K_2x_3,\end{aligned}\quad (6)$$

$$\begin{aligned}\dot{x}_3 &= K_2(x_2 - x_3) - K_3(x_3 - x_4) - \tau_3^{-1}x_3 = \\ &= K_2x_2 - x_3(K_2 + K_3 + \tau_3^{-1}) + K_3x_4, \\ &\dots\dots\dots \\ \dot{x}_i &= K_{i-1}x_{i-1} - x_i(K_{i-1} + K_i + \tau_i^{-1}) + K_ix_{i+1} \\ &\dots\dots\dots \\ \dot{x}_{n-1} &= K_{n-2}x_{n-2} - x_{n-1}(K_{n-2} + K_{n-1} + \tau_{n-1}^{-1}) + K_{n-1}x_n, \\ \dot{x}_n &= K_{n-1}x_{n-1} - x_n(K_{n-1} + K_n + \tau_n^{-1}),\end{aligned}$$

where  $x_i$  is the angle of deviation of the dipole from its equilibrium position and  $\tau_i$  is treated as the effective relaxation time of the  $i$ th dipole, which is proportional to the friction coefficient  $\zeta_i$ .

The solution is written as expansion into a series

$$x_i = \sum_{j=1}^n a_{ij} \exp(-p_j t). \quad (7)$$

The relaxation time  $\lambda_i = p_i^{-1}$  is determined by the equation

$$D_n = \begin{vmatrix} \varphi_{11} & \varphi_{12} & 0 & 0 & \dots & 0 & 0 \\ \varphi_{21} & \varphi_{22} & \varphi_{23} & 0 & \dots & 0 & 0 \\ 0 & \varphi_{32} & \varphi_{33} & \varphi_{34} & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \varphi_{i,i-1} & \varphi_{i,i} & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \varphi_{n,n-1} & \varphi_{n,n} \end{vmatrix} = 0 \quad (8)$$

where  $\varphi_{11} = z_1 - (\tau_1^{-1} + K_0 + K_1)$ ;  $\varphi_{12} = K_1$ ;  $\varphi_{21} = K_1$ ;  $\varphi_{22} = z_2 - (\tau_2^{-1} + K_1 + K_2)$ ;  $\varphi_{23} = K_2$ ;  $\varphi_{i,i-1} = K_{i-1}$ ;  $\varphi_{i,i} = z_i - (\tau_i^{-1} + K_{i-1} + K_i)$ ;  $\varphi_{i,i+1} = K_i$ ;  $\varphi_{n,n-1} = K_{n-1}$ ;  $\varphi_{n,n} = z_n - \tau_n^{-1} + K_{n-1} + K_n$ ;  $z_i = 1/\lambda_i$ .

Analysis of the solution of Eqn (8) showed that if  $K_i \ll 1$  for any  $i$ , the elements relax independently with  $\lambda_i = \tau_i$ . In other words, in this case the relaxation is governed solely by the physical nature and by the magnitude of the local friction coefficient  $\zeta_i$ , *i.e.*, by the level of local intermolecular interaction. If  $K_i \gg 1$  for any  $i$ , the structure of the  $D_n$  matrix will be identical to the structure of the Rouse matrix for a free chain (at  $K_0 = K_n = 0$ ) or for an end-to-end cross-linked chain (at  $K_0$  and  $K_n \neq 0$ ). However, in this case the relaxation times increase by a factor of  $K$ . Thus, intrachain interaction causes relaxation of each element to be characterised by a spectrum of relaxation times.

To obtain a detailed description of the relaxation kinetics of the system in the framework of the model of coupled rotators, one should allow for the Brownian force<sup>11</sup> exerted on each element in the system. Therefore, each equation in system (6) should be augmented with the corresponding term.

Analysis of the solution of the modified system (6) showed<sup>12</sup> that, at times shorter than  $\lambda_{\min}$  (minimum relaxation time of the chain of rotators), the correlator  $\langle \cos x_j(t) \cos x_j(0) \rangle$  decreases exponentially with the characteristic time  $\lambda_1$ . In this region the effect of the neighbours of a given rotator can be ignored and the motion occurs as rotational diffusion, which is not affected by chain rigidity

$$\lambda_{\min} = \frac{\zeta^{\text{rot}}}{4K^{\text{rot}}}, \quad \lambda_1 = \frac{\zeta^{\text{rot}}}{4kT} = \frac{1}{4D}.$$

Here  $\zeta_1 = \zeta_2 = \dots = \zeta_i = \dots = \zeta^{\text{rot}}$  is the torsional friction coefficient,  $K_1 = K_2 = \dots = K_i = \dots = K^{\text{rot}}$  is the twisting rigidity of the chain and  $D$  is the rotational diffusion coefficient.

At times longer than  $\lambda_{\min}$ , relaxation is described by a ‘stretched’ exponent:  $\sim \exp[-(t/\lambda_2)^{1/2}]$ , where

$$\lambda_2 = \frac{\pi \zeta^{\text{rot}} K^{\text{rot}}}{(4kT)^2}.$$

In this time interval the motion of a rotator is strongly affected by the neighbouring rotators (manifestation of chain rigidity), the

length scale of the motion being equal to the length of the rigid chain fragment.

Note that the relations given above are valid for an infinite chain where the effect of the end groups can be ignored. Finite chains have also been studied.<sup>12</sup>

Thus, the character of local relaxation transitions is first of all determined by the local viscosity. An important additional factor is intrachain interaction, which manifests itself as the twisting rigidity of the chain. In all cases the activation model is inadequate.

## 2. On the nature of $\alpha$ - and $\beta$ -relaxation

At present there are two antipodes of opinion of the nature of  $\alpha$ - and  $\beta$ -relaxation. On the one hand, it is traditionally accepted (see references cited in Ref. 2) that different molecular groups are responsible for these transitions. Namely,  $\alpha$ -transition is due to segmental motion while  $\beta$ -transition is due to a smaller-scale motion of relaxers (here, the molecular mass of the relaxer is five to ten times smaller than that of a chain segment).

According to the other point of view (see Refs 14, 15), relaxation in the corresponding temperature and frequency ranges is due to the same chain fragments, namely, chain segments. This is reasoned by the following:

1. Amorphous low-molecular-mass glasses with rigid molecules (in *e.g.*, solutions of chlorobenzene, *o*-dichlorobenzene and 1-chloronaphthalene in decalin, blends of chlorobenzene with pyridine, blends of tetrahydrofuran with bromobenzene and 1-chloronaphthalene, *etc.*) exhibit not only the  $\alpha$ -transition but also a low-temperature transition, which can be associated with  $\beta$ -relaxation.<sup>16–23</sup> The systems in question contain no other relaxers, except for the rigid molecules, capable of moving as a whole. Therefore, both relaxation transitions are due to the same structural elements. Characteristics of the low-temperature transition are similar to those of  $\beta$ -relaxation in polymeric systems, namely, it obeys an Arrhenius-type temperature dependence with an activation energy lying in the range 17–33 kJ mol<sup>−1</sup>. As the temperature increases, both transitions approach each other. Finally, both relaxation processes in the system including low-molecular-mass components are also observed in the polymeric reaction product, but here the relaxation times are longer, which is quite natural.<sup>22</sup>

2. Bershtein *et al.*<sup>15, 24–26</sup> showed that for certain polymers the dependences of the heats of the  $\beta$ - and  $\alpha$ -transitions on the number,  $n$ , of monomer units are given by similar curves that reach the plateau zone at the same  $n$  value. This is indicative of the identity of the  $\beta$ - and  $\alpha$ -relaxers in polymeric systems.

3. Liquid systems characterised by one relaxation transition, namely, the glass transition, show a second low-temperature transition upon compression.<sup>27</sup> Apparently, new relaxers cannot appear under these conditions. A possible reason is an increase in the density of the system and, as a consequence, an increase in the concentration of high-density fluctuations.

4. Theoretical analysis<sup>14, 28, 29</sup> of the relaxation of bulk amorphous systems that show a unique structural feature (density fluctuations) showed the following.

The temporal correlation function  $\psi(t)$  is given by the Kohlrausch – Williams – Watts (KWW) formula

$$\psi(t) = \alpha_1 \exp \left[ - \left( \frac{t}{\tau_1} \right)^{\beta_1} \right] + \alpha_2 \exp \left[ - \left( \frac{t}{\tau_2} \right)^{\beta_2} \right], \quad (9)$$

where  $\alpha_1$  and  $\alpha_2$  are the pre-exponents,  $\beta_1 = 0.33$  and  $\beta_2 = 0.14–0.27$ .

Analysis of expression (9) revealed the existence of two relaxation regions. The first region corresponds to a short relaxation time, being almost temperature independent, while the second region corresponds to a long relaxation time and extends with temperature. The temperature dependence of  $\tau_1$  obeys an Arrhenius relationship while that of  $\tau_2$  is described by the Williams – Landell – Ferry (WLF) equation, which is typical of

$\alpha$ -relaxation. It was also found that the activation energy for the first region  $E_1 = 35$  kJ mol<sup>−1</sup> and  $80 \leq E_2 \leq 139$  kJ mol<sup>−1</sup> for the second region.

The frequency dependence of the imaginary component of the bulk modulus exhibits two maxima. The temperature dependence of the high-frequency peak obeys an Arrhenius relation and that of the low-frequency peak obeys the WLF equation.

These processes,  $\alpha$ - and  $\beta$ -relaxations, are characteristic of all amorphous systems and both transitions can be initiated by the same elements. The appearance of two regions is due to a nonuniform density distribution, *viz.*,  $\alpha$ -relaxation occurs in the high-density fluctuations while  $\beta$ -relaxation occurs in the low-density ones. The former process is essentially a co-operative one for which an important role is played by structural rearrangements in the environment; as a consequence, the temperature dependence is of the WLF type. The latter process is non-co-operative; therefore it is described by the Arrhenius equation.

Recent studies of the structure and properties of thin polymer films (see, *e.g.*, Ref. 30) showed that the glass transition temperature decreases appreciably if the thickness of the polymer film approaches the diameter of the unperturbed coil. It was assumed that this effect is due to violation of the co-operative character of molecular motion in thin films (namely,  $\alpha$ -transition manifests itself as a  $\beta$ -transition). If by this is understood a known decrease in the packing density in near-surface layers and thin films, this assumption can be considered quite reasonable.

The aforesaid does not mean that  $\beta$ -relaxation in polymeric systems always has segmental character. Some other mechanism, which is due to the presence of other molecular groups, *i.e.*, a complex structure of polymer chains, can also be involved in addition to the mechanism described above.

## III. Manifestation of the topological structure of polymers in their relaxation properties

Certain structural meaning can be assigned with ease to local relaxation transitions that are mainly responsible for the level of internal friction in a polymeric material. This level governs, *e.g.*, the brittleness of the material. At the same time the relaxation properties in a broad sense determine the deformability, long-term strength and other characteristics related to the conformational rearrangements and motions of macromolecules. Apparently, the topological structure plays the key role in this case. But it is a rather complicated task to relate the topological structure to the relaxation behaviour of the polymer, although this problem is undoubtedly topical. In addition it is the relaxation techniques that can become basic to the development of non-destructive methods of structural characterisation of polymeric materials.<sup>31–34</sup>

### 1. Molecular mass

For linear polymers the dependence of the melt viscosity,  $\eta$ , on the average molecular mass ( $\bar{M}$ ) has the form<sup>4</sup>

$$\eta = K \bar{M}^\nu, \quad (10)$$

where  $\nu = 1$  at  $\bar{M} \leq 2 M_e$ ,  $\nu = 3.5 \pm 0.2$  at  $\bar{M} > 2 M_e$  and  $M_e$  is the molecular mass of the chain between entanglements in terms of the Doi – Edwards theory.<sup>11, 34</sup>

Expression (10) is a particular case of a more general dependence<sup>3, 35, 36</sup>

$$\eta \propto [\eta]^\nu$$

or

$$\eta \propto R^\nu,$$

where  $[\eta]$  is the characteristic viscosity, the exponent  $\nu$  lies between 6 and 7 and  $R$  is the coil radius. Validity of these relationships was shown for various types of polymers, *viz.*, linear polymers of different rigidity; cyclic, star-branched with different numbers of arms and comb-like polymers, randomly branched chains and

highly cross-linked polymer globules.<sup>3,37–42</sup> Therefore, the viscosity cannot serve as a unique characteristic of the molecular mass of a polymer. Other parameters of the topological structure, namely, the molecular mass distribution and the degree of branching also play a significant role.

The flow curves obtained for linear monodisperse polymers exhibit a specific shape.<sup>43,44</sup> At relatively low shear rates  $\dot{\gamma}$  (and, correspondingly, strain  $\tau$ ), one deals with a Newtonian flow, *i.e.*,  $\tau = \eta_0 \dot{\gamma}$ , where  $\eta_0 = KM^v$ . However, at a certain critical shear strain,  $\tau_c$ , the flow character changes. Here, flow breakdown occurs or the strain abruptly decreases with an increase in the shear rate (the former is characteristic of monodisperse polymers while the latter is typical of polydisperse polymers). The  $\tau_c$  value is independent of the molecular mass of the polymer. At the same time the shear rate corresponding to the  $\tau_c$  value can serve as a measure of the molecular mass of monodisperse polymers

$$\dot{\gamma}_c(M) = \frac{\tau_c}{KM^v}.$$

Knowing the temperature dependence of the stress,  $\varepsilon$ , of linear polymers (TMA method), it is possible to relate the molecular mass to the relaxation properties. Kargin and Slonimskii<sup>45</sup> first showed that the extension of a portion of the  $\varepsilon(T)$  curve, which is nearly parallel to the temperature axis (rubbery plateau zone,  $\Delta T = T - T_g$ , where  $T$  is the flow onset temperature and  $T_g$  is the glass transition temperature) is related to the molecular mass as follows

$$\log\left(\frac{M}{M_s}\right) \propto \frac{\Delta T}{C + \Delta T}, \quad (11)$$

where  $M_s$  is the molecular mass of the chain segment and  $C$  is a constant.

It should be noted that determination of the parameter  $\Delta T$  faces some difficulties, which are due to the diffuse character of the transition from the glassy to the rubbery state and from the rubbery state to a melt flow. The character of these transient regions depends on the width of the MMD. The validity of relationship (11) was confirmed<sup>46–48</sup> for a broad range of polymers. The authors studied narrow-MMD polymers, which made it possible to attain abrupt glass–elastomer and elastomer–melt transitions. The plot of the dependence (11) is shown in Fig. 1.

**Figure 1.** Correlation between the temperature interval corresponding to the rubbery plateau and the molecular mass of polymers plotted in the coordinates of Eqn (11) [ $X$  is the numerical value of the right side of Eqn (11),  $C = T_g$ ].<sup>48</sup> Polymers: polybutadiene (1), polyurethane-based polymers (2, 3) at  $T_g = 215$  (2) and 250 K (3) and polyacrylonitrile (4).

Using the temporal and the frequency dependences of the elastic modulus, one can also relate the relaxation properties of polymers to their molecular masses. Since the rubbery plateau zone extends from the minimum ( $\lambda_{\min}$ ) to the maximum ( $\lambda_{\max}$ ) relaxation time (see Refs 1, 24, 34), the  $\lambda_{\min}$  value being independent of the molecular mass and much shorter than  $\lambda_{\max}$ , the extension of the plateau zone is nearly equal (in time or frequency units) to  $\lambda_{\max}$ . But

$$\lambda_{\max} \propto M^v,$$

where the exponent  $v$  can take different values. Usually, it is assumed that  $v = 3.4$ . At the same time analysis of strain relaxation data showed<sup>49</sup> that  $v \approx 4$ . From the shift of the relaxation curves as functions of the molecular mass of the polymer (Fig. 2, lines 1, 2), *i.e.*, based on the estimate of the extension of the rubbery plateau zone, it was found that the  $v$  value lies between 3.3 and 3.5. Analysis of the frequency dependence of the elastic modulus revealed a similar  $v$  value ( $v = 3.5$  from the real component of the modulus, see Fig. 2, line 3, data were taken from Ref. 50). It should be noted that the maximum in the  $G''(\omega)$  plot correlates with the critical shear strain  $\tau_c$  (see Ref. 44), *i.e.*, it also characterises the molecular mass of linear monodisperse polymers, namely,  $v \approx 3.3$  (from the position of the maximum  $G''$  value).

**Figure 2.** Relaxation parameters of linear polymers (1–4) and a four-arm star-branched polymer (5) plotted vs. molecular mass using the data taken from different studies.

Parameter:  $\Delta \log t$  (1, 2),  $\Delta \log \omega$  (3, 5) and  $G''_{\max}$  (4); the plateau extension is denoted by  $\Delta$ ; *e.g.*,  $\Delta \log t = \log t_{\max} - \log t_{\min}$ .

The molecular mass is closely related to parameters of the terminal zone of the complex frequency modulus curves  $G^*(\omega)$ .<sup>4,51–54</sup> The effective relaxation time

$$\lambda_{\text{ef}, w}(\omega) = \frac{G'(\omega)}{\omega G''(\omega)} \quad (12)$$

in the terminal zone takes the limiting value, which is frequency independent and equals the ratio of the second to the first moment of the relaxation time distribution, *i.e.*, is the weight-average relaxation time

$$\langle \lambda \rangle_w = \frac{\sum_i h_i(\lambda) \lambda_i^2}{\sum_i h_i(\lambda) \lambda_i}. \quad (13)$$

At  $\omega \rightarrow 0$ , the effective relaxation time given by

$$\lambda_{\text{ef}, n}(\omega) = \frac{G''(\omega)}{\omega[G_N^0 - G'(\omega)]}, \quad (14)$$

is the number-average relaxation time, which is also frequency independent ( $G_N^0$  is the modulus corresponding to the rubbery plateau zone),

$$\langle \lambda \rangle_n = \frac{\sum_i h_i(\lambda) \lambda_i}{\sum_i h_i(\lambda)}. \quad (15)$$

It is well known that the average relaxation times in the terminal zone correlate with the rheological properties of polymers, namely, the number-average relaxation time correlates with viscosity and the product of the viscosity and the compliance correlates with the weight-average relaxation time. From here it follows that these relaxation times depend on the molecular mass. The data for a number of monodisperse polymers are listed in Table 1.

**Table 1.** Dependence of the average relaxation times in the terminal region on the molecular mass of polymers.

| Polymer                               | $\langle \lambda \rangle_n$ | $\langle \lambda \rangle_w$ | Ref.   |
|---------------------------------------|-----------------------------|-----------------------------|--------|
| Polystyrene                           | $M^{3,4}$                   | $M^{3,7}$                   | 50     |
| Poly(methyl methacrylate)             | $M^{3,4}$                   | $M^{3,65}$                  | 53     |
| <i>cis</i> -Polyisoprene <sup>a</sup> | $M^{3,62}$                  | $M^{3,69}$                  | 54     |
| 1,4-Polybutadiene                     | $M^{3,37}$                  | $M^{3,52}$                  | 55, 56 |

<sup>a</sup> Data from dielectric measurements.

The parameters of dielectric relaxation are related to the molecular masses of polymers in a similar way. Here one should keep in mind that this can concern only those polymers in which the dipoles and chains are aligned (A-type polymers according to Stockmayer<sup>57</sup>).

The effective dielectric relaxation times are defined as follows:

$$\langle \lambda_e \rangle_w = \frac{\varepsilon_0 - \varepsilon'(\omega)}{\omega \varepsilon''(\omega)}, \quad \langle \lambda_e \rangle_n = \frac{\varepsilon''(\omega)}{\omega \Delta \varepsilon}, \quad \omega \rightarrow 0, \quad (16)$$

where  $\varepsilon_0$  is the conductivity,  $\varepsilon'$  and  $\varepsilon''$  are the real and imaginary components of the complex dielectric permittivity,  $\Delta \varepsilon$  is the intensity of dielectric relaxation for the motion of the entire chain (analogue of  $G_N^0$  in mechanical relaxation).

The position of the maximum in the  $\varepsilon''(\omega)$  curve on the frequency axis is also related to the molecular mass by a power law (for *cis*-polyisoprene, the exponent is 3.8<sup>58</sup>).

The spin–spin relaxation measured by pulsed NMR spectroscopy is sensitive to the molecular mass of linear polymers.<sup>59–62</sup> At a sufficiently high temperature ( $T > T_g + 100$ ), the free induction decay,  $G(t)$ , is defined by

$$G(t) = \int_1^{N\pi/2} \int_0^{\pi/2} \{ [g(N, \theta, t) P(N) \sin \theta] d\theta \} dN, \quad (17)$$

where

$$g(N, \theta, t) \approx \exp \left[ -\omega_1^2 (3 \cos^2 \theta - 1)^2 t^2 \frac{\ln N}{N^2} \right],$$

$N$  is the number of segments in the chain and  $\theta$  is the angle between the vector connecting the chain ends and the direction of external magnetic field;  $\omega_1$  is the second moment of the free induction decay curve, expressed in frequency units and  $P(N)$  is the numerical MMD function.

However, since NMR spectroscopy is a high-frequency method, Eqn (17) is valid for the macromolecules with molecular masses smaller than  $M_e$ .

## 2. The molecular mass distribution

The problem of establishment of correlations between the MMD and the relaxation properties of polymers has a long history;<sup>2, 4, 34, 63–66</sup> however, no unambiguous solution has been reported so far.<sup>31, 32</sup> Only qualitative dependences were determined. For instance, it is assumed<sup>4</sup> that MMD is correctly allowed for in the following relationship for the viscosity

$$\eta \propto \bar{M}_w^v,$$

where  $\bar{M}_w = \sum_M \omega(M)M$ ,  $\omega(M)$  is the mass fraction of the polymer with molecular mass  $M$  and  $v \approx 3, 4$ . More complicated expressions, which take into account higher moments of the MMD function, are also used. For instance, the following expressions were proposed for creep compliance  $J_e$ :<sup>64–66</sup>

$$J_e \approx \frac{\bar{M}_{z+1} \bar{M}_z}{\bar{M}_w \bar{M}_n}$$

or

$$J_e \approx \left( \frac{\bar{M}_z}{\bar{M}_w} \right)^b,$$

Here  $\bar{M}_n = \mu_1/\mu_0$ ,  $\bar{M}_z = \mu_3/\mu_2$ ,  $\bar{M}_{z+1} = \mu_4/\mu_3$ ,  $\mu_k =$

$\sum_M \omega(M) M^k$  is the  $k$ th distribution moment; and  $b = 3.5–3.7$ .

As an example Fig. 3 presents the dependences of the compliance  $J_e = \langle \lambda \rangle_w / \langle \lambda \rangle_n$  and polydispersity index  $\bar{M}_w / \bar{M}_n$  on the composition of a bidisperse blend of polystyrenes with molecular masses  $4.27 \times 10^5$  and  $3.89 \times 10^4$  (data were taken from Ref. 67).

Because of polydispersity of the polymer the flow curve changes its shape.<sup>31, 68–71</sup> A sharp kink near the critical shear strain disappears and the viscosity gradually decreases from a constant value with an increase in the shear rate. The curves of the temporal and frequency dependences of the relaxation modulus behave analogously.<sup>32–34, 72–78</sup> In the rubbery plateau zone the modulus becomes time (or frequency) dependent; the wider the MMD, the stronger this dependence. Broadening of the MMD

**Figure 3.** Compliance- vs. polydispersity index correlations for polystyrene.<sup>67</sup>

$J_e$  (1) and  $\bar{M}_w/\bar{M}_n$  ratio (2) plotted vs. compositions of bidisperse polystyrene blends with the molecular masses  $M_1 = 3.89 \times 10^4$  and  $M_2 = 4.27 \times 10^5$ , where  $w_2$  is the mass fraction of the second component, and the  $Y = 0.2 + 3.4 \log(\bar{M}_w/\bar{M}_n)$  plot (3).

also leads to fundamental changes in the character of the temperature dependence of strain;<sup>32, 48, 79–82</sup> namely, the wider the MMD of the polymer, the less pronounced the transition from the rubbery state to flow.

Numerous attempts at establishing quantitative relations between the character of the MMD and the relaxation behaviour of polymers are usually based on the assumption of additivity of the contributions of each polymer fraction to the properties. For instance, it was proposed to describe the flow curve of a polydisperse polymer by the following relationship<sup>68, 71</sup>

$$\eta(\dot{\gamma}) = \left[ \int_0^{M_c} \omega(\mu) \mu d\mu + M_c \int_{M_c}^{\infty} \omega(\mu) d\mu \right]^v, \quad M_c = \left( \frac{\tau_c}{K \dot{\gamma}} \right)^{1/v},$$

where  $\mu$  is the integration variable.

The dynamical theory of polymers, which is based on the fixed tube model, predicts<sup>34</sup> that the relaxation modulus of a bidisperse polymer blend equals the weight-average of the relaxation moduli of the components. Correction of the model made it possible to derive much more complicated relationships.<sup>83</sup> Generalisation of various theoretical and experimental approaches led to the following strain relaxation equation<sup>84, 85</sup>

$$G(t) = G_N^0 \left[ \int_{\ln M_c}^{\infty} G^{1/\beta}(t, M) \omega(M) d \ln M \right]^\beta,$$

where  $G(t, M)$  is the function describing the relaxation behaviour of the polymer fraction with molecular mass  $M$  and the parameter  $\beta$  characterises the mixing rule (it allows for the mutual influence of macromolecules of different size).

It is this factor that allows the additivity principle to be used. However, opinions are different as to the mutual influence of macromolecules or its manifestation in the relaxation properties of polydisperse polymers. On the one hand, there is no denying a strong chain–chain interaction in polymeric systems, which is allowed for by the concepts of entanglements<sup>65, 66</sup> or physical networks.<sup>37, 86–89</sup> It was experimentally shown<sup>83, 84, 90–93</sup> that the longest relaxation time depends on the composition of bidisperse polymer blends.

On the other hand it was assumed<sup>52, 94, 95</sup> that the effect of this interaction can be ignored in the case of slow relaxation processes. This was substantiated by the results of IR dichroism studies<sup>96, 97</sup> of chain orientation relaxation in bidisperse blends of ethylene-*co*-propylene copolymers comprised of monodisperse fractions with the molecular masses  $M_S = 5.3 \times 10^4$ ,  $M_M = 1.25 \times 10^5$  and  $M_L = 3.7 \times 10^5$ . It was shown that the maximum effective relaxation time of long chains is virtually independent of the composition of the system (Fig. 4). As can be seen, the presence of shorter chains has almost no effect on the relaxation of long chains (curves 1, 2, 4) if the concentration of the long chains is not too low.<sup>93</sup> At the same time the relaxation times of the chains of different length are significantly different (*cf.* curves 1, 2 and curve 3).

The notion of a ‘low-molecular-mass’ component of a bidisperse blend is conditional. Probably, under certain conditions this component should be considered as a solvent, which dramatically decreases the concentration of entanglements in a physical network. It was suggested<sup>98</sup> that this occurs at  $M_L M_c^2 / M_S^3 < 0.1$ .

As applied to thermomechanical experiments, the additivity principle can be expressed as follows:<sup>48, 81</sup>

$$J_T = J_0 [1 - \omega(M)]^{-1}, \quad \omega(M) = \sum_M \varphi(M) \chi(T, M),$$

where  $J_T$  and  $J_0$  are the compliances of the polydisperse polymer and of a hypothetical polymer with infinite molecular mass (base line),  $\omega(M)$  is the integral MMD function,  $\varphi(M)$  is the differential MMD function and  $\chi$  is the Heaviside step function

**Figure 4.** Effective long-chain orientation relaxation time plotted vs. volume fraction of long chains in a bidisperse polymer blend.

Molecular mass of the polymer:  $M_S = 5.3 \times 10^4$ ,  $M_M = 1.25 \times 10^5$  and  $M_L = 3.7 \times 10^5$ . Curve 1 was plotted using the data taken from Ref. 97 and curves 2–4 were plotted using the data taken from Ref. 98.

(1, 2)  $M_S + M_L$ , (3)  $M_S + M_M$ , (4)  $M_M + M_L$ .

$$\chi(T, M) = \begin{cases} 0 & \text{for } T < T_{f,M} \\ 1 & \text{for } T \geq T_{f,M} \end{cases},$$

where  $T_{f,M}$  is the temperature at which the transition from the rubbery state to the flow of the polymer fraction with the molecular mass  $M$  occurs.

Only a few studies on relations between the character of dielectric relaxation and the MMD are available (see the bibliography in a review<sup>52</sup>). Probably, this is due to a narrow range of objects (A-type polymers). Studies of (mainly) bidisperse *cis*-polyisoprene blends showed<sup>99–104</sup> that the MMD manifests itself in dielectric and mechanical relaxation in a similar way, *i.e.*,

$$\frac{\varepsilon''(\omega)}{\Delta\varepsilon} \approx \frac{G''(\omega)}{G_N^0},$$

although the mechanisms of these processes are different, namely, dielectric relaxation is governed by orientation correlation of the *i*th and *j*th segments at different time instants while mechanical relaxation is determined by orientation anisotropy of a segment.

NMR experiments showed that the polydispersity of a polymer affects the shape of the free induction decay curve<sup>61, 62</sup> to the extent to which the  $M_c$  parameter limits the chain length.

### 3. Branching

Branching of polymers, as a structural factor, which manifests itself in the relaxation properties, has been much less studied compared to MMD. This problem has attracted attention only recently<sup>105</sup> owing to the extended possibilities of the synthesis of branched chains of a preset topological structure<sup>106</sup> including ‘living’ radical polymerisation techniques.<sup>107, 108</sup>

As mentioned above, the viscosity of polymers is independent of their topological structure. However, the coil size is highly sensitive to the chain structure, namely, the higher the degree of branching of a macromolecule, the smaller the root-mean-square radius of the coil at the same molecular mass.<sup>1, 4, 11</sup> For instance, the characteristic viscosities  $[\eta]$  (THF solution, 30 °C) of polystyrenes of different topological structure are related to their molecular masses by the following expressions:<sup>109</sup>

$$[\eta] = 9.6 \times 10^{-5} \bar{M}_w^{0.73} \text{ for a linear polymer,}$$

$$[\eta] = 1.42 \times 10^{-4} \bar{M}_w^{0.68} \text{ for eight-arm stars and}$$

$$[\eta] = 6.45 \times 10^{-4} \bar{M}_w^{0.39} \text{ for a hyperbranched polymer with}$$

more than twenty arms.

The rheological properties of branched molecules differ from those of linear molecules with the same molecular mass.<sup>109–111</sup> Namely, they show lower viscosities and higher critical shear rates, their melts are characterised by enhanced elasticity, which manifests itself in particular in the magnitude of the first normal stress difference. Branched polymers are characterised by high longitudinal viscosities.

A relation derived in the dynamical reptation theory of star-branched chains<sup>34, 112</sup> has the form

$$\eta \propto \left(\frac{M_a}{M_e}\right)^b \exp\left(\nu \frac{M_a}{M_e}\right),$$

where  $M_a$  is the molecular mass of the arm and  $b$  and  $\nu$  are the parameters of the model. Indeed, experiments<sup>113</sup> showed that the viscosities of star-branched polymers at equal molecular masses are independent of the number of arms, if this number is greater than three, being at the same time dependent on  $M_a$  (see Refs 114 and 115). This also holds for hyperbranched polymers.<sup>116–118</sup> It was also experimentally found<sup>41, 116, 119–121</sup> that  $0.5 \leq b \leq 2$ ,  $\nu < 1$  (theoretical values are  $b = 2$  and  $\nu = 15/8$ ).

A fundamental distinction of branched chains, which is due to a more compact coil structure compared to linear macromolecules, consists in complex thermorheological behaviour.<sup>41, 122–129</sup> Since the key parameter in rheology is the coil size, the effect of temperature on the viscosity is determined by not only the temperature dependence of the friction coefficient but also the thermal coefficient of the coil size<sup>130</sup>

$$\kappa = \frac{d \ln \langle r^2 \rangle}{dT},$$

where  $\langle r^2 \rangle$  is the root-mean-square radius of gyration of the macromolecule. The coefficient  $\kappa$  increases as the degree of branching increases.<sup>41, 125, 126</sup> Because of this the effective activation energy of viscous flow also increases.<sup>†</sup>

According to a hypothesis by Graessley,<sup>123</sup> a fraction of the activation energy, which is due to the branching effect, is related to the arm length as follows

$$E_b = A \frac{M_a}{M_e}. \quad (18)$$

The  $A$  coefficient depends on the chemical structure of the macromolecules and the  $\kappa$  parameter. However, the parameters  $A$  and  $\kappa$  are related in a rather complex fashion and can even not show any correlation (see the data listed in Table 2).

**Table 2.** Parameters of equation (18).

| Polymer                         | $10^3 \kappa \times /K^{-1}$ | $M_a/M_e$ | $A$         |
|---------------------------------|------------------------------|-----------|-------------|
| Hydrogenated polyisoprene       | −1.3                         | 23–33     | 0.169       |
| Hydrogenated polybuta-1,4-diene | −1.05                        | 12–39     | 0.25        |
| Polybuta-1,2-diene              | ~ −1                         | 12        | 0.17        |
| Polybuta-1,4-diene              | 0.39                         | 12–13     | 0.11        |
| Hydrogenated polybuta-1,2-diene | 0.5                          | 5–6       | 0           |
| Polyisoprene                    | 0.3                          | 15–44     | 0.07 ± 0.02 |

The extension of the rubbery plateau zone depends on the molecular mass of the branched polymers more strongly than in the case of the linear polymers. For instance, for linear monodisperse polystyrene<sup>50</sup> the exponent,  $\nu$ , equals 3.5 (cf.,  $\nu = 4.8$  for four-arm star-branched polyisoprene<sup>131</sup>). It was shown<sup>116</sup> that at equal molecular mass, ( $\bar{M}_w \approx 6 \times 10^4$ ), the  $G'(\omega)$  and  $G''(\omega)$

curves plotted for a linear polymer and a three-arm star-branched polymer nearly merge, whereas for an eight-arm star-branched polymer the terminal zone is shifted towards higher frequencies. At the same time the character of the frequency dependence of the relaxation modulus in the terminal zone is retained, namely,  $G'(\omega) \propto \omega^2$  and  $G''(\omega) \propto \omega$ . Hyperbranched polymers (number of arms is about 50) behave in a different fashion, viz., in the terminal zone one has  $G'(\omega) \propto \omega^{1.12}$  and  $G''(\omega) \propto \omega^{0.91}$  ( $\bar{M}_w \approx 2.5 \times 10^5$ );  $G'(\omega) \propto \omega^{1.1}$  and  $G''(\omega) \propto \omega^{0.85}$  ( $\bar{M}_w \approx 5.75 \times 10^5$ ).

An interesting method of classification of manifestations of the topological structure in the relaxation properties of polymers was proposed.<sup>132</sup> The technique is based on the analysis of the frequency dependence of the shear modulus in the  $\delta$ – $G^*$  coordinates [ $\delta$  is the loss angle,  $\delta = \arctan(G''/G')$ ;  $G^*$  is the complex

modulus,  $G^* = \sqrt{(G')^2 + (G'')^2}/G_N^0$ ], the so-called van Gurp–

Palmen plot.<sup>133</sup> Using experimental data for a rather large number of polymers having different topological structures (asymmetrical and symmetrical star-branched, H-shaped and comb-like, linear chains with variable MMD), a topology map was constructed. The  $\delta$ – $G^*$  curves exhibit a characteristic point  $P_c$ , which is assigned a meaning of a characteristic of the topological structure of the polymer. The set of points corresponding to a specific topology forms a particular region in the map. Thus, location of the  $P_c$  point in a certain region allows characterisation of the polymer structure.

It should be noted that this is an essentially empirical and physically unsubstantiated approach. In addition, the authors<sup>132</sup> pointed out that the boundaries between the areas characterising different topologies in the topology map are not sharp.

In some sense branching and polydispersity influence the relaxation properties of polymers in a similar fashion. The difference is that branching in the terminal zone retards the relaxation processes. In contrast to this, relaxation at high frequencies is accelerated.<sup>105, 134</sup>

#### 4. The gel point

The formation of polymer networks in any way (by polycondensation, polymerisation or cross-linking) is accompanied by considerable broadening of the MMD as the gel point is approached.<sup>3, 135</sup> The attainment of a gel point is associated with the formation of an infinite cluster,<sup>136</sup> which then undergoes a transformation into the gel fraction. This is accompanied by narrowing of the MMDs of the constituents of the sol fraction (they have a finite size).<sup>3, 135</sup> Thus, at the gel point a polymer has a specific topological structure, which can be characterised in terms of fractal theory.<sup>137</sup> The fractal dimension,  $D_f$ , of a cluster relates its volume to the mass

$$R \propto M^{1/D_f},$$

where  $R$  and  $M$  are the radius and the mass of the cluster. For linear ‘massless’ chains one has  $D_f = 2$  ( $D_f = 5/3$  with allowance for the excluded volume).<sup>1, 66, 137</sup> In accordance with percolation theory the fractal dimension of clusters in the region of critical conversion is 2.53.<sup>137</sup> Therefore, branched macromolecules in this region are more compact than linear chains.

The relaxation properties of a polymeric system at the gel point are described by a power law rather than an exponential function<sup>138–141</sup>

$$G(t) \propto t^{-n}. \quad (19)$$

The exponent  $n$  is related to the fractal dimension<sup>142</sup>

$$n = \frac{D}{D_f + 2},$$

where  $D$  is the dimension of the space ( $n = 0.66$  for three-dimensional space).

<sup>†</sup> See page 137 in Ref. 4.

If the degree of conversion  $\alpha$  is expressed in the form

$$\varepsilon = \left| \frac{\alpha - \alpha_c}{\alpha_c} \right|,$$

where  $\varepsilon$  is the relative conversion and  $\alpha_c$  is the critical conversion, at  $\alpha < \alpha_c$  the viscosity is given by  $\eta = \eta_0 \varepsilon^{-s}$  and at  $\alpha > \alpha_c$  the shear modulus is given by  $G = G_0 \alpha^r$  (see Refs 143–146). The exponents  $s$  and  $r$  are related to  $n$  as follows:

$$n = \frac{r}{s + r}.$$

A consequence of relationship (19) is that the frequency dependence of the shear modulus obeys a power law

$$G' \propto \omega^n \cos\left(\frac{\pi n}{2}\right), \quad G'' \propto \omega^n \sin\left(\frac{\pi n}{2}\right).$$

Therefore,  $\tan \delta$  is frequency independent

$$\delta = \frac{\pi n}{2}.$$

Theoretical estimates<sup>146</sup> give  $n = 0.706$ .

These relations were repeatedly confirmed by three-dimensional polymerisation of methacrylate-based oligomers<sup>147</sup> and by end-to-end cross-linking of poly(dimethylsiloxane),<sup>148</sup> *i.e.*, for irreversible processes. Similar behaviour is also characteristic of biopolymers;<sup>149,150</sup> here, reversible formation of an equilibrium network is due to a change in the physical conditions, *e.g.*, the temperature, pH value and concentrations of components. For instance, when xanthane interacts with  $\text{Al}^{3+}$  ions, the exponent  $\rho$  in the expression

$$\tan \delta \propto \omega^\rho$$

varies from  $-0.1$  to  $0.08$  depending on the solution temperature and becomes equal to zero at  $32^\circ\text{C}$ .<sup>150</sup> The  $\rho$  value varies within nearly the same limits as the pH value changes (critical pH value is  $2.9$ ).

A decrease in the temperature of spherical particles of *N*-isopropylacrylamide microgel in a water–methanol solution leads to a gel–sol transition (lowest critical solution temperature is  $32^\circ\text{C}$ ).<sup>151</sup> In this case the exponent  $\rho$  behaves in a similar way and takes a zero value at about  $29^\circ\text{C}$ .

It should be noted that almost all transitions from the liquid to the solid state pass through critical regions where critical clusters are formed, *i.e.*, nuclei of the solid phase (here, the notion ‘phase’ has a kinetic and not necessarily thermodynamical meaning), which have a similar fractal structure.<sup>152</sup>

The numerical value of the exponent  $n$  varies depending on the system. For instance, for polymerisation of methacrylate oligomers  $n$  varies from  $0.4 \pm 0.2$  to  $0.6 \pm 0.1$  and increases as the degree of functionality of the initial oligomer increases.<sup>147</sup> In cross-linking of bifunctional oligo(dimethylsiloxane) having vinyl terminal groups, with a polyfunctional reagent (degrees of functionality were equal to 4 and 11) containing  $\equiv\text{SiH}$  reactive groups, the  $n$  value varies from  $0.69$  to  $0.76$  depending on the system. The cross-linking of poly(dimethylsiloxane) is characterised by  $n = 0.5$  (see Ref. 140) and curing of an epoxy resin by  $n = 0.7$  (see Ref. 153). The  $n$  values for an equilibrium gel formation are much lower, namely,  $0.225$  (see Ref. 150) and  $0.06$  (see Ref. 151).

Components of the complex modulus of branched polyethylene are related to frequency by a power law, *i.e.*, here we deal with a similar dependence and, therefore, the loss factor is frequency independent<sup>105,154,155</sup> if the number of branches is larger than one per  $10^5$  carbon atoms in the main chain.<sup>155</sup> The fractal characteristics of the topological structure of the critical cluster and the branched polymer chains are fundamentally different.

## 5. Structural parameters of polymer networks

The topological structure of a polymer network is usually treated as a set of cross-link points, chain fragments between cross-link points and ‘tails’ (pendant chains).<sup>3</sup> The classical theory of the rubbery state relates the equilibrium modulus to the concentration of chains and, in the framework of the simplest model of network structure, to the concentration of cross-link points.<sup>1,3</sup> However, only active chains contribute to the elasticity of a polymer. Therefore, typical of sparse polymer networks are such cross-link points whose effective functionalities are lower than it follows from chemical considerations.<sup>3,156–158</sup> (Here, the functionality of a cross-link point is the number of attached elastically active chains.) The concentration of such chains is lower than the concentration of chain fragments between cross-link points, as is determined by the topological structure. The concentration of active chains in highly cross-linked polymer networks is larger than it follows from the calculations involving the concentration of cross-link points in the network, because in this case entanglements also contribute to the relaxation modulus.<sup>3</sup> Nonuniform spatial distribution of cross-link points manifests itself in the properties of polymer networks;<sup>159,160</sup> however, even qualitative structure–property relations have not been established as yet. At the same time the relaxation behaviour of polymer networks is immediately related to parameters of the topological structure.

Indeed, it was shown<sup>161–163</sup> that the  $g(t)$ ,  $G'(\omega)$  and  $G''(\omega)$  relaxation curves are rather ‘sensitive’ to the content and molecular mass of ‘pendant’ chains [polymer networks were prepared by co-polycondensation of divinyl- and monovinylpoly(dimethylsiloxanes) with tris(dimethylsiloxy)phenylsilane]. The results obtained were analysed using the empirical equation<sup>164</sup>

$$g(t) = g_\infty \left[ 1 + \varphi \left( \frac{\tau_c}{t} \right)^m \right],$$

where  $g_\infty$  is the equilibrium modulus,  $\varphi$  is the concentration of ‘pendant’ chains and  $\tau_c$  and  $m$  are the empirical parameters dependent on the structure of the polymer network and on the molecular mass of the monofunctional modifier, respectively.

Since polymer networks are characterised by the equilibrium modulus, the thermomechanical curve will reach some limiting equilibrium compliance value with an increase in temperature. By studying the transition from the rubbery state to the equilibrium state it is possible to extract information on the topological structure of the polymer similarly to the case of non-cross-linked systems.

In this case the additivity principle is expressed as follows:<sup>48</sup>

$$J_T = J_0 \left[ 1 - \left( 1 - \frac{J_0}{J_{eq}} \right) \sum_m \varphi(m) \chi(T, m) \right]^{-1}, \quad (20)$$

where  $J_T$ ,  $J_0$  and  $J_{eq}$  are the compliance of the polymer network at temperature  $T$ , the compliance of a hypothetical polymer with an infinite molecular mass (base line) and the limiting (equilibrium) compliance, respectively.

Based on experimental facts, it was assumed<sup>48</sup> that, similarly to linear macromolecules, the gel fraction includes chain fragments between cross-link points, which are characterised by some molecular masses. However, the hypothesis was based on a model of a perfect network, *i.e.*, the authors assumed that (i) the bulk of the polymer consisted of chain fragments between cross-link points, (ii) there were no pendant ‘tails’ and (iii) all cross-link points were characterised by the same degree of functionality. A real polymer network has an incomparably more complex topological structure and contains not only chain fragments between cross-link points but also the sol fraction, pendant chains (‘tails’), loops and cross-link points of different functionality. All these structural elements are also characterised by certain melt flow transition temperatures. Apparently, at equal molecular masses the ‘tails’ will ‘flow’ at a lower temperature than chain fragments between cross-link points. In the polymer network the macro-

molecules not attached to the network are characterised by a lower mobility compared to the mobility in a block polymer.<sup>165</sup> Therefore, Eqn (20) characterises the mass distribution of elements of the topological structure of a polymer network over the relaxation times express through the corresponding flow temperatures. The relations between the flow temperature and the elements of the topological structure should be established independently in special-purpose experiments.

While on the subject of thermomechanical properties, we must consider the relation between the glass transition temperature of a polymer and the concentration,  $n_c$ , of cross-link points in the network.

The glass transition temperature,  $T_g$ , increases as  $n_c$  increases (see, e.g., Refs 156, 166). One can assume that this is a specific manifestation of the topological structure. However, a number of methods have been developed, which allow the glass transition temperature to be calculated from the chemical structure of the polymer.<sup>167–169</sup> In this case it is assumed that the variations of  $n_c$  affect only changes in the chemical structure of the polymer. For instance, the epoxy ring opening in the course of curing of epoxy oligomers with amines produces hydroxyl groups whose concentration increases with an increase in  $n_c$ . It is this parameter, which strongly affects the level of intermolecular interaction, that determines the glass transition temperature. At the same time the glass transition is immediately affected by such factors as the supramolecular structure, packing character and density fluctuations.<sup>14</sup> With inclusion of all these factors we find that the topological structure itself does not influence the glass transition but the changes in the topological structure cause changes in the character of packing and in the fraction of the free volume. For instance, it is this effect that is attained by varying the topological structure of epoxy amine polymers by (i) introducing monofunctional reagents and (ii) changing the ratio of functional groups.<sup>170</sup> Using dielectric spectroscopy and dynamical light scattering, it was established<sup>171</sup> that the parameters of the  $\alpha$ -transition, which vary in the course of curing of the diglycidyl ether of diphenylolpropane with diethylenetriamine, depend on the density fluctuations. Thus, the topological structure at the glass transition of polymers manifests itself indirectly.

Compared to non-cross-linked polymers, polymer networks in the region of the rubbery plateau exhibit a weaker dependence of the relaxation modulus on time

$$G(t) \propto t^{-m}, \quad (21)$$

i.e., the exponent  $m$  decreases with an increase in the degree of cross-linking of the polymer.<sup>146, 153, 172</sup> At the same time in the terminal zone (long relaxation times or low frequencies) the  $G^*(\omega)$  and  $G(t)$  curves for the relaxation modulus and the  $J^*(\omega)$  and  $J(t)$  curves for compliance reach the limiting values corresponding to the equilibrium strain.<sup>173, 174</sup>

The relaxation behaviour of polymers is described by the Kohlrausch–Williams–Watts (9)<sup>175</sup> and Havriliak–Negami (HN)<sup>176–179</sup> equations

$$G^*(\omega) = G_{\text{lim}} + \frac{G_0 - G_{\text{lim}}}{[1 + (i\omega\tau_0)^\alpha]^\beta},$$

where  $\alpha$  and  $\beta$  are empirical constants related to the character of the relaxation spectrum.<sup>177</sup> Here  $G_0$  and  $G_{\text{lim}}$  are the limiting values of the elastic modulus corresponding to the low and high frequencies, respectively, and  $\tau_0$  is an empirical parameter which can be associated with the relaxation time. The HN equation is more often used when analysing dielectric relaxation data.

Numerical values of the empirical parameters of the KWW and HN equations depend on the polymer structure including its topology. For instance, the parameter  $\beta$  (for the KWW equation containing only one term) decreases with an increase in the concentration of cross-link points (Table 3).<sup>179, 180</sup>

Similar results were also obtained in a broadband dielectric spectroscopy study of the curing of the diglycidyl ether of

**Table 3.** Effect of chain length between cross-link points ( $M_c$ ) on the parameter  $\beta$ .<sup>179, 180</sup>

| 2040                | 0.49    | 3800              | 0.37    |
| 2900                | 0.58    | non-cross-linked  | 0.41    |

diphenylolpropane with bis(4-aminophenyl)methane.<sup>181</sup> Although the KWW dependence was obeyed only approximately, the following  $\beta$  values were obtained for the 10%, 20%, 40% and 70% conversions: 0.53, 0.45–0.52, 0.3–0.4 and 0.17–0.2, respectively. Despite the fact that the network is formed at degrees of conversion exceeding 60%, it is reasonable to assume that the trend disclosed also holds in this range of conversions. At the same time the increase in the parameter  $\beta$  during the chemical reaction gives grounds to assume whether or not the network density is an indirectly affecting factor, whereas the chemical structure has a direct effect on the parameter  $\beta$ .

A decrease in  $\beta$  means that the higher the concentration of cross-link points, the smaller the decrease in the modulus with time. This is in qualitative agreement with the data described by relationship (21), namely, an increase in the degree of cross-linking of the polymer leads to a decrease in the exponent  $m$ .

The parameters of the HN equation also depend on the degree of cross-linking of the polymer network. For  $G_0$ , this dependence is obvious, viz., the value of this equilibrium elastic modulus is proportional to the concentration of chains. For instance, it was shown<sup>182</sup> that changes in the ratio of functional groups in the reaction of polyoxypropylenetriol (POPT) with bis(4-aminophenyl)methane cause appreciable changes in the compliance  $J_0$  and elastic modulus  $G_0$  (Table 4).

**Table 4.** Effect of stoichiometric ratio of OH and NCO functional groups on the  $J_0$  and  $G_0$  values in the terminal region.<sup>182</sup>

The effect of cross-linking on the parameters  $\alpha$  and  $\beta$  can be followed using the data for the curing of the diglycidyl ether of diphenylolpropane with bis(4-aminophenyl)sulfone at 140 °C (see Table 5).<sup>183</sup> As can be seen, the parameter  $\alpha$ , which characterises the width of the relaxation time distribution,<sup>181, 184, 185</sup> decreases with an increase in the concentration of cross-link points (the calculated degree of critical conversion for this system is 0.57), whereas the parameter  $\beta$ , which characterises the asymmetry of the distribution function, remains unchanged. Probably, changes in the chemical structure of the system in the course of the reaction and, as a consequence, the glass transition also play a significant role in this case.<sup>186</sup> Indeed, it was shown<sup>184</sup> that an epoxy system (the diglycidyl ether of diphenylolpropane + diethylenetriamine), which undergoes a glass transition in the course of curing, is

**Table 5.** Dependence of the HN equation parameters on the degree of cross-linking of a polymer network.<sup>183</sup>

| Conversion | $\alpha$ | Conversion | $\alpha$ |

| 0.81       | 0.615    | 0.85       | 0.532    |
| 0.82       | 0.607    |            |          |

**Note.** At all conversion values,  $\beta = 0.9$ .

characterised by a decrease in the parameter  $\alpha$  and an increase in the parameter  $\beta$ . At the same time a study of the formation of an elastic urethane network in the reaction of hexamethylenediisocyanate with a poly(oxypropylene)-based triol revealed an identical trend in changes in the parameters  $\alpha$  and  $\beta$  with time, but these changes were small. An attempt<sup>181</sup> to establish a correlation between the degree of cross-linking and the  $\alpha$  value for a related system failed. Thus, it is hard to draw an unambiguous conclusion about the relation between the parameters of the HN equation and the cross-link density of polymer networks based on the results presented above.

The topological structure of polymers is correctly reproduced in their relaxation properties, which can be studied by NMR spectroscopy.<sup>59, 187, 188</sup> Gotlib *et al.*<sup>189</sup> established that the temperature dependence of the spin–spin relaxation time  $T_2$  in polymer networks reaches a plateau with an increase in temperature, the  $T_{2\text{ lim}}$  being proportional to the average chain mass (length) between cross-link points,  $M_c$ .

Studies<sup>190, 191</sup> of polymer networks based on poly(tetrahydrofuran) and polyfurite [poly(oxytetramethylene glycol)] showed that the shape of the free induction decay curve depends on the MMD chains of the network

$$G(t) = \int_0^{\infty} P(N) G_0(t, N) dN, \quad (22)$$

where  $G_0(t, N)$  is the dependence of the free induction decay for a monodisperse polymer with chain length  $N$ .

The theory of NMR spectra<sup>190, 191</sup> allows this function to be described as a solution to the problem inverse to problem (22). Some examples illustrating a relation between the MMD of the chain fragments between the cross-link points of polymer networks and the NMR data were considered in a review.<sup>187</sup>

Apparently, estimates of the MMD function by this method are of limited use due to at least two reasons. First, one should take into account physical junction points (entanglements), which behave as cross-link points in long chains. This factor ‘cuts off’ the high-molecular-mass region of the MMD function (see, *e.g.*, Ref. 192). The second reason is the difference of the actual set of topologies from that given by an ideal model of a network. The cross-link points in real polymers are characterised by different degrees of functionality<sup>3, 156–158</sup> and, hence, by different mobilities.<sup>156</sup> The latter was directly shown in pulsed NMR studies.<sup>193–195</sup> Analysis of the free induction decay curves in epoxy amine polymers modified by adding the monoepoxy component or by varying the ratio of epoxy/amine functional groups revealed the presence of two (and more) kinetic phases with different mobilities. It was found that the proton concentration in these phases is proportional to the concentration of cross-links having different functionalities and that the mobilities of the cross-links correlate with the mobilities of the chains emerging from the cross-links. This was shown<sup>180, 196</sup> by, *e.g.*, <sup>31</sup>P NMR, taking the reaction of poly(tetrahydrofuran) polymer network with tris(4-isocyanatophenyl)thiophosphate as an example (the latter compound served as the component for cross-link point formation in the polymer network).

## 6. Equilibrium (physical) networks

The topological structures of the equilibrium networks have been the subject of theoretical and experimental research.<sup>197–203</sup> According to Flory,<sup>204</sup> physical gels can be classified as follows:

- well ordered lamellar structures;
- completely disordered covalent polymer networks;
- mainly disordered polymer networks formed by aggregation and containing ordered regions; and
- specific disordered structures.

As can be seen, polymeric systems with cross-links formed by clustering are also included. Conventional non-cross-linked polymers, which exhibit, in a particular relaxation time interval, the properties of three-dimensional polymers due to formation of physical junction points (*e.g.*, entanglements and/or orientation clusters)<sup>85, 87, 205</sup> as well as labile networks with equilibrium cross-links are left out of consideration. It is the last-mentioned type of network that is of particular interest, because they can be treated as models for covalent networks on the one hand and for non-cross-linked polymers on the other hand.

In contrast to cross-link points in a polymer network, which represent more or less complex fragments of the molecular structure,<sup>3, 169</sup> the junction points in a reversible network are ‘points’ in essence. Their concentration can be described by a simple equilibrium<sup>201, 206–209</sup>

where  $X$  is the content of the functional groups capable of forming chemical bonds, whose concentration equals  $X_2$ . Such bonds are labile cross-links.

In contrast to the cross-link points in a reversible network, the temporary junctions in a non-cross-linked polymer, which manifest themselves within a particular relaxation time interval (rubbery plateau zone), are not related to the chemical nature of the polymer. Indeed, entanglements, which are usually treated as temporary junction points,<sup>34</sup> are only due to impenetrability of chains. The formation of nematic clusters, which can also play the role of temporary junction points,<sup>85, 87, 205</sup> is due to natural properties of polymers (segment anisotropy and confined space available for arrangement of a polymer chain due to the excluded volume effect) rather than some specific intermolecular interaction.<sup>205</sup>

Thus, the junction points of reversible networks are similar to and at the same time different from cross-link points in non-cross-linked and three-dimensional polymers (Table 6). The relaxation properties of these three types of networks are qualitatively compared in Fig. 5 (see also Ref. 201). Curve 1 is the temporal

**Figure 5.** Relaxation elastic modulus plotted vs. time for a non-cross-linked polymer (1) and equilibrium (2) and non-equilibrium (3 and 3') networks.

**Table 6.** Characteristics of cross-links in different types of networks.

| Chain entanglements<br>(non-cross-linked polymers) <sup>a</sup>       | Physical network <sup>a</sup>                                                                   | Chemical network<br>(three-dimensional polymers)                                                        |
|-----------------------------------------------------------------------|-------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------|
| Chemical structure of the polymer is immaterial                       | presence of polar H-bonding groups on the chains is essential                                   | presence of functional groups that can chemically react with one another                                |
| No energy is involved during cross-link creation – loss ( $\sim RT$ ) | energy of the order of units of kJ per mole ( $\leq 10 RT$ ) is involved during creation – loss | energy of the order of tens of kJ per mole ( $\geq 100 RT$ ) is involved during creation – loss         |
| Formation and loss are non-specific                                   | formation of cross-links requires specific site orientation and cooperative network mobility    | formation of cross-links obeys kinetic laws that are often complicated by diffusion and other processes |
| Non-cooperative                                                       | cooperativity effects are significant during zipping and unzipping of ladder-like structures    | usually, co-operative effects are ignored                                                               |
| Solvent does not affect physical networks                             | solvent effects can be crucial for the equilibrium constant                                     | conventional kinetic solvent effect                                                                     |

<sup>a</sup> According to Ref. 199.

dependence of the relaxation modulus of elasticity of a non-cross-linked polymer. In a particular relaxation time interval, from  $\lambda_{\min}$  to  $\lambda_{\max}$ , in the rubbery plateau zone, the polymer exhibits the properties of a network. Then, in the terminal zone, an abrupt decrease in the relaxation modulus characterises the transition to a viscous flow state. The relaxation modulus of a three-dimensional polymer (curve 3) in the vicinity of  $\lambda_{\max}$  either remains at the plateau level (highly cross-linked polymers for which chemical cross-link points and labile junction points are summed, curve 3'), or goes to the level of the equilibrium modulus (sparse networks for which only chemical cross-links are significant). Reversible networks (curve 2) are characterised by two plateau zones. The former corresponds to a physical network, in which an important role is played by both types of labile cross-link points. At relaxation times longer than  $\lambda_{\lim}$ , the relaxation modulus is determined by the concentration of the same cross-link points as in the non-cross-linked polymer. However, in the presence of functional groups interacting with one another to form cross-links with average lifetimes shorter than  $\lambda_{\lim}$ , the  $\lambda_{\max}$  value appreciably increases<sup>201</sup>

$$\lambda_{\max}^* = \lambda_{\max} \frac{2S^2 p^2}{12 - 9p + p^2},$$

where  $S$  is the average number of functional groups per chain and  $p$  is the probability of formation of a cross-link. The reason for the lowering of the relaxation rate is retardation of the diffusion motion of chains by the newly forming labile cross-links.

The relaxation behaviour of equilibrium polymer networks was studied<sup>206–211</sup> taking polybutadiene modified by 4-phenyl-1,2,4-triazolidine-3,5-dione as an example. On addition to polymers, the latter compound undergoes dimerisation and forms cross-links with a bond energy of  $57 \pm 15 \text{ kJ mol}^{-1}$  (see Ref. 206).

An increase in the concentration of modifier causes an increase in the relaxation modulus  $G_N^0$  in the rubbery plateau zone (Table 7).<sup>211</sup> Lowering the temperature leads to an increase in  $G_N^0$ , which is apparently due to the temperature dependence of the equilibrium constant (23). A significant effect of temperature on  $G_N^0$  is a distinctive feature of the equilibrium networks.<sup>208, 209</sup>

The extension of the rubbery plateau zone and the viscosity of polybutadiene ( $M_n = 2.6 \times 10^4$ ) are plotted vs. the concentration of modifier in Fig. 6 using the data taken from Refs 210 and 211. These results qualitatively substantiate theoretical conclusions, namely,<sup>201</sup> an increase in the concentration of active functional groups causes an appreciable increase in the viscosity and, as a consequence, an increase in  $\lambda_{\max}^*$ . The effect of temperature is also quite clear, that is, lowering the temperature leads to a corresponding increase in the viscosity. The extension of the rubbery plateau zone also increases.

**Table 7.** Effect of degree of cross-linking of an equilibrium network on the relaxation modulus in the region of the rubbery plateau at  $T = 273 \text{ K}$ .

<sup>a</sup> Data taken from Ref. 209 at  $T = 237 \text{ K}$ .

The concentration of functional groups also influences the parameters of the HN equation,<sup>208</sup> namely, with an increase in the concentration of functional groups the parameter  $\alpha$  slightly increases while the parameter  $\beta$  substantially decreases.

**Figure 6.** Rubbery plateau extension (1, 2) and viscosity (3, 4) of modified polybutadiene plotted vs. concentration of modifier at 273 (1, 3)<sup>210</sup> and 233 K (2, 4).<sup>211</sup>

#### IV. The relaxation time spectrum as a means of correct characterisation of topological structure

The possibility of obtaining a correct description of the relaxation behaviour of polymers using the relaxation time spectrum was initially considered as a hypothesis only.<sup>63, 64, 212</sup> Rouse<sup>213</sup> first showed that the dynamics of a polymer chain can be described using a discrete set of relaxation times that depend on the chain length (number of dynamical units). The totality of unambiguously determined pre-exponents can also be considered as a relaxation spectrum. Since then a number of models have been proposed, which describe the reptation motion of macromolecules with allowance for various relaxation mechanisms of the ‘tube’, *i.e.*, a region in which a restrained motion of a specified chain is realised.<sup>4, 11, 34, 52, 214, 215</sup> Each relaxation mechanism corresponded to a particular set of relaxation times and, hence, a relaxation spectrum. Comprehensive analysis of the dynamical models and consequences following from them was reported in a review.<sup>52</sup>

Some authors (see, *e.g.*, Refs 216–220) considered a theory which provides an alternative to the reptation theory. Basic to the new theory is the assumption that restrained chain motions are mainly due to close packing, which leads to intermolecular cooperativity on the length scale of a chain segment, rather than topological junctions. In this case the formation of nematic clusters also plays a significant role.<sup>89</sup>

Thus, in this case the relaxation spectrum, in contrast to local relaxation transitions, has a dynamical meaning. Namely, it is related to the polymer structure indirectly, through correlations between the dynamical properties and topology of macromolecules (of course, with allowance for the conditions under which the motion occurs).

## 1. Modified Rouse chain

The molecular structure can also to some extent affect parameters of the relaxation spectrum, but again this occurs due to specific features of dynamical processes. For instance, the relaxation properties of the modified Kargin–Slonimskii–Rouse model<sup>45, 213</sup> have been studied.<sup>214, 215, 221, 222</sup> The relaxation behaviour of these models was also analysed in other studies (see Refs 223 and 224), but this concerned the frequency or temporal dependences of the relaxation modulus while the effect of chain modification on the relaxation spectrum was not considered.

The modification consisted of the chain units being ascribed different friction coefficients. Stress relaxation of an unbalanced chain comprising  $n$  units is described by a system of  $n$  equations

$$\begin{aligned}\tau_1 \dot{x}_1 &= -x_1 + x_2 \\ \tau_2 \dot{x}_2 &= x_1 - 2x_2 + x_3 \\ &\dots\dots\dots \\ \tau_i \dot{x}_i &= x_{i-1} - 2x_i + x_{i+1} \\ &\dots\dots\dots \\ \tau_n \dot{x}_n &= x_{n-1} - x_n,\end{aligned}\tag{24}$$

where  $x_i$  is the coordinate of the  $i$ th unit; the relaxation characteristics of the units, which are due to different friction coefficients (*i.e.*, the interaction between the units and the environment), are described by the parameter  $\tau_i$ . Having solved the system (24), it is possible to derive the equations of motion for all units of the chain and to determine the change in the chain length,  $L = x_n - x_1$ , provided that the initial conditions are specified. An example of the initial conditions is given by  $L(0) = 1$ ,  $x_i(0) = (i - 1)/(n - 1)$ , which corresponds to a uniformly stretched equidistant chain.

The solution of system (24) in the form of a combination of exponents for relaxation of the chain length

$$L(t) = \sum_{i=1}^n h_i \exp(-p_i t),$$

where  $h_i$  is the relaxation time spectrum, is given by the roots  $z_i = \tau_i p_i$  of the polynomial  $D_n = 0$ , where  $D_n$  is the modified Rouse matrix

$$D_n = \begin{vmatrix} z_1 - 1 & 1 & 0 & 0 & \dots & 0 & 0 & 0 \\ 1 & z_2 - 2 & 1 & 0 & \dots & 0 & 0 & 0 \\ & & & & & & & \\ 0 & 0 & 0 & 0 & \dots & 1 & z_{n-1} - 2 & 1 \\ 0 & 0 & 0 & 0 & \dots & 0 & 1 & z_{n-1} \end{vmatrix} \quad (25)$$

Numerical solution of Eqn (25) makes it possible to obtain a total of  $(n - 1)$  roots  $p_1, p_2, \dots, p_i, \dots, p_{n-1}$ , which represent the reciprocal relaxation times ( $p_i = \lambda_i^{-1}$ ) characterising the relaxation behaviour of the entire chain. In the case of identical units the results obtained are exactly described by the Rouse relations

$$\lambda_i^{-1} = 4 \sin^2 \left( \frac{\pi}{2} \frac{i}{n+1} \right),$$

$$h_i = \frac{1}{2n} \left[ \tan\left(\frac{i\pi}{2n}\right) \right]^{-2},$$

where  $i$  is the mode number ( $i = 0$  corresponds to the maximum relaxation time);  $h_i = 0$  for the even  $i$  values.

Insertion of units with higher friction coefficients (type  $a$  units; type  $b$  was ascribed to unmodified units) into the chain causes significant changes in the set of relaxation modes. Figures 7 and 8 show that the total number of modes increases with an increase in the number of type  $a$  units, which divide the chain into blocks comprised of units with a low friction coefficient. However, higher-frequency modes are grouped into ‘packets’, *i.e.*, form groups characterised by similar relaxation times; a distinctive feature is that the higher the friction coefficient of the type  $a$  units, the smaller the separation between such modes (see Fig. 7). It is hard to assign the relaxation modes in the relaxation time spectrum characterising the Rouse chain to particular units. If the relaxation properties of the type  $a$  units inserted into the chain differ only slightly from those of the type  $b$  units ( $\tau_a/\tau_b = 2$ ), it is possible to select ‘packets’ of relaxation modes, which, although they have different parameters, are ‘clustered’ near the values characteristic of the type  $b$  blocks. The larger the  $\tau_a/\tau_b$  ratio, the smaller the separation between the modes in ‘packets’ (see Fig. 7). In the limiting case, chain elongation due to an increase in the number of blocks leads to a decrease in the number of modes.

**Figure 7.** Relaxation modes for monoblock (below horizontal lines) and tetrablock chains (above horizontal lines) for the  $a-(b-b-b-b-b-a)_m$  structure.<sup>215</sup>  $\tau_a/\tau_b = 1$  (1), 2 (2), 5 (3), 10 (4) and 100 (5).

**Figure 8.** Relaxation modes for the  $a-(b-b-b-b-b-a)_m$  structure.<sup>215</sup>  
 $\tau_a/\tau_b = 2$ . Figures denote the  $m$  values.

which becomes smaller than the total number of units because high-frequency modes merge.

A comparison of polyblock chains with a ‘monoblock’ one (see Fig. 8) showed that high-frequency relaxation modes are grouped near the values characteristic of the corresponding block. The number of relaxation modes in a ‘packet’ becomes equal to the number of blocks. (In Fig. 8 we present the data for  $\tau_a/\tau_b = 2$  in order to distinguish between components of the ‘packet’.) Thus, the units with a high friction coefficient separate blocks from one another; because of this, the relaxation modes characterising the units possessing different relaxation properties can be separated in the relaxation spectrum of any chain.

The relaxation spectra of the chains having the structures described in Table 8 are shown in Fig. 9.

If the modified unit is present in the terminal zone of the chain, the  $\lambda_{\max}$  value somewhat increases, but the statistical weight of the corresponding mode decreases. Separation of the blocks comprised of units with higher mobility by the units of lower mobility

**Figure 9.** Relaxation modes for chains of different structure. For notations (1–4), see Table 8.

**Table 8.** Effect of the structure of the modified Rouse chain on the parameters of the relaxation spectrum (in arbitrary units).<sup>215</sup>

| No. | Chain structure <sup>a</sup>                      | $\lambda_{\max}$ | $\langle \lambda \rangle_w$ | $\langle \lambda \rangle_n$ |
|-----|---------------------------------------------------|------------------|-----------------------------|-----------------------------|
| 1   | $1-(1)_{18}-1 \rightarrow F$                      | 174              | 143                         | 20                          |
| 2   | $5-(1)_{18}-1 \rightarrow F$                      | 265              | 224                         | 25                          |
| 3   | $5-(1)_{12}-5-(1)_5-1 \rightarrow F$              | 261              | 232                         | 27                          |
| 4   | $5-(1)_3-5-(1)_6-5-(1)_4-5-(1)_2-1 \rightarrow F$ | 331              | 282                         | 36                          |

<sup>a</sup> Figures are the ratios of the friction coefficients of the units  $a$  and  $b$ ; subscripts denote the number of units in the block and  $F$  is the force exerted on the chain.

leads to the appearance of peaks in the relaxation spectra, the number of peaks being changed antiparallel to the number of blocks. This is due to a decrease in the block length.

Thus, this example allowed us to follow how the ‘molecular’ structure manifests itself in the relaxation time spectra through the mobilities of units.

Analysis<sup>214, 215</sup> showed that the strain and stress relaxation processes affect not only the relaxation spectrum (this was shown earlier for the uniform Rouse model, see, e.g., Ref. 34) but also the set of relaxation times. This is illustrated in Fig. 10. Apparently, this is a consequence of an indirect relation between the relaxation spectrum and the polymer structure through the macromolecular

**Figure 10.** Correlation between the relaxation times  $\lambda_i$  and  $\lambda_{iR}$  (a) and the stress relaxation spectra (b, curves 1 and 2) and deformation relaxation spectra (b, curves 3 and 4) obtained for chains comprising ten (1, 3) and twenty (2, 4) units.

dynamics. This is also indicated by the fact that physically substantiated spectrum cannot be obtained under any initial relaxation conditions. For instance, if in the initial state the chain units are arranged nonuniformly, a number of pre-exponents can take negative values.<sup>225</sup>

## 2. Methods of calculation of the relaxation spectra from experimental data

The viscoelastic behaviour of polymers can be conveniently characterised by a spectrum of relaxation times. Usually, it is believed<sup>4,5</sup> that one can determine and predict the viscoelastic behaviour of polymers under any strain and loading conditions from the known relaxation spectrum. However, the relaxation spectrum was obtained in explicit form only for molecular models (see above). Comparison of the results of modelling with experimental data on certain relaxation properties gives no assurance of correctness of the former. In order to assess the ability of a theoretical model to describe experimental data, one should compare the model relaxation spectra with the experimental ones, which thus play the role of a generalised characteristic. Therefore, methods of calculation of relaxation spectra, which are based on analysis of experimental data (mainly temporal and frequency dependences of the elastic modulus) have been continuously developing.<sup>226</sup>

Calculations of the relaxation time spectrum from the known real and imaginary components of the elastic modulus belong to the class of ill-posed problems; therefore, the uniqueness problem of the results obtained poses.<sup>226–229</sup>

### a. Effective relaxation time as a characteristic of the relaxation spectrum

Is it always necessary to represent the relaxation time distribution function in explicit form? It was shown<sup>49,51,88</sup> that as a quantitative characteristic it is sufficient to use the effective relaxation time  $\lambda_{\text{ef}}$

$$\frac{1}{\lambda_{\text{ef}}} = -\frac{d \ln G(t)}{dt} = \frac{\sum_i h_i \lambda_i^{-1} \exp(-t/\lambda_i)}{\sum_i h_i \exp(-t/\lambda_i)} = \sum_i w_i(t) \lambda_i^{-1},$$

where  $h_i$  is the relaxation spectrum and  $w_i(t)$  is the relaxation time distribution function in the time domain, which is related to  $h_i$  at  $t = 0$  as follows

$$w_i = \frac{h_i}{\sum_i h_i}.$$

The use of the parameter  $\lambda_{\text{ef}}$  for comparison of experimental stress relaxation data with the dependences obtained using the polymer dynamics models led to good results.<sup>49,51</sup> For instance, the Rouse and Doi–Edwards models with the known (and different!) relaxation spectra give significantly different dependences  $\lambda_{\text{ef}}(t)$ . In the Rouse model the parameter  $\lambda_{\text{ef}}$  is proportional to  $t$  at  $\lambda_{\text{min}} \leq t \leq \lambda_{\text{max}}$ , i.e., in the region where the relaxation modulus of elasticity is proportional to  $t^{-1/2}$ . In the Doi–Edwards model the parameter  $\lambda_{\text{ef}}$  in the rubbery plateau zone is proportional to  $t^{1/2}$ .

The temporal dependences of the relaxation shear modulus and the effective relaxation time of narrow-MMD polystyrene ( $M_w/M_n = 1.03$ ) plotted using the data taken from Ref. 230 are shown in Fig. 11. In the transient region corresponding to transition from the glassy state to the rubbery plateau zone the parameter  $\lambda_{\text{ef}}$  is nearly proportional to the square root of time, the dependence in the rubbery plateau zone is nearly linear (the exponent is 1.2) and then it becomes weaker in the region where the effect of the molecular mass becomes pronounced. Eventually, the parameter  $\lambda_{\text{ef}}$  takes a constant value equal to the maximum relaxation time. It was shown<sup>49</sup> that the stress relaxation behaviour of other monodisperse polystyrenes (see Refs 74, 231, 232) also obeys these laws, with the maximum relaxation time being

**Figure 11.** Shear modulus (a) and effective relaxation time (b) of polystyrene plotted vs. time.<sup>230</sup>  $M_w \times 10^{-3} = 80$  (1), 125 (2), 193 (3), 239 (4), 267 (5). The reduction temperature was 129 °C.

proportional to  $M^4$  (Fig. 12). This dependence cannot always be revealed. Indeed, if the molecular masses vary with a not too large interval, the dependence mentioned above can be distorted. Besides, if the molecular mass of a polymer varies over a broad range, the relaxation measurements are usually carried out at appreciably different temperatures and then their results are reduced to a certain specified temperature using the principle of temperature–time superposition. Small uncertainties introduced when using this procedure can lead (and do lead, see the data shown in Fig. 12) to errors. Analysis of the whole array of experimental data showed validity of the power law mentioned above. This dependence was also reported in other studies.<sup>104,233</sup>

**Figure 12.** Maximum relaxation time plotted vs. molecular mass of polystyrene (1–4) using the data taken from Refs 231, 74, 230 and 232, respectively. Reduced temperature /°C: 160 (1), 139 (2, 3) and 127 (4). The dashed line describes the dependence  $\lambda_{\text{max}} \propto M^4$ .

The fact that for monodisperse polymers  $\lambda_{\text{ef}}$  in the rubbery plateau zone is proportional to  $t^{1.2}$  can indicate that the relaxation spectra of these compounds are more similar to the Rouse spectrum with respect to this characteristic.

Knowing the frequency dependence of the effective relaxation time, it is possible to determine<sup>51</sup> two parameters with different degrees of averaging over the relaxation times. In this case analysis is carried out using the real  $G'(\omega)$  and the imaginary  $G''(\omega)$  components of the relaxation modulus of elasticity separately.

Similarly to the case of the frequency dependence of the relaxation modulus, the frequency domain is divided into three zones with respect to the character of the frequency dependence of the effective relaxation time. These are the terminal zone (zone *I*, low frequencies), the rubbery plateau zone (zone *II*) and the high-frequency zone (zone *III*).

As mentioned above [see expression (12)] the effective relaxation time  $\lambda_{\text{efw}}(\omega)$  in the terminal zone *I* reaches a limiting value, which is frequency independent and equals the ratio of the second to the first moment of the relaxation time distribution, i.e., is the weight-average relaxation time [see relationship (13)].

In zone *III* at  $\omega \rightarrow \infty$  one has

$$\lambda_{\text{wIII}} = \frac{\sum_i h_i}{\sum_i (h_i/\lambda_i)}.$$

Since short relaxation times make a greater contribution to the last-mentioned expression, one gets  $\lambda_{\text{wIII}} < \lambda_{\text{wI}}$  and the  $\lambda_{\text{wII}}(\omega)$  dependence in zone *II* (rubbery plateau zone) is a decreasing function of frequency.

The effective relaxation time [see expression (14)] at  $\omega \rightarrow 0$  (region *I*) is the number-average relaxation time, which is also frequency independent

$$\langle \lambda \rangle_{\text{nI}} = \frac{\sum_i h_i(\lambda) \lambda_i}{\sum_i h_i(\lambda)}.$$

In region *III* one has

$$\lambda_{\text{efn}}(\omega) \rightarrow \frac{\sum_i h_i/\lambda_i}{\sum_i h_i/\lambda_i^2}.$$

This value can be either small or rather large depending on the character of the relaxation spectrum. Therefore, in region *II* the  $\lambda_{\text{efn}}(\omega)$  dependence can show rather complex behaviour.

Thus, analysis of the frequency dependence of the effective relaxation time makes it possible to estimate the relaxation time spectrum using a number of distribution moments. In particular, the ratio

$$\gamma_{\text{I}} = \frac{\langle \lambda \rangle_{\text{wI}}}{\langle \lambda \rangle_{\text{nI}}}$$

characterises the width of the relaxation time distribution in region *I*.

The relaxation spectrum of the Rouse model is given<sup>33</sup> by the relationship  $h_i = n^{-1}$ , where  $n$  is the chain length. Therefore, in the terminal zone one gets

$$\langle \lambda \rangle_{\text{wI}} = \lambda_{\text{max}} \frac{\sum_{i=1}^n i^{-4}}{\sum_{i=1}^n i^{-2}} \approx \lambda_{\text{max}}$$

and

$$\langle \lambda \rangle_{\text{nI}} = \frac{\lambda_{\text{max}}}{n} \sum_{i=1}^n i^{-2} \approx \frac{\lambda_{\text{max}}}{n}.$$

**Table 9.** Dependences of characteristics of the effective relaxation time on the chain length for various models.<sup>51</sup>

| Model                | $\langle \lambda \rangle_{\text{nI}}$ | $\langle \lambda \rangle_{\text{wI}}$ | $\lambda_{\text{max}}$ | $\gamma_{\text{max}}$ | $\omega_{\text{max}}$ | $\gamma_{\text{I}}$ |
|----------------------|---------------------------------------|---------------------------------------|------------------------|-----------------------|-----------------------|---------------------|
| Rouse model          | $n^1$                                 | $n^2$                                 | $n^2$                  | —                     | —                     | $n^1$               |
| Doi–Edwards model    | $n^3$                                 | $n^3$                                 | $n^3$                  | —                     | —                     | $n^0$               |
| Modified Rouse model | $n^1$                                 | $n^{1.66}$                            | $n^{1.7}$              | $n^{0.58}$            | $n^{-2.2}$            | $n^{0.66}$          |

Because, in accord with the Rouse model,  $\lambda_{\text{max}}$  is proportional to  $n^2$ , the parameter  $\langle \lambda \rangle_{\text{wI}}$  also increases in proportion to  $n^2$  and  $\langle \lambda \rangle_{\text{nI}}$  increases in proportion to  $n$ . The distribution width,  $\gamma_{\text{I}}$ , increases proportionally to the polymer chain length (Table 9).

The following relationships are valid in zone *III*:

$$\begin{aligned} \langle \lambda \rangle_{\text{wIII}} &= \lambda_{\text{max}} \frac{n}{\sum_{i=1}^n i^2} \approx \frac{\lambda_{\text{max}}}{n^2}, \\ \langle \lambda \rangle_{\text{nIII}} &= \lambda_{\text{max}} \frac{\sum_{i=1}^n i^2}{\sum_{i=1}^n i^4} \approx \frac{\lambda_{\text{max}}}{n^2}. \end{aligned}$$

Thus, the distribution width  $\gamma$  is independent of chain length in this frequency region.

In the Doi–Edwards reptation model the relaxation spectrum is given<sup>34</sup> by the expression  $h_i = i^{-2}$ ; therefore, in zone *I* one has

$$\begin{aligned} \langle \lambda \rangle_{\text{wI}} &= \lambda_{\text{max}} \frac{\sum_{i=1,3,\dots}^n i^{-6}}{\sum_{i=1,3,\dots}^n i^{-4}} \approx \lambda_{\text{max}}, \\ \langle \lambda \rangle_{\text{nI}} &= \frac{8}{\pi^2} \lambda_{\text{max}} \sum_{i=1,3,\dots}^n i^{-4} \approx \lambda_{\text{max}}. \end{aligned}$$

The distribution width  $\gamma_{\text{I}}$  is independent of chain length.

For zone *III* one has

$$\begin{aligned} \langle \lambda \rangle_{\text{nIII}} &= \lambda_{\text{max}} \frac{n}{\sum_{i=1}^n i^2} \approx \frac{\lambda_{\text{max}}}{n^2}, \\ \langle \lambda \rangle_{\text{wIII}} &= \lambda_{\text{max}} \frac{\sum_{i=1}^n i^{-2}}{n} \approx \frac{\lambda_{\text{max}}}{n}, \end{aligned}$$

and  $\gamma_{\text{III}}$  increases in proportion to  $n$ .

In the rubbery plateau zone (zone *II*) the parameter  $\lambda_{\text{wII}}$  is proportional to  $\omega^{-1}$  for the Rouse model and to  $\omega^{-1/2}$  for the Doi–Edwards model; respectively,  $\lambda_{\text{nII}} \propto \omega^{-1/2}$  and  $\lambda_{\text{nII}} \propto \omega^{-1}$ . From here the ratios of the average relaxation times for these models are also different, namely, the parameter  $\gamma_{\text{II}}$  decreases in the former and increases in the latter case nearly proportionally to the square root of the frequency.

Thus, different frequency dependences of the average relaxation times and their ratios reflect significant differences between the relaxation spectra of the models under consideration.

The average relaxation times and their ratios depend on the structures of the polymer chains. This dependence can be illustrated taking nonuniform Rouse chains (see above) as an example. We will consider chains whose structures can be expressed through the friction coefficients of units as follows:

**Figure 13.** Relaxation spectra calculated for modified Rouse chains  $F \leftarrow (1-1-1-5)_m-1-1-1-5$  with  $m = 0$  (1), 1 (2), 2 (3), 3 (4) and 4 (5).<sup>51</sup>

$F \leftarrow (1-1-1-5)_m-1-1-1-5$ , where  $m = 0, 1, 2, 3, 4$ . The relaxation spectra calculated for these model chains are shown in Fig. 13. As can be seen, in contrast to the Rouse and the Doi–Edwards models, the nonuniform Rouse chain model leads to the formation of an essentially non-monotonic discrete relaxation spectrum. Qualitatively, the frequency dependences of the average relaxation times (Fig. 14) obey the same pattern as the analogous theoretical dependences shown above. However, the  $\gamma(\omega)$  dependence is basically different, namely, pronounced maxima appear in the curves. Quantitative relation of these parameters to the chain length also differs from the corresponding relations derived for the models considered above (see Table 9).

In the frequency regions *I* and *III* the parameters  $\langle \lambda \rangle_w$ ,  $\langle \lambda \rangle_n$  and  $\gamma$  take constant values, the average relaxation times in zone *I* being proportional to the chain length  $n = 4(m+1)$  raised to the power 1.66 and 1.00 for  $\langle \lambda \rangle_w$  and  $\langle \lambda \rangle_n$ , respectively; here for the average relaxation time ratio one has  $\gamma_I \propto n^{0.66}$  (see Table 9); in zone *III* the parameters  $\langle \lambda \rangle_{wIII}$  and  $\langle \lambda \rangle_{nIII}$  are independent of  $n$ . The frequency dependence of the ratio of the average relaxation times in the rubbery plateau zone can be quite accurately described by a power law with an exponent of about 0.5. The height of the maximum and its position on the frequency axis depend on the chain length, namely,  $\gamma_{\max} \propto n^{0.58}$  and  $\omega_{\max} \propto n^{-2.2}$ .

Thus, the nonuniform Rouse chain model is intermediate between the Rouse and the Doi–Edwards models with respect to the relaxation properties. This shows that the relaxation characteristics in question (effective relaxation times and their ratio) are rather sensitive to both the type of motion (the Rouse and Doi–Edwards models) and the chain structure (the classical and nonuniform Rouse models).

As an example Fig. 15 presents the frequency dependences of the effective relaxation times of polystyrene, obtained<sup>51</sup> using the tabulated data.<sup>50</sup> In the terminal zone the effective relaxation times are frequency independent and can be determined as the average values  $\langle \lambda \rangle_{wI}$  and  $\langle \lambda \rangle_{nI}$ .

The dependence of the average relaxation times on the molecular mass is described by a power law  $\langle \lambda \rangle \sim M^a$ . The exponents for  $\langle \lambda \rangle_{wI}$  and  $\langle \lambda \rangle_{nI}$  differ from each other (see Table 9), being in the former case larger than in the latter. For all polymers under study (data were taken from Refs 53, 57, 58)

**Figure 14.** Frequency dependences of average relaxation times (*a*, *b*) and their ratios (*c*) obtained for the modified Rouse chains whose relaxation spectra are shown in Fig. 13.<sup>51</sup>

Notations (1–5) correspond to those used in Fig. 13.

the dependence of  $\langle \lambda \rangle_{nI}$  on the molecular mass is characterised by an  $a$  value of about 3.4. The same exponent value is also characteristic of the known dependence of viscosity on the molecular mass.<sup>4</sup>

The value of the exponent at  $M$  depends on the procedure of averaging over the relaxation times. This concerns both the limiting values and the rubbery plateau zone. Analysis of the dependences presented in Fig. 15 showed that at all molecular masses an increase in frequency causes a nearly linear (more exactly, the exponent approaches a value of 0.9) decrease in  $\langle \lambda \rangle_{nII}$  while  $\langle \lambda \rangle_{wII}$  is proportional to  $\omega^{-0.75}$ , so the corresponding ratio increases in proportion to  $\omega^{0.15}$ . With allowance for this dependence, which is common to all narrow-MMD polymers, one can assume that their relaxation spectra are intermediate between broad relaxation spectra characteristic of the Rouse model and narrow relaxation spectra characteristic of the Doi–Edwards model. The shape of the  $\gamma(\omega)$  plots points to a similarity between the relaxation spectra of real polymers and those of the polymers corresponding to the modified Rouse model.

**Figure 15.** Frequency dependences of average relaxation times (a, b) and their ratio (c) at  $T = 180\text{ }^{\circ}\text{C}$  obtained for monodisperse polystyrene using the data taken from Ref. 50.

$M \times 10^{-3} = 3000$  (1), 770 (2), 275 (3), 128 (4), 70 (5) and 39 (6).

Comparison of the distribution parameters in zone III is complicated by the fact that real polymers undergo glass transitions in this frequency region. In contrast to a similar dependence obtained in model calculations, here a pronounced maximum in the frequency dependence of the parameter  $\gamma_{II}$  is not an artifact; rather, it has a particular physical meaning. Probably, the appearance of this maximum characterises the glass transition. Thus, the  $\gamma(\omega)$  dependence, as well as the loss factor  $\tan \delta$ , can be used for the description of this transition.

Depending on the molecular mass, the transition points are located at different positions on the frequency axis (see Fig. 15 c), namely, an increase in the molecular mass leads to a shift of the transition point towards lower frequencies. The position of the maximum on the frequency axis is nearly proportional to  $M^{-2}$ ; the exponent being almost equal to that for the nonuniform Rouse model ( $n^{-2.2}$ ).

## b. Continuous relaxation spectrum

In fact, the development of the Kargin – Slonimskii – Rouse model led to the idea that the relaxation spectrum characterising the viscoelastic properties of polymers is a continuous function,<sup>213</sup> because the number of modes in the Rouse spectrum equals the number of chain units and the difference between the relaxation times of the 'neighbouring' modes is much less than the relaxation times, *i.e.*,  $(\lambda_{i+1} - \lambda_i) \ll \lambda_i$ . This concept dominated in the polymer science in the 1950s–1960s.<sup>63, 212</sup> The relaxation behaviour of polymers was described using relaxation spectra, which were represented by a wedge, 'box' or their combination.<sup>212</sup> Even at present some authors often use a continuous function instead of the calculated discrete spectrum (see, *e.g.*, Ref. 234) assuming that only this representation is physically substantiated. Moreover, an opinion was offered<sup>228</sup> that discretisation is a necessary prerequisite for using numerical methods of solving the problem of determination of continuous relaxation spectrum from experimental data.

In mathematics, the determination of a spectrum is reduced to inversion of the Laplace transforms (1), (1a) or the Fourier transform (2), *i.e.*, this is a quite solvable problem

$$H(\lambda) = \hat{H}(s) = \frac{1}{2\pi i} \int_0^{\infty} g(t) e^{st} dt, \quad (26)$$

where  $s = 1/\lambda$ .

The difference is that (if we ignore the problems of accuracy and ambiguity of experimental data), first, the integration limits in expressions (1a) and (26) are limited by the experimental conditions; second, the  $g(t)$  and  $G^*(\omega)$  curves are non-analytical curves and therefore integral (26) can be calculated only using approximate numerical methods.

Probably, the most efficient<sup>235</sup> and, at the same time, the oldest<sup>236</sup> is the method based on the use of the expansion of the inverse Laplace transform (1a) into a series<sup>237</sup>

$$H_n(\lambda) = \frac{1}{(n-1)!} \sum_{i=1}^n (-1)^i a_m \frac{d^i g(t)}{d(\ln t)^i} \Big|_{t=\lambda}, \quad (27)$$

which is a particular case of a general relationship

$$h(\lambda) = \lim_{n \rightarrow \infty} \left[ (-1)^n \frac{nt^{n-1}}{(n-1)!} \frac{d^n h(t)}{dt^n} \Big|_{t=n\lambda} \right].$$

The  $a_{ni}$  coefficients are calculated using the recurrent relation

$$a_{ni} = (n-1)a_{n-1,i} + a_{n-1,i-1},$$

$i \leq n$ .

Usually, only two first terms of the series (27) are included in calculations of the relaxation spectra, therefore

$$H(\lambda) = - \frac{dg(t)}{d \ln t} \Big|_{t=\lambda} + \frac{d^2 g(t)}{d (\ln t)^2} \Big|_{t=2\lambda}. \quad (28)$$

Recently, this method was evaluated and then widely used for the characterisation of the structures and for the prediction of the properties of materials based on polyolefins in the studies by Kimel'blat *et al.*<sup>238–242</sup> The initial data represented the curves of the pressure drop in the cylinder of a capillary viscosimeter in the non-steady-state flow of a polymer melt through a capillary after stopping the plunger. The authors believed that the pressure drop and a parallel decrease in the shear rate were due to the mechanism proposed by Vinogradov<sup>43, 44</sup> with allowance for a broad relaxation time spectrum due to polydispersity of the polymer.<sup>68–71</sup>

Thus, the calculated characteristics of the relaxation spectrum, namely, the average relaxation times  $\langle \lambda \rangle_n$ ,  $\langle \lambda \rangle_w$  and  $\langle \lambda \rangle_z$  should correlate with characteristics of the MMD of the polymer. For instance, it was stated<sup>243</sup> that 'dispersion in the MMD and

dispersion in the relaxation spectrum go hand in hand'. Indeed, corresponding correlations were established for polyethylene and polyethylene copolymers.<sup>242</sup> For instance in the case of high-density polyethylene one has

$$\log M_n = 4.14 + 0.147 \log \langle \lambda \rangle_n$$

with the correlation coefficient  $r^2 = 0.89$ ,

$$\lg M_w = 4.64 + 0.839 \lg \langle \lambda \rangle_w$$

with the correlation coefficient  $r^2 = 0.96$  and

$$\lg M_z = 4.57 + 1.131 \lg \langle \lambda \rangle_z$$

with the correlation coefficient  $r^2 = 0.92$ .

Here

$$\langle \lambda \rangle_n = \frac{\int H(\lambda) d \ln \lambda}{\int [H(\lambda)/\lambda] d \ln \lambda}, \quad \langle \lambda \rangle_w = \frac{\int \lambda H(\lambda) d \ln \lambda}{\int H(\lambda) d \ln \lambda},$$

$$\langle \lambda \rangle_z = \frac{\int \lambda^2 H(\lambda) d \ln \lambda}{\int \lambda H(\lambda) d \ln \lambda}.$$

Correlations between characteristics of the relaxation spectrum and the topological structures of polymers are illustrated in Fig. 16 where the average relaxation times are plotted vs. the composition of polymer blends with different molecular masses (Fig. 16a) and vs. the degree of cross-linking (Fig. 16b).

Numerous examples of correlations between characteristic features of the relaxation spectrum and the technological and physicomechanical properties of materials based on polyolefins can be found in a monograph.<sup>242</sup> It is the shape analysis of the spectral curve that allowed the author of the monograph<sup>242</sup> to

optimise the procedure of welding of high-density polyethylene pipes and predict the lifetime of such pipes. The curves of the relaxation spectra of ethylene-propylene rubbers served as criteria in evaluating the stability of the synthesis of such materials. Optimisation of the composition of thermoplastic composites and weldment are also based on analysis of specific features of the shape of the relaxation spectra. It is important that it was the relaxation spectra rather than the experimental pressure drop curves that were used as sensitive tools in the above-mentioned and similar research and development studies.

### c. Discrete relaxation spectrum. Regularisation methods

Methods of determination of a discrete relaxation spectrum have been analysed in detail in a review by Malkin<sup>226</sup> who tried to show that the determination of a relaxation spectrum in order to interpret experimental data has no physical meaning in the general case because the final result is not unique. Therefore, in comparing the properties of materials with different topological structures it is more appropriate to lean upon characteristic data points obtained in direct relaxation experiments rather than the relaxation spectrum calculated using these data, because, according to Malkin,<sup>226</sup> the relaxation spectrum is 'nothing more than a method of possible approximation of experimental data within the limits of measurement error, which is convenient for various applications in the framework of the theory of viscoelasticity of continuous media'. Nevertheless, numerous calculations of the relaxation spectra have been and are being reported.

Physically, an approach<sup>244</sup> widely used in the analysis of the free induction decay curves (see, e.g., Ref. 193) seems to be the most evident. The method involves successive determination of the exponents and pre-exponents of the  $\ln[g(t)]$  function at  $t \rightarrow \infty$ . In this case the kinetics of the decay is governed by the exponent with the longest relaxation time. Of course, such a division of the relaxation curve is quite rough and exponents with similar decay constants are indistinguishable.<sup>212, 244</sup> However, calculations of model functions (in particular, the Rouse relaxation curve) showed that the first three terms of the relaxation spectrum (with the longest relaxation times) can be determined quite accurately. The advantage of this approach is the possibility of estimating the maximum relaxation time. In particular, the relation  $\lambda_{\max} \propto M^4$  was established<sup>230</sup> using this procedure.

Essentially the same strategy was used in another study.<sup>245</sup> The orientation relaxation curve of polystyrene samples, expressed by the Legendre polynomial  $P_2(t)$ , was approximated by three exponents, which provided the best agreement with the experimental data. The relaxation times thus obtained were significantly different, e.g.,  $\lambda_1 = 0.7$ ,  $\lambda_2 = 39$  and  $\lambda_3 = 1.65 \times 10^4$  s (obtained for a polymer with a molecular mass of  $2.34 \times 10^6$  at a temperature, which is  $20^\circ$  higher than the glass transition temperature). The relaxation time  $\lambda_1$  was independent of the molecular mass while the other two relaxation times were related to  $M$  as follows:  $\lambda_2 \propto M^{0.5}$  and  $\lambda_3 = 2 \lambda_1 M^{1.6}$ .

To determine a relaxation spectrum is to find the solution to a problem inverse to problem (1). To this end, the following relation is used:

$$g(t) = K[h(\lambda)](t) + \varepsilon(t),$$

where  $K$  is the operator relating the function  $h$  to the experimental data  $g$ , and  $\varepsilon(t)$  is the error. Often,  $K$  is a linear operator, which corresponds to the Fredholm integral equation. Examples of linear inverse problems are provided by the analysis of experimental data obtained by NMR spectroscopy, static light scattering and results of resistor conductivity measurements. The linear rubbery state theory also includes nonlinear problems. Besides, as mentioned above (see Introduction), inevitable experimental errors complicate calculations of the relaxation spectrum using expression (1). Finally, experimental data are always available within a limited range of argument values. Taken altogether, this makes the problem of calculating the relaxation spectrum an ill-posed problem.<sup>226, 246–248</sup>

**Figure 16.** Average relaxation times  $\langle \lambda \rangle_n$  (1),  $\langle \lambda \rangle_w$  (2) and  $\langle \lambda \rangle_z$  (3) plotted vs. composition of a bidisperse blend of low-density polyethylenes (LDPE) (a) and vulcanisation time of butyl rubber (b).<sup>242</sup> Polymer blend: component 1 is LDPE-277 ( $M_w = 6 \times 10^4$ ,  $\bar{M}_w/\bar{M}_n \approx 5$ ), component 2 is LDPE-273 ( $M_w = 2 \times 10^5$ ,  $\bar{M}_w/\bar{M}_n \approx 15$ ).

The case for the problem inverse to the problem described by Eqn (3) is somewhat different. Indeed, Winter showed<sup>228</sup> that the frequency dependence of the relaxation modulus,  $G^*(\omega)$ , is the best source of initial experimental data for calculating the relaxation spectra. Also, mention was made<sup>228</sup> that the  $g(t)$  function can be determined more accurately from the same  $G^*(\omega)$  dependence rather than direct measurements. Systematic and statistical errors can be corrected using the Kramers–Kronig relation

$$\frac{G'(\omega)}{\omega^2} = \frac{2}{\pi} \int_0^\infty \frac{G''(x)}{\omega^2 - x^2} dx,$$

( $x$  is the integration variable), which leads to the following equality (at  $h > 0$ )

$$\frac{\lambda}{1 + (\omega\lambda)^2} = \frac{2}{\pi} \int_0^\infty \frac{x}{1 + (x\lambda)^2} \frac{dx}{\omega^2 - x^2}$$

for any  $\lambda$ .

Listed below are criteria which an algorithm for calculating a relaxation spectrum should satisfy. The choice of these criteria is an expression of personal preference rather than objective definition. The preferences of the author of Ref. 228 are as follows:

- good fit of experimental data;
- the algorithm should be able to find the optimum amount of detail which can be extracted from experimental data without producing artifacts;
- the format of the relaxation spectrum should not be predetermined; it has to be freely adjustable during the processing of the experimental data;
- the resulting parameters should have physical meaning;
- minimisation of the experimental data truncation errors;
- checking of experimental data quality is required (the data are always inconsistent to some extent, because the signal-to-noise ratios differ for  $G'$  and  $G''$ ; this may cause a large discrepancy between fit and experimental data);
- the relaxation spectrum  $H(\lambda)$  should be expressed by a function or a sum of functions, which can be integrated easily;
- the number of parameters of the model functions should not be large;
- the computation time should be short.

Calculations are based on the assumption that there exists a function  $H(\lambda)$ , which is sufficiently smooth that it can be taken as linear within small intervals  $[\lambda_i^-, \lambda_i^+]$  around  $\lambda_i$ .

To carry out calculations with a computer, the function  $g(t)$  should be discretised

$$g(t) = \int_0^\infty H(\lambda) d \ln \lambda = \sum_{i=1}^\infty \int_{\lambda_{i-1}}^{\lambda_{i+1}} H(\lambda_i) d \ln \lambda_i = \sum_{i=1}^\infty H(\lambda_i) \Delta_i,$$

where

$$\Delta_i = \frac{1}{2} \ln \frac{\lambda_{i+1}}{\lambda_{i-1}}.$$

The discretising frequency is given by  $\omega_i = 1/\Delta_i$ . The expression for  $g(t)$  takes the form

$$g(t) = g_0 + \sum_{i=1}^N h_i \exp\left(-\frac{t}{\lambda_i}\right), \quad (29)$$

where  $h_i = H(\lambda_i)\Delta_i$ .

The use of two data series ( $G'$  and  $G''$ ) eliminates the problem of ill-posedness. For the same reason simultaneous use of the  $g$  modulus and compliance data leads to the same result.<sup>249</sup> The uniqueness of the solution to the problem is due to the fact that the  $g$  modulus and compliance are interrelated.

The key point in calculations is minimisation of an error functional

$$\frac{1}{Z} \sum_{i=1}^Z \left[ \left( \frac{G'(\omega_i)}{\hat{G}'_i} - 1 \right)^2 + \left( \frac{G''(\omega_i)}{\hat{G}''_i} - 1 \right)^2 \right] = \min,$$

where

$$G' = \sum_{i=1}^N h_i \frac{(\omega\lambda_i)^2}{1 + (\omega\lambda_i)^2}, \quad G'' = \sum_{i=1}^N h_i \frac{\omega\lambda_i}{1 + (\omega\lambda_i)^2},$$

and  $\hat{G}'_i$  and  $\hat{G}''_i$  are the data measured at  $Z$  frequencies  $\omega_i$ .

The parameters  $\lambda_i$ ,  $h_i$ ,  $N$  are freely adjustable during the minimisation.

Analysis showed that the results of minimisation depend on the  $N$  value, but a stable solution is reached after a reasonably short time (in this case the error functional becomes independent of  $N$ ). Thus, the number of modes in the relaxation spectrum is limited by the minimum  $N$  value responsible for stability of the solution. Usually,  $N \leq 20$ .

A 'parsimonious' relaxation spectrum thus obtained is unique in the sense that different discrete sets of  $h_i$  and  $\lambda_i$  values lead to the same continuous function  $H(\lambda)$ .

Based on the results of experimental studies of polypropylene,<sup>250</sup> polybutadiene<sup>56, 141, 251</sup> and polystyrene,<sup>141, 234</sup> using the IRIS program (please visit a website at URL <http://128.119.197/Lab/IRIS.html>) it was concluded that the relaxation spectra of monodisperse polymers can be represented by two arms, a decreasing arm at  $\lambda \leq \lambda_1$  ( $\lambda_1$  corresponds to the inflection point) and an increasing arm at  $\lambda \geq \lambda_1$

$$H(\lambda) = \begin{cases} mG_N^0 \left[ \left( \frac{\lambda}{\lambda_c} \right)^{-n_g} + \left( \frac{\lambda}{\lambda_{\max}} \right)^{n_e} \right] & \text{at } \lambda \leq \lambda_{\max}, \\ 0 & \text{at } \lambda > \lambda_{\max}. \end{cases} \quad (30)$$

The  $\lambda_c$  value is determined from the equality  $H(\lambda_c) = H(\lambda_{\max}) = mG_N^0$  (the subscripts 'g' and 'e' at the exponents denote 'glass' and 'elastic', respectively).

Figure 17 presents some examples of this type of relaxation spectra, which are called the BSW spectra.<sup>†</sup>

**Figure 17.** Continuous relaxation spectra of polystyrene<sup>50</sup> (1–3) and low-density polyethylene<sup>263</sup> (4).  $M \times 10^{-3} = 39$  (1), 275 (2) and 3000 (3).

Taking polybutadienes with different topological structures as examples, it was shown<sup>251</sup> that the BSW relaxation spectra consist of three regions, viz., a decreasing arm at  $\lambda \leq \lambda_1$ , an increasing arm at  $\lambda_1 \leq \lambda \leq \lambda_{\max}$  and an abrupt cut-off region at  $\lambda > \lambda_{\max}$

<sup>†</sup> BSW abbreviation is an using the first letters in the surnames of the authors of Ref. 234.

$$H(\lambda) = \left[ H_g \left( \frac{\lambda}{\lambda_c} \right)^{-n_g} + n_e G_N^0 \left( \frac{\lambda}{\lambda_{\max}} \right)^{n_e} \right] \exp \left[ - \left( \frac{\lambda}{\lambda_{\max}} \right)^\beta \right], \quad (31)$$

where

$$H_g = n_e G_N^0 \left( \frac{\lambda}{\lambda_{\max}} \right)^{n_e} \left( \frac{\lambda_1}{\lambda_c} \right)^{n_g},$$

and  $\lambda_1$  is the instant at which the first two branches merge (or intersect). Usually,  $n_g \approx 0.67$ ,  $n_e \approx 0.30$  and  $\beta = 2$ .

It should be noted that the relaxation spectrum described by Eqn (31) does not meet the smoothness condition. At the  $\lambda_{\max}$  point, the curve exhibits an abrupt kink. In particular, if in the double logarithmic coordinates the spectrum is sectionally linear but has abrupt wings, the method cannot be used. It was shown<sup>252</sup> that in this case one should use regularisation methods.

A regularisation method involves minimisation of the error function  $V_\xi(\ln h)$  (see Refs 252 and 253).

$$V_\xi(\ln h) = \sum_{i=1}^M \frac{1}{(\sigma'_1)^2} \left[ G'_\sigma(\omega_i) - \int_{-\infty}^{\infty} \frac{(\omega_i \lambda)^2}{1 + (\omega_i \lambda)^2} H(\lambda) d \ln \lambda \right]^2 + \sum_{i=1}^M \frac{1}{(\sigma''_1)^2} \left[ G''_\sigma(\omega_i) - \int_{-\infty}^{\infty} \frac{\omega_i \lambda}{1 + (\omega_i \lambda)^2} H(\lambda) d \ln \lambda \right]^2 + \xi R(\ln h),$$

where  $\sigma$  is the standard deviation of the Gaussian error function. The regularisation term,  $R(\ln h)$ , imposes constraints based on the *a priori* information on the shape of the relaxation spectrum. The regularisation parameter  $\xi$  'weights' the constraints with allowance for the *a priori* knowledge.

At present, a number of program packages<sup>‡</sup> (e.g., NLREG,<sup>254</sup> GENEREG,<sup>253</sup> CONTIN<sup>255</sup> and FTIKREG<sup>256</sup>) developed for solving ill-posed problems by the regularisation method are available.

The assumption of smoothness means that

$$R(\ln h) = \int_{-\infty}^{\infty} \left[ \frac{d^2 \ln h}{d(\ln \lambda)^2} \right]^2 d \ln \lambda.$$

Taking into account abrupt changes in the function in the wings leads to a more general expression for  $R$

$$R(\ln h) = \int_{-\infty}^{\infty} \frac{[d^2 \ln h / d(\ln \lambda)^2]^2}{\sqrt{1 + [\alpha d^2 \ln h / d(\ln \lambda)^2]^2}} d \ln \lambda, \quad \alpha \geq 0.$$

The problem thus formulated was solved<sup>252</sup> using the Edge Preserving Regularisation (EPR) and Edge Preserving Nonlinear Regularisation (EPNREG) programs. The approach considered here can be employed if there are reasons to assume that the relaxation spectrum is smooth except for the inflection points in the  $\lambda_1$  and  $\lambda_{\max}$  regions (at  $10^{-4}$  and  $10^0$  s, respectively). A decrease in the long-time region was reported<sup>154</sup> to be a linear function in the double logarithmic coordinates (slope is  $\sim -10$ ). It should be noted that both the EPR and IRIS calculations give nearly identical results in the region  $\lambda \leq \lambda_{\max}$ .

In essence, the criterion for uniqueness of solution formulated by Winter<sup>228</sup> means that the set of relaxation times is insignificant for the determination of a continuous relaxation spectrum. Therefore, a relaxation spectrum can be determined as a solution of the 'semi-inverse' problem (i.e., a problem with a prescribed set of relaxation times). It is this solution that was proposed in Refs 257 and 258.

Liu<sup>257</sup> reported a mathematical approach to the determination of a discrete relaxation spectrum from the temporal dependence of the relaxation modulus or creep compliance. The method is based on approximation theory.<sup>259</sup> According to Liu, 'discrete relaxation and retardation times do not necessarily have any physical meaning since the continuous relaxation modulus and creep compliance can be approximated arbitrarily closely by discrete variables with different sets of relaxation and retardation times'. Starting from this point, Liu experimented with the following sets of relaxation times:  $\lambda_k = \lambda/k$ ,  $\lambda_k = \lambda/k^2$ ,  $\lambda_k = \lambda/\rho^k$  ( $k$  is the mode number and  $\rho$  is an empirical constant). The function was minimised using the non-negative least squares method and the MATLAB software package,

$$F(g_0, g_1, \dots, g_n) = \sum_{i=1}^m w_i [G^*(t_i, n) - G(t_i)]^2,$$

where  $F(G_0, G_1, \dots, G_n) = \min F(g_0, g_1, \dots, g_n)$  at  $g_0, g_1, \dots, g_n \geq 0$ ,  $w_1, w_2, \dots, w_m$  are non-negative weights,

$$G^*(t, n) = g_0 + \sum_{j=1}^n g_j e^{-t/\lambda_j}.$$

Yet another set of relaxation times is given by:<sup>258</sup>

$$\lambda_i = \lambda_{\min} \left( \frac{\lambda_{\max}}{\lambda_{\min}} \right)^{(i-1)/(N-1)},$$

where  $i$  is the mode number and  $N$  is the limiting number of modes.

Then, the function  $\|\vec{K}\vec{h} - \vec{G}\|$  was minimised by the least squares method with a constraint  $\vec{h} \geq 0$ .

$$\vec{K}_{i,j} = \frac{(\omega_i \lambda_j)^2}{1 + (\omega_i \lambda_j)^2}, \quad i = 1, \dots, m; j = 1, \dots, N,$$

$$\vec{h} = \{h_i\},$$

$$G'_i = h'_i(\omega_i), \quad i = 1, \dots, m,$$

$$G''_i = h''_i(\omega_i), \quad i = m + 1, \dots, 2m,$$

$$m \geq N.$$

Experimental data on the frequency dependence of the relaxation modulus  $G^*(\omega)$  of poly(dimethylsiloxane) were used as the input data. The relaxation spectrum thus determined was used for calculating the viscosity  $\eta_0$  and compliance  $J_e^0$  as follows

$$\eta_0 = \sum_{i=1}^N h_i \lambda_i, \quad J_e^0 = \frac{1}{\eta_0^2} \sum_{i=1}^N h_i \lambda_i^2.$$

The results obtained were in good agreement with experimental data,

$$\eta_0 = \frac{G'(\omega)}{\omega}, \quad \omega \rightarrow 0; \quad J_e^0 = \frac{G''(\omega)}{[G'(\omega)]^2}, \quad \omega \rightarrow 0.$$

An interesting method of calculation of a relaxation spectrum was proposed by Davies and Anderssen.<sup>260, 261</sup> The relaxation spectrum  $h(\lambda)$  was related to

$$g_{ab} = \int_a^b h(\lambda) d\lambda = \int_{\ln a}^{\ln b} H(\lambda) d \ln \lambda.$$

A narrow frequency range  $[ab]$  was divided into a small odd ( $2L - 1$ ,  $L = 2, 3, 4$ ) number of intervals and centred on an experimental frequency range, which in turn was divided into  $k$  discrete frequencies  $\omega_k = \omega_0 \exp(kr)$ . Usually, one had  $\omega_0 = 10^{-3} - 10^{-2}$  and  $r = \pi/(2L - 1)$ . The expressions for the relaxation modulus components were as follows

<sup>‡</sup> These programs are available on the Internet at URLs  
<http://www.itp.ac.cn/english/itpnet/cpcindex/cpcindex.html> and  
<http://cpc.cs.qub.ac.uk/simmaries/ADOQ>.

$$g'_j = -\frac{1}{2} \int_{\ln \omega_{j-1} - \pi/2}^{\ln \omega_{j+1} + \pi/2} \left[ E'' \left( \ln \frac{\omega}{\omega_j} + r \right) - E'' \left( \ln \frac{\omega}{\omega_j} - r \right) \right] G'(\omega) d \ln \omega,$$

$$g''_j = -\frac{1}{2} \int_{\ln \omega_{j-1} - \pi/2}^{\ln \omega_{j+1} + \pi/2} \left[ E' \left( \ln \frac{\omega}{\omega_j} + r \right) - E' \left( \ln \frac{\omega}{\omega_j} - r \right) \right] G''(\omega) d \ln \omega,$$

$$E'(x) = E'_\varepsilon(x), \quad E''(x) = E''_\varepsilon(x), \quad \varepsilon \rightarrow 0,$$

$$E^*_\varepsilon(x) = E'_\varepsilon(x) + iE''_\varepsilon(x) = \frac{1}{\pi} \operatorname{erf} \left( \frac{x + \pi i/2}{\sqrt{2\varepsilon}} \right), \quad \varepsilon > 0.$$

As can be seen, this method also does not require a search for discrete relaxation times; it involves calculations of the function  $h(\lambda_i)$  for a set of relaxation times  $\lambda_i$ .

Among the key sources of ill-posedness of the problem of determination of a discrete relaxation spectrum is that the function being minimised is linear with respect to  $h(\lambda)$  and nonlinear with respect to  $\lambda$ . A method<sup>262</sup> of linearisation of functions involves transformation of the components of the complex modulus into new functions  $U_n$  and  $V_n$  using the polynomial  $P_n$

$$U_n(\omega)^2 = G'(\omega) \prod_{i=1}^n (1 + \lambda_i^2 \omega^2) = \sum_{i=1}^n u_i(\omega^2)^i,$$

$$V_n(\omega)^2 = \omega G''(\omega) \prod_{i=1}^n (1 + \lambda_i^2 \omega^2) = \sum_{i=1}^n v_i(\omega^2)^i,$$

$$P_n(\omega)^2 = \prod_{i=1}^n (1 + \lambda_i^2 \omega^2) = \sum_{i=1}^n p_i(\omega^2)^i.$$

Now we have a linear problem, *viz.*, search for the coefficients  $p_i$  and  $u_i$  or  $p_i$  and  $v_i$ , which can be solved using the least squares method. Each pair of these coefficients is in mutually unique correspondence with the pair  $\lambda_i$  and  $h(\lambda_i)$ , which is given by a system of simple algebraic equations.

Applicability of this linearisation technique was demonstrated by comparing an artificially constructed relaxation spectrum with a relaxation spectrum calculated from the corresponding relaxation function. Besides, calculations of the relaxation spectrum from  $G'$  and  $G''$  (polystyrene, 179 °C) gave almost coinciding results (Fig. 18).

Finally, Jensen<sup>263</sup> reported determination of a relaxation spectrum using a version of the Monte Carlo method called 'simulating annealing'.<sup>§</sup> The technique involves the generation of trial values of  $h_i$  and  $\lambda_i$  and the search for a global minimum of the error function. The method imposes no constraints on the relaxation spectrum and does not require smoothness or even continuity. A drawback of the technique is a rather long computation time (in some cases more than  $10^6$  functions should be calculated in order to reach a global minimum). Similarly to the study by Winter<sup>228</sup>, the number of modes was limited to avoid fitting of noise, so the so-called 'parsimonious' relaxation spectrum was determined. The number of modes was chosen to be equal to that at which the dependence of the minimum value on the number of modes reached a plateau.

The relaxation spectrum of low-density polyethylene calculated using this technique is presented in Table 10.

**Figure 18.** Relaxation spectra of polystyrene calculated from  $G'$  (1) and  $G''$  (2).<sup>262</sup>

**Table 10.** Relaxation spectrum of low-density polyethylene at 150 °C.<sup>263</sup>

| $k$ | $\lambda_k$ / s | $h_k$ / Pa | $k$ | $\lambda_k$ / s | $h_k$ / Pa  |

The relaxation spectrum was also calculated<sup>103</sup> from dielectric relaxation data using the 'false position' algorithm. The method involves a comparison of experimental dependence (in this case the spectrum of dielectric loss  $\varepsilon''$ ) with a calculated dependence obtained using an arbitrary distribution function. The distribution function is refined by taking into account the error obtained and the iterative procedure is repeated until coincidence of the calculated and experimental data. Of course, the method requires *a priori* knowledge of the form of the distribution function; otherwise, a problem of uniqueness of the results obtained is posed.

Except for the authors of Refs 262 and 263, researchers are inclined to believe that only a continuous relaxation spectrum has physical meaning. In this case the relaxation spectrum can serve for characterisation of both the topological structure and the specific features of macromolecular dynamics. Discretisation can be arbitrary, being no more than a trick for computations. But here, first, it remains unclear how this inference can be related to the results of calculations of the models, which either directly or indirectly lead to the concept of a discrete relaxation spectrum. Second, a comparison of the continuous relaxation spectra shown in Figs 17 and 18 reveals ambiguity in the results of calculations. Therefore, one has to conclude that attempts at calculating a discrete relaxation spectrum (at least most of those considered above) failed.

Unfortunately, it is impossible to put forward a criterion for 'correctness' of a relaxation spectrum, because it can be determined if the condition for coincidence of the calculated and experimental data for  $g(t)$  or  $G^*(\omega)$  with certain accuracy is met. This inevitably means fulfillment of rheological characteristics, because the stress tensor components  $\sigma_{ij}$  are related to the relaxation function  $g(t)$  (see Ref. 4)

$$\sigma_{12} = \sigma_{21} = \dot{\gamma} \int_0^t g(t - t_1) dt_1,$$

$$\sigma_{11} - \sigma_{22} = 2\dot{\gamma}^2 \int_0^t (t - t_1) \cdot g(t - t_1) dt_1,$$

where  $\dot{\gamma}$  is the shear rate.

We believe that discussion of relaxation spectrum calculations concerns in fact two independent problems. One of them is concerned with the physical correctness of the mathematical models describing interrelations between viscoelastic characteristics and based on the concept of a relaxation spectrum. The other problem is to develop a corresponding mathematically correct formalism. Of course, it is irrational to criticise and reject a convenient fundamental concept of the relaxation spectrum on the basis of non-reliable results of spectrum reconstruction obtained in the framework of (mathematically) unstable models. Therefore, in the text below we will consider a stable method of calculation of a relaxation spectrum.

### 3. Stable method of calculation of a relaxation spectrum. The relaxation times distribution function

An approach<sup>264, 265</sup> to the representation of a relaxation spectrum using the distribution functions<sup>266</sup> and Stieltjes integral<sup>267</sup> provides an alternative to the methods considered above. Let  $P(\lambda)$  denote the integrated intensity of a relaxation spectrum. Then, the functions  $g(t)$  and  $G(\omega)$  can be expressed via the Stieltjes integral with respect to  $P(\lambda)$

$$g(t) = \int_0^\infty \exp\left(-\frac{t}{\lambda}\right) dP(\lambda), \quad (32)$$

$$G(\omega) = \int_0^\infty \frac{i\omega\lambda}{1 + i\omega\lambda} dP(\lambda). \quad (33)$$

A discrete relaxation spectrum corresponds to a step distribution function

$$P(\lambda) = \sum_{k=1}^N h_k \chi(\lambda - \lambda_k), \quad (34)$$

where  $\chi$  is the Heaviside step function. A continuous relaxation spectrum corresponds to the distribution function given by

$$P(\lambda) = \int_0^\lambda h(\xi) d\xi \quad (35)$$

( $\xi$  is the integration variable), i.e.,  $P(\lambda)$  is an antiderivative of the density  $h(\lambda)$ .

The problem of uniqueness of the function  $P(\lambda)$  and stability of  $P(\lambda)$  to perturbations in  $g(t)$  and  $G^*(\omega)$  has been studied.<sup>265</sup> In constructing  $P(\lambda)$  from the kinetic function  $g(t)$  (the procedure for relaxation spectrum reconstruction in the frequency domain differs insignificantly) it was shown that uniqueness of  $P(\lambda)$  follows from one-to-one reversibility of the Laplace transform. The notion of stability was formulated in terms of the weak convergence of monotonic functions in the positive semiaxis  $R_+$  as the following continuity principle.<sup>267, 268</sup>

Let  $g_n, P_n$  ( $n = 1, 2, \dots$ ),  $g, P$  be a sequence of kinetic curves and corresponding distribution functions. Then convergence  $g_n(t) \rightarrow g(t)$  at any  $0 \leq t < \infty$  is equivalent to weak convergence  $P_n \Rightarrow P$  in  $R_+$ .

This statement was proved<sup>265</sup> by combining the Helly selection principle for a converging subsequence of monotonic functions and the property of uniqueness.

The properties of uniqueness and continuity mean that a problem inverse to problem (35) with respect to  $P(\lambda)$  rather than  $h(\lambda)$  is well-posed and solution to this problem does not require application of a regularisation technique.

The development of a method of stable reconstruction of  $P(\lambda)$  from approximate values of the kinetic and frequency moduli required introduction of the notion of a generalised solution as a

solution to the problem of error functional minimisation. In the simplest case (quadratic functional) the procedure involves solution of the following problems

$$\int_T v(t) \left[ \int_0^\infty \exp\left(-\frac{t}{\lambda}\right) dP(\lambda) - g(t) \right]^2 dt \rightarrow \min, \quad (36)$$

$$\int_\Omega \mu(\omega) \left[ \int_0^\infty \frac{i\omega\lambda}{1 + i\omega\lambda} dP(\lambda) - G(\omega) \right]^2 d\omega \rightarrow \min, \quad (37)$$

where  $v(t)$  and  $\mu(\omega)$  are some non-negative weighting functions, which determine the error functional, and  $T$  and  $\Omega$  are respectively the domains in which the experimentally measured  $g(t)$  and  $G(\omega)$  functions are defined. The search for a minimum is carried out in the class of all distribution functions.

A solution  $P(\lambda)$  to problems (36) and (37) is called an optimum integral representation (OIR) of the corresponding functions of the kinetic or frequency moduli. In setting these problems it is possible to impose, without significant complication, various constraints that allow for the *a priori* information on the relaxation spectrum. The choice of the weighting functions is free, being governed by the *a priori* knowledge of the distribution of experimental errors. For instance, it is appropriate to use the coefficients  $v(t)$  and  $\mu(\omega)$  for relatively narrow (2–3 decades) ranges of changes in  $t$  and  $\omega$ , respectively. The choice of the  $v(t) = t^{-1}$  and  $\mu(\omega) = \omega^{-1}$  weighting functions provides a logarithmically uniform error functional, which can naturally be used in treatment of data characterised by a broad range of changes in  $t, \omega$  (more than four decades). The properties of existence, uniqueness and stability of OIR have been proved.<sup>264</sup> It was found that the over stability is unexpectedly high, namely, the OIR is stable to both integrally small errors of the functions  $g(t)$  and  $G(\omega)$  and to white noise of finite amplitude superimposed on these functions. All the results are also valid for a more general combined error functional, which permits reconstruction of  $P(\lambda)$  from the real and imaginary components of  $G(\omega)$  or from their combination.

Numerical implementation of this method requires a finite set of measuring times  $\{t_j\}, j = 1, \dots, n$ . When a continuous problem is discretised by introducing a grid with a fixed arrangement of nodes  $\{\lambda_i\}, i = 1, \dots, m$ , the desired distribution function is approximated by the step function

$$P(\lambda) = \sum_{i=1}^m h_i \chi(\lambda - \lambda_i), \quad (38)$$

where  $h = \{h_i\}, i = 1, \dots, m$  is the set of unknown non-negative coefficients. Application of some linear quadrature formulae to the outer integrals in expressions (36) and (37) gives the following discrete analogues, respectively

$$\sum_{j=1}^n v_j \left[ \sum_{k=1}^m \exp\left(-\frac{t_j}{\lambda_k}\right) h_k - g(t_j) \right]^2 \rightarrow \min, \quad h \geq 0, \quad (39)$$

$$\sum_{j=1}^n \mu_j \left[ \sum_{k=1}^m \frac{i\omega_j \lambda_k}{1 + i\omega_j \lambda_k} h_k - G(\omega_j) \right]^2 \rightarrow \min, \quad h \geq 0. \quad (40)$$

Here  $v_j, \mu_j$  is a set of positive weighting coefficients determined by the totalities of the nodes  $\{t_j\}$  and  $\{\omega_j\}$ . These coefficients are included in the quadrature scheme. For instance, constant weighting coefficients are obtained when the rectangle formula is applied to uniformly distributed nodes at  $v(t) = 1, \mu(\omega) = 1$  or to logarithmically uniformly distributed nodes at  $v(t) = t^{-1}, \mu(\omega) = \omega^{-1}$ .

Problems (39) and (40) are solved by the quadratic programming technique using some efficient finite-step algorithms incorporated into standard mathematical software (MAPLE, MATLAB) and FORTRAN libraries (IMSL, CXML), including the non-negative least squares method algorithm NNLS.<sup>269</sup> Some

difficulties in numerical solution can arise from the high dimensions of these problems ( $m$  and  $n$  can be of the order of several hundreds); good approximation of initial continuous problems (36) and (37) by discrete analogues requires about 10 to 30 nodes ( $t_j, \omega_j, \lambda_k$ ) per decade of corresponding range.

When a relaxation spectrum is reconstructed from model and experimental data, the experimental and calculated grid patterns have no effect on the quality of the solution, only the node density is significant. Different grid patterns require calculations of different sets of weights. The resulting antiderivative step distribution function  $P(\lambda)$  coincides with an accuracy determined by the grid densities and errors in  $g(t)$  and  $G(\omega)$ . Non-uniqueness of the solution (this is possible at  $m > n$ ) is of no concern because any set of the parameters  $h$ , at which minima of expressions (39) and (40) are reached, gives an equivalent approximation of the relaxation spectrum distribution.

Because the relaxation spectrum distribution functions reconstructed by this method are only stable in a specific 'weak' sense, it is appropriate to mention those characteristics of the relaxation spectrum that are related to this kind of stability. By definition of weak continuity, stable are linear integral average distribution functions of the type

$$\int_{R_+} f(\lambda) dP(\lambda),$$

where  $f(\lambda)$  is some continuous averaging function. A particular case of averaging is provided by the moments for which  $f(\lambda) = \lambda^n$ . The plot of the distribution function is stable in the sense mentioned above, namely, as 'entire geometric figure'. On the contrary, local numerical characteristics, in particular, the density  $h(\lambda) = dP(\lambda)/d\lambda$ , are unstable. Conversion of a discrete relaxation spectrum into the density function by direct interpolation of a comb-like plot of  $\delta$ -functions does not lead to 'weak stability', as was postulated by Winter.<sup>141</sup> A correct smoothing of arbitrary, in particular, discrete relaxation spectra requires an integral averaging over one or another kernel.

The working efficiency of this method was exemplified<sup>265</sup> by reconstructing the relaxation spectrum of an oligomeric nonuniform Rouse chain,<sup>214,215</sup> a continuous BSW-spectrum<sup>141</sup> and the frequency modulus of polystyrene from experimental data.<sup>234</sup>

A model example of relaxation spectrum reconstruction from the relaxation kinetics of the length of an equidistant chain containing  $n = 6$  nonuniform units involved calculations of the frequency dependence of the relaxation modulus  $G^*(\omega)$  using relationship (2). Noise produced by a software generator of evenly distributed random numbers was applied at the calculated  $(t, \omega)$

nodes, the noise intensity,  $\varepsilon$ , being equal to  $10^{-2}$  and  $10^{-3}$  of the corresponding amplitude. The calculated  $h_i$  and  $\lambda_i$  coefficients and the corresponding moments

$$\mu_k = \int \lambda^k dP(\lambda)$$

for  $k = 0, 1, 2$  are listed in Table 11. Simulation of experimental data was carried out using  $n = 300$  logarithmically uniform time values and frequencies in the ranges  $t \in [10^{-4} \text{ and } 10^3]$   $\omega \in [10^{-1}, 10^5]$ , respectively, and the spectrum reconstruction was performed following the scheme given by expressions (39) and (40) on a logarithmically uniform grid containing  $m = 400$  nodes in the range  $\lambda \in [10^{-2}, 10^2]$ .

Analysis of the data listed in Table 11 showed that the relaxation spectrum reconstructed from  $G$  is more similar to the exact spectrum than the relaxation spectrum reconstructed from the  $g$  data. As noise ( $\varepsilon$  value) decreases, the accuracy of the calculations increase. Although the calculated relaxation spectrum is somewhat different from the theoretical spectrum, in all cases the moments coincide excellently.

Yet another example involved the relaxation spectrum reconstruction from the frequency-dependent stress relaxation modulus determined in a series of experiments.<sup>234</sup> Data for monodisperse polystyrene with  $M = 3 \times 10^6$  were analysed using a complex data array ( $n = 44$ ). Calculations following scheme (40) involved a logarithmically uniform grid with  $m = 400$  in the range  $\lambda \in [10^{-5}, 10^4]$ .

A discrete relaxation spectrum reconstructed using the OIR technique is shown in Fig. 19. Experimental data were fitted to the theoretical curve  $G(\omega)$  calculated after reconstruction with a quadratic error of about 1% (see Fig. 19a). In Fig. 19 the OIR and IRIS reconstructed plots are superimposed. The errors in the approximation of the frequency-dependent relaxation moduli in both reconstructed relaxation spectra are similar (with respect to the order of magnitude), but the error of the OIR method is 'random' while the plot of the error of the IRIS procedure clearly exhibits systematic 'waves' (see Fig. 19b). The plots of the distribution functions in Fig. 19d are parallel in the range  $\lambda \in [10^{-4}, 10^1]$ . In this case a parallel shift of the distribution functions owing to initial jumps indicates a significant discrepancy between the reconstructions, which is due to insufficient width of the data window in the high-frequency region.

Thus, in the intermediate range the OIR and IRIS reconstructed relaxation spectra are similar in terms of the distribution functions, although the parameters of individual lines are appreciably different (see Fig. 19c).

**Table 11.** Parameters of the relaxation spectrum of a modified Rouse chain calculated using the OIR technique ( $\lambda$  in arbitrary units).

**Figure 19.** Relaxation spectrum of monodisperse polystyrene with  $M = 3 \times 10^6$  reconstructed from the complex frequency modulus  $G(\omega)$  using the data taken from Ref. 50.

(a) Experimental  $G'(\omega)$ ,  $G''(\omega)$  curves (1) and the corresponding calculated curves (2, 3); (b) relative errors in approximation  $G'(\omega)$ : error in OIR reconstruction (1), error in IRIS reconstruction (2); (c) reconstructed discrete relaxation spectrum: the OIR spectrum (1) and the IRIS spectrum (2); (d) distribution functions of reconstructed discrete relaxation spectra: the OIR spectrum (1) and the IRIS spectrum (2) (data were taken from Ref. 265).

The Stieltjes OIR theory provides an explanation for similarity of integral characteristics of seemingly distinct results obtained using different versions of relaxation spectrum reconstructions. Consistency occurs if these results are quite well approximated by experimental data and meet the condition of belonging to a 'convex local weakly compact set', which can be separated out by, e.g., a simple non-negativity condition. In accord with the OIR theory in this case the relaxation spectrum will be similar to the exact spectrum in terms of distribution functions, irrespective of the procedure employed to obtain the spectrum.

It should also be noted that representation of the relaxation spectrum in the form of integral distribution function  $P(\lambda)$  eliminates the problem of non-uniqueness of such a representation. Examples given in Ref. 265 show that seemingly different relaxation spectra give almost the same function  $P(\lambda)$ . Probably, this is the reason why experimental data are 'insensitive' to the local shape of the relaxation spectrum, as was shown in many studies and summarised in a review.<sup>226</sup>

The OIR technique makes it possible to determine stable values of the moments (as well as any integral characteristic) of a relaxation spectrum. Local characteristics of the relaxation spectrum, in particular, the limiting relaxation times, are unstable and of little informativity. Therefore, the dependence of the maximum relaxation time on the procedure for relaxation spectrum reconstruction<sup>226, 229</sup> is insignificant because the relaxation properties are determined by the distribution moments, which are highly stable characteristics.

At the same time this mathematical approach allows experimental methods of determination of relaxation spectra of polymers to be divided into methods producing artifacts and those providing rational results. Formally, the problem of minimisation of an error functional on the class of monotonic distribution

functions always has a unique solution, i.e., the OIR. By definition the resulting spectrum provides the best plausible explanation for experimental data when using a linear model with a non-negative relaxation spectrum, which has a physical meaning and is related to the polymer structure. But in linear theory one can face a problem of sign-alternating expansion of the viscoelastic functions in terms of exponential modes. This is indicated by the impossibility of correctly (with an accuracy to noise) reproducing the experimental dependences,  $g(t)$  and  $G(\omega)$ , using the OIR found. For instance, if in the chain retraction problem considered above the initial state of the chain is not equidistant, it is impossible to obtain a non-negative relaxation spectrum reproducing the model relaxation because some pre-exponents in expression (1) are negative. This shows that determination of a relaxation spectrum as a characteristic of the polymer structure requires a particular experimental design.<sup>225</sup> It is known that relaxation of a Rouse chain under stress and strain gives somewhat different relaxation spectra (see Ref. 33 and Fig. 10). Apparently, this is due to the fact that the polymer structure manifests itself indirectly if the entire chain moves (therefore the relaxation spectrum depends on the character of chain motion). This is clearly seen when comparing the Rouse and Doi–Edwards models.<sup>33</sup>

Thus, the problem of reconstruction of a monotonic relaxation time distribution function from the kinetic curve or frequency modulus is mathematically correct. But it should be interpreted in the framework of the OIR method rather than traditional methods for fitting a set of parameters of a point spectrum or as a solution of an integral equation of the first kind with respect to the density function of a continuous spectrum.

Summing up, the method<sup>264, 265</sup> of calculation of relaxation spectra is characterised by the following features.

The accuracies of reconstruction of the relaxation spectrum distribution function and any integral average characteristics of this distribution function are only limited by the systematic error and the 'density' of experimental data.

Theoretically, the OIR technique allows a relaxation spectrum to be reconstructed with arbitrary accuracy from a set of kinetic or frequency data obtained in any range. However, when narrowing such ranges, one should significantly improve the accuracy of data and the size of the data array.

Reliable reconstruction of the relaxation spectrum requires that the experimental data window be wider than the interval in which the relaxation spectrum is located (by 1–2 orders of magnitude for the 'kinetic' reconstruction and by 3–4 orders of magnitude for the 'frequency' reconstruction). Otherwise the distribution function can be determined with an accuracy of the initial jump, the local structure of which is not informative, and the accuracy of determination of moments decreases abruptly.

Statements that the relaxation spectrum is a fiction are senseless, because they are based on mathematically incorrect formalisms for both discrete and continuous descriptions. Of course, stable OIR mathematical formalism for reconstruction of relaxation spectra from the data of dynamical experiments does not mean that the relaxation spectrum is a physical reality. However, this approach makes revision of the results of relaxation experiments on the basis of stable interpretation of the relaxation spectrum in terms of distribution functions, aimed at establishing the applicability range of the notion of a relaxation spectrum as a fundamental characteristic and its relation to the polymer structure, promising and topical.

#### 4. Manifestation of topological structure in relaxation spectra

Interrelations between the relaxation behaviour and topological structure of polymers have been well documented (see Section III). However, information on immediate relations between the relaxation spectrum and parameters of topological structure is scarce. The reason is quite understandable, that is, ambiguity of calcu-

lations (see Section IV.2). Nevertheless, a little body of data are available.

First of all mention may be made of the studies of the BSW spectra and of the studies carried out by Winter *et al.*<sup>57, 83, 138–141, 152, 172, 228, 234, 250, 251, 270</sup>

The dependence of the characters of the BSW spectra on the molecular masses of the monodisperse polymers [see relationship (31) and Fig. 17] is determined by two parameters,  $\lambda_{\max}$  and  $\lambda_1$ . The former parameter is related to  $M$  by a conventional expression

$$\lambda_{\max} = KM^a,$$

or, according to Ref. 56,

$$\lambda_{\max} = \lambda_c \left( \frac{M}{M_c} \right)^a.$$

The  $\lambda_{\max}/\lambda_c$  ratio determines the extension of the rubbery plateau zone, the physical meaning of  $M_c$  is similar to that of  $M_e$ . Correspondingly,  $\lambda_1$  is defined by

$$\lambda_1 = \lambda_c \left( \frac{M}{M_c} \right)^{an_c/(n_c+n_g)}.$$

The numerical values of the parameters of the BSW spectra of polystyrene and polybutadiene listed in Table 12 were taken from Refs 57 and 83.

**Table 12.** Numerical values of parameters of the BSW spectra of polystyrene and polybutadiene.

| Parameter            | Polystyrene        | Polybutadiene         |
|----------------------|--------------------|-----------------------|
| $G_N^0/\text{Pa}$    | $2.28 \times 10^5$ | $1.65 \times 10^6$    |
| $n_c$                | 0.23               | 0.23                  |
| $n_g$                | 0.67               | 0.73                  |
| $\lambda_c/\text{s}$ | $2 \times 10^{-4}$ | $4.04 \times 10^{-7}$ |
| $M_c$                | $1.66 \times 10^4$ | $2.714 \times 10^3$   |
| $a$                  | 3.43               | 3.52                  |
| $T/^\circ\text{C}$   | 180                | 28                    |

Based on the results of studies of monodisperse polystyrene/monodisperse polybutadiene binary blends,<sup>83, 234</sup> it was concluded that the resulting relaxation spectrum can be expressed as follows

$$H(\lambda) = \sum_i B_i H_i \left( \frac{\lambda}{A_i} \right),$$

where

$$\sum_i B_i = 1, B_2 = w_2^2 + aw_1w_2, a \approx 0.1,$$

if the molecular masses of the components differ insignificantly and  $w_i$  is the mass proportion of the fraction. The  $A_i$  coefficients weakly depend on the blend composition. They are related to the molecular masses of the components, namely,  $A_i = \lambda_{\max, i, b}/\lambda_{\max, i}$  is the ratio of the maximum relaxation times of the blend component and of the homopolymer.

Clearly, this ratio is inconsistent with the postulated<sup>34, 271</sup> additivity with respect to relaxation times.

However, it should be noted that the relaxation spectrum of a blend, calculated by the EPR method,<sup>252</sup> has little in common with the BSW spectrum, although for monodisperse polymers both methods, EPR and IRIS, give identical relaxation spectra (see above).

When establishing relations between the relaxation properties and MMD of polymers, the dependences of relaxation times on the molecular mass are often considered. If the case in point is the dependence of  $\lambda_{\max}$  or any other average characteristic (*e.g.*,  $\langle \lambda \rangle_w$ ) on the molecular mass of the type  $\lambda_{\max} \sim M^a$ , this is quite understandable. But some authors (see, *e.g.*, Refs 104, 258, 271–273) assume this dependence for each relaxation time in the relaxation spectrum and simply use the function  $h(M^a)$  instead of  $h(\lambda)$ . It can be shown with ease, taking, *e.g.*, the Rouse relaxation spectrum as a simple example, that this replacement is incorrect because a change in the chain length first of all leads to a change in the number of modes.

Studies of star-branched polymers<sup>251</sup> revealed a much more complicated form of the BSW spectrum compared to the spectrum described by the equation of the type (31). Namely, it was found that expression (31) should be augmented with the following term

$$n_0 G_0 \left( \frac{\lambda}{\lambda_0} \right)^{n_0} \exp \left( \frac{\lambda}{\lambda_0} \right)^\beta.$$

The relaxation parameters of the (thus) modified BSW spectra of various star-branched polybutadienes of regular structure are listed in Table 13. Within the limits of experimental error, the parameters  $G_N^0$ ,  $H_g$  and  $\lambda_c$  can be considered independent of the molecular mass and the number of arms, whereas the parameters  $G_0$ ,  $\lambda_{\max}$  and  $\lambda_1$  seem to be stronger dependent on the molecular mass rather than the number of arms. The  $\lambda_0$  parameter is affected by both structural characteristics. The authors of Ref. 251 believed that these results are consistent with theoretical concepts.<sup>274, 275</sup> However, the available data are insufficient for making quantitative estimates.

Analysis of the relaxation spectra calculated by the OIR technique is also based on a very small amount of data<sup>276, 277</sup> because the problem, as applied to polymers, was formulated only recently.<sup>264, 265</sup>

Figure 20 presents the relaxation spectra of polymers in terms of the integral distribution functions, which were reconstructed using the OIR technique and the data taken from Ref. 50. In this connection a problem is posed by the methods for comparison and, hence, quantitative characterisation of distribution func-

**Table 13.** Numerical values of parameters of the relaxation spectra of star-branched polybutadienes (for all polymers,  $n_g = 0.67$ ,  $n_c = 0.30$  and  $\beta$  lies between 0.8 and 1).<sup>251</sup>

| Number of arms       | $10^{-3} M_a$ | $G_N^0/\text{MPa}$ | $\lambda_c/\text{s}$ | $10^{-4} \lambda_{\max}/\text{s}$ | $\lambda_1/\text{s}$ | $H_g/\text{MPa}$ | $10^3 G_0/\text{MPa}$ | $10^{-6} \lambda_0/\text{s}$ |

**Figure 20.** Relaxation spectra of monodisperse polystyrene-based polymers plotted in the form of distribution functions  $P(\lambda)$  using the data taken from Ref. 50.

$M \times 10^{-3} = 39$  (1), 70 (2), 128 (3), 275 (4), 770 (5) and 3000 (6).

tions. The most obvious is the method of central moments,<sup>278</sup> which in the case of the Stieltjes integral are defined by

$$\mu_k(\lambda) = \int (\lambda - \langle \lambda \rangle)^k dP(\lambda),$$

where  $\langle \lambda \rangle$  is the arithmetic mean of a random quantity  $\lambda$ . A set of appropriate characteristics includes the dispersion  $\sigma = (\mu_2)^{1/2}$ , asymmetry (skewness)  $\gamma_1 = \mu_3/\sigma^3$  and excess  $\gamma_2 = \mu_4/\sigma^4 - 3$ . Corresponding characteristics of the distribution functions shown in Fig. 20 are listed in Table 14. As can be seen, the average relaxation times and dispersions depend on the molecular mass (see also Table 1), whereas the asymmetry and excess show no dependence within the limits of data scatter. Therefore, one can state that the relaxation spectra of monodisperse polymers with different molecular masses, expressed in terms of the distribution function  $P(\lambda)$ , are similar.

The data listed in Table 15 show that the MMD of polymers affects their relaxation spectra. This manifests itself not only in the average and maximum relaxation times and dispersion but also in the  $\gamma_1$  and  $\gamma_2$  values (relaxation spectra were constructed using the OIR technique and the results reported by Watanabe and Kotaka<sup>67</sup>). A comparison with various polymer blends showed that the additivity principle is not valid for at least one binary blend (molecular masses were  $4.27 \times 10^5$  and  $3.89 \times 10^4$ ). Namely, the maximum relaxation time was composition independent; correspondingly, the dispersion was much larger than the value characteristic of the polymer blend.

**Table 14.** Characteristics of the distribution functions  $P(\lambda)$  for monodisperse polystyrene-based polymers having different molecular masses.

| $M$       | $\langle \lambda \rangle_n / s$ | $\langle \lambda \rangle_w / s$ | $\sigma$               | $\gamma_1$ | $\gamma_2$            |
|-----------|---------------------------------|---------------------------------|------------------------|------------|-----------------------|

| 770 000   | 19.93                           | 56.05                           | 32.01                  | 1.702      | 4.566                 |
| 275 000   | 0.916                           | 3.245                           | 4.326                  | 2.807      | 6.387                 |
| 128 000   | 0.0465                          | 0.09115                         | 0.0379                 | -0.984     | -0.707                |
| 70 000    | 0.0045                          | 0.00706                         | 0.0029                 | -0.965     | -0.776                |
| 39 000    | $9.456 \times 10^{-4}$          | $6.32 \times 10^{-4}$           | $1.423 \times 10^{-4}$ | 0.834      | $6.57 \times 10^{-4}$ |

This is qualitatively consistent with the conclusions drawn in another study.<sup>83</sup> Unfortunately, data for quantitative characterisation are insufficient. Nevertheless, it is clear that representation of a relaxation spectrum in the form of the distribution function  $P(\lambda)$  can serve as a reliable basis for establishment of interrelation between the relaxation spectrum and the topological structure of the polymer. This research avenue requires intensive development.

## V. Conclusion

Many researchers have put forward the idea of using the relaxation properties of a polymer for non-destructive quantitative characterisation of topological structure. This first of all concerns the MMD as the key structural parameter of high-molecular-mass compounds.<sup>31–33</sup> However, experience showed that the use of the relaxation curves leads to incorrect conclusions, because these methods are based on quite different and arbitrary mixing rules.<sup>83</sup> We believe that it would be more appropriate to use the relaxation spectrum, because it is obviously related to the polymer structure. Indeed, '...a normalised relaxation spectrum is a replica of the shape of the MMD curve'.<sup>243</sup> Here, two problems arise, namely, (i) calculations of relaxation spectra from relaxation data and (ii) establishment of a relation between the relaxation spectrum and the polymer structure.

In this review we tried to show some ways of attacking these problems. The OIR technique provides a means of stable calculations of relaxation spectra in the form of the distribution function  $P(\lambda)$ , which in turn serves as a reliable basis for the establishment of correlations between the relaxation spectrum and the polymer structure.

This approach seems to be not unique. For instance, the Havriliak–Negami equation (see above) is related<sup>177,243</sup> to the empirical relaxation spectrum, which is based on the Cole–Cole model.<sup>279</sup> The spectral parameters thus obtained correlate with the MMDs of some polyethylenes.<sup>243</sup> Probably, other characteristics of the topological structure can also be extracted from this type of relaxation spectra.

Nearly five decades ago G L Slonimskii put forward a basically different approach to analysis of the relaxation properties of polymers.<sup>280</sup> The method involves expression of the

relaxation relations between stress  $\sigma$  and strain  $\varepsilon$  using fractional derivatives

$$\sigma(t) = E\lambda^\alpha \frac{d^\alpha \varepsilon(t)}{dt^\alpha}, 0 \leq \alpha \leq 1.$$

At  $\alpha = 0$ , one gets an equation for the Hooke model (pure elasticity) while the equation derived at  $\alpha = 1$  describes a Newtonian flow.

However, attempts at using this approach in studies of particular systems (see, e.g., Ref. 281) have been undertaken only recently. Clearly, in this case we deal with quite a new view of the mathematical formalism and physical meaning of the relaxation spectrum. Here, one must keep in mind that ‘... if modelling is intended to understand or to discover new phenomena, the exact mathematical model should be sufficiently sophisticated, especially when several branches of solutions have different physical meanings. Hence, the study of a sophisticated exact inverse problem may be not only a pure mathematical research but also an applied one, where interactions between ways of modelling and inverse theory are essential’.<sup>282</sup>

**Abstract.** Studies on applications of microwave irradiation to organic synthesis published over 2000–2002 are surveyed. The theoretical concepts concerning the influence exerted by microwave irradiation on the course of organic reactions are briefly discussed. The bibliography includes 354 references.

## I. Introduction

Nowadays, great investigation efforts in diverse fields of science and industry are put into the development of resource- and energy-conserving environmentally friendly technologies. In this regard, microwave irradiation (hereinafter, MWI) is becoming increasingly important, since it enables exceptional intensification of various processes, including those that cannot be optimised using traditional techniques.

The pioneering work on the utilisation of MWI as an efficient heating source dates back to the late 1940s, and over the 1970s and 1980s it came into common use in inorganic and analytical chemistry for analysis of various objects, drying and dehydration of samples, synthesis of inorganic materials, elucidation of polymorph transitions, *etc.*<sup>1</sup> An impetus to the use of MWI in organic synthesis was given by the studies of Gedye *et al.*<sup>2</sup> and Giguere *et al.*,<sup>3</sup> who observed a significant reduction in the time required for

the completion of several classical chemical reactions under MWI irradiation as compared to traditional heating conditions. Other advantages of MWI included the saving of electric power or other energy resources, the possibility of conducting a reaction at an elevated pressure at a temperature significantly exceeding the boiling point of the solvent used or under solvent-free conditions, the synthesis of compounds that are unattainable or difficult to prepare with other activation methods.

These factors favouring the use of MWI for the activation of organic reactions were rapidly appreciated by synthetic chemists. It is of note that the wide acceptance of the method was partly due to the simplicity of the experiments: they only required availability of an ordinary commercial MW-oven. Nevertheless, the use of such ovens for the realisation of microwave-assisted chemical reactions have several drawbacks:

- the ovens are not specifically suited for chemical experiments;
- the microwave field in a reaction vessel is inhomogeneous;
- changes in temperature and pressure of a reaction mixture during an experiment cannot be controlled;
- the MWI power varies over time.

All these factors result in poor reproducibility of results and sometimes give rise to explosion or ignition of solvents. Dedicated chemical microwave reactors are now available commercially, which provide homogeneous distribution of the electromagnetic field throughout the reaction volume and computer-controlled adjustment of the radiation power. Such reactors are normally equipped with magnetic stirrers and temperature and pressure gauges. Such special reactors are one order of magnitude more expensive than normal household MW-ovens and thus ~70% of experiments are still performed using the latter.

Several aspects of the application of MWI to organic synthesis have been surveyed in previous reviews, including the theoretical background and recent achievements of MW-assisted organic synthesis,<sup>4–8</sup> solvent-free synthesis,<sup>9</sup> reactions on solid sup-

ports,<sup>10,11</sup> synthesis under the conditions of phase-transfer catalysis,<sup>12</sup> preparation of heterocyclic compounds<sup>13</sup> and cycloaddition reactions.<sup>14</sup>

Despite the great number of experimental works describing practical aspects of MWI utilisation, the theory of microwave-assisted organic synthesis has not been elaborated in sufficient detail. Potentially, MWI affects the course of a chemical process in several ways, including purely thermal effects (heating rate, overheating or 'hot spots'), the selective absorption of the radiation by polar compounds and the specific microwave effect (MWE) related to the nonthermal action of MWI.

The term MWE first introduced by Perreux and Loupy<sup>6</sup> is now frequently quoted in studies related to microwave-assisted organic synthesis. Based on the well-known Hammond postulate,<sup>15</sup> Perreux and Loupy suggested<sup>6</sup> that the transition state is close to the ground state for reactions characterised by low activation energies. In such cases, the difference in polarities of the transition and ground states is small and thus the microwave effect is insignificant. In contrast, for reactions characterised by high activation energies, the transition state is rather close to the reaction products. This means that the polarity change in the course of the reaction is prominent and thus the MWE is enhanced.

If polar aprotic solvents strongly absorbing MWI are used, it is the solvent molecules that predominantly feed the reagents with energy (*i.e.*, the energy transfer is indirect) and therefore the MWE is expected to be masked with MWI absorption by the solvent. As a result, the difference in the reaction rates under the conditions of microwave irradiation and convection heating is diminished.

On the other hand, if nonpolar solvents (*e.g.*, CCl<sub>4</sub>, alkanes, benzene, *etc.*) weakly interacting with microwaves are used, the

MWI directly interacts with the reagents, and the MWE in its pure form is manifested.<sup>6</sup>

The MWE is most prominent under solvent-free conditions, *i.e.*, when no external factors hinder the interaction of microwaves with reagents such that the overall MWI absorption is determined solely by their nature.

Unfortunately, in the vast majority of studies devoted to microwave organic synthesis, the influence of the MWI power, the stirring intensity and the reaction medium type on the reaction rates and yields of products were not considered systematically. Thus, the aim of the present review is to serve as a general source of reference data. It covers microwave-assisted syntheses of various classes of organic compounds published over the period from 2000 to 2002. Earlier studies have been reviewed by Lindstrom *et al.*<sup>7</sup> and are not cited here.

The literature data presented below are grouped according to the types of organic compounds concerned and reactions involving them.

## II. Formation of new C = C and C – C bonds under microwave irradiation

The most common reactions utilised for the formation of carbon – carbon bonds are the aldol-crotonic condensation or related reactions (examples Nos 1–7 in Table 1); the condensation of nitromethane or its derivatives with 5-nitro-6-chloromethylimidazothiazole (No. 8), benzaldehyde or its derivatives (No. 9); Wittig reaction (Nos 10–12) and elimination reactions (No. 13).

Unfortunately, comparative data on different activation methods were reported only in a few studies.<sup>22,25,26</sup> In particular, Gellis *et al.*<sup>22</sup> showed that the microwave-assisted condensation of

<sup>a</sup> BSA is *N,O*-bis(trimethylsilyl)acetamide; <sup>b</sup> L means different diamide ligands; <sup>c</sup> dba is dibenzylideneacetone; <sup>d</sup> PEG is polyethylene glycol.

chloromethylimidazothiazole with 9 nitromethane derivatives proceeded 240 times faster than the respective reactions under thermal activation (see Table 1). Evidently the MWE can be observed here.

The microwave-assisted introduction of double bonds into organic molecules following the Wittig method (reactions Nos 10–12) is slightly accelerated as compared to the thermally activated reaction; the use of reagents grafted to a solid substrate does not result in a further reduction in the reaction time.

Table 1 also lists some examples of the formation of new single C—C bonds under MW conditions, including allyl substitution, C-alkylation, C-aminoalkylation and oxidative coupling reactions (Nos 14–22).<sup>†</sup> Unfortunately, no conclusions on the MWE involvement can be deduced in those cases owing to the absence of comparative data. Among them, the work by Kaiser *et al.*<sup>29</sup> is worth a special mention, where the allyl alkylation of methyl-(*E*)-3-phenylallylcarbonate (No. 17) was studied and the influence of several factors, such as the nature of catalyst (*cf.* with No. 15) and solvent, radiation power and grafting of the reagent on a solid substrate, on the yield of the target product was analysed.

### III. Reactions involving multiple carbon—carbon bonds

Table 2 lists examples of reactions involving C=C bonds, which are activated by microwave irradiation. The hydrogenation of double bonds is illustrated with three examples (Nos 1–3). These data show that the microwave-assisted hydrogenation proceeds nearly as fast as the thermally activated reaction but the use of a support in the former case results in a 360-fold acceleration.

The C-arylation of compounds containing a double bond in the presence of Pd-based catalysts is represented by reactions Nos 4–7. Olofsson *et al.*<sup>40</sup> found that the microwave-activated

C-arylation following the Heck method proceeds 200 times faster than the thermally activated one (reaction No. 6, Table 2).

In the case of the addition of aldehydes to alkenes with non-activated double bonds (reaction No. 8), the yields of target products are virtually the same for the microwave and thermal activations but the use of MWI gives rise to a 24-fold acceleration of the reaction.

The addition of compounds with reactive methylene or methine groups to alkenes with activated double bonds (*i.e.*, the Michael addition) is illustrated with reactions Nos 9–14 (see Table 2).

Michaud *et al.*<sup>47</sup> showed that the double Michael addition of benzylidenecyanoacetic esters to nitromethane (reaction No. 13) catalysed by piperidine followed by intermolecular cyclisation yields a mixture of functionalised cyclohexenes with either two (compound **A**) or one (compound **B**) methoxycarbonyl groups in a ratio dependent on the MWI parameters and amount of piperidine. For instance, with piperidine taken in equimolar proportion to nitromethane, the monomethoxycarbonyl product (**B**) is predominantly formed, and *vice versa*, the maximum yield (80%) of dimethoxycarbonylcyclohexene (**A**) is achieved with piperidine used in catalytic amounts.

The microwave-assisted Diels–Alder cycloaddition reactions that yield polycyclic systems with isolated double bonds are significantly accelerated both in the presence (reaction No. 16, see Table 2) and in the absence (reaction No. 15) of solvents as compared to the respective thermally activated reactions. It has to be noted that, although the yields of products under different conditions are comparable, some reactions (*e.g.*, see Ref. 50) can be realised only under microwave irradiation.

Table 3 gives some examples of catalytic reactions involving acetylene derivatives, such as Mannich aminomethylation (reactions Nos 1, 2), Sonogashira cross-coupling (No. 3–6), desilylation (No. 7), Glaser synthesis of conjugated diacetylene derivatives (No. 8), metathesis (No. 9) and C-acylation (No. 10).

The data presented indicate that the reaction times in the case of MWI activation are substantially reduced as compared to the

<sup>†</sup> For other examples of the formation of C—C bonds, see Table 2, which lists reactions involving C=C bonds.

**Table 2.** Reactions involving the C=C bond.

The microwave-assisted Suzuki cross-coupling reactions are complete in 1–15 min giving yields as high as 40%–98%. Unfortunately, no results for activation methods other than MWI have been reported in those cases, thus no conclusion on the extent of the MWE can be deduced.

The use of MWI for the activation of aromatic nucleophilic substitution reactions is not as efficient. In only a few cases, slight acceleration of the reactions (*e.g.*, Nos 8 and 10) and an increase in the yields of target products by 10%–20% were registered. An exception to this is the substitution of the hetarylthio group for the chlorine atom in the aromatic core (No. 21). In this specific case, the reaction rate increased ~140-fold in the presence of a solvent and 480-fold when the reaction was conducted in the absence of solvents on a solid support, which is plain evidence for the MWE.

**Table 4.** Synthesis of aromatic compounds and reactions with them.

<sup>a</sup>The total yield of isomers is given. Hereinafter, <sup>b</sup>NMP is *N*-methylpyrrolidone-2; <sup>c</sup>HMPA is hexamethylphosphortriamide, <sup>d</sup>EPZG is a support material.

## V. Deuterated derivatives

Examples of the use of MWI for the introduction of deuterium labels through the substitution of a hydrogen (examples Nos 1 and 2) or halogen (No. 3) atom with deuterium or addition of deuterium to a double bond are given in Table 5. These data imply that neither microwave nor thermal activation is sufficient to complete the deuterioexchange, although the reaction proceeds somewhat faster in the former mode.

## VI. Synthesis of alcohols and phenols. Deprotection of the OH group

Studies reporting the application of MWI to the synthesis of alcohols and phenols are quite numerous. Most frequently, alcohols are produced by the reduction of aldehydes, ketones or esters with Pr<sup>i</sup>OH or NaBH<sub>4</sub> (reactions Nos 1–3, Table 6). In addition to reduction, the hydrolysis of esters (reaction No. 4) and opening of oxirane rings (reaction No. 5) are utilised. The

hydroxymethylation of uracils in basic media (reaction No. 6) and controlled Claisen rearrangement (No. 7) have also been reported.

The above reactions under MWI are complete in a few minutes affording the respective hydroxy-containing products in yields as high as 90%–99%. In particular, the reaction times of the Claisen rearrangement (No. 7) and benzaldehyde reduction (No. 1) were reduced by factors of 28 and 84, respectively, as compared to the thermally activated reactions, although the product yields remained essentially unchanged.

Several authors reported the microwave-assisted deprotection of OH groups (reactions Nos 8 and 9 in Table 6).

## VII. Reactions involving alcohols and phenols

Examples of chemical modifications of alcohols assisted by MWI given in Table 7 include substitution (No. 1), O-sulfonylation (No. 2), O-alkylation (Nos 3–11), O-glycosylation (Nos 12

and 13) and protection of the OH group (Nos 14–17). These data indicate that in some cases, the MWI reduces the reaction times and increases the yields of products as compared to the reactions under ordinary heating. For instance, the yields of 3,4-dialkoxybenzaldehydes (reaction No. 9) increased from 60% in the classical synthesis ( $K_2CO_3$ , boiling acetone) to 86% in the solvent-free MWI synthesis under conditions of phase-transfer catalysis with a simultaneous reduction of the reaction times from 1440 min to 10 min. The use of MWI proved promising in the opening of the aziridine ring with alcohols (reaction No. 11). The reaction time in this case was reduced by a factor of 480 as compared to the thermally activated reaction. Furthermore, the opening of the aziridine ring with phenol appeared possible only under the MWI conditions. This is a clear manifestation of the MWE.

Nevertheless, the use of MWI does not give positive results in all cases. For instance, the microwave-assisted O-alkylation (No. 3) proceeds 2 times slower than the thermally activated

**Table 6.** Synthesis of alcohols and phenols. Deprotection of the OH group.

<sup>a</sup> The reaction is impossible with aliphatic alcohols and phenols; <sup>b</sup> Hereinafter, K-10 is a montmorillonite modification; <sup>c</sup> the yield of the disubstituted product is 15%–17%.

reaction. In a few cases, the yields of MWI reactions were lower than those of the thermal reactions, despite some acceleration (No. 6).

## VIII. Synthesis of aldehydes and ketones.

### Protection and deprotection of the carbonyl group

Among methods used for the microwave-assisted synthesis of carbonyl compounds, the most common are: oxidation of an activated methylene group (Table 8, reaction No. 1); selective oxidation of alcohols [in particular, oxidation of benzyl alcohols

with calcium hypochlorite (No. 2), mild oxidation of benzoin over alumina or zeolites without oxidants (No. 3) and oxidation of 1-hydroxyphosphonates on solid supports (No. 4)]; selective dealkylation (No. 5); oxidative deprotonation of tetrahydropyranyl (No. 6) or trimethylsilyl ethers (No. 7), the Heck reaction (No. 8), intramolecular condensation of dicarboxylic acids over graphite (No. 9), condensation of carboxylic acid chlorides with 2-methyl-quinolines (No. 10), cross-coupling of sodium organoborates with acyl and aroyl chlorides (No. 11), catalytic [2 + 2 + 1]-cycloaddition (the Pauson–Khand reaction, see Nos 17 and 18 in Table 2).

**Table 8.** Synthesis of aldehydes and ketones.

<sup>a</sup> HNIB is hydroxy(*p*-nitrobenzylsulfonyl)iodobenzene; <sup>b</sup> for Ar<sup>1</sup> = Ar<sup>2</sup> = Ph; <sup>c</sup> zeofen is Fe(NO<sub>3</sub>)<sub>3</sub>/HZSM-5 oxidant; <sup>d</sup> the reaction is impossible for carboxylic acid anhydrides with R<sup>2</sup> = Bu<sup>t</sup> and Pr<sup>i</sup>.

A comparison of the microwave and thermal methods for the activation of these reactions indicate that the yields of target products are virtually identical in both cases, but the use of MWI accelerates the reactions. Furthermore, the condensation of carboxylic acid chlorides with 2-methylquinolines (No. 10) is possible only under the MWI conditions.

Acid anhydrides (Table 9, No. 1), polyatomic alcohols (Nos 2 and 3) or hydroxylamine (No. 4) are commonly used to protect the carbonyl groups in various chemical transformations.

As deprotection methods, the oxidative deprotonation of acetals and ketals (Nos 5 and 6), mild oxidative conversion of

oximes (Nos 7 and 8), hydrazones (Nos 8 and 9) and semicarbazones (No. 10) over various supports (*e.g.*, K-10, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, *etc.*) are utilised.

## IX. Synthesis of carboxylic acids, esters and lactones

Table 10 summarises examples of the utilisation of MWI in the synthesis of carboxylic acids. The hydrolysis of esters over solid supports (No. 1) and amides in the presence of sulfuric acid with variable concentrations (No. 2) and the so called Mathews dry

**Table 9.** Microwave-assisted protection and deprotection of the carbonyl group.

<sup>a</sup> Envirocat EPZ10 is a support material; <sup>b</sup> BTSC is bis(trimethylsilyl)chromate; <sup>c</sup> Cr-MSM-4 is an ion-exchange aluminosilicate; <sup>d</sup> CAN is cerium ammonium nitrate.

hydrolysis of amides and nitriles in the presence of phthalic acid under the solvent-free conditions (Nos 3 and 4) are the most common routes.  $\beta,\gamma$ -Unsaturated carboxylic acids can be prepared by Knoevenagel condensation of aldehydes with maleic acid followed by double bond isomerisation (No. 5). For the latter reaction, the use of solvent-free MWI conditions not only reduced the reaction time but also increased the yield of the product by 43%, which is evidence of the MWE.

Carboxylic acid esters can be prepared under MWI conditions by the interaction of acids with alcohols (Table 11, Nos 1–3). Polyesters are formed in the intermolecular polycondensation of L-2-hydroxy-3-phenylpropionic acid (No. 4) or catalytic polymerisation of lactones (No. 5).

Several examples of solid-state microwave synthesis of esters (Nos 6 and 7) by the interaction of aliphatic or aromatic acids with *para*-substituted benzyl chloride grafted to a solid support or

Table 11 (continued).

<sup>a</sup> Different durations of irradiation and radiation power were used; <sup>b</sup> products of the substitution of the second OH group were also obtained; <sup>c</sup> the acetylation of substituted 5-hydroxyflavones was also accomplished; <sup>d</sup> DBU is 1,2-diazabicyclo[5.4.9]undec-7-ene; <sup>e</sup> 25 support types were elucidated, the support indicated provided the maximum yield of products.

The esterification of carboxylic acids can also be realised with O-alkylated isoureas (No. 12).

The acetylation of alcohols and phenols with acetic anhydride affords the respective acetic acid alkyl and aryl esters (Nos 13 and 14).

Lactones can be prepared by the mild oxidation of furan with *N*-bromosuccinimide (Table 11, reaction No. 15). The reaction was applied to the synthesis of naturally occurring biologically active limonoids. Gopalakrishnan *et al.*<sup>154</sup> reported the prepara-

tion of lactones under the conditions of thermal, ultrasound and microwave activation. The maximum yield was obtained with microwave activation, whereas the reaction time was the minimum in the case of ultrasound activation: it was 4 and 190 times shorter than those under microwave and thermal activations, respectively.

The three-component condensation of acetic anhydride, *p*-hydroxybenzaldehyde and hippuric acid afforded azlactones (No. 16).

## X. Synthesis of amines, imines, oximes, substituted hydroxylamines, hydrazines and hydrazones and reactions with them

Table 12 lists examples of microwave-assisted syntheses of anilines (No. 1), imines (Nos 2 and 3), hydroxylamines (No. 4), hydrazines (Nos 5 and 6) and hydrazones (Nos 7 and 8). The yields of target products in these reactions were in the range of 81%–99% and the reaction times were from 0.5 to 30 min.

For several of the above reactions, comparative results on the microwave and thermal conditions were reported, which indicated that the MWI gave rise to their substantial acceleration.

Among the microwave reactions of amines, the following classes are of note: reductive elimination of styrenes (Table 13, No. 1) and alkynes (No. 2), numerous reactions of N-alkylation (Nos 3–11) and N-arylation (Nos 12–20) and hydrogenation (No. 21).

According to the studies reporting comparative data (which are, unfortunately, rather sparse, see Table 13), the use of MWI somewhat accelerates the reactions but the respective improvement in the yields of products is only insignificant.

**Table 12.** Synthesis of amines, imines, substituted hydroxylamines, hydrazines and hydrazones.

| No. | Reaction                                                                                                                                                                                                                                                                             | Conditions                                                                                                                                                                                                             | Number of examples | Yield (%)       | Ref.       |

<sup>a</sup> Ethyl esters of substituted cinnamic acids ArCH=CHCO<sub>2</sub>Et are also afforded in yields of 87%–34%; <sup>b</sup> the monosubstitution products are formed in low yields.

## XI. Synthesis of carboxylic acid amides and imides, their thio analogues, thioureas and thiosemicarbazides

Amides and imides can be synthesised by the microwave-assisted reactions of amines with carboxylic acids (or, alternatively, amine hydrochlorides with metal carboxylates) (Table 14, Nos 1–6) or

with their derivatives, such as esters (No. 7), chlorides (Nos 8 and 9) or anhydrides (Nos 9–14). Other methods for the formation of amides include the specific Wolff rearrangement of α-diazoketones (No. 15), Heck aminocarbonylation of aryl bromides catalysed by palladium with DMF as a source of carbon oxide (No. 16) and hydrolysis of aromatic nitriles using different catalysts (No. 17). The preparation of amides from ketones and

**Table 14.** Synthesis of carboxylic acid amides and imides, their thio analogues, thioureas and thiosemicarbazides.

<sup>a</sup> DIC is *N,N*-diisopropylcarbodiimide.

hydroxylamine (No. 18) was also reported. The MWI synthesis of thioanalogues of carboxylic acid amides is illustrated with reactions Nos 19 and 20, whereas the synthesis of thioureas is represented by reactions Nos 21–23. 1,4-Disubstituted thiosemicarbazides were obtained by nucleophilic substitution under solvent-free MWI conditions (Nos 24–26).

Some of the aforementioned reactions are impossible without microwave activation (Nos 4 and 15), which implies MWE manifestation. The involvement of MWE is also supported by increases in the yields of amines in the MWI-activated reactions as compared to the thermally activated ones (see reactions Nos 3, 4, 7, 18 and 20).

## XII. Preparation of nitriles

Aliphatic and aromatic nitriles can be prepared in high yields using the microwave-assisted reaction of aldehydes with hydroxylamine hydrochloride (Table 15, No. 1). The reaction is performed either in the presence of ammonium acetate (conditions *a*) or under solvent-free conditions over zeolites (conditions *b*) or in

*N*-methyl-2-pyrrolidone (conditions *d*). Aromatic nitriles can also be synthesised by the dehydration of the respective oximes (No. 2) with phthalic anhydride either in the presence of a solvent (*a*) or using molecular sieve A4 in the absence of solvents (*b*) or on the alumina surface in the presence of tetrachloropyridine (*c*). A catalytic conversion of aryl and vinyl halides into nitriles by the substitution of the cyano group for the bromine atom was realised (No. 3). In all those cases, the use of MW accelerated the reactions but did not noticeably increase the yields of products.

## XIII. Ionic liquids

Examples of the microwave-assisted preparation of ionic liquids composed of heterocyclic cations and inorganic anions are compiled in Table 16. For this purpose, the interaction of 1-methylimidazole (Nos 1 and 2) or pyridine (No. 3) with alkyl halides was exploited. The results presented indicate that the reaction times of the MW-activated reactions were substantially shorter than those of the thermal reactions at nearly the same yields of products.

Table 15. Synthesis of nitriles.

MWI also enabled anion exchange reactions (Nos 4, 5) significantly increasing their yields as compared to the thermal conditions. This means that the MWE is involved.

## XIV. Synthesis of heterocyclic compounds

### 1. Three-membered heterocycles

Chanda *et al.*<sup>218</sup> described a method for the catalytic microwave-assisted synthesis of diverse aziridines by the reaction of olefins with sodium haloamines (TsNXNa) (Table 17, No. 1). The oxidation of alkenes with hydrogen peroxides under MWI afforded epoxides (No. 2), whereas the reductive cyclisation of  $\alpha$ -haloketones and diethyl dithiophosphoric acid in the presence of alumina-supported sodium borohydride yielded thiiranes (No. 3). The yields of products depend on the structure of reagents and the reaction type. The MWE was manifested in all those cases both in the significant acceleration of the reactions and increases of yields of products.

### 2. Four-membered heterocycles

Table 18 lists some examples of the microwave-assisted preparation of four-membered heterocyclic compounds (*e.g.*,  $\beta$ -lactams, oxetanes and thietanes). The Staudinger reaction was utilised for the synthesis of  $\beta$ -lactams (Table 18, Nos 1–5). Oxetanes were prepared by the [2 + 2]-cycloaddition of alkynes to  $\beta$ -formylenamines. The reaction was accomplished over the alumina surface under solvent-free conditions (No. 6). Functionalised thietanes were prepared using the nucleophilic addition of HSP(S)(OEt)<sub>2</sub> to the double bond of  $\alpha,\beta$ -unsaturated ketones followed by the reductive cyclisation initiated by nucleophiles (No. 7).

### 3. Five-membered heterocycles

#### a. Five-membered heterocycles with one nitrogen atom

The microwave-assisted three-component condensation of amines, ketones (or aldehydes) and nitro compounds was utilised to synthesise substituted pyrroles (Table 19, Nos 1–3). Functionalised indoles were prepared by the Fischer reaction (No. 4) and by the condensation of *o*-iodoanilines with alkynes (Nos 5 and 6).

<sup>a</sup> DMA is *N,N*-dimethylacetamide; <sup>b</sup> different temperature modes and solvents were tested.

The coupling of  $\alpha$ -amino acids with alkenes afforded pyrrolidine derivatives (Nos 7 and 8). The microwave 1,3-dipolar cycloaddition of alkynes to pyridinium salts was applied to the synthesis of 7,7'-bisindolizines (No. 9). Indolines were synthesised by the Cope rearrangement from *N*-allylamines (No. 10).

In the case of the Fischer synthesis of indoles (No. 4), the reaction proceeded at the same rates under microwave and thermal activations, but the yields of products were 2 times higher

in the former mode. An increase in the yield of products under microwave irradiation (by 30%, on average) was also registered for the 1,3-dipolar cycloaddition (No. 9), which is indicative of the MWE.

#### b. Five-membered heterocycles with one oxygen atom

<sup>a</sup> NMF is *N*-methylformamide.

lar cyclisation of dihalides (No. 2), rearrangement of phenol and allyl alcohol ethers (No. 3) were applied to the microwave synthesis of dihydrofurans. Benzofurans were prepared by the Mannich reaction (No. 4), condensation of chloroacetic acid esters with substituted salicylic aldehydes under phase-transfer catalysis conditions (No. 5) and intramolecular cyclisation of  $\alpha$ -phenoxyacetophenones (No. 6). The condensation of furans (or alkylfurans) with acrylic acid derivatives giving rise to tetrahydrofurans (No. 7) was performed under the conditions of both microwave and thermal activation. The microwave reaction was 32 times faster than the reaction activated by convection heating at nearly the same yields of products. The use of MWI also accelerated the synthesis of dihydrofurans (No. 2) but the yields of products were sometimes lower as compared to the thermally activated reactions.

### c. Five-membered heterocycles with two nitrogen atoms

The microwave-assisted synthesis of pyrazole derivatives from hydrazines and compounds with carbonyl groups was realised (Table 21, Nos 1–5). Non-substituted pyrazolylpyrazolino[60]-fullerenes were synthesised by the 1,3-dipolar cycloaddition of C<sub>60</sub> to arylhydrazones (No. 6), whereas the *trans*-amination of dimethylaminoacrylates followed by the cyclo-condensation of enehydrazines afforded 3-pyrazolones (No. 7). Non-substituted triarylimidazoles can be prepared by the condensation of  $\alpha$ -diketones, aldehydes and ammonium acetate; the condensation of the same reagents with amines afforded substituted derivatives (No. 8). Indolyl-substituted imidazoles were obtained by cyclisation of the respective ketoamides with ammonium acetate (No. 9). Benzimidazole derivatives were synthesised by the microwave cyclocondensation of *N*-trifluoromethylacetylphenylenediamine (No. 10) and condensation of *o*-phenylenediamines with carbonyl compounds (Nos 11–13). Imidazolones can be prepared by the

**Table 21.** Synthesis of pyrazole and imidazole derivatives.

Hereinafter, <sup>a</sup>NBS is *N*-bromosuccinimide; <sup>b</sup>PPA is polyphosphoric acid; <sup>c</sup>PPE is polyphosphoric ester; <sup>d</sup>PS–DMAP is polystyrene-grafted dimethylaminopyridine.

reactions of *o*-phenylenediamine with urea or thiourea (No. 14) or of hetarylamine with oxazolones (No. 15). The condensation of  $\alpha$ -ketaldehydes with urea or thiourea can be applied to the preparation of hydantoins and thiohydantoins (No. 16); the latter compounds were also synthesised by the microwave cyclisation of glycine with isothiocyanates (Nos 17 and 18).

The yields of reaction products varied over a wide range, depending on the structure of reagents. In the majority of cases, the use of MWI accelerated the reactions.

#### d. Five-membered heterocycles with one nitrogen and one oxygen atom

Two methods, *viz.*, the 1,3-dipolar cycloaddition of aromatic aldehydes to imidates, *i.e.*, potential azomethine ylides, (Table 22, No. 1) and the intramolecular rearrangement of the

aziridine ring (No. 2) were used in the microwave synthesis of oxazolones.

Isoxazolines were synthesised by the 1,3-dipolar cycloaddition of oximes to allyl alcohols (Table 22, Nos 3–5) or of  $\alpha,\beta$ -unsaturated ketones to hydroxylamine (No. 6) under microwave activation. Isoxazolidines were prepared in a similar way using the 1,3-dipolar cycloaddition of alkenes to oximes (No. 7). The condensation of  $\alpha$ -amino acid derivatives with formaldehyde (No. 8) or other aldehydes (see Table 11, No. 15) and the intramolecular rearrangement of the aziridine ring (Table 22, No. 9) were utilised in the synthesis of oxazolones, whereas oxazolidines were prepared similarly from  $\alpha$ -aminoalcohols and aldehydes (No. 10). Although the use of MWI accelerated the reactions in some cases as compared to the thermal activation, the yields of products either remained unchanged or even decreased.

**Table 22.** Microwave-assisted synthesis of oxazole and isoxazole derivatives.

<sup>a</sup> The total yield of isomers is given.

The synthesis of isoxazolidines (No. 7) is worth a special discussion. Kusurkar and Kannadkar<sup>263</sup> compared three types of activation, *viz.*, UV, thermal and microwave. The reaction time

under the microwave conditions was shorter than 0.5 h, whereas it was in the range of 12–120 h and 72–168 h for the thermal and

Substituted pyridines can be synthesised using the Bohlmann–Rahtz (Table 24, No. 1) or Diels–Alder (Nos 2 and 3) reactions or by the aromatisation of 1,4-dihydropyridine with various oxidants (No. 4) (urea nitrate was found to be the best one). Symmetrical dipyrazolopyridine was afforded by the condensation of 5-amino-1,3-dimethylpyrazole with *p*-methylbenzaldehyde (No. 5). The three-component condensation of aldehydes, secondary amines and 2-azidobenzophenones gave rise to quinoline derivatives (No. 6) and the condensation of 2-amino substituted benzaldehyde or benzimides with different heterocyclic compounds yielded polycondensed quinolines (No. 7). The condensation of diarylamine with carboxylic acids (the Berthsen reaction) was applied to the synthesis of acridine (Nos 8–10). The Hantzsch method was used to synthesise 1,4-dihydropyridine derivatives (Nos 11–15), and 1,2-dihydroquinolines were prepared by the Skraup reaction (No. 16). Dihydroisoquinolines

| No. | Reaction                                                                                                                                                                                                                                               | Conditions                                                                                                                                                                                      | Number of examples | Yield (%) | Ref. |

| 5   | <br>R <sup>1</sup> = H, Me, Cl; R <sup>2</sup> , R <sup>3</sup> = H, OMe. | DBU, Na <sub>2</sub> SO <sub>4</sub> , MW, 20 min | 5                  | 0–27      | 306  |

were prepared by the cyclocondensation of the respective amides (No. 17) and direct oxidation of tetrahydroisoquinolines (Nos 18 and 19). The microwave-assisted cyclocondensation of amines (for instance, tryptophan derivatives) with compounds having a carbonyl group (No. 20) was achieved. Table 24 also gives some examples of syntheses of different quinolinones (Nos 21–23), octahydroquinoline-2,5-diones (No. 24) and hexahydropyridine-2,6-diones (No. 25).

Typically, the use of MWI substantially reduced the reaction times as compared to the thermal activation (Nos 7, 14 and 17); in some cases, an increase in the yields of heterocyclic products was registered (see, for instance, Nos 7, 10, 14, and 17), which indicated the MWE.

#### b. Six-membered heterocycles with one oxygen atom

Table 25 lists examples of applications of MWI to the synthesis of six-membered heterocyclic compounds with one oxygen atom,

*viz.*, substituted  $\gamma$ -pyrans through the condensation of Meldrum's acid with  $\beta$ -carboxy- $\beta$ -cyanostyrenes (No. 1) or benzylidenemalonodinitriles (No. 2) or three-component condensation of malonodinitrile, aromatic aldehydes and 3-methyl-1-phenyl-2-pyrazolin-5-one (No. 3), dihydropyrans through the intramolecular cyclisation of hydroxyketones (No. 4) and flavones through the intramolecular cyclocondensation of chalcones (No. 5).

For all of the above examples except for No. 5, the reaction times under the MWI conditions were 1.5–8 min and the yields of products were up to 90%, which confirms the high efficiency of this activation method.

#### c. Six-membered heterocycles with two heteroatoms

The microwave activation appeared equally efficient in the synthesis of heterocyclic compounds with two nitrogen atoms in a ring, such as pyrazine, pyridazine, pyrimidine (Table 26, Nos 1–11) and pyrimidopyrimidine (Nos 12–14). 1,3-Oxazin-2-

<sup>a</sup> Hereinafter, KSF is a support material.

ones were synthesised by the intramolecular cyclisation of substituted semicarbazones of salicylic aldehyde (Table 26, No. 15); the condensation of 2-aminothiophenols with  $\beta$ -diketones afforded 1,4-benzothiazines (No. 16).

The results compiled in Table 26 clearly demonstrate the superiority of the microwave activation over the thermal one.

#### d. Synthesis of six-membered heterocycles with three nitrogen atoms

Examples of the use of MWI in the synthesis of 1,2,4- and 1,3,5-triazines are given in Table 27.

One of the listed studies is worth a special note. Kidwai *et al.*<sup>320</sup> explicitly demonstrated the advantages of microwave activation as compared to thermal for 12 model reactions. Using alumina as a support they achieved quantitative yields of 1,2,4-triazines with simultaneous acceleration of the reactions by 3 orders of magnitude. This is a striking manifestation of the MWE action.

#### 5. Heterocyclic compounds with 7 or more atoms in a ring

Results of the application of MWI to the synthesis of heterocyclic compounds containing  $\geq 7$  atoms are summarised in Table 28. In particular, seven-membered heterocycles with two nitrogen atoms were prepared by the condensation of *o*-phenylenediamines with ketones in different catalytic environments (No. 1) and reaction of unsaturated amines with *N*-carboxyanthranilic anhydride (No. 2). The condensation of hydrazides with orthoesters yielded 4,7-dihydro-1,2,4-triazepin-8-one derivatives (No. 3). The reaction of *o*-aminothiophenols with  $\alpha,\beta$ -unsaturated ketones gave rise to 2,3-dihydro-1,5-benzothiazepines (No. 4). A 8-membered dibenzodiazocinoquinazolinone was synthesised from 3-hydroxyquinazolinones and *N*-carboxyanthranilic anhydride (No. 5). The cyclocondensation of benzaldehydes with pyrrole afforded tetraarylporphyrins (No. 6). The cyclocondensation of phthalic acid or its derivatives was employed for the synthesis of phthalocyanines (No. 7). Cationic cyclophanes were afforded by the cyclocondensation of precyclophanes with *m*-terphenyl dibromides (No. 8). Two types of binuclear phthalocyanines (Nos 9 and 10) were

<sup>a</sup> If lithium methoxide is used, a complex with two lithium atoms is formed; <sup>b</sup> if phthalic imide or anhydride or RC<sub>6</sub>H<sub>3</sub>(CO<sub>2</sub>H)<sub>2</sub> in the presence of urea is used instead of RC<sub>6</sub>H<sub>3</sub>(CN)<sub>2</sub>, the yields of products decrease; <sup>c</sup> the monosubstitution product is formed in a yield of 28%.

synthesised using the cyclocondensation of 1,2-bis(3,4-dicyanophenoxymethyl)benzene.

## XV. Organophosphorus compounds

Alkylphosphonates were prepared by the microwave-assisted reaction of trialkyl phosphites with alkyl halides (the Arbuzov rearrangement) (Table 29, Nos 1 and 2) or aldehydes (the modified Arbuzov reaction) (No. 3). The Kabachnik–Fields reaction was utilised to synthesise aminoalkylphosphonates either under solvent-free conditions on a solid support (Nos 4 and 5) or using a catalyst in an ionic liquid (No. 6) or 1,2-dichloroethane (No. 7). The interaction of triphenylphosphine with alkyl halides gave rise to phosphonium salts (No. 8). The MWE is manifested in an increase in the yields of products in the cases of microwave activation (Nos 4 and 5).

## XVI. Miscellaneous reactions

Table 30 lists several additional examples of microwave-assisted reactions not covered by Tables. 1–29.

## XVII. Conclusion

The history of the utilisation of microwave technology in organic synthesis extends only over two decades. We may consider that it is now mainly in the stage of gathering empirical results. Despite the fact that the number of papers reporting the use of MWI for heating and activation of chemical reactions exceeded 2000, there is still no solid theoretical background underlying the experimentally observed specific microwave effect.

The above analysis of the published data indicates that the microwave method for the activation of chemical processes is applicable to nearly all known types of organic reactions. The net result of a microwave chemical reaction depends primarily on the nature of reactants (*i.e.*, on their structural features and distribution of the electron density therein), the reaction mechanism (the

<sup>a</sup> Various Pd catalysts were used; <sup>b</sup> the synthesis of other polythiophenes with a common formula  $X-\text{S}_n-\text{Y}$  (X, Y = H, Br; R = H, Me; n = 2–6) was also reported.

stronger the change in the polarity of the medium during the reaction, the more evident is the microwave effect), the duration and power of MWI, the types of supports, catalysts and solvents utilised. Therefore, the factors listed above have to be considered as a whole for any specific reaction type.

Numerous attempts have been undertaken (see, for instance, Refs 5–7,9,12,42) to reconcile the current theoretical concepts regarding the physics of microwave processes with the experimental results on organic syntheses performed under microwave activation. However, by no means all the factors affecting the overall output of a specific chemical reaction have been properly taken into account. In particular, the effects of MWI wavelength and power and support type on the direction, chemical and stereochemical yields of a chemical reaction are unknown up to date. Several studies emphasising these issues were published after 2002. In particular, Nüchter *et al.*<sup>348</sup> considered the best practices of microwave experiments, Kappe<sup>349</sup> and de la Hoz *et al.*<sup>350</sup> gave examples of successful applications of controlled MWI-heating to organic synthesis and Romanova *et al.*<sup>351</sup> described the influence of MWI on the direction and stereochemistry of reactions.

The rapidly increasing number of publications devoted to microwave syntheses clearly confirms the growing perception of MWI as a powerful tool in hands of organic chemists. The first monographs on MWI synthesis have already appeared.<sup>352–354</sup> Without doubt, the near future will witness expanding application of the method both on the laboratory and industrial scales, especially provided that its theoretical substantiation is elaborated. The efforts put into the optimisation of conditions of microwave organic syntheses will be definitely rewarded by the quickness and simplicity of experimental implementations, energy saving and cost efficiency intrinsic to MWI.

**Abstract.** Studies on procedures for the analysis of high-purity solids by inductively coupled plasma atomic emission spectroscopy and mass spectrometry published over the last decade are considered. The analytical scope of the methods is outlined. Specific features of sampling procedures, matrix effects and possibilities of decreasing the detection limits of impurities based on their preconcentration are discussed. The bibliography includes 95 references.

## I. Introduction

The problem of substance purity control is always topical, because pure substances are used in the preparation of materials with special properties, which in turn determine parameters of devices constructed from these materials. At present, the influence of the trace element and its concentration, especially in the presence of other impurities, on the aim parameters of the device is often unknown. Therefore, the purpose of technological processes is to purify substances from all possible contaminants to the highest extent, which makes it necessary to monitor the purification process by analytical methods. These are characterised by the number of elements that can be detected and the detection limits of impurities (analytes). Up to the end of the previous century, spectrochemical techniques with arc excitation irradiation and mass spectrometry with spark or laser ionisation were widely used for the determination of the composition of impurities in high-purity substances. At present, these methods are virtually superseded by the methods of atom excitation and ionisation in inductively coupled plasma (ICP). Inductively coupled plasma atomic emission spectroscopy (ICP-AES) and mass spectrometry (ICP-MS) are the most important of them. In these methods, atom excitation and ionisation are induced by an electrode-less discharge generated in an inductor high-frequency field in an argon atmosphere. As a rule, the capacity of generators employed in analytical instruments with ICP is up to 5 kW and the working

frequency is 27.12 MHz. The capacity achieved in ICP is 1–2 kW. The electron temperature reaches 6000–8000 K, while the concentration of electrons is  $10^{13}$ – $10^{16}$  cm<sup>-3</sup>. Under such conditions, virtually total dissociation of molecules occurs, and atoms are effectively excited and ionised (the degree of ionisation of > 75% of the elements in the Periodic Table is ~90%), and the portion of multiply ionised atoms is very low (~1%). This type of discharge has stable parameters, which ensures high (up to tenth parts of percent) reproducibility of the analytical signal. There are several ways to introduce samples into the ICP. Together with the traditional dispersion of solutions (either pneumatic or ultrasonic), vaporisation can be effected using an electrothermal atomiser (ETA) or by laser- or spark-induced dispersion (ablation). The low starting energy of ions (10–15 eV) and high stability of the plasma parameters enable the use of ICP ionisation in combination with relatively simple mass analysers of quadrupole or time-of-flight types.

## II. Instrumentation

The instruments for inductively coupled plasma atomic emission spectroscopy and mass spectrometry (ICP-AES and ICP-MS, respectively) are commercially available.

As regards the number of instruments for multielement analysis, those for ICP-AES produced by the instrument-making companies in the last decades play a leading role. Wide distribution of this equipment is due to low matrix effects, high reproducibility of the results, low detection limits for elements (down to  $10^{-2}$  ng ml<sup>-1</sup> or  $10^{-7}$  mass % for solid samples) and relatively low cost (from USD 60 000 to 100 000). In the modern instruments for ICP-AES, linear detectors (as in spectrometers of the Pashen–Runge type) or matrix detectors (as in spectrometers with diffraction echelle gratings) with charge coupling and with charge carrier injection are used for recording the spectra. These detectors provide simultaneous photoelectric recording of the entire working range of wavelengths and allow complete automation of spectra processing using personal computers. The latest models of ICP spectrometers contain an option to perform axial measurement of plasma along with radial, which allows further reduction of the element detection limits (from two- to five-fold) due to an increase in the signal-to-noise ratio.<sup>1,2</sup>

Recently, ICP-MS has acquired wide use due to excellent analytical characteristics, viz., the possibility of simultaneous detection of up to 70 elements as contaminants in mineral acid solutions, including rare-earth elements (REE) and transuranium

elements, in a wide (up to 9 orders of magnitude) range of concentrations and with high (up to 99%) reproducibility. In the majority of publications devoted to mass spectrometric analysis of high-purity solids with the use of ICP, quadrupole mass spectrometers 'Plasma Quad' (Vacuum Generator, UK), 'ELAN' (Perkin Elmer, USA) and a magnetic sector field high resolution mass spectrometer 'ELEMENT' (Finnigan MAT, Germany) have been used most often. Note the higher cost of these instruments (from USD 80 000 to 300 000) as compared to those for ICP-AES.

An advantage of ICP-MS is the possibility of performing an isotope analysis.<sup>3–5</sup>

The resolution of a mass spectrometer is a crucial parameter determining the element detection limits. As a rule, the lowest detection limits (1–2 orders of magnitude lower than those achievable with quadrupole mass spectrometers) are provided by Finnigan MAT double-focusing instruments, due to the higher sensitivity, lower detector noise and the possibility of overcoming problems associated with overlap, in the analytical signal, of molecular ion lines and analyte lines generated in the ICP.<sup>3, 6, 7</sup>

One of the problems of using ICP-MS is the memory effect caused by deposition of a sample material on the introduction system and on parts of the separation and ion-beam formation devices. This effect can be reduced by high dilution of the sample solution (10<sup>3</sup>-fold and larger), preliminary cleaning of the entrance cones (sampler and skimmer), prolonged (up to 2–3 h) washing of the sample introduction system with 2%–5% solutions of high-purity nitric or hydrochloric (sometimes sulfuric) acid.

The sample introduction system consists of a peristaltic pump, a nebuliser and a dispersion chamber. The peristaltic pump regulates the rate of solution feeding. The nebuliser and the dispersion chamber produce aerosol drops with sizes of 1–2  $\mu\text{m}$ , which ensure equilibrium loading of the plasma and prevent its overcooling. Different constructions of dispersion chambers provide the uniformity of aerosol drop sizes or the sample particles in the case of laser ablation, thus reducing the element detection limits and random errors of the analysis.<sup>8–10</sup> With the use of pneumatic nebulisers, only ~1% of the analytical sample is transferred to the plasma, which decreases the efficiency of the sample usage. Ultrasonic nebulisers are about an order of magnitude more efficient.

### III. Sampling procedures

Sampling procedures are determined, on the one hand, by the nature of the analysed material and, on the other hand, by the method of analysis and sample introduction into the ICP. One of the main steps in the analysis of high-purity solids by ICP-AES and ICP-MS is the dissolution of the sample. Dissolution eliminates the problems of non-uniformity of the sample, but instead brings a problem of importation of contaminants from the solvent. Those methods are preferred that require the least quantity of reagents. For example, dissolution in an autoclave was used for the analysis of indium,<sup>11</sup> and microwave-assisted dissolution for the analysis of pure carbon.<sup>9</sup> In certain cases, complete dissolution of analysed substances requires their preliminary fusion with alkali metal salts. For example, carbon ash samples were fused with lithium metaborate.<sup>9</sup> While choosing the solvent, it is necessary to keep in mind that this can damage the equipment parts. In particular, hydrofluoric, hydrochloric or sulfuric acid, even diluted to ~1% concentration, may cause corrosion of the metallic parts of the ion-beam forming system of the mass spectrometer.

For the ICP-AES, the admissible content of a matrix element in a solution is 1%–5%. In the case of ICP-MS, the concentration of a solid sample in a solution (preferably, in 1 M HNO<sub>3</sub>) should not exceed 0.1%–0.05% to protect the instrument's entrance cones from the probe material deposition.<sup>12</sup> Such a dilution reduces the matrix effect. Due to the extremely low detection limits of analytes in solutions (up to several femtograms per ml)

attainable with the double-focusing spectrometers, the detection limits of non-common contaminants in solids can reach 10<sup>–9</sup> mass %–10<sup>–7</sup> mass %.

When analysing high-purity substances using ICP-AES and ICP-MS, advantage is taken of introducing of sample into the ICP in the form of a vapour from an electrothermal atomiser.<sup>13–16</sup> The preliminary dissolution of the sample is still necessary for this method, however, the solution may not be highly diluted. Optimisation of the pyrolysis and evaporation temperatures and the use of matrix modifiers allows selection of the conditions for the separation of analytes from the matrix. In the determination of contaminants in high-purity phosphorus, arsenic, antimony, sulfur, tellurium and iodine, ICP-MS and ETA were used with preliminary thermal separation (80%–97%) of the sample matrix.<sup>13</sup> In simultaneous determination of 45 contaminants, detection limits of 10<sup>–7</sup> mass % were reached, while in the case of optimised conditions for analysis for each element separately, they were as low as 10<sup>–8</sup> mass %.

In a number of studies, the electrothermal analyser was fed with a homogeneous (for example, ultrasonicated) aqueous slurry of a finely dispersed sample rather than with its solution.<sup>17–19</sup> On the one hand, this method reduces the risk of contamination or analyte loss during the sampling, but on the other hand, it complicates the process due to the necessity of very fine desintegration of the sample (< 5–45  $\mu\text{m}$ ). Such a dispersity is achieved by treatment in special apparatuses for many hours. In the analysis of alumina, a dry sample mixed with a matrix modifier was introduced into the graphite atomiser.<sup>20</sup> In the determination of contaminants in coals by ICP-AES and ICP-MS, Ebdon *et al.*<sup>21, 22</sup> introduced the samples directly into the ICP in the form of an aqueous suspension using the PTFE nebuliser for highly concentrated solutions.<sup>23</sup> Obviously, such a sampling procedure requires high dispersity of the sample and high uniformity and stability of the suspension. The sample content in the suspension was 0.2%–0.002% (ICP-MS) and 0.5% (ICP-AES). The same procedure was employed for the analysis of silicon nitride.<sup>24</sup>

At present, the search for new ways of introducing of powder samples into ICP without dissolution is in progress. For the direct introduction of powders into an instrument for ICP-AES, Bukar' <sup>25</sup> has used a special device. It is of note that certain difficulties are thus inevitable due to the low capacity of the ICP. The calibration problem becomes more serious due to the absence of standard samples adequate to the analytical ones. In our view, a more powerful (10–15 kW) plasma of double-jet arc plasmotron<sup>26</sup> is more promising for the direct analysis of powder samples.

The direct analysis of bulk solids by ICP-AES and ICP-MS is possible with the use of laser ablation (LA). The vaporisation of the material occurs under the action of a UV-laser ( $\lambda = 266 \text{ nm}$ ) focused on the sample surface to a spot 10–100  $\mu\text{m}$  in diameter. With a plasma power density of 10<sup>8</sup>–10<sup>9</sup> W cm<sup>–2</sup>, non-selective sample vaporisation occurs. The aerosol is transported to the plasma by an argon flow. This method is especially efficient in the cases where solubilisation of the analytes without losses or contamination is complicated or for an express semi-quantitative analysis. The time- and labour-consuming steps of sample dissolution or desintegration are eliminated, and there is the possibility of local analysis. However, the non-uniformity of the sample and especially its surface can import essential errors into the results. LA-ICP-MS was used for the analysis of pure coal and graphite,<sup>9, 27</sup> aluminium and copper<sup>28</sup> and a quartz glass.<sup>29, 30</sup> Unfortunately, the detection limits in this method are usually not lower than 10<sup>–7</sup> mass %–10<sup>–5</sup> mass %.<sup>27, 31</sup> Lower values (10<sup>–10</sup> mass %–10<sup>–7</sup> mass %) were reached only by Becker and Tenzler<sup>29</sup> in the analysis of a quartz glass with the use of a powerful IR-laser at a wavelength of 1064 nm. In this case, as opposed to the UV-laser case, the sample was decomposed by the plasma formed from the surrounding gas (argon), so it was unnecessary to focus the laser beam.<sup>32</sup>

Both laser and spark ablation are used in combination with the ICP-AES. By the examples of ICP atomic emission analysis of

a series of metals and alloys,<sup>33</sup> it was shown that the detection limits of analytes with the use of spark and laser ablation are comparable and have values of  $10^{-6}\%$ – $10^{-4}\%$ . These limits depend on the matrix and the nature of the element under study. In this method, it is possible to spend substantially more sample material (as compared with the LA-ICP mass spectrometric method) without the risk of its deposition on the equipment parts.

It is possible to substantially reduce the detection limits of contaminants in solid high-purity substances by preconcentration. This refers in particular to the mass spectrometric method. For the preconcentration coefficient  $K > 10^3$ , *i.e.*, where the sample matrix is virtually completely separated, the detection limits, for non-common impurities can reach values comparable to those in pure water, *viz.*, of about  $10^{-11}$  mass %– $10^{-10}$  mass % (and even lower). It is substantial that preconcentration allows one to level the matrix effect, to avoid deposition of sample material on the entrance cones of the mass spectrometer, to eliminate the 'memory effect'<sup>34</sup> and to diminish the probability of overlap of lines of molecular ions of the matrix element and the analyte lines in the output signal. Numerous methods of preconcentration used in conjunction with ICP-AES and ICP-MS are sorption, chromatographic separation, extraction, distillation of the probe matrix (also in the form of a volatile compound) and its precipitation. A column for anion-exchange chromatography to separate the matrix (tantalum) from impurities was built directly into the system of sample introduction into the ICP.<sup>10</sup> Determination of contaminants in silicon and germanium on the ICP-MS spectrometer ELEMENT achieved their preconcentration by halogenation and distillation of the probe matrix from the solution.<sup>35</sup> The detection limits for the contaminants were  $10^{-11}$  mass %– $10^{-6}$  mass %. With the same mass spectrometer, the detection limits of fourteen rare-earth elements as impurities in lanthanum oxide of  $10^{-10}\%$ – $10^{-8}\%$  were reached following preliminary separation of the matrix from impurities by high-performance liquid chromatography.<sup>36</sup> The detection limits of the same order of magnitude were obtained with the use of the 'Plasma Quad3' mass spectrometer for fifteen contaminants in cadmium separated from the matrix by sorption.<sup>37</sup> Chromatographic separation of impurities from the matrix has been used<sup>14,15</sup> in combination with ICP-AES and ETA for the analysis of lanthanum and cerium oxides.

The lowest possible detection limits of the common impurities could be achieved using minimum volumes of specially purified reagents, 'clean rooms', disposable glassware and special precautions to prevent contamination during sampling.<sup>9,10</sup> The contaminants introduced during sampling were taken into account in a control experiment. It can be noted that the reagent-free methods of preconcentration are the most effective, since the extent of contamination in this case is a minimum. One of these methods is the vacuum distillation of the sample matrix. The preconcentration methods based on sample dissolution and its reaction with other reagents (in particular, with solid and liquid extractants) do not provide low detection limits for common impurities even at high preconcentration coefficient.<sup>35</sup>

#### IV. Matrix effects

Matrix effects related to ICP-AES and ICP-MS manifest themselves in the control of the aerosol droplet size and its transport to plasma, thermal properties of plasma, and spectral overlaps.<sup>38</sup> An efficient method of compensating non-spectral matrix effects is the use of an internal standard.<sup>39</sup> Usually, the role of the internal standard introduced into the sample solution is played by a chemical element not to be determined and is absent from the sample and from the control experiment (most often, indium, rhodium and single-isotope rare-earth elements are used). In the LA-ICP-MS, the working gas components (krypton, xenon) and molecular ions of the matrix ( $\text{MAr}^+$ ,  $\text{MO}^+$  where M is the matrix element) serve as the standards. In the analysis of a quartz glass by this method, the compensation of the signal instability by virtue of

the internal standard  $\text{SiAr}^+$  allowed one to decrease four- to five-fold the random error.<sup>30</sup>

Spectral overlaps of the analyte lines, mainly with the molecular ions, are among the main limitations of the mass spectrometric method. Steep gradients of the plasma density and temperature in the plasma beam formation area favour the formation of different molecular ions, the mass spectra of which override the spectra of the analytes. In particular, components of the solvent ( $\text{H}_2\text{O}$ ,  $\text{HNO}_3$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{HClO}_4$ ,  $\text{HCl}$ ) can serve as one of the sources of molecular ions,<sup>9,40</sup> which combine with the sample matrix element and with argon to form  $\text{MCl}^+$ ,  $\text{MO}^+$ ,  $\text{MN}^+$ ,  $^{40}\text{Ar}^{35}\text{Cl}^+$ ,  $^{40}\text{Ar}^{16}\text{O}^+$ ,  $^{40}\text{Ar}^{14}\text{N}^+$ , and also argides ( $\text{MAr}^+$ ), oxides ( $\text{MO}^+$ ), hydrides ( $\text{MH}^+$ ) and other compounds of the matrix elements with the plasma components. Elements from the matrix modifiers also participate in molecular ion formation.<sup>18</sup> The sample introduction into the ICP by laser ablation allows elimination of these interference sources (except for  $\text{MAr}^+$ ). The problem of molecular ion line overlap is especially vital for the light elements with atomic masses  $< 80$  a.m.u. Possible overlaps of the molecular ion lines and atomic ones from  $^{24}\text{Mg}^+$  to  $^{76}\text{Ge}^+$  are documented.<sup>41</sup> The paper cited also contains a discussion of the problems of element determination in different matrices using a double-focusing mass spectrometer with a resolution up to 10 000.

Systematic studies of molecular ion formation have been carried out.<sup>42–45</sup> The problem of molecular ion overlap in the mass spectrometric analysis of dissolved coal samples with the use of ICP and LA was considered in detail.<sup>9</sup> Possible approaches to avoid these overlaps are also discussed. It is obvious that the ability to solve the problem of overlaps depends on the resolution of the instrument. They can largely be avoided by the use of double-focusing mass spectrometers with medium (3000–4000) and high (10000) resolution. However, the use of high resolution in these instruments leads to an increase in the element detection limits due to the reduced ion transfer efficiency.<sup>3</sup> The intensity of molecular ion lines can be reduced by their 'desolvation' in special collision cells. Molecular ions decompose in these cells due to collisions with the filler gas. For example, a collision cell was used<sup>46</sup> in the analysis of pure graphite by LA-ICP-MS on a quadrupole mass spectrometer. By the example of the reduction of intensity of  $^{40}\text{Ar}^{16}\text{O}^+$  and  $^{40}\text{Ar}^{14}\text{N}^+$  lines, which complicate the determination of iron in graphite, the efficiency of a collision cell with hydrogen and helium as filler gases is shown. The fundamental aspects and the practical usage of collision cells in mass spectrometric analysis have been considered.<sup>47</sup> It should be noted that the so-called isobaric interferences, *i.e.*, overlap of the lines of the matrix element oxides and those of the analyte isotopes with equal masses still present an unsolved problem. This problem is especially critical in the case of the determination of REE contaminants in rare-earth-containing matrix materials, for example,<sup>159</sup> of Tb in neodymium oxide ( $^{143}\text{Nd}^{16}\text{O}^+$ ).

Usually, in the ICP-AES method it is possible to find analytical lines free from overlap. Otherwise, chemometric methods and the subtraction of control spectra from the sample spectra are used to account for the overlap.<sup>48</sup> Fractional evaporation of impurities and the matrix in the form of fluorides from a graphite atomiser was used in the analysis of alumina by ICP-AES in order to suppress the non-spectral matrix effects.<sup>48</sup>

#### V. Quantitative analysis

The advantages of the use of ICP as a tool for excitation and ionisation of atoms in the analysis of solutions of high-purity solids include the possibility of using aqueous solutions of analytes as standards and the ease of using the methods of additives and isotopic dilution. For example, the method of additives in atomic emission spectroscopy was successfully used for the determination of impurities in alumina, gallium and scandium oxides.<sup>20,49,50</sup> The influence of the matrix on the analytical signal value is levelled owing to the use of an internal

standard.<sup>8,9,51–56</sup> Reliable results were obtained in the mass spectrometric analysis with use of the isotopic dilution method and introduction of a suspension into the ICP<sup>19</sup> and the method of additives with aqueous solutions of the analytes.<sup>18,20,31</sup>

It is much more difficult to obtain quantitative results from the LA-ICP-MS due to the absence (as a rule) of certified standards. Some researchers employ calibration by analyte solutions for determination of the relative sensitivity coefficients using the standards with the similar matrix.<sup>27</sup> With internal standards, the correction of different sensitivity of mass spectrometric methods based on ICP only or LA-ICP is also possible.<sup>31,57</sup> Specially synthesised standards based on the material to be analysed are also employed. For example, such samples were used<sup>58</sup> in the LA-ICP mass spectrometric analysis of GaAs. Becker<sup>46</sup> proposed an original method of calibration by LA-ICP-MS in the analysis of graphite: an aqueous solution of the analyte passed through the nebuliser is mixed with high-purity graphite atomised by laser ablation, and the graphite sample atomised in the same way is mixed with the pure solvent. In the author's opinion, this method allows one to obtain reliable results and to reduce the detection limits for a series of elements due to the reduction of the background level and the increase in the sensitivity coefficient.

For the verification of the correctness of the result of analysis, the method 'added–found' is often used,<sup>59–61</sup> together with comparison with the results from independent analytical methods<sup>18,20,62</sup> and with those obtained for synthetic standards. The most reliable results are obtained where the certified standards are used. Unfortunately, their list for the high-purity substances is short. Standards of the SARM, BCR and NIST series (SRM 1635, SRM 1630a, SRM 1632b and SRM 1633b) are used for the ICP-MS analysis of coal and ash,<sup>9,17,19</sup> NIST (SRM 8171) for the analysis of silver,<sup>63</sup> NIST (SRM 681) for platinum,<sup>31,46</sup> NIST

(SRM 699) for alimina,<sup>18,20</sup> State Standard Sample 7287-96 for gold,<sup>64</sup> JCRM (R004) and JCRM (R005) for Si<sub>3</sub>N<sub>4</sub>,<sup>24</sup> CRM (JSS 003-2) for iron,<sup>65</sup> and silicate glasses NIST (SRM 610-615) for the analysis of oxide crystals.<sup>66–68</sup> According to the results of the inter-laboratory measurements, these glasses contain ~50 elements as impurities in the  $1 \times 10^{-4}$  mass % –  $5 \times 10^{-2}$  mass % concentration range.

As a rule, in all versions of ICP-AES and ICP-MS, the random error of element determination is not larger than 10%, and sometimes it is much lower.

## VI. Specific analytical procedures

Properties of materials used in semiconductor and nuclear engineering, as well as in micro- and optoelectronics, are extremely sensitive to the content of impurities. Therefore, analytical monitoring in all steps of the purification technology of these materials is very important. At present, the methods discussed above are the leaders in the field of such monitoring.

It is of note that numerous procedures are devoted to the determination of contaminants in REE oxides, the majority of them being developed and published in China. The problems of atomic-emission spectroscopic analysis of REE are related to the multilinear character of their emission spectra. A general approach to the development of procedures for the quantitative determination of contaminants in pure REE and their oxides was proposed,<sup>60</sup> which is based on the preliminary quantitative determination of the matrix effect on the analytical signal.

The main data on the specific analytical procedures for pure substances using atomic emission spectroscopy and mass spectrometry are summarised in Tables 1 and 2.

**Table 1.** Methods of analysis of some pure metals, semiconductors and other substances by ICP-AES and ICP-MS.

| Matrix                                                             | Method | Instrument                |                    | Sampling procedure                                                                                                                                                                                                                                                    | Contaminants determined                                   | $C_{\min}$                                                        | Ref. |

## VII. Conclusion

The main advantages of ICP as the ion source in mass spectrometry and the radiation source in atomic emission spectroscopy for the analysis of high-purity solids are as follows:

- relatively easy combination with different sample introduction systems (solution nebulisers, graphite atomisers, laser and spark ablation);
- multielement analysis with low element detection limits;
- plasma stability, which provides the reproducibility of the analytical signal;
- simple calibration (in the analysis of solutions);
- small non-spectral matrix effects.

Let us also denote the drawbacks of ICP:

- the necessity of dissolution of a sample, which may lead to uncontrolled introduction of contaminants, especially common ones, and to the risk of losses of the analytes;
- low capacity, usually not higher than 2 kW, which results in plasma instability in the case of direct introduction of powders and suspensions;
- formation of a great variety of molecular ions, which increases the element detection limits by ICP-MS due to interferences, especially in the mass range from 25 to 80 a.m.u.;
- high cost of the equipment, especially for mass spectrometric analysis.

The record-breaking low absolute detection limits (down to  $10^{-14}$  g) that can be provided by multielement ICP-MS on a double-focusing instrument with introduction of 0.05%–0.2% solution of a sample (or a concentrate) into the plasma, make it possible to reach detection limits of  $10^{-9}\%$ – $10^{-7}\%$  without concentration and down to  $10^{-11}\%$ – $10^{-9}\%$  with virtually complete sample matrix separation for non-common contaminants the analytical lines of which are free from molecular ion overlap. The detection limits for the elements in the mass range from 24 to 80 a.m.u. and for a number of rare-earth elements in REE-containing matrices (neodymium, europium, cerium) are several orders of magnitude larger ( $10^{-6}\%$ – $10^{-3}\%$ ). The element detection limits in the direct analysis of solids by LA-ICP-MS lie generally in the range  $10^{-7}\%$ – $10^{-5}\%$ , and the use of powerful IR laser reduces the limits to  $10^{-10}\%$ – $10^{-7}\%$ . It should be noted that ICP-MS covers a broad range of analyte detection limits.

In the majority of published works, the analyte detection limits with ICP-AES on echelle spectrometers with introduction of 1% solutions into the plasma are no lower than  $10^{-6}\%$ – $10^{-4}\%$  for direct analysis and  $10^{-8}\%$ – $10^{-5}\%$  for the method with preconcentration. It is obvious that low detection limits of trace-elements in the matrices with multilinear spectra (d-

and f-elements) require the sample matrix to be separated. The use of ultrasonic nebulisers, instruments with an axial observation of plasma<sup>65</sup>, and ETA also reduces the detection limits.

Considering multielement analysis, both methods allow simultaneous determination of several tens of contaminants in pure substances. However, according to the published works, usually no more than ten elements were determined. Determination of several tens of impurities simultaneously at the level of  $10^{-7}$  mass %– $10^{-6}$  mass % and non-common elements with a detection limits as low as  $10^{-11}$  mass % (see<sup>35</sup>) by ICP-MS represents an exception.<sup>9, 11–13, 35</sup> The limited number of contaminants that can be determined is often explained by the purposes of the study (for example, in the graphite nuclear reactor, only neutron-absorbing REE were determined),<sup>27</sup> and by the capacities of the concentration procedures.

Inductively coupled plasma atomic emission spectroscopy and mass spectrometry supplement each other, and their parallel use for the characterisation of high-purity substances allows verification of the correctness of the analysis by methods different in principle, and determination of the elements the analytical lines of which in one of the methods are hidden by spectral overlaps.<sup>9, 11, 70</sup> In other words, due to the multielement nature and low detection limits, the combination of the two methods makes it possible to fully characterise a high-purity substance regarding virtually all elements from the Periodic Table, excluding the gaseous ones. For the analysis of certain high-purity compounds by ICP-MS, see also Refs 3, 6, 7 and 46.

This review is prepared with financial support from the Division of Chemistry and Materials Science of the RAS (Programme of basic research 'Development of Effective Methods of Chemical Analysis and Structural Studies of Compounds and Materials') and the Russian Foundation for Basic Research (Grant No. 02-05-33018).

**Abstract.** Modern quantum-chemical methods for the construction of approximate many-electron wave functions differing from the traditional Hartree–Fock approximation are considered. Attention is focused on the methods based on the use of symmetric groups and nodal surfaces of many-electron wave functions. A new interpretation of the Pauli exclusion principle is discussed. The bibliography includes 75 references.

## I. Introduction

The latest achievements in theoretical chemistry are largely related to quantum chemistry. The advent of computers with vector processors such as CRAY and CYBER in the late-1970s–early-1980s affected appreciably the status of quantum-chemical calculation.<sup>1</sup> Even more pronounced changes in computational quantum chemistry were induced by the appearance of computers with parallel processors.

The applications of computational quantum-chemical methods have now gone far beyond the limits of traditional fields of chemistry (organic, inorganic, physical) and have extended into many fields of physics, biology, pharmacology, materials science, *etc.* The range of these applications is being extended because more and more problems can be tackled by the techniques of computational chemistry, which has become a generally recognised source of valuable information. Computers can supplement (and in some cases replace) conventional laboratory techniques if experimental information is either insufficient or cannot be gained due to temperature, concentration or procedural restrictions.

Reliable quantum-chemical predictions of the electronic structure and physicochemical parameters of molecular systems are based on *ab initio* methods, which are more rigorous than the single-electron Hartree–Fock (HF) approximation and take into account electron correlation. The development of these methods receives most attention.<sup>1–5</sup> Numerous computer programmes taking account of the electron correlation effects, to some extent, have now been developed.

Owing to all-round computerisation and the availability of major quantum-chemical software programmes to chemists, some of these programmes have lately been regarded as routine. Whereas 30 years ago the predictions of quantum chemists were met, at best, with scepticism, now there is rather a risk of overestimating the reliability of quantum-chemical results. It should be borne in mind that the magical words *ab initio* do not always ensure high accuracy computations.

One can hardly be confident that quantum-chemical predictions are correct, if, for example, the errors in determining the system energy, which are involved in any *ab initio* computation due to the neglecting of or incomplete allowance for the electron correlation effects, prove to be much greater than the estimated activation energies, barriers to internal rotation and inversion, chemical bond dissociation energies, *etc.* Therefore, to obtain reliable physicochemical information using *ab initio* methods, effective ways of taking account the electron correlation are required. It is not by chance that the problems of accurately calculating correlation effects based on primary principles are regarded as highly important in quantum chemistry.

Unfortunately, computational procedures for the elimination of correlation errors are not embedded in all routine quantum-chemical programmes. Until chemists who run modern computing machinery realise its limited scope, even the most expensive *ab initio* computations will be fraught with artifacts and illegitimate conclusions.

A critical analysis<sup>1–3</sup> of the trends and prospects for the development of modern quantum chemistry has shown that traditional *ab initio* calculations have reached a sort of limit. This calls for searching for new ways of solving the Schrödinger equation for many-electron systems, other than those based on the HF approximation. While working along this line, we proposed an approximate method for solving this equation and called it the many-electron wave function (MWF) method.<sup>6</sup>

The MWF technique is based on in-depth mathematical analysis of the generally accepted interpretation of the fundamental Pauli exclusion principle, which actually forbids not only ‘trivial’, but also many other seemingly quite allowable electron configurations. A specific feature of the proposed method is that, in conformity with the views of the founders of quantum mechanics — W Heisenberg, P Dirac and E Schrödinger — paramount importance is ascribed to analysis of the properties of the nodal surfaces of antisymmetric MWFs.

The foundation of the MWF method is composed of two fundamental statements.

1. Generalisation<sup>7</sup> of the Courant–Hilbert theorem for the case of precise non-relativistic many-electron wave function  $\Psi$  for the electronic state with a specified spin.

2. An original hypothesis,<sup>8</sup> according to which the Pauli exclusion principle should be interpreted as the prohibition for two electrons with identical spins to occur on the same equipotential surface in a given configuration space.

The MWF method has now been tested using a number of ‘test systems’ most representative of quantum mechanics.

## II. Retrospective view on the development of *ab initio* methods in quantum chemistry

Since the HF method in *ab initio* approximation is free from experimental or adjustable parameters, and allows a simple and vivid interpretation of the calculated properties, many quantum chemists do not see the point in developing alternative approaches, referring to the sharp increase in the degree of computerisation of theoretical investigations observed in the last decade and to the progress in computer engineering already attained (and expected in the future). Indeed, the last ~50 years have seen the transition from scalar computers (three successive generations) to modern vector computers and computing potential has sharply increased.

Chemists already have powerful computers of a new architecture at their disposal. Perhaps, not only supercomputers but also sets of computers operating in parallel with hundreds or thousands of simultaneously operating units could play an important role in the further development of quantum chemistry and could initiate a new avalanche of more accurate *ab initio* calculations based on the HF approximation. However, most likely, this would have an adverse effect on the development of theoretical quantum chemistry, as it is much easier to apply well-developed theoretical methods to new systems than to develop absolutely new approaches.

One should bear in mind that apart from the obvious advantages, the Hartree–Fock approximation has substantial drawbacks. These drawbacks are due to the fact that in the use of this approximation, the number of two-electron integrals grows as  $m(m+1)/2$ , where  $m = n(n+1)/2$ , and  $n$  is the number of the basis functions. This sharp ( $\sim n^4$ ) dependence imposes natural restrictions on high-precision *ab initio* calculations for large molecular systems. In addition, the electron correlation effects are often great. For example, the HF approximation does not describe adequately the dissociation of even diatomic molecules, especially  $\text{Be}_2$  and  $\text{F}_2$  (Table 1). Usually, such drawbacks can be eliminated only partially on switching to Configuration Interaction (CI) methods, despite the impressive number ( $\sim 10^6$ ) of configurations additionally taken into account.

However, the popularity of the CI methods is held up by the fact that the *ab initio* calculation, which reaches in accuracy the

‘Schrödinger’ limit, is not physically obvious, its results requiring interpretation like experimental data. The point is that in high-precision *ab initio* methods, taking into account the configurational interaction, the total wave function is ‘smeared’ over many thousand determinants, whose clear interpretation is impossible. It is noteworthy that the implementation of CI methods for complex molecular systems currently does not provide even a 90% allowance for the electron correlation energy.

At first glance, this is surprising. Indeed, for  $N = 2$  ( $N$  is the number of electrons) for example, for a helium atom or a hydrogen molecule, the problem is solved by a high-precision *ab initio* method using an advanced computer with an accuracy in energy down to  $10^{-8}$  a.u. in fractions of a second. Meanwhile, for  $N = 3$  (Li atom) or  $N = 4$  (LiH molecule), the same computer can ensure, at best, an accuracy of  $\sim 0.001$  a.u. after running for several hours, *i.e.*, the duration of an equivalent high-precision calculation increases on passing from  $N = 2$  to  $N = 4$  by approximately ten (!) orders of magnitude. This is accompanied by a catastrophic complication of the problem, to such an extent that equally high-precision *ab initio* calculations are absolutely impracticable for complex electron systems.

This means that on passing to systems with  $N = 3$ , the computational situation changes in principle. This brings about the viewpoint that, due to the substantial growth of the number of mathematical operations involved in the use of the Self Consistent Field (SCF) scheme, even for an insignificant increase in the number of electrons, high-precision *ab initio* calculations have no prospects in most fields of chemistry and materials science, because they are forcibly meant for relatively small molecules. Therefore, researchers still pay considerable attention to further development of semi-empirical methods. However, this is not a priority line of research, although it is still important. At present, the problem of searching for fundamentally new methods to solve the Schrödinger equation for many-electron systems is being brought to the forefront.<sup>1</sup>

The specialists engaged in quantum chemistry refuse more and more often basis concepts related to the model of independent particles, which are fairly well known to most of physical chemists. Instead, they have started to borrow diverse theories from solid-state physics, nuclear physics and related fields,<sup>1–3</sup> in which  $N$ -particle problems are solved for  $N \rightarrow \infty$ . The mathematical apparatus used to solve these problems, which had been developed for ideal translationally invariant systems, was modified in the last decade; first of all, the simplifications related by translational symmetry were eliminated, because this is not inherent in finite molecular systems.

*Ab initio* methods using the concept of Atomic Pseudopotential or Effective Core Potential (ECP) have been developed. The introduction of this notion made the computation much simpler and reduced it to considering only valence electrons. Due to the ‘passivity’ of the core electrons of the inner electron shells, their influence on the valence electrons is often not taken into account explicitly, but is modelled by the ECP. Therefore, the work content of *ab initio* quantum-chemical calculations sharply decreases. In addition, it becomes possible to include, without much difficulty, the relativistic effects created mainly by the core electrons.<sup>9</sup>

Many pseudo-potential methods imply the presence of  $N_v$  valence active and  $N_c$  core passive electrons. The full Hamiltonian (in atomic units) for a system of  $N = N_v + N_c$  electrons is represented in the form

$$\hat{H}_v = \sum_{i=1}^{N_v} \left[ -\frac{1}{2} \nabla_i^2 + \sum_A \hat{W}^A(r_i) \right] + \sum_{i < j} \frac{1}{r_{ij}} + \sum_{A < B} \frac{Z_v^A Z_v^B}{R_{AB}}, \quad (1)$$

where  $\hat{W}^A(r_i)$  is the model pseudo-potential describing the interaction of valence electrons with the nucleus and with core electrons of atom  $A$ ;  $r$  is the distance between the electrons,  $Z_v^A$  is the shielded charge of the atomic nucleus ( $Z_v^A = Z^A - N_c^A$ ),  $R$  is the distance between the nuclei;  $A$  and  $B$  are the numbers of atom

**Table 1.** Dissociation energy (in eV) of diatomic molecules.<sup>1</sup>

| Molecule      | HF calculation   | Experiment |
|---------------|------------------|------------|
| $\text{H}_2$  | 3.64             | 4.75       |
| $\text{Li}_2$ | 0.17             | 1.07       |
| $\text{Be}_2$ | see <sup>a</sup> | 0.10       |
| $\text{B}_2$  | 0.89             | 3.09       |
| $\text{C}_2$  | 0.79             | 6.32       |
| $\text{N}_2$  | 5.20             | 9.91       |
| $\text{O}_2$  | 1.28             | 5.22       |
| $\text{F}_2$  | –1.37            | 1.66       |
| LiH           | 1.49             | 2.52       |
| HF            | 4.38             | 6.10       |

<sup>a</sup> The HF approximation gives a purely ‘repulsive’ curve for the dependence of energy on the distance between the nuclei.

nuclei, and  $i$ , and  $j$  are the numbers of electrons. For any chemical element,  $\hat{W}^A(r_i)$  is a fixed and transferable operator that is usually determined from calculations of atomic wave functions in the HF approximation.

The authors of many publications have used, not without success, by analogy with ECP, schemes of effective single-fragment potentials that simulate the presence of chemically inactive functional groups in molecular systems. The intuitive reasons in favour of these schemes look rather convincing, although they can hardly be called substantiated.

In view of the above, one can plainly see why some researchers<sup>10–20</sup> have started bringing Density Functional Theory (DFT) to the forefront of quantum chemistry. The idea of using DFT to calculate the ground-state total energies of many-electron systems was put forward by Thomas and Fermi.<sup>21,22</sup> Their model implies a completely uncorrelated electron motion. A real  $N$ -electron object is matched to some fictitious system of non-interacting electrons, which is not identical but equivalent to this object. This system has the same electron density  $\rho(r)$  as the initial system, consisting of interacting electrons.

Initially, the Thomas–Fermi model was perceived as a useful simplification based on the assumption that the energy of this quantum system can be expressed in terms of the electron density. This hypothesis has been formally proven by the Hohenberg–Kohn theorem,<sup>10</sup> according to which the ground-state energy of a system of electrons in an external field is the functional (moreover, the only) of the single-particle density  $\rho(r)$ . After the appearance of this theorem, the interest of researchers in the DFT has sharply grown.

Modifications of DFT have been described in numerous publications (see, for example, the studies<sup>12–14</sup>). It is worthy to note that the early Slater model, borrowed from the solid-state physics, actually reduces the problem of solving the many-particle Schrödinger equation to the solution of the one-particle differential equation

$$\left[ -\frac{1}{2}\nabla_i^2 + V_c^{X_z}(r) + V_e^{X_z}(r) \right] \Psi_i^{X_z}(r) = \varepsilon_i^{X_z} \Psi_i^{X_z}(r), \quad (2)$$

where  $V_c^{X_z}(r)$  is the Coulomb potential (including the contribution of the electron self-action),  $V_e^{X_z}(r)$  is the exchange Slater potential

$$V_e^{X_z}(r) = -3\alpha \left[ \frac{3}{4\pi} \rho(r) \right]^{1/3} = \alpha V_e^S(r), \quad (3)$$

$\Psi_i^{X_z}$  is a single-electron orbital and  $\varepsilon_i^{X_z}$  is its energy.

Expressions (2) and (3) reflect the essence of the so-called  $X_z$  method. A scaling parameter  $\alpha$  appeared historically during the development of the  $X_z$  method and is included in its name. An  $\alpha$  value, chosen from the 2/3 to 1 range, is usually accepted for the calculations.

The Slater potential has been successfully used in quantum chemistry for many years, despite the lack of a strict theoretical substantiation of its use for inhomogeneous electron density. A lot of effort was concentrated on the problem of improving of potential (3), which favoured to a considerable extent the successful development of general DFT methods involving the exchange-correlation potential

$$V_{ec} = \frac{dE_{ec}}{d\rho}, \quad (4)$$

where  $E_{ec}$  is the exchange-correlation energy functional.

Among the variants of DFT, the Kohn–Sham (KS) variant is currently the most popular and best developed.<sup>11</sup> This version can, in principle, be considered as a quantum-mechanical generalisation of the Thomas–Fermi model. In this scheme, the solution of the many-electron Schrödinger equation is reduced to the solution of a single-electron equation of type (2), in which the full effective potential is the sum of three potentials: nuclear  $V_{nuc}(r)$ , the classical Coulomb electron  $V_{el}(r)$ , and the exchange-correlation  $V_{ec}(r)$  potentials. The magnitude of the exchange-correlation potential at point  $r$  is assumed to depend only on the

electron density  $\rho(r)$  at this point. The resulting single-electron equation is solved by iterations; hence, this scheme is self-consistent.

The KS equation closely resembles the Hartree–Fock equation. The difference is that in the KS equation, the orbital-dependent exchange HF operator is formally replaced by the exchange-correlation (taking into account the electron correlation) operator  $V_{ec}(r)$ , which depends on  $\rho(r)$  (and on the spin density in the spin-polarised DFT versions). Therefore, the form of the matrix elements of the ‘modified Fockian’ become simpler and, in practice, single-electron molecular orbitals (MO)  $\psi_i$  can be represented by linear combinations of not only Gaussian type functions (GTF) but also other functions such as Slater type orbitals (STO), numerical Hartree–Fock atomic orbitals, planar waves, *etc.* The use of GTF in the KS, as in the Hartree–Fock theory, accelerates the computation of multicentre integrals, opens up the way for constructing efficient and precise basis sets that are still relatively small, simplifies the analytical determination of the energy gradients, *etc.* Moreover, all the experience accumulated in the HF theory regarding the selection of basis sets can be used in the DFT calculation of molecular systems.

As applied to molecules with large numbers of atoms, some variants of the SCF approach based on DFT prove to be much more attractive than *ab initio* methods, because the number of arithmetic operations in DFT increases as  $\sim N^3$ , rather than  $\sim N^4$  as in the HF approximation or  $\sim N^5$  as in the CI scheme. At present, DFT is a rapidly developing field of quantum chemistry. The popularity of DFT is largely determined by the fact that it allows one to study complicated and real rather than model objects, while requiring much fewer resources and less computer time than the HF calculations. Moreover, DFT usually provides much better agreement with experiment, especially for transition element compounds.<sup>15</sup>

In the KS model, the equality of the densities  $\rho(r)$  in the real and equivalent systems is provided by the functional  $V_{KS}(r)$ . If this functional was known exactly, it would be possible to determine the energy of a real system by solving a model single-particle KS equation. Unfortunately, the exact form of this functional is most often unknown; therefore, the only way forward than is to use model forms.

The exchange-correlation functional should be defined in such a way as to ensure the required accuracy of property calculations. As a rule, it exhibits an appreciable dependence on the accepted geometry of the system and the set of basis functions chosen; the convergence of the results is often deteriorated upon increasing the size of the basis set.<sup>23</sup> Therefore, it is not always clear whether the recommended functionals tested for determination of particular characteristics would be suitable for accurate prediction of other, qualitatively different characteristics of chemical compounds.

A number of expressions for  $V_{ec}(r)$  have now been proposed within the framework of the Local Density (LD) approximation.<sup>12–15</sup> Almost all these expressions can formally be reduced to the following formula

$$V_{ec}(r) = \alpha(r) V_e^S(r), \quad (5)$$

whose form emphasises the relationship between the LD approximation and the  $X_z$  method [*cf.* Eqn (3)]. Note also that numerous Local Spin Density (LSD) and Gradient-Corrected Local Spin Density (GCLSD) functionals have been developed; in addition to the spin densities  $\rho^\alpha$  and  $\rho^\beta$ , these contain their gradients  $\nabla\rho^\alpha$  and  $\nabla\rho^\beta$ , which take into account the non-uniformity of spin distributions in real systems compared to the spin distributions in the homogeneous electron gas models, in which the motion of electrons is uncorrelated.<sup>18</sup> Gradient-corrected functionals have markedly increased the reliability of the DFT-based methods.

It should be especially emphasised that the LD approximation plays more or less the same role in modern DFT as ascribed to the HF approximation in the theory of many-electron systems. Meanwhile, the LD approach has a substantial benefit as it is less

labour-consuming, despite the partial allowance for electron correlation (within the electron gas model). The main difficulty in using LD approximation is the lack of strict systematic methods for correcting errors, *i.e.*, the corrections applied often rely on the researcher's flair.

Apart from the inclusion of gradient corrections into the energy functional, the idea of combining the HF and LD approximations has been implemented beyond the LD scheme,<sup>19</sup> giving rise to a more labour-consuming but more efficient method. This method makes use of a special three-parameter hybrid B3LYP functional (Becke–Lee–Yang–Parr) that contains three semi-empirical coefficients ( $a_0 = 0.80$ ,  $a_e = 0.72$ ,  $a_c = 0.81$ ), selected by experimental data adjustment of 56 atomisation energy, 42 ionisation potential, 8 proton affinity and 10 atomic energy values for a specially selected set of molecules. Currently, the B3LYP approximation is universally used to perform high-precision calculations of thermochemical and spectroscopic parameters for relatively simple molecular systems. The B3LYP functional in combination with specially constructed basis sets of a moderate size have also proved applicable for studying structure–property relationships (see the references cited in Ref. 23).

Analysis of the use of local approximation for the exchange contribution<sup>24,25</sup> has shown that the most serious errors are due to the changes that take place to the ‘angular’ nodal surfaces of wave functions.

The Quantum Monte Carlo (QMC) methods brought to quantum chemistry in the 1970s–1980s from nuclear physics may appear quite promising.<sup>26–28</sup> The most widely used QMC approaches are the Variational Quantum Monte Carlo (VQMC), Diffusion Quantum Monte Carlo (DQMC) and Green's Function Quantum Monte Carlo (GFQMC) methods. These methods are closely related to one another, but each has its own specific features, advantages and disadvantages.

The main approximations of VQMC are, in principle, the same as those of the traditional analytical variational approach; however, the required integrals should be found using special Monte Carlo methods. In this approximation, the expected total electron energy  $\langle E \rangle$  is estimated using the local energies ( $E_{\text{loc}} = \hat{H}\Psi_0/\Psi_0$ ) for the trial wave function  $\Psi_t$  and using its square as the weight factor

$$\langle E \rangle = \frac{\int \Psi_t^2 (\hat{H}\Psi_t/\Psi_t) d\tau}{\int \Psi_t^2 d\tau} = \lim_{n \rightarrow \infty} \frac{\sum_{i=1}^n \Psi_t^2 (\hat{H}\Psi_t/\Psi_t)}{\sum_{i=1}^n \Psi_t^2}. \quad (6)$$

In expression (6), summation is usually carried out over the arbitrary points in the electron configuration space, which is characterised by probabilities proportional to  $\Psi_t^2$ . As in analytical variational computations, the  $\langle E \rangle$  value is an upper estimate of the Schrödinger energy.

With this approach there is no need to carry out numerical integration; to determine  $E_{\text{loc}}$ , one only has to calculate the  $\hat{H}\Psi_t/\Psi_t$  values at specified points. Therefore, this function can acquire any form and even contain the electron–electron distances  $r_{ij}$  in an explicit form. Hence, by using relatively simple trial functions, one can take into account the electron correlation effects with much higher accuracy, which would result in a much lower expected energy for a molecular system than that corresponding to the Hartree–Fock limit.<sup>26,27</sup>

The so-called diffusion version of the QMC method is physically explicit and provides high accuracy to the energetic characteristics of atoms and molecules, because the correlation energy is often taken into account to 80%–100%. The expediency of using the DQMC method to solve the stationary Schrödinger equation

$$-\sum_i \frac{\hbar^2}{2m_e} \nabla_i^2 \Psi(\mathbf{R}) + \hat{V} \Psi(\mathbf{R}) = E \Psi(\mathbf{R}) \quad (7)$$

can be easily understood by paying attention to the formal similarity between the non-stationary Schrödinger equation for a single electron of mass  $m_e$  in imaginary time  $\tau = it$

$$\hbar \frac{\partial \Psi(\mathbf{r}, \tau)}{\partial \tau} = \frac{\hbar^2}{2m_e} \nabla^2 \Psi(\mathbf{r}, \tau) - \hat{V}(\mathbf{r}) \Psi(\mathbf{r}, \tau) \quad (8)$$

and the branching diffusion equation

$$\frac{\partial C(\mathbf{R}, t)}{\partial t} = D \nabla^2 C(\mathbf{R}, t) - k C(\mathbf{R}, t), \quad (9)$$

where  $\mathbf{R}$  is a  $3N$ -dimensional vector that specifies the coordinates of  $N$  electrons in a molecular system. The potential energy operator for the system has the form

$$\hat{V}(\mathbf{R}) = \sum_{i>j}^N \sum_{l=1}^N \frac{e^2}{r_{ij}} - \sum_{i=1}^N \sum_{A=1}^M \frac{Z_A e^2}{r_{iA}} + \sum_{A>B}^M \sum_{l=1}^M \frac{Z_A Z_B e^2}{r_{AB}}. \quad (10)$$

As previously, the  $i$  and  $j$  subscripts designate the electrons,  $A$  and  $B$  correspond to the nuclei,  $e$  is the charge of the electron and  $Z_A$  is the charge of nucleus  $A$ . The second term in the right-hand part of Eqn (9) describes the concentration  $C$  of particles that diffuse with probability  $k$  (the first-order rate constant for a chemical reaction), the random path  $\Delta r$  they effectively travel in time  $\Delta t$  being determined through the diffusion coefficient  $D$  using the Einstein relation

$$D = \frac{1}{2} \frac{(\Delta r)^2}{\Delta t}. \quad (11)$$

It is assumed that the  $\Psi(\mathbf{R}, \tau)$  value corresponds to  $C(\mathbf{R}, t)$ ,  $V(\mathbf{R})$  to  $k$  and  $\hbar^2/2m_e$  to  $D$ .

In the diffusion version of the QMC method, the function  $\Psi(\mathbf{R}, \tau)$  acquires the meaning of the density of imaginary ‘walkers,’ the search for the solution of stationary Eqn (7) is equivalent to the search for the solution of a type (8) equation for an equilibrium stable state. When simulating the Schrödinger equation in imaginary time,  $\Delta r$  and  $\Delta t$  in relation (11) are chosen in such a way as to ensure that  $D$  is close to  $\hbar^2/2m_e$ . In particular, for the  $\text{H}_2$  molecule with fixed  $A$  and  $B$  nuclei (the Born–Oppenheimer approximation), the Schrödinger equation in imaginary time has the following form (in atomic units):

$$\frac{\partial \Psi}{\partial \tau} = \frac{1}{2} \nabla_1^2 \Psi + \frac{1}{2} \nabla_2^2 \Psi - V \Psi, \quad (12)$$

the potential energy operator ( $\hat{V}$ ), without allowance for the internuclear repulsion, being determined using the formula

$$\hat{V} = -\frac{1}{r_{1A}} - \frac{1}{r_{1B}} - \frac{1}{r_{2A}} - \frac{1}{r_{2B}} + \frac{1}{r_{12}}, \quad (13)$$

where  $r_{1A}$  is the distance between electron 1 and the proton  $A$ , and  $r_{12}$  is the interelectron distance. Then, in designations of the diffusion equation, we have  $D = 1/2$  and  $k = V$ .

Along with DQMC, the GFQMC technique is often used;<sup>26</sup> this is underlain by the fact that the time-independent Schrödinger equation can be written in the form

$$-\sum_i \nabla_i^2 \Psi(\mathbf{R}) + k^2 \Psi(\mathbf{R}) = k^2 \frac{V(\mathbf{R})}{E} \Psi(\mathbf{R}), \quad (14)$$

where  $k^2 = -2mE/\hbar^2$ . For the  $k^2$  value to be positive, the energy value should be negative. Hence, it is necessary to specify an appropriate reference level of the potential energy. The Green function for Eqn (14) that satisfies the required boundary conditions ( $\Psi \rightarrow 0$  for  $\mathbf{R} \rightarrow \infty$ ) can be represented as follows

$$G(\mathbf{R} \rightarrow \mathbf{R}') = \frac{K_{3N/2-1}}{(2\pi)^{3N/2}} \frac{k|\mathbf{R}' - \mathbf{R}|}{k|\mathbf{R}' - \mathbf{R}|^{3N/2-1}}, \quad (15)$$

where  $K$  is the modified Bessel function and  $N$  is the number of electrons.

The search for  $\Psi(\mathbf{R})$  within the framework of the GFQMC method is accomplished by iterations using the arbitrary initial wave function  $\Psi_0(\mathbf{R})$

$$\Psi_{n+1}(\mathbf{R}') = \int G(\mathbf{R} \rightarrow \mathbf{R}') \frac{V(\mathbf{R})}{E} \Psi_n(\mathbf{R}) d\mathbf{R}. \quad (16)$$

The iteration procedure is carried out until the verification shows that the process convergence has been attained. In essence,  $G(\mathbf{R} \rightarrow \mathbf{R}')$  in Eqn (16) is the probability of transforming one electron configuration ( $\mathbf{R}$ ) into the other ( $\mathbf{R}'$ ) through arbitrary motion of each electron.

The solution of the Schrödinger equation for molecules by the GFQMC method is faced with substantial difficulties caused, first of all, by the properties of the Coulomb potential and the antisymmetry requirement. The time-dependent many-electron wave function  $\Psi(\mathbf{R}, t)$  is represented at the initial instant [ $\Psi(\mathbf{R}, 0)$ ] as a set of  $3N$  coordinates of electrons. For example, for LiH, this ensemble would consist of 12 Cartesian coordinates that determine the spatial arrangement of each of the four electrons. Any specified electron configuration defines one point ( $\mathbf{R}$ ) in a  $3N$ -coordinate space, the set of these allowed configurations is considered as a configurational ensemble.

If the second addend in the right-hand part of Eqn (8) were missing, this would correspond to the usual diffusion equation with coefficient  $D$ , and would describe particle ‘walk’ in the configuration space. However, only in the presence of this addend, is Eqn (8) applicable to branching processes, for example radioactive decay, or the exponential development of populations. This branching is due to a decrease in the probability density in the regions with greater values for the  $V(\mathbf{R})$  potential and its increase in the regions with a low potential energy.

The interpretation of Eqn (8) as a diffusion equation implies that the ‘walker’ density [i.e.,  $\Psi(\mathbf{R}, t)$ ] should always be positive. Since the phase of the function  $\Psi(\mathbf{R}, t)$  is arbitrary, the function can also always be negative; it must have one sign. This requirement is equivalent to the absence of nodes in the  $\Psi(\mathbf{R}, t)$  function.

However, in the case of Fermi systems, the MWF can have nodes or a change in the sign. Therefore, to retain the analogy with the diffusion equation, the regions of positive and negative MWF values should be considered separately. The exclusion of the ‘walk’ between these regions is called the fixed-node approximation of the QMC method. Equation (8) is solved by the variational method separately for each node-free region, with application of the conditions  $\Psi(\mathbf{R}, t) = 0$  only at the boundary of this region. As applied to the branching diffusion process, this means that as soon as a ‘walker’ reaches the boundary of its region, it is destroyed.

Until recently, researchers have paid relatively little attention to the topological structure and other properties of MWF nodal hypersurfaces. In practice, the QMC method was used most often to upgrade the existing MWFs with known nodal hypersurfaces.

The trial function  $\Psi_t(\mathbf{R}, t)$  should possess the following properties:

- (1) be rather simple, which would allow fast calculation of the value of the function and its derivatives;
- (2) be a smooth and well-defined function of the argument  $\mathbf{R}$ , in order to avoid difficulties in the calculation of the local energies ( $\hat{H}\Psi_t/\Psi_t$ );
- (3) have nodal surfaces close to the Schrödinger ones, in order to ensure a sufficiently high accuracy calculated to the energy.

The last two requirements are better fulfilled when  $\Psi_t$  is close to the exact solution of the Schrödinger equation. Therefore, when determining  $\Psi_t$ , it is expedient to invoke everything that is known about the sought-after exact solution (symmetry conditions, boundary conditions, etc.).

It has been recommended<sup>27,28</sup> to divide the electron configuration space into two parts by means of a hypersurface in which  $\Psi(\mathbf{R}) = 0$  for any electron pair with parallel spins. Then, the resulting MWF would possess the required antisymmetry if it is specified to be positive on one side and negative on the other side

of the nodal hypersurface. For describing excited electron states, a larger number of such hypersurfaces are required.

However, it is no confidence that the above arbitrary division of the electron configuration space would give a wave function corresponding to the ground state. Moreover, a mathematically feasible solution of the Schrödinger equation does not always have a physical meaning. Without strict rules for defining the nodal hypersurfaces, finding a sufficiently accurate upper estimate of the desired energy may require variation of the chosen nodal hypersurfaces.

The application of Eqn (8) to the branching walk is faced with certain difficulties. The point being that the branching rate, proportional to the Coulomb potential, can become very high when the ‘walkers’ closely approach each other, which would entail a pronounced fluctuation of their number. However, such fluctuations and hence the statistical uncertainty in solving equations such as Eqn (8), can be substantially reduced by using the so-called Importance Sampling (IS) procedure proposed ~35 years ago.<sup>29</sup> The essence of IS is the use of preliminary knowledge of the properties of MWF in order to make quantum-chemical calculations more accurate; the procedure involves the introduction of a ‘controlling’ function  $g(\mathbf{R})$ , meant to meet the symmetry requirements of the desired function  $\Psi(\mathbf{R}, t)$ . This allows one to operate with  $\Phi(\mathbf{R}, t) = \Psi(\mathbf{R}, t)g(\mathbf{R})$  rather than with  $\Psi(\mathbf{R}, t)$ . This markedly enhances the accuracy of QMC estimates of the mean values of physical quantities.<sup>26–28</sup>

In order to be interpretable as the probability density corresponding to the Schrödinger equation, the function  $\Phi(\mathbf{R}, t)$  should be non-negative [ $\Phi(\mathbf{R}, t) \geq 0$ ]. This means that the functions  $\Psi(\mathbf{R}, t)$  and  $g(\mathbf{R})$  have identical signs. However, they change the sign on permutation of electrons with identical spins, i.e., they are positive in some regions of the configuration space and negative in other regions; the dimensions and shapes of these regions being entirely determined by the nodal surfaces. Thus, the requirement for non-negative definiteness of the function  $\Phi(\mathbf{R}, t)$  is equivalent to the requirement of coincidence for the nodal surfaces of  $\Psi(\mathbf{R}, t)$  and  $g(\mathbf{R})$ .

The condition of the presence of identical nodes for MWF and  $g(\mathbf{R})$  restricts the arbitrariness in choosing the function  $\Psi(\mathbf{R}, t)$ . Due to the use of the fixed-node approximation, any electron configuration should be excluded from the configuration ensemble (see above) if it crosses the nodal surface for  $\Psi(\mathbf{R}, t)$  upon shifting from  $\mathbf{R}$ . This requirement is equivalent to the presence of an infinitely high barrier (potential) at  $g(\mathbf{R}) = 0$ . With this formalism, the ‘controlling’ function  $g(\mathbf{R})$  fixes the nodes of the MWF and thus influences the accuracy of calculations. The closer the nodal surfaces of the ‘controlling’ and the proper (exact) functions, the more accurate the obtained solution of the Schrödinger equation.<sup>26–28</sup>

The choice of optimal trial MWF is dictated by a compromise between two criteria. On the one hand, it is desirable that the function  $\Psi_t$  in the QMC calculation be as simple as possible, because this markedly shortens the time it takes to calculate its first and second derivatives at points  $\mathbf{R}$  of the spinless configuration space (this computation has to be repeated up to  $10^7$  times).<sup>26–28</sup> On the other hand, it would be better if the trial function  $\Psi_t$  were as close as possible to the Schrödinger one, because in this case, the statistical deviations decrease and the MWF nodes are located more correctly.

The results of particular computations (see the references cited in Ref. 26) have shown that a plausible compromise results from using an expression for  $\Psi_t$  equal to the product of the Slater determinant  $\det(Q_{kl})$  ( $k, l$  are the numbers of lines and columns in the determinant), and the electron–electron and electron–nuclear Jastrow’s factors (see the references in Refs 26, 28), which impose the required conditions on  $\Psi_t$  for  $r_{ij} \rightarrow 0$  and  $r_{iA} \rightarrow 0$ ,

$$\Psi_t(\mathbf{R}) = \det(Q_{kl}) \exp \left( \sum_{i>j} \frac{a_{ij}r_{ij}}{1 + br_{ij}} - \sum_{i,A} \frac{Z_A a_{i,A}r_{i,A}}{1 + br_{i,A}} \right). \quad (17)$$

Jastrow's factors allow one to explicitly take into account the correlation in the electron motion. Usually, it is taken that  $a_{ij} = 1/8D$  for electrons  $i$  and  $j$  with parallel spins,  $a_{ij} = 1/4D$  in the case of antiparallel spins and  $a_{i,A} = 1/2D$ ; the parameter  $b$  is considered as a variable parameter during energy minimisation [ $D$  is the diffusion coefficient, see expression (11)].

Since the Jastrow's factors are positive, they do not affect the trial function (17) nodes, which are totally dictated by the Slater determinant. The molecular orbitals  $\phi_k(\mathbf{r})$  are usually linear combinations of exponential functions (linear combinations of atomic orbitals), determined by the SCF procedure. Attempts at using multideterminant SCF trial functions instead of one Slater determinant are still few and far between.<sup>26–28</sup>

The energy characteristics calculated by the QMC method for both small and large molecules and for clusters are usually much more accurate than those obtained when using other quantum-chemical approaches. During recent years, substantial progress has been made by using QMC methods.<sup>28</sup> QMC methods have proved highly efficient in studies of rather complex molecules, electron–positron systems, vibronic effects and so on. However, the difficulties encountered in their use are still great, especially for many-electron compounds containing atoms heavier than fluorine. In these cases, the accuracy of the QMC methods decreases sharply. The statistical error inherent in QMC calculations is, most often, proportional to  $t^{-1/2}$  ( $t$  is the computer time spent).<sup>30</sup>

Currently, QMC methods are used most of all, for the improvement of the existing wave functions of which the nodal hypersurfaces are known. Unfortunately, a strict definition of MWF nodal hypersurfaces is problematic.

The testing of various QMC versions (see the references cited in Ref. 31) has shown that most of them are unstable. This accounts for the inadmissible expenses of computer provision needed to attain high accuracy. Among the innovations discussed in detail in the literature, mention should be made of the uncoupled node procedure with subspace design<sup>32</sup> and a version of the mirror potential method<sup>33</sup> meant for electron systems. Some known approaches have been modified rather successfully.<sup>34,35</sup>

Unfortunately, in most cases, it is only possible to evaluate the correctness of choice of MWF nodal hypersurfaces that separate the configuration space into the regions with constant sign by solving the Schrödinger equation with a plausible accuracy. To have physical meaning, the MWF thus found should satisfy the general principles of quantum mechanics (spin and symmetry ones), which were defined back in 1925–1926 by Pauli, Dirac and Heisenberg.<sup>36–38</sup> In 1927–1928, Wigner, Hund and Heitler formulated these principles in terms of group theory.<sup>39–41</sup> In the 1920s, researchers paid much attention to a thorough investigation into the properties of MWF nodal surfaces.

After Slater<sup>42</sup> had introduced (in 1929) a determinant representation for the MWF, the problem of nodal surfaces receded into the background for a long period. Indeed, when Slater determinants are used, the antisymmetry of trial many-electron functions is ensured automatically. In addition, according to the theorem proven by Levdin,<sup>43</sup> an exact MWF for the ground or excited state of an  $N$ -electron system can be represented as a linear combination of all sorts of Slater determinants (with  $N \times N$  dimensionality), which include single-electron spin orbitals that constitute the mathematically full set of basis functions.

Probably, due to the above, the interest in detailed investigations of the structures of MWFs in solving the Schrödinger equation by the variational method has been lost. In the MWF method being developed, this problem has acquired again a prime importance (thus illustrating the well-known proverb that new is well-forgotten old).

### III. Many-electron wave functions

Antisymmetry and diversity of the nodal surfaces are fundamental characteristics of the MWF. If the potential possesses the sym-

metry property, the Hamiltonian eigen functions  $\Psi_i$  (solutions of the stationary Schrödinger equation  $\hat{H}\Psi = E\Psi$ ) can be classified according to irreducible representations of an appropriate symmetry group. Unlike single-electron orbitals, a physically acceptable MWF reflects not only the point symmetry of the Hamiltonian but also its invariance with respect to permutations of the spin and space electron coordinates; in addition, it vanishes on nodal surfaces predetermined by permutation symmetry. It is obvious that even for  $N = 3$  and for the ground state of an  $N$ -electron system, it is impossible to construct a many-electron wave function  $\Psi_0$  without nodes.

The nodal surfaces divide the whole coordinate space in which the MWF is specified into the regions in which its sign is constant (positive on one side and negative on the other side of each nodal surface). Since the MWF is  $3N$ -dimensional, one can hardly rely on intuition in attempts to visualise the nodal hypersurfaces. Visual representation of these, even for very simple systems (He and  $\text{H}_3$ ), is possible only by constructing 3D cross-sections of the  $3N$ -dimensional space with fixed positions for all particles, except for one electron.<sup>44,45</sup>

The antisymmetry requirements of the function  $\Psi_i$  relative to the permutations of the spatial coordinates of electrons with parallel spins, except for systems such as He ( $^3\text{S}$ ), do not suffice for correct determination of the coordinates of the nodal surfaces, although this strongly restricts the arbitrariness of the *a priori* selection of the shape of these surfaces.<sup>31</sup> In essence, the Wigner approach (discussed in a publication<sup>46</sup>) is unable to provide efficient assistance, as it does not contain any practical recommendations on constructing the coordinate (spinless) MWF with the required symmetry properties. The method outlined below takes into account the limitations of the generally accepted interpretation of the fundamental Pauli exclusion principle.

The canonical interpretation of the Pauli principle for a many-electron atom states that two electrons with identical spins cannot exist in the same state specified by four quantum numbers. In the HF approximation, the sought-after MWF is represented by the Slater determinant, thus ensuring fulfilment of the Pauli principle and antisymmetry with respect to the corresponding electron permutations.

The antisymmetry requirement for the MWF means the presence of a definite set of nodal surfaces in the multidimensional configuration space. The probability of finding an electron configuration on this surface is equal to zero. It is beyond doubt that for any many-electron system, solution of the stationary Schrödinger equation should vanish on a nodal surface. Among the possible diverse multidimensional nodal surfaces, there exist some that determine the configurations corresponding to the occurrence of a pair of electrons with the same orientation of spins at the same point in space. The exclusion of such configurations by the Pauli principle is taken into account automatically when the antisymmetric MWF is constructed. However, in reality, apart from these configurations, the Pauli principle forbids a multitude of other, seemingly quite acceptable configurations.<sup>47</sup>

The main feature distinguishing this approach from the Hartree–Fock one is the investigation of the possible form of nodal surfaces. This essentially narrows down the excessively broad set of acceptable antisymmetric functions by distinguishing the functions that satisfy the boundary conditions derived from the modern interpretation<sup>47</sup> of the Pauli principle. It can be demonstrated, for example, that the Slater determinants corresponding to different electron configurations turn to zero on non-coincident surfaces. Therefore, the CI calculations converge slowly, as one has to consider a very large number of determinants with different nodal surfaces in order to approach the true (Schrödinger) MWF and corresponding nodal surface. If it was possible to determine *a priori* the nodal surfaces and use them for constructing the trial MWF, the convergence of quantum-chemical calculations would be substantially faster and the accuracy higher.

In addition, owing to the use of a symmetric group in the MWF construction, the computational procedure becomes much simpler, because for a system of  $N$  electrons, the initial problem is finally reduced, without loss of accuracy, to  $N!$  identical problems, but with a smaller integration region.<sup>47,48</sup> Indeed, if a system with spin  $S$  has  $K = (N/2) + S$  electrons with the spin coordinates  $s_i = +1/2$  (set  $I$ ) and  $N - K = (N/2) - S$  electrons with  $s_j = -1/2$  (set  $J$ ), then among the total group of permutations  $S_N$ , one can distinguish the subgroups  $S_K$  and  $S_{N-K}$  acting on the elements of sets  $I$  and  $J$ , respectively. The direct product of these subgroups  $S_K \times S_{N-K} \equiv S(I, J)$  can be reasonably termed as a ‘spin-invariant subgroup’, as its elements act only on the electrons with the same projections of the spin.<sup>49</sup>

The use of ‘spin-invariant subgroups’ for solving the Schrödinger equation allows one to handle only the part of the wave function which is antisymmetric with respect to electron permutations contained in  $S(I, J)$  rather than the whole many-electron wave function  $\Psi(r_1, s_1; \dots; r_N, s_N)$ . The full MWF is easily restored from this part by means of appropriate symmetry operations. With this approach, the number of integrals needed to calculate the matrix elements of the Hamiltonian decreases by a factor of  $M = N! / \{[(N/2) + S]![(N/2) - S]!\}$ .

The problem of methods suitable for the practical construction of the functions  $\Psi(r_1, s_1; \dots; r_N, s_N)$  having a different physical meaning from spinless functions, which depend only on spatial coordinates  $r_i$  and possess the required symmetry properties, has been studied comprehensively by Fok.<sup>46</sup> Both the Pauli principle and the equation for the full spin angular momentum

$$\hat{S}^2 \Psi(x_1, \dots, x_N) = S(S+1) \Psi(x_1, \dots, x_N) \quad (18)$$

( $x_i$  designates the set of spatial coordinates and the spin variable for  $i$ th electron) were taken into account<sup>46</sup> by strict mathematical techniques. By representing the operator  $\hat{S}^2$  as

$$\hat{S}^2 = N - \frac{N^2}{4} + \sum_{i < j} \hat{P}_{ij}, \quad (19)$$

where  $\hat{P}_{ij}$  is the permutation operator for spin variables  $s_i$  and  $s_j$ , Fok expressed the full MWF for a system of  $N$  electrons through only the spinless wave function [for  $k$  electrons with parallel spins and  $(N-k)$  electrons with antiparallel spins]

$$\Psi = \Psi(r_1, r_2, \dots, r_k | r_{k+1}, r_{k+2}, \dots, r_N) \quad (20)$$

and formulated the following necessary and sufficient symmetry properties for the latter:

(1) antisymmetry with respect to  $k$  arguments on the left of the vertical line in series (20), for example,

$$\Psi(r_2, r_1, \dots, r_k | r_{k+1}, \dots, r_N) = -\Psi(r_1, r_2, \dots, r_k | r_{k+1}, \dots, r_N);$$

(2) antisymmetry with respect to  $(N-k)$  arguments on the right of the vertical line in series (20), for example

$$\Psi(r_1, \dots, r_k | r_{k+2}, r_{k+1}, \dots, r_N) = -\Psi(r_1, \dots, r_k | r_{k+1}, r_{k+2}, \dots, r_N);$$

(3) so-called cyclic symmetry, expressed by the following equalities:

when  $(N-k)$  is even

$$(1 + P + P^2 + \dots + P^{N-k}) \Psi = 0, \quad (21)$$

when  $(N-k)$  is odd

$$(1 - P + P^2 - \dots - P^{N-k}) \Psi = 0, \quad (22)$$

where  $P$  designates the cyclic permutation of the arguments  $(r_k, r_{k+1}, \dots, r_N)$ , i.e., the permutation in which each term of the cycle  $(r_k, r_{k+1}, \dots, r_N)$  is replaced by the next one, and the last term by the first one.

It follows from expressions (21) and (22) that a system of two electrons with a total spin of zero ( $S = 0$ ,  $N = 2$ ,  $k = 1$ ) is described by a symmetric Schrödinger function, while its triplet state ( $S = 1$ ,  $N = 2$ ,  $k = 0$ ) is described by an antisymmetric function relative to the spatial coordinates of the electrons. The

Schrödinger wave function does not depend on spin variables; however, in this case, the resultant spin is reflected in its properties by governing the symmetry and the nodal surface.

An example of a many-electron function that satisfies the three above-indicated conditions of symmetry, exceptionally important for quantum chemistry, is the product of two determinants<sup>46</sup>

$$\Psi = |A| \times |B|, \quad (23)$$

where

$$|A| = \begin{vmatrix} \varphi_1(r_{k+1}) & \dots & \varphi_{N-k}(r_{k+1}) \\ \dots & \dots & \dots \\ \varphi_1(r_N) & \dots & \varphi_{N-k}(r_N) \end{vmatrix}, \quad |B| = \begin{vmatrix} \varphi_1(r_1) & \dots & \varphi_k(r_1) \\ \dots & \dots & \dots \\ \varphi_1(r_k) & \dots & \varphi_k(r_k) \end{vmatrix}$$

and  $2k \leq N$ .

These determinants are composed of one set of single-electron orbitals  $\{\varphi_1(r), \varphi_2(r), \dots, \varphi_{N-k}(r)\}$ , the greater of them containing all  $(N-k)$  orbitals, and the smaller of them containing only the first  $k$  wave functions present in the set.

A similar consideration<sup>48,50–55</sup> of the symmetry properties and nodal MWF having a physical meaning, and taking into account the most meaningful properties of nodal surfaces, has resulted in the formulation of a theorem<sup>7</sup> that is a generalisation of the Courant–Hilbert<sup>56</sup> theorem, concerning the nodes of the eigen functions of elliptical operators, and the theorem proven by Zhislin<sup>57</sup> on the nodes of the eigen functions of the Schrödinger operator, without the requirement of their permutation antisymmetry. According to the formulation of this theorem in the study,<sup>7</sup> there exists an eigen function  $\Psi_0(r_1, r_2, \dots, r_N)$  of an  $N$ -electron Schrödinger operator

$$\hat{H} = -\frac{1}{2} \sum_{i=1}^N \nabla_i^2 + \sum_{i=1}^N \sum_{j>i}^N \frac{1}{r_{ij}} - \sum_{A=1}^M \sum_{i=1}^N \frac{Z_A}{r_{Ai}}, \quad (24)$$

that corresponds to the ground electronic state with the spin  $S$ , and whose nodal surfaces divide the Euclidean space  $|R^{3N} = \{r_1, r_2, \dots, r_N\}$  into at least

$$L = (N/2 + S)! (N/2 - S)!$$

regions  $\Omega_1, \dots, \Omega_L$  with constant sign. Any of these  $\Omega_i$  regions can be regarded as fundamental, while the others are regarded as its copies. The total many-electron wave function  $\Psi_0$  can be restored, based on the distinguished part, by using symmetry operations.

The continuous function  $\Psi_0$  within each constant-sign region is not equal to zero but becomes zero at the boundary. Due to the splitting of the whole space  $|R^{3N}$  into  $L$   $\Omega_i$  regions, the determination of MWF becomes  $\sim L$  times simpler, without a loss of accuracy due to the transition from the integration over  $|R^{3N}$  to the  $\Omega_i$  region. In the case of a large value of  $N$ , the number  $L$  is great. Moreover, in this case, there is no need to consider the symmetry of the desired function or its spin part, isolated as a multiplier; instead, it is sufficient that the function is equal to zero at the boundary of the fundamental region.

The possibility of restoring the full MWF by means of symmetry operations should certainly facilitate high-precision calculation of the observed values and the construction of a trial MWF for the stationary states of given multiplicity. In view of the possibility of replacing the antisymmetrisation over the whole group of permutations  $S_N$  by antisymmetrisation over the spin-invariant subgroup  $S(I, J)$  of this group (see above), strictly substantiated mathematically, the degree of computation involved in the numerical solution of the Schrödinger equation is expected to be reduced by a factor of  $L \times M = N!$ . For example, for the molecule LiH ( $N = 4$ ), one can expect a 24-fold increase in the calculation performance compared to that used traditionally; for the CH<sub>4</sub> molecule ( $N = 10$ ), this increase may be up to 3 628 800-fold.

For any atomic or molecular system, each electronic state is matched by the MWF nodal surfaces. The antisymmetry of the MWF with respect to particle permutations is inherent only in

many-electron systems. Many-electron wave functions differ appreciably from the single-electron functions familiar to chemists, namely AOs or MOs. (Note that the MWF is represented in the CI method as the sum of antisymmetrised derivatives of single-electron functions.<sup>43</sup>) For example, the spatial part of the MWF for the triplet state of a helium atom in the HF approximation has the form

$${}^3\Psi(\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{\sqrt{2}} [\varphi_1(\mathbf{r}_1)\varphi_2(\mathbf{r}_2) - \varphi_1(\mathbf{r}_2)\varphi_2(\mathbf{r}_1)], \quad (25)$$

where  $\varphi_1$  and  $\varphi_2$  are the Hartree-Fock AOs. Even if the coordinates of, for example, electron 1 are such that they correspond to the node of the  $\varphi_1$ -AO, *i.e.*,  $\varphi_1(\mathbf{r}_1) = 0$ , the function  ${}^3\Psi(\mathbf{r}_1, \mathbf{r}_2)$  still does not necessarily become zero, because the term  $[-\varphi_1(\mathbf{r}_2)\varphi_2(\mathbf{r}_1)]$  can be non-zero. The condition  ${}^3\Psi(\mathbf{r}_1, \mathbf{r}_2) = 0$  is attained only when both constituents in the right-hand part of Eqn (25) coincide. Similarly, it can be considered that (except for the ground states of two-electron systems, for which spatial antisymmetry is completely ruled out) an antisymmetrised MWF has nodes even when it is constructed from nodeless AOs or MOs.

In the case of the  ${}^3S$  state of helium, the MWF can be expressed exactly through the electron–nuclear ( $r_1, r_2$ ) and electron–electron ( $r_{12}$ ) distances.<sup>58</sup> The MWF should be antisymmetric with respect to the permutation of electrons 1 and 2, *i.e.*,

$$\Psi(r_1, r_2, r_{12}) = -\Psi(r_2, r_1, r_{21}); \quad (26)$$

hence, taking into account that  $r_{12} = r_{21}$ , we get the condition  $r_1 = r_2$ , at which the MWF vanishes.

Unfortunately, the cases in which the exact form of the  $(3N-1)$ -dimensional MWF nodal surface can be established *a priori* from symmetry considerations alone are very scarce. As a rule, this task cannot be solved, first of all due to the large number of variables.

In view of the special significance of the MWF nodes, it appears expedient to introduce a special factor into the expression for the trial wave function, which could specify explicitly the form of its nodal surface. One more factor should be defined only in one of the constant-sign MWF regions (see above). According to a hypothesis,<sup>8,47</sup> the eigen functions of the  $N$ -electron Schrödinger operator have nodal surfaces defined by the equation with the potential functions of form

$$U_{ij} = \sum_{k \neq i, j}^N \left( \frac{e^2}{r_{ki}} - \frac{e^2}{r_{kj}} \right) - \sum_{A=1}^M \left( \frac{Z_A e}{r_{Ai}} - \frac{Z_A e}{r_{Aj}} \right) \equiv 0. \quad (27)$$

It is assumed that electrons ( $i, j$ ) have the same spin orientation. This means that any two electrons with parallel spins are prohibited from occurring on the same equipotential surface (the equipotential surface prohibition principle).

In the general case, one should expect that for isoelectronic compounds of different types, the forms of the equipotential surfaces would be different, first of all, due to differences between their nuclear configurations. According to the equipotential surface prohibition principle, the function  $\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N)$  must have the same nodes as found for the set of potential functions  $U_{ij}$  of the electron–nuclear system. This requirement specifies the form and the minimum number of nodal surfaces related to the coordinate permutations for any electron pair. This eliminates the necessity of solution antisymmetry, because, as noted above, it is ensured automatically by the procedure of further construction of the full MWF.

The sought-after function  $\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N)$  can, of course, have additional nodal surfaces, which are missing from the set of potential functions  $U_{ij}$ . Moreover, it cannot be ruled out that the proposed hypothesis would not find a reasonable substantiation; however, it appears expedient to verify this hypothesis by means of high-precision *ab initio* calculations for simple test objects.

## IV. Testing of many-electron wave functions

The statements outlined above form the basis of the MWF method. They can be validated using a simple example — the calculation of the ground triplet state of helium ( ${}^3S$ ). Experimental chemists usually treat the ‘quantum chemistry of helium’ as useless and dull. However, the unique opportunity to obtain results of exceptionally high accuracy has become the reason why the helium atom is most often chosen as the test system to verify many-electron theories.

In 1959, Pekeris<sup>59</sup> used a 1078-term trial function and obtained the best, at that time, value for the total energy of the  $1s^2$  ( ${}^1S$ ) state of helium

$$E_0 = -2.903724375 \text{ a.u.}$$

Later,<sup>60</sup> using the approach proposed by Fok,<sup>61</sup> the basis set was reduced to 246 functions and the accuracy of calculations was increased, giving the value

$$E_0 = -2.9037243770326 \text{ a.u.}$$

The same procedure, together with additional analysis<sup>62</sup> using only a 230-term function of the same form, gave the value

$$E_0 = -2.90372437703407 \text{ a.u.}$$

Note that according to some estimates,<sup>63</sup> attaining a comparable accuracy in the CI method would require  $\sim 10^4$  terms in the Legendre expansion and  $\sim 10^{12}$  electron configurations.

Calculations for the  $1s2s$  ( ${}^3S$ ) state should be better performed by a different technique.<sup>64</sup> Formally, the permutation of particles in the configuration space  $\{r_1, r_2, r_{12}\}$  implies the interchange of  $r_1$  and  $r_2$  for  $r_{12} = r_{21}$ . Thus, the  $r_1 = r_2$  surface divides the configuration space into two regions, and in one of them ( $r_1 \geq r_2$  or  $r_2 \geq r_1$ ), one has to find the solution of the Schrödinger equation that takes into account the boundary condition imposed on the wave function

$$\Psi(r_1, r_2, r_{12})|_{r_1=r_2} = 0.$$

With this approach, it is possible to use trial wave functions of two types

$$\Psi(r_1, r_2, r_{12}) = (e^{-\alpha r_1} - e^{-\alpha r_2})e^{-\beta(r_1+r_2)}\Psi_n^s(r_1, r_2, r_{12}), \quad (28)$$

$$\Psi(r_1, r_2, r_{12}) = (e^{-\alpha r_1} - e^{-\alpha r_2})e^{-\beta(r_1+r_2)}\Psi_n^u(r_1, r_2, r_{12}), \quad (29)$$

where  $\Psi_n^s$  is symmetric and  $\Psi_n^u$  is an arbitrary polynomial containing  $n$  terms. The first exponential factor in these functions corresponds to the antisymmetry condition, while the second one corresponds to the requirement of fast vanishing at large distances between the nucleus and the electrons. Function (28) is antisymmetric, unlike function (29); however, it can be reflected on the other half of the configuration space antisymmetrically, relative to the  $r_1 = r_2$  surface.

A practical advantage of expression (29) is that the class of functions used to approximate the solution of the Schrödinger equation is much broader, as the set of symmetric polynomials  $\{\Psi_n^s\}$  is a subset of the arbitrary polynomials  $\{\Psi_n^u\}$ ; therefore, the polynomial expansion (29) converges much faster than the expansion of (28). Rejection of the symmetry restrictions allows one to construct a broader class of trial functions using arbitrary polynomials. For example, in the case of a second-order polynomial, expressions (28) and (29) acquire the form

$$\Psi_7^s = a_0 + a_1(r_1 + r_2) + a_2r_{12} + a_3(r_1^2 + r_2^2) + \quad (30)$$

$$+ a_4r_1r_2 + a_5(r_1 + r_2)r_{12} + a_6r_{12}^2 \quad (n = 7),$$

$$\Psi_{10}^u = b_0 + b_1r_1 + b_2r_2 + b_3r_{12} + b_4r_1^2 + b_5r_2^2 + \quad (31)$$

$$+ b_6r_1r_2 + b_7r_1r_{12} + b_8r_2r_{12} + b_9r_{12}^2 \quad (n = 10).$$

For the  $^3S$  state of the helium atom and with an arbitrary five-order  $\{\Psi_{47}^u\}$  polynomial (47 variable linear coefficients<sup>64</sup>), the energy value  $^3E = -2.1752288$  a.u. was obtained; this is  $5 \times 10^{-7}$  a.u. lower than the value calculated by Pekeris<sup>59</sup> using a function containing 715 parameters (the experimental  $^3E$  value is  $-2.175230$  a.u.). This example is indicative of the advantage of the MWF method in applied quantum-chemical calculations.

This is exemplified in Fig. 1, which shows the nodal surface of the triplet helium atom, complying with the equipotential surface prohibition principle, in Cartesian coordinates. The Figure clearly illustrates the fact that in this state, irrespective of the distance between the electrons, their location in one sphere, centred in the atom nucleus, should be prohibited.

**Figure 1.** Spherical shape of the nodal surface for the triplet state of a helium atom.

Apart from helium, lithium is often used as the test system. The lithium atom has three electrons and can serve as the simplest model species for which the electron correlation effects are, firstly, rather substantial (due to the incomplete electron shell) and, secondly, include contributions from both the core and valence electrons. Therefore, it is not by chance that in recent years, a number of high-precision quantum-mechanical calculations for the  $^2S$  ground state of this atom have been carried out.

It is noteworthy in this context that in the case of three-electron systems with one unpaired electron, the structure of the three 9-dimensional subspaces and the action of  $P_{ij}$  transpositions (pair permutations belonging to the spin-invariant  $S_3$  group) on them can be depicted, as shown in Fig. 2. It can be seen that each of the three 9-dimensional subspaces is divided into two regions of constant MWF sign (wavy line). Any point of the configuration space  $(r_1s_1; r_2s_2; r_3s_3)$  with specified coordinates  $(r)$  and spins  $(s)$  of the three electrons is allocated one of these subspaces. Obviously, the three spatial functions corresponding to the scheme shown in Fig. 2 are interrelated, and it is sufficient to find the solution of the stationary Schrödinger equation for only one of the subspaces.<sup>7</sup>

Among the most accurate is the detailed variational calculation<sup>65</sup> of the lithium atom carried out using the trial wave function

**Figure 2.** Scheme of the configuration space for the ground state of a three-electron system (see text).

$$\Psi_t = A \sum_{\mu=1}^M C_{\mu} \varphi_{\mu} \chi_{\mu}, \quad (32)$$

where  $A$  is the antisymmetriser,  $M$  is the number of basis functions,  $C_{\mu}$  are the expansion coefficients determined by the variational method

$$\varphi_{\mu} = R_{\varphi}(r_1, r_2, r_3, r_{12}, r_{13}, r_{23}) \exp(-\alpha_{\mu}r_1 - \beta_{\mu}r_2 - \gamma_{\mu}r_3), \quad (33)$$

[ $R_{\varphi}(r_1, r_2, r_3, r_{12}, r_{13}, r_{23})$  is the product of the distances  $r$  raised to relatively small powers,  $\alpha_{\mu}, \beta_{\mu}, \gamma_{\mu}$  are the varied parameters],  $\chi_{\mu}$  are the eigen doublet spin functions (all identical)

$$\chi_{\mu} = \chi = \alpha(1)\beta(2)\alpha(3) - \beta(1)\alpha(2)\alpha(3), \quad (34)$$

and  $\alpha$  and  $\beta$  are functions dependent on the spin coordinates of the electron.

In the case of polynomial trial function (32), the number of variable power exponents is excessively high. Therefore, this function was constructed term-by-term, only the exponents of newly added terms being optimised. Without this restriction, the calculation on a CRAY-1M type computer proved impossible. However, it should be emphasised that for a 296-term function, a new attempt at optimising the power exponents for the first five basis functions ( $\varphi_1, \dots, \varphi_5$ ) resulted in a negligibly minor correction to the total energy; therefore, the researchers<sup>65</sup> no longer performed the new optimisation procedure.

Analysis of the 296-term function<sup>65</sup> for the lithium atom, taking into account its component distribution among the three subspaces (see Fig. 2), has shown<sup>66</sup> that a substantial part of these components have  $r_i = r_j$  nodal surfaces corresponding to the hypothesis stated in a publication.<sup>8</sup> The other components possess nodal surfaces whose differences from the  $r_i = r_j$  surfaces are insignificant. The results of this analysis can also be interpreted as an argument supporting the equipotential surface prohibition principle.

In addition, special comparative calculations on the lithium ground state ( $^2S$ ) have been carried out<sup>67</sup> in identical basis sets [function of type (33)], but using either a standard antisymmetrisation procedure ( $E_1$ )<sup>65</sup> or boundary conditions corresponding to the equipotential surface prohibition principle ( $E_2$ ). The values for the total energy obtained by IBM PC-486 (in a.u.) are as follows:

| $n$ | $m$ | $E_1$    | $E_2$    |
|-----|-----|----------|----------|
| 1   | 5   | 7.421257 | 7.444296 |
| 2   | 17  | 7.465906 | 7.470490 |

[ $n$  is the maximum order of the type (33) function in the basis set,  $m$  is the number of functions in the basis set]. Comparison of the energies presented above with the experimental value  $E = -7.478069$  a.u.<sup>65</sup> has shown that on application of the boundary conditions corresponding to the above-mentioned principle, one can obtain better agreement with the experimental value by using small and moderately-sized basis sets. For the lithium atom, as for the helium atom, convergence has been substantially improved.<sup>67</sup>

For the ground state of the lithium atom, the equipotential surfaces and their cross-sections have more complex shapes than those of the excited triplet state of the helium atom. Nevertheless, a clear idea of the nodal surfaces for electrons 1 and 2, with parallel spins, can be gained by fixing the position of electron 3, with the opposite spin at some distance  $r_3$  from the lithium nucleus. According to the equipotential surface prohibition principle [see Eqn (27)], one should analyse the expression

$$\frac{3}{r_1} - \frac{1}{r_{13}} = C, \quad (35)$$

in which  $C$  can be represented by any real number. For example, a set of equipotential lines is formed in the  $(x, y)$  plane when the Cartesian coordinates of the lithium nucleus are  $(0, 0)$  and those of the third electron are  $(2, 0)$ . One of these lines, corresponding to

**Figure 3.** Equipotential surface ( $C = 0.3$ ) for the ground state of a lithium atom.

(a) Vertical cross-section, (b) three-dimensional image, (c) enlarged concave part of the nodal surface.

$C = 0.3$ , is shown in Fig. 3a. Its rotation around the  $x$  axis yields a slightly distorted spherical surface with a rather small cavity (Fig. 3b,c). For  $C \sim 0.25$ , the cavity becomes closed and is located inside the closed, somewhat distorted spherical surface.

The role of pre-determination of the nodal surfaces in the quantum-chemical calculations of molecular systems should be even more weighty, because for these, almost every basis function has its own nodal surface, often markedly different from the surfaces of other functions.

Thus a calculation of the  $^3\Sigma_u^+$  triplet state of the hydrogen molecule by the DQMC method for a nuclear–nuclear distance of 1.4 a.u. had been carried out<sup>31</sup> assuming that the trial wave function  $\Psi_t$  should be symmetric with respect to rotation around the internuclear axis  $z$  and antisymmetric with respect to the inversion centre on axis  $z$ . The following trial wave function, satisfying these conditions, was used:<sup>31</sup>

$$\Psi_t = \{\exp[-a(r_{1A} + r_{2B})] - \exp[-a(r_{2A} + r_{1B})]\} \exp\left[\frac{br_{12}}{(1 + cr_{12})}\right], \quad (36)$$

where  $a = 1.0$ ,  $b = 0.25$  and  $c = 0.25$  (a.u.)<sup>−1</sup>. It can be seen that  $\Psi_t = 0$  for  $r_{1A} - r_{1B} = r_{2A} - r_{2B}$ . The use of function (36) gave  $E = -0.7838 \pm 0.0007$  a.u., which is in good agreement with a value of  $-0.7830$  a.u. found<sup>68</sup> by the variational method.

For the triplet state of the hydrogen molecule, with allowance for the equipotential surface prohibition principle [see Eqn (27)], the following expression should be analysed

$$\frac{1}{r_{1A}} + \frac{1}{r_{1B}} = C; \quad (37)$$

**Figure 4.** Form of the equipotential surfaces for the triplet state of a hydrogen molecule for  $C = 2$  (a),  $C < 2$  (b) and  $C > 2$  (c).

here  $C$  is any positive number, and  $r_{1A}$  and  $r_{1B}$  are the distances from electron 1 to each of the two protons located at distances  $R$  from each other. The nodal surfaces for the triplet state of the hydrogen molecule are shown in Fig. 4. When  $C = 2$  (see Fig. 4a), the equipotential surface has a dumbbell shape.

When  $C < 2$ , the point of contact between the two distorted spheres disappears and, as  $C$  successively approaches zero, every outer equipotential surface in the set under consideration becomes more and more like a sphere flattened from above and below (see Fig. 4b). This was to be expected, bearing in mind the ‘limiting transition’ of the helium atom into the triplet state with an increase in  $r_{1A}$  and  $r_{1B}$  to such an extent that the distance  $R$  between the protons can be neglected.

When  $C > 0$ , the dumbbell becomes broken into two closed topologically separate parts of the equipotential surface, the centre of each being occupied by its own proton (see Fig. 4c). When the first electron is located on one fragment of this separated surface, e.g., that concentrated around nucleus  $A$ , the positions of the second electron, not only on the same surface, but also on the other part of this surface, i.e., that centred at nucleus  $B$ , are forbidden.

## V. Conclusion

The subject matter of today’s conferences on quantum chemistry and its computational applications include theoretical sections devoted to molecular spectroscopy, intermolecular interactions, quantum molecular dynamics, the modern theory of valence bonding, methods for taking into account electron correlation, achievements of density functional theory, computational quantum-chemical prediction of the properties of new materials for emerging technologies, the biological activity of compounds, the results of the analysis of elementary processes in condensed media, calculation of potential energy surfaces, elucidation of the mechanisms of chemical reactions, and the development of new quantum chemical methods for studying the electronic structures of molecular systems in their ground and excited states. The method of many-electron wave functions belongs to the last of these lines of research.

The current state of high-precision *ab initio* calculations cannot be considered satisfactory, despite the progress achieved. The problems of taking account of electron correlation in molecular systems with partially filled electron shells and quasi-degenerate states still have not been solved. Problems related to the mathematics also exist. If they are solved, the development of the MWF method will be substantially accelerated.

In recent years, interest in the Valence Bond (VB) method has been revived, and has been clearly depicted in a small review.<sup>69</sup> The inevitability of the revival of the VB method, which had once lost its primary position in theoretical chemistry, is a result of the fact that it is based on the chemical bond concept.

The VB theory became widespread in the 1930s owing to L. Pauling's work. However, by the 1950s, MO theory, which has developed successfully since, became more popular. Among other reasons, the loss in popularity of the VB method was due to the fact that it predicts a diamagnetic ground state with a Lewis pairing of electrons for the oxygen molecule rather than the paramagnetic state (established experimentally and reproduced by the MO method). The results of this and some other applications of the VB method were responsible for it being regarded as a failure.

The reason for the lack of success was the imperfection of an early variant of this method: at that time, the method was actually reduced to a simplified resonance variant with a non-productive counting of resonance structures. Compared with the resonance theory, even the simple MO method looked much more fruitful. Firstly, it has attracted the attention of spectroscopists (owing to a unified interpretation of optical, IR and UV spectra), radiospectroscopists (who started interpreting their EPR spectra using the new notion of 'spin density') and finally organic chemists (who recognised the reliability of the proposed qualitative explanation of the stability of diverse systems and, hence, the possibility of deliberate planning of new purpose-directed experiments).

Analysis of the reactivity of organic compounds at the time of rapid development of MO theory was carried out almost exclusively within the framework of this theory, as indicated by the exceptional popularity of the Woodward–Hoffmann rules. The MO schemes were universally preferred in the interpretation of spectroscopic data.

Undoubtedly, the skew towards MO theory has been due, among other reasons, to advances in computing machinery. In particular, the versatile quantum-chemical software package GAUSSIAN, with exceptionally high computation potential, has become universally available. Therefore, experimental chemists started to resort, more and more often, to specialists who were able to perform at least semi-quantitative quantum-chemical calculations for the systems they were interested in.

However, it has become clear with time that the MO method with full allowance for the configuration interaction is equivalent to the VB method taking into account all ionic structures. The relationship between the MO and VB methods is reflected in the growing trend to localise the calculated MO, although consideration of localised orbitals implies the VB theory.

The use of the MO method is more expedient in cases where electron delocalisation is essential. In calculations on large molecules, the MO method is preferred, as the obtained wave functions are less cumbersome than those of the VB method.

However, using the VB theory, one can more easily represent the electron redistribution during chemical transformations or mechanisms of forming of activation barriers in diverse chemical processes by means of correlation diagrams of valence bonds. These diagrams allow one to predict the activation barriers proceeding from the structural parameters, ionisation potentials and electron affinities of the reactants, the singlet–triplet splitting energies of the chemical bond being cleaved, the substituent and solvation effects, *etc.* Resorting to VB models resulted in the discovery of a new type of bonding in metal clusters (ferromagnetic bonding), determination of the structures of unusual transition metal complexes, and so on. The above is indicative of the

significant role played by the VB method in theoretical chemistry.<sup>69</sup>

Experimental chemists are unlikely to do away with using vivid resonance structures. However, it should be borne in mind that two approaches to the description of the electronic structure and physicochemical properties of molecules exist that fruitfully supplement rather than exclude each other.

In order to increase the reliability of the results of any quantum-chemical method, a more adequate description of the electron motion is required. From general considerations, taking account of the correlation in motion of 'separate' electron pairs is expected to be most important. This assumption is based on the fact that the Pauli principle generally forbids three or more electrons from being at the same point in the configuration space, thus decreasing the correlation error for such electron groups (conglomerates). Therefore, many modern techniques for investigation correlation effects imply the 'intuitive concept' of electron pairs in some form.

The exclusion by the Pauli principle of ternary electron collisions clearly demonstrates that this principle has something in common with nodal surfaces. We attempted to reflect the correspondence between the Pauli exclusion principle and nodal surfaces, which can hardly provoke serious objections, by means of a simple physical hypothesis, according to which two electrons with parallel spins cannot occur on the same equipotential surface.

Undoubtedly, this hypothesis requires comprehensive verification and further development. It might prove untenable for complex molecular systems, or perhaps, it will have to be corrected or modified. In any case, the problem definition will remain topical. Successful solution of this problem will open up new prospects for the elaboration of high-precision quantum-chemical methods. Indeed, of the multitude of sets of antisymmetrical MWFs that can serve as the basis for finding approximate solutions to the Schrödinger equation, this method allows one to choose reliably the optimal solution for each particular system.

Some MWF nodal surfaces (including those for the degenerate states) can be established *a priori* by a generalised graph-theoretical method, according to which the MWF nodes are classified to an accuracy of equivalence and the configuration space is split into the smallest number of regions of constant sign.<sup>70</sup> The Fermi correlation of electrons with parallel spins, caused by the Pauli principle and related to the geometry of the MWF nodal surfaces, has a special significance.<sup>71,72</sup> Of interest are a new type of correlation effect, called geometrical,<sup>71</sup> which are closely related to electron density minima in the excited states of a two-electron atom. These effects result in the prohibition of seemingly quite plausible electronic configurations, as one of the electrons is 'ejected' from the inner three-dimensional region of the coordinate space when another electron is located at a definite distance from the atomic nucleus.

Detailed analysis of the wave functions of the beryllium atom in a Hartree–Fock approximation has shown<sup>73</sup> that particular quantum-chemical calculations may give rise to false nodes for the functions obtained due to the incompleteness and specificity of the basis set, limited convergence of the iteration procedure, and so on. It should also be borne in mind that even if the search for fundamentally new avenues in modern quantum chemistry does not always prove successful, this field of science would still gain new valuable experience.

The Pauli exclusion principle seems to be common knowledge, so no comments on this point are needed. However, in actual fact, it turns out that even the question 'what does the Pauli principle exclude in a particular many-electron system?' has not been answered as yet. The difficulty of understanding the Pauli principle was noted a long time back by L. de Broglie: '... currently, it is almost impossible to understand how two identical particles forbid each other to occupy the same state'.<sup>74</sup> R. Feynman expressed an even more categorical opinion concerning this principle: 'Probably, this is one of the few items in physics where

the rule formulation is very simple, but no equally simple explanation has been found. Apparently, this means that we do not fully understand the principle that underlies it. Let us consider it, as yet, to be a Law of the Universe'.<sup>75</sup>

**Abstract.** The published data on heterogeneous catalytic redox reactions involving uranium, neptunium, plutonium and americium ions in acidic and alkaline media as well as on catalytic decomposition of some organic and nitrogen-containing inorganic components of liquid inorganic wastes are generalised. The results of kinetic studies of these reactions are analysed and possible mechanisms are considered. The bibliography includes 93 references.

## I. Introduction

The perfection of technological processes aimed at increasing the productivity and reducing production costs is of particular interest in the realisation of any industrial chain. The overgrowing environmental demands call for minimisation of industrial wastes, development of non-waste technologies and a switch, in a more remote perspective, to completely closed operation cycles.

In the chemical industry, these problems have long and successfully been solved by resort to technologies based on the use of catalytic reactions. To date, it is next to impossible to find an area of 'great' chemistry, be it sulfuric acid production, ammonia synthesis, petroleum cracking, fundamental organic synthesis or any other field, where catalysts are not employed. It is not incidental therefore that the branch of chemistry concerned with the study of catalytic reactions and properties of catalytic materials long ago became an independent science.

Radiochemical technology, which is an integral part of the nuclear fuel cycle, includes the fabrication of nuclear fuel compositions, reprocessing of the used nuclear fuel aimed at isolation of a fissile material for its reuse and separation of nuclear wastes for storage and safe disposal. The majority of existing technologies of hydrometallurgy of nuclear fuel and aqueous methods for reprocessing of the used heat-releasing elements are based on redox reactions intended for the stabilisation of components of the

dissolved fuel in predetermined oxidation states suitable for their separation, isolation and purification.

Manufacture of uranium, neptunium and americium in predetermined oxidation states is sometimes complicated by low rates of redox reactions, especially if non-salt-forming molecular reducing agents are used. Heterogeneous catalysts are used to increase the rates of these reactions.

In practical terms, final reprocessing of radioactive wastes, which includes fractionation and vitrification in glass or ceramic matrices as the back end of the fuel cycle, cannot successfully be implemented without preliminary removal of organic and nitrogen-containing inorganic impurities (*e.g.*, oxalic acid, complexons, urea, hydrazine, ammonium nitrate, excess nitric acid, *etc.*) from the so-called 'water-tail' fractions. The problem of their removal can also be solved using heterogeneous catalysis as a means to increase the rates of oxidative decomposition of hazardous impurities as components of liquid radioactive wastes.

To date, a large body of experimental results has been accumulated concerned with the studies of heterogeneous catalytic redox reactions of actinide ions and the use of catalysts for the decomposition of some organic and nitrogen-containing inorganic compounds in aqueous media. However, the literature data are often fragmentary and incomplete. Therefore, the present review is an attempt at systematic generalisation of the published data on heterogeneous catalytic redox reactions already applied, or potentially applicable, for radiochemical technological wet processes.

## II. Heterogeneous catalytic redox reactions of actinide ions in aqueous solutions

Heterogeneous catalytic processes can successfully be used for the stabilisation of predetermined valent forms of actinides in technological solutions at radiochemical plants. Activated charcoal or finely dispersed platinum on an inert support with a well-developed surface are commonly employed as heterogeneous catalysts. The role of a support is played by activated charcoal, alumina, silica gel or ion-exchange resins. Catalytic systems based on nickel, PdS, Re<sub>2</sub>S<sub>7</sub>, *etc.*, have also been investigated.

### 1. Uranium

The reduction of U(VI) to U(IV) is the most important process in the hydrometallurgy of the nuclear fuel cycle. Several methods for the conversion of U(VI) into U(IV) in a solution exist, *viz.*, electrochemical, photochemical and heterogeneous catalytic. The latter makes use of molecular hydrogen, hydrazine, formic acid and other compounds as reducing agents.

The reduction of U(VI) with hydrogen was carried out in carbonate solutions at 100–150 °C in the presence of a nickel catalyst (3–10 g litre<sup>-1</sup>).<sup>1–3</sup> The U(IV) formed precipitated as  $\text{UO}_2 \cdot x\text{H}_2\text{O}$ . It was found that the reduction rate was proportional to  $p_{\text{H}_2}^{0.5}$  ( $p_{\text{H}_2}$  is partial hydrogen pressure). Thus, one can suggest the following scheme of the process. Hydrogen is dissolved and adsorbed on the nickel surface:

The adsorbed hydrogen undergoes dissociation:

The hydrogen atoms react with U(VI) adsorbed on the adjacent sites on the surface of the nickel catalyst:

The pentavalent uranium disproportionates both on the nickel surface and in the solution:

Considering that equilibria (1)–(3) are attained sufficiently fast, the kinetic equation for this process appears as:

$$\frac{d[\text{U(IV)}]}{dt} = K[\text{H}_2]_{\text{gas}}^{0.5}[\text{U(VI)}] = Kp_{\text{H}_2}^{0.5}[\text{U(VI)}].$$

Large-scale production of U(IV) in acid solutions by reduction with hydrogen under pressure with Pt/SiO<sub>2</sub> as a catalyst was realised at the La Hague nuclear installation (France).<sup>4</sup>

The hydrogen technology was recommended for the production of  $\text{UO}_2$  sols.<sup>3</sup> Treatment of a solution of uranyl nitrate (pH ~ 1) with hydrogen was carried out at 7–35 atm and 30–80 °C in the presence of platinum on charcoal.

The reduction of U(VI) with hydrazine was the subject of several investigations.<sup>5–8</sup> Thus U(VI) was reduced with  $\text{N}_2\text{H}_4 \cdot \text{HNO}_3$  in nitric acid solution in the presence of 0.5% Pt/Al<sub>2</sub>O<sub>3</sub><sup>5</sup> both in a static and a flow regime (on a column) at constant temperature. Analysis of gaseous reaction products revealed that no hydrogen was formed.

With regard to the reaction stoichiometry

it was noted<sup>5</sup> that one mole of U(VI) consumed ~1.5 moles of  $\text{H}^+$ , but the consumption of hydrazine exceeded 0.5 moles. In the author's opinion, decomposition of hydrazine on the catalyst yields  $\text{H}_2$ , and it is hydrogen that reduces U(VI) to U(IV) and hydrazine to ammonium ion. This conclusion seems to be erroneous, since in more recent studies<sup>9</sup> no hydrogen formation was observed upon catalytic decomposition of hydrazine on platinised catalysts in nitric acid solutions.

The kinetics of reaction (5) was studied predominantly in 1.2 M  $\text{HNO}_3$  containing 1.5 and 0.5 mol litre<sup>-1</sup> of U(VI) at 52 °C. The increase in the hydrazine concentration from 0.3 to 0.9 mol litre<sup>-1</sup> caused a pronounced increase in the reaction rate. A decrease in the  $\text{HNO}_3$  concentration from 1.2 to 0.5 mol litre<sup>-1</sup> also increased the accumulation of U(IV). In the temperature range 46–65 °C, the activation energy of this reaction for the solution under study [1.8 mol litre<sup>-1</sup> U(VI) + 1.4 mol litre<sup>-1</sup>  $\text{HNO}_3$  + 1.1 mol litre<sup>-1</sup>  $\text{N}_2\text{H}_5^+$ ] was estimated to be equal to 58 kJ mol<sup>-1</sup>. At 65 °C, the formation rate of U(IV) decreased as its concentration exceeded 0.3 mol litre<sup>-1</sup>. Presumably,<sup>5</sup> these conditions favour the oxidation of U(IV) by nitric acid.

Under conditions of column chromatography, the rate of accumulation of U(IV) diminished nearly twofold on going from 0.6 to 1.2 M  $\text{HNO}_3$ . A twofold reduction in the reaction rate was also observed upon a twofold decrease in the hydrazine concentration.

It was shown that technological solutions of U(VI) poison the catalyst. The search for impurities responsible for the decrease in

the catalytic activity did not give any positive result despite the thorough analysis of cations and compounds present in the uranium(VI) solutions prior to their purification for catalytic experiments.

The stability of the catalyst with respect to prolonged exposure to U(VI) solutions (2 mol litre<sup>-1</sup>) in 1.6 M  $\text{HNO}_3$  at 50 °C has been studied. It was found that the catalytic activity decreased as a result of platinum entrainment. The result obtained can be attributed to the improper choice of the substrate (Al<sub>2</sub>O<sub>3</sub>), which possesses limited resistance to nitric acid-containing media. Platinised SiO<sub>2</sub> was used as a catalyst for the preparation of U(IV) solutions in nitric acid.<sup>6,7</sup> Solutions of 0.42 mol litre<sup>-1</sup> U(VI) and hydrazine in 1.5–4 M  $\text{HNO}_3$  were made to react with 1% Pt/SiO<sub>2</sub> (C : R was 1 : 10<sup>†</sup> at 55–70 °C). The reaction mixture was stirred by passing nitrogen at a controlled rate. The kinetic curves for the accumulation of U(IV) in the coordinates  $\ln[c_0/(c_0 - c)]$  vs. time [where  $c_0$  is the initial concentration of U(VI) and  $c$  is the running concentration of U(IV)] are nearly straight lines, which can formally be interpreted as the first reaction order with respect to uranium(VI). Therefore, the kinetic regularities of this reaction were described by the equation:

$$-\frac{d[\text{U(VI)}]}{dt} = k'[\text{U(VI)}].$$

Here,  $k'$  (in min<sup>-1</sup>) is the frequency factor or the apparent rate constant; its value is proportional to the initial reaction rate. Obviously,  $k'$  is not a true first-order rate constant, since the initial concentrations of uranium and hydrazine in this reaction mixture are commensurable and the decrease in the concentration of the reducing reagent during the reaction cannot be insignificant. The dependence of  $k'$  on the concentration of nitric acid is well approximated by a straight line in the logarithmic coordinates with an angular coefficient of about -0.6, which can be attributed to the apparent reaction order with respect to nitric acid. However, this value does not provide an unambiguous conclusion on the involvement of hydrogen ions in the rate-determining step of the reduction, since the experiments were carried out at various ionic strengths. At the same time, it is expected that higher concentrations of  $\text{HNO}_3$  will increase the yields of nitrate complexes of uranium(VI), which manifest different (in comparison with free uranyl ions) reactivities with respect to hydrazine. Based on the general considerations, it may be assumed that the true order of this reaction with respect to  $\text{H}^+$  will be equal to -1. This conclusion is based on an assumption that only neutral  $\text{N}_2\text{H}_4$  molecules preactivated by adsorption on the surface of platinum are involved in the reaction with uranium(VI). The yield of the molecular form of hydrazine is inversely proportional to  $[\text{H}^+]$ , which should result in the -1 order of this reaction with respect to hydrogen ions. However, the catalytic activation of  $\text{N}_2\text{H}_5^+$  ions and, as a consequence, the zero order of the reaction with respect to  $\text{H}^+$  cannot be ruled out either.

Changes in the concentration of the reducing agent in the range 0.5–2 mol litre<sup>-1</sup> do not influence the reaction rate, *i.e.*, the reaction is of the zero order with respect to hydrazine. The activation energy of the reduction was estimated in the temperature range 55–70 °C and was equal to  $85.4 \pm 3.0$  kJ mol<sup>-1</sup>.

The increase in the platinum content on silica gel from 0.25% to 2% resulted in a monotonic increase in the reaction rate. Increases in the catalyst concentration in the reaction mixture (the C : R ratio) accelerated the reduction.

The reduction of U(VI) (0.75 mol litre<sup>-1</sup>) with hydrazine in  $\text{HNO}_3$  has been studied by Shilov *et al.*<sup>7</sup> The catalyst was prepared by impregnation of silica gel (grain size 0.5–1 mm) with  $\text{H}_2\text{PtCl}_6$  followed by drying and treatment with a hot solution of hydrazine hydrate (2–4 mol litre<sup>-1</sup>). The experiments

<sup>†</sup> C : R is the ratio of the amount of the catalyst (in g) to the volume of the reaction mixture (in ml).

**Figure 1.** Kinetic curves of the reduction of U(VI) with hydrazine in the presence of Pt/SiO<sub>2</sub> containing different concentrations of Pt.<sup>7</sup> [U(VI)]<sub>0</sub> = 0.75 mol litre<sup>-1</sup>, [HNO<sub>3</sub>]<sub>0</sub> = 2.0 mol litre<sup>-1</sup>, [N<sub>2</sub>H<sub>5</sub><sup>+</sup>]<sub>0</sub> = 1.0 mol litre<sup>-1</sup> at 58.5 °C, C: R = 1:10; Pt content (%): (1) 0.76, (2) 0.83, (3) 1.0, (4) 1.0 (another sample).

were carried out in a thermostated cell mounted onto a shaker. The kinetic curves for U(IV) accumulation represent virtually straight lines up to the concentration of 0.5 mol litre<sup>-1</sup>, which testified to a zero order of the reaction with respect to the metal (Fig. 1). For certain catalyst samples, the kinetic curves occupied an intermediate position between those for the zero and first order. In solutions of U(VI) (0.75 mol litre<sup>-1</sup>) containing 2 mol litre<sup>-1</sup> HNO<sub>3</sub> and 1–1.5 mol litre<sup>-1</sup> N<sub>2</sub>H<sub>5</sub><sup>+</sup>, about 0.55 mol litre<sup>-1</sup> of U(IV) was usually formed when the reaction was carried out for 2 h at 58 °C in the presence of 1% Pt/SiO<sub>2</sub> as a catalyst (C: R = 1:10). The reproducibility of the results with the same catalyst sample was satisfactory. The rate of formation of U(IV) decreased with a decrease in the platinum concentration on the support. A decrease in the N<sub>2</sub>H<sub>5</sub><sup>+</sup> concentration to 0.75 mol litre<sup>-1</sup> or an increase in the HNO<sub>3</sub> concentration to 3–4 mol litre<sup>-1</sup> decelerated this process. Altogether, 1.2 mol of U(IV) was formed per mol of hydrazine. Thus, the reaction (5) paralleled catalytic decomposition of hydrazine or its reaction with HNO<sub>3</sub> in this system. It is known that the latter process yields N<sub>2</sub>, N<sub>2</sub>O, NH<sub>4</sub><sup>+</sup> and HN<sub>3</sub> (see Ref. 10). However, it was shown in special experiments that the gas evolved contained no HN<sub>3</sub>. The activation energy of this reaction was measured in the temperature range 23–66 °C and was equal to 84 kJ mol<sup>-1</sup>.

It may be assumed that this reaction proceeds through preliminary sorption of the reactants on the catalyst and is followed by their reaction

In this case, metallic platinum plays the role of a bridge in the electron transfer from hydrazine to uranyl. U(V) disproportionates into U(IV) and U(VI) [reaction (4)], the radicals react with U(VI), NO<sub>3</sub><sup>-</sup> and one another:

In a series of experiments, leaching of silicon from the catalysts was studied. The concentration of silicon in a solution of U(VI) and hydrazine in 1 M HNO<sub>3</sub> in the presence of 1% Pt/SiO<sub>2</sub> (C: R = 1:10; 58 °C) amounted to 13, 36 and 58 mg litre<sup>-1</sup> after 1, 2 and 3 h, respectively. An increase in HNO<sub>3</sub> concentration diminished leaching.

The catalyst 1% Pt/SiO<sub>2</sub> was used for the reduction of U(VI) with hydrazine in H<sub>2</sub>SO<sub>4</sub> solutions.<sup>8</sup> The kinetic curves are well described by the first-order equation with respect to U(VI) over the

whole range of experimental conditions. The reaction rate decreased slightly on going from 0.1 to 1.0 M H<sub>2</sub>SO<sub>4</sub>. The increase in the hydrazine content from 0.1 to 0.4 mol litre<sup>-1</sup> only slightly increased the rate constant. The activation energy in the temperature range 30–60 °C was equal to 69.0 ± 4.0 kJ mol<sup>-1</sup>. The reduction of uranium(VI) in H<sub>2</sub>SO<sub>4</sub> solutions was not complicated by reverse oxidation of uranium(IV) and catalytic decomposition of hydrazine, which became apparent only at the temperatures above 60 °C, whereas the reduction of U(VI) occurred at a much higher rate even at 30 °C. The method described can be used for the preparation of H<sub>2</sub>SO<sub>4</sub> solutions of uranium(IV) with concentrations of up to 0.25 mol litre<sup>-1</sup> with respect to the metal. Further increase in uranium concentration is impossible due to the limited solubility of U(SO<sub>4</sub>)<sub>2</sub>.

The mechanism of U(VI) reduction by hydrazine in H<sub>2</sub>SO<sub>4</sub> solutions is similar to that in HNO<sub>3</sub> solutions in general features.

The applicability of formic acid for the reduction of uranium(VI) in the presence of various catalysts was studied. Thus, 2%–5% Pt on Al<sub>2</sub>O<sub>3</sub> was used as a catalyst in the preparation of U(IV) in HNO<sub>3</sub> solutions containing HCO<sub>2</sub>H and (NH<sub>2</sub>)<sub>2</sub>CO.<sup>11</sup>

The catalyst Pt/Al<sub>2</sub>O<sub>3</sub> was used for the reduction of U(VI) (0.1 mol litre<sup>-1</sup>) in 0.4 M HCO<sub>2</sub>H at 46–59 °C. (NH<sub>2</sub>)<sub>2</sub>CO was added to the solution to remove traces of HNO<sub>2</sub>.<sup>12</sup> The reduction rate was found to be proportional to [U(VI)] and did not depend on [HCO<sub>2</sub>H].

The method for the reduction of U(VI) by formic acid in HNO<sub>3</sub> solutions (0.5 mol litre<sup>-1</sup>) in the presence of a platinum catalyst has been patented in Germany.<sup>13</sup> Virtually complete conversion of UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub> (100 g litre<sup>-1</sup> of uranium) into U(NO<sub>3</sub>)<sub>4</sub> served as an example; the residual content of U(VI) was less than 10 mg litre<sup>-1</sup>.

Platinum-group catalysts were used for the preparation of U(IV) in HNO<sub>3</sub> solutions.<sup>7,14,15</sup> It was found that formic acid containing no hydrazine failed to reduce U(VI) in 2 M HNO<sub>3</sub> in the presence of 1% Pt/SiO<sub>2</sub> (58 °C).<sup>7</sup> The addition of N<sub>2</sub>H<sub>5</sub><sup>+</sup> resulted in the formation of U(IV), the threshold concentration of hydrazine being ~0.02 mol litre<sup>-1</sup>. The increase in [N<sub>2</sub>H<sub>5</sub><sup>+</sup>] up to 0.05 mol litre<sup>-1</sup> favoured accelerated accumulation of U(IV). Further increase in the hydrazine concentration up to 0.1 mol litre<sup>-1</sup> had little effect on the reaction rate. The reaction was decelerated with an increase in HNO<sub>3</sub> concentration; higher concentrations of HCO<sub>2</sub>H increased the reduction rate. In the temperature range 17–65 °C, the activation energy was 48 kJ mol<sup>-1</sup>.

The consumption of 1 mole of HCO<sub>2</sub>H (with consideration of hydrazine consumed) was accompanied by formation of 0.83 mole of U(IV), i.e., the catalytic reduction occurred mainly according to the reaction:

This mechanism includes sorption of UO<sub>2</sub><sup>2+</sup> and HCO<sub>2</sub>H on the active sites of the catalyst with subsequent formation of UO<sub>2</sub><sup>+</sup> and the radical ·CO<sub>2</sub>H. This radical reduces UO<sub>2</sub><sup>2+</sup> and UO<sub>2</sub><sup>+</sup>. In addition, disproportionation of UO<sub>2</sub><sup>+</sup> occurs [reaction (4)]. In this reaction, the role of hydrazine is confined to stabilisation of U(IV) and prevention of the reaction of HCO<sub>2</sub>H with HNO<sub>2</sub> by fast reduction of trace amounts of the latter and nitrogen oxides. Primary and secondary amines and (NH<sub>2</sub>)<sub>2</sub>CO also serve as HNO<sub>2</sub> acceptors, however, control experiments have shown that urea does not replace hydrazine in the catalytic reaction of U(VI) with HCO<sub>2</sub>H due to the low binding rate of HNO<sub>2</sub>. The reduction of U(VI) by formic acid in the presence of 1% Pt/VP-1AP anion-exchange resin as a catalyst was studied. Its efficiency was found to be similar to that of 1% Pt/SiO<sub>2</sub>.<sup>7</sup>

In addition to platinum-group catalysts, Re<sub>2</sub>S<sub>7</sub> (see Refs 16 and 17) and PdS were used for the reduction of U(VI).<sup>18</sup> Dirhenium heptasulfide proved to be an efficient catalyst in the reactions of U(VI) with formaldehyde, formic acid and ethanol. These studies were carried out in acidic solutions at temperatures of 20–100 °C with stirring. It was found that U(VI) was com-

pletely reduced by formaldehyde at temperatures above 80 °C. The reduction was complete in 20–30 min in the presence of  $\text{Re}_2\text{S}_7$  (0.2–0.3 g per g of uranium) and a threefold excess of  $\text{HCHO}$ .  $\text{Cl}^-$  ions decelerated, while  $\text{F}^-$  ions accelerated this reaction. The concentration of  $\text{H}^+$  had little effect on the reaction rate. Ethanol and formic acid reacted with  $\text{U(VI)}$  at a slower rate than formaldehyde.

The kinetics of the reaction of  $\text{U(VI)}$  with  $\text{C}_2\text{H}_5\text{OH}$  in  $\text{H}_2\text{SO}_4$  solutions in the presence of  $\text{Re}_2\text{S}_7$  was studied at 50.6–90 °C.<sup>17</sup> The content of  $\text{Re}_2\text{S}_7$  was  $\sim 0.8$  g per g of uranium. Under these conditions, the reaction was of the first order with respect to  $\text{U(VI)}$ . The increase in  $[\text{C}_2\text{H}_5\text{OH}]$  from 0.17 to 2.52 mol litre<sup>-1</sup> favoured a nearly proportional increase in the reaction rate. The increase in  $[\text{H}_2\text{SO}_4]$  from 0.81 to 1.53 mol litre<sup>-1</sup> had no effect on the reaction rate. The activation energy of this reaction was 69.4 kJ mol<sup>-1</sup>.

Palladium sulfide was used as a catalyst in the reduction of  $\text{U(VI)}$  by formaldehyde in solutions of sulfuric, nitric or hydrochloric acids.<sup>18</sup> The concentration of uranium in the starting solutions was 50 g litre<sup>-1</sup> (0.2 mol litre<sup>-1</sup>). As the specific surface of powdered  $\text{PdS}$  was  $\sim 3.5$  m<sup>2</sup> g<sup>-1</sup>, more than 0.8 g  $\text{PdS}$  per g of uranium was required for efficient reduction. The efficiency of uranyl reduction depended on the anion present in the solution and increased in the series chloride < nitrate < sulfate. Fluoride ions increased the reduction rate. At a concentration of  $\text{HF}$  up to 1.5 mole per mole of uranium, all the  $\text{U(IV)}$  was present in the solution. Further increase in the  $\text{HF}$  concentration resulted in partial precipitation of  $\text{U(IV)}$  in the form of  $\text{UF}_4 \cdot x\text{H}_2\text{O}$ .

The catalytic reduction of uranyl by formaldehyde occurred at temperatures above 50 °C. In  $\text{H}_2\text{SO}_4$  solutions, the concentration of formaldehyde should be in the range from 2 to 3 moles per mole of uranium. The change in  $\text{H}_2\text{SO}_4$  concentration from 0.3 to 1 mol litre<sup>-1</sup> had virtually no effect on the yield of  $\text{U(IV)}$ .

The oxidation of formaldehyde by uranyl ions in solutions yields formic acid. Under similar conditions,  $\text{HCO}_2\text{H}$  competed favourably as a reducing agent with formaldehyde. Uranyl is not reduced by methanol. Repeated use of the catalyst demonstrated that  $\text{PdS}$  was not poisoned in the aqueous solutions under study and it could be employed many times without recourse to regeneration.

## 2. Neptunium

The known heterogeneous catalytic reactions of neptunium occur in acidic and alkaline media. Nitric acid plays the role of an oxidant, while hydrogen, hydrazine, hydroxylamine, formic acid and formaldehyde are reducing agents. Platinum-on-platinum, platinum-on-silica gel, platinum black and support-free palladium are used as catalysts.

Nitric and nitrous acids oxidise neptunium(IV) to a hexavalent state according to the reactions:<sup>19</sup>

However, these thermodynamically allowed reactions are extremely slow for kinetic reasons and the fact that the accumulation of  $\text{Np(V,VI)}$  over tens of hours in  $\text{HNO}_3$  solutions is insignificant can be associated with radiolytic rather than chemical processes.<sup>20,21</sup> Being quite stable in 0.5–3 M  $\text{HNO}_3$ , neptunium(IV) undergoes fast oxidation in the presence of 1%  $\text{Pt/SiO}_2$  as a solid-phase catalyst.<sup>22</sup> The catalytic oxidation of neptunium(IV) in  $\text{HNO}_3$  solutions takes place even in the presence of antinitrite reagents, such as  $\text{NH}_2\text{SO}_3\text{H}$ , although in this case the reaction rate is somewhat smaller. The kinetics of heterogeneous catalytic oxidation of  $\text{Np(IV)}$  in  $\text{HNO}_3$  solutions has been studied.<sup>22</sup> This reaction yields  $\text{Np(V)}$  with admixture of  $\text{Np(VI)}$  (up to 5%); the content of the latter depends on the concentrations of nitric and nitrous acids. The oxidation of neptunium(IV) by nitric acid follows first-order kinetics with respect to  $\text{Np(IV)}$  over the whole range of experimental conditions. An increase in the

catalyst concentration results in a monotonic increase in the reduction rate. The linear dependence  $k'$  vs.  $(\text{C}:\text{R})$  in logarithmic coordinates allows the estimation of the apparent reaction order with respect to the active sites of the catalyst. For the reaction under consideration, it is equal to  $0.97 \pm 0.07$  in the  $\text{C}:\text{R}$  range under study (0.025–0.1). The oxidation rate of  $\text{Np(IV)}$  by nitric acid decreases with an increase in the solution acidity from 0.5 to 4.0 mol litre<sup>-1</sup>  $[\text{H}^+]$  at a constant concentration of nitrate ions ( $[\text{NO}_3^-] = 0.5$  mol litre<sup>-1</sup>). The linear dependence of the rate constants on the  $\text{H}^+$  concentration in the logarithmic coordinates has an angular coefficient corresponding to the apparent reaction order of  $0.7 \pm 0.1$  with respect to  $\text{H}^+$ . The increase in the total concentration of nitrate ions in the concentration range 0.5–4.0 mol litre<sup>-1</sup> at constant acidity ( $[\text{H}^+] = 0.5$  mol litre<sup>-1</sup>) causes a slight increase in the reaction rate which corresponds to the apparent reaction order of  $0.25 \pm 0.07$  for  $\text{NO}_3^-$ . The increment in  $[\text{HNO}_3]$  in the range 0.5–4.0 mol litre<sup>-1</sup> slows down the reaction up to its complete cessation, which occurs at  $[\text{HNO}_3] > 4.0$  mol litre<sup>-1</sup>. The apparent reaction order for nitric acid varies from  $-0.3$  at low  $[\text{HNO}_3]$  to  $-3.3$  at a concentration of  $\text{HNO}_3 > 3$  mol litre<sup>-1</sup>, which suggests a complex type of heterogeneous catalytic interaction in the  $\text{Np(IV)}-\text{HNO}_3-\text{Pt/SiO}_2$  system. The deceleration of the catalytic oxidation of  $\text{Np(IV)}$  in the presence of sulfamic acid can be attributed to the effect of nitrous acid formed in one of the reaction steps, which increases the rate of the catalytic oxidation of neptunium(IV).

The dependence of the apparent activation energy ( $E^*$ ) on the concentration of nitric acid has a complex form.

| $[\text{HNO}_3]$<br>/mol litre <sup>-1</sup> | $E^*$<br>/kJ mol <sup>-1</sup> | $[\text{HNO}_3]$<br>/mol litre <sup>-1</sup> | $E^*$<br>/kJ mol <sup>-1</sup> |
|----------------------------------------------|--------------------------------|----------------------------------------------|--------------------------------|
| 0.5                                          | 60.1                           | 2.0                                          | 83.3                           |
| 1.0                                          | 61.0                           | 3.0                                          | 85.1                           |

These data show that an abrupt increase in  $E^*$  (by more than 20 kJ mol<sup>-1</sup>) occurs in the concentration range of  $\text{HNO}_3$  of 1.0–2.0 mol litre<sup>-1</sup> where the change in the reaction mechanism apparently occurs.

The oxidative properties of nitric acid are usually considered in relation to the oxidising effect of nitroyl cations ( $\text{NO}_2^+$ ) present in nitric acid solutions in a certain equilibrium concentration.<sup>10,23,24</sup> The  $\text{NO}_2^+$  species are formed in the solution as a result of a fast equilibrium reaction:

One should not rule out the possibility of the formation of nitroyl ions in the system under consideration as a result of fast heterogeneous reactions.

The fact that the catalytic oxidation of  $\text{Np(IV)}$  is decelerated in the presence of antinitrite reagents suggests that  $\text{HNO}_2$  or one of its transformation products is involved in the formation of an activated complex on the surface of the catalyst. Taking into account the disproportionation equilibrium of  $\text{HNO}_2$  and  $\text{NO}_2$ ,

the following scheme for heterogeneous catalytic conversions in the  $\text{Np(IV)}-\text{HNO}_3-\text{Pt/SiO}_2$  system can be proposed:

Here, Z is the active site of the catalyst;

ZA is the intermediate oxidising species (quite probably, the oxidising species are formed from  $\text{NO}_3^-$  and  $\text{HNO}_2$  and are then adsorbed on the active catalytic sites).

In dilute solutions ( $[\text{HNO}_3] < 1 \text{ mol litre}^{-1}$ ), the catalytic oxidation of neptunium(IV) can result from the following rate-limiting step:

Nitrous acid is formed in the reaction:

In the presence of antinitrite reagents,  $\text{HNO}_2$  and nitrogen oxides that are in equilibrium with it are absent from the solution. Such conditions apparently favour the direct oxidation of  $\text{Np(IV)}$  by  $\text{NO}_2^+(\text{ads})$  species, although the rate of this is much lower.

As mentioned above, the mechanism of this reaction markedly changes in the  $[\text{HNO}_3]$  range  $1-2 \text{ mol litre}^{-1}$ . Here, the concentration of  $\text{Np}^{4+} \cdot n\text{H}_2\text{O}$  becomes negligibly small as a result of complexation with nitrate ions.<sup>25,26</sup> Under these conditions, it is nitrate complexes of neptunium(IV) that are the only oxidisable species. The formation of neptunium(V) dioxo cation from the aqua-ions  $\text{Np}^{4+} \cdot n\text{H}_2\text{O}$  should occur more easily than from the nitrate  $\text{Np(IV)}$  complex where the  $\text{H}_2\text{O}$  molecules are partly displaced from the coordination sphere of Np by nitrate ions. Therefore, the increase in  $[\text{HNO}_3]$  above  $1 \text{ mol litre}^{-1}$  is accompanied by a significant decrease in the oxidation rate and an increase in the activation energy.

The effect of neptunium(IV) concentrations on the yield of neptunium(III) in  $\text{HClO}_4$  solutions under the action of hydrogen in the presence of a platinum-on-platinum catalyst using  $^{237}\text{Np}$  and  $^{239}\text{Np}$  was studied.<sup>27</sup> The degree of neptunium oxidation was established using extraction with tenoyltrifluoroacetone (TTA) in xylene:  $\text{Np(IV)}$  was extracted into the organic phase and  $\text{Np(III)}$  remained in the aqueous solution. The concentration of neptunium was determined from  $\alpha$ - ( $^{237}\text{Np}$ ) and  $\gamma$ - ( $^{239}\text{Np}$ ) activities. It was shown that at neptunium concentrations above  $10^{-3} \text{ mol litre}^{-1}$  in  $1 \text{ M HClO}_4$  its reduction to  $\text{Np(III)}$  was virtually complete. The contribution of  $\text{Np(III)}$  diminished with a decrease in the total neptunium concentration; no reduction of  $\text{Np(IV)}$  took place when its concentration dropped below  $10^{-8} \text{ mol litre}^{-1}$ . Neither purification of hydrogen by activated copper and pyrogallol, nor the prolongation of the reaction time with hydrogen to 3 h favoured this process. It was first suggested that if reoxidation of  $\text{Np(III)}$  that had been generated on the catalyst surface occurred in the bulk of the solution, the proportion of reduced neptunium depended on the surface area of the catalyst. However, even a 10-fold increase in the surface area of the catalyst did not affect the proportion of reduced neptunium. It was therefore suggested that the solution contained oxidising admixtures. Their effect could be neutralised where the oxidised forms of cations with redox potentials below the  $\text{Np}^{4+}/\text{Np}^{3+}$  pair [0.155 V relative to the normal hydrogen electrode (NHE)] were added to a support-free solution of  $^{239}\text{Np}$ . The following pairs,  $\text{Zn}^{2+}/\text{Zn}$  (−0.763 V),  $\text{U}^{4+}/\text{U}^{3+}$  (−0.631 V),  $\text{Cr}^{3+}/\text{Cr}^{2+}$  (−0.41 V),  $\text{Cd}^{2+}/\text{Cd}$  (−0.403 V) and  $\text{Ti}^{4+}/\text{Ti}^{3+}$  (−0.055 V), with potentials lower than the hydrogen potential could not enhance  $^{239}\text{Np(IV)}$  reduction. However support-free  $^{239}\text{Np(IV)}$  was quantitatively reduced to a trivalent state when  $\text{H}_2$  was passed for 2 h in the presence of  $\text{Sn(IV)}$  ( $10^{-2} \text{ mol litre}^{-1}$ ). At a concentration of tin(IV) of  $10^{-3} \text{ mol litre}^{-1}$ , its effect began to fade away and at concentrations  $< 10^{-4} \text{ mol litre}^{-1}$  no  $\text{Np(III)}$  could be detected. It should be noted that the results of these experiments are rather obscure, since oxidised forms of the added cations reacted with neither  $\text{Np(III)}$  nor hydrogen. In our opinion, it is adsorption of  $\text{H}_2$  and its dissociation into hydrogen atoms that occur on the platinum surface [reactions (1)–(3)] and part of the H atoms are desorbed and pass into the solution. Pulse radiolysis of  $\text{Np(III)}$  in  $1 \text{ M HClO}_4$  revealed<sup>28</sup> that  $\text{Np(III)}$  is oxidised by

hydrogen atoms at a rate of  $6 \times 10^7 \text{ litre mol}^{-1} \text{ s}^{-1}$ . Thus, the hydrogen atoms leaving the platinum surface convert  $\text{Np(III)}$  into  $\text{Np(IV)}$ . The oxidation of  $\text{Np(III)}$  by perchloric acid should not be ruled out either.

The effect of  $[\text{HClO}_4]$  on the reduction of  $\text{Np(IV)}$  has been studied.<sup>27</sup> It was found that the fraction of  $\text{Np(III)}$  decreased with a decrease in  $[\text{HClO}_4]$  and no reduction of  $5 \times 10^{-7}$  or  $4 \times 10^{-3} \text{ mol litre}^{-1}$  solutions of  $^{237}\text{Np(IV)}$  occurred in  $2 \times 10^{-3} \text{ M HClO}_4$ . The absorption spectrum of the latter solution was similar to that of  $\text{Np(IV)}$  hydroxide. A decrease in yields of  $\text{Np(III)}$  seems to be due to hydrolysis of  $\text{Np(IV)}$ , which brings about a shift of the potential of  $\text{Np(IV)}/\text{Np(III)}$  to a more negative region. This argument seems tenable. Thus calculations performed with consideration of  $\text{Np(IV)}$  hydrolysis constants (see Ref. 29) gave a more negative potential of the  $\text{Np(IV)}/\text{Np(III)}$  pair at  $[\text{H}^+] = 2 \times 10^{-3} \text{ mol litre}^{-1}$  than that of the  $\text{H}_2/\text{H}^+$  pair.

Hydrazine in the presence of  $\text{Pt/SiO}_2$  was also used for the reduction of  $\text{Np(VI)}$  and  $\text{Np(V)}$  in nitric acid.<sup>30</sup> Upon exposure to a catalyst (0.25%  $\text{Pt/SiO}_2$  or 2%  $\text{Pt/SiO}_2$ ) (C : R = 1 : 40 at  $15^\circ\text{C}$ ), the rate of reduction of  $\text{Np(VI)}$  ( $2.5 \times 10^{-4} \text{ mol litre}^{-1}$ ) in  $2 \text{ M HNO}_3$  containing  $\text{N}_2\text{H}_5\text{NO}_3$  ( $1 \times 10^{-3} \text{ mol litre}^{-1}$ ) depended on the intensity of stirring, and the reaction occurred under diffusion control. An increase in the rate of mechanical stirring in order to attain the kinetic regime failed because of attrition wear of the catalyst. The kinetic curves were rectified in semilogarithmic coordinates. The values of the first-order rate constants calculated from the slopes of the straight lines prompted the following conclusions. The increase in the platinum content on silica gel from 0.25 to 1% caused an increase in the reduction rate, while further increases in the platinum concentration had virtually no effect on the reaction rate. The rate constant changed in a virtually linear manner with a change in the C : R ratio as could be expected for the reaction occurring on a surface. The increase in  $[\text{HNO}_3]$  from 1 to  $2 \text{ mol litre}^{-1}$  slightly inhibited this process, while the increase in hydrazine concentration in the range  $(0.1-100) \times 10^{-3} \text{ mol litre}^{-1}$  accelerated it. At  $15-40^\circ\text{C}$ , the activation energy was about  $19 \text{ kJ mol}^{-1}$ , i.e., typical of reactions whose rates are diffusion-controlled.<sup>31</sup>

Upon addition of a catalyst ( $\text{Pt/SiO}_2$ ) to solutions of  $\text{Np(V)}$  and hydrazine in  $\text{HNO}_3$  at  $30-40^\circ\text{C}$ , the formation of  $\text{Np(IV)}$  occurred. The rate of the reduction was virtually independent of the intensity of stirring of the solution with the catalyst, therefore it was easy to select the stirring regime allowing the experiments to be carried out under kinetic control. The reaction rate is described by a first-order equation with respect to  $\text{Np(V)}$ . The first-order rate constants obtained under different conditions characterised the reduction process and made it possible to estimate the contribution of each factor. First, the rate constant increased linearly with the platinum concentration on the support and the C : R ratio. Second, the rate constant increased with the acid concentration (from 0.2 to  $7 \text{ mol litre}^{-1}$ ). Third, in the range  $30-60^\circ\text{C}$  the activation energy is nearly  $32 \text{ kJ mol}^{-1}$ , which is much smaller than in the homogeneous catalytic reduction of  $\text{Np(V)}$  by hydrazine in the presence of  $\text{Mo(VI)}$  [ $100 \text{ kJ mol}^{-1}$  at  $60-88^\circ\text{C}$  (see Ref. 32)].

If the concentration of  $\text{HNO}_3$  in solution is lower than  $2 \text{ mol litre}^{-1}$ , the reduction of  $\text{Np(V)}$  is incomplete with 2% to 4% of  $\text{Np(V)}$  remaining. Complete conversion of  $\text{Np(V)}$  into  $\text{Np(IV)}$  occurred in  $4 \text{ M HNO}_3$  where the catalytic reduction of  $\text{Np(V)}$  is accompanied by simultaneous oxidation of  $\text{Np(IV)}$ . The higher extent of reduction in  $4-6 \text{ M HNO}_3$  is due to complexation with nitrate ions and the resistance of the complexes to oxidation. The rates of oxidation and reduction increase with temperature, but the degree of passage of neptunium into a hexavalent state at  $30-60^\circ\text{C}$  changes only insignificantly. However, at temperatures above  $70^\circ\text{C}$  the yields of  $\text{Np(IV)}$  decrease as a result of rapid decomposition of hydrazine in the presence of a catalyst, especially in  $0.5-2 \text{ M HNO}_3$ . The mechanism of this process is similar to that of  $\text{U(VI)}$  reduction.

In alkaline hydrazine solutions, the concentration of Np(V) did not change in the temperature range from 40 to 80 °C. Finely dispersed metallic palladium formed from palladium salts under these conditions plays the role of a catalyst in the reduction of Np(V). The Np(IV) formed precipitates as the hydroxide.<sup>33</sup> The amount of Np(V) reduced is proportional to the concentration of Pd(II). The increase in the alkali (LiOH) concentration inhibits this process. The increase in the hydrazine concentration from 0.02 to 0.2 mol litre<sup>-1</sup> in 2 M NaOH slightly increases the reduction rate. The activation energy was estimated to be equal to ~88 kJ mol<sup>-1</sup> (40–80 °C).

The kinetics and mechanism of the Np(V) to Np(IV) reduction by hydroxylamine in nitric acid solutions in the presence of platinum black have been studied,<sup>34</sup> although no information on the procedure of the preparation of platinum black and the grain size and the catalyst surface was provided. No reaction occurred at room temperature in the absence of the catalyst. The solutions were magnetically stirred at 22.4 °C. The reaction rate did not depend on [NH<sub>3</sub>OH<sup>+</sup>] in the range 0.25–1.87 mol litre<sup>-1</sup> and was described by the kinetic equation:

$$-\frac{d[\text{Np(V)}]}{d\tau} = k_0[\text{Np(V)}]^{0.54}[\text{H}^+]^{1.52}[\text{Pt}_{\text{black}}]^{1.01}$$

at [Np(V)] = (0.83–5.82) × 10<sup>-3</sup> mol litre<sup>-1</sup>; [H<sup>+</sup>] = 0.5–3.0 mol litre<sup>-1</sup>; [Pt<sub>black</sub>] = 2.04–10.16 g litre<sup>-1</sup>. Based on the data obtained, the following mechanism was proposed:

(this reaction is probably preceded by sorption of NH<sub>3</sub>OH<sup>+</sup> on the surface of platinum black):

Formic acid plays the role of a reducing agent; the redox potential of the pair CO<sub>2</sub>H<sup>+</sup>/HCO<sub>2</sub>H is equal to 0.199 V (NHE).<sup>35</sup> The redox potentials of the pairs Np(VI)/Np(V) and Pu(VI)/Pu(V) (1.24 and 1.02 V, respectively<sup>36</sup>) are much larger than that of formic acid. However, Np(VI) and Pu(VI) are not reduced in formate solutions.<sup>37</sup> A possible reason for the kinetic stability of hexavalent neptunium and plutonium ions in formate solutions is that formic acid, being a two-electron reducing agent, reacts with one-electron oxidants *via* formation of a radical.<sup>38</sup>

For the first step, ΔG° = 157.2 kJ mol<sup>-1</sup> (see Ref. 39), which is equivalent to the potential of 1.63 V, thus preventing the reduction of Np(VI) and Pu(VI). The above-said holds for Np(V), Pu(IV) and U(VI), since the redox potentials of the Np(V)/Np(IV), Pu(IV)/Pu(III) and U(VI)/U(IV) pairs are below 1 V.<sup>36</sup> It might be expected that the catalytic reduction of Np(VI) occurs at noticeable rates. This was demonstrated<sup>40</sup> in a study of kinetic regularities of the reaction of Np(VI,V) with HCO<sub>2</sub>H in HClO<sub>4</sub> solutions in the presence of 1% Pt/SiO<sub>2</sub>, the reaction mixture being stirred by a flow of argon.

The analysis of the kinetic curves revealed that the catalytic reduction of Np(VI) to Np(V) is a first-order reaction with respect to Np(VI) over the whole range of experimental conditions. The contributions of different factors to Np(VI) reduction were estimated based on the analysis of apparent rate constants *k*<sub>1</sub>. The increase in *k*<sub>1</sub> with an increase in the stirring intensity points to the diffusion-controlled mechanism of this reaction.

An increase in the catalyst content in the reaction mixture results in a monotonic increase in *k*<sub>1</sub>. The reaction rate increases with the concentration of formic acid in the range from 0.2 to

1.5 mol litre<sup>-1</sup>. The apparent order of the reaction with respect to HCO<sub>2</sub>H is 0.43 ± 0.01. The increase in the concentration of perchloric acid in the range from 0.2 to 4.0 mol litre<sup>-1</sup> results in a slight decrease in the reaction rate. The apparent order of this reaction with respect to HClO<sub>4</sub> is -0.26 ± 0.02. The activation energy in the temperature interval from 30 to 60 °C is 18.3 ± 0.9 kJ mol<sup>-1</sup>, which is consistent with the corresponding values for the diffusion-controlled processes.

The catalytic reduction of Np(VI) with formic acid is not stopped at the formation of Np(V), the concomitant accumulation of Np(IV) occurs in parallel (Fig. 2). The reduction rate of Np(V) does not depend on the stirring intensity, hence the reaction is kinetically controlled.

**Figure 2.** Time-dependent changes in the concentrations of valence forms of neptunium in the presence of 0.1 g ml<sup>-1</sup> 1% Pt/SiO<sub>2</sub> at 60 °C (see Ref. 40). [HClO<sub>4</sub>] = 1.0 mol litre<sup>-1</sup>, [HCO<sub>2</sub>H] = 0.1 mol litre<sup>-1</sup>. (1) Np(VI), (2) Np(V), (3) Np(IV).

The stoichiometry of the catalytic reduction of Np(V) with formic acid was studied in solutions with [Np] = 6.20 × 10<sup>-3</sup> mol litre<sup>-1</sup> and [HCO<sub>2</sub>H] = 1.01 × 10<sup>-3</sup> mol litre<sup>-1</sup>. The stoichiometric coefficient, *i.e.*, Δ[Np(V)]/Δ[HCO<sub>2</sub>H], was equal to 2.15 ± 0.08.

The S-shaped curves of the Np(V) reduction, *i.e.*, the presence of an induction period is characteristic of reactions in solutions with [HClO<sub>4</sub>] = 2 mol litre<sup>-1</sup>. At [HClO<sub>4</sub>] > 2 mol litre<sup>-1</sup>, the reaction rate obeys the first-order law. The appearance of the induction period depends also on the concentration of HCO<sub>2</sub>H. If the concentration of HCO<sub>2</sub>H in 1 M HClO<sub>4</sub> is < 0.05 mol litre<sup>-1</sup>, the induction period is absent and the reaction kinetics follows the first order with respect to Np(V). Using different initial concentrations of Np(V), it was possible to determine the orders of reactions described by kinetic curves with induction periods. The reaction rates were determined by the slopes of the tangents in the points corresponding to 50% conversion. The dependence of the reaction rate on [Np(V)]<sub>0</sub> was a straight line with the angular coefficient 1.05 in logarithmic coordinates. This suggests that the catalytic reduction of neptunium(V) with formic acid is a first-order reaction with respect to Np(V) for any composition of the reaction mixture. The duration of the induction period depends on the order of the reactants. If Np(V) is added last, the induction period is much longer than if it was formic acid or the catalyst (Fig. 3).

In solutions of HClO<sub>4</sub> with the concentration ≥ 2 mol litre<sup>-1</sup>, the reaction rate was characterised by an apparent first-order rate constant *k*'. If [HClO<sub>4</sub>] was smaller than 2 mol litre<sup>-1</sup>, induction periods were observed in the kinetic curves and the reaction rates were measured in the points corresponding to the 50% conversion of Np(V).

An increase in the catalyst concentration in the reaction mixture resulted in a monotonic increase in the reduction rate.

**Figure 3.** Effect of the mode of initiation of the reaction on the shapes of the kinetic curves in the catalytic reduction of neptunium(V) with formic acid in the presence of 0.1 g ml<sup>-1</sup> of 1% Pt/SiO<sub>2</sub>.<sup>40</sup> [HClO<sub>4</sub>] = 1.0 mol litre<sup>-1</sup>; [HCO<sub>2</sub>H] = 0.5 mol litre<sup>-1</sup>; 59 °C. The reaction was initiated by the addition of Np(V) (1), the catalyst (2) and HCO<sub>2</sub>H (3).

The linear type of the logarithmic dependence  $k'$  vs. (C : R) allowed the estimation of the apparent reaction order with respect to the active sites of the catalyst. For the reaction under consideration, it is equal to  $1.11 \pm 0.04$  in the C : R range from 1 : 100 to 1 : 10.

The rate of the catalytic reduction of neptunium(V) increases with the increase in acid concentration in the solution. At low concentrations of HClO<sub>4</sub> (0.1–1.5 mol litre<sup>-1</sup>) where the reaction occurs with an induction period, the apparent reaction order with respect to perchloric acid changes from 0 to ~0.25, while at 2–4 M HClO<sub>4</sub> it is constant and is equal to  $1.38 \pm 0.06$ . Taking into account the changes in the activity coefficients  $\gamma$  (1.055 and 2.08 for 2 M and 4 M HClO<sub>4</sub>, respectively<sup>41</sup>) the reaction order with respect to hydrogen ions is less than unity.

The rate of the catalytic reduction of Np(V) is independent of [HCO<sub>2</sub>H] in the concentration range 0.04–1.0 mol litre<sup>-1</sup>, but a certain statistically significant increase in the reaction rate with a decrease in [HCO<sub>2</sub>H] from 0.04 to 0.002 mol litre<sup>-1</sup> is observed.

From the temperature dependences of the rate constants measured for 0.1 and 0.005 mol litre<sup>-1</sup> HCO<sub>2</sub>H in 2 M HClO<sub>4</sub>, the apparent activation energy values of  $60 \pm 2$  and  $28.4 \pm 0.8$  kJ mol<sup>-1</sup>, respectively, were determined.

Considering that in 2–4 M HClO<sub>4</sub> the reduction rate is proportional to the activities of the hydrogen ions, the reaction begins with the adsorption of protonated Np(V) ions and HCO<sub>2</sub>H molecules in the active sites Z:

The adsorbed reactants form an activated complex (AC) which is then slowly decomposed:

The independence of  $k'$  of [HCO<sub>2</sub>H] concentration above 0.04 mol litre<sup>-1</sup> is characteristic of catalytic reactions where the surface of the catalyst is saturated with one of the reactants. A decrease in [HCO<sub>2</sub>H] below the adsorption threshold level favours the adsorption of Np(V) ions, which increases the reaction rate

with a decrease in the concentration of the reducing agent. Significant difference in the activation energies obtained at the reducing agent concentrations of 0.1 and 0.005 mol litre<sup>-1</sup> seems to be due to the same reasons. The change in  $E^*$  reflects the fact that the experimental values of the activation energy of a heterogeneous catalytic reaction are in fact apparent, they are related to the true activation energy of a heterogeneous process by an equation:

$$E^* = E_{\text{true}} - \lambda,$$

where  $\lambda$  is the integral heat of adsorption. In the general case,  $\lambda$  depends on the heats of adsorption of the reactants and their molar ratios. The heat of adsorption is the function of the degree of occupation of the active sites, which in turn is determined by the energetic nonuniformity of the catalyst surface. An increase in the concentration of formic acid favours its adsorption on the surface of a platinum catalyst. Since formic acid is used in a large excess, its molecules occupy the most energetically favourable active sites, thus diminishing the heat of adsorption of neptunoyl ions and, as a consequence, increasing the apparent activation energies.

The presence of an induction period in solutions with [HClO<sub>4</sub>] < 2 mol litre<sup>-1</sup> suggests the acceleration of the reaction by one of the reaction products. The fast disappearance of the radical  $\cdot\text{CO}_2\text{H}$  is accompanied by accumulation of Np(IV) (which is probably responsible for the catalytic effect). This ion takes part in several reactions:

The formation of the  $\text{Np}^{4+} \cdot \text{NpO}_2^+$  complex is very likely, since the formation of the  $\text{Th}^{4+} \cdot \text{NpO}_2^+$  complex is now well established (see Ref. 43). The cation–cation complex is adsorbed on the active site. A decrease in the HCO<sub>2</sub>H concentration results in a decrease in the concentration of the formate complex of Np(IV) and in an increase in the yield of the cation–cation complex Np(IV)·Np(V).

After introduction of a catalyst into a solution of Np(V) and HCO<sub>2</sub>H in 1 M HClO<sub>4</sub>, Np(V) ions and HCO<sub>2</sub>H molecules simultaneously attack the surface, which is occupied in proportion to their concentrations and free energies of adsorption. Neptunium(V) occupies only a very small part of the active sites. As the reaction proceeds, Np(IV) is accumulated, the cation–cation complex occupies more active sites than  $\text{NpO}_2^+$ , the reaction is accelerated and the induction period is over.

If HCO<sub>2</sub>H is added last to the reaction mixture, its molecules occupy free active sites and partly displace  $\text{NpO}_2^+$  ions from the occupied positions. Then the reaction follows the scenario described above.

If Np(V) ions are added last, they have to displace HCO<sub>2</sub>H molecules from the occupied active site. As this step is usually very slow, the induction period becomes longer (see Fig. 3).

The catalytic reduction of neptunium(VI) to neptunium(V) with formic acid on Pt/SiO<sub>2</sub> in HNO<sub>3</sub> solutions does not go to completion.<sup>44</sup> Neptunium(VI) remains in the solution at a certain steady-state concentration determined by the fast equilibrium reaction:<sup>19</sup>

In the presence of antinitrite reagents (urea, 0.05–0.5 mol litre<sup>-1</sup>), the reduction of neptunium(VI) to neptunium(IV) proceeds *via* neptunium(V). In this case, the reduction of Np(VI) to Np(V) follows the same kinetic regularities as in HClO<sub>4</sub>. At the same time, the reduction of Np(V) to Np(IV) in HNO<sub>3</sub> in the presence of urea has a number of features that make it different from the reduction in HClO<sub>4</sub>. Thus the absence of an induction period in the catalytic curves of neptunium(V) reduction may be due to complexation, since in HNO<sub>3</sub> the cation–cation interaction  $\text{Np}^{4+} - \text{NpO}_2^+$  is impossible because of the substitution of nitrate ions for water molecules in the hydrate shell of  $\text{Np}^{4+}$ .

Processing of the kinetic curves has shown that the best fit of the experimental results is achieved with the kinetic equation:

$$-\frac{d[\text{Np(V)}]}{d\tau} = k_{0.5}[\text{Np(V)}]^{0.5}.$$

In other words, in this case the order of the reaction is 0.5 with respect to neptunium(V). This is not changed with the increase in neptunium concentration from  $10^{-3}$  to  $10^{-2}$  mol litre $^{-1}$ , which allows one to consider it as a true order [with respect to Np(V)] of the reaction occurring according to a redox mechanism rather than an apparent order of a heterogeneous process. Kinetic measurements performed at different concentrations of formic acid showed that the decrease in  $[\text{HCO}_2\text{H}]$  from 1.0 to 0.01 mol litre $^{-1}$  caused a significant increase in the rate of neptunium(V) reduction. It is of note that in the  $\text{HCO}_2\text{H}$  concentration range from  $\sim 0.1$  to 0.05 mol litre $^{-1}$  the reaction order changes from 0.5 to 1 with respect to Np(V). The rate of the catalytic reduction of neptunium(V) with formic acid increased with the concentration of nitric acid. The reaction orders with respect to  $\text{HNO}_3$  are the same and constitute  $0.71 \pm 0.02$  and  $0.71 \pm 0.01$  for the reaction orders 0.5 and 1, respectively. The temperature dependences  $k_{0.5}$  and  $k_1$  in the range from 40 to 70 °C correspond to the values of apparent activation energies ( $43.6 \pm 1.5$  and  $30 \pm 2$  kJ mol $^{-1}$ , respectively).

It was suggested<sup>44</sup> that the mechanism of the catalytic reduction of Np(V) with formic acid in  $\text{HNO}_3$  in the presence of urea is generally similar to that in  $\text{HClO}_4$  and can be described by reactions (10)–(16). However, this reaction scheme cannot be regarded as a comprehensive presentation of events that take place in the catalytic reduction of Np(V) with formic acid in  $\text{HNO}_3$ . This covers a relatively narrow range of experimental conditions ( $[\text{HCO}_2\text{H}] < 0.1$  mol litre $^{-1}$ ) where the reaction follows the first order with respect to neptunium(V). The reason for the order of 0.5 with respect to Np(V) at  $[\text{HCO}_2\text{H}] < 0.1$  mol litre $^{-1}$  is still obscure. In the general case, the reaction order 0.5 with respect to a reagent in heterogeneous catalytic processes is associated with its chemisorption on two adjacent sites of the catalyst, as follows from the Langmuir equation of the chemisorption isotherm.<sup>45</sup> Thus, it may be assumed that at a high degree of occupation of the catalyst with formic acid, secondary adsorption of  $\text{NpO}_2^+$  ions occurs on two adjacent catalytic sites formed by the adsorbed  $\text{HCO}_2\text{H}$  molecules. The composition of the activated complex formed is conventionally described by the formula  $\{\text{ads}\cdot\text{HO}_2\text{C}-\text{H}\cdots\text{O}=\text{Np}^+=\text{O}\cdots\text{H}-\text{CO}_2\text{H}_{\text{ads}}\}^*$ , while decomposition of this charge-transfer complex is accompanied by the generation of the species ( $\text{O}=\text{Np}^+-\text{OH}$ ,  $\text{CO}_2\text{H}$ ) and a molecule of formic acid followed by the fast reactions (15) and (16).

The catalytic reduction of neptunium with formic acid using 1% Pt/ $\gamma$ - $\text{Al}_2\text{O}_3$  (grain size = 3–5 mm) as a catalyst for the preparation of neptunium(IV) sols has been studied.<sup>46</sup> The most complete reduction of Np(V) occurred where the initial concentrations of Np(V) and  $\text{HCO}_2\text{H}$  were 0.5 mol litre $^{-1}$ . Higher concentrations of  $\text{HCO}_2\text{H}$  resulted in a higher percentage of Np(V) in the sols. At a concentration of Np(V)  $\leq 0.1$  mol litre $^{-1}$ , the reduction was incomplete.

The concentration of Np(V) did not change over 5 h at 50–60 °C in 1–5 M NaOH solutions containing formate. The addition of  $\text{PdCl}_2$  ( $2 \times 10^{-3}$  mol litre $^{-1}$ ) resulted in formation of metallic palladium where Np(IV) hydroxide sedimented.<sup>47</sup> This process includes the reaction of hydrolysed Pd(II) ions with formate ions and formation of Pd(0). Palladium ions aggregate to form particles with a well-developed surface. Adsorption of formate and Np(V) ions on the active sites of the catalyst results in the reduction of Np(V). Platinum derivatives appeared to be less efficient in the reduction of Np(V) with formate.

The reduction of Np(V) with formate in alkaline solutions was studied in the presence of palladium or platinum on anion-exchange resins.<sup>47</sup>

### 3. Plutonium

The heterogeneous catalytic reactions of plutonium ions reported so far include reduction with hydrogen, hydrazine and formic acid in acidic media and reduction of plutonium(VII) with water in alkaline media.

In the presence of platinised platinum, Pu(VI) was reduced to Pu(V) with gaseous hydrogen. Hydrogen was passed through a solution of Pu(VI) ( $3.1 \times 10^{-3}$  mol litre $^{-1}$ ) in 0.5 M HCl for 15 min at room temperature. Forty minutes later, the composition of the solution was as follows: 10% Pu(VI), 14% Pu(V), 6% Pu(IV) and 70% Pu(III). In 0.5–4 M HCl, the reduction of Pu(IV) (0.02 mol litre $^{-1}$ ) with hydrogen (40 min, room temperature) reaches 99% provided that 2 cm $^2$  of platinised platinum per ml of the solution was used and hydrogen was passed at a rate of 5 ml min $^{-1}$  per ml of the solution.<sup>48</sup>

A mixture of  $\text{H}_2$  (4%) and Ar (96%) was used for the reduction of Pu(IV) to Pu(III) in tributyl phosphate (TBP) with simultaneous reextraction of Pu(III) into the aqueous phase.<sup>49</sup> This was carried out on a column. Equal volumes of 0.5 M  $\text{HNO}_3$  and 30% TBP containing U(VI) (95 g litre $^{-1}$ ), Pu(IV) (1 g litre $^{-1}$ ) and  $\text{HNO}_3$  (0.1 mol litre $^{-1}$ ) were passed through a column filled with  $\text{Al}_2\text{O}_3$  beads coated with 0.5% Pt; the elution time was  $\sim 10$  min. The extent of the Pu reduction was 99% and that of U, 1%. The reduction of U reached  $\sim 3\%$  if pure hydrogen was used.

A 0.5% Pt/ $\text{Al}_2\text{O}_3$  catalyst was used<sup>5</sup> to increase the reaction rate of Pu(IV) with hydrazine in argon at 25 °C. The results obtained in the presence and in the absence of U(VI) are summarised in Table 1.

**Table 1.** Catalytic reduction of plutonium(IV) in 2 M  $\text{HNO}_3$  containing 0.1 mol litre $^{-1}$  of  $\text{N}_2\text{H}_5\text{NO}_3$  at 25 °C.<sup>5</sup>

| [Pu(IV)] $\times 10^3$<br>/mol litre $^{-1}$ | Exposure time<br>/min | [Pu(III)] $\times 10^3$ /mol litre $^{-1}$            |                            |

| 4.7                                          | 1                     | 1.6                                                   | 1.4                        |
|                                              | 3                     | 3.3                                                   | 2.8                        |
|                                              | 5                     | 4.3                                                   | 3.8                        |
|                                              | 7                     | —                                                     | 4.4                        |

These data suggest that the reduction of Pu(IV) occurs according to two routes, *viz.*, as the catalytic reduction of Pu(IV) itself with hydrazine and as the catalytic reduction of U(VI) to U(IV), which then quickly reduces Pu(IV). The kinetic dependences for U(IV)-free Pu(IV) solutions appear as straight lines, *i.e.*, the reaction rate does not depend on the concentration of Pu(IV).

The catalytic reduction of Pu(IV) with hydrazine on platinum-on-silica gel (grain size = 0.5–1 mm) as a catalyst was studied in more detail.<sup>50</sup> The reaction rates of Pu(IV) [ $(0.7-1) \times 10^{-2}$  mol litre $^{-1}$ ] with hydrazine (0.025–0.2 mol litre $^{-1}$ ) in 1.5–4 M  $\text{HNO}_3$  (C : R = 1 : 100) depended only slightly on the stirring intensity.

The kinetic curves for the loss of [Pu(IV)] were rectified in the semilogarithmic coordinates, *i.e.*, the reduction virtually followed the first-order law. The rate constant of the first-order reaction  $k'$  increased linearly with the catalyst concentration. An increase in the platinum content on the support resulted in a linear increase in the rate constant. The reaction order with respect to hydrazine was 0.5. In 1.5–4 M  $\text{HNO}_3$ , hydrogen ions had no effect on the reaction rate. The activation energy in the temperature range 30–60 °C was equal to 23 kJ mol $^{-1}$ . This is somewhat higher than the corresponding values for the mass transfer-controlled

reactions. It may thus be concluded that the catalytic reaction occurred in a virtually kinetic regime.

The reduction process can schematically be presented as follows. Its first step includes adsorption of  $\text{N}_2\text{H}_3^+$  and  $\text{Pu(IV)}$  ions [ $\text{Pu}^{4+}$  forms nitrate complexes  $\text{PuNO}_3^{3+}$ ,  $\text{Pu(NO}_3)_2^{2+}$ , etc.]. Adsorbed hydrazine reacts with  $\text{Pu(IV)}$  either in an electron-transfer mode (from hydrazine to plutonium) through Pt–Pt bridges or by preliminary formation of an activated complex, which is further decomposed to  $\text{Pu(III)}$ ,  $\text{N}_2\text{H}_3$  and  $\text{H}^+$ . Part of the radicals reduce  $\text{NO}_3^-$  and  $\text{Pu(IV)}$ , while the other part undergoes dimerisation to give  $\text{NH}_4^+$  and  $\text{N}_2$ .

Catalysts based on ruthenium,<sup>51</sup> activated charcoal<sup>52</sup> and heteropoly compounds were also used for the reduction of  $\text{Pu(IV)}$  with hydrazine.<sup>53</sup> The ruthenium catalysts were prepared by treatment of silica gel (grain size = 0.5–1 mm) with ruthenium nitronitrate with subsequent drying and reduction with hydrogen at 350–500 °C. Studies of the catalytic reduction of  $\text{Pu(IV)}$  solutions ( $1 \times 10^{-2}$  mol litre<sup>-1</sup>) with hydrazine revealed that the reaction rate depended on the stirring intensity. Therefore, the rate of stirring was selected so as to ensure the kinetic regime. The concentration of  $\text{Pu(IV)}$  decreased with time according to the first-order reaction, and the reaction rate increased linearly with the amount of the catalyst (the C:R ratio varied from 1:100 to 1:10) and the Ru content (the latter varied from 0.5% to 5%). The orders of the reactions with respect to hydrazine (0.1–0.5 mol litre<sup>-1</sup>) and hydrogen ions (0.5–4.8 mol litre<sup>-1</sup> of  $\text{HNO}_3$ ) were ~1 and –1, respectively. The activation energy was 78 kJ mol<sup>-1</sup> at 30–60 °C.

It was suggested that  $\text{N}_2\text{H}_3^+$  and  $\text{Pu(IV)}$  ions adsorbed on the catalyst formed an activated complex with simultaneous elimination of a hydrogen ion:

The activated complex was slowly converted into  $\text{Pu(III)}$ ,  $\text{N}_2\text{H}_3$  and  $\text{H}^+$ .

Ruthenium catalysts are less effective than their platinum analogues, but their advantage over the latter is very slow decomposition of hydrazine.

It was recommended to use activated charcoal for the reduction of  $\text{Pu(IV)}$  (1–20 g litre<sup>-1</sup>) in  $\text{HNO}_3$  solutions (0.1–1 mol litre<sup>-1</sup>) containing  $>0.2$  mol litre<sup>-1</sup>  $\text{N}_2\text{H}_5\text{NO}_3$ .<sup>52</sup> Activated charcoal (50–100 g litre<sup>-1</sup>) effected 99.5% reduction of  $\text{Pu(IV)}$  (1.2 g litre<sup>-1</sup>) in 30 min.

It was found<sup>53</sup> that support of  $\text{Cs}_5\text{PV}_2\text{Mo}_{10}\text{O}_{40}$  onto silica gel increased the rate of  $\text{Pu(IV)}$  reduction with hydrazine in  $\text{HNO}_3$ . The catalyst was prepared by impregnating silica gel (grain size = 0.5–1 mm) with a solution of a heteropolyacid or its sodium salt and subsequent treatment with a solution of a caesium salt. This resulted in formation of a poorly soluble heteropoly compound (HPC) on the surface of  $\text{SiO}_2$ . The concentration of HPC on  $\text{SiO}_2$  was 1 mol.%–10 mol.%. The reduction of  $\text{Pu(IV)}$  depended only slightly on the stirring intensity, *i.e.*, it occurred in a nearly kinetically-controlled mode. The reaction rate was described by a first-order equation with respect to  $\text{Pu(IV)}$ . In the presence of 10% HPC/ $\text{SiO}_2$ , the first-order rate constant increased linearly with a change in C:R from 1:100 to 1:20, while the decrease in the HPC content on the support decreased the rate constant. The calculated value of the activation energy was 80 kJ mol<sup>-1</sup> at 25–80 °C.

In contrast to platinum catalysts, HPC/ $\text{SiO}_2$  did not increase the rate of  $\text{U(VI)}$  reduction with hydrazine in  $\text{HNO}_3$  solutions. It was suggested<sup>53</sup> that hydrazine caused the reduction of the heteropolyanion (HPA)  $\text{PV}_2\text{Mo}_{10}\text{O}_{40}^{5-}$  to the so-called 'heteropolyblue' which had a heteropolyanionic structure. For  $\text{PV}_2\text{Mo}_{10}\text{O}_{40}^{5-}$ , the first half-wave of reduction  $E_{1/2}$  was about 0.65 V;<sup>54</sup> therefore, the 'heteropolyblue' was able to convert  $\text{Pu(IV)}$  into  $\text{Pu(III)}$  through oxidation to the original HPC.

As mentioned above, finely dispersed platinum accelerates the reduction of  $\text{Np(VI)}$ ,  $\text{Np(V)}$  and  $\text{Pu(IV)}$  with hydrazine in  $\text{HNO}_3$  solutions to give  $\text{Np(IV)}$  and  $\text{Pu(III)}$ . In 6–8 M  $\text{HNO}_3$ , the former

yields anionic complexes with the composition  $\text{Np(NO}_3)_n^{4-n-}$ , which can be adsorbed on anion-exchange resins. This is not inherent in  $\text{Pu(III)}$  nitrate complexes. Therefore, 1% Pt/VP-1Ap was used as a catalyst for the reduction and separation of neptunium and plutonium.<sup>55</sup> Passage of a solution of a neptunium–plutonium mixture of any valence state in 6–7 M  $\text{HNO}_3$  containing hydrazine through a layer of the anion-exchange resin with supported platinum resulted in sorption of  $\text{Np(IV)}$ , while  $\text{Pu(III)}$  remained in the eluate. The effects of various factors (*e.g.*, the mode of preparation of the catalyst, temperature variation from 30 to 50 °C, hydrazine concentration [0.1–0.2 mol litre<sup>-1</sup>]) on the separation of the neptunium–plutonium mixture have been studied.<sup>55</sup> Under optimum conditions, neptunium contained no more than  $2 \times 10^{-3}\%$  of plutonium. In addition to platinum-based catalysts, the separation of neptunium and plutonium was carried out on anion-exchange resins with a supported heteropolyanion in  $\text{HNO}_3$  containing hydrazine.<sup>56</sup> The catalysts were prepared by sorption of  $\text{PV}_2\text{Mo}_{10}\text{O}_{40}^{5-}$  on various anion-exchange resins (VP-1Ap, VPBs, PX-1, AV-17), the former being catalysts of choice (the grain size was 0.18–0.63 mm). The effects of the catalyst preparation procedure, the content of HPA on the resin, the concentration of hydrazine in the solution as well as of temperature on the degree of separation of neptunium and plutonium were investigated.

The catalytic reduction of  $\text{Pu(IV)}$  in the process of denitration with excess of formic acid in highly radioactive solutions containing palladium and ruthenium was studied.<sup>57</sup> Partial reduction of  $\text{Pu}$  to the trivalent state was also observed<sup>58</sup> in the final step of the catalytic denitration of plutonium-containing solutions in the presence of 1% Pt/ $\text{SiO}_2$ . It was suggested<sup>57</sup> that  $\text{Pu(IV)}$  was reduced with atomic hydrogen formed upon catalytic decomposition of  $\text{HCO}_2\text{H}$  on the surface of reduced blacks of noble metals. No hydrogen formation was observed upon catalytic denitration on Pt/ $\text{SiO}_2$ ,<sup>58</sup> therefore, it was concluded that the reduction of  $\text{Pu(IV)}$  under these conditions results from direct catalytic reaction of  $\text{Pu(IV)}$  with  $\text{HCO}_2\text{H}$ . More recent investigations (including kinetic studies)<sup>59</sup> have shown that  $\text{Pu(IV)}$  was completely and irreversibly reduced to the trivalent state in 0.27–2.0 M  $\text{HNO}_3$  containing formic acid and urea in the presence of 1% Pt/ $\text{SiO}_2$ . In the presence of urea, the catalytic reduction of  $\text{Pu(IV)}$  with formic acid proceeded at a noticeable rate even at room temperature. If the reaction was carried out at 60 °C, the reduction of  $\text{Pu(IV)}$  (0.01 mol litre<sup>-1</sup>) with formic acid (0.5 mol litre<sup>-1</sup>) in 1 M  $\text{HNO}_3$  was complete within less than 10 min. The rate of catalytic reduction of plutonium(IV) did not depend on the intensity of stirring of the reaction mixture with nitrogen, *i.e.*, in this case we deal with a kinetically controlled first-order reaction with respect to  $\text{Pu(IV)}$ . The fact that the reaction rate did not depend on the urea concentration in the range 0.05–1.0 mol litre<sup>-1</sup> places additional emphasis on the role of  $(\text{NH}_2)_2\text{CO}$  as an antinitrite agent. Virtually no effect of the concentration of formic acid (from 0.2 to 1.0 mol litre<sup>-1</sup>) on the rate constant  $k'$  was observed. The rate of plutonium(IV) reduction depended only slightly on the concentration of  $\text{HNO}_3$  in the range from 0.3 to 2.0 mol litre<sup>-1</sup>. Further increase in nitric acid concentration resulted in rapid decomposition of urea accompanied by abundant gas evolution and denitration of the solution. Under these conditions, plutonium(IV) was first partly reduced to the trivalent state and then oxidised as urea decomposed. The activation energy of this process at 30–60 °C was  $29.6 \pm 1.8$  kJ mol<sup>-1</sup>.

In the authors' opinion, the reduction of  $\text{Pu(IV)}$  on the catalyst surface proceeds *via* an activated complex:

its slow decomposition yields  $\text{Pu(III)}$  and the radical  $^*\text{CO}_2\text{H}$

The radical  $^*\text{CO}_2\text{H}$  formed reacts with  $\text{Pu(IV)}$  ions:

The overall stoichiometry of this reaction appears as:

A possibility of adsorption of Pu(IV) ions on the active sites vicinal to  $(\text{HCO}_2\text{H})_{\text{ads}}^*$  with subsequent charge transfer through the catalytic bridge Pt–Pt and decay of the radical  $(\cdot\text{HCO}_2\text{H})_{\text{ads}}^*$  into  $\cdot\text{CO}_2\text{H}$  and the hydrogen ion was also considered. However, these two processes were found to be kinetically indistinguishable.

It was also found<sup>58</sup> that formic acid derivatives, *viz.*, formaldehyde and formamide, also efficiently reduce plutonium(IV) in the presence of a catalyst (1% Pt/SiO<sub>2</sub>).

The effect of immersion of platinum, graphite and lead dioxide electrochemically deposited on a platinum support on the stability of Pu(VII) solutions in 0.5 M NaOH was studied.<sup>60</sup> It was found that these conductive non-reducing materials decreased markedly the stability of Pu(VII) as could be judged from the formation of oxygen bubbles on the surface of the submerged materials. However, no visible changes occurred with the materials themselves. Thus, they exerted a purely catalytic effect on the Pu(VII) reduction. The reduction of Pu(VII) with water in the presence of the assayed electrode materials proceeded as a first-order reaction with respect to Pu(VII). The rate constants  $k'$  increased linearly with the increase in the visible surface area of the electrode materials, which is in good accord with the concepts of heterogeneous kinetics. Under comparable conditions, the rates of catalytic reduction of Pu(VII) being in contact with these electrode materials decreased in the following order: Pt > PbO<sub>2</sub>/Pt > graphite. In the authors' opinion, the catalytic effect of the conductive materials on the Pu(VII) reduction with water is electrochemical in its character. Plutonium(VII) created a high potential on the surface (0.98 V), which exceeded the sum of the equilibrium potential for H<sub>2</sub>O oxidation in alkaline solutions and the overvoltage of liberation of oxygen on this material. Hence, the electrode material becomes an anode where oxygen evolves owing to the catalytic reduction of Pu(VII).

Presumably, the molecular mechanism of the catalytic reduction of Pu(VII) with water in the presence of platinum, graphite and PbO<sub>2</sub> on platinum consists merely of electron transfer from hydroxyl ions and water molecules adsorbed on the surface to Pu(VII) ions.

#### 4. Americium

Americium(V) is rather stable in weakly acidic aqueous solutions. Many reducing agents including multielectron agents, *e.g.*, hydrazine, hydroxylamine, formic acid and other organic acids, virtually do not react with Am(V). The chemical stability of Am(V) is determined by kinetic rather than thermodynamic factors [the potential of the Am(V)/Am(III) pair is 1.72 V (see Ref. 36)]. However, the low potential of the Am(V)/Am(IV) pair and high first potentials of the reducing agents should be taken into consideration. Therefore, catalysts should accelerate the reduction.

Some reduction reactions of americium(V) in the presence of 1% Pt/SiO<sub>2</sub> as a catalyst have been studied.<sup>61</sup> The reduction pattern depended on the intensity of an air flow through the reaction mixture. However, in the majority of cases where the air passed through a 20 ml solution at 5 litre h<sup>−1</sup> and higher rates, the reaction rate only slightly depended on the stirring efficiency. Thus, these reactions are predominantly kinetically controlled. The results of the experiments carried out at 25 °C (C : R = 1 : 20) and an air flow of 6 litre h<sup>−1</sup> are summarised in Table 2. It can be seen that finely dispersed platinum increased the reaction rate not only in the presence of conventional reducing agents (N<sub>2</sub>H<sub>5</sub><sup>+</sup>, H<sub>2</sub>O<sub>2</sub>), but also in the presence of nitrilotriacetic acid (NTA), EDTA and even ethylene glycol.

The change in pH from 1 to 4 had little effect on the reduction. This was accelerated with an increase in temperature and decreased almost linearly with a drop of C : R ratio from 1 : 5 to

**Table 2.** Reduction of Am(V) [(0.6–1.5) × 10<sup>−3</sup> mol litre<sup>−1</sup>] in the presence of 1% Pt/SiO<sub>2</sub> (0.05 g litre<sup>−1</sup>) at 25 °C.<sup>61</sup>

| Reducing agent (X)                         | [X] / mol litre <sup>−1</sup> | pH  | Reduction time (50%) / min |
|--------------------------------------------|-------------------------------|-----|----------------------------|
| N <sub>2</sub> H <sub>5</sub> <sup>+</sup> | 0.05                          | 1   | 6.5                        |
| H <sub>2</sub> O <sub>2</sub>              | 0.0075                        | 1   | 120                        |
|                                            | 0.18                          | 1   | 50                         |
| HCO <sub>2</sub> H                         | 0.5                           | 1   | 6                          |
| Tartaric acid                              | 0.5                           | 4   | < 5                        |
| Nitrilotriacetic acid (NTA)                | 0.4                           | 3   | ~ 50                       |
| EDTA                                       | 0.01                          | 1   | 150                        |
| Acetoxime                                  | 0.25                          | 2.3 | ~ 50                       |
| Formaldehyde                               | 0.5                           | 1   | ~ 60                       |
| Ethylene glycol                            | 0.5                           | 1   | 50                         |

1 : 50. The reduction rate increased with the increase in the Pt content on the silica gel surface from 0.1% to 4%, however, to a lesser degree than the increase in the platinum content.

These data prompt several conclusions about the mechanisms of this reduction. Presumably, transfer of an electron or a hydrogen atom from the adsorbed reducing agent to the Am(V) ion also adsorbed on the platinum surface is the limiting step. The Am(IV) ions formed either undergo disproportionation or react with the reducing agent. Higher local concentration of Am(IV) favours disproportionation due to adsorption on the catalyst. Moreover, by virtue of its high oxidation potential Am(IV) is highly reactive with respect to the reducing agents mentioned above.

It was found<sup>62</sup> that trace amounts of metallic platinum accelerated dramatically the reduction of Am(VI) with formic acid, especially at pH > 4.

### III. Catalytic decomposition of organic and inorganic components of liquid radioactive wastes

The reprocessing of radioactive wastes (including those of the nuclear fuel cycle) is often complicated without preliminary removal of certain organic and inorganic impurities, such as complexones, oxalic acid, hydrazine, hydrazoic acid, urea, excess nitric acid, nitrates, *etc.* This problem is successfully overcome by heterogeneous catalytic decomposition of these compounds in HNO<sub>3</sub> solutions or the use of strong oxidants, *e.g.*, ozone, bichromate, permanganate.<sup>63,64</sup> Catalytic reactions are preferable, since no additional reactants are needed.

#### 1. Decomposition of complexones

It was found<sup>65</sup> that polyaminopolycarboxylic complexones are decomposed at moderate rates upon heating of their solutions in HNO<sub>3</sub> in the presence of heterogeneous catalysts, such as Pt/SiO<sub>2</sub>, Pt/anion-exchange resin AV-17, activated charcoals AG-3, BAU, SKT, *etc.*

The decomposition of diethylenetriaminopentaacetic acid (DTPA) (0.05 mol litre<sup>−1</sup>) in HNO<sub>3</sub> in the presence of 1% Pt/SiO<sub>2</sub> (C : R = 1 : 10) at 40–80 °C proceeded as a first-order reaction with respect to DTPA. The quantitative characteristics of this reaction were calculated from the half-time  $\tau_{1/2}$ , *i.e.*, the time required for a twofold decrease in the complexone concentration.

The decomposition rate of DTPA increased with the increase in the HNO<sub>3</sub> concentration from 0.5 to 2.0 mol litre<sup>−1</sup>. Further increase in [HNO<sub>3</sub>] inhibited the reaction. The reaction rate increased as the content of Pt on SiO<sub>2</sub> changed from 0.5% to 2%. The activation energy was 67 kJ mol<sup>−1</sup>. The use of the anion-exchange resin AV-17 instead of silica gel as a support for platinum decreased the decomposition rate of DTPA 20-fold. This suggests direct involvement of the support in the formation of active sites of the catalyst.

Organic and inorganic impurities can be removed from all known brands of activated charcoals by washing. Their concen-

tration was the lowest in BAU, therefore, this was selected for kinetic studies. The rate of DTPA decomposition in the presence of BAU charcoal (C : R = 1 : 10) increased with the HNO<sub>3</sub> concentration, although to a far lesser degree than in the presence of Pt/SiO<sub>2</sub>. The activation energy at 50–80 °C was equal to ~61 kJ mol<sup>-1</sup>.

In contrast to DTPA, the decomposition of EDTA (0.05 mol litre<sup>-1</sup>) in 0.3–0.5 M HNO<sub>3</sub> in the presence of BAU charcoal (C : R = 1 : 10) was described by a zero- or a close to zero-order rate constant with respect to the complexone. In 1–2 M HNO<sub>3</sub> solutions, the decomposition rate increased nearly twofold.

A series of experiments were devoted to the elucidation of the role of the anion in the decomposition of DTPA and EDTA in the presence of BAU (C : R = 1 : 10, 80 °C). Hydrochloric, perchloric and sulfuric acids (0.5–2.0 M) had similar effects on the catalytic decomposition of complexones and were nearly 100 times less efficient than HNO<sub>3</sub>. Similar results were obtained in the presence of Pt/SiO<sub>2</sub>.

The following scheme for the process was suggested. The first step included sorption of the complexone molecule on the active site of the catalyst. The adsorbed molecule underwent thermal decomposition in HCl, HClO<sub>4</sub> and H<sub>2</sub>SO<sub>4</sub>. In HNO<sub>3</sub> solutions, the adsorbed species were subject to an attack by NO<sub>3</sub><sup>-</sup> (or NO<sub>2</sub><sup>+</sup>) ions and were oxidised. No complexone decomposition products were identified, therefore, it is difficult to specify the details of the reaction mechanism.

## 2. Decomposition of oxalic acid

Decomposition on solid-phase catalysts is the most convenient and reliable method for removal of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> from nitric acid solutions.<sup>66</sup> Different brands of activated charcoals, platinum on silica gel and on anion-exchange resins AV-17 and VP-3Ap were assayed as such catalysts.

In semilogarithmic coordinates, the kinetic curves for H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> decomposition in the presence of 1% Pt/SiO<sub>2</sub> appeared as straight lines up to the degree of conversion of 85%–90%. Then the reaction rate showed a further increase. In the authors' opinion, the gaseous products generated in the first steps of the reaction prevent penetration of the solution into the pores. Gas evolution slowed down to the end of the process, which results in an increase in the effective surface area of the catalyst and a parallel increase in the reaction rate. The decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> to the degree of conversion of 90% is characterised by a first-order equation with respect to H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> and a first-order rate constant.

An increase in the rate of air flow through the solution (10 ml) from 50 to 400 ml min<sup>-1</sup> caused only a small (1.4-fold) increase in *k*. This suggests that the decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> is predominantly under kinetic control.

The rate of the catalytic decomposition increased threefold with an increase in the HNO<sub>3</sub> concentration from 1 to 3 mol litre<sup>-1</sup>. No catalytic decomposition of oxalic acid took place in HCl, HClO<sub>4</sub> and H<sub>2</sub>SO<sub>4</sub>. An increase in the amount of the catalyst resulted in an increase in the reaction rate. The activation energy of decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> (0.3 mol litre<sup>-1</sup>) in 2.5 M HNO<sub>3</sub> in the presence of 1% Pt/SiO<sub>2</sub> (C : R = 1 : 10) was 54.8 kJ mol<sup>-1</sup> at 40–70 °C. The decomposition rate of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> increased ~ fourfold with an increase in the Pt content on silica gel from 0.25% to 4%.

The catalysts prepared by reduction of H<sub>2</sub>PtCl<sub>6</sub> with hydrogen or boiling hydrazine hydrate possessed similar efficiencies.

The effect of impurities on the catalytic decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> in 2.5 M HNO<sub>3</sub> at 60 °C in the presence of 1% Pt/SiO<sub>2</sub> (C : R = 1 : 10) has also been studied. The presence of Ni(II) (0.1 g litre<sup>-1</sup>) and U(VI) (5 g litre<sup>-1</sup>) had little effect on the reaction rate. At the same time, the decomposition rate decreased in the presence of Cr(III) (2 g litre<sup>-1</sup>), Fe(III) (5 g litre<sup>-1</sup>) and Pu(IV) (0.3 g litre<sup>-1</sup>), apparently as a result of formation of oxalate complexes.

Stirring of solutions with catalysts results in attrition wear and crushing of silica gel. The concentration of silicon during H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> decomposition at 60 °C reached 20–30 mg litre<sup>-1</sup>. This drawback is absent from the catalysts prepared by absorption of PtCl<sub>6</sub><sup>-</sup> on the anion-exchange resins AV-17 and VP-3Ap and subsequent reduction of platinum with hydrazine. The catalysts thus prepared were activated by refluxing in 2–4 M HCO<sub>2</sub>H for 15–30 min and were only slightly inferior to catalysts based on silica gel in the ability to decompose H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>.

The decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> in HNO<sub>3</sub> solutions in the presence of seven different brands of activated charcoals without additional stirring has been studied. Stirring was effected by the gas evolved during the reaction. Upon heating to 80–100 °C, the decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> in the presence of activated charcoals proceeded at moderate rates. The reaction rate increased with the increase in the C : R ratio. With BAU charcoal, the maximum value of C : R did not exceed 1 : 3.5.

In addition to static experiments, the decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> was studied upon continuous passage of the solution through a column filled with the catalyst. The solution was fed into the thermostated column from the bottom. The degree of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> decomposition depended on the flow rate of the solution.

In the presence of hydrazine, the mode of decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> changed considerably.<sup>67</sup> The concentration of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> remained constant until the decomposition of N<sub>2</sub>H<sub>5</sub><sup>+</sup> was nearly complete and diminished only thereafter. This suggests that hydrazine inhibits the catalytic decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> in HNO<sub>3</sub> solutions and that its effect is related to removal of HNO<sub>2</sub> from the solution.

The stoichiometry and the mechanism of heterogeneous catalytic decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> in nitric acid solutions have been studied.<sup>68</sup> Under the conditions specified (1% Pt/SiO<sub>2</sub>, 80 °C, [H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>] = 0.3 mol litre<sup>-1</sup>, exposure time 30 min), the ratio  $n = \Delta[\text{HNO}_3]/\Delta[\text{H}_2\text{C}_2\text{O}_4]$  was 0.4–0.5; it changed only slightly in 0.2–0.5 M HNO<sub>3</sub> and increased to 1.01 and 1.74 in 5 and 7 M HNO<sub>3</sub>, respectively. In 7 M HNO<sub>3</sub>, the value of *n* dropped to 1.1 with an increase in the exposure time. A decrease in temperature had no effect on this parameter (at 50 °C in 7 M HNO<sub>3</sub>, *n* was equal to 0.9). In an argon atmosphere, the value of *n* exceeded those in aerated solutions.

In the presence of Pt/anion-exchange resins, the decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> proceeded with virtually the same stoichiometry as with 1% Pt/SiO<sub>2</sub>.

Nitric acid at a concentration ≥ 7 mol litre<sup>-1</sup> behaves as a one- or two-electron oxidant of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>.

This was concomitant with more profound partial reduction of nitric acid.

In dilute solutions, the reaction of HNO<sub>3</sub> with H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> is described by the equation:

The reaction:

also takes place.

Thus, the increase in HNO<sub>3</sub> concentration prevents its more complete reduction with oxalic acid.

The IR spectra of gaseous products obtained under different conditions of catalytic oxidation of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> contained the bands corresponding to NO<sub>2</sub>, N<sub>2</sub>O<sub>4</sub>, CO<sub>2</sub> and H<sub>2</sub>O. No bands corresponding to NO or N<sub>2</sub>O were detected.

The decomposition of H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> in solutions containing HNO<sub>3</sub> (0.2 mol litre<sup>-1</sup>) and variable amounts of HClO<sub>4</sub> in the presence of 1% Pt/SiO<sub>2</sub> (C : R = 1 : 2, 60 °C) reached 6%, 31% and 68% after 60 min, [H<sup>+</sup>] being 0.2, 1.2 and 2.2 mol litre<sup>-1</sup>, respectively.

This suggests that  $H^+$  ions are involved in the rate-determining step or in a preceding step.

The dependence of the decomposition rate of  $H_2C_2O_4$  ( $0.33 \text{ mol litre}^{-1}$ ) on the reaction conditions (1% Pt/SiO<sub>2</sub>, C:R = 1:2, 60 °C, 90 min) in the presence of  $HNO_2$  ( $0.17 \text{ mol litre}^{-1}$ ) can be seen from the following data (no decomposition occurred in the absence of  $HClO_4$  and  $HNO_3$ ):

| $[HClO_4]/\text{mol litre}^{-1}$ | $[HNO_3]/\text{mol litre}^{-1}$ | Degree of decomposition (%) |
|----------------------------------|---------------------------------|-----------------------------|
| 2                                | —                               | 5                           |
| —                                | 0.2                             | 80                          |

The decomposition of  $H_2C_2O_4$  depends on  $[HNO_2]$ : the loss of  $H_2C_2O_4$  in a solution containing  $0.2 \text{ mol litre}^{-1}$   $HNO_3$  and  $0.17 \text{ mol litre}^{-1}$   $HNO_2$  was 80% (*cf.* 6% in  $0.2 \text{ M}$   $HNO_3$  containing minor amounts of  $HNO_2$ ). The reaction does not go further after removal of trace amounts of  $HNO_2$  with hydrazine. In the absence of  $HNO_3$  no reaction occurred either. It is the simultaneous presence of nitric and nitrous acids that brings about the catalytic decomposition of  $H_2C_2O_4$ .

The catalytic reaction occurs through sorption of the reducing agent ( $H_2C_2O_4$ ) and the oxidant. In the authors' opinion,<sup>68</sup> the role of the oxidant is played by  $NO_2^+$  ions and NO molecules formed in the equilibrium reactions (6) and (7). The formation of the intermediate oxidising species ZA in the active catalytic site Z proceeds in conformity with reactions (8) and (9). Subsequent conversions include the following reactions:

If the concentration of  $HNO_3$  (and, correspondingly, of  $NO_2^+$ ) is small, the reaction probably follows another pathway:

High concentrations of  $NO_3^-$  ions trigger the reaction:

In addition, molecular oxygen oxidises intermediate reducing species.

### 3. Decomposition of hydrazine

The kinetics and mechanisms of catalytic decomposition of hydrazine in the presence of various catalysts were studied in detail. The results of these investigations are generalised in a monograph.<sup>69</sup> The studies cited therein are devoted to the catalytic decomposition of anhydrous  $N_2H_4$  or the hydrate  $N_2H_4 \cdot H_2O$  in the gaseous or liquid state. Therefore, the available data do not provide an adequate explanation for the behaviour of hydrazine in the presence of heterogeneous catalysts in acidic solutions where it exists in the form of the hydrazinium ion,  $N_2H_5^+$ .

The stoichiometry, kinetics and mechanism of the catalytic decomposition of hydrazine were studied in solutions of perchloric and sulfuric acids in the presence of 1% Pt/SiO<sub>2</sub> as a catalyst.<sup>70</sup> It was found that the catalytic decomposition of hydrazine was accompanied by the formation of ammonium ions and nitrogen. It is noteworthy that the stoichiometric ratio  $[N_2H_5^+]:[NH_4^+]$  was  $0.746 \pm 0.08$  and did not depend on the nature of the acid ( $HClO_4$  or  $H_2SO_4$ ) or the concentration of hydrogen ions in the range from  $0.3$  to  $3 \text{ mol litre}^{-1}$ , *i.e.*, the decomposition of hydrazine occurred according to the equation:

Kinetic studies revealed that the reaction order with respect to hydrazine was variable and changed from 0.2 to 1 with the decrease in  $[N_2H_5^+]_0$  from  $0.2$  to  $0.01 \text{ mol litre}^{-1}$ . The fractional order of the reaction with respect to hydrazine was probably

apparent and reflected the adsorption-type character of heterogeneous catalytic decomposition of hydrazine. Actually, this reaction was of zero and first orders with respect to  $N_2H_5^+$  and the contribution of each of them to the overall process depended on the concentrations of hydrazine and the amount of the catalyst in the reaction system. At low initial hydrazine concentrations ( $0.01 \text{ mol litre}^{-1}$ ) where the catalytic decomposition strictly followed first-order kinetics with respect to  $N_2H_5^+$ , the reaction rate decreased monotonically with an increase in the concentration of hydrogen ions. The reaction order with respect to  $H^+$  was  $-0.24 \pm 0.1$ . The negative fractional order of the reaction with respect to  $H^+$  suggests that hydrogen ions are not directly involved in the chemical reaction leading to the decomposition of hydrazine. Apparently, the inhibitory effect is due to competitive adsorption on the active sites of the catalyst.

The experimental values of the activation energies for the catalytic decomposition of hydrazine increased monotonically with the acid concentration.

| $[H^+]$<br>/mol litre <sup>-1</sup> | $E^*$<br>/kJ mol <sup>-1</sup> | $[H^+]$<br>/mol litre <sup>-1</sup> | $E^*$<br>/kJ mol <sup>-1</sup> |
|-------------------------------------|--------------------------------|-------------------------------------|--------------------------------|
| $\sim 10^{-5}$                      | $31.6 \pm 1.6$                 | 1.2                                 | $59.2 \pm 2.2$                 |
| 0.1                                 | $36.1 \pm 2.4$                 | 3.4                                 | $79.9 \pm 1.4$                 |
| 0.2                                 | $36.4 \pm 2.1$                 |                                     |                                |

The monotonic increase in  $E^*$  with an increase in the acid concentration reflects the fact that the experimental values of activation energies of the heterogeneous catalytic reactions are apparent. The true activation energy of any chemical conversion always exceeds that determined experimentally by a value of the heat of adsorption. The latter depends on the degree of occupation of the active sites of the catalyst, which in turn reflects the non-uniformity of the catalyst surface with respect to energy. Adsorption of hydrogen ions on the surface of a platinum catalyst increases with the increase in acid concentration in the solution. Being present in large excess,  $H^+$  ions occupy the most energetically favourable active sites, which results in a decrease in the heats of adsorption of interacting species and hence in an increase in apparent activation energy of a heterogeneous catalytic reaction.

The mechanism of catalytic decomposition of hydrazine in  $HClO_4$  and  $H_2SO_4$  postulated on the basis of stoichiometric and kinetic data can be described by the following scheme:

The dissociation of adsorbed hydrazine molecules seems to be the rate-limiting step of the overall process (reaction 18). The first order of the reaction with respect to hydrazine is determined by the adsorption equilibrium (17). The reaction of the adsorbed radical  $NH_2^+(\text{ads})$  with the hydrazinium ion must be fast, otherwise further dissociation of the amino radical would result in the production of hydrogen:

The disproportionation of  $N_2H_3^+$  radicals into nitrogen and ammonium ions [reaction (19)] is yet another example of a very fast reaction: ( $k > 3 \cdot 10^{12} \text{ litre mol}^{-1} \text{ s}^{-1}$ ).<sup>71</sup>

The catalytic decomposition of hydrazine ( $0.20$ – $0.23 \text{ mol litre}^{-1}$ ) in  $HNO_3$  was studied in a thermostated cell mounted onto a shaker.<sup>67</sup> The loss of  $[N_2H_5^+]$  in  $1.25 \text{ M}$   $HNO_3$  in

the presence of 0.7% Pt/SiO<sub>2</sub> (50–80 °C) was described by kinetic curves; their initial segments correspond to the first-order reaction, which changes to the zero order in the terminal steps of the process. The decomposition of N<sub>2</sub>H<sub>5</sub><sup>+</sup> in the presence of activated charcoal occurred at a slower rate than on Pt/SiO<sub>2</sub> and strictly obeyed the zero-order kinetics. When BAU and Pt/SiO<sub>2</sub> containing up to 1% platinum were used as catalysts in 0.2–7 M HNO<sub>3</sub> at 50–80 °C, the reaction rate did not depend on the stirring intensity, *i.e.*, the reaction was kinetically controlled.

With an increase in [HNO<sub>3</sub>], the kinetic parameters of the N<sub>2</sub>H<sub>5</sub><sup>+</sup> decomposition on Pt/SiO<sub>2</sub> changed: the zero-order rate constant, *k*<sub>0</sub>, was invariable, whereas the first-order rate constant *k*<sub>1</sub> manifested a peak around 1–2 M HNO<sub>3</sub>. The overall effect of [HNO<sub>3</sub>]-dependent changes in *k*<sub>0</sub> + *k*<sub>1</sub> led to a situation where the maximum decomposition rate of hydrazine was observed in 1–2 M HNO<sub>3</sub>. The activation energies of first- and zero-order reactions in the presence of Pt/SiO<sub>2</sub> (50–80 °C) were equal to 61 and 50.6 kJ mol<sup>−1</sup>, respectively. For BAU, the activation energy was 68.6 kJ mol<sup>−1</sup> at 70–95 °C. With an increase in the Pt content on SiO<sub>2</sub> from 0.5% to 4%, *k*<sub>0</sub> and *k*<sub>1</sub> showed a tendency to increase, this increase being more pronounced for *k*<sub>1</sub>.

The stoichiometry, kinetics and mechanism of the catalytic decomposition of hydrazine in HNO<sub>3</sub> in the presence of 1% Pt/SiO<sub>2</sub> were studied in detail.<sup>9</sup> The results obtained by chemical and mass spectrometric methods suggest that N<sub>2</sub>, N<sub>2</sub>O and ammonium nitrate are the main decomposition products of hydrazine in HNO<sub>3</sub>. The formation of trace amounts of NO and NO<sub>2</sub> was also noted. The reaction products contained no hydrazoic acid (HN<sub>3</sub>), which made this reaction totally different from homogeneous oxidation of hydrazine with nitric acid.<sup>10</sup> The stoichiometric ratios [NH<sub>4</sub><sup>+</sup>]<sub>∞</sub>: [N<sub>2</sub>H<sub>5</sub><sup>+</sup>]<sub>0</sub> and ([NO<sub>3</sub><sup>−</sup>]<sub>0</sub> − [NO<sub>3</sub><sup>−</sup>]<sub>∞</sub>): [N<sub>2</sub>H<sub>5</sub><sup>+</sup>]<sub>0</sub> reflecting accumulation of ammonium ions and decrease in the total nitrate content vary depending on the concentration of nitric acid. Thus the increase in [HNO<sub>3</sub>] in the range 0.075–9.34 mol litre<sup>−1</sup> results in a decrease in [NH<sub>4</sub><sup>+</sup>]<sub>∞</sub>: [N<sub>2</sub>H<sub>5</sub><sup>+</sup>]<sub>0</sub> from 0.65 ± 0.01 to 0.36 ± 0.03, whereas ([NO<sub>3</sub><sup>−</sup>]<sub>0</sub> − [NO<sub>3</sub><sup>−</sup>]<sub>∞</sub>): [N<sub>2</sub>H<sub>5</sub><sup>+</sup>]<sub>0</sub> increased from 0.40 ± 0.01 to 0.97 ± 0.04. These data suggest a complex mechanism of catalytic decomposition of hydrazine in nitric acid-containing media. Presumably, the overall process is a superposition of two or more reactions where the contribution of each component is determined by the concentration of nitric acid. In 0.5–5 M HNO<sub>3</sub>, changes in these ratios are insignificant, which suggests that in the given range of [HNO<sub>3</sub>] the catalytic decomposition of hydrazinium nitrate occurs according to the stoichiometric equation:

The kinetics of the catalytic decomposition of hydrazine was studied in a thermostated glass reactor equipped with a reflux condenser. Stirring of the reaction mixture was carried out by a flow of argon at a controlled rate. Kinetic studies were performed at low initial concentrations of hydrazine (0.01 mol litre<sup>−1</sup>) in order to avoid problems in determining the reaction order with respect to N<sub>2</sub>H<sub>5</sub><sup>+</sup> due to adsorption saturation of active catalytic sites. The rate of catalytic decomposition of hydrazine increased with the intensity of the argon flow, which suggests that either this reaction proceeded in the diffusion regime or one of the volatile decomposition products decelerated the primary reaction by blocking the catalyst active sites.

The reaction order with respect to N<sub>2</sub>H<sub>5</sub><sup>+</sup> is not a constant value and varies from 0 to 1 with a change in [HNO<sub>3</sub>]. The dependence of the rate of the catalytic decomposition of hydrazine on the concentration of nitric acid is complex and has a minimum around [HNO<sub>3</sub>] 3.0–3.7 mol litre<sup>−1</sup>. The kinetic curves for this reaction are well described by the equation

$$-\frac{dc}{dt} = k_1c + k_0$$

over the whole range of experimental conditions.

The nature of the changes in the rate constants of the first- and zero-order reactions reflects the complex nature of heterogeneous catalytic reactions in the N<sub>2</sub>H<sub>5</sub><sup>+</sup>–HNO<sub>3</sub>–Pt system with an increase in [HNO<sub>3</sub>] (Fig. 4). At low concentrations of HNO<sub>3</sub> (0.25–2.0 mol litre<sup>−1</sup>), the changes in the first-order rate constant correspond with the negative fractional order (−0.24 ± 0.01) with respect to nitric acid. At higher concentrations of HNO<sub>3</sub> (4.0–8.0 mol litre<sup>−1</sup>), the value of the constant *k*<sub>1</sub> increases according to the apparent reaction order with respect to HNO<sub>3</sub> equal to 2.6 ± 0.2. The changes in the zero-order rate constants are consistent with the apparent reaction orders (1.96 ± 0.3 at 1.0–4.0 mol litre<sup>−1</sup> HNO<sub>3</sub> and −3.07 ± 0.3 at 4.0–7.0 mol litre<sup>−1</sup> HNO<sub>3</sub>). It is noteworthy that in 3 M nitric acid the catalytic decomposition of hydrazine strictly follows zero-order kinetics with respect to N<sub>2</sub>H<sub>5</sub><sup>+</sup>.

**Figure 4.** Changes in the zero- (1) and first- (2) order rate constants in the catalytic decomposition of hydrazine at 42 °C in the presence of 0.06 g ml<sup>−1</sup> of 1% Pt/SiO<sub>2</sub> with an increase in the concentration of nitric acid.<sup>6</sup>

The temperature dependences of these rate constants were studied at three different concentrations of nitric acid (0.25, 3.1 and 6.2 mol litre<sup>−1</sup>).

In 0.25 M HNO<sub>3</sub>, the catalytic decomposition of hydrazine occurred predominantly as a first-order reaction with respect to N<sub>2</sub>H<sub>5</sub><sup>+</sup>. Therefore, only the *k*<sub>1</sub> values were used for the calculation of apparent activation energies. The value of *E*<sup>\*</sup> = 34.2 ± 0.5 kJ mol<sup>−1</sup> measured at 30.5–69 °C agreed, within the limits of experimental error, with that previously established for the catalytic decomposition of hydrazine in 0.2 M HClO<sub>4</sub> (36.4 ± 2.1 kJ mol<sup>−1</sup>) (see Ref. 70).

In 3.1 M HNO<sub>3</sub>, the values of apparent activation energies determined from the temperature dependences *k*<sub>0</sub> and *k*<sub>1</sub> were equal to 114.6 ± 4 kJ mol<sup>−1</sup> (22–52 °C) and 33.7 ± 2 kJ mol<sup>−1</sup> (22–41 °C) for zero- and first-order reactions with respect to N<sub>2</sub>H<sub>5</sub><sup>+</sup>, respectively. In 6.2 M HNO<sub>3</sub>, the apparent activation energy of the first-order reaction with respect to [N<sub>2</sub>H<sub>5</sub><sup>+</sup>] was 44.73 kJ mol<sup>−1</sup> in the temperature range 28–50 °C. The zero-order component was not taken into consideration, since its contribution to the overall process was extremely small under the given conditions. It is of note that the increase in temperature increased the contribution of the zero-order (with respect to N<sub>2</sub>H<sub>5</sub><sup>+</sup>) reaction to the overall process in 3.1 M HNO<sub>3</sub>, whereas in 6.2 M HNO<sub>3</sub> an opposite regularity was observed. The experimental apparent activation energies markedly exceeded those of diffusion-controlled processes [~19 kJ mol<sup>−1</sup> (see Ref. 31)], thus suggesting that all reactions involved in the heterogeneous cata-

lytic decomposition of hydrazine in  $\text{HNO}_3$  solutions are under kinetic control.

The analysis of kinetic curves revealed that the catalytic decomposition of hydrazine in nitric acid in the presence of  $\text{Pt}/\text{SiO}_2$  is a superposition of three independent first- and zero-order processes with respect to  $\text{N}_2\text{H}_5^+$ . These reactions occur in parallel and their contributions to the overall process are determined by the concentration of nitric acid. At low concentrations of  $\text{HNO}_3$  ( $0.25\text{--}2.0\text{ mol litre}^{-1}$ ), the first-order reaction with respect to  $\text{N}_2\text{H}_5^+$  and the negative fractional order with respect to the concentration of nitric acid are determined by heterogeneous decomposition of hydrazine on the platinum surface; the mechanism of this process was described previously for non-nitric acid solutions.<sup>70</sup> This conclusion is derived from the formal coincidence of reaction orders with respect to acid and apparent activation energies for solutions in perchloric and nitric acids. With an increase in the nitric acid concentration up to  $1\text{ mol litre}^{-1}$ , the contribution of the zero-order reaction with respect to  $\text{N}_2\text{H}_5^+$  becomes more apparent. In  $3\text{ M HNO}_3$ , the reaction rate is of the zero order with respect to hydrazine. At low concentrations of hydrazine ( $0.01\text{ mol litre}^{-1}$ ) in the C : R range from 1 : 100 to 1 : 10, no saturation of the catalyst surface with hydrazine occurs<sup>70</sup> and the appearance of a zero-order component with respect to  $\text{N}_2\text{H}_5^+$  cannot be attributed to the adsorption nature of this process. Most probably, the zero order of the reaction with respect to hydrazine is determined by its fast reaction with hydrazoic acid or one of its derivatives generated on the catalyst surface upon contact with  $\text{HNO}_3$ . The rate of hydrazine loss depends on the rate of formation of  $\text{HNO}_2$ . The possibility of oxidation of the surface of the platinum catalyst with nitric acid was substantiated<sup>9</sup> by thermodynamic calculations of equilibrium electrochemical potentials of platinum and nitric acid. It was shown that the equilibrium potential of the  $\text{HNO}_3/\text{HNO}_2$  pair in  $3\text{ M}$  nitric acid at nitrous acid concentrations of  $10^{-6}\text{--}10^{-4}\text{ mol litre}^{-1}$  (where  $\gamma_{\text{HNO}_2}$  was taken equal to unity) varied from 1.14 to 1.08 V relative to NHE. At the same time, assuming arbitrarily that  $[\text{Pt}^{2+}] = 10^{-6}\text{ mol litre}^{-1}$  and  $\gamma_{\text{Pt}^{2+}} = 1$ , the equilibrium potential values for the  $\text{Pt}^{2+}/\text{Pt}$  and  $\text{PtO}_2/\text{Pt}^{2+}$  pairs in  $3\text{ M HNO}_3$  are 1.011 and 1.077 V (NHE), respectively. A comparison of experimental values of equilibrium oxidation potentials suggests that metallic platinum is oxidised in  $\text{HNO}_3$  solutions to a tetravalent state ( $\text{PtO}_2$ ). This process is accompanied by the reduction of nitric acid to  $\text{HNO}_2$ . The following reaction scheme can be proposed:

The adsorbed nitrosyl cations derived from nitrous acid according to the equilibrium

react with hydrazine by a cascade of fast reactions on the catalyst surface, which determines the zero order of the overall process with respect to  $\text{N}_2\text{H}_5^+$ :

The oxidised active sites of the catalyst are regenerated as a result of their reaction with hydrazine

and thus become accessible for the next catalytic act.

From the above scheme, it can be seen that  $\text{HN}_3$  is a product of reaction (24). However, as mentioned above, no hydrazoic acid was detected either in the solution or in the effluent gases. Presumably, the  $\text{HN}_3$  molecules adsorbed on the catalyst were not desorbed into the solution, but underwent catalytic decomposition directly on the platinum surface.

The rate of the catalytic decomposition of hydrazine increases with an increase in the concentration of nitric acid in the range  $4\text{--}8\text{ mol litre}^{-1}$  simultaneously with a rapid change in the reaction order from zero to first with respect to  $\text{N}_2\text{H}_5^+$ . Presumably, in the region of high concentrations of  $\text{HNO}_3$  the crucial role should be ascribed to the catalytic oxidation of hydrazine with nitric acid. The rate-determining step of this reaction is the reaction of hydrazine molecules adsorbed on the catalyst surface with nitroyl cations generated in the equilibrium reaction (6):

The concentration of adsorbed hydrazine is directly proportional to its solution concentration, which determines the first order of the reaction with respect to  $\text{N}_2\text{H}_5^+$ . The diimide and the nitrosyl cation generated in the reaction (29) undergo a series of fast transformations (23)–(27) both on the catalyst and in the solution.

A comparative analysis of experimental results<sup>9,67</sup> of the catalytic decomposition of hydrazine in nitric acid suggests that the kinetic characteristics of this process depend critically on the mode of stirring of the reaction components. Thus the decomposition rate of hydrazine showed virtually no dependence on the shaking intensity<sup>67</sup> and passed through a maximum with an increase in  $[\text{HNO}_3]$  from 0.2 to  $7\text{ mol litre}^{-1}$ , whereas more intense stirring by a flow of argon caused a monotonic increase in the reaction rate. With an increase in the nitric acid concentration from 0.25 to  $8\text{ mol litre}^{-1}$ , the decomposition rate first slowed down and then showed an increase passing through a minimum around  $3.0\text{--}3.7\text{ mol litre}^{-1}$ . The reason for such a difference is that shaking of the reaction components in a closed volume results in accumulation of the gaseous decomposition products in the solution and on the catalyst surface, which inhibits the catalytic process by blocking the active sites. At the same time, passage of argon favours degassing of the solution and faster regeneration of the active surface of the catalyst.

#### 4. Decomposition of hydrazoic acid

The use of hydrazine together with nitric acid in reprocessing of the used nuclear fuel results in the formation of hydrazoic acid as an undesirable intermediate.  $\text{HN}_3$  is formed in the reaction of hydrazine with nitrous acid. The overall oxidation reaction

occurs in two steps:

In solutions of moderate acidity,  $k_1 \approx 5k_2$  (see Ref. 72). From the above scheme it follows that the oxidation of excess hydrazine results in the accumulation of hydrazoic acid in the solution. At elevated temperatures,  $\text{HN}_3$  is formed by direct oxidation of hydrazine with nitric acid.<sup>31</sup>

The pertechnetate ions present in technological solutions catalyse hydrazine oxidation to give  $\text{HN}_3$ .<sup>73</sup>

Hydrazoic acid is related to the class of potentially hazardous chemical compounds due to its toxicity and explosive risk under certain conditions.<sup>74</sup> Therefore, its uncontrolled accumulation in technological solutions is inadmissible from the standpoint of

environmental and technological safety. The problem of elimination of hydrazoic acid from solutions can successfully be solved by using heterogeneous catalysis due to its ability to undergo catalytic decomposition in the presence of platinum black.<sup>75</sup> The kinetics and the decomposition mechanism of hydrazoic acid in solutions of nitric and perchloric acids in the presence of a catalyst (1% Pt/SiO<sub>2</sub>) have been studied.<sup>76</sup> The rate of the catalytic decomposition of HN<sub>3</sub> did not depend on the intensity of stirring of the reaction mixture. The reaction rate followed first-order kinetics with respect to HN<sub>3</sub> over the whole range of experimental conditions. An increase in the amount of the catalyst resulted in a proportional increase in the rate constant. The catalytic decomposition of HN<sub>3</sub> in nitric acid solutions first slowed down with an increase in the nitric acid concentration followed by its acceleration after passage through a minimum at [HNO<sub>3</sub>] 6 mol litre<sup>-1</sup>. In perchlorate solutions, the reaction rate decreased monotonically over the whole range of HClO<sub>4</sub> concentrations (0.5–8 mol litre<sup>-1</sup>) (Fig. 5). The apparent reaction orders with respect to nitric acid determined in 0.5–6 M HNO<sub>3</sub> and in 0.5–8.0 M HClO<sub>4</sub> were equal to -0.37 and -0.47, respectively. The negative fractional order of the reaction with respect to the acid in the concentration range specified suggests that neither hydrogen ions nor HNO<sub>3</sub> molecules directly participate in the chemical reaction resulting in the catalytic decomposition of hydrazoic acid. The inhibitory effect of H<sup>+</sup> ions may be due to competitive adsorption on the active catalytic sites.

**Figure 5.** Effect of acid concentration on the decomposition rate of hydrazoic acid at [HN<sub>3</sub>]<sub>0</sub> = 0.025 mol litre<sup>-1</sup> and 64 °C in the presence of 0.1 g ml<sup>-1</sup> of 1% Pt/SiO<sub>2</sub>.<sup>76</sup> (1) HNO<sub>3</sub>, (2) HClO<sub>4</sub>.

The effect of temperature on the decomposition rate of HN<sub>3</sub> was studied in solutions of various compositions. The values of apparent activation energies are listed in the table below:

| Acid                   | <i>E</i> <sup>*</sup> / kJ mol <sup>-1</sup> | Acid                    | <i>E</i> <sup>*</sup> / kJ mol <sup>-1</sup> |
|------------------------|----------------------------------------------|-------------------------|----------------------------------------------|
| 1.0 M HNO <sub>3</sub> | 63.5 ± 1.8                                   | 6.2 M HNO <sub>3</sub>  | 74.6 ± 2.3                                   |
| 3.1 M HNO <sub>3</sub> | 69.0 ± 2.0                                   | 3.0 M HClO <sub>4</sub> | 67.2 ± 1.6                                   |

The increase in *E*<sup>\*</sup> with an increase in the acid concentration is due to the same reasons as in the catalytic decomposition of hydrazine in non-nitric acid media.<sup>70</sup> The mechanisms of the catalytic decomposition of hydrazoic acid in 0.5–8 M HClO<sub>4</sub> and in 0.5–6 M HNO<sub>3</sub> are virtually identical and based on heterogeneous catalytic decomposition of HN<sub>3</sub> adsorbed on the active sites of the catalyst.

The fast reactions (30) and (31) may occur both on the catalyst surface and in solution. The general stoichiometric equation for both reactions is as follows:

The rate of the catalytic decomposition of HN<sub>3</sub> in solutions with [HNO<sub>3</sub>] > 6 mol litre<sup>-1</sup> increases considerably due to an increase in the contribution of oxidation reactions involving nitric acid.<sup>76</sup> The catalytic oxidation of hydrazoic acid consists of heterogeneous reactions of adsorbed HN<sub>3</sub> molecules with nitroyl ions in nitric acid media according to the equilibrium (6) followed by a series of fast homogeneous transformations *via* intermediate radicals.

In general, the oxidation process can be presented as follows:

It is noteworthy that the kinetic regularities and catalytic decomposition mechanisms of hydrazoic acid and hydrazine in nitric acid are roughly similar. In both cases, in solutions of low or medium acidities, the heterogeneous catalytic disproportionation of these compounds due to increase in [HNO<sub>3</sub>] is followed by heterogeneous catalytic oxidation, which involves nitroyl cations. It may thus be assumed that the catalytic decomposition of HN<sub>3</sub> in nitric acid, as of hydrazine, occurs through a catalytic redox cycle on the surface of platinum, which is similar to reactions (20), (21) and (28). However, in the case of HN<sub>3</sub> this process is kinetically indistinguishable, since its rate is considerably lower than the rates of catalytic disproportionation and oxidation of HN<sub>3</sub>, which occur in parallel.

The catalytic decomposition of hydrazoic acid in nitric acid was studied in the dynamic regime<sup>77</sup> using 1% Pt/SiO<sub>2</sub> as a catalyst. It was shown that the main characteristics of the continuous process, *viz.*, the effects of nitric acid concentration and temperature on the decomposition rate of HN<sub>3</sub>, were in good agreement with the kinetic data obtained in the static regime. The presence of sodium nitrate (20 g litre<sup>-1</sup>) and uranium (0.1 g litre<sup>-1</sup>) in the solution had no effect on the efficiency of the catalytic decomposition of hydrazoic acid. The decomposition rate of HN<sub>3</sub> decreased slightly when 0.5 M nitric acid saturated with spent TBP was used. However, such an effect was not related to the progressive poisoning of the catalyst, since the effects of TBP and its decomposition products on the reaction rate were of a steady and therefore reversible character. The decrease in the decomposition rate of HN<sub>3</sub> in the presence of TBP might be attributed to the equilibrium adsorption of organic molecules on the catalyst surface, as a result of which part of the active sites appeared to be occupied and did not take part in the catalytic process. The decrease in the reaction rate can be compensated for by mere elevation of temperature or by reduction of the flow rate of the working solution.

The catalytic decomposition of hydrazoic acid in the dynamic regime is a technologically efficient process and can be recommended for removal of HN<sub>3</sub> from radioactive wastes before their final processing.

## 5. Catalytic denitration of nitric acid solutions

Modern wet technologies for processing waste nuclear fuels starting from the dissolution of fuel elements and ending with separation and purification of isolated radioactive components are based on the use of nitric acid solutions. However, the problem of processing of water-tail fractions by their further vitrification cannot successfully be solved without removal of excess nitric acid and nitrates. This is usually accomplished by chemical denitration

of solutions with formic acid or formaldehyde.<sup>78–82</sup> The main problem in this procedure consists of the autocatalytic mode of the reaction of nitric acid with  $\text{HCO}_2\text{H}$  and  $\text{HCHO}$ . Such reactions are usually characterised by induction periods where accumulation of threshold concentrations of nitrous acid in the solution occurs and subsequent fast propagation of the process. Under certain conditions, the denitration assumes the form of an explosive process that is difficult to control. This circumstance makes chemical denitration a potentially dangerous process. Numerous cases of grave accidents upon denitration at pilot-plant and industrial installations for processing used materials are documented in the literature.<sup>83,84</sup>

It has been established<sup>58</sup> that the reaction of nitric acid with formic acids in the presence of a catalyst ( $\text{Pt}/\text{SiO}_2$ ) begins without any induction period and proceeds without any pressure surge in the reaction system (Fig. 6). The kinetics and stoichiometry of the catalytic reaction of  $\text{HNO}_3$  with  $\text{HCO}_2\text{H}$  were studied in a broad range of experimental conditions ( $[\text{HNO}_3]_0 = 0.7\text{--}8.0\text{ mol litre}^{-1}$ ;  $[\text{HCO}_2\text{H}]_0 = 0.5\text{--}4.3\text{ mol litre}^{-1}$ ; temperature  $55\text{--}85\text{ }^\circ\text{C}$ ;  $\text{C}:\text{R} = 1:10\text{--}1:50$ , 1%  $\text{Pt}/\text{SiO}_2$ ). In all cases, the reaction began without any induction period. If such a period did exist, its duration would be no longer than the time required for the mixing of the reactants. In dilute ( $2\text{ mol litre}^{-1}$ )  $\text{HNO}_3$  solutions, the kinetic curves were described by a first-order equation with respect to  $\text{HCO}_2\text{H}$ . In more concentrated  $\text{HNO}_3$  solutions, the reaction was of the first order with respect to formic acid until the extent of decomposition reached 40%–50%; at higher degrees of conversion, the reaction rate decreased. In these cases, the first-order equation was used for the estimation of the initial rate of the reaction. The increase in the stirring intensity on passing an inert gas through the reaction mixture resulted in deceleration of the reaction, which points to the involvement of intermediate gaseous products in the oxidation of  $\text{HCO}_2\text{H}$ . A similar phenomenon was observed where the reaction was carried out in the absence of the catalyst.<sup>78</sup> The rate of the reaction of  $\text{HCO}_2\text{H}$  with  $\text{HNO}_3$  increased linearly with the increase in the  $\text{C}:\text{R}$  ratio, which points to the catalytic nature of the process. The reaction rate increased rapidly with the concentration of nitric acid. The dependence of the rate constant on  $[\text{HNO}_3]$  had a complex form, which did not permit an unambiguous estimation of the reaction order with respect to nitric acid. It may be concluded, however, that the apparent order of the reaction with respect to nitric acid approximated 3 with an increase in  $[\text{HNO}_3]$  above  $2\text{ mol litre}^{-1}$ , which is characteristic of reactions occurring in the absence of a catalyst.<sup>78,80</sup> The apparent reaction order with respect to hydrogen ions at a constant concentration of nitrate ions changed monotonically from 0 to 4 with an increase in  $[\text{H}^+]$  from 0.7 to  $5\text{ mol litre}^{-1}$ . The activation energy of the reaction of

$\text{HNO}_3$  with  $\text{HCO}_2\text{H}$  in the presence of a platinum catalyst was determined at different concentrations of nitric acid:

| $[\text{HNO}_3]/\text{mol litre}^{-1}$ | $E^*/\text{kJ mol}^{-1}$ |
|----------------------------------------|--------------------------|
| 0.94                                   | $84.2 \pm 2.2$           |
| 3.14                                   | $105.0 \pm 4.0$          |
| 4.92                                   | $113.2 \pm 3.1$          |

It can be seen that the increase in the concentration of nitric acid results in a considerable increase in the apparent activation energy, which gradually approximates that for a denitration process occurring in the absence of a catalyst [ $126\text{ kJ mol}^{-1}$  (see Ref. 80)].

This fact and the effects of acidity and total concentration of nitric acid on the reaction rate suggest that two parallel processes, viz., catalytic reaction of nitric acid with  $\text{HCO}_2\text{H}$  and homogeneous denitration, occur in the system under study, the contribution of the latter to the overall process being increased with  $[\text{HNO}_3]$ . Earlier studies<sup>38</sup> have demonstrated the absence of autocatalytic accumulation of nitrous acid at low ( $1\text{ mol litre}^{-1}$ ) concentrations of  $\text{HNO}_3$ . If  $\text{HNO}_2$  was present in the solution from the very first steps, its concentration diminished gradually during its reaction with  $\text{HCO}_2\text{H}$ . Here, the denitration occurred only in the presence of a catalyst according to a heterogeneous catalytic mechanism. Therefore, the value of  $E^* = 84.2\text{ kJ mol}^{-1}$  obtained at  $[\text{HNO}_3] = 0.94\text{ mol litre}^{-1}$  can be regarded as an apparent activation energy of the catalytic process. At higher concentrations of nitric acid that favour the accumulation of  $\text{HNO}_2$ , the contribution of the autocatalytic reaction increased and at  $[\text{HNO}_3] > 4\text{ mol litre}^{-1}$  the process occurred mainly according to the kinetic regularities of homogeneous denitration.

The catalytic denitration gaseous products are represented by  $\text{CO}_2$ ,  $\text{NO}_2$ ,  $\text{NO}$  and  $\text{N}_2\text{O}$ ; the evolution of  $\text{N}_2\text{O}$  was suppressed upon increase in the concentration of nitric acid. The fact that no hydrogen was found in the gaseous reaction products suggests the absence of catalytic self-decomposition of formic acid under the given experimental conditions. Calculations of the gas balance of  $\text{HCO}_2\text{H}$  based on the results of gas analysis and kinetic measurements show the formation of 1 mole of  $\text{CO}_2$  per mole of the consumed formic acid. Stoichiometric measurements demonstrated that the consumption of formic acid in the catalytic denitration was 1.1–1.5 moles of  $\text{HCO}_2\text{H}$  per mole of the consumed  $\text{HNO}_3$  (Table 3), which is virtually the same as in a non-catalysed reaction, all other experimental conditions being the same.

**Table 3.** Stoichiometry of the denitration reaction in the presence of a catalyst (1%  $\text{Pt}/\text{SiO}_2$ ) at  $60\text{ }^\circ\text{C}$ .<sup>58</sup>

| $[\text{HNO}_3]_0$<br>/mol litre <sup>-1</sup> | $[\text{HCO}_2\text{H}]_0$<br>/mol litre <sup>-1</sup> | $\text{C}:\text{R}$<br>/g ml <sup>-1</sup> | Time<br>/min | Degree of<br>conversion of<br>$\text{HCO}_2\text{H}$ (%) | $\frac{\Delta[\text{HCO}_2\text{H}]}{\Delta[\text{HNO}_3]}$<br>(see <sup>a</sup> ) |
|------------------------------------------------|--------------------------------------------------------|--------------------------------------------|--------------|----------------------------------------------------------|------------------------------------------------------------------------------------|
| 4.72                                           | 1                                                      | 0.04                                       | 30           | 50                                                       | $1.19 \pm 0.04$                                                                    |
| 4.75                                           | 1                                                      | 0.04                                       | 30           | 50                                                       | $1.18 \pm 0.03$                                                                    |
| 4.75                                           | 1                                                      | 0.04                                       | 60           | 80                                                       | $1.25 \pm 0.01$                                                                    |

C : R / g ml<sup>-1</sup>: 0.20 (1), 0.15 (2), 0.10 (3), 0.05 (4).

The mechanism of catalytic denitration and the role of a platinum catalyst in the initiation of the reaction and suppression of the induction period have been reviewed.<sup>58, 85</sup> It was found<sup>58</sup> that the addition of a catalyst (Pt/SiO<sub>2</sub>) to 0.5–4 M solutions of HNO<sub>3</sub> resulted in rapid accumulation of nitrous acid (Fig. 7), which reacts with HCO<sub>2</sub>H to initiate the denitration.

Accelerated formation of HNO<sub>2</sub> in nitric acid solutions upon a contact with a platinum catalyst results from oxidation of surface platinum atoms with nitroyl cations [see reactions (20)–(22)], as is the case with catalytic decomposition of hydrazine in HNO<sub>3</sub> solutions.<sup>9</sup> In the absence of a reducing agent, the catalyst surface is passivated and the formation of hydrazoic acid is discontinued.<sup>85</sup> After addition of formic acid to the reaction system, the oxidised platinum atoms react with HCO<sub>2</sub>H molecules and thus become accessible to a new attack by nitric acid resulting in the formation of HNO<sub>2</sub>. Thus, the surface catalytic redox cycle is implemented in the system, which favours fast initial accumulation of the threshold concentration of nitrous acid [ $\sim 10^{-2}$  mol litre<sup>-1</sup> (see Ref. 79)] required for triggering the denitration reaction. The mechanism of the catalytic denitration is schematically depicted in Fig. 8.

A significant advantage of catalytic denitration over the homogeneous process is that it occurs even in the presence of the

**Figure 8.** A schematic representation of a catalytic denitration mechanism.

antinitrite reagent (urea), although the reaction is slowed down.<sup>58</sup> However, the reaction rate increases after complete decomposition of (NH<sub>2</sub>)<sub>2</sub>CO. The same is true for hydrazine. Studies on catalytic decomposition of excess nitric acid in plutonium-containing solutions have shown that in the presence of Pt(IV) (2–25 g litre<sup>-1</sup>) the denitration proceeds without any induction period and complications in a broad range of initial concentrations of nitric and formic acids. In the presence of excess of HCO<sub>2</sub>H, partial (up to 30%) reduction of Pu(IV) to Pu(III) is observed at the end of the process.<sup>58</sup> The catalytic denitration in the presence of excess of HCO<sub>2</sub>H enables virtually complete decomposition of nitric acid. Thus no nitric acid could be detected by potentiometry in a solution containing  $\sim 1$  mol litre<sup>-1</sup> of formate following denitration. Long-term use of catalysts for denitration does not result in their poisoning. After more than 100 cycles, not a single case of a decrease in the catalytic activity of the catalyst (1% Pt/SiO<sub>2</sub>) taken from the same batch was noted.<sup>58</sup>

## 6. Decomposition of urea and ammonium nitrate in the catalytic denitration

Urea (carbamide) is widely employed in radiochemical processes as an antinitrite reagent, *e.g.*, for electrochemical reduction of uranium(VI) in nitric acid solutions.<sup>19</sup> Like any other antinitrite reagent, urea is decomposed by an addition of sodium nitrite to nitric acid solutions<sup>72</sup> or by passage of gaseous nitrogen oxides NO and NO<sub>2</sub> (NO<sub>x</sub>-gases) through a solution.<sup>86</sup> However, despite the obvious simplicity and efficiency of these procedures, the addition of NaNO<sub>2</sub> to the solution is not always desirable, since it is accompanied by an increase in the total salt content, whereas the latter method requires an additional source of NO<sub>x</sub> gases.

As shown above, the platinum-catalysed reaction of nitric acid with formic acids (catalytic denitration) occurs successfully in the presence of urea and is accompanied by its efficient decomposition.<sup>58</sup> At the same time, this reaction is impossible in the absence of a catalyst and carbamide-containing HNO<sub>3</sub>–HCO<sub>2</sub>H mixtures remain stable over indefinitely long periods of time even at elevated temperatures. The specific behaviour of urea in the catalytic denitration in the presence of a catalyst (1% Pt/SiO<sub>2</sub>) has been studied.<sup>87, 88</sup> It was shown that in the absence of formic acid carbamide was not subject to catalytic decomposition in 0–8 M HNO<sub>3</sub> even at temperatures close to the boiling point of the solution. However, the addition of 0.1–2 mol litre<sup>-1</sup> of HCO<sub>2</sub>H to 2 M HNO<sub>3</sub> containing 0.5 mol litre<sup>-1</sup> of carbamide and 0.02–0.2 g ml<sup>-1</sup> of 1% Pt/SiO<sub>2</sub> induced the decomposition of (NH<sub>2</sub>)<sub>2</sub>CO at 60 °C resulting in the denitration of the solution. The catalytic decomposition of urea in the presence of 0.2–1.3 mol litre<sup>-1</sup> of HCO<sub>2</sub>H and at C : R = 1 : 50 began at 60 °C at a concentration of nitric acid equal or higher than 2 mol litre<sup>-1</sup> (see Ref. 87). The kinetic curves of the consumption of (NH<sub>2</sub>)<sub>2</sub>CO changed significantly with an increase in [HNO<sub>3</sub>] (Fig. 9). In the HNO<sub>3</sub> range 2–2.5 M, the reaction occurred with an induction period followed by accelerated decomposition of urea. At higher concentrations of nitric acid, the decomposition of urea occurred without the induction period and is zero order with respect to (NH<sub>2</sub>)<sub>2</sub>CO. The rate of this zero-order process did not depend on the intensity of stirring of the solution, *i.e.*, the reaction proceeded under kinetic control. The increase in C : R in the range 1 : 50–1 : 10 resulted in a proportional increase in the reaction rate, which is characteristic of heterogeneous catalytic processes in solutions. The reaction rate increases with the concentration of formic acid; the reaction order with respect to HCO<sub>2</sub>H was close to unity. With an increase in the initial concentration of nitric acid from 2.3 to 7.0 mol litre<sup>-1</sup>, the decomposition rate of urea decreased considerably. The dependence of *k*<sub>0</sub> on [HNO<sub>3</sub>] in logarithmic coordinates was not approximated by a straight line, which excluded the unambiguous interpretation of the reaction order with respect to nitric acid. The apparent activation energy of this reaction determined at [HNO<sub>3</sub>]<sub>0</sub> = 2.9 mol litre<sup>-1</sup>, [HCO<sub>2</sub>H]<sub>0</sub> = 1.0 mol litre<sup>-1</sup> and [(NH<sub>2</sub>)<sub>2</sub>CO]<sub>0</sub> = 0.2 mol litre<sup>-1</sup> was 58.7 ± 1.6 kJ mol<sup>-1</sup>.

**Figure 9.** Kinetic curves for the decomposition of urea ( $0.2 \text{ mol litre}^{-1}$ ) in nitric acid solutions of variable concentrations in the presence of  $0.1 \text{ g ml}^{-1}$  of 1% Pt/SiO<sub>2</sub> at  $[\text{HCO}_2\text{H}]_0 = 1.0 \text{ mol litre}^{-1}$  and at  $60^\circ\text{C}$ .<sup>87</sup>  $[\text{HNO}_3] / \text{mol litre}^{-1}$ : 2.0 (1), 2.1 (2), 2.3 (3), 2.6 (4), 5.6 (5).

The kinetic data altogether, namely, the threshold type of the reaction with respect to  $[\text{HNO}_3]$ , the induction period, the zero reaction order with respect to  $(\text{NH}_2)_2\text{CO}$ , the impossibility of performing the catalytic decomposition of carbamide in the absence of  $\text{HCO}_2\text{H}$ , prompt a conclusion that the decomposition of urea is a result of its reaction with nitrous acid generated in the reaction system upon catalytic denitration according to the equations (32)–(34). The rate of decomposition of carbamide is determined by the rate of formation of  $\text{HNO}_2$  generated upon catalytic reaction of nitric acid with  $\text{HCO}_2\text{H}$  according to a mechanism presented in Fig. 8.

As mentioned above, the kinetics of decomposition of urea manifests a rather complex dependence on the concentration of nitric acid. The threshold type of this reaction with respect to  $[\text{HNO}_3]$  and the induction period in the range  $2.0\text{--}2.3 \text{ M HNO}_3$  are determined by the autocatalytic type of the reaction of nitric acid with formic acid. The concentration of nitrous acid in the  $\text{HNO}_3\text{--HCO}_2\text{H}$  mixture increases in an autocatalytic manner at  $[\text{HNO}_3] = 1\text{--}3.8 \text{ mol litre}^{-1}$  and decreases at  $[\text{HNO}_3] < 1 \text{ mol litre}^{-1}$ .<sup>38</sup> This is associated with a strong effect of  $[\text{HNO}_3]$  on the rate and the equilibrium of the reaction (34).<sup>89</sup> In a system containing  $\text{HCO}_2\text{H}$ ,  $\text{HNO}_3$  and carbamide, a positive balance of  $\text{HNO}_2$  generated by reaction (34) with respect to  $\text{HNO}_2$  consumed in reactions (37) and (38) (see below) in the presence of Pt/SiO<sub>2</sub> is established at  $[\text{HNO}_3] > 2 \text{ mol litre}^{-1}$ . Reaction of excess nitrous acid with urea leads to the decomposition of the latter. At  $[\text{HNO}_3] = 2\text{--}2.3 \text{ mol litre}^{-1}$ , the formation of nitrous acid occurs with acceleration, which results in the appearance of an induction period. Urea is related to the class of ‘mild antinitrite reagents’. The rate of its reaction with nitrous acid is relatively low, but shows a rapid increase with an increase in the solution acidity.<sup>73</sup> It is this fact that is responsible for the decrease in the rate of the catalytic decomposition of urea with an increase in the concentration of nitric acid. Indeed, the formation of nitrous acid in the solution (the reaction system) results from two different processes, *viz.*, the catalytic redox cycle involving nitric acid and  $\text{HCO}_2\text{H}$  on the platinum surface and autocatalytic generation of  $\text{HNO}_2$  in the solution [see reactions (32)–(34)]. The rapid acceleration of the rate of the reaction of nitrous acid with carbamide at increasing  $[\text{HNO}_3]$  leads to the inhibition of autocatalytic formation of  $\text{HNO}_2$ . As a result, the rate of formation of nitrous acid in the solution decreases with a concomitant decrease in the decomposition rate of urea with an increase in  $[\text{HNO}_3]$ .

The composition of the reaction products and the stoichiometry of the catalytic decomposition of urea in the  $\text{HNO}_3\text{--HCO}_2\text{H}\text{--Pt/SiO}_2$  system have been studied in detail.<sup>88</sup> Gaseous decomposition products of urea include  $\text{CO}_2$ ,  $\text{N}_2\text{O}$  and

$\text{N}_2$ . A small amount of  $\text{NO}_2$  and trace amounts of  $\text{H}_2$  are also formed. Ammonium nitrate and formamide are formed in the solution. In general, the decomposition of urea under catalytic denitration conditions can be described in terms of the stoichiometric equation:

Although this process is based on the reaction of  $(\text{NH}_2)_2\text{CO}$  with nitrous acid formed, the compositions of gaseous and soluble decomposition products of urea in the  $\text{HNO}_3\text{--HCO}_2\text{H}\text{--Pt/SiO}_2$  system differ essentially from that expected for the generally accepted scheme of the reaction of carbamide with  $\text{HNO}_2$ .<sup>72, 86, 90</sup>

The reason for this discrepancy is that carbamide, being in excess under catalytic denitration conditions, reacts with  $\text{HNO}_2$  formed. In this case, the following reaction sequence leading to ammonium nitrate as a result of acid hydrolysis of the intermediate product, *viz.*, cyanic acid, is implemented:<sup>91</sup>

Formamide and nitrogen(I) oxide also seem to be partial oxidation products of urea with nitrous acid in the presence of excess of  $(\text{NH}_2)_2\text{CO}$ .

Formamide is less subject to acid hydrolysis in comparison with cyanic acid<sup>92</sup> and is therefore accumulated in the solution until the decomposition of carbamide is complete.

The rate of catalytic denitration increases after urea decomposition is over. This is accompanied by a jump-like increase in  $[\text{HNO}_2]$  in the solution with subsequent rapid return to the quasi-steady state;  $[\text{HNO}_2]$  remains at this level up to the end of the denitration (Fig. 10). Under these conditions, soluble decomposition products of urea, *viz.*, formamide and ammonium nitrate, are unstable and undergo further degradation.<sup>88</sup> Apparently, these reactions can be described by the following equations:

It was suggested<sup>88</sup> that the decomposition of formamide and ammonium nitrate is accelerated in the presence of catalysts. The regularities of decomposition reactions of nitrogen-containing compounds present substantial scientific and practical interest.

**Figure 10.** Dynamics of changes in the concentrations of urea (1) and nitrous acid (2) in the decomposition of urea in the presence of  $0.1 \text{ g ml}^{-1}$  of 1% Pt/SiO<sub>2</sub> at  $70^\circ\text{C}$ .<sup>87</sup>  $[\text{HNO}_3]_0 = 3.3 \text{ mol litre}^{-1}$ ,  $[\text{HCO}_2\text{H}]_0 = 1.0 \text{ mol litre}^{-1}$

In the first place, this concerns ammonium nitrate. The search for approaches to its removal from water-tail fractions of radiochemical plants presents a serious problem for the technology of the nuclear fuel cycle. The decomposition of ammonium nitrate under conditions of denitration was considered in detail.<sup>93</sup> A series of experiments on the denitration of nitric acid solutions containing ammonium nitrate under static conditions have been carried out recently in order to elucidate the role of platinum catalysts in the homogeneous and catalytic decomposition of ammonium nitrate formed in the reaction of  $\text{HNO}_3$  with  $\text{HCO}_2\text{H}$ . As expected, in the absence of catalysts the denitration was preceded by an induction period of 3–60 min, which varied depending on the initial concentration of nitric acid, and followed by a fast reaction characteristic of homogeneous denitration. In all cases, in the presence of a platinum catalyst this reaction proceeded without an induction period. The results obtained suggest that the presence of  $\text{Pt}/\text{SiO}_2$  in the reaction system has virtually no effect on the degree of decomposition of ammonium nitrate in the course of denitration. From the kinetic point of view, the role of the catalyst is only reduced to the elimination of the induction period, *i.e.*, to the initiation of the reaction of nitric acid with  $\text{HCO}_2\text{H}$ . As a consequence, the chemical reaction resulting in the oxidation of the ammonium ion takes place in the solution rather than on the catalyst surface, *i.e.*, is homogeneous. It was found that the degree of decomposition of ammonium nitrate increases with an increase in the initial concentration of nitric acid in the range 0.5–4 mol  $\text{litre}^{-1}$ . Further increase in  $[\text{HNO}_3]$  slightly reduces the reaction yield. The increase in the concentration of formic acid in the presence of an excess of  $\text{HNO}_3$  enhances the decomposition of  $\text{NH}_4\text{NO}_3$ . However, the efficiency of this reaction diminishes at the molar ratios  $[\text{HCO}_2\text{H}]:[\text{HNO}_3] > 0.8\text{--}1.0$ . The increase in temperature from 80 to 100 °C increases the reaction yields by 12%. These regularities were interpreted under the assumption that the disappearance of ammonium nitrate is due to the homogeneous oxidation of ammonium ions with nitrous acid [reaction (39)]. In this case, the role of a nitrous acid precursor is played by the  $\text{HNO}_3\text{--HCO}_2\text{H}$  system where  $\text{HNO}_2$  is accumulated by an autocatalytic mechanism [reactions (32)–(34)] underlying chemical denitration of nitric acid solutions. Obviously, the oxidation rate of the ammonium ion with nitrous acid is lower than its formation rate, otherwise the presence of ammonium nitrate in the solution will prevent denitration in the absence of a platinum catalyst due to inhibition of the autocatalytic formation of  $\text{HNO}_2$ . The efficiency of ammonium nitrate decomposition should be determined by the steady-state concentration of nitrous acid rather than its formation rate. The equilibrium concentrations of  $\text{HNO}_2$  in nitric acid solutions in the absence of other oxidants and reducing agents are largely determined by the interrelated reversible reactions (34) and (35). A comparison of these equilibria shows that an increase in the concentration of nitric acid in the reaction system results, on the one hand, in an increase in the yield of  $\text{HNO}_2$  and, on the other hand, in its decomposition due to oxidation to nitrogen dioxide. If reactions are carried out in open systems, the yields of  $\text{NH}_4\text{NO}_3$  decomposition products are lower as a result of removal of gaseous  $\text{NO}_2$  from the reactor. It is this factor that accounts for the decrease in the reaction rate and prevents further increases in the yields of decomposition of ammonium nitrate at  $[\text{HNO}_3] > 4$  mol  $\text{litre}^{-1}$ . The non-monotonic changes in the degree of decomposition of ammonium nitrate with an increase in the ratio  $[\text{HCO}_2\text{H}]:[\text{HNO}_3]$  can be attributed to the changes in the stoichiometry of the denitration reaction, which in turn is determined by the ratio of concentrations of nitric and formic acids.<sup>57</sup> The maximum yield of  $\text{NO}$  involved in the formation of nitrous acid is observed at the  $[\text{HCO}_2\text{H}]:[\text{HNO}_3]$  molar ratio  $\approx 0.8\text{--}1.0$ , which accounts for the observed pattern of changes in the degree of decomposition of  $\text{NH}_4\text{NO}_3$ . The maximum (close to 100%) degree of decomposition of ammonium nitrate is reached upon continuous addition of formic acid to solutions of ammonium nitrate in nitric acid in the presence of a catalyst ( $\text{Pt}/\text{SiO}_2$ ). This

method can be used for the decomposition of ammonium nitrate in solutions with complex compositions. Thus it was shown<sup>93</sup> that the presence of caesium or uranyl nitrates (10 g  $\text{litre}^{-1}$  with respect to the metal) in the solution has no effect on the reaction efficiency. If compounds containing  $\text{NH}_2$  groups (*e.g.*, hydrazine, urea or acetamide) are added, their catalytic degradation precedes the decomposition of ammonium nitrate. In this case, the process occurs only in the presence of a catalyst.

#### IV. Conclusion

Analysis of the literature data on the kinetics of heterogeneous catalytic redox reactions of actinide ions in aqueous media revealed that the majority of publications on the subject are devoted to studies of reduction of actinide ions with molecular reducing agents to the lowest oxidation states. The array of catalysts assayed is confined to activated charcoal and finely dispersed metals of the platinum group (as a rule, Pt) on inert supports. Despite the fact that catalytic properties of palladium and rhenium sulfides are now well established, these materials have not found wide application because of poorly developed surfaces. It seemed therefore tempting to prepare  $\text{PdS}$  or  $\text{Re}_2\text{S}_7$  immobilised on supports with a more developed surface and to examine their activities in reactions with  $\text{U(VI)}$ ,  $\text{Np(V)}$  and  $\text{Pu(IV)}$ . It would also be interesting to broaden the range of non-platinum catalysts and to study catalytic properties of  $\text{Tc}_2\text{S}_7$  or a  $\text{Re}_2\text{S}_7 + \text{Tc}_2\text{S}_7$  mixture.

The choice of a support for active catalytic components is a task of no less importance due to demands from radiochemical technology. Aggressive nitric acid media and high-intensity radiation pose serious restrictions on the choice of supports. They should possess high chemical stability and radiation resistance, high mechanical strength and ease of application of the active component. Catalysts with finely dispersed platinum supported on spherical silica gel beads ( $\text{Pt}/\text{SiO}_2$ ) were chosen for the totality of properties. Silica gel is most often used as a support; it possesses high chemical stability in nitric acid media, however, it is not a support of choice due to low mechanical strength and low abrasion resistance, which inevitably leads to mechanical degradation of the catalyst grains upon long-term utilisation. Moreover, the use of  $\text{SiO}_2$  is restricted to acidic media. The use of silica gel as a support in alkaline and carbonate solutions is impossible due to its low chemical stability in these media. Therefore, a search for novel supports is a topical task in heterogeneous catalysis in aqueous media. In this respect, composite materials based on titanium, zirconium and thorium dioxides are promising. By virtue of their high chemical stability in acidic and alkaline media, sintered porous microgranules prepared by the sol-gel procedure should manifest sufficiently high mechanical strengths and high durability. Of special interest are studies of the effect of the nature of the support on the catalytic properties of the active component.

As regards the mechanisms of heterogeneous catalytic reactions of actinide ions, many of their aspects remain obscure. The ionic–molecular schemes of heterogeneous catalytic processes are largely based on the formal kinetics and the generally accepted concepts on the existence of different actinide species in the media under study. As a rule, there are three possible mechanisms of adsorption-type reactions that are discussed. These include: (1) activated adsorption and dissociation (atomisation) of molecular reagents on the active sites of the catalyst followed by reactions of reactive radicals with metal ions in solution, as in the case of reduction of actinide molecules with molecular hydrogen and, probably, hydrazine; (2) complexation of reactants in solution and its activated adsorption on the catalyst surface followed by decomposition due to charge transfer within the complex; (3) adsorption of reactants on the adjacent catalytic sites and charge transfer through the  $\text{Pt}\text{--Pt}$  bridge with subsequent desorption of the reaction products. As a rule, these

mechanisms are kinetically indistinguishable and the choice of a reaction relies on indirect data and is purely arbitrary.

The role of active catalytic components in the initiation of heterogeneous redox reactions in aqueous solutions remains to be elucidated. All the substances previously described in the literature that manifest catalytic activities in redox reactions of actinide ions in aqueous media are conductive or electrode materials. In electrolyte solutions, to which category all the above-mentioned systems belong, these materials acquire a surface charge the magnitude of which is determined by the potential-forming components of the aqueous medium. Catalysts play the role of electrodes on which electrochemical processes occur at rates that obey the laws for the electrode kinetics. Such a mechanism is realised in the catalytic reduction of Pu(VII) with water [the potential-forming pair is Pu(VII)/Pu(VI)] and probably in the catalytic oxidation of Np(IV) with nitric acid (the potential-forming pair is  $\text{HNO}_3/\text{HNO}_2$ ). Here, the platinum catalyst plays the role of an anode on which electrochemical decomposition of water or oxidation of Np(IV) takes place. A similar approach can be applied, in principle, to any other catalytic reaction of actinide ions. In the general case, the analysis of mechanisms of heterogeneous catalytic reactions in aqueous solutions should take into consideration both the adsorption-type and electrochemical constituents of the process.

Catalytic decomposition of organic compounds in nitric acid media largely occurs as redox reactions of organic molecules adsorbed on the surface of a catalyst with oxidising species generated in homogeneous equilibrium reactions ( $\text{NO}_2^+$ ) or in a heterogeneous catalytic redox cycle involving nitric acid and reducing agents on the catalyst surface ( $\text{HNO}_2$ ). In the latter case, the reaction occurs first as a heterogeneous process, but can further be extended to the bulk of the solution owing to the autocatalytic formation of nitrous acid (catalytic denitration with formic acid). Here, the platinum catalyst does not accelerate the process but only initiates it by 'triggering' the reaction of  $\text{HCO}_2\text{H}$  with  $\text{HNO}_3$ . In acidic solutions devoid of nitrate ions, molecular inorganic nitrogen-containing compounds (hydrazine, hydrazoic acid, etc.) decompose in the presence of platinum catalysts through an adsorption–dissociation mechanism. This consists of cleavage of the N–N bond as a result of chemisorption. Taking into account the oxidation states of nitrogen in the starting compounds and reaction products, the overall process can be defined as heterogeneous catalytic disproportionation. In nitric acid media, the contribution of this reaction to the decomposition of nitrogen-containing compounds decreases with an increase in  $[\text{HNO}_3]$ . Under these conditions, the catalytic redox cycle involving surface platinum atoms and direct heterogeneous catalytic oxidation of adsorbed molecules with nitroyl cations are the main processes determining the decomposition.

The behaviour of catalysts themselves in the reaction systems under study is among the main problems of heterogeneous catalysis in aqueous media that still await solution. Indeed, the published data are devoted to chemical conversions of reaction components in aqueous media. At the same time, studies on hydrazine decomposition and catalytic denitration have shown that the catalytic redox reactions involve surface atoms of the active component of the catalyst, i.e., platinum (the surface catalytic redox cycle). Therefore, elucidation of the role of catalysts in the initiation of heterogeneous catalytic redox reactions in aqueous media demands a deeper insight into the mechanisms of their action and in-depth studies of the catalyst surface, determination of the forms of atoms of active components existing on the surface and studies of the effects of chemical environment on their changes.

Despite the obvious progress in the application of catalysts based on platinum-group metals in radiochemical practice, the use of heterogeneous catalytic processes in the technology of the nuclear fuel cycle opens up broad opportunities for their more extensive application. This is explained by obvious advantages

and high competitiveness of catalytic methods in comparison with electrochemical and chemical technologies.

The main disadvantage of the recently developed catalytic methods is the use of expensive and scarce platinum as an active component of catalysts, which are materials subject to strict control. At the same time, due to naturally occurring attrition wear and corrosion of the catalysts, it inevitably falls into the radioactive wastes and its recovery is impossible due to specific features of the radiochemical technology. It is this fact that often restricts the use of catalytic processes in large-scale technologies of the nuclear fuel cycle. From this standpoint, a search for novel catalysts able to initiate redox reactions in aqueous media and their in-depth studies still remain an important scientific and practical problem.

Once such problems have been solved, heterogeneous catalysis will occupy a worthy place in the chemistry and technology of wet processes relevant to the nuclear fuel cycle.

**Abstract.** Methods for preparation of high-melting carbides, nitrides and borides in the form of ultradisperse powders, nanotubes, nanowires, and nanoporous and compact nanostructured materials are considered. Information concerning the structure, physicochemical and physicomechanical properties and application fields of these objects are presented. Prospects for the use of nanomaterials based on high-melting compounds are discussed. The bibliography includes 161 references.

## I. Introduction

Carbides, nitrides and borides of various elements are characterised by high values of melting temperatures, hardness, strength, elasticity, chemical passivity and a broad spectrum of electrical properties. This predetermines the use of these compounds in mechanical engineering, electronics, power engineering, chemical industry and other fields of technology. Recently, interest in high-melting compounds has increased in connection with the design of nanostructured materials (from this point on they are called nanomaterials). Nanostructuring is responsible for significant changes in the physicomechanical, physicochemical and biological properties and, correspondingly, for unique operating characteristics of nanomaterials. A characteristic feature of the structure of nanomaterials is the presence of grains (or phase inclusions and pores) of size less than 100 nm. This limit is not a strong physicochemical or physicomechanical criterion and was chosen conditionally.

The state-of-the-art in the field of research on nanocrystalline high-melting compounds was first analysed<sup>1,2</sup> by the author of this review a decade ago. It is of interest to revise the situation now. More than thirty review articles reported in the last decade (see, *e.g.*, Refs 3–36) indicate that research in the field is topical. They are more or less concerned with problems in nanocrystalline high-melting compounds. However, additional analysis of the data available is required. In this review the emphasis is placed on recent information on the synthesis and properties of nanopowders, compacts and nanofilms based on metal and non-metal

carbides, nitrides and borides and their composites; novel species, namely, nanotubes and nanowires are also characterised.

The total number of high-melting carbides, borides and nitrides approaches a hundred (see Ref. 37); however, only a few of them have been well studied. Meeting the condition of nanocrystallinity decreases this number to a total of 15 to 20 binary phases (TiC, ZrC, NbC, WC, VC, TiN, ZrN, NbN, TiB<sub>2</sub>, ZrB<sub>2</sub>, SiC, B<sub>4</sub>C, BN, AlN, Si<sub>3</sub>N<sub>4</sub>, *etc.*), which will be analysed below. In this review, we left the oxide and intermetallic nanocrystalline high-melting compounds out of consideration. Indeed, a wide variety of compounds in the former group require a separate consideration, while the compounds belonging to the latter group have almost not been studied as yet.

## II. Nanopowders.† Nanotubes. Nanowires

### 1. Silicon carbide and silicon nitride, aluminium nitride, boron carbide and boron nitride

Covalent high-melting materials, such as SiC, Si<sub>3</sub>N<sub>4</sub>, AlN, B<sub>4</sub>C and BN are most often obtained by carbothermal reduction (in particular, in the presence of magnesium),<sup>36,38,39</sup> plasma chemical synthesis,<sup>40,41</sup> pyrolysis of organosilicon and inorganic precursors,<sup>42–44</sup> nitridation (including explosion of wires),<sup>45–47</sup> sol–gel techniques,<sup>48</sup> self-propagating high-temperature synthesis<sup>36,49,50</sup> and laser-assisted synthesis.<sup>51</sup> At present, particular attention is focussed on preparation of complex composite nanopowders of the types Si<sub>3</sub>N<sub>4</sub>/SiC,<sup>43</sup> TiN/Si<sub>3</sub>N<sub>4</sub>,<sup>47</sup> AlN/BN (see Ref. 42), *etc.*, and nanopowders with narrow fraction composition (see, *e.g.*, Ref. 51). Various starting compounds for the synthesis of carbides, borides and nitrides and possible strategies of fabrication of silicon carbonitrides and boron nitride have been analysed.<sup>43,50,52</sup>

For instance, a Si<sub>3</sub>N<sub>4</sub>/SiC composite was synthesised from mixtures of the individual compounds necessary for the preparation of SiC and Si<sub>3</sub>N<sub>4</sub>, from a mixture of polysilane with silicon powder or from a complex compound containing reactive groups, SiH, NH and CH<sub>2</sub>CH.<sup>43</sup> Pyrolysis in a nitrogen atmosphere was followed by an X-ray phase analysis (XPA) study, which revealed the formation of composites of desired compositions in all three cases. Monodisperse Si<sub>3</sub>N<sub>4</sub>/SiC nanopowder was obtained after the Si<sub>3</sub>N<sub>4</sub> and carbon (in the form of spherical particles) powders synthesised by heating organosilicon precursors in nitrogen were annealed in argon at 1450 °C.<sup>53</sup> A comparison of different methods of synthesis of BN nanopowder showed that the most

† Nanopowders (or ultradisperse powders) are powders whose particles are less than 100 nm in size.

efficient method consists of the reduction of  $B_2O_3$  with magnesium in nitrogen atmosphere.<sup>50</sup> MgO particles thus formed play an important role in prevention of the BN [and SiC (see Ref. 39)] particles from further growth; however, the mechanism of the process is still poorly understood. In a general form, combustion in the  $B_2O_3$ –Mg– $N_2$  system can be described by the following reaction

where R is the additive precluding the formation of magnesium borides. The semiproduct, BN + MgO, sintered in the course of self-propagating high-temperature synthesis is then chemically dispersed in sulfuric or hydrochloric acid solutions.<sup>50</sup>

$\beta$ -SiC nanopowder characterised by narrow particle size distribution (15–20 nm) is obtained by laser-assisted synthesis from a silane–acetylene mixture containing diborane (this additive is introduced to form a small amount of boron (~1 mass %), which activates the subsequent sintering of particles).<sup>22, 51</sup> For comparison, mention may be made that a conventional SiC nanopowder prepared using this procedure has a much wider particle size distribution (*e.g.*,  $50 \pm 25$  nm).<sup>22</sup>

Vapour-phase self-propagating high-temperature synthesis with controllable formation of condensed phases is considered promising for the preparation of nanopowders. However, these reactions, as applied to the synthesis of ultradisperse powders comprising particles of preset size, are still poorly understood.<sup>36</sup>

Often, the synthesis of nanopowders results in X-ray amorphous phases. Analysis of the data listed in Table 1 shows that the temperature affects the phase composition and particle size in the  $Si_3N_4$  powders synthesised from a  $SiCl_4$  +  $NH_3$  gaseous mixture in high-frequency plasma. The amorphous phase is quite stable and exists up to ~1500 °C. The particle size increases as a result of grain-coarsening. The results cited<sup>54</sup> can be considered reliable because the grain size was measured using two independent methods, X-ray analysis and transmission electron microscopy (TEM).

**Table 1.** Change in the phase composition [*c* (vol. %)] and  $Si_3N_4$  particle size (*d*/nm) after annealing.<sup>54</sup>

| Phase composition | Before annealing |          | $T = 1350$ °C |          | $T = 1500$ °C |          |
|-------------------|------------------|----------|---------------|----------|---------------|----------|
|                   | <i>c</i>         | <i>d</i> | <i>c</i>      | <i>d</i> | <i>c</i>      | <i>d</i> |
| Amorphous phase   | 80               | 30       | 65            | 50       | 20            | —        |
| $\alpha$ -Phase   | 17               | 35–75    | 32            | 50–60    | 67            | 95       |
| $\beta$ -Phase    | 3                | —        | 3             | —        | 13            | 95       |

More complex amorphous high-melting systems such as Si–N–C and Si–N–C–B can be synthesised using organometallic polymers and monomers based on polysilazanes (*e.g.*,  $[(Si(Me)R-NH)_n-C(O)NH]_m$ , a polyborazole (of the  $[B_3N_3H_4]_n$  type), an oligomer of boron-modified vinylsilazane, *etc.*<sup>55, 56</sup> as precursors. Products of thermolysis of these compounds are used for both the preparation of nanopowders (after additional ball milling) and subsequent high-temperature pressure treatment in order to obtain amorphous or nanocrystalline materials.

Information on the synthesis of nanotubes and nanowires of high-melting compounds is scarce at the moment, but the number of studies on the subject is increasing. For instance, the following methods of synthesis of boron nitride nanotubes have been reported: laser ablation (a 1 kW  $CO_2$  laser focussed on a 7.5 mm spot);<sup>57</sup> nitridation of finely disperse boron powder at 1200 °C for 16 h;<sup>58</sup> synthesis involving catalysts (FeB) (see Ref. 59), *etc.* Encapsulation of  $ZrO_2$  and cobalt nanorods inside the BN nanotubes was reported.<sup>60, 61</sup> It was pointed out that some methods allow nanotubes to be fabricated in gramme<sup>57</sup> and even kilogramme quantities.<sup>58</sup>

Boron nitride nanowires ~20 nm in diameter and several tens of micrometres long can be formed by the interaction of an  $N_2$  +  $NH_3$  vapour mixture with nanoscale iron boride ( $\alpha$ -FeB) particles at 1100 °C.<sup>62</sup> At this temperature, aluminium nitride nanowires are synthesised from a mixture of the aluminium and  $Al_2O_3$  powders and carbon nanotubes are obtained, which in this case play the role of not only the reducing agent but also a kind of template that specifies the shape and size of the nanowires.<sup>63</sup> Different methods of synthesis of nanotubes and nanowires (or nanofilaments) based on silicon carbide and silicon nitride have been reported.<sup>64, 65</sup> Figure 1 presents the electron micrographs of SiC specimens with different morphologies. Nanowires, nanofilaments, nanoporous materials and SiC nanoparticles were fabricated from a carbonaceous silicon precursor synthesised by the interaction of a phenol-formaldehyde polymer with tetraethoxysilane and treated in a different fashion.<sup>65</sup> However, the stability and reproducibility of the treatment regimes still remain unclear.

**Figure 1.** Electron micrographs of carbide silicon specimens with different morphologies:<sup>65</sup>

nanowires (*a*), nanofilaments (*b*), a nanoporous specimen with an average pore size of about 5 nm and a specific surface area of  $200 \text{ m}^2 \text{ g}^{-1}$  (*c*) and nanoparticles (*d*).

## 2. High-melting transition-metal compounds (WC, TiC, TiN, $TiB_2$ , *etc.*)

Tungsten carbide, as a base for widely used hard alloys, has attracted particular attention of researchers. A method of preparation of WC/Co nanopowders by low-temperature reduction and carbidisation of a mixture of ammonium metatungstate and cobalt chloride in a fluid bed reactor followed by spray drying (this favours good mixing of nanocomponents),<sup>66</sup> which was advertised in a big way in the early 1990s, this did not gain acceptance in industry. This was mainly due to the fact that at present it is impossible to retain the nanostructure in the course of subsequent sintering. Nevertheless, extensive searches for optimum methods of fabrication of WC and WC/Co nanopowders have been carried out with allowance for the general trend towards fabrication of strong, wear-resistant ultrafinely-disperse hard alloys. Doping tungsten carbide with vanadium carbide and with VC–TaC solid solution precludes grain-coarsening in the sintering stage.<sup>67, 68</sup> A process involving mechanochemical and plasma chemical syntheses has been reported.<sup>69–74</sup> Micro- and nanopowders of more complex compositions, *e.g.*, WC–35% TiC–Co (see Ref. 75) and  $Ti(C,N)$ –WC–Ni (see Ref. 76) were prepared by carbothermal reduction and co-milling. It should be kept in mind that nanopowders with particle sizes less

than 100 nm were not obtained by the authors of all the studies cited above;<sup>67–76</sup> often, characterisation of the powders with respect to the impurities and fraction distributions was also incomplete. Usually, the advertising circulars of most of big manufacturers of hard-alloy WC powders [H.C.Starck (Germany), Wolfram BHG (Austria), Dow Chemical Company (USA), *etc.*] indicate a particle size less than 0.2 to 0.3  $\mu\text{m}$ .<sup>68, 77, 78</sup> Inframat Corporation (IMC, USA) offers the WC and WC–(5%–15%)Co nanopowders characterised by a size 40–80 nm of the carbide grains, which are then agglomerated to form particles with the average size 0.2–0.4  $\mu\text{m}$ .<sup>79</sup> Agglomeration is carried out in order to prepare the charge material to pressing.

Various methods of synthesis of TiN, TiC, TiB<sub>2</sub> nanopowders and related high-melting compounds have been reported. Methods used in addition to the plasma-enhanced and laser-assisted syntheses, carbothermal reduction and conventional ball milling<sup>1, 2</sup> mentioned above include self-propagating high-temperature synthesis, mechanochemical synthesis, high-temperature vapour-phase reactions, high-energy ball milling and some others. As in the case of nanopowders of covalent high-melting compounds, the emphasis is placed on the preparation of multi-component and multicomposition nanoparticles. For instance, nanoparticles of TiN/TiB<sub>2</sub> composite are obtained by high-energy ball milling and mechanochemical synthesis of the starting Ti + TiB<sub>2</sub> mixtures in a nitrogen atmosphere of Ti + BN mixtures in a argon atmosphere.<sup>80–82</sup> A procedure proposed for the preparation of TiB<sub>2</sub>/TiN/Ti(C,N) nanocomposites included high-energy ball milling of the starting powders, (Ti + B<sub>4</sub>C) and (Ti + BN), to give products (TiC + B<sub>amorph</sub>) and (TiN + B<sub>amorph</sub>) and subsequent ball milling of the products to produce TiB<sub>2</sub> following the reaction

The final ball milling step followed by non-isothermal annealing to 1300 °C (at a heating rate of 10 °C/min) produces TiB<sub>2</sub> + TiN + Ti(C,N) nanoparticles of size 30–60 nm, which can be detected by XPA, X-ray analysis and TEM.<sup>83</sup> Methods of synthesis of transition-metal high-melting compounds are characterised in Table 2.

However, in spite of a large number of studies on the synthesis of nanocrystalline high-melting compounds (over 60 publications), in most cases the efficiency of different methods are difficult to compare. The reason is that many important details (impurity content, nanoparticle size distribution, pressing and sintering behaviour of ultradisperse powders, properties of consolidated compacts, *etc.*) are still out of researchers' eyeshot.

### 3. Selected properties of nanopowders and nanotubes

It should be noted that the particle and crystallite sizes reported in the most representative studies<sup>54, 70, 74, 83, 88, 91</sup> were obtained by at least two independent methods (*e.g.*, X-ray analysis and TEM). The results of specific surface area measurements and the estimates of the average particle size cannot be considered sufficient without analysing the particle size distribution. This can be explained by the fact that even a small amount of coarse grains can initiate significant grain growth in the course of subsequent sintering and thus favour the disappearance of the nanostructure.

Unfortunately, not all authors of synthetic studies report such characteristics of ultradisperse powders and nanoparticles as the content of impurities (especially, oxygen) and adsorbed gases, interfacial segregations and deviation from stoichiometry. An investigation<sup>99</sup> of WC, NbC, TiC, SiC, Si<sub>3</sub>N<sub>4</sub>, AlN and TaN nanopowders prepared by plasma chemical synthesis showed that the overall content of oxygen increases as the specific surface area increases, the major contribution to this increase coming from the oxygen-containing gases adsorbed on the surface. Studies of gas evolution in the course of high-vacuum annealing of TiN and Si<sub>3</sub>N<sub>4</sub> nanopowders showed that the vapour phase mainly con-

**Table 2.** Methods of preparation of high-melting compound nanopowders.

( $V$  is the reduced total volume of the gases).<sup>100</sup>

The quantum-chemical methods suitable for prediction of the adsorption of gases (water vapours, ammonia, *etc.*) on the Si<sub>3</sub>N<sub>4</sub> surface have been considered.<sup>101</sup> Changes of the surface charge density in the interaction of ultradisperse Si<sub>3</sub>N<sub>4</sub> powder with nitrate solutions were analysed.<sup>102</sup>

The properties of nanotubes, nanowires and nanofilaments of high-melting compounds have become the subject of more and more extensive research (see, *e.g.*, Refs 103–106), but a considerable body of data available require an additional substantiation. Studies on boron nitride hold a leading position; in particular, it was revealed that the bandgap of the BN nanotubes is ~5.5 eV, being independent of the nanotube diameter. As to the elastic characteristics, there are at least two different results for the elastic modulus,  $E = 1.22 \pm 0.24 \text{ GPa}$ ,<sup>59</sup> which exceeds all the known  $E$  values for nanofilaments, and  $E = 722 \text{ GPa}$ .<sup>103</sup> Methods of synthesis and the properties of BN, BCN, SiC, AlN, Si<sub>3</sub>N<sub>4</sub>, TiC and BC<sub>x</sub> nanowires have been reviewed.<sup>106</sup>

### III. Consolidated compacts

#### 1. Consolidation processes: general

Conventional regimes of pressing and sintering of compounds are almost inapplicable to nanopowders.<sup>1,2</sup> No significant densification occurs even in the case of high-pressure pressing (at  $>1$  GPa), because the compactibility appreciably decreases due to the developed surface and strong intergrain friction forces.<sup>107</sup> The residual porosity of the TiN and Si<sub>3</sub>N<sub>4</sub> nanopowders pressed at 7–9 GPa exceeded 10%–15%; magnetic-pulse pressing of the TiN powder (particle size 70–80 nm) at pressures to 2–3 GPa also did not lead to significant decrease in porosity.<sup>108,109</sup> At the same time further sintering of powders is usually accompanied by intense grain growth due to recrystallisation occurring at high temperatures. As a result, the nanostructure disappears and the physicochemical and mechanical characteristics are not improved.

At present, there are a number of methods of consolidation of powder nano-objects, which make it possible to prepare materials with the desired nanostructure. These are high-pressure treatment at relatively moderate temperatures,<sup>4,5,110</sup> non-isothermal sintering,<sup>34,111</sup> reactive hot-pressing,<sup>112</sup> arc-discharge (plasma-assisted) sintering,<sup>88,113</sup> short-term liquid-phase sintering,<sup>66</sup> sintering activated by phase transitions<sup>114</sup> and some others. Here, recrystalli-

sation in the course of sintering and, correspondingly, grain growth are precluded due to either lowering the temperature and shortening the duration of sintering under high pressure,<sup>4,5,110</sup> activation of diffusion,<sup>88,112–114</sup> or optimisation of the shrinkage and recrystallisation processes in different temperature intervals.<sup>34,111</sup> Methods combining mechanochemical synthesis and consolidation deserve attention because of considerable promise for preparation of TiB<sub>2</sub>/TiN-type nanocomposite materials.<sup>81,112</sup>

The effect of the disorder–order transition on the sintering of silicon carbide is quite demonstrative.<sup>114</sup> The effect of temperature on the change (in the course of sintering) in the relative density of the SiC nanopowders prepared by mechanochemical synthesis under intense milling (grain size 5 to 10 nm, agglomeration into larger grains of size 100–150 nm) is illustrated by Fig. 2. For comparison, we present the data on the sintering of commercially available SiC nanopowder (grain size of about 30 nm). A dramatic increase in the relative density at  $\sim 1700$  °C was interpreted as a consequence of structural ordering in the ball milling synthesised SiC, which was confirmed by X-ray analysis data, namely, sharper reflections and the appearance of a peak at  $2\theta \sim 40^\circ$ . Besides, an analogy between the X-ray diffraction patterns of the commercially available SiC powder and the carbide sintered at 1800 °C is obvious (see the X-ray diffraction patterns in Fig. 2).

However, in practice the methods listed above always lead to nanomaterials with a grain size of at least about 30 nm and low residual porosity (at least  $\sim 2\%$ ), which of course affects the physicomechanical and physicochemical properties.

The laws of sintering of WC nanopowders are of particular interest (see, e.g., Refs 66–68, 4–78, 115) because of the wide use of this high-melting compound. It is known that the VC, Cr<sub>3</sub>C<sub>2</sub> and TaC additives act as inhibitors of grain growth in sintering of hard alloys. A dilatometric study of shrinkage of conventional WC + 7.8% Co + 0.7% VC powders and nanopowders of the same composition showed that shrinkage of the latter is carried out in the solid phase while that of the coarse-grain powders occurs under conditions of liquid-phase sintering.<sup>115</sup>

A method of synthesis of nanoporous materials based on SiC by reactive sintering of highly disperse silicon–colloidal graphite (Si + 30% C) mixtures at relatively moderate temperatures (1100–1200 °C) has been reported.<sup>116</sup> This technique permits preparation of micro- and nanomaterials with porosities ranging between 50% and 65% and a specific surface area of the order of 30 to 40 m<sup>2</sup> g<sup>−1</sup>; the calculated effective pore size in the materials is  $\sim 20$  nm and the maximum pore size is at most 300 nm.

#### 2. Structure and properties

The most widely used methods of studying the structure of nanomaterials include TEM, scanning electron microscopy (SEM), atomic force microscopy (AFM) and X-ray analysis. High resolution of the electron microscopy methods is necessary for the disclosure of such peculiar features as the presence of very small particles, pores and grains (of size less than 10–20 nm), observation of dislocations and establishment of the structure of interfaces (grain boundaries and phase boundaries) and the character of breakdown of nanostructures (see, e.g., Refs 117–119). Figure 3 presents a high-resolution TEM image of a TiN film.<sup>117</sup> A characteristic strip-like structure can be seen, which corresponds to the atomic planes, and a number of intracrystalline edge dislocations (the possibility for them to exist in the nanomaterials based on high-melting compounds was confirmed by the estimates<sup>117</sup> made with allowance for the concepts developed in another study<sup>120</sup>).

A bright-field electron micrograph of the structure of hot pressed ZrC nanopowders obtained by mechanochemical synthesis (crystallite size is about 5 nm, agglomerate size of nearly 3  $\mu$ m) and the grain size distribution are shown in Fig. 4.<sup>88</sup> As can be seen, hot pressing at relatively moderate temperatures is accompanied by intense grain growth. The specimens obtained were characterised by an average grain size of nearly 95 nm, which

**Figure 2.** Relative densities of SiC nanopowders plotted vs. sintering temperature (a) and X-ray diffraction patterns of commercially available SiC powder and specimens sintered at different temperatures (b);<sup>114</sup>

(a): commercially available SiC powder (1); powder obtained by mechanochemical synthesis (2); the same powder sintered at 1700 °C for 0 (3) and 2 min (4). The duration of heating to corresponding sintering temperatures was the same for all specimens. The sintering time of specimens 1 and 2 was 10 min;

(b):  $T = 1400$  (1), 1600 (2), 1700 (3), 1800°C (4); commercially available powder (5).

**Figure 3.** HRTEM image of TiN nanostructure obtained in the direct resolution mode.<sup>117</sup> Shown are the edge dislocations ( $\perp$ ).

**Figure 4.** Bright-field electron micrograph of nanocrystalline zirconium carbide obtained by hot pressing at 1300 °C and a pressure of 1.5 GPa (a) and the grain size distribution (b).<sup>88</sup>

approaches the upper size limit for nanostructures, and a rather broad grain size distribution.

Electron energy dispersive analysis of the TEM and SEM images makes it possible to determine the chemical composition, but the most informative method of investigation of nanomaterials is electron energy loss spectroscopy, which provides information on the interfacial segregations. However, the necessary equipment is available in a few research laboratories and information on impurity segregations on grain boundaries of high-melting compounds is restricted to the data for silicon nitride and to some extent for WC–Co hard alloys.<sup>100, 121</sup>

Hardness is the best studied characteristic of nanomaterials based on high-melting compounds. This can be explained by the availability of measuring instruments and relative ease of speci-

men preparation. Knowledge of hardness is important in manufacturing of tool materials. Data on the hardness of nanocrystalline high-melting compounds have been the subject of several review articles (see, *e.g.*, Refs 9, 15, 21, 23, 30, 31, 122). These results, as well as the new data<sup>43, 67, 69, 77, 78, 88</sup> showed that the hardnesses of nanocrystalline titanium nitride<sup>110</sup> and tungsten carbide<sup>123</sup> ( $\sim 30$  and  $\sim 40$  GPa, respectively) are 1.5–2 times higher than those of conventional coarse-grained materials only if the specimens were thoroughly prepared and well-characterised. The hardnesses of nanocrystalline SiC,<sup>‡</sup> Si<sub>3</sub>N<sub>4</sub>, ZrC, TiC, *etc.* specimens were comparable with those of polycrystals and single crystals, which can be explained by porosity and poorly developed nanostructures. For instance, the hardness of the ZrC specimens with the morphology shown in Fig. 4a was  $\sim 27$  GPa,<sup>88</sup> while the corresponding polycrystals and single crystals showed 24 to 26 GPa.<sup>37</sup> Thus, methods of fabrication of certain consolidated nanomaterials based on high-melting compounds are still far from being perfect.

The effect of the relative density on the microhardness and elastic modulus of the specimens prepared from TiN nanopowders of different dispersity can be followed using the data shown in Fig. 5. As can be seen, hardness depends on the porosity and grain size, while the elastic modulus depends only on porosity in this range of grain sizes. From simple estimates it follows that a decrease in the elastic modulus of nanomaterials can be expected at grain sizes less than 10 nm, where the proportion of interfaces (grain boundaries) exceeds 20% of the total volume.

The dependences of hardness ( $H_V$ ) and elastic modulus on porosity  $\vartheta$  ( $\vartheta = 1 - \tau$ , where  $\tau$  is the relative density) have the form

$$H_V = H_{V_c}(1 - 4.7\vartheta) \text{ for } d = 70 - 80 \text{ nm,}$$

**Figure 5.** Microhardness (a) and elastic modulus (b) plotted vs. relative density ( $\tau$ ) of TiN nanocrystalline specimens obtained at 4–7.7 GPa and  $T = 1200$ – $1400$  °C from ultradisperse powders with the particle size 16–18 (1) and 70–80 nm (2).<sup>110</sup> The open and solid circles denote the results of two series of experiments.

<sup>‡</sup> Even greater hardness, 32–41.5 GPa, was reported<sup>124</sup> for superstoichiometric silicon carbide specimens (grain size  $\sim 330$  nm) obtained at high pressures and high temperatures.

$$H_V = H_{V_c}(1 - 2.1 \vartheta) \text{ for } d = 16 - 18 \text{ nm},$$

$$E = E_c(1 - 3.9 \vartheta),$$

where  $H_{V_c}$  and  $E_c$  are the hardness and the elastic modulus for the compacted state ( $\vartheta = 0$ ,  $\tau = 1$ ), which are respectively equal to 26.2 ( $d = 70 - 80$  nm), 28.8 ( $d = 16 - 18$  nm) and 490 GPa ( $d$  is the average initial particle size of the TiN nanopowder).

The linear character of the plots shown in Fig. 5 is typical of many powder materials characterised by narrow porosity ranges.<sup>37</sup>

In discussing the properties of nanomaterials one should take into account not only the role of the nanostructure but also the impurity content and the possibility of interfacial impurity segregations; porosity, residual stress, nonequilibrium phases and structural vacancies (deviation from stoichiometry); interface states and many other factors (as applied to hardness, these are, *e.g.*, the measuring technique, load magnitude and surface roughness). Taken altogether, this makes the interpretation of the properties of nanomaterials a complicated task and the results reported should be accompanied by detailed discussion and conclusions should be thoroughly substantiated.<sup>8</sup>

A fracture toughness study of nanostructured materials based on high-melting compounds revealed an intercrystallite character of crack propagation. This can be confirmed by the micrographs of the TiN fracture surface and the crack (Fig. 6).<sup>10</sup> As can be

**Figure 6.** SEM micrographs of the surface of nanocrystalline TiN.<sup>10</sup> Fracture surface (a) and crack propagation (b).

§ For instance, the microhardness values of 60–80 GPa reported<sup>95</sup> for the specimens with ~30% porosity, sintered from vanadium carbide (VC<sub>0.875</sub>) nanopowders at 1700 °C cast some doubt. Extrapolation of these data to zero porosity leads to a microhardness of about 200 GPa, which seems to be unrealistic (the hardness of diamond is ~100 GPa).

seen, the fracture occurs at grain boundaries. The intercrystallite character of fractures provides an explanation for the fact that such an important characteristic of brittle single-phase materials as the crack resistance, remains almost unchanged as the grain size decreases.<sup>10</sup>

Information on the high-temperature strength of nanostructured high-melting compounds is scarce. The possibility for superplasticity (high creep rates) to occur in microcrystalline composites of the Si<sub>3</sub>N<sub>4</sub>/TiB<sub>2</sub> type at 1600 °C was pointed out.<sup>125</sup> At the same time extremely low creep rates were found in Si<sub>3</sub>N<sub>4</sub>/SiC nanocomposites (see Ref. 126) and in amorphous ternary (Si/C/N) and quaternary (Si/B/C/N) specimens synthesised by pyrolysis of organosilicon polymers.<sup>56</sup>

The effect of the TiN content on the resistivity ( $\rho$ ) of Si<sub>3</sub>N<sub>4</sub>/TiN composite (grain size 100–600 nm) is illustrated in Fig. 7.<sup>47</sup> As the TiN concentration in this composite changes, the  $\rho$  value changes by nearly fifteen orders of magnitude, from the values characteristic of dielectrics (Si<sub>3</sub>N<sub>4</sub>) to those typical of metals and metal-like compounds (TiN), the latter being observed at the TiN concentrations of less than 20 vol. %.

**Figure 7.** Resistivity of Si<sub>3</sub>N<sub>4</sub>–TiN system plotted vs. its composition.<sup>47</sup>

Numerous interfaces in nanomaterials produce natural barriers to the motion of charge carriers. Therefore, a decrease in the grain size is accompanied by a decrease in the resistivity and thermal conductivity. A good example of the latter is provided by SiC.<sup>22</sup> At room temperature, the thermal conductivities of nanocrystalline (grain size about 70 nm) and coarse-grained SiC (grain size 3 to 5  $\mu$ m) specimens differed by a factor of 8. At 1400 °C, only a twofold difference was observed, due to the change in the contribution of phonon–phonon scattering.

Numerous interfaces in nanomaterials can favour enhancement of their radiation stability due to the increase in the number of escape channels of radiation-induced defects and, hence, lower degree of swelling of specimen.<sup>22</sup>

An interesting size effect related to the superconducting properties was found in a number of high-melting compounds. The effect of the particle size of nanopowders on the change in the critical magnetic field in TiN, NbN, VN, Nb (N,C) and V<sub>3</sub>Si,<sup>127</sup> which seems to be related to the evolution of the phonon spectrum of nanoparticles, is illustrated in Fig. 8.

However, the physical, mechanical and physicochemical properties of nanomaterials based on high-melting compounds are still poorly understood. Owing to limited quantities of well-characterised specimens, studies of the size effects (*e.g.*, evaluation of the familiar Hall–Petch relation for strength and hardness) are in the early stage of development. Data on the constitutional diagrams of these materials in the nanocrystalline state are almost unavailable. This important information is limited to the old estimates obtained in the simplest regular approximation for the ZrC–C, TiN–AlN, TiN–TiB<sub>2</sub> and TiC–TiB<sub>2</sub> systems.<sup>128–130</sup>

**Figure 8.** Critical magnetic field plotted vs. grain size of high-melting compounds obtained by plasma chemical synthesis.<sup>127</sup>  $H_{c2}^d$  is the second critical field strength for nanopowders and  $H_{c2}^b$  is the same for the coarse-grained specimen. ## IV. Nanostructured films

### 1. Methods of fabrication: general

General information concerning physical and chemical methods of fabrication of films and coatings has been reported in a number of review articles (see, *e.g.*, Refs 1–5, 9, 15, 30, 31). Division of methods into physical and chemical ones is conditional because chemical reactions play a significant role in a number of physical methods (*e.g.*, physical deposition of films) while chemical methods involve many physical phenomena. The most widely used methods of fabrication of nanostructured films belong to the so-called physical deposition techniques, namely, reactive and non-reactive magnetron sputtering (high-frequency and d.c. modes), cathode (or arc-ion) sputtering, laser ablation and ion beam treatment of surface. High-temperature chemical deposition methods are employed more rarely. Coatings several tens of micrometres thick are fabricated using gas-thermal (plasma and detonation) deposition. Therefore, a variety of technological procedures for fabrication of nanostructured films and coatings are available; many of them have found large-scale applications. For instance, very hard multilayered (Ti,Al,Y)N/VN nitride films used as wear-resistant coatings for metal-working instruments are manufactured on large-scale high-vacuum multicathode magnetron sputtering equipment.<sup>30</sup>

The use of an additional magnetic field in the course of deposition permits efficient control of the crystallite sizes and the crystallite size distribution (Table 3).<sup>131, 132</sup> Mention may be made that nanostructured films can have much smaller grain sizes

**Table 3.** Average crystallites size (nm) in nitride/boride films prepared by non-reactive magnetron sputtering with  $\sim 400$  G external magnetic field switched off and on.<sup>131, 132</sup>

| Target                       | Field off     | Field on       |
|------------------------------|---------------|----------------|
| TiB <sub>2</sub>             | $3.6 \pm 1.8$ | $3.3 \pm 1.1$  |
| 75 TiB <sub>2</sub> + 25 TiN | $2.3 \pm 1.1$ | not determined |
| 50 TiB <sub>2</sub> + 50 TiN | $2.9 \pm 1.5$ | $1.8 \pm 0.3$  |
| 25 TiB <sub>2</sub> + 75 TiN | $5.9 \pm 4.0$ | $6.5 \pm 2.5$  |
| TiN                          | $29 \pm 15$   | $8.8 \pm 2.2$  |

compared to powder compacts. The lattice constant of a titanium nitride film with the NaCl-type structure is  $\sim 0.42$  nm; the crystallite of size  $\sim 2$  nm contains only  $\sim 5^3 = 125$  unit cells, *i.e.*, such films can be treated as cluster-consolidated materials.<sup>133</sup>

### 2. Investigation of the structure and composition

In addition to the methods of investigation of the structure of powders mentioned above (TEM, SEM, XPA, X-ray analysis and AFM), films are also studied by X-ray photoelectron spectroscopy, Auger electron spectroscopy (AES), Rutherford back-scattering spectroscopy, positron annihilation spectroscopy, secondary ion mass spectrometry, local electron diffraction, *etc.*

Table 4 lists the characteristics of some films we have studied.<sup>134</sup> The dark-field TEM image of the structure of the film fabricated in regime IV and the crystallite size distribution are shown in Fig. 9.<sup>133</sup> The size distribution in the case of magnetic field assisted deposition is shifted towards smaller sizes and becomes narrower (see Table 3). Approximate chemical formulae listed in Table 4 were calculated based on the AES data. Table 4 shows that the films deposited can be both superstoichiometric (regimes IV–VI for the TiN-based films) and understoichiometric (regimes I–III for the TiB<sub>2</sub>-based films); some films were amorphous after deposition. Considerable attention should be given to high solubility of components in the metallic and non-metallic sublattices. For instance, an equilibrium pseudobinary system TiB<sub>2</sub>–TiN is characterised by low mutual solubility of the components at room temperature.<sup>37</sup> However, in the film state the degree of mutual solubility of the boride and nitride becomes high (regimes III–V lead to single-phase composites) due to highly non-equilibrium character of the films deposited.

Thus, the properties of nanostructured films should be analysed with allowance for the possibility of high solubility of metallic and non-metallic components and for the non-stoichiometry of specimens, which is much higher than that of coarse-grained specimens of high-melting compounds. Yet another feature of such films is that their deposition and subsequent cooling to room temperature is accompanied by production of

**Table 4.** Composition and structures of films (1–3  $\mu$ m thick) plated in the d.c. regime (I) and in high-frequency regimes (II–X).<sup>134</sup>

| Target                         | Sputtering regime | Approximate formula                                                                          | Grain size/nm | Type of structure | Lattice constant/nm |                |
|--------------------------------|-------------------|----------------------------------------------------------------------------------------------|---------------|-------------------|---------------------|----------------|
|                                |                   |                                                                                              |               |                   | <i>a</i>            | <i>c</i>       |

<sup>a</sup> Approximate formula (Ti<sub>0.55</sub>Al<sub>0.37</sub>Fe<sub>0.08</sub>)(N<sub>0.73</sub>O<sub>0.11</sub>C<sub>0.16</sub>)<sub>1.075</sub>.

**Figure 9.** Dark-field TEM image of a Ti(B,N) film (regime IV, see Table 4) (a) and the grain size distribution (b).<sup>133</sup> Reflection: 111 (I), 200 (2) and 220 (3).

large residual stress (most often, compressive stress), which can be as high as several GPa;<sup>9</sup> this also affects the film properties.

In the text above we listed not all factors responsible for the properties of nanostructured films of high-melting compounds. But even a brief look at them revealed the need for thorough and comprehensive studies of such films by independent methods. Unfortunately, it does not always happen.

### 3. Properties of films

Complete information on the hardness, resistivity and elastic characteristics of single- and multilayered films of high-melting carbides, borides and nitrides is available from review articles.<sup>9, 23</sup> These data can be complemented with the following results.

The record hardness values (80–100 GPa) were obtained for (Ti, Si)N films fabricated using plasma-assisted chemical deposition.<sup>15</sup> However, these results appeared to be poorly reproducible. This was explained<sup>135</sup> by possible film degradation caused by impurities, in particular, oxygen.

High hardnesses (50 to 70 GPa) of single-layer films based on TiB<sub>2</sub> and B<sub>4</sub>C and of multilayered (Ti,Al)N/VN, TiN/TiB<sub>2</sub> and ZrN/ZrB<sub>2</sub> films have been reported (see, e.g., Refs 9, 15, 29, 30, 131–138). Earlier,<sup>23, 122</sup> it was pointed out that progress made in the field of fabrication of films of novel ultrahard materials based on nanostructured high-melting compounds is more pronounced compared to fabrication of consolidated powder compacts. This is due to the possibility of forming nanostructures with a crystallite size of less than 10 nm in films.

Layered nanocomposites of the TiC/C<sub>amorphous</sub> and WC/C<sub>amorphous</sub> types, characterised by low and stable friction coef-

ficients and high wear resistance, have been developed.<sup>139</sup> These properties are of paramount importance for fabrication of elements of highly efficient friction units used in various fields of technology.

Coatings with a hardness of about 10.6 GPa (under a load of 300 g) were fabricated by gas-thermal (plasma-assisted) deposition of nanopowders of WC–Co hard alloys agglomerated into grains of size 0.3–0.5 μm.<sup>140</sup>

High-resolution SEM and AFM studies of the film behaviour revealed two types of deformation, homogeneous and inhomogeneous.<sup>10, 117, 118, 141, 142</sup> The former is mainly observed in films having a columnar structure, e.g., TiN films. Localised inhomogeneous deformation is accompanied by indentation, which is particularly pronounced in the case of TiB<sub>2</sub> films.

As mentioned above, the use of an additional external magnetic field in the course of sputtering<sup>131, 132</sup> permits fabrication of films with different grain size, which enhances the possibilities of studying the size effects in nanomaterials. It is also noteworthy that the magnetic field has a strong effect on the roughness of film surface (roughness appreciably decreases) and affects the properties of not only the nanocrystalline but also amorphous films, which can be seen by taking films of boron carbide based nanomaterials as examples (Table 5).

**Table 5.** Average crystallite sizes and microhardness values of films of boron carbide based materials with external magnetic field switched off (I) and on (II).

| Target                                     | Average crystallite size /nm |           | Microhardness H <sub>0</sub> /GPa |       |
|--------------------------------------------|------------------------------|-----------|-----------------------------------|-------|
|                                            | I                            | II        | I                                 | II    |
| TiB <sub>2</sub>                           | 3.6 ± 1.8                    | 3.3 ± 1.1 | 32–39                             | 42–48 |
| 75% TiB <sub>2</sub> /25% B <sub>4</sub> C | 8.5 ± 4                      | 2.9 ± 0.3 | 40–46                             | 54–58 |
| 50% TiB <sub>2</sub> /50% B <sub>4</sub> C | amorphous films              |           | 44–50                             | 60–68 |
| 25% TiB <sub>2</sub> /75% B <sub>4</sub> C | the same                     |           | 44–50                             | 62–71 |
| B <sub>4</sub> C                           | "                            |           | 42–50                             | 48–56 |

A study of the galvanomagnetic and electrical properties of TiN films with grain sizes of 29 ± 15 and 8.8 ± 2.2 nm showed that only the charge carrier (electron) mobility and, correspondingly, the conductivity of these films changes, while the charge carrier concentration remains unchanged.<sup>143</sup> These results also indicate a possible absence of large oxygen and carbon segregations at grain boundaries in these films.

A study of high-temperature oxidation of AlN–TiN, AlN–TiB<sub>2</sub> and AlN–SiC–TiB<sub>2</sub> films revealed high thermal stabilities and scale resistances, which exceed those of coarse-grained bulk materials.<sup>144</sup> The results obtained by differential thermal (DTA) and thermogravimetric (TG) analyses at temperatures below 1500°C are presented in Fig. 10. AlN–SiC–TiB<sub>2</sub> films having a self-reinforced nanostructure and aluminium-enriched surface were found to show the highest scale resistance.

Nanostructured boride films and films of some other high-melting compounds are thermally stable up to 1000–1100 °C.<sup>26, 132–136, 144–147</sup> Changes in the microhardness of multilayered TiN/AlN films after annealing in argon atmosphere for 2 h can be followed using the data presented in Fig. 11.<sup>144</sup> As can be seen, films having thinner individual layers are more thermally stable.

An interesting method of improving the thermal stability of multicomponent nanocrystalline high-melting compounds involves the use of spinodal decomposition accompanied by the formation of ultradisperse thermally stable binary structures. The temperature dependences of the microhardness of the coatings based on titanium nitride and zirconium nitride (systems TiN–ZrN and TiN–AlN in amorphous Si<sub>3</sub>N<sub>4</sub> matrix) are

**Figure 10.** DTA (1) and TG (2) curves for AlN–TiN (a), AlN–TiB<sub>2</sub> (b) and AlN–TiB<sub>2</sub>–SiC (c) films.<sup>143</sup>

**Figure 11.** Effect of annealing temperature on microhardness of multi-layered TiN/AlN films (overall thickness is 300 nm).<sup>144</sup> Thickness of individual layers is 16 (1) and 2.9 nm (2).

shown in Fig. 12. In the former case the hardness of the alloyed (Ti,Zr)N films considerably increases (see Fig. 12a); the corresponding solid solution decomposes into finely disperse phases on heating, which was detected by X-ray analysis.<sup>147</sup> In the latter case the increase in microhardness is not so large (see Fig. 12b); nevertheless, it affects the thermal stabilities of the films based on titanium nitride and aluminium nitride.<sup>135</sup>

The effect of annealing at 900 °C on the composition and structure of films of silicon carbonitride based materials was studied.<sup>148</sup> Using various methods (IR spectroscopy, X-ray photoelectron spectroscopy, X-ray analysis, Raman spectroscopy, etc.), the post-annealing changes in the crystallite size and a decrease in the proportion of the amorphous component were revealed.

## V. Conclusion

In essence, each type of the nanomaterials (powders, compacts and films) considered in this review deserves a relevant comprehensive analysis. For instance, powders obtained by plasma

**Figure 12.** Effect of annealing temperature on microhardness of the coatings based on the TiN–ZrN (a) and (Al<sub>1-x</sub>Ti<sub>x</sub>)N/a-Si<sub>3</sub>N<sub>4</sub> systems (b). (a): ZrN (1); TiN (2); TiN–ZrN, 10 layers (3); alloyed films: (Ti,Zr)N (4) and TiN–ZrN, 20 layers (5); (b): microhardness (1), crystallite size (2).

chemical synthesis have been the subject of a monograph.<sup>149</sup> A joint study makes it possible to compare the results obtained for different types of nanomaterials; however, we had to leave some details out of consideration and only refer to original publications because of limitations on the length of the article. In the text below we present the key results obtained in the last decade in the field under study.

Methods for preparation of nanopowders, nanotubes and nanowires, nanostructured compacts and films of practically important high-melting compounds have been elaborated on a laboratory scale (and in some cases on a large scale). Films have been the best studied and can serve as the basis for fabrication of nanomaterials (grain size of 2 to 3 nm; cluster-consolidated objects) possessing the highest physicochemical characteristics. It was shown that application of an external magnetic field in the course of film deposition has a strong effect on the film structure and hardness.

The self-propagating high-temperature synthesis and mechanochemical synthesis have found wide use in the preparation of nanopowders. However, a comparison of the cost–performance ratios for different methods of production of ultradisperse powders and disclosure of optimum ones is complicated by the lack of many necessary characteristics.

A number of methods for consolidation of powder nanomaterials have been elaborated, which allow the nanostructure (with a grain size of about 50 nm) to be retained and specimens of low porosity to be obtained. Of particular interest are the methods that combine mechanochemical synthesis and densification of nanopowders. There is a need in comparing the efficiency of these techniques.

The hardness of nanostructured films based on high-melting compounds can compete with that of the classical ultrahard (> 50 GPa) materials. It was shown that the nanostructures of the films based on borides, nitrides and carbides are thermally stable up to 1000–1100 °C. Highly wear-resistant, nanostructured, single- and multilayered coatings based on high-melting

compounds (with a hardness of at least 40–50 GPa) for tool applications are now produced in the United Kingdom, Germany, Czech Republic and other countries.<sup>30, 31, 135</sup>

A considerable body of information on the structure, physicochemical and physicomechanical properties of nanocrystalline high-melting compounds has been accumulated; selected data on their properties have been reported in a collection of studies.<sup>150</sup> However, there are still many 'blind spots' due to insufficient knowledge of fundamental characteristics of these species (*e.g.*, the electronic structure and constitutional diagrams, the semiconductor and thermodynamic properties, radiation-induced and other types of defects, *etc.*).

Prospects for the design of and research into nanomaterials based on high-melting compounds are associated with both investigation of the nature of the size effects and stability of nanostructures<sup>151</sup> and disclosure of novel (compared to traditional tool and tribotechnical applications) fields of application. For instance, the possibility of using films based on molybdenum and tungsten carbides for electrocatalysis was pointed out;<sup>152, 153</sup> however, by and large the catalytic properties of nanostructured high-melting compounds are poorly studied.

It was shown (see, *e.g.*, Refs 154–158) that nanocrystalline films based on high-melting compounds can be used not only as coatings for tool materials but also for biomedical applications and in data storage systems. There is increasing interest in these compounds from specialists working in electronics and nuclear engineering. Particular attention has been given to silicon carbide, silicon nitride and aluminium nitride. Silicon carbide is thought to be quite promising high-temperature semiconductor material for the Schottky diode type devices,<sup>65</sup> while silicon nitride and aluminium nitride are considered as efficient barrier materials. It is of interest to study the possibility of synthesis and the properties of semiconductor heterostructures based on SiC and other high-melting compounds. The high mechanical and dielectric properties of nanocrystalline films based on, *e.g.*, Si<sub>3</sub>N<sub>4</sub> are attractive for the design of novel types of microbolometric devices for various measuring systems in transport, in biological studies and in industrial and environmental monitoring. Nanocrystalline silicon carbide is considered as a promising structural material for pressurised water-cooled nuclear reactors and boiling water-cooled reactors. Materials based on SiC can be used as the matrix and shell components and for production of units for the fuel core and the plasma-faced wall of a thermal reactor (see, *e.g.*, Refs 159–161).

Clearly, realisation of these promising avenues will require extensive technological and materials science investigations of nanocrystalline structures based on the high-melting compounds described above.

This review has been written with financial support from the NATO (in the framework of the Programme 'Science for Peace', NATO-SfP, Project No. 973529), the Presidium of the Russian Academy of Sciences (in the framework of the Basic Research Programme No. 8) and the Russian Foundation for Basic Research (Project Nos 05-03-32248 and 05-03-07008).

**Abstract.** Stereoselective reactions of nucleophilic addition to the C=N bond in aromatic azines resulting in chiral products are reviewed. Various methods of inducing the optical activity are discussed. The bibliography includes 60 references.

## I. Introduction

Reactions of nucleophilic substitution of a hydrogen atom ( $S_N^H$ ) in  $\pi$ -electron deficient (hetero)aromatic compounds and azines in particular belong to the abundant class of two-step addition–elimination processes.<sup>1</sup> The initial formation of nucleophilic addition products —  $\sigma^H$ -adducts of **A** and **B** — as a result of a direct attack of C-, N-, O-, P-, S- and other nucleophiles on a non-substituted carbon atom of the azine ring is a general feature of these reactions. The intermediates **A** and **B** themselves are of great synthetic and sometimes industrial interest.

R = H, Ac, R\* (R\* is a chiral substituent); Nu is a nucleophile.

The pro-chiral  $sp^2$ -carbon atom of the C=N bond of the azine ring acquires  $sp^3$ -hybridisation upon formation of  $\sigma^H$ -adducts and therefore becomes chiral. In most cases, these intermediates are mixtures of *R*- and *S*-enantiomers.<sup>2</sup> The adducts exist in the form of diastereomeric pairs where a symmetric carbon is present in either the substrate or the nucleophile. The attack of an achiral nucleophile on the chiral substrate should result in stereoselective

formation of a new chiral centre. In the ideal case, the addition yields an individual stereoisomer.

Numerous publications (see, for example, reviews<sup>3–7</sup>) on the synthesis of alkaloids and on nucleophilic addition reactions in the series of azines (chiral azines as well) neither specially emphasised nor systematised chiral transformations with asymmetric induction. Nor were stereochemical aspects of the formation of the type **A** or **B** intermediates discussed in the book<sup>1</sup> on the reactions of nucleophilic substitution of the aromatic hydrogen atom. The present review is intended to fill this gap. The results of the studies on stereoselective nucleophilic addition to the carbon atom of the azine C=N bond published over the last 15 years are presented.

## II. Stereochemical effects in the attack of an achiral nucleophile on an optically active azine

In spite of the fact that a pyridine-type nitrogen atom increases the  $\pi$ -deficiency of heterocycles, very few examples of the direct introduction of neutral C-nucleophiles into non-activated azines are known.<sup>1</sup> Activated forms of azine substrates, *viz.*, azinium cations, and highly reactive nucleophiles, primarily organometallic compounds, are used as a rule in the induction of chirality upon the nucleophilic attack. In this section, some examples of stereoselective reactions of azines with other C-nucleophiles (cyanide ions, enolates, indoles) as well as with Si- and O-nucleophiles are discussed.

### 1. Reactions of azines with chiral substituents at the nitrogen atom

#### a. The effect of a chiral substituent on the diastereoselectivity of the reaction

The reactions of C-nucleophiles with azinium cations containing nitrogen atoms quaternised with chiral substituents are the best studied. The corresponding salts are usually synthesised by alkylation or acylation (often *in situ*) of an azine substrate with an optically active reagent. The fragments of chiral hydrocarbons, alcohols (including natural ones), amino acids and heterocyclic compounds may be used as the asymmetric inductors. The electrophilicity of the azinium cation depends on the nature of the substituent at the nitrogen atom: less reactive *N*-alkyl-substituted salts react only with carbanions (organometallic compounds), while for *N*-acyl derivatives there is a wide range of potential nucleophiles. The data presented in this Section are ordered according to the type of the nucleophilic agent and in the order of increasing complexity of the azine substrate.

Stereoselective addition reactions of cyanide to chiral isoquinolinium salts have been described.<sup>8</sup> The starting salts have been

synthesised *in situ* by acylation of isoquinolines with optically active (–)-menthyl chloroformates in the presence of Lewis acids. Trimethylsilyl cyanide (TMSCN) was used as a C-nucleophile.

Thus isoquinolines **1a,b** in the reaction with (–)-(*R*)-menthyl chloroformate yield optically active salts **2a,b**, which add the CN group with high diastereoselectivity. The diastereomeric ratio (*dr*) in the products **3a,b** exceeds 95 : 5.<sup>8</sup>

R = H [**a** (98%)], Br [**b** (96%)].

Isoquinolinium salts **4a** obtained from protected amino acid fluorides react with TMSCN in a similar way.<sup>8</sup> In these reactions, the stereoselective formation of Reissert compounds **5a** was observed. The diastereomeric ratio of the reaction products depends on the structure of the original amino acid.

PG is protection group (Z is benzyloxycarbonyl, Fmoc is 9-fluorenylmethyloxycarbonyl).

| R                  | PG   | Yield of <b>5a</b> (%) | <i>dr</i> |
|--------------------|------|------------------------|-----------|
| Me                 | Z    | 89                     | > 95 : 5  |
| Me                 | Fmoc | 44                     | 71 : 29   |
| Pr <sup>i</sup>    | Fmoc | 47                     | 70 : 30   |
| CH <sub>2</sub> Ph | Z    | 51                     | 82 : 18   |

The chiral *N*-acylazinium salts of the quinoline (compounds **6**) and isoquinoline (compounds **7**) series were obtained by acylation of the corresponding heterocycles with an optically active derivative of 2-oxooxazolidine-3-carbonyl chloride **8**.<sup>9</sup> The study of their reactions with TMSCN has revealed a different diastereomeric ratio of the resulting diastereomeric Reissert compounds **9**, **10** and **11**, **12**. The stereoselectivity of this reaction depends not only on the structure of the anion X<sup>–</sup>, but on the temperature of the reaction as well (Scheme 1).

It was suggested<sup>9</sup> that the reason for the observed diastereoselectivity of the reaction is that *N*-acylazinium triflates **6** and **7** adopt the most favourable conformation with maximum  $\pi$ – $\pi$ -interaction between the (iso)quinolinium aromatic ring and the phenyl ring of the acyl substituent. Such a conformation results in shielding of one of the diastereotopic sides of the reacting C=N<sup>+</sup> bond. Two possible conformations **A1**, **A2** and **B1**, **B2** can be suggested for the iminium salts **6** and **7**, respectively (Scheme 2). In contrast to the conformers **A2** and **B2**, the *trans*-configuration (relative to the single N<sup>+</sup>–CO bond) of the iminium and carbonyl groups in conformers **A1** and **B1** makes the  $\pi$ – $\pi$ -interaction possible. The attack of the cyanide-ion (the front side is marked by a solid arrow in Scheme 2, the rear side, by dashed one) on the less sterically hindered side of the conformers **A1** (salt **6**) and **B1** (salt **7**) leads to the predominant formation of the diastereomers **9** and **12**, respectively.

The triflate anion also favours the  $\pi$ – $\pi$ -interactions in the acylazinium intermediate due to weaker interaction with the iminium part of the molecule than in the case of the chloride

Scheme 2

anion. As a consequence, the stereoselectivity of the addition increases.<sup>9</sup>

Azines may be quaternised not only by chiral acyl groups, but by alkyl groups as well. Thus chiral *N*-alkylpyridinium salts **13a,b** show a high degree of diastereoselectivity in reactions with benzyl-type Grignard reagents.<sup>10</sup> The reduction of the products with sodium borohydride leads to diastereomeric tetrahydropyridines **14a,b** (the main product) and **15a,b**.

$R^1 = R^2 = \text{Me}$  (**a**, *de*† 82%);  $R^1 - R^2 = (\text{CH}_2)_4$  (**b**, *de* 78%).

Such a relatively high selectivity was rather unexpected for the authors,<sup>10</sup> because the chiral alkyl group in the starting salt **13** is quite mobile and relatively freely rotates around the N–C bond.

The structures **A** and **B**, in which the C–H bond of the chiral group is coplanar to the plane of the pyridine ring, are probably the most energetically favourable conformations of the salts **13**. In such a case, there are several possible directions of the nucleophilic attack: pathways *a* and *b* for the conformation **A** and pathways *c* and *d* for the conformation **B**. But only the pathway *c* leads effectively to stereoisomers **14**, because only in this case is the approach of the nucleophile to the pyridine ring unhindered by the small- (H atom) and medium-sized (methyl group) substituents of the chiral alkyl fragment.<sup>10</sup>

The reaction of the chiral isoquinolinium salts **16** with the Grignard reagents afforded unstable 1-substituted 1,2-dihydroisoquinolines **17** and **18** in good yields (90%–95%).<sup>11</sup> However, the observed diastereoselectivity of this reaction is lower than that in the case of 3,4-disubstituted pyridinium salts.

| R                                                          | Ratio <b>17</b> : <b>18</b> |
|------------------------------------------------------------|-----------------------------|
| Me                                                         | 64:36                       |
| Ph                                                         | 87:13                       |
| <i>m</i> -MeOC <sub>6</sub> H <sub>4</sub>                 | 90:10                       |
| <i>m</i> -MeOC <sub>6</sub> H <sub>4</sub> CH <sub>2</sub> | 62:38                       |

In a similar reaction of the Grignard reagents with the isoquinolinium salt **19**, which contains a chiral hydroxy(phenyl)ethyl group at the nitrogen atom, the 1,2-dihydroisoquinoline intermediates **20** cyclise spontaneously upon hydrolysis.<sup>11</sup> The main reaction products are tetrahydrooxazoloisoquinolines **21** and **22**. Small amounts of dihydroisoquinolines **23** are also isolated.

† *de* is diastereomeric excess.

| R                                          | Ratio <b>21</b> : <b>22</b> : <b>23</b> |
|--------------------------------------------|-----------------------------------------|

| Pr <sup>i</sup>                            | 49 : 34 : 17                            |
| <i>m</i> -MeOC <sub>6</sub> H <sub>4</sub> | 72 : 20 : 8                             |

Presumably,<sup>11</sup> the destabilising steric interactions between the phenyl groups of the oxazolidine ring and the substituent R at C(5) are responsible for the preferable formation of the oxazolidines **22** rather than of their stereoisomers **23**.

A series of papers on the influence of chiral substituents at the nitrogen atom of azine substrates on the stereoselectivity of the reactions with organometallic reagents have been published by the Comins group. Thus 1-acylpyridinium salts **24** containing a

residue of an optically active alcohol (R\*OH) have been studied.<sup>12–16</sup> These salts have been synthesised from 4-methoxy-3-(triisopropylsilyl)pyridine and the corresponding chiral chloroformates. The salts **24a,b** react with organomagnesium compounds under very mild conditions.<sup>13</sup> Acid hydrolysis of the reaction mixture yields mainly dihydropyridones **25a,b**. The stereoselectivity of the reaction is relatively high, stereoisomers **26a,b** are the minor products.

The effect of chiral acyl groups on the stereoselectivity of the addition reaction may be increased by introducing aromatic substituents into the alcohol residue.<sup>14,15</sup> Thus the diastereoselectivities of the reactions of *trans*-2-( $\alpha$ -cumyl)cyclohexyl derivatives of the salts **24c–f** with *p*-tolyl- and cyclohexylmagnesium halides were equal to 83%–93%. Acylpyridinium salts **24g–i**, containing an isopropyl group in a similar chiral substituent, appeared to be slightly more effective as asymmetric inductors in this stereoselective synthesis (Table 1).<sup>15</sup>

**Table 1.** Reaction of 1-acylpyridinium salts **24a–j** with Grignard reagents.

<sup>a</sup> Compound **25** is the predominant stereoisomer; <sup>b</sup> in these cases X = Br, in other examples X = Cl; Cy is cyclo-C<sub>6</sub>H<sub>11</sub>.

Presumably,<sup>15</sup> it is the steric shielding of one side of the pyridinium ring of salt **24** by bulky chiral acyl groups that determines the predominant direction of the nucleophilic attack. The process is enhanced by aryl substituents in these groups. The  $\pi$ - $\pi$ -donor-acceptor interaction (further in the text,  $\pi$ - $\pi$ -interaction) between the substituent and the pyridinium cation stabilises the staggered conformation.<sup>16,17</sup> The positive effect of the isopropyl group of the 8-arylmethyl moiety on the stereoselectivity of the process is more difficult to rationalise. It was suggested<sup>15,16</sup> that the isopropyl group might affect the ratio of the possible rotamers leading to the optimum  $\pi$ - $\pi$ -interaction between the aromatic rings.

The non-stereoselectivity of the reaction of phenylmagnesium bromide with the salt **24j** where *vic*-substituents in the cyclohexane ring adopt a *cis*-configuration may be explained by the same reason.

The configuration of the optical centre of the acyl group determines the ratio of the diastereomeric products. Thus the reaction of a homochiral 1-acylpyridinium salt **24k**, obtained by the reaction of chloroformate (as the acylating agent),  $R^* = (+)$ -*trans*-2-( $\alpha$ -cumyl)cyclohexyl [(+)-TCC], with alkenylmagnesium bromides yielded dihydropyridones **27k**.<sup>18,19</sup> In the case of its optical antipode, *i.e.*, (–)-TCC-chloroformate, the reaction of acylpyridinium salt **24l** leads to the diastereomer of **27**, *i.e.*, dihydropyridone **28l**.<sup>20,21</sup> A similar result has been observed in the reaction of substrate **24b** containing a (–)-8-phenylmethyl substituent.<sup>22</sup>

| Salt <b>24</b> | $R^*$            | Reaction product |     |           |          | Ref.   |
|----------------|------------------|------------------|-----|-----------|----------|--------|
|                |                  | compound         | $n$ | yield (%) | $de$ (%) |        |
| <b>b</b>       | (–)-8-Ph-menthyl | <b>28b</b>       | 2   | 100       | 91       | 18     |

|                |                  | <b>27k</b>       | 2   | 95        | 93       | 15     |
| <b>l</b>       | (–)-TCC          | <b>28l</b>       | 1   | —         | 90       | 16, 17 |

Similar stereochemistry of the addition products was observed with lithium acetylides used as C-nucleophiles instead of alkenylmagnesium bromides. Thus treatment of the salt **24k** with a Li-derivative of ethyl propiolate leads to dihydropyridone **29**.<sup>23</sup>

$R^* = (+)$ -TCC.

The reaction of 3-(triisopropylsilyl)pyridine with chiral bicyclic acyl bromide **30a** in pyridine yields solid *N*-acylpyridinium salt **31a**.<sup>24</sup> The addition of 2-(1,3-dioxolan-2-yl)ethylmagnesium bromide at  $-90^\circ C$  to this heterogeneous system affords 6-substituted *N*-acyl-1,6-dihydropyridine **32**. The reaction is regio- and diastereoselective (yield 41%,  $de$  100%). An analogous reaction was carried out with acyl chloride **30b** under homogeneous conditions,<sup>24</sup> which are more suitable for this reaction. In presence of trimethylsilyl triflate (TMSOTf), the addition product **32** is formed *via* intermediate salt **31b**. The yield of the product increased to 62%, but the diastereoselectivity of the process decreased to 88%.

The asymmetric induction in the considered processes may be explained by preliminary complex formation. The reaction mechanism includes the initial coordination and addition of organometallic reagent to the carbonyl group of the chiral acyl substituent with formation of complex **33**. Judging from the stereochemistry of the addition product **32**, the attack of the nucleophilic agent on the iminium moiety proceeds as follows:

Later, this reaction was extended<sup>25</sup> to methyl dimethyl(phenyl)silylnicotinate in order to avoid addition at position 4. Compound **34** was isolated as the main product, while the stereoisomer **35** was a minor product (ratio **34**:**35** = 87.2:12.8).

An example of diastereoselective addition of C-nucleophile to isouquinoline **36**, activated by a chiral rhenium complex, has been described.<sup>26</sup> The reactions of compound **36** with organometallic compounds occur under very mild conditions and start at a temperature as low as  $-100^{\circ}\text{C}$ . The metallocomplex **37** is the main reaction product (*de* 46%–88%); small amounts of the diastereomer **38** were observed [reaction (1)].

This reaction with  $\text{Me}_3\text{SiCH}_2\text{MgCl}$  is significantly slower than that with  $\text{Me}_3\text{SiCH}_2\text{Li}$ . In the former case, the diastereoselectivity noticeably decreases with an increase in temperature. However, the Grignard reagent containing the secondary alkyl group, *viz.*,  $\text{Pr}^i\text{MgCl}$ , reacts with the complex **36** rapidly even at  $-100^{\circ}\text{C}$ . It is worth noting that  $\text{MeMgCl}$  is the least reactive nucleophile in this reaction.<sup>26</sup>

| RM                                    | Temperature / $^{\circ}\text{C}$ | Ratio <b>37</b> : <b>38</b> |
|---------------------------------------|----------------------------------|-----------------------------|

| $\text{AlEtMgBr}$                     | $-100$                           | 73 : 27                     |

$\pi$ -Electron-donating heterocycles can be used as C-nucleophiles in reactions with azines. Thus 3-phenyl-1,2,4-triazin-5(4*H*)-one was acylated with *N*-protected  $\alpha$ -amino acids **39a–f** activated by dicyclohexylcarbodiimide (DCC) and reacted with indole.<sup>27</sup> The addition products at the position 3 of indole, compounds

**40a–f**, were obtained with high diastereoselectivity (*dr* > 95 : 5). The predominant formation of only one pair of diastereomers in this reaction was explained by a significant steric hindrance for the attack of the triazine ring caused by the amino acid residue. However, it is the same circumstances that are the reason for the low yields.<sup>27</sup>

| Compound <b>40</b> | Starting amino acid <b>39</b>  | Yield (%) |
|--------------------|--------------------------------|-----------|
| <b>a</b>           | <i>N</i> -Boc-glycine ‡        | 42        |
| <b>b</b>           | <i>N</i> -Bn-D,L-leucine       | 26        |
| <b>c</b>           | <i>N</i> -Ac-D-alanine         | 28        |
| <b>d</b>           | <i>N</i> -Ac-L-tryptophan      | 21        |
| <b>e</b>           | <i>N</i> -Ac-L-valine          | 17        |
| <b>f</b>           | <i>N</i> -Ac-D,L-phenylalanine | 22        |

These examples illustrate the significant influence of chiral substituents at the azine nitrogen atom on the stereoselectivity of the reactions with C-nucleophiles.

#### b. The effect of an achiral substituent at a carbon atom of the azine ring on the reaction diastereoselectivity

The most detailed investigation into the effect of the character and size of a 3-substituent in the pyridine ring on the diastereoselectivity of the addition of the Grignard reagents was carried out by Comins *et al.*<sup>14</sup> The authors of the cited paper studied the reactions of a series of optically active 4-methoxy-*N*-[(–)-menthyloxycarbonyl]pyridinium salts **24b,m–t** with arylmagnesium chlorides leading to 6-substituted compounds **25** and **26** (**25** being the main stereoisomer).

The original idea<sup>14</sup> was to increase the regioselectivity of the reaction by introducing a 3-substituent in the pyridinium ring, which would prevent nucleophilic attack on C(2). However, the substituent also affected the stereochemistry. Although no rigorous regularities were established, some qualitative conclusions could be drawn. The best diastereoselectivity (*de* 94%) was obtained in the reaction of 4-methoxy-3-(triisopropylsilyl)-pyridinium salt **24b** with phenylmagnesium chloride. The use of pyridinium salts with less bulky 3-alkylsilyl substituents in the reactions with aromatic Grignard reagents resulted in a decrease in *de* (in the range of 34%–40%). The triphenylsilyl substituent reduced the diastereoselectivity of the process even more (down to 18%).<sup>14</sup>

### c. The effect of the character of the nucleophile on the stereochemistry of addition reactions of nucleophilic reagents to chiral *N*-acylazinium salts

As was mentioned above, a broad spectrum of addition products have been obtained in reactions of chiral *N*-acylpyridinium salts with Grignard reagents.<sup>13,28,29</sup> Derivatives of indolizine,<sup>21,30</sup> quinolizidine,<sup>31</sup> piperidine<sup>30,32–36</sup> and *cis*- and *trans*-decahydroquinoline<sup>19,22</sup> alkaloids were synthesised from other optically active *N*-acylazinium salts and organometallic compounds. Only one of the possible diastereomers is formed predominantly in these reactions and its stereochemistry depends on the configuration of the chiral acyl group.<sup>13,14,22</sup> Examples of the effect of the character and stereochemistry of the attacking nucleophilic reagent on the product configuration are given below.

**Characteristic features of the introduction of the triphenylsilyl group into chiral *N*-acyl-4-methoxypyridinium salts.** The reaction of triphenylsilylmagnesium bromide (Si-nucleophile) with chiral *N*-acyl-4-methoxypyridinium salt **24b** at –78 °C is stereoselective and results in diastereomerically pure *N*-acyl-2-(triphenylsilyl)-2,3-dihydropyridin-4-one **41b** (yield 73%, *de* 96%).<sup>37</sup> The reaction of this nucleophile with 3-unsubstituted salt **24m** leads to compound **41m** (*de* 96%) in 88% yield. It appeared that the absolute configuration of the newly formed chiral centre C(2) of dihydropyridones **41b,m** is opposite to that of the main reaction product of pyridinium salts **1** with arylmagnesium chlorides as C-nucleophiles (see above). In addition, it was shown that the trimethylsilyl group at position 3 of the starting salt did not affect the asymmetric induction in this reaction.<sup>37,38</sup>

R = Me<sub>3</sub>Si (**b**), H (**m**); R\* = (–)-8-phenylmenthyl.

The preferential formation of *S*-isomer is explained<sup>38</sup> by the interaction of the magnesium atom of the Grignard reagent with the carbonyl group of the acyl fragment (Fig. 1). This coordination results in the alteration of the direction of the nucleophilic attack, which was confirmed by quantum-chemical calculations.

**Figure 1.** The molecular mechanic model of addition of triphenylsilyl-magnesium bromide to chiral *N*-acyl-4-methoxypyridinium salts **24**.<sup>38</sup>

**Characteristic features of the addition of metalloenolates to chiral *N*-acylpyridinium salts** The addition reactions of prochiral metalloenolates of ketones and lactones with salts **24** are highly stereoselective and result in the formation of two new chiral centres.<sup>3,39</sup> The *2R,2'S*-diastereomer **42** is the main reaction product, while (*R,R*)-**43**, (*S,R*)-**44** and (*S,S*)-**45** stereoisomers were obtained in minor amounts.

R\* = (–)-TCC.

| R <sup>1</sup>                                                     | R <sup>2</sup> | Ratio<br><b>42</b> : ( <b>43</b> + <b>44</b> + <b>45</b> ) | Yield of <b>42</b> (%) |
|--------------------------------------------------------------------|----------------|------------------------------------------------------------|------------------------|
| –CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> –                 |                | 88 : 12                                                    | 82                     |
| –CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> – |                | 86 : 14                                                    | 79                     |
| Me                                                                 | Et             | 92 : 8                                                     | 83                     |

Interestingly, this reaction with the enol form of 2,2-dimethyl-1,3-dioxan-5-one (*E*-isomer) yields compound **46** with (*2S,2'S*)-configurations of chiral centres. Compound (*2S,2'R*)-**47** with the opposite configuration is formed as the main product in a similar reaction with 1,3-bis(benzyloxy)propan-2-one in the enol form, which exists as *Z*-isomer due to formation of a chelate.<sup>39</sup>

R\* is (–)-TCC, LDA is lithium diisopropylamide, LHMDs is lithium hexamethyldisilazide.

The selectivity of the addition of *E*-enolate may be explained by the existence of a transition state

This transition state is the most probable due to a non-covalent interaction between the pyridinium ring and the phenyl ring of the chiral acyl group ( $\pi$ – $\pi$ -interaction) and also due to electrostatic attraction between the positively charged nitrogen atom and the negatively charged enolate oxygen atom.<sup>39</sup>

## 2. Reactions of azines containing a chiral atom in the ring

The presence in the azine ring of substituents capable of coordinating the attacking particle is an important factor determining the stereochemical composition of products of a nucleophilic reaction on a carbon atom of a double C=N bond in azines. Thus examples of insertion of functional groups capable of complexation with nucleophiles at the  $\beta$ -position of pyridine and quinoline rings are given in papers<sup>40–42</sup>.

One of the first reported reactions of diastereoselective nucleophilic addition to pyridinium salts and quinolinium salts with initial complexation is the reaction of chiral 2-(3-pyridyl)- (49a) and 2-(3-quinolyl)oxazolines (49b) with organolithium and -magnesium reagents followed by treatment with methyl chloroformate.<sup>42</sup> This reaction affords the corresponding 1,4-dihydro-derivatives 50a,b and 51a,b in good yields and high diastereomer ratio (*de* > 95%). Replacement of pyridine by quinoline increases the diastereoselectivity of the process. Thus in the reaction of compound 49a with methyl lithium the ratio of the corresponding diastereomers 50a:51a is 93:7, while in the case of quinoline derivative 49b this ratio is equal to 98:2.

| Compounds 49–51 | R <sup>1</sup> , R <sup>2</sup> | R <sup>3</sup> M or R <sup>3</sup> MX | T / °C | Ratio 50:51 | Total yield (yield of 50) (%) |
|-----------------|---------------------------------|---------------------------------------|--------|-------------|-------------------------------|
| a               | H                               | MeLi                                  | –40    | 93:7        | 79                            |

|                 |                                 |                                       | –78    | 98:2        | 84 (70)                       |

The high stereoselectivity of the addition was explained by initial coordination of an organometallic compound (RM or RMX) to the nitrogen atom and the methoxy group of oxazoline, which leads to the formation of a complex 52 followed by the attack of the group R on the position 4 of the pyridine ring. The addition of RM (or RMX) from different sides of the plane of the ring (paths *a* and *b*) results in products with different stereochemistry. High stereoselectivity of the studied reactions implies that the most common reaction pathway is the path *a*. It was suggested that lithium or magnesium derivatives 53, formed upon addition of organometallic compound RM (or RMX) to pyridine 49a, are acylated with methyl chloroformate to afford compound 50.<sup>40</sup>

However, an alternative mechanism for the formation of adducts 50 and 52 was suggested:<sup>13</sup> the initial *in situ* formation of *N*-acylazinium salts upon acylation with chloroformate with consequent addition of an alkyl or phenyl group R to the C(4) atom of the pyridine heterocycle. Obviously, the reaction mechanism depends on the order of addition of the reagents.

Pyridinium salts 55a,b were obtained by alkylation of nicotinamide 54 with methyl iodide and benzyl bromide, respectively, and then reacted with lithium organocuprates.<sup>43</sup> The expected adducts 56a,b (diastereomer ratio varies from 2.5:1 to 9:1, only the main product is shown in the Scheme) and 57a,b (*dr* = 1:1) were isolated after acylation of the reaction mixture with trichloroacetic anhydride.

$R^1 = \text{Me (a), Bn (b)}$ ;  $X = \text{I (a), Br (b)}$ ;  $R^2 = \text{Me, Bu}^n, \text{Ph}$ .

An example of the complexation effect on the stereoselective addition of nucleophiles to pyridinium salts is documented.<sup>41</sup> Reactions of 1-methyl- (**58a**) and 1-benzylpyridoxazepinone (**58b**) salts with alkyl-, alkenyl- and phenyl-magnesium bromide result in the products **59a,b** with high stereoselectivity and in good yields. Stereo- and regioisomers **60a,b**–**62a,b** are found in minor amounts. The process becomes less selective where organolithium compounds are used instead of the Grignard reagents.

$R^1 = \text{Me (a), Bn (b)}$ .

In this case, the high regio- and stereoselectivity of the reaction is explained by the coordination of the Grignard reagent to the amide oxygen atom, which leads to the formation of complex **63**. The transfer of the organic fragment from the magnesium atom to C(4) of the pyridine ring results in the enolate **64**; its hydrolysis leads to compounds **59**–**62**.<sup>41</sup>

Studies on the conformational behaviour of compounds **58a,b** reveal that the seven-membered ring is relatively rigid and only two energetically favourable conformations are possible (only one is shown).<sup>41</sup>

In this conformation, the amide carbonyl group is located above the pyridinium ring plane in an *anti*-position relative to the hydrogen atom in the chiral centre, while in the second conformer the carbonyl group and the pyridinium ring are coplanar. It is remarkable that the conformations of compounds **58** where the carbonyl amide group is arranged under the pyridinium ring are energetically unfavourable. Therefore, the intermolecular shift of the group  $R^2$  of the complex **63** through a six-membered transition state can lead predominantly to the isomer **64**.<sup>43</sup>

Diastereoselective addition of (trimethylsilyl)ethynylmagnesium bromide to optically active quinolines **65** in the presence of alkyl (or aryl) chloroformates produces compounds **66** and **67** in good yields and moderate diastereoselectivity.<sup>44,45</sup> This is the result of steric hindrance created by bulky substituents at position 4 of the quinoline ring.

| R  | Temperature /°C | Total yield (%) | Ratio (±)-66 : (±)-67 |
|----|-----------------|-----------------|-----------------------|

| Ph | –78 to 0        | 87              | 68 : 32               |
| Ph | –78             | 66              | 67 : 33               |

An example of nucleophilic addition to isoquinoline with a chiral substituent at position 3 is known.<sup>46</sup> Diastereoselective addition of (trimethylsilyl)ethynylmagnesium bromide to isoqui-

nolines **68** in the presence of aryl chloroformates yields compounds **69** and **70** with high diastereoselectivities due to the presence of a chiral substituent at position 3 of the isoquinoline ring.

| R                                 | Total yield (%) | Ratio <b>69</b> : <b>70</b> |
|-----------------------------------|-----------------|-----------------------------|
| SiMe <sub>2</sub> Bu <sup>t</sup> | 88              | 87.3 : 12.7                 |
| SiPh <sub>2</sub> Bu <sup>t</sup> | 82              | 94.6 : 5.4                  |
| CPh <sub>3</sub> (Tr)             | 30              | 90.4 : 9.6                  |

In the total synthesis of antibiotic dynemycin A, alkyne radicals were introduced into a substituted tetrahydrophenanthridine containing chiral centres in the cyclohexane moiety.<sup>42</sup> A mixture of diastereomers in the ratio of 9 : 1 was obtained upon treatment of compound **71** with chloroformate in the presence of the Grignard reagent, (triisopropylsilyl)ethynylmagnesium bromide. Compound **72** was the main isomer, which was formed as a result of *cis*-addition (relative to the 4- and 7-substituents) of the alkyne fragment to the pyridinium C(2) atom.<sup>42</sup>

TBS is *tert*-butyldimethylsilyl; R = Me, All.

The starting compound **71** is sterically severely hindered for the attack along the path *b*; therefore, the addition is stereoselective and proceeds with predominant formation of compound **72** (path *a*).<sup>42</sup>

Tetrahydrophenanthridines **73a,b** react similarly with phenylethynylmagnesium bromide in the presence of methyl chloroformate. It was found<sup>47</sup> that the non-protected compound **73a** forms predominantly a *cis*-addition product **74a** (relative to the methyl group), the ratio **74a** : **75a** = 11 : 1, while TBS-protected analogue **73b** produces a diastereomer mixture in which *trans*-addition product **75b** is dominant (ratio **74b** : **75b** = 1 : 1.5).

R = H (**a**), TBS (**b**).

This fact was explained by a half-chair conformation of the intermediate alkoxide formed from compound **73a** in which the magnesium counterion is chelated by one or two oxygen atoms of the methoxy groups. This leads to *pseudo*-equatorial orientation of the methyl substituent in compound **74a**. As a result, the axial addition of acetylide at the *cis*-position relative to this Me group is facilitated.<sup>47</sup>

The reaction of 9-acyl- $\beta$ -carboline **76a-i** activated by 2,2,2-trichloroethyl formate with allyl(tri-*n*-butyl)tin produces 1,2-dihydroadducts **77a-i**; their subsequent hydrolysis occurs with elimination of optically active sodium salt of 5-oxoproline.<sup>48,49</sup> The configuration of the remaining chiral centre in the obtained alkylated dihydro- $\beta$ -carboline **78a-i** depends on the character of substituent R in the adduct **77**.

| Compounds <b>76, 77</b> | R                                                          | Yield of <b>77</b> (%) | Product <b>78</b> |        |

The stereoselectivity of the addition reaction of  $\beta$ -carboline **76a–e** containing *N*-alkylpyroglutaminy fragments linearly increases with an increase in the size of the substituent R. One side of the  $\beta$ -carboline molecule is shielded, probably due to steric hindrance. In the case of *N*-acylpyroglutaminy derivatives **76f–i**, stereoisomers with opposite configuration of the chiral centre are formed with virtually the same enantioselectivity.<sup>48</sup> One can suggest that in this case another conformation of the adduct **77** is more favourable and therefore the size of the substituent little affects the selectivity of the process.

### III. Stereoselective addition of an optically active nucleophile to an achiral azine

In all previously discussed cases, optically active azine substrates reacted with nucleophilic agents. Steric factors caused by the presence of a chiral azine substituent effectively determined the asymmetric character of the synthesis. Another variant of obtaining optically active azine derivatives where a chiral nucleophile reacts with an achiral amine is rather interesting and much less investigated. In this case, the direction of a nucleophilic attack mostly depends on the structure of the attacking species. It is possible to achieve stereoselective formation of products with the desired configuration by varying the reaction conditions.

Yamaguchi and co-authors<sup>50</sup> have performed the enantioselective addition of chiral (*R*)-phenyl-3-trimethylsilylprop-1-ene (**79**) with *N*-acylisoquinolinium salts obtained from isoquinolines **1a–c**. (*S*)-1-[(*E*)-3-phenylprop-2-enyl]-1,2-dihydroisoquinolines **80a–c** are formed in this process with high enantioselectivity.

| Compounds <b>7, 80</b> | R                  | Yield (%) | ee (%) |
|------------------------|--------------------|-----------|--------|
| <b>a</b>               | H                  | 54        | 95     |
| <b>b</b>               | Br                 | 86        | 94     |
| <b>c</b>               | CO <sub>2</sub> Me | 78        | 93     |

The authors suggest<sup>50</sup> that this addition proceeds with formation of an antiperiplanar transition state **81**, which leads to the *S*-adduct. The transition state **82**, which is a precursor of the *R*-adduct, is less energetically favourable.

Stereoselective addition of chiral allylsilane **79** to activated quinolines has been described.<sup>51</sup> As a result of the reaction with quinolinium salt **83**, an optically active 2-substituted 1,2-dihydroquinoline **84** (ee 77%) is formed.

Several possible reaction pathways have been proposed.<sup>51</sup> The most preferential is believed to be that including the formation of intermediate **85**. Elimination of the trimethylsilyl group yields the product with *S*-configuration of the chiral centre.

No reactions of stereoselective addition of chiral C-nucleophiles to triazines have been described yet; however, a reaction with an optically active O-nucleophile, viz., a natural alcohol L-menthol is known. Thus the addition of enantiomerically pure L-menthol at the unsubstituted carbon atom of 3-phenyl-1,2,4-triazin-5(4*H*)-one activated by acid anhydrides yields a mixture of diastereomers **86** and **87**,<sup>52, 53</sup> the diastereomers **86** being the major products. It was also established that the diastereoselectivity of the reaction depends on the size of the acylating agent. In the case of acetic anhydride (R = Me), the diastereomer ratio **86**:**87** is equal to 60:40, while with the more sterically hindered isobutyric anhydride (R = Pr<sup>i</sup>) this ratio is increased to 85:15.<sup>52, 53</sup>

R = Me, Pr<sup>i</sup>.

The predominant formation of stereoisomers **86** is explained<sup>53</sup> by steric factors.

#### IV. Asymmetric induction in the attack of an achiral nucleophile at an achiral azine

Asymmetric induction in a reaction of an achiral nucleophile with an achiral azine substrate is possible only where optically active solvents, additives or catalysts are used.

Shibasaki *et al.*<sup>54–57</sup> have investigated the formation of Reissert compounds **88a–f** and **89a,d–f** from quinolines **90a–f** and isoquinolines **1a,d–f** catalysed by chiral bifunctional catalysts based on binaphthyl **91**. The enantioselectivity of the reactions (2) and (3) is believed to depend on the character of the substituent  $R^3$  in the acyl chloride. For example, in the presence of the electron-rich and, therefore, relatively inert 2-furoyl chloride the reactions are more selective than in the case of acetyl chloride. The polarity of the solvent also strongly affects the enantioselectivity. Thus it was found that the *ee* of the reaction of quinoline with the most reactive benzoyl chloride in non-polar solvents (toluene, benzene) increases from 71% to 78%, although the yield decreases. The use of more polar acetonitrile in this reaction results in a decrease in *ee* down to 37%. The substitution of  $P(O)(o-Tol)_2$  for  $P(O)Ph_2$  (**Z**) in the catalyst **91** makes it a stronger Lewis base and as a result the yield and the enantioselectivity of reaction (2) increase.

Although the mechanisms of reactions (2) and (3) have not been elucidated so far, it is obvious that the reactions should be accelerated due to double activation of *N*-acyl(iso)quinolinium ion and of TMSCN by the catalyst **91**. Azinium ion is activated by the Lewis acid (an Al atom) and TMSCN, by the Lewis base (an oxygen atom of the P=O group), which are constituents of the structure of catalyst **91**. In a control run with the catalyst **91** where  $Z = CHPh_2$ , which provides only steric restrictions, the direction of the addition process changes and enantioselectivity decreases significantly. Thus the reaction of quinoline with TMSCN in the presence of benzoyl chloride and catalyst **91** ( $Z = CHPh_2$ ), which is not a Lewis base, leads to the formation of 1-benzyl-1,2-dihydroquinoline-2-carbonitrile mainly with *S*-configuration of the chiral centre (yield 73%, *ee* 24%).

| Azine      | R <sup>1</sup>   | R <sup>2</sup>     | R <sup>3</sup> | Z                                 | Yield (%) | ee (%) |

A scheme of the catalytic cycle with unsubstituted quinoline as a model compound has been suggested<sup>54–57</sup> (Scheme 3). In the first step, the reaction of quinoline with acyl chloride results in formation of *N*-acylquinolinium intermediate **92a**. Then the acylquinolinium ion is activated due to complexation of the

amide oxygen with the Lewis acid (Al atom of chiral catalyst). Two conformers, *s-trans*-**93** and *s-cis*-**93**, exist in equilibrium. However, the reaction will occur with preferable formation of compound *s-trans*-**93** upon activation of TMSCN with the catalyst **91**. The distance between the coordinated TMSCN and the electrophilic carbon atom in the *s-cis*-isomer is too large for successful catalytic reaction. Hypothetical transition state *s-trans*-**93** explains the formation of the product with *R*-configuration.

Later, the asymmetric bifunctional catalyst **91** was modified, which provided the possibility of performing similar reactions with pyridine derivatives **94a–c**. Thus the reaction of pyridine **94b** with TMSCN catalysed by chiral binaphthyl **91** [Z = P(O)Ph<sub>2</sub>] in the presence of carboxylic acid chlorides occurs with low enantioselectivity (*ee* < 9%) to give a mixture of addition products with the cyano group at positions 2 and 6 of the pyridine ring in a ratio of 2.3 : 1.<sup>57</sup> The use of the catalyst **95** increased the regioselectivity of the process. 2-Cyano-substituted pyridines **96a–c** with *S*-configuration (*ee* 96%) were predominantly formed (the ratio of 2- and 6-addition products varied from 12 : 1 to 50 : 1 depending on the substituent R<sup>1</sup>).<sup>54–57</sup>

Enantioselective addition of organolithium compounds to isoquinoline under very mild conditions in the presence of a chiral ligand (–)-sparteine (**97**) has been described.<sup>58</sup> These reactions produce either a mixture of chiral dihydroisoquinolines **98a**, **99a** (for R = Me, Bu<sup>n</sup>) or compound **98a** (R = Ph) alone.

Later, the reactions of azines with organolithium reagents were studied in detail<sup>59,60</sup> using non-substituted quinoline (**90a**) as a substrate. Not only were the conditions (temperature, solvent) varied, but also a large number of chiral catalysts were used including sparteine (**97**), bisoxazolines **100**, chiral diether **101**, as well as symmetrical (**102**) and non-symmetrical (**103**) 1,2-diamines.

Treatment of the reaction mixture with methyl chloroformate affords dihydroisoquinolines **104a** or **105a**, the chiral centre formed having *R*- or *S*-configuration depending on the type of the chiral catalyst and the nature of the radical R in the organolithium compound.

The results of these investigations are listed in Table 2. The following conclusions can be drawn on the basis of data obtained.

(*R,R*)-Dimethoxydiphenylethane (**101**) appeared to be an inefficient chiral catalyst: dihydroquinolines **104a** were obtained in reasonable yields but with low enantioselectivity (*ee* 2%–26%). Dihydroquinolines **105a** with opposite configuration of the chiral centre were prepared using (–)-sparteine (**97**) as the catalyst; the enantioselectivity of this process increased (especially in the reaction with phenyllithium) and in some cases (R = Bu<sup>n</sup>) the yield of the product was quantitative. Bis(oxazolines) showed the best selectivity as chiral catalysts; in the reaction of quinoline with methyllithium and catalyst **100a**, *ee* was equal to 63%; the resulting dihydroquinolines had *S*-configurations.<sup>59,60</sup>

The use of *N,N'*-tetramethylcyclohexane-1,2-diamine **102a** (TMCDa) was rather successful with 1-naphthyllithium as a nucleophile: the yield of dihydroquinoline **105a** (R = 1-naphthyl) was 75% (*ee* 64%). Replacement of methyl substituents at the nitrogen atoms of the catalyst **102a** by bulkier alkyl groups (compounds **102b–d**) resulted in reduction of the yields and a sharp decrease in diastereoselectivity of the reaction (4).<sup>60</sup>

The study of *N,N'*-tetramethylethane-1,2-diamines **103a–c** as chiral catalysts gave the following results. Catalysis by the diamine **103a** resulted in virtually racemic product. The reaction in the presence of the diamine **103c** (symmetry C<sub>2</sub>) produced the addition products with moderate enantioselectivity. And, finally, the catalyst **103b** operated as a pseudo-C<sub>2</sub>-diamine, because the

<sup>a</sup> Stereochemical data are unavailable.

results with this catalyst are similar to those obtained with the diamine **103c**.<sup>60</sup>

## V. Conclusion

Thus, the nucleophilic addition reactions with aromatic azines are stereoselective in most cases due to either steric effects of chiral groups in the azine or in a nucleophile, or the presence of optically active catalyst. The stereoselectivity of the process is affected by a number of factors. Among them, the most important are the character and stereochemistry of the nucleophile, the configuration of the chiral centre of the azine, the ability of the nucleophile to form complexes with the substrate and also the possibility of using chiral catalysts in these reactions.

**Abstract.** Data on lanthanide coordination compounds with organic ligands used in the design of electroluminescent diodes are summarised and systematically represented. The molecular and electronic structures and spectroscopic characteristics of these compounds are considered. A comparative analysis of the properties of organic electroluminescent diodes with different compositions of emitting and conductive layers is presented. The bibliography includes 147 references.

## I. Introduction

The design of organic electroluminescent diodes (or organic light-emitting diodes, OLEDs) for the construction of planar multicolour information displays and high-value-in-use multicolour indicators, as well as of low-cost and efficient light sources, is a new field of investigation in molecular electronics and applied synthetic chemistry. Organic electroluminescent diodes are multilayer sandwich structures capable of converting electrical energy into light energy. There is good reason to expect that, in the near future, this unique property of OLEDs will make it possible to construct planar lightweight and very cheap displays and display panels, which will be superior to liquid-crystal analogues in the main parameters, and produce unconventional light sources for different purposes. The following two most important aspects of this area of scientific research should be mentioned: the development and construction of radically new superthin flexible polychromatic displays and a gradual change from luminescent bulbs and incandescent lamps to organic and hybrid light-emitting diodes as illuminants. Nowadays, the power efficiency of laboratory light sources based on organic materials is already better than the light output of incandescent lamps ( $15\text{--}20\text{ lm W}^{-1}$ ) and is in excess of  $50\text{ lm W}^{-1}$ , the theoretically possible efficiency being higher than  $300\text{ lm W}^{-1}$ . The service lifetime of these lamps

(10 000 hours) is more than 50 times longer than that of modern incandescent lamps. The light efficiency of gas luminescent tubes is slightly higher than that of modern OLED sources. However, these tubes are essentially inferior to OLED devices in many respects (explosion hazard, toxicity, inadequacy of perception of light by human eye, etc.).

Lanthanide complexes with organic ligands (hereinafter referred to as lanthanide complexes) belong to one of the most promising classes of compounds for the design of electroluminescent devices owing to specific electronic structures of these metals. Although these complexes have found application in the design of OLEDs about 10 years ago, this aspect has been already considered in several exhaustive reviews published in leading journals.<sup>1–4</sup> Investigations in this field are progressing so rapidly that, although a short period of time has passed since the latest review publication,<sup>4</sup> a need has arisen to generalise and analyse the available data once again. The present review summarises data on the molecular structures and spectroscopic characteristics of luminescent-active rare-earth complexes. The principles of selection and combination of such complexes in the design of OLED devices are considered. Problems in the design of light-emitting diodes on the basis of these compounds, which are associated with optimisation of their compositions by introducing additional luminescent and transport layers, are discussed. The review covers all data published in this area up to the present day. The data are classified and represented according to the nature of the ligand. In some cases, the photoluminescent properties of complexes are used as the key feature.

## II. Main characteristics of electroluminescent devices based on organic compounds

Electroluminescence was discovered by Losev (Nizhny Novgorod Radiolaboratory),<sup>5</sup> who found electrically induced light emission in silicon carbide crystals. However, during the period of vigorous development of semiconductor physics, light-emitting recombination in semiconductors seemed to be unlikely, at least from practical point of view. The situation changed radically after the discovery of intense light emission in p–n transitions in gallium arsenide. In the early 1960s, the General Electric Company produced a commercial light-emitting device (LED) based on the inorganic semiconductor GaAsP.

Electroluminescence of organic compounds was described for the first time for anthracene in 1963.<sup>6</sup> However, the efficiency of these devices was too low for practical applications, and this discovery did not stimulate research on light-emitting devices. Only in the late 1980s, after the construction of a new type of light-

Figure 1. Scheme of an organic light-emitting diode (see the text).

emitting diode based on aluminium hydroxyquinolate ( $\text{Alq}_3$ )<sup>7</sup> and poly(*p*-phenylenevinylene) (PPV),<sup>8</sup> was a new line of investigation aimed at designing and studying organic light-emitting diodes opened.

Typical OLED devices have single-layer or multilayer sandwich structures  $\sim 100$  nm thick (Fig. 1).

Cells consist of the following sequence of components: a glass support coated with a transparent conducting layer of indium tin oxide (ITO) serving as the anode; an organic hole-transport layer (HTL), an emitting layer (EL), an electron-transport layer (ETL) and a metallic cathode as an aluminium film.

Below are given the formulas of organic and complex compounds, which are most often used in lanthanide-containing OLED devices (these abbreviations are used hereinafter).

Theoretical models of charge transport in these compounds were considered in detail.<sup>9–11</sup>

Lanthanide complexes studied as emitters, OLED devices constructed on the basis of these compounds, and the maximum brightnesses of the latter are presented in Table 1.

The efficiency of conversion of absorbed energy into light emission is characterised mainly by the luminescence quantum yield, *e.g.*, the number of photons per absorbed light quantum (in the case of photoluminescence) or per injected electron–hole pair (in the case of electroluminescence). The quantum yield, which ignores the possibility of absorption of this emission in the device, is called the internal quantum yield, whereas the external quantum yield is associated with directly measured light emission from the device. The external quantum efficiency of a light-emitting diode is determined as a ratio of the number of quanta emitted from the material to the number of charge carriers passing through the light-emitting diode during the same period of time.<sup>72</sup>

Nowadays, cells based on the organic compound rubrene (5,6,11,12-tetraphenyltetracene) exhibit the highest electroluminescence efficiency of all the known OLED devices. In these cells, the maximum brightness exceeds  $200\,000\text{ cd m}^{-2}$  and the light emission efficiency is  $\sim 8\text{ lm W}^{-1}$ .<sup>73</sup> Of complex compounds, tris(2-phenylpyridine)iridium has the best characteristics in cells: the maximum brightness is  $100\,000\text{ cd m}^{-2}$ , the light emission efficiency being the same ( $\sim 8\text{ lm W}^{-1}$ ).<sup>74</sup> The maximum brightness of the best lanthanide-containing device based on terbium pyrazolone complex **51(Tb)** is  $20\,000\text{ cd m}^{-2}$ , and the efficiency of this device is  $3.24\text{ lm W}^{-1}$ .<sup>66</sup>

However, in spite of the fact that rare-earth complexes are considerably less efficient than organic compounds, they have attracted great attention because of specific features of the mechanism of luminescence providing monochromatic radiation. Electronic spectra of lanthanide ions are associated with *f–f* transitions in the 4*f* layer shielded from external fields by the closed 5*s* and 5*p* shells. This provides narrowing of the emission line to 10 nm, which is inaccessible for other luminophores. At the same time, the fact that transitions within the same electronic configuration are parity-forbidden results in low absorptivity of *f–f* transitions ( $\epsilon \leq 10\text{ mol}^{-1}\text{ litre cm}^{-1}$ ) and, as a consequence, in low luminescence efficiency of free ions.<sup>75</sup> Interactions of 4*f* electrons with the crystal field lead to a change in the radius of the *f*

**Table 1.** Emitting lanthanide complexes with organic ligands.

<sup>a</sup> In this case, only two of six identical ligands are shown; <sup>b</sup> in the structural formula, the phen ligand is omitted for simplicity.

shell and partial or complete removal of degeneracy resulting in splitting of the energy levels (Fig. 2).<sup>76</sup>

It should be noted that emission can occur only from particular excited levels, which are indicated in the diagram presented in Fig. 2 by black semicircles. The schemes of electron transitions for selected lanthanide ions are shown in Fig. 3.

Some transitions can be made parity-allowed by admixing states of excited electron levels of the ligand to the states of the 4f<sup>n</sup>-electronic configuration.<sup>77</sup> As a consequence, the luminescence intensity of lanthanide ions sharply increases upon complexation with certain organic ligands. In these compounds, the light energy is absorbed primarily by the organic moiety of the complex, *i.e.*, the ligand serves as an 'antenna' (Fig. 4).<sup>78</sup>

The mechanism of electroluminescence of lanthanide compounds includes three steps. The first step involves electron–hole recombination, resulting in exciton generation and excitation of the ligand to the singlet (S<sub>1</sub>) and triplet (T<sub>1</sub>) levels. In the second step, the energy of the excited ligand is transferred (from the triplet level) to the emitting level of the metal ion. The latter step involves emission from the corresponding level of the metal atom. There-

Figure 4. Scheme of energy transfers in lanthanide complexes.

fore, photoluminescence differs from electroluminescence only in the nature of excitation energy. It should be noted that, in the case of electroluminescence, the excitation of the T level of the ligand is not forbidden by quantum-mechanics. Since it is this level from which the energy transfer to metal occurs, the emitting level of the metal atom can be efficiently filled in the presence of an appropriate ligand. It is quite evident that the efficiency of energy transfer to the emitting levels of a lanthanide ion depends primarily on the nature of the ligand coordinated to this ion.<sup>4</sup> Of the rare-earth derivatives,  $\beta$ -diketonate, carboxylate, pyrazolone and hydroxyquinolate complexes are presently the most efficient electroluminescent materials for OLED devices.

### III. Light-emitting diodes based on lanthanide coordination compounds

#### 1. Light-emitting diodes based on rare-earth $\beta$ -diketonates

The use of lanthanide complexes in the design of electroluminescent cells was documented for the first time in 1990.<sup>12</sup> Kido *et al.*<sup>16</sup> described a two-layer OLED with a structure of ITO/TPD/1(Tb)/Al based on terbium acetylacetonate [1(Tb)] with a maximum brightness of 7 cd m<sup>-2</sup> at a current density of 0.4 mA cm<sup>-2</sup>. In this case, the electroluminescence spectrum was found to be identical to the photoluminescence spectrum. The maximum emission was observed at 544 nm, which cor-

Figure 3. Diagrams of emission transitions in lanthanide ions.

responds to the  $^5D_4 \rightarrow ^7F_5$  transition of the  $Tb^{3+}$  ion. Shortly thereafter, the first europium OLED was constructed based on trifluoroacetylacetonate complex **5(Eu)**, which was molecularly dispersed in polymethylphenylsilane (PMPS) serving as a hole-transport layer.<sup>16</sup> The ITO/PMPS-**5(Eu)**/PBD/Mg/Ag device exhibited red emission characteristic of europium compounds with a maximum brightness of  $0.3 \text{ cd m}^{-2}$  at 18 V. Campos *et al.*<sup>79</sup> improved the luminescence characteristics of an analogous device based on complex **5(Eu)** with the use of a diamine hole-transport layer instead of polysilane, and a maximum brightness of  $\sim 10 \text{ cd m}^{-2}$  was achieved.

It should be noted that europium complexes proved to be the most promising luminescent materials for red emitters, because they generate monochromatic light with a wavelength of 614 nm, whereas known organic materials serving as emitters for the red spectral region give a broad band ( $\sim 100 \text{ nm}$ ) resulting in colour distortion. At the same time, the theoretically predicted high luminescence efficiency of lanthanide complexes remains so far unachievable under real conditions. Some authors relate this problem to poor transport properties of lanthanide complexes and believe that this problem can be solved by choosing organic ligands, which improve this property of materials.

Nakaya and co-workers<sup>34</sup> used compound **15(Eu)** for the construction of the two-layer device ITO/TPD/**15(Eu)**/AlLi with a maximum brightness of  $34 \text{ cd m}^{-2}$  at 12 V. A comparison of these data with the properties of complex **18(Eu)** ( $7 \text{ cd m}^{-2}$ ), which has been used earlier for this purpose, led these authors to conclude that compound **15(Eu)** has good charge-transport properties in the solid state. More recently, this research group<sup>35</sup> used complex **16(Eu)** as an emitting and electron-transport layer in a two-layer OLED device. The characteristics of this device ( $32.0 \text{ cd m}^{-2}$  at 9 V) were also attributed to the improved electron-transport properties due to the presence of the furyl fragment. Okada *et al.*<sup>36</sup> used 1,3-di(2-thionyl)propane-1,3-dione (dtp) as the  $\beta$ -diketonate ligand and 4,7-diphenyl-1,10-phenanthroline (bath) as the neutral ligand to prepare complex **17(Eu)**, and the latter was used for the construction of a three-layer OLED. The researchers observed bright red emission with a maximum brightness of  $450 \text{ cd m}^{-2}$  at 15 V. In the study,<sup>41</sup> the external efficiency of 3.5% and the maximum brightness of  $924 \text{ cd m}^{-2}$  at  $380 \text{ mA cm}^{-2}$  were achieved with the use of complex **25(Eu)** with mixed ligands.

Taking into account the good luminescent properties of azaindole, Wang *et al.*<sup>18</sup> synthesised terbium and yttrium complexes with the modified acetylacetonate ligands  $[\text{Ln}(\text{acac-azin})_3]_2$  [**7(Ln)**] and established their molecular structures by X-ray diffraction. The photoluminescence quantum yield of complex **7(Tb)** (11%) is lower than that of complex **1(Tb)** (19%). The low quantum yield is apparently associated with the fact that the triplet level of the ligand ( $22\,220 \text{ cm}^{-1}$ ) is only  $1720 \text{ cm}^{-1}$  higher than the  $^5D_4$  level of  $Tb^{3+}$  ( $20\,500 \text{ cm}^{-1}$ ) and it does not provide essential excitation of the metal cation. However, the authors of the cited study succeeded in achieving the efficiency of  $0.65 \text{ cd A}^{-1}$  at 13 V by choosing an appropriate composition of PVK and PBD.

Wang *et al.*<sup>15</sup> focussed their attention on the synthesis of  $\beta$ -diketonate ligands containing oxadiazole fragments. These fragments were chosen because oxadiazole derivatives are widely used as electron-transport and hole-blocking materials. The external efficiency of the OLED device ITO/PVK : PBD : **4(Tb)**/Al(pop)<sub>3</sub>/CsF/Al was  $\sim 1.1\%$  and  $0.6\%$  and the brightness was 100 and  $550 \text{ cd m}^{-2}$  at 15 and 20 V, respectively.

In the study,<sup>44</sup> the oxadiazole substituent was introduced into 2-(2-pyridyl)benzimidazole and the resulting compound was used as the neutral ligand in the europium complex  $\text{Eu}(\text{dbm})_3(\text{pybm-OXD})$  [**29(Eu)**]. A two-layer OLED device containing this compound [ITO/TPD/**29(Eu)**/LiF/Al] had an external quantum efficiency of 1.7% at 612 nm and a maximum brightness of  $322 \text{ cd m}^{-2}$  at 21 V. This study demonstrated that the introduction of the oxadiazole fragment into the lanthanide complex

improves the charge-transport properties of the complex and simplifies the structure of an electroluminescent cell.

Chinese researchers<sup>43,45</sup> combined the phenanthroline fragment possessing the electron-transport properties and the triphenylamine fragment with the hole-transport properties in a neutral ligand. The resulting europium complex **30(Eu)** was used for the construction of the single-layer OLED ITO/**30(Eu)**/MgAg/Ag with a maximum brightness of  $19 \text{ cd m}^{-2}$  at 13.5 V and the four-layer device ITO/TPD/**30(Eu)**/BCP/Alq<sub>3</sub>/MgAg/Ag with an external quantum efficiency of 0.85%, a light efficiency of  $1.44 \text{ lm W}^{-1}$  and a maximum brightness of  $1305 \text{ cd m}^{-2}$  at 16 V. With the aim of synthesising new highly efficient luminescent compounds, these authors<sup>46</sup> introduced the carbazole fragment into the neutral phenanthroline ligand. Devices based on compound **31(Eu)** exhibited excellent luminescent properties and had good stability. For example, the two-layer OLED ITO/TPD/**31(Eu)**/MgAg/Ag exhibited a maximum brightness of  $537 \text{ cd m}^{-2}$  at 13 V and an efficiency of  $0.089 \text{ lm W}^{-1}$ , the three-layer device ITO/TPD/**31(Eu)**/**14(Eu)**/MgAg/Ag exhibited a maximum brightness of  $1050 \text{ cd m}^{-2}$  at 16 V and an efficiency of  $0.50 \text{ lm W}^{-1}$ , and the four-layer device ITO/TPD/**31(Eu)**/BCP/Alq<sub>3</sub>/MgAg/Ag had the highest brightness of  $1460 \text{ cd m}^{-2}$  at 14 V and an efficiency of  $0.54 \text{ lm W}^{-1}$ .

In the study,<sup>43</sup> two new ligands, viz., 2-(2-pyridyl)benzimidazole (hpbm) and 2-(2-pyridyl)-1-ethylbenzimidazole (epbm), were used instead of phenanthroline. Europium complexes with these ligands, **27(Eu)** and **28(Eu)**, were used for the design of the OLED devices ITO/TPD/**27(Eu)**/Al, ITO/TPD/**28(Eu)**/Al and ITO/TPD/**28(Eu)**/Alq<sub>3</sub>/Al. The brightness of ITO/TPD/**27(Eu)**/Al ( $29 \text{ cd m}^{-2}$  at 11 V) is much higher than that of ITO/TPD/**28(Eu)**/Al ( $1.14 \text{ cd m}^{-2}$  at 23 V). The authors believed that compound **27(Eu)**, like most europium complexes, has poor transport properties. More recently, these authors used thenoyl trifluoroacetate (tta) as the central ligand<sup>47</sup> and found that the brightness of the OLED based on  $\text{Eu}(\text{tta})_3(\text{epbm})$  [**33(Eu)**] ( $36.6 \text{ cd m}^{-2}$ ) is much higher than that of the OLED based on  $\text{Eu}(\text{tta})_3(\text{hpbm})$  [**32(Eu)**] ( $< 7 \text{ cd m}^{-2}$ ).

In the study,<sup>48</sup> complex **34(Eu)** was synthesised with the use of substituted phenanthroline (dppz) as the central ligand, and the OLED ITO/TPD/**34(Eu)**:CBP/BCP/Alq<sub>3</sub> was constructed based on this complex; the external quantum efficiency of this device was 2.1% and the brightness was  $1670 \text{ cd m}^{-2}$ .

Presently, it is believed that ligands in complexes destined for the design of OLED devices should satisfy the following main requirements: (1) the triplet level of the ligand should match the emission level of metal; (2) the ligands should have the electron- and hole-transport properties to promote charge injection and exciton generation in the complex; (3) the complex should be easily deposited onto a support without the formation of aggregates and crystals and should be compatible with other components of the device.<sup>26</sup> It is evident that the position of the triplet level of the ligand relative to the corresponding level of metal is of considerable importance. However, in spite of numerous experimental and theoretical studies devoted to this problem, a theoretical model allowing the synthesis of the desired highly luminescent lanthanide complexes is lacking.

To simplify the task, comparative studies of related complexes are carried out with the aim of developing theoretical models. For example, Zheng *et al.*<sup>13</sup> investigated the photo- and electroluminescent properties of four terbium complexes, **1(Tb)**, **3(Tb)**, **8(Tb)** and **10(Tb)**. The comparative characteristics of OLED devices based on these complexes are given in Table 2.

It can be seen from this table that the introduction of fluorine atoms into the acetylacetonate ligand and additional coordination of the metal ion by the neutral phenanthroline ligand lead to an increase in the electroluminescence intensity. The emission bands of the ligand in the spectra of the complexes were not observed, which confirms high efficiency of excitation transfer from the levels of the ligand to the terbium ion in all four complexes. This led the authors to conclude<sup>13</sup> that the electroluminescence inten-

**Table 2.** Characteristics of the OLED devices ITO/PVK/PVK:Tb-complex:PBD/PBD/Al.<sup>13</sup>

| Tb complex    | Luminescence yield $\eta$ (%) | Voltage /V | Maximum brightness /cd m <sup>-2</sup> |
|---------------|-------------------------------|------------|----------------------------------------|
| <b>10(Tb)</b> | 0.25                          | 8          | 58                                     |
| <b>8(Tb)</b>  | 0.16                          | 10         | 36                                     |
| <b>3(Tb)</b>  | 0.11                          | 11         | 25                                     |
| <b>1(Tb)</b>  | 0.08                          | 13         | 17                                     |

sity of lanthanide complexes is determined primarily by the ratio of the energy of the triplet level of the ligand to the energy of the emission level of lanthanide. Theoretical and experimental studies demonstrated that for the ligand-to-metal energy transfer to occur, the emission level of the metal must be somewhat lower than the triplet level  $T_1$  of the ligand, and the optimal difference  $\Delta E(T_1 - {}^5D_4)$  for terbium complexes should be  $2400 \pm 300$  cm<sup>-1</sup>. The triplet level of the fluorine-containing acetylacetonate ligand ( $22\,720$  cm<sup>-1</sup>) is lower than that of the acetylacetonate ligand ( $25\,310$  cm<sup>-1</sup>). Hence, the electroluminescence efficiency of complex **3(Tb)** with the Tb<sup>3+</sup> ion ( ${}^5D_4 = 20\,500$  cm<sup>-1</sup>) is higher than that of **1(Tb)** with the same ion.<sup>80–84</sup> The fact that the introduction of phenanthroline also increases luminescence was attributed to the intramolecular energy transfer from the  $\beta$ -diketonate ligand to phenanthroline (the triplet level of the  $\beta$ -diketonate ligand is much higher than that of phenanthroline), with the result that  $\Delta E(T_1 - {}^5D_4)$  approaches the optimal value.<sup>13</sup>

The intramolecular ligand-to-ligand energy transfer providing the necessary height of the triplet level of the ligand was observed also in samarium complex **12(Sm)**.<sup>26</sup> Lowering of the energy of the triplet level of the bfa ligands ( $T_1 = 21\,480$  cm<sup>-1</sup>) to  $21\,277$  cm<sup>-1</sup> (in the complex) due to the introduction of the phen ligand ( $T_1 = 21\,400$  cm<sup>-1</sup>) is accompanied by a decrease in the distance between the triplet level and the emission level of the metal ( ${}^4G_{5/2} = 18\,000$  cm<sup>-1</sup>) and provides bright emission of the samarium ion. It should be noted that the luminescence spectrum of samarium consists of three main peaks at 563, 598 and 643 nm corresponding to the  ${}^4G_{5/2} \rightarrow {}^6H_{5/2}$ ,  ${}^4G_{5/2} \rightarrow {}^6H_{7/2}$  and  ${}^4G_{5/2} \rightarrow {}^6H_{9/2}$  transitions, respectively, which is responsible for the orange colour of emission.<sup>50</sup> The two- and three-layer OLED devices ITO/MTCD/**36(Sm)**/Alq<sub>3</sub>/Al and ITO/MTCD/**36(Sm)**/Al were constructed on the basis of complex **36(Sm)**; however, the luminescence intensity of both devices appeared to be low ( $\sim 0.5$  cd m<sup>-2</sup>).<sup>2,50</sup>

The spectrum of thulium shows a narrow blue line at 480 nm assigned to the electron transition  ${}^1G_4 \rightarrow {}^3H_6$ .<sup>85</sup> This is presently the most desired colour of luminescence. However, data on the use of thulium compounds for the design of OLED devices are so far very scarce, probably because of the high price of this lanthanide. Li and co-workers<sup>20</sup> used complex **8(Tm)** for the construction of an OLED, but its characteristics unexpectedly appeared to be noticeably worse than those of the terbium analogue (the maximum brightness was as low as 6 cd m<sup>-2</sup> at 16 V). The authors of the cited study believed that this is associated with large  $\Delta E(T_1 - {}^1G_4)$  for the thulium complex (the triplet level of the acetylacetonate ligand is  $25\,500$  cm<sup>-1</sup>, the  ${}^1G_4$  level of the Tm<sup>3+</sup> ion is  $21\,196$  cm<sup>-1</sup>). In the study,<sup>86</sup> the  ${}^1D_2$  level was considered as the emission level of the Tm<sup>3+</sup> ion, and the absence of luminescence in complexes with the terphenyl ligands (the energy of the  $T_1$  level in these ligands is  $\sim 23\,500$  cm<sup>-1</sup>) was attributed to the high energy of the  ${}^1D_2$  level ( $\sim 27\,800$  cm<sup>-1</sup>). However, an investigation of the photoluminescent properties of thulium  $\beta$ -diketonate complexes<sup>85</sup> confirmed emission in thulium from the  ${}^1G_4$  ( $21\,275$  cm<sup>-1</sup>) and  ${}^3H_4$  ( $12\,500$  cm<sup>-1</sup>) levels:  ${}^1G_4 \rightarrow {}^3H_6$  (475 nm) (this transition has the maximum intensity),  ${}^1G_4 \rightarrow {}^3F_4$  (650 nm),  ${}^1G_4 \rightarrow {}^3H_5$  (780 nm) and  ${}^3H_4 \rightarrow {}^3H_6$  (795 nm) (Fig. 5).

It was found<sup>30</sup> that the replacement of the acac ligand with the dbm ligand gives rise to electroluminescence in the ITO/TPD/

**Figure 5.** Diagrams of emission transitions in the Tm<sup>3+</sup> ion.<sup>85</sup>

**13(Tm)**/Mg:Ag and ITO/TPD/**14(Tm)**/Mg:Ag devices in the near-IR region. However, the emission intensity appeared to be much lower than that in analogous erbium complexes **13(Er)** and **14(Er)**.

Holmium complex **14(Ho)** in an analogous OLED device with a structure of ITO/TPD/**14(Ho)**/Mg:Ag shows photo- and electroluminescence in the visible and near-IR regions.<sup>33</sup> Due to the presence of an intense band at a wavelength of 1500 nm, these complexes hold promise as materials for optical communications devices, for which the 1.3–1.5  $\mu$ m region (a frequency window of modern light pipes) is of great importance.

Dysprosium tris(acetylacetonate) complex **8(Dy)** was used as an emitter for the construction of a white-emitting OLED cell.<sup>21</sup> The Dy<sup>3+</sup> cation has two intense emission bands in the visible region, blue ( $\sim 480$  nm) and yellow ( $\sim 580$  nm), corresponding to the  ${}^4F_{9/2} \rightarrow {}^6H_{13/2}$  and  ${}^4F_{9/2} \rightarrow {}^6H_{15/2}$  transitions. However, the drawbacks of this device are low resistance of the complex to voltage and weak luminescence (lower than  $20$  cd m<sup>-2</sup>) associated, apparently, with inefficient energy transfer from the triplet level of the ligands to the dysprosium ion.

However, analysis of the spectra of numerous substituted europium  $\beta$ -diketonate complexes showed that the change in the luminescence intensity cannot be attributed solely to the difference in the energy of the triplet levels of the ligands.<sup>87</sup> In the cited study, the electron system of the  $\beta$ -diketonate ligand was changed by introducing substituents possessing different donor–acceptor properties and steric characteristics, the relative arrangement of the substituents in the ligands being varied and particular linking groups, which block energy transfer within the ligands, being constructed. These experiments demonstrated that an increase in the donating ability of the  $\beta$ -diketonate ligand, weakening of the Eu–N bonds, strengthening of the Eu–O bonds and the introduction of the methylene or oxymethylene bridges separating the  $\pi$ -electron system of the ligand from the Eu<sup>3+</sup> ion lead to a decrease in the efficiency of the ligand-to-metal excitation energy transfer and, as a consequence, to a decrease in the luminescence intensity of europium.<sup>87,88</sup>

Bazan and co-workers<sup>25</sup> found that, in spite of the different nature of the substituents, the triplet levels of the tta, dbm, flta, flpa and flha ligands present in complexes **5(Eu)**, **2(Eu)**, **21(Eu)**, **22(Eu)** and **23(Eu)** are located in close proximity (in the region of  $20\,500$  cm<sup>-1</sup>). Hence, the corresponding  $\beta$ -diketonates should have similar efficiency of energy transfer from these ligands to the europium ion. However, the luminescence intensities of these complexes and cells constructed on their basis appeared to be

different. The best result was obtained for the ITO/TPD/**24(Eu)**:AZM-Hex/Mg device with a maximum brightness of  $10 \text{ cd m}^{-2}$ . It is expected that an increase in the purity of the starting compounds and optimisation of the structure of the device would allow an increase in the luminescence brightness.

Recently, Chinese researchers have achieved remarkable results by replacing the flha ligand in complexes **23(Eu)** and **23(Sm)** with the hfnh ligand.<sup>40</sup> New complexes **20(Eu)** and **20(Sm)** exhibited electroluminescence in the OLED devices ITO/TPD/**20(Eu)**:CBP/BCP/Alq<sub>3</sub>/LiF/Al and ITO/TPD/**20(Sm)**:CBP/BCP/Alq<sub>3</sub>/LiF/Al with maximum brightnesses of 967 and  $42 \text{ cd m}^{-2}$ , respectively.

It should be noted that a search for new organic ligands for lanthanide complexes destined for the construction of OLED devices was traditionally limited to oxygen- and nitrogen-containing compounds. However, the synthesis of terbium complex **52(Tb)** with the imidodiphosphinate ligands has been recently documented.<sup>67</sup> This compound showed photoluminescence with a quantum yield of 14%, the maximum brightness of electroluminescence in the OLED device based on this compound (ITO/TPD/**52(Tb)**/Alq<sub>3</sub>/Mg:Al) was  $20 \text{ cd m}^{-2}$  at 25 V, and the external efficiency was  $0.7 \text{ cd A}^{-1}$ .

The Yb<sup>3+</sup>, Nd<sup>3+</sup>, Pr<sup>3+</sup> and Er<sup>3+</sup> ions are known to have emission bands in the near-IR region, *i.e.*, in the region of communications frequencies. However, complexes of these metals are of limited use as materials for OLED devices because of a low luminescence intensity. For example, the maximum quantum yield of neodymium, praseodymium and erbium acetylacetonate complexes is as low as  $2.8 \times 10^{-2}\%$ .<sup>89</sup>

In attempting to find new luminescent materials, Voloshin *et al.*<sup>52</sup> synthesised neodymium and ytterbium thiodiketonate complexes **37(Nd)** and **37(Yb)**. However, the luminescent properties of these complexes appeared to be substantially worse than those of oxygen-containing analogues **36(Nd)** and **36(Yb)**, which was attributed to a substantially lower position of the triplet level of the sulfur-containing ligand (slightly higher than  $12\,000 \text{ cm}^{-1}$ ). These authors studied also Pr<sup>3+</sup>  $\beta$ -diketonates and carboxylates<sup>90</sup> and demonstrated that emission in praseodymium complexes occurs not only in the IR region but also in the visible region depending on the energy of the triplet level of the ligand. However, the quantum yield is also very low (at most 0.2%).

The most efficient energy transfer from the triplet level of the ligand to the metal ion in fluorinated neodymium  $\beta$ -diketonates was observed in a compound containing the pentafluorophenyl substituents, which is characterised by the lowest triplet level of the ligand ( $\Delta E \approx 1400 \text{ cm}^{-1}$ ) and the largest overlap between the phosphorescence spectrum of the ligand and the absorption spectrum of Nd<sup>3+</sup> in the 400–650 nm region.<sup>91</sup> An increase in the luminescence intensity was observed in neodymium complexes with asymmetric  $\beta$ -diketonate ligands, in which all C–H bonds are replaced with C–F or C–D bonds.<sup>92</sup> However, this increase is more likely to be attributable to weakening of luminescence quenching rather than to a change in the position of the triplet level.

In actuality, quenching processes play an essential role not only for lanthanides exhibiting luminescence in the near-IR region but also for all rare-earth metals. Hence, when searching for highly luminescent complexes for OLED devices, it is necessary to take into account the possibility of such processes occurring. For example, OH oscillators in coordinated water molecules were found to be the most efficient quenchers both in the solid state and in solution.<sup>93–95</sup> Other oscillators (NH, CH and C=O) are less active. The degree of quenching by water molecules is inversely proportional to the energy gap between the emission level and the ground state, and each oscillator independently quenches the excited state. The energy gaps for Yb<sup>3+</sup>, Eu<sup>3+</sup>, Tb<sup>3+</sup>, Sm<sup>3+</sup> and Dy<sup>3+</sup> are approximately equal to 10 200, 12 300, 14 200, 7400 and  $7850 \text{ cm}^{-1}$  respectively.<sup>86,96</sup> Consequently, the emitting states of ytterbium and europium correspond to the third vibrational overtone of an OH oscillator ( $\nu_{\text{OH}} \approx 3300\text{--}3500 \text{ cm}^{-1}$ ), whereas

the emitting state for terbium corresponds to the fourth harmonics. Hence, the efficiency of quenching by coordinated water molecules is much lower for the terbium ion. It is necessary to take into account the distance to the europium and terbium ions in the case of CH oscillators ( $\nu_{\text{CH}} \approx 3050 \text{ cm}^{-1}$  for aromatic and  $\nu_{\text{CH}} \approx 2950 \text{ cm}^{-1}$  for aliphatic). For example, quenching does not occur in complexes in which this distance is shorter than  $3.4 \text{ \AA}$ .<sup>86</sup> Luminescence is not observed in Ho<sup>3+</sup> complexes containing C–H bonds, because the energy transition  $^5\text{S}_2 \rightarrow ^5\text{F}_5$  [ $\Delta E(\text{Ho}^{3+}) \approx 3000 \text{ cm}^{-1}$ ] resonates with the CH vibrational mode ( $\nu_{\text{CH}} \approx 2900\text{--}3100 \text{ cm}^{-1}$ ). Deuteration of the ligand is inefficient in the case of Pr<sup>3+</sup> [ $\Delta E(\text{Pr}^{3+}) \approx 4100 \text{ cm}^{-1}$ ] and Nd<sup>3+</sup> [ $\Delta E(\text{Nd}^{3+}) \approx 5300 \text{ cm}^{-1}$ ], because the energy gaps in neodymium and praseodymium correspond to the first CD vibrational overtone.<sup>86</sup> The inductive resonance mechanism of radiationless transitions between the electronic levels of lanthanide ions in the condensed phase has been considered in detail in publications by Ermolaev and co-workers.<sup>97–99</sup>

## 2. Light-emitting diodes based on mixed $\beta$ -diketonate complexes

In recent years, along with a selection of neutral ligands in complex compounds, a new line of research on the introduction of the second metal ion into complex molecules has assumed increasing importance.<sup>19,100</sup>

Li and co-workers<sup>101</sup> were the first to use the mixed Eu<sub>x</sub>Tb<sub>1–x</sub>(acac)<sub>3</sub>(phen) complexes **8(Eu,Tb)** as an emitting layer. However, no data in support of the composition of this compound were presented. The device was reported to generate white emission resulting from mixing of the green emission of Tb<sup>3+</sup> (550 nm), red emission of Eu<sup>3+</sup> (616 nm) and blue emission of the NPB compound (450 nm). It was noted that the device is simple, but the luminescence characteristics were not published. More recently, these authors<sup>19</sup> considered the emission mechanism of complex **8(Eu,Tb)**. Interestingly, the maximum brightness of the composite ITO/PVK/**8(Tb)**/Al is  $210 \text{ cd m}^{-2}$ , whereas the maximum brightness of an analogous device with a europium complex, ITO/PVK/**8(Eu)**/Al, is as low as a few units of  $\text{cd m}^{-2}$ . In the luminescence spectrum of a device containing complex **8(Eu,Tb)** as the emitting layer, the red peak (615 nm) belonging to Eu<sup>3+</sup> is much stronger than the green peak (545 nm) belonging to Tb<sup>3+</sup>. The intensity of red emission in the mixed complex is 10 times higher than that of the mononuclear europium complex. The probable energy transfer process is shown in Fig. 6.

Figure 6. Energy diagram of dinuclear europium–terbium complexes.<sup>19</sup>

As can be seen from Fig. 6, several radiationless  $\text{S}_1 \rightarrow \text{T}_1$  ( $\text{Tb}^{3+} \rightarrow \text{Eu}^{3+}$ ) transitions are possible. As a result, the energy can be predominantly released through the  $^5\text{D}_0 \rightarrow ^7\text{F}_2$  emission of the Eu<sup>3+</sup> ion. Hence, the red emission in the mixed compound is an order of magnitude more bright than that in the compound containing only europium.

An increase in the emission brightness from 32 to 99  $\text{cd m}^{-2}$  on going from a mononuclear to dinuclear emitter was observed also for the OLED devices ITO/TPD/**18(Eu)**/Alq<sub>3</sub>/Mg:Ag and ITO/TPD/**18(Eu,Y)**/Alq<sub>3</sub>/Mg:Ag. It was hypothesised that the presence of the  $\text{Y}^{3+}$  ion promotes energy transfer from the triplet level of the ligand to the europium ion, resulting in an increase in the emission intensity.<sup>39</sup>

An alternative approach, which is also based on the use of several lanthanides in one OLED device, was described in the study.<sup>23</sup> With the aim of designing a white-emitting diode, a multilayer cell containing complex **9(Tb)** as the green (548 nm) emitting layer, complex **18(Eu)** as the red emitting layer (612 nm), the compound TPD as simultaneously the hole-transport and emitting (blue, 405 nm) layer and Alq<sub>3</sub> as the electron-transport layer was constructed. Actually, the device exhibited white emission, the emission brightness being 95  $\text{cd m}^{-2}$ .

### 3. Light-emitting diodes based on rare-earth carboxylates

As mentioned above, most studies on luminescent lanthanide complexes with organic ligands dealt with  $\beta$ -diketonate complexes because they are readily accessible, stable in air and show rather high emission activity. However, a considerable drawback of these compounds is their low photo and thermal stability.<sup>53</sup> In this respect, another class of rare-earth complexes, *viz.*, lanthanide carboxylates, have advantages. The latter not only have good ultraviolet absorption properties but also possess luminescence and thermal stability, which is better compared to the corresponding characteristics of  $\beta$ -diketonates.

It should be noted that lanthanide carboxylates are traditionally extensively studied by spectroscopic methods.<sup>102, 103</sup> In the review by Vicentini *et al.*,<sup>104</sup> the relationship between the molecular structure and emission spectra of metal ions was demon-

strated with the use of numerous europium complexes (primarily, with carboxylates). The emission spectra were found to depend on the coordination number and symmetry. For example, the presence of two peaks belonging to the  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  transition and a large number of peaks belonging to the  $^5\text{D}_0 \rightarrow ^7\text{F}_{1,2}$  transition are indicative of two different states of the europium ion. It was hypothesised that compounds characterised by broadened and poorly resolved  $^5\text{D}_0 \rightarrow ^7\text{F}_{1,2}$  transition bands have a polymeric nature. However, it was noted that a deep insight into the relationship between the structure and the luminescent properties requires that the structural data for complexes studied by spectroscopic methods be substantially extended.

Lanthanide carboxylates were used for the development of the concept of modeling of highly luminescent lanthanide systems. Latva *et al.*<sup>105</sup> studied more than 40 compounds with various carboxylate ligands **L1**–**L41** and confirmed the already known principle that the synthesis of luminescent europium and terbium compounds should be performed with the use of ligands having a high absorption coefficient and an efficient intrasystem transition from the singlet to triplet level. The efficiency of ligand-to-metal energy transfer and the luminescence quantum yield of  $\text{Ln}^{3+}$  depend on numerous factors, among which are the energy of the lower triplet level of the ligand (which plays the major role), the distance between the donor and acceptor in the luminophore molecule, quenching mechanisms, *etc.*

A range of compounds under study was chosen in such a way that the distance between the donor and acceptor remained virtually constant, the energy of the triplet level of the ligand being varied from 18 600 to 27 000  $\text{cm}^{-1}$ . It was found for the first time that the triplet level of the ligand in the complex should be not only somewhat higher than the resonance level of the ion but also somewhat different, each lanthanide being characterised by its

own optimum  $\Delta E$ . In the publication,<sup>105</sup> it was concluded that the difference between the triplet level of the ligand and the resonance level of terbium in terbium compounds should be no smaller than  $1850\text{ cm}^{-1}$ . However, the exact energy gap for europium compounds remains unknown. The dependence of the quantum yield of terbium and europium compounds on the position of the triplet level of the ligand is shown in Fig. 7.

The following dependence (the so-called Latva rule) was revealed: the optimum gap widths for  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  are  $2500 < \Delta E(^3\pi\pi^* - ^5D_0) < 3500$  and  $2500 < \Delta E(^3\pi\pi^* - ^5D_4) < 4000\text{ cm}^{-1}$ , respectively.<sup>105</sup>

In addition, investigation of carboxylate complexes<sup>106</sup> demonstrated that the intrasystem transfer is efficient when the difference between the singlet and triplet levels of the ligand  $\Delta E(^1\pi\pi^* - ^3\pi\pi^*)$  is  $\sim 5000\text{ cm}^{-1}$ . For example, the luminescence quantum yields for europium and terbium complexes with the 5'-methyl-2,2'-bipyridyl ligands containing the carboxyl or phosphonium substituent at position 6 do not satisfy the Latva rule. The ratio of the quantum yields opposite to the above rule was

attributed to the fact that  $\Delta E(^1\pi\pi^* - ^3\pi\pi^*)$  for a phosphonium-containing ligand ( $6750\text{ cm}^{-1}$ ) is closer to the ideal value ( $5000\text{ cm}^{-1}$ ) compared to the carboxyl-containing analogue ( $7100\text{ cm}^{-1}$ ).

The introduction of the neutral coordinated phenanthroline ligand into lanthanide carboxylates was found<sup>107, 108</sup> to increase luminescence. Presumably, a new ligand-to-ligand transition occurs if the level of the neutral ligand is lower than the triplet level of the main ligand and, as a consequence, the energy transfer from phenanthroline to the lanthanide ion increases. Tsaryuk *et al.*<sup>109</sup> studied photoluminescence of europium acetates  $\text{Eu}(\text{OAc})_3(\text{phen-R})$ , where phen-R is 3,4,7,8-tetramethyl-, 5-methyl-, 5-phenyl-, 4,7-diphenyl- or 5-nitrophenanthroline, and found that the nature of phenanthroline has no effect on the luminescent properties of the complexes.

An alternative approach to the design of highly luminescent lanthanide carboxylates was developed by Selvin and co-workers.<sup>110–114</sup> This method is based on the use of well-known organic laser dyes, which enhance emission in complexes, as substituents

**Figure 7.** Plots of the quantum yields of terbium (a) and europium (b) carboxylate complexes vs. the energy of the triplet level of the ligand.<sup>105</sup> (The letter L in the notations of the ligands is omitted for simplicity.)

in the carboxylate ligand. However, this modification of the carboxylate ligand appeared to be inefficient.

In spite of considerable progress in theoretical studies concerned with luminescence of lanthanide carboxylates, publications on the use of these compounds in electroluminescent devices are few in number.

Edwards *et al.*<sup>54</sup> synthesised europium and terbium benzoylbenzoate complexes, which gave rather high photoluminescence quantum yields: **39(Tb)**, 4%; **40(Eu)**, 16%; and **40(Tb)**, 27%. However, electroluminescence was not observed in compound **40(Eu)**, and the maximum brightnesses of OLED devices based on compounds **39(Tb)** and **40(Tb)** are as low as 7 and 0.7 cd m<sup>-2</sup>, respectively.

The OLED devices with structures of ITO/PVK/PVB:PBD:**38(Tb)**/PBD/Alq<sub>3</sub>/Al and ITO/PVK/PVB:PBD:**38(Tb)**/PBD/Al were designed on the basis of terbium acetylsalicylate **38(Tb)**.<sup>53</sup> The electroluminescence spectrum of the terbium ion was not observed for the former device, whereas the latter showed strong green emission characteristic of Tb<sup>3+</sup> with a maximum brightness of 4.0 cd m<sup>-2</sup> at 22 V.

Electroluminescence typical of the terbium ion (545 nm) was observed in the OLED cell ITO/PEDOT/PVK/**41(Tb)**/Al based on terbium acetylsalicylate containing neutral triphenylphosphine oxide.<sup>55</sup> Bright green electroluminescence of terbium at 547.5 nm was observed also in the three-layer OLED device ITO/PVK:**42(Tb)**/Al.<sup>56</sup>

A drawback of carboxylate derivatives of lanthanides as luminophores for OLED devices is their low solubility. To increase solubility, oligomeric hydrocarbon substituents are introduced into the organic moiety of complexes. For example, Chinese researchers<sup>58</sup> synthesised readily soluble terbium hexadecylphthalate complex **44(Tb)** and designed the OLED device ITO/PPV/PVK:**44(Tb)**:PBD/Alq<sub>3</sub>/Al on the basis of this complex with a maximum brightness of 74 cd m<sup>-2</sup> at 18 V. In the discussion, these authors noted that, according to the Latva rule, luminescence of the Tb<sup>3+</sup> ion was observed at the difference T<sub>1</sub>(22 951 cm<sup>-1</sup>) – <sup>5</sup>D<sub>4</sub>(20 500 cm<sup>-1</sup>) = 2331 cm<sup>-1</sup>. The position of the triplet level of the ligand was determined using an analogous gadolinium complex.

More recently, terbium monododecylphthalate complex **43(Tb)** containing a shorter alkyl chain was synthesised.<sup>57</sup> The OLED device ITO/PVK/PVK:PBD:**43(Tb)**/Alq<sub>3</sub>/Al also showed green emission with a maximum brightness of 16 cd m<sup>-2</sup> at 24 V.

In the study,<sup>59</sup> terbium monotetradecylphthalate phenanthroline complex **45(Tb)** was used to design the OLED device ITO/PPV/PVK:**45(Tb)**:PBD/Alq<sub>3</sub>/Al with a maximum brightness of 152 cd m<sup>-2</sup> at 24 V and an external quantum efficiency of 0.017%. The electroluminescence spectrum of the cell was identical to the photoluminescence spectrum in which the most efficient transition is observed from <sup>5</sup>D<sub>4</sub> to <sup>7</sup>F<sub>5</sub> at 545 nm with a linewidth of at least 10 nm.

Zheng *et al.*<sup>60</sup> synthesised a new carboxylate ligand, *o*-amino-4-cetylbenzoate, and used it to prepare terbium complex **46(Tb)**. The OLED device ITO/PPV/PVK:**46(Tb)**:PBD/Alq<sub>3</sub>/Al showed characteristic emission of the terbium ion with a maximum brightness of 35 cd m<sup>-2</sup> at 20 V, the characteristics of the device ITO/PVK:**46(Tb)**:PBD/Al being worse (the maximum brightness was only 18 cd m<sup>-2</sup>).

#### 4. Light-emitting diodes based on rare-earth complexes containing pyrazolone ligands

In recent years, a new class of compounds, *viz.*, lanthanide complexes with pyrazolone ligands coordinated to the metal ion through the chelate β-diketonate group (Table 1, compounds **47–51**), has attracted the attention of researchers concerned with the design of materials for image converters.<sup>63</sup> The hetero-ligand complex Eu(tta)<sub>2</sub>(pmbbp)(phen) [**35(Eu)**] synthesised by Tsutsui and co-workers<sup>49</sup> is one of the first compounds belonging to this class. The light-emitting diode ITO/TPD/**35(Eu)**/Alq<sub>3</sub>/Mg:Al prepared on the basis of the above complex generated emission at a wavelength of 613 nm with a brightness of 16 cd m<sup>-2</sup> at 12.5 V, which is twice as good as for compound **18(Eu)**. By contrast, the Eu(pmabbp)<sub>3</sub>(phen) complex does not show luminescence at all because of the low position of the triplet level of the ligand. It was expected that luminescence in mixed-ligand complex **35(Eu)** would be low due to energy transfer from the thiophenediketonate ligand to the pyrazolonediketonate one. The observed increase in luminescence was attributed to the improvement of the charge-transport properties of the complex.

Huang and co-workers<sup>61</sup> found that compound **47(Tb)** also possesses good electron-transport properties. The diode ITO/TPD/**47(Tb)**/Alq<sub>3</sub>/Al designed on the basis of this complex has a maximum brightness up to 920 cd m<sup>-2</sup> at 18 V and a luminescence efficiency of 0.51 lm W<sup>-1</sup> at a current density of 0.70 mA cm<sup>-2</sup>.

In the study,<sup>63</sup> a brightness of 2200 cd m<sup>-2</sup> at 14 V was achieved in the OLED device ITO/MTDATA/TPD/**48(Tb)**/TAZ/Al designed with the use of new terbium pyrazolone complex **48(Tb)**. The maximum efficiency of the device was 2.6 lm W<sup>-1</sup> at a brightness of 25 cd m<sup>-2</sup>. Interestingly, the maximum brightness of the single-layer cell ITO/**48(Tb)**/Al was only 6 cd m<sup>-2</sup> at 23 V. The use of a potassium cathode made it possible to increase the maximum brightness and the efficiency to 226 cd m<sup>-2</sup> and 0.67 cd A<sup>-1</sup>, respectively.<sup>64</sup> However, the maximum brightness of 2200 cd m<sup>-2</sup> was achieved with the use of an appropriate combination of electron- and hole-transport layers. This result shows once again that the efficiency of devices substantially depends on their composition.

Complex **49(Gd)** was used<sup>65</sup> as the electron-transport and emission layer. The observed green emission at 535 nm characterises the pyrazolone complex as ligand-emitting. The maximum brightness of an OLED device designed on the basis of this complex is 230 cd m<sup>-2</sup> at 17 V. Another example of the use of lanthanide complexes as ligand-emitting rather than traditional metal-emitting compounds was given in the study,<sup>62</sup> where the synthesis of three lutetium pyrazolone complexes, **47(Lu)**, **49(Lu)** and **50(Lu)**, was documented. Complex **47(Lu)** was studied by X-ray diffraction. The results of this study confirmed the fact that

the nature of the neutral ligand may strongly affect the luminescence intensity. The photoluminescence spectra of all complexes are similar. However, the intensity for complex **47(Lu)** appeared to be 100 times higher. At the same time, the brightness of electroluminescence of the OLED device ITO/TPD/**47(Lu)**/BCP/Alq<sub>3</sub>/Mg:Ag/Ag constructed with the use of this complex was at most 119 cd m<sup>-2</sup> at 19 V, whereas a brightness of 1010 cd m<sup>-2</sup> at 16 V was achieved in the ITO/TPD/**50(Lu)**/BCP/Alq<sub>3</sub>/Mg:Ag/Ag device designed on the basis of a bipyridyl complex, whose photoluminescence characteristics are worse, and the brightness of the ITO/TPD/**49(Lu)**/BCP/Alq<sub>3</sub>/Mg:Ag/Ag device designed with the use of a phenanthroline complex was 776 cd m<sup>-2</sup> at 17 V. Triphenylphosphine oxide complex **47(Lu)** was found to have good transport properties, whereas the bipyridyl [**50(Lu)**] and phenanthroline [**49(Lu)**] complexes easily form exciplexes with TPD having high emission brightness. These data show that not only highly photoluminescent complexes but also compounds, which are weakly photoluminescent but form exciplexes with high electroluminescence efficiency, can be used as emitters for OLEDs. The authors believed that the function of a neutral ligand is to provide energy exchange between the neutral and valence-bound ligands. In the bipyridyl [**50(Lu)**, 280 nm] and phenanthroline [**49(Lu)**, 265 nm] complexes, the luminescence decreases as a result of energy transfer from the pyrazolone ligand to the neutral ligand, whereas this transfer does not occur in TPPO-containing complex **47(Lu)**.<sup>115</sup> It should be noted that the ITO/TPD/**47(Tb)**/Alq<sub>3</sub>/Al device has the better luminescent properties with a maximum brightness of 2680 cd m<sup>-2</sup>. These data suggest that the main role of the neutral ligands is to change the transport properties of materials. More recently, Huang *et al.*<sup>116</sup> successfully used compound **47(Tb)** as an electron-transport layer instead of Alq<sub>3</sub>, which also confirmed the excellent electron-transport properties of this compound.<sup>66</sup> In complex **51(Tb)**, the number of coordinated triphenylphosphine oxide groups was decreased due to the steric effect of the new pyrazolone ligand, which provides a balance between the hole- and electron-transport properties of the complex. However, the brightness of a single-layer device based on this compound is as low as 46 cd m<sup>-2</sup>. The use of additional hole- (TPD) and electron-transport (Alq<sub>3</sub>) layers made it possible to increase the emission brightness of the diode ITO/TPD/**51(Tb)**/Alq<sub>3</sub>/Mg:Ag/Ag to 20 000 cd m<sup>-2</sup> at 20 V, and the efficiency was increased to 3.24 lm W<sup>-1</sup>. A further optimisation of the device [ITO/NPB/**51(Tb)**/BCP/Alq<sub>3</sub>/Mg:Ag/Ag] resulted in an increase in the efficiency to 11.4 lm W<sup>-1</sup> at 7 V and the maximum brightness to 12 000 cd m<sup>-2</sup> at 18 V.

### 5. Light-emitting diodes based on rare-earth complexes containing quinoline derivatives as ligands

In spite of the fact that the first brief communication<sup>117</sup> on the design of a single-layer light-emitting diode with the use of neodymium 8-hydroxyquinolate was published almost 10 years ago, 8-hydroxyquinoline derivatives of lanthanides have attracted considerable attention only in 1999 after a series of publications on infrared emission in an erbium 8-hydroxyquinolate-based OLED device, in which the erbium compound was used as the emission and electron-transport material.<sup>2,3</sup> The electroluminescence at a wavelength of 1.53  $\mu$ m associated with the <sup>4</sup>I<sub>13/2</sub> → <sup>4</sup>I<sub>15/2</sub> transition was observed in the ITO/TPD/**53(Er)**/Al device containing erbium 8-hydroxyquinolate.<sup>68,69</sup> Analogous diodes based on Nd<sup>3+</sup> complexes show electroluminescence at 0.9, 1.06 and 1.32  $\mu$ m (Nd<sup>3+</sup>),<sup>70</sup> whose highest peak (1.06  $\mu$ m) corresponds to the <sup>4</sup>F<sub>3/2</sub> → <sup>4</sup>F<sub>11/2</sub> transition. The luminescence of a diode containing ytterbium 8-hydroxyquinolate at 0.98 nm is associated with the interatomic <sup>2</sup>F<sub>5/2</sub> → <sup>2</sup>F<sub>7/2</sub> transition.<sup>71</sup> Investigation of the kinetics of electroluminescence of the Erq<sub>3</sub> complex revealed two different times (0.23 and 2.2 ms). In the study,<sup>118</sup> this was attributed to the occurrence of different intraatomic transitions in the erbium ion.

It was noted that the electroluminescence in devices based on hydroxyquinoline derivatives of lanthanides is substantially weaker than the photoluminescence of the same complexes. Additional studies by time-resolved photoluminescence<sup>119</sup> demonstrated that the luminescence intensity is substantially influenced by deactivation processes, which depend on the nature of the solvent and ligands. It was estimated<sup>119</sup> that the luminescence efficiency of erbium 8-hydroxyquinolate can vary in the range of 0.002%–0.03%.

It should be noted that rare-earth 8-hydroxyquinolates, which were used for the construction of the above-mentioned OLED devices, were not structurally investigated. It was believed that all these compounds are structurally similar to the well-known aluminium analogue Alq<sub>3</sub>. This assumption was indirectly confirmed by investigation of thin films of erbium and ytterbium 8-hydroxyquinolates by X-ray photoemission spectroscopy.<sup>120</sup> However, recent X-ray diffraction studies demonstrated that rare-earth 8-hydroxyquinolates have various structures, which are sharply different from that of the aluminium compound. It was found that none of lanthanide complexes corresponds to the formula Lnq<sub>3</sub>.<sup>121</sup> Compound **A**, which is most compositionally similar to Lnq<sub>3</sub>, contains, in addition to the metal atom and three 8-hydroxyquinolate ligands, an ammonium cation. In complex **B**, the metal ion is coordinated by two water molecules.

All other known lanthanide quinolates are trinuclear clusters containing Ln<sup>3+</sup> cations coordinated by the 8-hydroxyquinolate anions.

In complexes **C** and **D**, the central atom in the Ln–Ln–Ln group is coordinated by the acetate anion, whereas one of the terminal erbium atoms in compound **E** is coordinated by both the quinolate ligands and the hydroxy group. Compound **F**<sup>122</sup> studied by X-ray diffraction and <sup>1</sup>H NMR spectroscopy is of particular interest. In the molecules of the latter, one of the 8-hydroxyquinolate ligands is coordinated in a monodentate fashion, which is unusual for such complexes, and contains the N–H group.

Electroluminescence of the above-mentioned complexes, as well as of the recently prepared quinolates containing no water and acidic residues, was not studied.<sup>122</sup> However, their photoluminescence spectra confirm the above-mentioned quenching with coordinated water molecules, organic solvent molecules or acidic residues.

#### IV. Optimisation of lanthanide-containing light-emitting diodes

In the design of highly efficient lanthanide-based OLED devices, not only a high luminescence intensity of these complexes but also optimisation of the construction of a light-emitting element, *i.e.*, the use of an optimal combination of materials of electrodes and electron-transport, hole-transport and emitter layers, is of great importance. For example, the maximum brightness of compound **13(Eu)** in a single-layer OLED device is as low as 0.3 cd m<sup>−2</sup>, whereas the maximum brightness of the ITO/TPD/**13(Eu)**:PBD/Alq<sub>3</sub>/Mg:Ag device, which was prepared<sup>27</sup> by introducing this compound into a layer of 1,3,4-oxadiazole (PBD) possessing good electron-transport properties, is 460 cd m<sup>−2</sup>. Presumably, a substantial increase in the maximum brightness is associated with primary excitation of oxadiazole due to charge recombination. The excitation energy is transferred to the ligand and then to lanthanide. Li *et al.*<sup>123</sup> noted that an OLED device, which was constructed with the use of PVK as the hole-transport layer and complex **8(Tb)** as the emission layer, showed bright luminescence with a maximum brightness of 210 cd m<sup>−2</sup>, whereas pure green emission of the Tb<sup>3+</sup> cation at 545 nm was not observed in a device constructed with the use of TPD as the hole-transport layer.

Doping of the TPD layer with complex **14(Eu)** led to an increase in the brightness of the two-layer device ITO/TPD/**14(Eu)**/Mg:Ag from 150 to 820 cd m<sup>−2</sup>; the external quantum efficiency was 1%.<sup>31</sup> Simultaneously, the emission time was increased from 18 to 200 h and the colour purity was considerably improved. The authors believed that compound **14(Eu)** possesses excellent electron-transport properties.

Study of the electroluminescent properties of europium complex **13(Eu)** showed<sup>29</sup> that the two-layer device ITO/TPD/**13(Eu)**/Mg:Ag/Ag based on this complex has a narrow emission peak at 613 nm; however, the maximum brightness is low (3.7 cd m<sup>−2</sup> at 17 V). The poor performance was attributed to the insufficiently good electron-transport properties of the complex. The introduction of Alq<sub>3</sub> as an additional electron-transport layer into a device resulted in yellow emission due to simultaneous emission of Alq<sub>3</sub> and **13(Eu)**. With the aim of improving the electroluminescent device, a BCP layer was added as a hole-blocking layer. The resulting ITO/TPD/**13(Eu)**/BCP/Alq<sub>3</sub>/Mg:Ag/Ag diode showed

pure red emission (615 nm) with a maximum brightness of 42 cd m<sup>−2</sup> at 16 V. Luminescence of Alq<sub>3</sub> was found to be absent in this device due to the presence of the BCP layer, which blocks hole injection, with the result that electron–hole recombination occurs only within the layer composed of the europium compound.

Forrest and co-workers<sup>37</sup> studied electroluminescence of complex **18(Eu)** doped into a CBP layer with a wide energy gap, which is responsible for bipolar charge transfer. In the cited study, a maximum external quantum efficiency of 1.4% was achieved for a ‘guest–host’ system at a low current density. An increase in the density from 1 to 100 mA cm<sup>−2</sup> led to a substantial decrease in the efficiency due to triplet–triplet annihilation. The OLED devices ITO/TPD/**18(Eu)**:CBP/BCP/Alq<sub>3</sub>/MgAg, which differ in the concentration of **18(Eu)** (1%, 2% and 100%), possess different characteristics. The device containing 100% of the europium complex as an emitter exhibited the poorest performance (the maximum brightness was 32 cd m<sup>−2</sup>), whereas the device containing 1% of the europium complex had the best performance (the maximum brightness was 500 cd m<sup>−2</sup> at 100 mA cm<sup>−2</sup>).

The light-emitting diode based on compound **26(Eu)**, ITO/TPD/**26(Eu)**/BCP/Alq<sub>3</sub>/Mg:Ag or Al:Li, exhibited pure red emission with a maximum brightness of 320 cd m<sup>−2</sup> at 14.5 V, whereas the OLED device ITO/TPD/**26(Eu)**/Alq<sub>3</sub>/Mg:Ag, which does not include a BCP layer serving as a hole-blocking material, showed only yellow emission with a brightness of 420 cd m<sup>−2</sup> (see Refs 42, 124).

The introduction of complex **13(Eu)** (20%) into a matrix possessing the hole-transport properties led to an increase in the brightness of the OLED device ITO/CuPc/**13(Eu)**:NPD/BCP/Alq<sub>3</sub>/LiF/Al to 200 cd m<sup>−2</sup> (see Ref. 125).

In the study,<sup>126</sup> it was demonstrated that doping of complex **13(Eu)** into phosphorescent layers of dimethoxybenzophenone or triphenylacetophenone also led to a slight increase in electroluminescence.

According to the results of the investigation,<sup>32</sup> compound **14(Eu)**, unlike phenanthroline complex **13(Eu)**, possesses excellent electron-injection, transport and luminescent properties. This compound combined with PVK in the ITO/PVK/**14(Eu)**/Mg:Ag diode exhibits pure monochromatic red emission with a brightness 400 cd m<sup>−2</sup> at 15 V. The replacement of PVK with NPB (ITO/NPB/**14(Eu)**/Mg:Ag) leads to a substantial change in the emission colour: a broad band at 483 nm appears in addition to the narrow emission band of Eu<sup>3+</sup> at 615 nm with the result that the colour of the device becomes white with a maximum brightness of 550 cd m<sup>−2</sup> at 9 V. The authors of the study<sup>32</sup> believed that the presence of electroluminescence at a low operating voltage (~2 V) is proof of the excellent electron-injection and electron-transport properties of complex **14(Eu)**. Since the broad band at 483 nm cannot be assigned to the NPB compound, which has its own luminescence band at 440 nm, this band is, apparently, caused by emission of an exciplex, that appears between the layers of NPB and compound **14(Eu)**.

After introduction of complex **18(Eu)** into hole-transport PVK, the OLED device gives a maximum brightness of 30 cd m<sup>−2</sup>. The addition of the same complex to electron-transport PBD leads to an increase in the brightness of 417 cd m<sup>−2</sup>.<sup>127</sup> The maximum luminescence intensity of the single-layer OLED device ITO/**18(Eu)**:PVK/Mg:In was observed at a concentration of 0.12 mol.% of **18(Eu)** in PVK.<sup>128</sup> The use of another electron-transport material (PBD) as a matrix for compound **18(Eu)** made it possible to construct the OLED ITO/TPD/**18(Eu)**:PBD/PBD/Mg with a maximum brightness of 320 cd m<sup>−2</sup> and an external quantum efficiency of 1%.<sup>38</sup> The maximum brightness of 137 cd m<sup>−2</sup> was observed,<sup>129</sup> when complex **18(Eu)** was used as a dopant (5%) to the azomethine zinc complex in the emitter layer.

Wong and co-workers<sup>130, 131</sup> studied electroluminescence of europium and samarium complexes **36(Eu)** and **36(Sm)**. The observed luminescence of samarium complexes compared to that of europium complexes was too low. Hence, single-, two and

three-layer OLED devices were constructed with the use of europium complexes. A single-layer device exhibited very low quantum efficiency. A two-layer device was much more efficient due to the presence of TPD as the HTL layer. The introduction of the third ETL layer ( $\text{Alq}_3$ ) did not lead to substantial changes. In another study,<sup>51</sup> a maximum brightness of  $10 \text{ cd m}^{-2}$  at an operating voltage of 18 V was achieved by constructing an analogous OLED device consisting of compound **36(Eu)**, TPD and  $\text{Alq}_3$ .

An orange-emitting OLED device with a maximum brightness of  $135 \text{ cd m}^{-2}$  has been recently constructed<sup>26</sup> with the use of complex **12(Sm)** in combination with PVK and PBD.

Dispersion of compound **8(Er)** into a polymeric PVK matrix afforded the OLED device ITO/PVK: **8(Er)**/Al:Li/Ag with infra-red electroluminescence at  $1.54 \mu\text{m}$ .<sup>22</sup> Li and co-workers<sup>132</sup> studied interactions between PVK and various Tb and Eu complexes and found that efficient energy transfer processes occur between PVK and lanthanide complexes.

The above data show that energy transfer processes from a matrix to a compound should be taken into account when rare-earth compounds are used as dopants. It is generally agreed<sup>14</sup> that the energy, which is generated in OLED devices containing lanthanide  $\beta$ -diketonates as dopants upon charge recombination, is transferred from the matrix to the singlet excited state of the ligand, from which it is transferred to the triplet level of the ligand as a result of intersystem crossing, and is finally transferred to the metal ion. In this connection, two main problems should be taken into account in the design of devices: (1) the efficiency of energy transfer from the matrix to lanthanide  $\beta$ -diketonates; (2) the efficiency of energy transfer from the triplet level of the ligand to the metal ion.

In the study,<sup>125</sup> three main mechanisms of excitation of lanthanide complexes in a matrix were proposed.

1. A complex is excited as a result of energy transfer from the matrix to the complex. In this case, the Frenkel exciton should be formed within the emitter layer, in which the resonance transfer of the electronic excitation energy to the complex molecule occurs. If the energy transfer occurs by the Forster mechanism (a dipole mechanism), the spectral overlap between emission bands of the matrix and absorption bands of the complex should take place. If the energy transfer is based on exchange interactions according to the Dexter mechanism (an exchange mechanism), the correspondence between the energy levels and interactions of the involved orbitals are of importance.

2. A complex becomes excited as a result of charge transfer from the matrix, *i.e.*, electrons and holes, which are separately transported to the complex molecule, recombine with the result that the energy is released, and the latter is transferred to the metal ion serving as an emission centre. This requires particular properties of the complex providing simultaneous electron and hole capture.

3. If the emission layer consists only of complex molecules, the latter, as in the previous case, are excited due to recombination of the opposite charges on the complex molecules. Excitation of the complex is most efficient if the charge injection (electron and hole injection) in a layer is balanced and the charges are present at a high concentration and are highly labile. The charge balance can be controlled by introducing an additional charge-blocking layer.

Bazan and co-workers<sup>25</sup> demonstrated that the correspondence between the absorption spectra of the matrix and the dopant is of importance for the design of 'guest-host' systems. For example, the electroluminescence efficiency in a polycyanophenylene (CN-PPP) matrix decreases in a series **19(Eu)** (1.1%) > **13(Eu)** (0.7%) > **11(Eu)** (0.1%) > **8(Eu)** (0.03%), which corresponds to absorption spectra of europium complexes and emission spectra of CN-PPP (Fig. 8).

It was hypothesised<sup>133</sup> that complexes with higher emission energy compared to the absorption energy of the dopant should be used as a matrix for the design of devices with europium-based

**Figure 8.** Absorption spectra of the europium  $\beta$ -diketonate complexes  $\text{EuR}_3(\text{phen})$  (1–4) and the emission spectrum of polycyanophenylene (5).<sup>25</sup>

R = acac (1), mppy (2), dbm (3), and dnm (4).

pure red emission. Compound **19(Eu)** was found to be the dopant of choice for TPD used as the matrix.<sup>133</sup>

Li and co-workers<sup>134</sup> found that the hole injection in a layer formed from lanthanide complexes leads to luminescence quenching and is responsible for decomposition of the compound, and these authors suggested an alternative approach to the problem based on interactions between the layers.<sup>31</sup> They constructed several types of OLED devices containing different layers between which europium complex **14(Eu)** was placed. The ITO/TPD/**14(Eu)**/TPD/ $\text{Alq}_3$ /Ag:Mg device differs from the ITO/**14(Gd)**/**14(Eu)**/**14(Gd)**/Ag:Mg device in that the europium complex is enclosed between the layers of a hole-transport material (TPD) in the former device and between the layers of an electron-transport material [**14(Gd)**] in the latter device. In the ITO/**14(Eu)**/Ag:Mg device containing no separating layers, electroluminescence was not observed due apparently to the fact that hole injection in the europium complex from the ITO anode is hindered. In yet another device, ITO/TPD/**14(Eu)**/Ag:Mg, hole injection occurs from the TPD layer, resulting in red emission. However, the emission time of the latter device is short compared to the other devices. The best results were achieved with the use of the second light-emitting diode with an external quantum efficiency of 4.6% at a current density of  $0.01 \text{ mA cm}^{-2}$  and a maximum brightness of  $\sim 100 \text{ cd m}^{-2}$ . Based on these results, the authors concluded that the first device contains an excess of holes, the third device contains an excess of electrons, whereas the concentrations of holes and electrons are balanced in the second device.

The same authors<sup>28</sup> studied the electron-transport properties of yttrium, lanthanum and gadolinium (their ions show no emission)  $\beta$ -diketonates using complexes **8(Ln)** as an example. These chelates were used as an additional layer in OLED devices. These complexes were found to have good electron-transport properties. The introduction of compound **8(Gd)** as an additional layer into the electroluminescent devices ITO/**13(Eu)**/ $\text{Alq}_3$ /**8(Gd)**/ $\text{Alq}_3$ /Al and ITO/TPD/**13(Eu)**/ $\text{Alq}_3$ /**8(Gd)**/ $\text{Alq}_3$ /Al increases the quantum efficiency of both devices (for the latter device, the efficiency was increased by a factor of almost two, from 0.6% to 1.0%) and changes the colour of emission from red (characteristic of Eu) to yellow.<sup>135</sup>

Low-molecular-weight lanthanide complexes are widely used for the construction of OLED devices. However, many such complexes are non-technological because film deposition is often accompanied by undesired crystallisation or aggregation. To solve this problem, attempts were made to synthesise high-molecular-weight lanthanide complexes. However, the simplest procedure is apparently based on the introduction of low-molecular-weight europium, terbium and thulium compounds into polymeric matrices, *i.e.*, the design of the above-mentioned 'host-guest' systems with all their drawbacks and advantages.<sup>1, 136–142</sup>

Another solution of this problem is to synthesise polymers containing chemically bound lanthanide ions. An example is a carbon-chain polymer containing europium  $\beta$ -diketonate in side fragments.<sup>143</sup>

The luminescence efficiency of an OLED device constructed on the basis of this polymer is  $2.87 \times 10^{-4} \text{ lm W}^{-1}$ , and its brightness is  $0.228 \text{ cd m}^{-2}$  at 29 V. More recently, with the aim of improving the luminescent properties and constructing a single-layer OLED device, oxadiazole fragments were additionally introduced<sup>144</sup> into a copolymer, resulting in the presence of an emission, electron-transport and hole-transport layers in the same layer and, moreover, in the same polymeric matrix.

The resulting single-layer OLED device shows monochromatic green emission at 545 nm. However, the authors mentioned that the brightness of this device is unsatisfactory. A device constructed with the use of a polymeric matrix containing simultaneously europium and terbium shows white emission.<sup>145</sup>

One of the main procedures for the design of OLED devices involves deposition of the corresponding layers of working materials onto an ITO layer. This technological step has a strong effect on the characteristics of light-emitting diodes. The following two main methods are used for layer deposition: sublimation or spraying of a material and the preparation of films from solutions by evaporation of the solvent in a centrifugal field (spin-coating) or under standard conditions. This, as applied to rare-earth compounds, imposes the following additional requirements: rather high thermal stability and good solubility of the compound in an organic solvent suitable for the above operations. The surface quality of thin films of terbium carboxylate complexes prepared from various solvents was studied<sup>146</sup> by scanning atomic force microscopy and optical near-field microscopy. A device prepared from THF was found to have the best performance.

For lanthanide  $\beta$ -diketonate complexes, poor solubility is often a considerable obstacle. Complexes **6(NaEu)**, **6(LiEu)** and **6(KEu)** are readily soluble in chloroform, ethanol, acetonitrile and acetone,<sup>17</sup> their photoluminescence spectra are analogous to those of the  $\text{Eu}^{3+}$  ion, but the fluorescence intensity strongly depends on the nature of the solvent. It was attributed to the fact that high dielectric constants and the coordination ability lead to better solvation of alkali metal ions, which prevents undesired aggregation of europium species. These compounds were used to construct single-, two- and three-layer OLED devices with a maximum brightness of  $36.7 \text{ cd m}^{-2}$  at 26 V, which is substantially higher than that for the above-described devices based on compound **5(Eu)**.

## V. Conclusion

The data considered in the present review show that there are real prospects for the use of lanthanide complexes in organic light-emitting devices. The most substantial results were achieved in the design of OLED devices based on pyrazolonate complexes (Fig. 9).

**Figure 9.** Relative brightnesses of the most efficient OLED based on lanthanide  $\beta$ -diketonates (1),<sup>48</sup> carboxylates (2)<sup>59</sup> and pyrazolonates (3)<sup>66</sup> and Alq<sub>3</sub> (4).<sup>147</sup>

As mentioned above, the OLED device constructed with the use of the purely organic compound rubrene still provides record brightness (higher than  $200\,000 \text{ cd m}^{-2}$ ).<sup>73</sup> The brightness of a diode constructed with the use of tris(2-phenylpyridine) iridium is somewhat lower ( $100\,000 \text{ cd m}^{-2}$ ).<sup>74</sup> The characteristics of lanthanide-based OLED devices are noticeably worse. However, the latter devices have the following undeniable advantages: generation of 'pure'-coloured emission and a much lower price compared to the iridium device. In addition, there is good reason to hope that the emission brightness, efficiency, quantum yield and other characteristics of diodes containing organic lanthanide complexes will be sharply improved by choosing an optimum ligand environment.

Analysis of the published data shows that the compositions of lanthanide-containing OLED devices cannot be considered as completely optimised. Elucidation of the factors of interactions between organic matrices and lanthanide compounds is one of the most important problems. A more complete theoretical description of the mechanisms of intramolecular energy transfer is required. An extension of the range of ligands used in these complexes is of considerable significance. This will allow one to synthesise new highly luminescent complexes. Studies of the dependence of the luminescent properties on the nature of the chemical bonds between metals and ligands, the structures of the latter and organisation of the complexes are also of importance. Evidently, a combination of fundamental and applied investigations will provide interesting results and assist in constructing highly efficient OLED devices.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 03-02-16734 and 04-03-32093) and the Federal Program 'Leading Scientific Schools' (Grants NSh-58.2003.3 and NSh-1345.2003.02).

| IV. Oxidative coupling of methane and related processes             | 1129 |

**Abstract.** The data on various aspects of oxidative conversion of methane published in 1998–2004 are considered. The bibliography includes 295 references.

## I. Introduction

The advent of the 21st century brought about radical changes in the views on the future prospects of the world power engineering and the role of various sources of hydrocarbon raw materials. It has become evident that the oil era is not everlasting and its decline is not far off.<sup>1</sup> It is small-power energetics that make use of alternative renewable energy sources, solar energy in particular. The power flux densities are still so low that they cannot, in principle, meet the rapidly growing demands of the world economy despite the declaratory statements on the developments in this field. Renewable bioresources are obviously inadequate to satisfy the demands of the population inhabiting our planet for food or to solve the problems of the world energetics. As for thermonuclear energy, it has virtually not been called into being yet and according to the most optimistic prognoses will hardly become a reality before the end of this century. Atomic energy introduces well-known problems and causes alarm in view of environmental safety, but will hardly have a reasonable alternative within the next few decades. This all means that, till the end of this century, mankind will have to rely mainly upon fossil fuel, viz., carbon and natural gas. In this context, their efficient exploitation and development of novel resource-saving and environmentally friendly technologies are of paramount importance. Considerable efforts should be given to further improvement of chemical processes for the conversion of gaseous and solid hydrocarbon raw material into more convenient types of energy carriers and promising chemical products.

Today, the crucial role of natural gas and gas-chemical processes in the economy of the 21st century and the fact that they will gradually replace the existing oil stock and petrochemical technologies are not in doubt. The recent 7th Natural Gas Conversion Symposium (NGCS7), the largest international meeting devoted to the problems of reforming of natural gas and light

hydrocarbons,<sup>2,3</sup> has demonstrated a real breakthrough in the technology and commercialisation of chemical conversion of natural gas. In the three years elapsed from the previous Symposium, the leading world companies have brought into operation several large-scale pilot plants and started the realisation of several jumbo projects. The overall output of liquid products is expected to amount to  $2 \times 10^6$  barrels per day with an overall gas consumption of about  $166 \times 10^9$  m<sup>3</sup> per year. There are more than 20 large oil and gas producers all over the world continuously patenting their developments; the total number of patents in different aspects of 'gas-to-liquid' (GTL) technologies has reached 8000.<sup>4</sup> Several hundred reports on the use of catalysis in natural gas reforming presented at the 13th International Congress on Catalysis are evidence of high scientific activity in this field.

The main recent trend has become the intention of leading chemical companies to broaden the range of natural gas conversion products other than motor fuels. For example, the market of such products can be expanded owing to the greater manufacture of polymers, which has been implemented by several companies.

The world capital of gas-chemical technologies is now moving to Qatar. Recently, the state-owned company Qatar Petroleum completed agreements with the largest oil-and-gas producing and developing companies (Sasol, Chevron, ConocoPhillips, Shell, ExxonMobil, etc.) to the total sum of USD  $\sim 23 \times 10^9$ , which corresponds to daily liquid product output of  $\sim 700\,000$  barrels. This means that the total investment in the infrastructure of the gas industry of this small country will amount to USD  $\sim 60 \times 10^9$ . Considerable activity in the establishment of new gas-chemical enterprises is shown by Iran and other Middle Eastern countries as well as by Nigeria, Australia, Trinidad, etc. Unfortunately, Russian gas- and oil-producing companies still continue to direct their exclusive efforts to the export of raw materials despite the fact that for Russia, the world leader in the resources and production of natural gas, its reforming is of strategic importance. So far, not a single oil- or gas producing company or a representative of a state-owned or academic institution within Russia has shown interest in the work of the NGCS7. However, Russian scientists will hardly be able to carry out research at a really high level in this technologically complicated area that requires expensive modern equipment without financial support from large companies.

The specific nature of the domestic gas industry determines the need for financial support of fundamental research. The bulk of Russian natural gas is extracted from the gas fields of Urengoi and Yamburg, regions that are difficult of access, with inclement climate where the use of the existing foreign technologies is unprofitable or impracticable. In addition, Russia possesses substantial reserves in the form of nearly 600 marginal or low-

pressure gas fields that are hitherto unexplored due to the lack of efficient technologies for their transportation or reforming.

The results of investigations carried out by Foster Wheeler Energy Ltd. by request of Sasol<sup>5</sup> and those reported at the NGCS6<sup>6</sup> suggest that an enterprise on natural gas oxidative conversion and Fischer—Tropsch synthesis with a productive capacity of 30 000 barrels per day (1 400 000 tons per year) located in seaside regions in order to ensure easy sea transportation of the final products, costs capital outlays per unit of USD 25 000 per barrel of the daily product, *i.e.*, about USD 530 per ton per year. According to technical-and-economic assessments,<sup>7</sup> the investment cost for the construction of a gas-converting plant in the vicinity of the gas fields of the Yamal Peninsula exceeds USD  $4 \times 10^9$  with a provisional pay-back period of  $\sim 20$  years, which makes such projects unacceptable *a priori*.

All of the current chemical productions and works-in-project (WIP) are based on the preliminary conversion of natural gas, which contains methane as the main component, into synthesis gas which represents a mixture of carbon monoxide and hydrogen. This technologically complicated energy-consuming process takes up from 50% to 75% of the total cost of the basic chemical products prepared from natural gas (ammonia, methanol, GTL-products, *etc.*), which is the reason for their high prime cost and high capital intensity. Even an insignificant reduction of the cost of synthesis gas significantly reduces the production costs of the final products. Therefore, the main goal of the studies on methane reforming is both the reduction of the cost price of the synthesis gas, which can also be achieved with the use of oxidative conversion, and development of new in principle approaches to oxidative conversion of methane irrelevant to the production of synthesis gas.

The number of publications devoted to different aspects of oxidative conversion of methane is increasing annually. However, in this review only the investigations carried out in the past 6–7 years are reviewed, since the literature data on this subject published before 1998 were considered in detail in the monograph<sup>8</sup> and earlier papers.

## II. Oxidative conversion of methane into synthesis gas and hydrogen

Recently, the interest in hydrogen fuels has increased substantially, particularly with regard to its possible utilisation in vehicles.<sup>9</sup> Although about 97% of motor fuels are currently oil reforming products, it is expected that by the end of the next decade hydrogen will be extensively used as a fuel for the most popular production cars. Hydrogen will be used as an additive to organic fuels, as a fuel itself for internal combustion engines and as a power supply for fuel cells. The main hydrogen source is synthesis gas ( $\text{CO} + \text{H}_2$ ).

There exist three methods for preparing synthesis gas:

- 1) steam reforming of methane (SRM)

- 2) partial oxidation of methane (POM)

- 3) carbon-dioxide ('dry') reforming of methane (CDR).

Only the first of these reactions is widely employed in the large-scale production of nearly 95% of synthesis gas. A Shell plant in Bintoulou (Malaysia) that makes use of non-catalytic POM is an exception. Different modifications are reported that represent combinations of the above reactions. Irrespective of the process used to prepare synthesis gas, further elucidation of the reaction mechanism, the choice of effective and stable catalysts and efficient technological design still remain the topical tasks.

## 1. Steam reforming of methane

Since the introduction, in 1966, of SRM over nickel catalysts into industrial practice, a systematic solution of a wide range of problems related to sulfur poisoning of catalysts, coke formation and reduction of reactor size has begun. The SPARG technology developed by Haldor Topsoe Ltd. allowed solution of the problem of sulfur poisoning by reducing the overall catalyst activity and using a preconverter. Supported nickel and cobalt catalysts promoted by basic oxides possessed the highest activities. At present, the activity of a catalyst is not a limiting factor in SRM and the main efforts are focused on improving heat- and mass-exchange, optimisation of the process and minimisation of the reactor size.

The theoretical aspects of SRM were considered by Rostrup-Nielsen *et al.*<sup>10–12</sup> Steam reforming is accompanied by carbonisation of nickel catalysts, since carbon fibres appear upon decomposition of methane; their growth results in destruction of the catalyst, prevents interaction of the gas flow with the surface and impairs heat exchange.

A simplified scheme of this process was developed based on the concept of ensembles on surfaces of metals.<sup>13</sup>

( $m > n$ ).

The state and reactivity of the surface carbon are the key problems in the mechanism of SRM. The adsorbed carbon atoms do not react with gas molecules and are dissolved in Ni to generate carbon filaments that block the catalyst surface. A carbon-free mode is reached where the concentration of dissolved carbon  $[\text{C}, \text{Ni}]$  is below the equilibrium concentration of carbon. This ratio can be achieved by increasing the steam-to-carbon ratio and, correspondingly, adsorption of water vapour and the rate of the surface reaction with a simultaneous decrease in the rate and degree of activation and dissociation of  $\text{CH}_4$ .

The Topsoe company is the world leader in both the development of technologies for the production of synthesis gas and the use of the newest physical methods for the study of the reaction mechanism. Electron microscopic *in situ* studies on a specially designed instrument with the atomic resolution<sup>14</sup> enabled detailed investigations into the mechanism of methane activation over Ni.  $\text{CH}_4$  molecules interact with the steps of Ni nanocrystals to form graphite-like clusters, which were further transformed into multi-layered carbon nanotubes. Growth of the nanotube occurs in parallel with the rearrangement of the nickel particles which changes their shapes and sizes. After complete encapsulation of Ni, the growth of the nanotube stops and the catalyst is poisoned. Synthesis gas is formed in the reaction of the  $\text{CH}_x$  groups with the OH groups formed upon  $\text{H}_2\text{O}$  adsorption. A scheme was proposed that explained the promoting effect of  $\text{MgO}$ ,  $\text{La}_2\text{O}_3$ ,  $\text{Ce}_2\text{O}_3$  and alkalis favouring adsorption of water. Total adsorption of  $\text{H}_2\text{O}$  over  $\text{Ni}/\text{Al}_2\text{O}_3$  or  $\text{Ni}/\text{MgAl}_2\text{O}_4$  exceeded that over  $\text{Ni}/\text{MgO}$  where a larger amount of the OH groups is formed as followed from the data on the isotope exchange with  $\text{D}_2\text{O}$ .<sup>14</sup> This accounts for the little coke formation over  $\text{MgO}$ . In this case, the amount of the OH groups increased despite a decrease in the dissociation rate of  $\text{CH}_4$  by more than an order of magnitude. Over Co, the value of  $x$  in the  $\text{CH}_x$  groups was larger than over Ni, and over  $\text{Ni}/\text{MgO}$  it was larger than over  $\text{Ni}/\text{SiO}_2$ .

The mechanism of SRM was studied at the level of elementary reactions<sup>15</sup> using Ni single crystals as surface catalysts. The data obtained were consistent with the results of quantum-chemical calculations obtained by the DFT (Density Functional Theory) method. A comparison of reactions occurring on the plain surface of  $\text{Ni}(111)$  single crystal and on the step-like surface of  $\text{Ni}(211)$

revealed that in the latter case the values of the activation energies in all the stages of the sequence:

were smaller than on the plain surface, although the corresponding values for different stages of this sequence were different. The SRM reaction was structure-sensitive: the facet of Ni(111) was catalytically active in SRM, but was inactive in carbon deposition. In contrast, both the catalytic reaction and carbon deposition occurred on the facet of Ni(211). On the whole, the presence of steps and other structural defects is unfavourable for SRM.

It was found that the degree of methane conversion was low at low metal-to-carbon binding energies.<sup>16</sup> The optimum energies of the M–C and metal-to-hydrogen (M–H) bonds are equal to 160–169 and 64–67 kcal mol<sup>−1</sup>, respectively, which have been recommended as criteria for the selection of promoters for Ni catalysts.

#### a. Catalysts

As usual, supported nickel catalysts are mainly employed in SRM. The improvements applied largely to the shape of the pellets. Some newly developed catalysts have the shape of complex rings with multiple holes. Heat transfer on the walls of the reactor tubes is often a limiting factor in SRM, therefore, application of a thin layer of a catalyst directly onto the reactor walls is beneficial.

A highly active catalyst for SRM at a low H<sub>2</sub>O : CH<sub>4</sub> ratio was prepared from perovskite LaNi<sub>x</sub>Fe<sub>1−x</sub>O<sub>3</sub> (0 < x < 1).<sup>17</sup> At 800 °C, the selectivity towards CO reached 96%. In the majority of catalytically active systems (0.2 < x < 0.4), perovskite LaFeO<sub>3</sub> and finely dispersed Ni particles are formed under the conditions of SRM. Carbon deposition was the lowest over catalysts with this composition.

CaAl<sub>2</sub>O<sub>4</sub> was found to be a good support for Ni and Rh catalysts.<sup>18</sup> The equilibrium conversion over Ni/CaAl<sub>2</sub>O<sub>4</sub> and Rh/CaAl<sub>2</sub>O<sub>4</sub> was reached at 400 °C and 480 °C, respectively, the volumetric gas flow rate being 10-fold larger than in conventional industrial reactors.

#### b. Kinetics and mechanism

Removal of hydrogen or CO from the reaction zone favours a shift of the equilibrium in SRM to the right and thus favours the increase in the yields of the target products. Metal membranes can be used to remove hydrogen,<sup>19,20</sup> which also reduces the risk of poisoning of the catalyst with hydrogen sulfide present in methane. Removal of CO<sub>2</sub> from the reaction zone can be carried out by binding it with an adsorbent, *e.g.*, CaO.<sup>21</sup>

In this case, regeneration of the adsorbent, *i.e.*, decomposition of CaCO<sub>3</sub>, is required. A gas containing more than 95% of dry H<sub>2</sub> can be prepared in one step. After 25 cycles, the activity of the adsorbent decreased insignificantly.

Extensive studies into SRM are currently underway at the Institute of Catalysis of the Siberian Branch of the RAS. It was found<sup>22</sup> that the reaction rate decreased with the increase in the amount of the catalyst (Ru/Al<sub>2</sub>O<sub>3</sub> or Ni/Al<sub>2</sub>O<sub>3</sub>), which is believed to support a hypothesis on a homogeneous–heterogeneous mechanism of this reaction. The maximum activity of Ni/Al<sub>2</sub>O<sub>3</sub> corresponds to the activity of a wire of metallic nickel. At higher content of the catalyst, the reaction is purely heterogeneous (800 °C). The introduction of hydrogen decreases the activation energy and increases the rate of carbon formation.

The application of a thick layer of a catalyst (Ni/Al<sub>2</sub>O<sub>3</sub>/Al) onto the surface of a tubular reactor for SRM facilitates heat exchange on the tube walls.<sup>23</sup> A tubular heat-exchange reactor for SRM has been considered<sup>24</sup> where deep oxidation of methane took place on the outer surface coated with Ni–Cr-foam over perovskite, while steam reforming occurred on the inner surface of the Ni-foam catalyst. A combination of exothermic and endo-

thermic reactions separated by the reactor wall enables a design of a virtually thermoneutral reactor.

The kinetics of SRM over a Ni/α-Al<sub>2</sub>O<sub>3</sub> catalyst were studied.<sup>20</sup> The reaction rate was proportional to the partial pressure of hydrogen *p*<sub>H<sub>2</sub></sub>. The surface interaction CH<sub>4</sub><sub>ads</sub> + H<sub>2</sub>O<sub>ads</sub> is the limiting step of this reaction, which occurs according to the Langmuir–Hinshelwood mechanism. As noted previously,<sup>20</sup> the first study<sup>25</sup> devoted to the steam reforming of CO had been published nine years before the frequently cited paper.<sup>26</sup>

#### c. Technological features

The start-up of a BP large pilot plant in Alaska constructed according to an original technology was a prominent event in the history of SRM technologies. Its daily capacity is 300 barrels of liquid GTL products at a production cost of USD 86 × 10<sup>6</sup>. The SRM process enables the reduction of the prime cost of synthesis gas by excluding expensive oxygen. It was claimed<sup>2</sup> that it was possible to design a much more compact SRM apparatus with the mass smaller by 75% than that of analogous units.

Microchannel Process Technology (MPT) developed by Velocys Inc. is a novel promising approach to the study of SRM, since it substantially intensifies heat and mass exchange. A typical MPT reactor consists of stacks of closely spaced thin plates that form microchannels with diameter < 1 mm. The stacks where heat carrier is circulating or fuel is combusted alternate with those where reforming of natural gas occurs, which is accompanied by absorption of heat. A nearly 100-fold increase in the heat exchange intensity in comparison with conventional SRM processes made it possible to reduce significantly the overall dimensions of the equipment and to diminish the residence time. The latter circumstance is especially important for steam reforming, since soot formation takes much more time than the reforming itself. Very fast (< 10 ms) attainment of equilibrium concentrations in MPT reactors makes it possible to avoid soot formation, to increase the productivity and to reduce production costs. The trials conducted for several months demonstrated the durability of the MPT reformer. With this design, higher capacity is achieved by merely multiplying the number of stacks; no scaling-up is required. The operation principle of the MPT reactor is applicable to the subsequent steps of reprocessing of synthesis gas, *viz.*, the Fischer–Tropsch synthesis or synthesis of methanol.<sup>27</sup>

Despite the intensive search for alternative methods for methane conversion into synthesis gas and the appearance and ever increasing number of production technologies based on them, the SRM reaction is still the main industrial method for the production of synthesis gas. Although this reaction is highly endothermic, it is considered to be a candidate of choice as a hydrogen source in hydrogen technology. Steam reforming of methane is a high-tech process ensuring lower prime cost of H<sub>2</sub> in comparison with its production from biomass or using nuclear, solar and electric energy or wind power.

## 2. Partial oxidation of methane (POM)

Despite the indisputable achievements in the practical application of SRM, partial oxidation and combined steam-oxygen reforming of methane are the most popular trends of research. In addition to minimisation of power input, these methods allow production of synthesis gas with the composition (H<sub>2</sub>:CO = 2:1), which is especially favourable for the Fischer–Tropsch synthesis and synthesis of methanol. The main problems include the necessity of using expensive oxygen, high explosion hazard and local overheating. Besides, the large size of POM reactors is a considerable obstacle to their commercialisation. Continuous search for novel technologies for oxidative conversion of methane into synthesis gas is underway.

A gas-phase method for the oxidation of methane to synthesis gas is being developed in Russia. This approach is based on the use of modified diesel or compression engines that also serve as the chemical reactors.<sup>28,29</sup> The process first implemented on a large

scale in 1998 is characterised by much higher overall productivity of the process per unit volume (10 000 m<sup>3</sup> of the synthesis gas per hour). The possible use of low-pressure natural gas (including that obtained from gas wells that can no longer be exploited for commercial purposes) and coal mine methane and oxidation by atmospheric air are its obvious advantages. However, the synthesis gas thus produced contains ~60% of nitrogen, which impedes its further processing. At the same time, simultaneous generation of electric energy is a very attractive feature of this process, although future prospects for its wide application are still ambiguous.<sup>30</sup>

Synthesis gas generators based on rocket technologies is yet another achievement of Russian scientists in the field of oxidative conversion of methane. The productivity of this process per unit volume exceeds those of conventional large-scale units by a factor of tens. Both processes are based on the gas-phase oxidation of methane at high temperatures and yield mixtures with nearly equilibrium composition. However, the composition of the synthesis gas is difficult to control by reason of high specific capacity of such units.<sup>30</sup> A pilot plant for motor fuels with a productivity of 432 kg h<sup>-1</sup> with respect to methane has been constructed on the basis of a synthesis gas generator using rocket technologies.<sup>31</sup> Nevertheless, the Shell plant at Bintulu (Malaysia) is the only example of a successful industrial application of a gas-phase high-temperature (1100–1200 °C) POM process. Apparently, the POM technology will further be developed in connection with agreements on the construction of a supergiant plant at Qatar with the participation of the Shell Corporation.<sup>32</sup>

#### a. Catalysts

As a rule, the POM technology employs supported nickel<sup>33–39</sup> or, less frequently, cobalt<sup>40</sup> catalysts or catalysts based on precious metals.<sup>41–46</sup> Most of the studies in this field are aimed at increasing the stability of Ni over various oxide supports and the resistance of the catalyst against carbon poisoning rather than at enhancing its activity and selectivity. Studies of supported Ni catalysts revealed that Ni/CeO<sub>2</sub> and Ni/TiO<sub>2</sub> were much less active and selective in comparison with Ni/ZrO<sub>2</sub> and Ni/Al<sub>2</sub>O<sub>3</sub>, but less prone to carbon poisoning.<sup>33</sup> Nickel catalysts supported onto perovskites CaTiO<sub>3</sub>, SrTiO<sub>3</sub> and BaTiO<sub>3</sub> by solid-phase crystallisation were less active and less stable than those prepared by impregnation.<sup>34,35</sup> High dispersity of Ni prevents coke formation. Ni/SrTiO<sub>3</sub> possessed the highest dispersity. High stability and activity were observed for Ni/CeO<sub>2</sub>–ZrO<sub>2</sub>.

Promotion of Ni/γ-Al<sub>2</sub>O<sub>3</sub> with Li and La oxides increased its stability and suppressed sintering, which results in a loss of activity.<sup>36,37</sup> LiLaNiO/γ-Al<sub>2</sub>O<sub>3</sub> not only manifested high activity and high resistance to carbon deposition, but also possessed a stable porous crystalline structure, which remained unchanged even after 500-hr heating at 800 °C. The activity and stability of the nickel catalyst were considerably enhanced upon promotion with CeO<sub>2</sub> or Y<sub>2</sub>O<sub>3</sub>.<sup>38,39</sup> Cerium dioxide suppressed the interaction of Ni with Al<sub>2</sub>O<sub>3</sub> and the growth of Ni crystals, and the latter remain as small particles. Carbon deposition decreased, while the stability of the catalyst increased.

Among a variety of supports for cobalt catalysts, only MgO proved to be suitable.<sup>40</sup> Following calcination at 800 °C, 24% Co/MgO possessed stable and high activity. The results of X-ray phase analysis suggest that only solid solutions of Co<sub>x</sub>Mg<sub>1-x</sub>O formed at *T* > 800 °C, while heating at *T* < 800 °C yielded Co<sub>3</sub>O<sub>4</sub> and MgCo<sub>2</sub>O<sub>4</sub>.

Catalysts based on the platinum group metals, rhodium in particular, possess high activities and selectivities. Studies of Rh-catalysts have shown<sup>41</sup> that easily reducible supports, such as CeO<sub>2</sub>, Nb<sub>2</sub>O<sub>5</sub>, Ta<sub>2</sub>O<sub>5</sub>, MnO<sub>2</sub>, UO<sub>2</sub>, did not enable as high stability and selectivity as non-reducible supports did, e.g., MgO, γ-Al<sub>2</sub>O<sub>3</sub>, La<sub>2</sub>O<sub>3</sub>, Y<sub>2</sub>O<sub>3</sub> and SiO<sub>2</sub>. Rh/MgO was the catalyst of choice. Presumably,<sup>41,42</sup> its high stability is attributed to the strong interaction of Rh with MgO. The ease of formation of transient compounds in the course of preparation of the supported

Rh-catalysts decreased in the following order: MgRh<sub>2</sub>O<sub>4</sub> > LaRhO<sub>3</sub> > YRhO<sub>3</sub> > RhTaO<sub>4</sub>.<sup>44</sup> The catalysts Rh/MgO and Rh/La<sub>2</sub>O<sub>3</sub> retained their activities and selectivities for 100 h at 750 °C, while Rh/Y<sub>2</sub>O<sub>3</sub> and Rh/Ta<sub>2</sub>O<sub>5</sub> rapidly deactivated under these conditions, but were active at higher temperatures (900 °C). The stability and selectivity of Rh/Al<sub>2</sub>O<sub>3</sub> increased with an increase in the concentration of rhodium.<sup>46</sup> Rhodium catalysts supported onto hexaaluminates BaAl<sub>12</sub>O<sub>19</sub>, SrAl<sub>12</sub>O<sub>19</sub> and CaAl<sub>12</sub>O<sub>19</sub> were both active and selective, but less stable than Rh/α-Al<sub>2</sub>O<sub>3</sub>. Composite La–Co–Ni-perovskites containing 5% Rh supported on a honeycomb corundum monolith with channels 1 mm in diameter manifested high activity and stability.<sup>47</sup> At 850 °C, carbon deposition on these catalysts was negligibly small.

Bimetallic catalysts Pt–Co/α-Al<sub>2</sub>O<sub>3</sub> manifested higher selectivity in the reaction CO + H<sub>2</sub> than their monometallic platinum analogue;<sup>48</sup> in addition, no coke formation occurred on their surface for 80 h. According to X-ray phase analysis data, Pt and Co phases were formed under the conditions of the catalytic reaction. Doping of Pt/Al<sub>2</sub>O<sub>3</sub> with CeO<sub>2</sub> increased the dispersity of platinum, suppressed deep oxidation and noticeably increased the activity and selectivity of the catalytic system in the POM. This reaction proceeded in accordance with the following redox mechanism:

Partial oxidation of methane over an oxide catalyst (CeO<sub>2</sub>–ZrO<sub>2</sub>) was studied at 400–475 °C under steady-state conditions and in the transient regime.<sup>49</sup> The reaction products contained CO, CO<sub>2</sub>, H<sub>2</sub>, H<sub>2</sub>O, CH<sub>2</sub>O and HCO<sub>2</sub>H and traces of C<sub>2</sub> hydrocarbons. The reaction proceeded *via* the intermediate formation of CH<sub>2</sub>O.

Molybdenum and tungsten carbides constitute a novel class of POM catalysts. Molybdenum carbide, β-Mo<sub>2</sub>C, is active only at elevated pressures; it is unstable at ordinary pressure. The oxidised species MoO<sub>x</sub>C<sub>y</sub> are formed on its surface. The degree of conversion of CH<sub>4</sub> at 900 °C and 0.8 MPa was 83%, and that of O<sub>2</sub> reached nearly 100%, which corresponds to the thermodynamic equilibrium.<sup>50</sup> The POM reaction occurs according to a redox mechanism with involvement of surface oxycarbides:

Ni-Containing carbides also proved to be active and stable compounds.<sup>51</sup> The reaction of Ni(NO<sub>3</sub>)<sub>2</sub> with WO<sub>3</sub> yields NiWC<sub>x</sub>, which differs from both NiC and W in catalytic properties.

#### b. Mechanism

In the past years, the mechanism of catalytic POM was studied in considerably more detail than other methane reforming reactions. Numerous data suggest (see a monograph<sup>8</sup> and references cited therein) that this reaction occurs according to two mechanisms, *viz.*, a stepwise mechanism where deep oxidation of methane to CO<sub>2</sub> and H<sub>2</sub>O is followed by steam and carbon dioxide reforming, and a direct mechanism involving complete dissociation of methane and oxygen on the catalyst surface:

This is followed by the interaction of the adsorbed atoms:

The mechanism of POM was studied at the level of an elementary act in the analysis of the reaction of CH<sub>4</sub> with

adsorbed oxygen using the molecular beam method.<sup>51,52</sup> The Pt(110) facet occupied with O atoms with the structure (1 × 2) was irradiated with a beam of CH<sub>4</sub> molecules. CO<sub>2</sub> was formed at surface temperatures below 280 °C, while CO was formed at higher temperatures. This reaction also yielded H<sub>2</sub>, but no H<sub>2</sub>O was observed. Short-lived chemisorbed molecular oxygen was also detected.

With the use of a TAP (Temporal Analysis of Products) reactor for the study of POM over Pt/MgO, dissociation of methane over partly reduced Pt surface was revealed.<sup>53</sup> Adsorption of CO<sub>2</sub> included the formation of a weakly bound precursor that was further converted into a carbonate and a hydrogencarbonate. Under the reaction conditions, CO existed in two adsorption states, *i.e.*, weakly bound (mobile) and chemisorbed. Oxidation of CO occurred on oxygen islets. Under these conditions, surface oxygen is converted into subsurface oxygen and *vice versa*.

Two oxygen species were detected on the surface of Pt-catalyst using a TAP reactor.<sup>54</sup> If CH<sub>4</sub> and O<sub>2</sub> pulses were injected separately onto the catalyst at 600–1000 °C with considerable intervals between the pulses, the products formed were CO (94%) and H<sub>2</sub> (99%) at a degree of conversion of CH<sub>4</sub> of ~90%. Pulses of CH<sub>4</sub> + O<sub>2</sub> resulted in CO<sub>2</sub> and H<sub>2</sub>O as the main products. It was thus concluded that the Pt surface contains stable subsurface oxygen and labile surface oxygen, the latter being involved in deep oxidation.

It has been shown<sup>55</sup> that the catalytic activities of the supported catalysts Pt/Ce–ZrO<sub>2</sub> are associated with their abilities to absorb and release oxygen. Removal of carbon from the catalyst is mediated by CeO<sub>x</sub> and proceeds by a redox mechanism.

In the majority of cases, the kinetics of POM is of the first order with respect to methane and of the zero order with respect to oxygen. However, the zero order with respect to methane and an order larger than the first order with respect to O<sub>2</sub> were found over Pd/Si<sub>3</sub>N<sub>4</sub> at 700–900 °C and at larger CH<sub>4</sub>:O<sub>2</sub> ratios.<sup>56</sup> This suggests that CO is a primary product and the catalyst surface is predominantly occupied by carbonaceous compounds rather than by oxygen.

Partial oxidation of methane over Ni/Al<sub>2</sub>O<sub>3</sub> was studied.<sup>57–62</sup> The IR spectra recorded after adsorption of methane at low temperatures revealed the presence of bands at 2998 and 3005 cm<sup>–1</sup>, which were attributed to chemisorbed methane. These bands disappeared upon heating to 250 °C, and CO, H<sub>2</sub>O, CO<sub>2</sub> and H<sub>2</sub> appeared in the gas phase, which suggests that these bands are due to intermediate species. Studies of temperature-programmed decomposition (TPD) of methane and IR spectroscopic studies showed that carbon was predominantly formed over Ni/Al<sub>2</sub>O<sub>3</sub> as a result of the Boudouard reaction.<sup>58</sup> The decomposition rate of CH<sub>4</sub> passed through a maximum at ~700 °C.

The mechanism of POM over Ni/γ-Al<sub>2</sub>O<sub>3</sub> was studied using the pulse method, TPD and XPES.<sup>59</sup> Under the reaction conditions (800 °C), the catalyst contained both Ni and NiO. The reduction of NiO began at 520–560 °C. The dissociation of CH<sub>4</sub> took place on the reduced centres and was followed by the reaction C + O → CO and the reduction of NiO by the carbon atoms. The use of the ion response method showed<sup>60</sup> that POM over Ni/La<sub>2</sub>O<sub>3</sub> results in dissociation of methane and oxygen on Ni-centres to yield a carbide (Ni<sub>x</sub>C) and an oxide (NiO), respectively. Their interaction yields CO.

Dissociation of methane occurs over a reduced catalyst Ni/γ-Al<sub>2</sub>O<sub>3</sub> (direct mechanism), while oxidation of CH<sub>4</sub> to CO<sub>2</sub> and H<sub>2</sub>O and the reduction of NiO to the metal over NiO/Al<sub>2</sub>O<sub>3</sub> proceeded by a sequential mechanism.<sup>61,62</sup> The scheme below takes into account both mechanisms, but the direct mechanism is predominant.

The use of IR diffuse reflectance spectroscopy showed<sup>58</sup> that POM over Ni/La<sub>2</sub>O<sub>3</sub> follows a sequential mechanism, but the direct mechanism is also possible at very low pressures of O<sub>2</sub>. La<sub>2</sub>O<sub>3</sub> forms oxycarbonates of the type La<sub>2</sub>O<sub>2</sub>CO<sub>3</sub>, which favour removal of carbon from the surface of Ni. No decomposition of oxycarbonates occurs in a helium or oxygen atmosphere at 600 °C. This reaction also yields Ni, NiO and NiC phases. Presumably,<sup>63</sup> two routes of this reaction correspond to two limiting steps, *viz.*, dissociation of CH<sub>4</sub> and reaction of NiO with Ni<sub>x</sub>C, which yields CO.

In the majority of studies devoted to the measurement of the kinetic isotope effect (KIE), *i.e.*, the  $k_{\text{CH}_4}/k_{\text{CD}_4}$  ratio, its value was more than unity. For the reaction CH<sub>4</sub> + CO<sub>2</sub> carried out over Pt/α-Al<sub>2</sub>O<sub>3</sub> at 550–650 °C resulting in CO, the  $k_{\text{CH}_4}/k_{\text{CD}_4}$  ratio was > 1; however, no KIE was observed in the direct POM.<sup>64</sup> It was concluded that it is the surface reaction between the adsorbed CH<sub>x</sub> and O species, which yields CO, that is the limiting step, rather than the dissociation of CH<sub>4</sub>. This implies that CO is formed by CDR (CH<sub>4</sub> + CO<sub>2</sub>) or SRM (CH<sub>4</sub> + H<sub>2</sub>O) rather than directly from CH<sub>4</sub> and O<sub>2</sub>.

Studies of POM over Rh-foam, Rh/α-Al<sub>2</sub>O<sub>3</sub> or Rh/SiC using a TAP-reactor revealed<sup>65–67</sup> that the reaction occurs according to a sequential mechanism over fully oxidised Rh species, while on reduced species the reaction followed the direct route. With an increase in the O<sub>2</sub> pressure, the responses of CO, CO<sub>2</sub> and H<sub>2</sub>O were shifted towards smaller residence times. The concentrations of the reaction products, *i.e.*, CO and H<sub>2</sub>, increased as oxygen was removed from the catalyst surface.

The results of yet another IR spectroscopic study of the mechanism of POM in a TAP-reactor with Rh black as a catalyst suggest that at 700 °C the inhibition of dissociation of CH<sub>4</sub> was due to saturation of the metal centres with oxygen. Methane dissociated on reduced centres, whereas the newly generated carbon reacted with oxygen to yield CO<sub>2</sub>. The role of active centres was played by partly reduced Rh<sup>+</sup> or dispersed Rh particles. The following mechanism was proposed:

The mechanism of POM over Pt/MgO was also studied using a TAP reactor.<sup>68</sup>

The POM reaction over Rh/SiO<sub>2</sub> was studied using TPD, IR and NMR spectroscopy and XPES.<sup>69</sup> Only the bands corresponding to CO adsorbed on the catalyst surface were observed in the IR spectra. Nevertheless, the following mechanism was proposed:

A more detailed study of the POM mechanism by IR and Raman spectroscopy *in situ*, made it possible to monitor CO, CO<sub>2</sub> and other oxygen-containing species on the surface. The Rh-catalysts were found to contain various forms of adsorbed CO, while adsorbed CO<sub>2</sub> and large amounts of O<sup>2-</sup> were detected on the Ru catalysts. It was assumed that the direct reaction is the main route over Rh/SiO<sub>2</sub>, while the consecutive mechanism (combustion → conversion) is more typical of reactions over Ru/SiO<sub>2</sub> and Ru/Al<sub>2</sub>O<sub>3</sub>.<sup>70</sup>

A surface compound with the adsorption band at 2000 cm<sup>-1</sup> was observed in the IR spectra recorded *in situ* for POM over Rh/α-Al<sub>2</sub>O<sub>3</sub> and Rh/δ-Al<sub>2</sub>O<sub>3</sub>.<sup>71</sup> Its concentration correlated with the rate of formation of CO. Presumably, the oxidation of CH<sub>4</sub> occurred *via* the surface hydride H–Rh–CO. Partly reduced oxide clusters with Rh<sup>+</sup> ions played the role of active sites. Hydrogen spillover occurs between Rh and the OH groups of the support. According to the KIE, over Rh/γ-Al<sub>2</sub>O<sub>3</sub> at low (0.05%) concentrations of Rh, POM was mediated by a consecutive (combustion → reforming) mechanism.<sup>72</sup> At high concentrations of Rh (1%) and at temperatures below 500 °C, the mechanism of POM represented a combination of reforming and direct oxidation, while direct dissociation of methane was the dominant mechanism at temperatures above 650 °C.

A difference between the mechanisms of POM over rhodium and iridium catalysts was observed.<sup>73–75</sup> In the pulse injection (2 CH<sub>4</sub> + O<sub>2</sub>) onto Rh/TiO<sub>2</sub> and Rh/Al<sub>2</sub>O<sub>3</sub>, heating occurred of the upper layer of the catalyst, while in the case of Ir/TiO<sub>2</sub> this occurred in the bottom layer. It was concluded that in the former case the reaction proceeded by a consecutive mechanism, which began with the most exothermic step of deep oxidation, whereas in the latter case the mechanism was direct. At 650 °C, Rh/TiO<sub>2</sub> exceeded all other catalysts in the catalytic activity.

The study of the reaction CH<sub>4</sub> + <sup>18</sup>O<sub>2</sub> over Ru/SiO<sub>2</sub> and Ru/Al<sub>2</sub>O<sub>3</sub> revealed<sup>76</sup> that in both cases POM proceeded by a consecutive mechanism. C<sup>18</sup>O<sup>16</sup>O formed the first followed by C<sup>18</sup>O and C<sup>16</sup>O.

According to the results of IR spectroscopic and isotope exchange (<sup>16</sup>O<sub>2</sub>–<sup>18</sup>O<sub>2</sub>) studies carried out over Ca<sup>2+</sup>-modified Ru/TiO<sub>2</sub> in a transient regime, the interaction of CH<sub>4</sub> with the Ru surface resulting in the formation of CH<sub>x</sub> was a limiting step of POM.<sup>77</sup> The adjacent Ru sites and atomic oxygen are involved in the subsequent abstraction of H from CH<sub>x</sub>. Initially, the CO molecule is formed in the interaction of carbon with oxygen on the Ru sites, while CO<sub>2</sub> is formed upon oxidation of CO on the oxidised sites. The IR spectra revealed the presence of bands corresponding to the OH groups (3600 cm<sup>-1</sup>) and a broad band at 1995 cm<sup>-1</sup> assigned to the carbonyl hydrides H–Ru–CO or H<sub>2</sub>Ru–CO. The following reaction mechanism was proposed:

Hereinafter, (S) is the surface. There are two different states for the Ru/TiO<sub>2</sub> catalyst under study, namely, the inactive state at low values of  $P_{\text{CH}_4}/P_{\text{O}_2}$  and the highly active and selective state (the selectivity is up to 90%) at higher values of the  $P_{\text{CH}_4}/P_{\text{O}_2}$  ratio. This selectivity increases with the increase in  $P_{\text{CH}_4}/P_{\text{O}_2}$  and temperature.

Theoretical calculations showed<sup>78</sup> that adsorbed oxygen favours the dissociation of CH<sub>4</sub> on Pt, Cu, Ag and Au, but not on Ru, Os, Ir, Rh or Pd. The differences in the selectivities of H<sub>2</sub> formation are associated with different stabilities of the OH groups on metals. Higher selectivity towards CO<sub>2</sub> is observed on oxygen-enriched surfaces. CO<sub>2</sub> is more readily formed over Ir, Pd and Pt than over Ru, Os and Rh. Low selectivity towards H<sub>2</sub> over Pd and Pt is attributed to the ease of the reaction:

Kinetic simulation of gas-phase reactions over 0.3% Rh/α-Al<sub>2</sub>O<sub>3</sub> under conditions of POM (780–1130 °C, 800 kPa) has been carried out.<sup>79</sup> Altogether, 40 elementary reactions were considered and the importance of the gas-phase reactions in the overall scheme was noted. Free radical uptake by the reactor walls or by an inert diluent (*e.g.*, non-porous Al<sub>2</sub>O<sub>3</sub>) inhibited reforming. In addition to synthesis gas, C<sub>2</sub> hydrocarbons were found in the gas phase. The conversion of O<sub>2</sub> increased, whereas the selectivity towards C<sub>2</sub>H<sub>6</sub> decreased upon dilution of the catalyst with an inert material.

Experiments carried out at the Institute of Chemical Physics of the RAS<sup>80–82</sup> have demonstrated that POM combines, in a complicated manner, both heterogeneous and homogeneous reactions. The so-called ‘hot spot’ formed on porous Ni-foam and Pt/ZrO<sub>2</sub> within a short (<0.01 s) period of time after the loading of the reaction mixture at temperatures above 600 °C, which moved rapidly towards the gas flow into the frontal layer and even beyond it. If a quartz-glass wool pad is placed in front of the catalyst, its heating (~900 °C) exceeded that observed on the catalyst itself. Obviously, the catalyst generates reactive species (most probably, free radicals) which diffused towards the gas flow thereby triggering reactions in the gas-phase before the catalyst layer where the mixture was rich in O<sub>2</sub>, but its content was insufficient to effect true gas-phase combustion. This reaction occurred in selectively and yielded predominantly CO + H<sub>2</sub>, whereas CO<sub>2</sub> was formed in subsequent radical reactions:

The overall selectivity of this process corresponds to the selectivity of the reaction occurring in the pre-catalyst layer and this can be modified, *e.g.*, by placing, in front of the active catalyst layer, a small amount of less reactive MgO where deep oxidation to CO<sub>2</sub> occurs. If the positions of the active catalyst and MgO are changed, no change in the selectivity is observed. No change in the selectivity occurs either if inert SiO<sub>2</sub> is placed in front of the catalyst.

Studies of the reaction CH<sub>4</sub> + O<sub>2</sub> over Pt/ZrO<sub>2</sub> in the presence of <sup>13</sup>CO<sub>2</sub> revealed the absence of the label in the reaction products,<sup>80–82</sup> which suggests that the reaction follows a direct mechanism. However, the formation of <sup>13</sup>CO was observed over porous Ni, which occurs presumably<sup>80</sup> due to the redox reactions involving H<sub>2</sub>, H<sub>2</sub>O, CO, CO<sub>2</sub>.

Among those, only the first two reactions are related to POM. The key factor that determines the differences between the porous Ni and Pt/ZrO<sub>2</sub> is their different abilities to be oxidised by CO<sub>2</sub>. This is probable for Ni, but is unlikely for Pt.

From the results considered in this Section one may state that the results of numerous studies into the mechanism of POM by physical methods, *viz.*, IR and Raman spectroscopy, XPES, the use of TAP-reactors, tracer technique and molecular beam methods, clearly indicate that this process occurs according to

two well-defined mechanisms, *viz.*, direct and consecutive mechanisms. High temperature, short residence time and reduction of catalysts to the metals favour the former. At lower temperatures and prolonged residence times on the oxidised surfaces of supported catalysts, the oxidation of CH<sub>4</sub> occurs predominantly by a consecutive mechanism.

### c. Technological features

The analysis of a kinetic model of POM over Pt/MgO revealed a high degree of heating at the reactor inlet due to deep oxidation of methane.<sup>83</sup> At the inlet temperature of 600 °C and the linear velocity of 3 m s<sup>-1</sup>, the 'hot spot' was formed in the frontal layer with the temperature of up to 1400 °C at 0.1 MPa and up to 2200 °C at 2.5 MPa. The 'hot spot' temperature can be reduced using supports with high thermal conductivities (down to 1100 °C at 0.1 MPa and down to 1800 °C at 2.5 MPa).

An original reactor with a moving catalyst layer for conducting pilot-scale POM has been described.<sup>84</sup> Gas from a small nozzle enters the layer of a powdered catalyst (Ni/La<sub>2</sub>O<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub>) to produce the spouted bed. The ejectile particles of the catalyst come in contact with the gas and fall down. The residence time is <0.5 s, the temperature is 850–1000 °C, the pressure is 0.2–0.8 MPa, the particle size varies from 120 to 150 µm.

The use of oxygen in POM is a crucial factor responsible for the high cost of synthesis gas and the explosive risk of the process. Therefore, considerable attention is currently given to technologies based on the use of heat-resistant O<sub>2</sub>-permeable ceramic membranes. This makes it possible to combine the generation of synthesis gas and air separation and to avoid the use of expensive oxygen-generating equipment. According to the existing estimates, this technology saves from 20% to 50% of funds. The membranes must be strong, one of their surfaces must withstand temperatures above 900 °C in a highly oxidative atmosphere, whereas the other surface must be resistant to highly reducing media. In addition, the membranes must be resistant to poisoning, corrosion, deformation and differential pressure. Non-porous membranes were designed based on, *e.g.*, perovskites ABO<sub>3</sub> with variable charges, where the size of one cation is comparable to that of the anion, while the size of the second cation is much smaller.<sup>85</sup> Replacement of one cation by another with a lower valence leads to the disbalance of charges and generates a vacancy [ ]<sub>O<sub>2</sub></sub><sup>-</sup>. The ion flux through the membrane is proportional to  $(\delta/L) \times (P_{O_2})_1 / (P_{O_2})_2$ , where  $\delta$  is the membrane area,  $L$  is its thickness and  $(P_{O_2})_1 / (P_{O_2})_2$  is the concentration gradient of O<sub>2</sub> through the membrane. Membranes with improved characteristics exhibit a permeability (diffusion) plateau in the temperature range from 650 to 1000 °C. The appearance of hot spots and the generation of temperature gradients in such membranes is not hazardous. A high degree of conversion was achieved over a non-perovskite membrane (SrFeCo<sub>5</sub>O<sub>x</sub>) at 750–850 °C.

In 1997, five manufacturing companies (Amoco, BP, Sasol, Statoil and Praxair) launched an extensive research project devoted to the study of oxygen-permeable membranes for the preparation of hydrogen by the OTM Syngas (Oxygen Transport Membrane Synthesis Gas) process. The initial step of these studies is now complete.<sup>86,87</sup> Yet another research group (headed by Air Products Ltd.) including ChevronTexaco, Ceramtec and other partners, developed, in collaboration with the U.S Department for Energy, a technology for large-scale production of Ion Transport Membranes (ITM) for obtaining synthesis gas. These ceramic non-porous multicomponent membranes are prepared from metal oxides [perovskites (La<sub>x</sub>Ce<sub>1-x</sub>)FeO<sub>3-y</sub>] with supported noble metals, they possess both ion and electron conductivities. The membranes operate at temperatures above 800 °C, at pressures up to ~30 atm and very high gas flow rates manifesting high selectivity towards oxygen. Considerable progress has been achieved in the choice of materials, design, manufacture of membranes and support of catalysts, which is prerequisite for the successful commercialisation of the ITM Syngas technology.

The economic estimates testify to high potentials of this technology.<sup>88</sup>

Hydrogen-permeable membranes constitute yet another class of membranes for POM.<sup>89,90</sup> As for the O<sub>2</sub>-permeable membranes, the addition of water vapour to CH<sub>4</sub> efficiently suppressed coke formation and increased the yield of the product. Hydrogen removal shifts the equilibrium and enables a high degree of conversion. Under specific conditions, pure hydrogen can be prepared containing no CO admixture. The use of membranes prepared from 5 µm-thick Pd/Ag/Al<sub>2</sub>O<sub>3</sub> films also gave good results: at 578 °C, the degree of conversion exceeded the equilibrium value by 20%.

High production costs of synthesis gas and hydrogen stimulated the search for alternative methods of their preparation. Redox methods are based on separate interactions. Metals react with water vapour to give oxides and hydrogen, while the interactions of oxides with methane yield CO<sub>2</sub>, H<sub>2</sub>O and the metal. Such a reaction scheme is actually a modification of a classical iron steam procedure where hydrogen has been prepared by the reaction of iron with water vapour and iron oxide has been reduced by the producer gas. Nowadays, it is methane that is used as a reducing agent.

A cyclic POM process over the perovskite catalyst La<sub>1-x</sub>Sr<sub>x</sub>FeO<sub>3</sub> has been studied.<sup>86</sup> The catalyst circulated between two reactors at 800–900 °C. In one reactor, methane was oxidised into synthesis gas using the lattice oxygen, while in the second reactor perovskite was reoxidised by air. The duration of each cycle was several minutes. The main advantages of this cyclic process are explosion safety and exclusion of oxygen-generating units. Later, studies of a similar cyclic process over Ce, Zr, La and Sm oxides with supported Pt was carried out at the Institute of Catalysis of the Siberian Branch of the RAS.<sup>55</sup>

Some of the results on selective POM were reported at the 6th Natural Gas Conversion Symposium. Among various catalytic systems of the metal–oxide type explored by specialists of Snamprogetti, a pure iron–iron oxides system proved to be the system of choice.<sup>91</sup> The following reactions occur:

The Snamprogetti technology enables the preparation of pure hydrogen without intermediate isolation of synthesis gas. Modified oxides Cu–Cr–FeO<sub>x</sub> and Cu–Ni–FeO<sub>x</sub> were also used for this purpose.<sup>92</sup> Additives to iron oxide decrease the temperature of FeO<sub>x</sub> reduction from 600–700 to 300–400 °C and prevent sintering of the oxide. Copper and nickel also generate sites where the activation of methane takes place.

In studies of a similar system (PbO–Pb), the kinetics of PbO/Al<sub>2</sub>O<sub>3</sub> reduction by methane in the temperature range 760–927 °C was investigated.<sup>93</sup> The reaction order with respect to methane was equal to 1; the apparent activation energy was ~40 kcal mol<sup>-1</sup>. The degree of PbO reduction of 0.5–0.6 was the threshold as regards the selectivity of methane conversion: at lower degrees of reduction, CO<sub>2</sub> formed exclusively, while at higher degrees, the formation of CO was predominant.

### 3. Oxidation of methane at millisecond contact times

Oxidative catalytic reactions that occur at short (millisecond) contact times ( $\tau$ ) were known and have found industrial application (*e.g.*, the Andrussov reaction: NH<sub>3</sub> + CH<sub>4</sub> + O<sub>2</sub>) since the first half of the past century. Systematic studies of these reactions were carried out by Schmidt,<sup>94,95</sup> who has demonstrated advantages of hydrocarbon oxidation (including POM) over solid catalysts (gauzes, foamy metal blocks, open-channel blocks, *etc.*) at small contact times and, correspondingly, at high volume flow rates, which ensured very high productivity.

The catalytic oxidation of hydrocarbons over solid catalysts at low  $\tau$  was especially efficient in simple small-size reactors; no carbon formation occurred.<sup>94,95</sup> High temperature and high concentration gradients are the characteristic features of such processes. As a rule, the temperature gradients are of the order of  $10^6 \text{ deg s}^{-1}$  and  $10^5 \text{ deg cm}^{-1}$ . These processes are autothermic and proceed under virtually adiabatic conditions, since the energy released in the exothermic reactions causes rapid heating of the gases and the catalyst to  $\sim 1000^\circ\text{C}$ , whereas the heat release rate is far too high to enable effective cooling through the reactor walls.

The axial temperature profile in a millisecond reactor depends on the ratio of gas-phase and surface reactions. Very often, the reaction occurs in a two-zone mode; but the reactions on blocks and gauzes follow different mechanisms. In the first metal layers (1  $\mu\text{m}$  thick) of block catalysts, highly exothermic oxidation of hydrocarbons into  $\text{CO}_2$  and  $\text{H}_2\text{O}$  is accompanied by heating to temperatures above  $1000^\circ\text{C}$ . If methane is used as a hydrocarbon, the reaction yields synthesis gas. Endothermic reactions, *e.g.*, direct dehydrogenation of  $\text{C}_2\text{H}_6$  to  $\text{C}_2\text{H}_4$ , take place on the remaining solid. The addition of small amounts of hydrogen to an ethane–oxygen mixture resulted in 85% selectivity towards  $\text{C}_2\text{H}_4$  over Pt–Sn-catalysts. At millisecond  $\tau$ , only part of the molecules has sufficient time to come in contact with the surface of gauze-like or spiral catalysts, to be heated up to  $\sim 900\text{--}1000^\circ\text{C}$  and oxidised. The rest of the molecules ‘skip’ the catalyst without being heated and interact with heated particles in the post-catalyst zone at intermediate temperatures. The formation of peroxy radicals and hydroperoxides is possible in this case.

At short contact times, the conditions for gas-phase reactions are difficult to predict because of high axial and radial concentration and temperature gradients. However, the switch from millisecond laboratory-scale reactors to industrial-type reactors is believed<sup>94</sup> to pose no problems. It is merely necessary to increase the diameter of the reactor with retention of the linear gas flow rate. It is suggested that the increase in the reactor diameter to 30 cm at a flow rate of  $10^6 \text{ h}^{-1}$  enables the daily output of several tons, while in reactors with a diameter of up to 180 cm the daily productivity can reach 1000 tons.

Non-linear processes, such as self-oscillations and autowaves in POM over nickel catalysts, were discovered by researchers of the Institute of Chemical Physics of the RAS.<sup>80</sup> The analysis of these phenomena prompts a conclusion that a crucial role in their appearance is played by oxygen and carbon accumulated in the catalyst.

A reactor based on a ceramic block with microchannels coated with  $\text{Al}_2\text{O}_3$  and an Ni–Co–Cr–O alloy has been developed at the Institute of Catalysis of the Siberian Branch of the RAS.<sup>96</sup> The catalyst manifested high thermal and mechanical stability under conditions of high-temperature POM.

Stable and complete conversion of methane was achieved at  $800^\circ\text{C}$  and a linear gas flow rate of  $0.75\text{--}1.50 \text{ m s}^{-1}$  in a reactor with a fluidised bed of a catalyst ( $\text{Ni}/\alpha\text{-Al}_2\text{O}_3$ ) designed for small contact times,<sup>97</sup> the yields of  $\text{H}_2$  and CO constituted 97% of the thermodynamically permissible values. The design of a fluidised bed reactor has been described elsewhere.<sup>98</sup>

The mechanism of POM over a Pt gauze at  $800\text{--}1100^\circ\text{C}$  was studied in a TAP reactor.<sup>99</sup> Experiments with alternating pulses of  $\text{CH}_4$  and  $\text{O}_2$  showed that CO and  $\text{H}_2$  are the primary reaction products of  $\text{CH}_4$  with  $\text{O}_2$  over Pt. In the absence of gas phase  $\text{O}_2$ , the maximum attainable selectivities to CO and  $\text{H}_2$  were 97% and 96%, respectively.

At low surface oxygen concentrations, oxygen incorporated in the Pt bulk diffuses to the surface and reacts with carbon to form CO, *i.e.*, a direct mechanism operates.

The oxidation of a microstructure honeycomb-like catalyst prepared from rhodium foil<sup>100</sup> in the presence of oxygen was carried out at 2 MPa. High thermal conductivity of Rh provided more efficient (in comparison with Pt–Rh gauzes) heat dissipation. The temperature of the catalyst under the reaction conditions

reached  $1080\text{--}1200^\circ\text{C}$ . The analysis of electron micrographs revealed signs of Rh corrosion upon POM.

The oxidative coupling and partial oxidation of methane were studied at  $\tau < 5 \mu\text{s}$ .<sup>101</sup> Over  $\text{Rh}/\alpha\text{-Al}_2\text{O}_3$ , the selectivity towards  $\text{C}_2$  products was rather low, but increased to 20% over  $\text{Pt}/\alpha\text{-Al}_2\text{O}_3$ , acetylene being the major product. A peculiar temperature profile along the catalyst layer is believed to be the driving force of this process: the inlet temperature was  $200^\circ\text{C}$ , and the outlet temperature was as high as  $\sim 1500^\circ\text{C}$ .<sup>102</sup> Homogeneous reactions predominate at high temperatures. The scheme of methane oxidation into synthesis gas proposed in this study included 277 homogeneous and 19 heterogeneous steps. The conclusions based on the analysis of this model were compared with the experimental results obtained at  $750\text{--}1150^\circ\text{C}$  and pressures of up to 3.5 MPa. It was established that homogeneous reactions were predominant at  $\tau > 10 \text{ ms}$ , at high temperatures and at high pressures. The adiabatic heating reached  $1365^\circ\text{C}$ , while the true ‘hot spot’ temperature in the catalyst layer measured by the emission thermography may be even higher.

It was shown<sup>103</sup> that the selectivity towards CO and  $\text{H}_2$  was as high as 95% in POM and CDR over  $\text{Rh}/\text{MgO}/\text{Al}_2\text{O}_3$  at  $750^\circ\text{C}$  and at  $\tau = 12 \text{ ms}$ . This catalyst appeared to be more selective than  $\text{Rh}/\text{MgO}/\text{Al}_2\text{O}_3$ , but the latter was more efficient in the activation of  $\text{CH}_4$  and less efficient in the activation of  $\text{O}_2$ .

The temperature of the catalyst ( $> 650^\circ\text{C}$ ) over  $\text{Rh}/\alpha\text{-Al}_2\text{O}_3$  at contact times  $< 12 \text{ ms}$  was high enough to initiate POM or even carbon-dioxide reforming of methane. No synthesis gas was formed at  $\tau > 12 \text{ ms}$ .

Studies into methane oxidation into synthesis gas over a Pt-gauze in the temperature range from  $680$  to  $930^\circ\text{C}$  and at variable contact times ( $0.2\text{--}0.02 \text{ ms}$ ) revealed that the conversion of  $\text{CH}_4$  and  $\text{O}_2$  was limited by their transport to the catalyst, while the selectivity towards CO was determined by the reaction on the surface.<sup>104</sup> Hydrogen formation took place only at  $1000^\circ\text{C}$ .

## 4. Carbon dioxide reforming of methane

### a. Catalysts

Carbon dioxide reforming of methane (CDR) is carried out at higher temperatures ( $\sim 900^\circ\text{C}$ ) than SRM or POM. The interest in this reaction stems from the possibility of obtaining synthesis gas with the composition  $\text{CO}:\text{H}_2 = 1:1$ , which is required for the synthesis of dimethyl ether.

Similar to SRM and POM, supported nickel catalysts are used for CDR most often. In addition, catalysts based on Co, Fe, Pt, Pd, Rh and Ir have also found application for this purpose, as in SRM and POM processes. In numerous studies, the activities of metal catalysts on various supports were compared. Basic supports such as  $\text{MgO}$ ,  $\text{La}_2\text{O}_3$ , *etc.*, better withstand poisoning than acidic ones and presumably are involved in the activation of  $\text{CO}_2$ . Bimetallic catalysts exceed monometallic catalysts in both the activity and stability. It was found<sup>105,106</sup> that the catalytic activities and stabilities of 2%  $\text{Ni}/\text{La}_2\text{O}_3$  and 2%  $\text{Ni}/\text{ZrO}_2$  increased substantially upon promotion with 0.2% Rh.

Japanese investigators<sup>107,108</sup> demonstrated very high activity of the catalyst  $\text{Ni}_{0.03}\text{Mg}_{0.97}\text{O}$  and its resistance against carbon deposition. A comparison of catalytic properties of solid solutions of  $\text{Ni}_x\text{Mg}_{1-x}\text{O}$  and supported  $\text{Ni}/\text{MgO}$  catalysts revealed that significantly smaller amounts of carbon are produced over the former, which can be attributed to the small size of Ni particles, surface basicity and interaction of Ni with the support. The size of Ni particles in  $\text{Ni}_{0.03}\text{Mg}_{0.97}\text{O}$  was 3–4 nm; that in  $\text{Ni}_{0.10}\text{Mg}_{0.90}\text{O}$  and in  $\text{Ni}/\text{MgO}$  was 6–8 nm and 3–10 nm, respectively. The degree of reduction of the metal in 30%  $\text{Ni}/\text{MgO}$  was higher than in 10%  $\text{Ni}/\text{MgO}$ . According to X-ray phase analysis data, the catalyst comprised three phases, *viz.*, Ni,  $\text{MgO}$  and a solid solution with high content of NiO. The formation of carbon nanotubes was observed over  $\text{Ni}/\text{MgO}$ . The least changes during operation occurred in  $\text{Ni}_{0.03}\text{Mg}_{0.97}\text{O}$ .<sup>109</sup>

Researchers from the Institute of Chemical Physics of the RAS and the Institute of Petrochemical Processes of the Azerbaijan

Academy of Sciences established that CDR occurred over oxide Mn-containing catalysts.<sup>110</sup> Later, supported metal catalysts came to be used for this reaction. The reaction  $\text{CH}_4 + \text{CO}_2$  was studied over various catalysts [ $\text{Ni}/\alpha\text{-Al}_2\text{O}_3$ ,<sup>111</sup>  $\text{Co}/\alpha\text{-Al}_2\text{O}_3$  (see Ref. 112) and  $\text{Pt}/\alpha\text{-Al}_2\text{O}_3$  (see Ref. 113)] in flow and pulse regimes using differential scanning calorimetry. Treatment of  $\text{NiO}/\text{Al}_2\text{O}_3$  with hydrogen at 700 °C resulted in partial reduction of  $\text{NiO}$  to  $\text{Ni}$ . Methane virtually did not react with oxidised  $\text{Ni}$  or  $\text{Co}$ , but interacted actively with the reduced catalyst to give  $\text{H}_2$  and surface carbon. With the lattice oxygen, the latter reacted slowly, but its reaction with adsorbed oxygen was fast. A fast rate was also characteristic of the reaction of  $\text{CO}_2$  with surface carbon to yield  $\text{CO}$ , while the reaction with the metal ( $\text{M}$ ) resulting in  $\text{CO}$  and  $\text{MO}$  was slow. It may thus be concluded that the main route of CDR over  $\text{Ni}/\alpha\text{-Al}_2\text{O}_3$  and  $\text{Co}/\alpha\text{-Al}_2\text{O}_3$  includes dissociative adsorption of  $\text{CH}_4$  resulting in  $\text{C} + 2\text{H}_2$  and the reverse Boudouard reaction of the carbon formed with  $\text{CO}_2$ . The side routes include the reactions of  $\text{CH}_4$  chemisorption products with oxygen incorporated into a catalyst and dissociative adsorption of  $\text{CO}_2$  on the metal. A competitive reaction of surface carbon with adsorbed oxygen reduced the degree of conversion of  $\text{CO}_2$  in the main reaction; therefore, the rate of the reaction  $\text{CH}_4 + \text{CO}_2$  decreased in the presence of  $\text{O}_2$  due to oxygen poisoning of the catalyst.

A broad range of catalysts based on  $\text{Ni}/\text{MgO}$  has been studied.<sup>114</sup> High activity was observed for  $\text{Ni}/\text{MgO}$  doped with  $\text{CeO}_2$ ,  $\text{CuO}$ ,  $\text{Cr}_2\text{O}_3$  and  $\text{MnO}_2$ . Under conditions of catalysis, these dopants underwent oxidation or reduction.  $\text{Ni}/\text{MgO}-\text{Cr}_2\text{O}_3$  proved to be the most active catalyst. The degree of conversion over the catalyst 6%  $\text{Ni}-1\%$   $\text{Cr}_2\text{O}_3/\text{MgO}$  reached virtually the equilibrium value even at 700 °C. Even small amounts of  $\text{Ni}$  and  $\text{Cr}_2\text{O}_3$  had a promoting effect on each other. The  $\text{Co}/\alpha\text{-Al}_2\text{O}_3$  system manifested high activity and stability in an analogous study<sup>115</sup> of supported cobalt catalysts.

The catalyst 5%  $\text{Ni}/\text{CaO}-\text{Al}_2\text{O}_3$  prepared by deposition of nickel onto the preformed layer of aluminate  $\text{CaAl}_2\text{O}_4$  manifested higher activity and was less subject to carbon deposition than the catalyst prepared by simple mixing of  $\text{Ca}$ ,  $\text{Ni}$  and  $\text{Al}$  salts.<sup>116</sup> The differences observed were attributed to the formation of various amounts of  $\text{NiO}$  on the surface of these catalysts. The catalyst  $\text{Ni}/\text{CaO}-\text{SiO}_2$  used in the study of CDR at 650 °C was prepared by impregnation of  $\text{CaO}$ -modified  $\text{SiO}_2$  with  $\text{Ni}$  salts.<sup>117</sup> This procedure increased the metal dispersion. The carbon fibres formed caused deactivation of the catalyst.

The oxide  $\text{ZrO}_2$  in the catalyst  $\text{Ni}/\text{ZrO}_2/\text{MgO}$  stabilised nickel on the support.<sup>118</sup> The reduction temperature of  $\text{NiO}$  increased with the increase in the  $\text{MgO}$  content. In the absence of  $\text{MgO}$ , the catalyst  $\text{Ni}/\text{ZrO}_2$  was inactive, whereas the addition of only 1%  $\text{MgO}$  brought the conversion to virtually the equilibrium value.

Potassium promotes the activity of  $\text{Ni}/\text{Al}_2\text{O}_3$ . The addition of potassium had little effect on the dissociation rate of  $\text{CO}_2$  and the reaction rate of  $\text{CH}_x$  with  $\text{O}_{\text{ads}}$ .<sup>119</sup> Potassium plays a role in dividing the  $\text{Ni}$  surface into small ensembles, thus carbon deposition is suppressed. The addition of  $\text{MnO}$  also inhibited carbon deposition.<sup>120</sup> The catalyst  $\text{Ni}-\text{MnO}_x/\text{Al}_2\text{O}_3$  prepared by co-precipitation was more active than  $\text{Ni}-\text{MnO}_x/\gamma\text{-Al}_2\text{O}_3$  prepared by impregnation and the above-described  $\text{Ni}_{0.03}\text{Mg}_{0.97}\text{O}$ .

The stable catalyst  $\text{Ni}/\text{Al}_2\text{O}_3$  was prepared by repeated deposition of carbon from methane and subsequent elimination of carbon by treatment with carbon dioxide.<sup>121</sup> The assumption that active sites of the catalyst differ from those where carbon filaments are formed was the idea of this method. The repetition of the deposition-elimination cycles decreased the overall carbonisation.

The catalyst  $\text{Ni}/\text{CeO}_2-\text{Al}_2\text{O}_3$  manifested higher activity than  $\text{Ni}/\gamma\text{-Al}_2\text{O}_3$  and  $\text{Ni}/\text{CeO}_2$ .<sup>122, 123</sup> The addition of  $\text{CeO}_2$  suppressed the interaction of  $\text{Ni}$  with the support, facilitated reduction and increased the dispersion of  $\text{Ni}$ . Owing to the addition of  $\text{CeO}_2$ , the carbon atom reacts more efficiently with oxygen-containing sub-

stances following dissociation of adsorbed  $\text{CO}_2$  eventually resulting in a reduction of coke formation.

Perovskites  $\text{La}_{1-x}\text{Fe}_x\text{Fe}_{1-x}\text{O}_y$  effect complete conversion of  $\text{CH}_4$  and  $\text{CO}_2$  at 800 °C and are highly reactive catalysts for CDR.<sup>124</sup> Under conditions of the catalytic process, the mixed perovskite-type structures are destroyed, but at  $x < 0.5$  these catalysts can be recovered by calcination.  $\text{Ni}-\text{Fe}$  alloys with variable compositions were formed at  $0.3 < x < 0.8$ . It was suggested that fusion prevented poisoning of the catalyst with carbon due to inhibition of carbon diffusion through  $\text{Ni}$  particles.

The catalytic activities and resistance of the perovskites  $\text{La}_{1-x}\text{Sr}_x\text{NiO}_3$  ( $x = 0.01, 0.1$ ) and  $\text{La}_{2-x}\text{Sr}_x\text{NiO}_4$  ( $x = 0.1$ ) against coke formation at 600 °C and ambient pressure depended on the type and stoichiometry of the perovskite.<sup>125</sup> Thus  $\text{LaNiO}_3$  manifested high catalytic activity, while  $\text{LaNiO}_4$  was totally inactive.  $\text{La}_{0.9}\text{Sr}_{0.1}\text{O}_3$  and  $\text{La}_{1.8}\text{Ni}_{0.2}\text{NiO}_4$  manifested the highest activity among strontium-substituted catalysts. Under CDR conditions, the catalyst was converted into a mixture of  $\text{La}_2\text{O}_3\text{CO}_2$  and  $\text{SrCO}_4$  with metallic  $\text{Ni}$  (X-ray phase analysis data). This may result from replacement of the lattice oxygen, which is accelerated in a reducing atmosphere at a ratio  $\text{CH}_4:\text{CO}_2 = 1:1$ . Presumably, high activity was determined by the presence of two sites, *viz.*,  $\text{La}_2\text{O}_3$  responsible for the activation of  $\text{CO}_2$ , and  $\text{Ni}$  responsible for the activation of  $\text{CH}_4$ .

CDR over  $\text{Ni}$  catalysts supported on  $\alpha\text{-Al}_2\text{O}_3$ ,  $\gamma\text{-Al}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3\cdot\text{SiO}_2$ ,  $\text{SiO}_2$ ,  $\text{MgO}$ ,  $\text{ZrO}_2$  and modified with transition metals ( $\text{Co}$ ,  $\text{Cu}$ ,  $\text{Fe}$ ) and alkaline promoters ( $\text{Na}$ ,  $\text{K}$ ) has been studied.<sup>126</sup> The catalytic activities of  $\text{Ni}/\alpha\text{-Al}_2\text{O}_3$  and  $\text{Ni}/\gamma\text{-Al}_2\text{O}_3$  were very similar, but coke formation over the latter was faster by virtue of its acidic properties. According to the resistance against coke formation, the supports are arranged in the following order:  $\alpha\text{-Al}_2\text{O}_3 > \gamma\text{-Al}_2\text{O}_3 > \text{SiO}_2 > \text{Al}_2\text{O}_3\cdot\text{SiO}_2 > \text{ZrO}_2 > \text{MgO}$ . The activities of the catalysts doped with transition metals decreased in the following order:  $\text{Ni}-\text{Co} > \text{Ni} > \text{Ni}-\text{Cu} > \text{Ni}-\text{Fe}$ , while those of the catalysts containing alkaline promoters appeared as  $\text{Ni} > \text{Ni}-\text{Na} > \text{Ni}-\text{K}$ . Metal additives inhibit reduction of  $\text{Ni}$ , but enhance its dispersion. After 12 h operation in the absence of a modifier, the  $\text{Ni}$ -catalyst was completely deactivated, whereas the activity of the  $\text{Ni}-\text{Co}$ -catalyst increased noticeably with no coke formation. Cobalt catalysts were comparable to nickel catalysts in catalytic activity and stability.<sup>126</sup>  $\text{Co}/\text{MgO}/\text{SiO}_2$  containing 50%  $\text{MgO}$  being the most active. The activity characteristics of  $\text{Co}/\gamma\text{-Al}_2\text{O}_3$  were similar to those of  $\text{Ni}/\gamma\text{-Al}_2\text{O}_3$ . The stabilities and activities of  $\text{Co}$  catalysts depended on the concentration of  $\text{Co}$  and calcination temperature. At high cobalt content, deactivation occurred due to carbon deposition.

The activity of  $\text{Co}/\text{TiO}_2$  strongly depended on the reduction temperature.<sup>127</sup> Only the catalyst reduced at  $T > 850$  °C manifested high activity and stability. Doping with  $\text{Pt}$  and  $\text{Ru}$  improved these characteristics.

The activities and stabilities of catalysts prepared by support of  $\text{Co}$ ,  $\text{Ni}$ ,  $\text{Ru}$ ,  $\text{Rh}$ ,  $\text{Ir}$  and  $\text{Pt}$  on  $\text{SiO}_2$  or  $\text{Al}_2\text{O}_3$  at 400–750 °C have been studied.<sup>128</sup> The nature of the metal and, to a lesser degree, properties of the support were of critical importance. At 450 °C, deactivation was only observed over supported iridium, while at 750 °C other metals were deactivated due to sintering.  $\text{Ni}$ ,  $\text{Co}$  and  $\text{Rh}$  were found to be the most resistant to deactivation. The activities of the catalysts supported on  $\text{Al}_2\text{O}_3$  decreased in the following order:  $\text{Rh} > \text{Ni} > \text{Ir} > \text{Ru} > \text{Pt} > \text{Co}$ ; the catalysts supported on  $\text{SiO}_2$  manifested much lower activities.

Because of lesser solubility of carbon in the platinum-group metals, these were more active in CDR than  $\text{Fe}$ ,  $\text{Co}$  and  $\text{Ni}$  and suffered less from carbon deposition.<sup>129</sup> The CDR was performed over  $\text{Ni}$ -,  $\text{Co}$ -,  $\text{Ru}$ -,  $\text{Rh}$ -,  $\text{Ir}$ - and  $\text{Pt}$ -catalysts supported on  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  at low and moderate temperatures (400–800 °C). At 500 °C, only iridium catalysts were deactivated, while at 800 °C many catalysts underwent deactivation due to sintering.  $\text{Ni}$ -,  $\text{Co}$ - and  $\text{Rh}$ -catalysts manifested the highest stabilities. The activities of the tested catalysts decreased in the following order:

Rh > Ni > Ir > Ru > Pt. Catalysts supported on SiO<sub>2</sub> were much less active.

At 600 °C, Pt/ZrO<sub>2</sub>, Rh/ZrO<sub>2</sub> and Rh/γ-Al<sub>2</sub>O<sub>3</sub> manifested high activities and stabilities in CDR.<sup>130</sup> The activity of Pt/ZrO<sub>2</sub> was determined by the available perimeter of the supported platinum. In contrast, the activities of Rh/ZrO<sub>2</sub> and Rh/γ-Al<sub>2</sub>O<sub>3</sub> depended on the concentration of surface Rh atoms rather than on the nature of the support. Pt/SiO<sub>2</sub> manifested a much lower activity. It was suggested that ZrO<sub>2</sub> favours the dissociation of CO<sub>2</sub> and, as a consequence, elimination of carbon.

As in POM, molybdenum and tungsten carbides were active in CDR at high pressures and at elevated temperatures.<sup>131–133</sup> According to activities at 950 °C and 0.8 MPa, the metal carbides are arranged in the following order: Mo<sub>2</sub>C ~ VC ~ WC > NbC > TaC. The supported molybdenum carbides could be arranged in the following order of stabilities: Mo<sub>2</sub>C/Al<sub>2</sub>O<sub>3</sub> > Mo<sub>2</sub>C/SiO<sub>2</sub> > Mo<sub>2</sub>C/TiO<sub>2</sub>. At low pressures, the oxidation of carbides resulted in their deactivation. Among other carbide catalysts (Mo<sub>2</sub>C/SiO<sub>2</sub>, WC/SiO<sub>2</sub>, Mo<sub>2</sub>C/Al<sub>2</sub>O<sub>3</sub> and Mo<sub>2</sub>C/ZrO<sub>2</sub>), the former manifested the highest activity in CDR.<sup>134</sup> The conversion of Mo<sub>2</sub>C into MoO<sub>3</sub> resulted in the deactivation of the catalyst. The activity of Mo<sub>2</sub>C per mass unit of the catalyst was one or two orders of magnitude lower than the activities of metal catalysts due to its smaller specific surface.

However, despite extensive studies into catalytic systems, the overwhelming majority of papers are devoted to the analysis of only one type of active and stable CDR catalysts, *viz.*, Group VIII metals (most often, Ni and Co supported on basic oxides, such as MgO, MnO and CaO). Rhodium catalysts possess the highest activities and stabilities, but they are very expensive. Of the oxide supports, preference should be given to moderately basic oxides that can undergo oxidation–reduction, *e.g.*, MnO. In the metal–metal oxide pair, the CH<sub>4</sub> is activated by the metal, while the oxide activates the CO<sub>2</sub> molecule.

## b. Kinetics

The kinetic aspects of CDR on the material presented in more than 60 papers were discussed in 1996.<sup>135</sup>

The values of the activation energy,  $E_a$ , determined from the consumption of CH<sub>4</sub> and CO<sub>2</sub> vary from 30 to 350 and from 35 to 130 kJ mol<sup>−1</sup>, respectively, while those determined from the yields of CO and H<sub>2</sub> are 30–318 and 38–250 kJ mol<sup>−1</sup>, respectively. The largest out-of-order value of  $E_{CH_4}$  was noted for reactions carried out over Re/Al<sub>2</sub>O<sub>3</sub> (350 kJ mol<sup>−1</sup>). It is suggested<sup>135</sup> that the values of  $E_a$  obtained for the reaction carried out over Pt/MgO<sup>136</sup> should be excluded from the reliable data. In this study,  $E_{CO} > E_{CH_4}$ , whereas in all other papers this ratio was the opposite. Also,  $E_{CO}$  was found to be equal to 921 kJ mol<sup>−1</sup>, although this value usually amounts to 230 ± 20 kJ mol<sup>−1</sup>, *i.e.*, similar to the values of the energy of activation of cracking of CH<sub>4</sub> over Ni(110) and Ni(111) (233 ± 27 and 221 ± 20 kJ mol<sup>−1</sup>, respectively). The  $E_a$  values for the catalytic reactions over noble metals are usually close to 314–337 kJ mol<sup>−1</sup>. The apparent energy of activation strongly depends on the degree of the steam conversion of CO, which seems to be manifested in larger  $E_{CO}$  upon an increase in the space velocity. The degree of conversion decreases considerably, and the effect of the reverse reaction, *i.e.*, hydrogenation of CO to CH<sub>4</sub>, becomes less significant.

The data on the activities of different catalysts expressed as the reaction turnover number (t.n.) at 450 °C are documented.<sup>135</sup> The t.n. values obtained by extrapolation vary from 0.1 to 1, but are higher for Ru/TiO<sub>2</sub> (4.3–7.3) and Ru/Al<sub>2</sub>O<sub>3</sub> (1.5–4.3) catalysts. The t.n. values for reactions over Rh crystals on different supports decrease in the following order:<sup>137</sup> ZrO<sub>2</sub> > TiO<sub>2</sub> > Al<sub>2</sub>O<sub>3</sub> > La<sub>2</sub>O<sub>3</sub> ~ SiO<sub>2</sub> > MgO.

In the overwhelming majority of studies, the rate of CDR was directly proportional to  $P_{CH_4}$ , whereas  $P_{CO_2}$  enters the kinetic equations cited in certain papers as both a numerator and a denominator with the exponent  $n$  varying from 0 to 2.<sup>138</sup>

The positive kinetic isotope effect  $k_{CH_4}/k_{CD_4}$  observed in CDR over Ni/γ-Al<sub>2</sub>O<sub>3</sub>,<sup>139</sup> Ni/SiO<sub>2</sub> (see Ref. 140) and Ni/La<sub>2</sub>O<sub>3</sub> catalysts<sup>141</sup> suggests that the reaction of oxygen with the catalyst is the limiting step, whereas dissociation of CO<sub>2</sub> is a rather smooth process. The KIE value over Ni/Al<sub>2</sub>O<sub>3</sub> and Ni/La<sub>2</sub>O<sub>3</sub> increases with temperature, being much larger over Ni/La<sub>2</sub>O<sub>3</sub> than over Ni/Al<sub>2</sub>O<sub>3</sub>.

A highly dispersed, firm and stable catalyst Ni/La/α-Al<sub>2</sub>O<sub>3</sub> is particularly suitable for performing CDR in a fluidised bed.<sup>142</sup> At 700–900 °C and 16–40 kPa, the activation energy of this reaction was 90 kJ mol<sup>−1</sup>. According to the kinetic Langmuir–Hinshelwood model proposed for this reaction, the equilibrium is achieved at longer contact times. CDR in a fluidised bed reaction was carried out over Ni<sub>0.15</sub>Mg<sub>0.85</sub>O (see Ref. 143). Inhibition of carbon deposition even at elevated pressures can be attributed to carbon gasification. The electron micrographs of the catalyst show the presence of carbon filaments formed by the catalyst in the fixed bed reactor. No such effect is observed in the fluidised bed reactor.

## c. Mechanism

Numerous studies have shown that carbon formation and its reactions on the metal surfaces are the crucial factors in the mechanism of CDR. The most popular concept consists of the formation of adsorbed C, H, O, CO species on the surface and their reactions with each other that yield CO and H<sub>2</sub>.<sup>135</sup> Carbon oxide is formed from methane or CO<sub>2</sub>.

A kinetic model for the formation and gasification of carbon over nickel catalysts under conditions of CDR and SRM has been discussed.<sup>144,145</sup> At 500–550 °C, carbon filaments were formed predominantly by the Boudouard reaction. This reaction was accelerated in the presence of alkali concomitantly with an increase in the surface concentration of oxygen and a decrease in the lumped forward rate coefficient for the methane cracking. The gasification of filamentous carbon was effected by CO<sub>2</sub>, H<sub>2</sub>O and H<sub>2</sub>. Two competing processes, *viz.*, growth of carbon filaments (nanotubes) involving carbon dissolution in Ni, diffusion and segregation of carbon on the opposite side of the particle and shortening of the filaments due to gasification.

The data from XPS, Auger spectroscopy and CDR by the pulse method suggest transient formation of carbides over cobalt catalysts.<sup>146</sup> Similar results were obtained in experiments over Ni/La<sub>2</sub>O<sub>3</sub>, Ni/γ-Al<sub>2</sub>O<sub>3</sub>, Ni/CaO and Ni/CaO–La<sub>2</sub>O<sub>3</sub> using <sup>13</sup>CH<sub>4</sub> and C<sup>18</sup>O<sub>2</sub> as the reactant gases.<sup>147,148</sup> The formation of nanotubes from carbon is also possible. Presumably, the active sites of the catalyst Ni/La<sub>2</sub>O<sub>3</sub> lie at the boundary between Ni and La<sub>2</sub>O<sub>3</sub>, where the following reactions occur:

These data suggest that cracking of CH<sub>4</sub> over Ni/La<sub>2</sub>O<sub>3</sub> occurs over Ni and is a limiting step, whereas the activation of CO<sub>2</sub> occurs on La<sub>2</sub>O<sub>3</sub>. In contrast, the activation of CO<sub>2</sub> over Ni/Al<sub>2</sub>O<sub>3</sub> is a slower step than that of CH<sub>4</sub>.

The mechanism of the initial steps of CDR over NiSiO<sub>2</sub>, La<sub>2</sub>O<sub>3</sub> or La<sub>2</sub>O<sub>3</sub>·SiO<sub>2</sub> was studied by the pulse response method.<sup>139</sup> The adsorption of CO<sub>2</sub> on NiO competed with the cracking of CH<sub>4</sub>. The adsorption of carbon dioxide on La<sub>2</sub>O<sub>3</sub> resulted in the formation of formates and carbonates, which

further decomposed with evolution of CO and recovery of the oxygen vacancies. The oxygen required for the formation of CO from CH<sub>4</sub> is provided by its transfer from La<sub>2</sub>O<sub>3</sub> to Ni. Methane reduced NiO and formed vacancies in La<sub>2</sub>O<sub>3</sub>.

The CDR reaction over Ni–La<sub>2</sub>O<sub>3</sub>/zeolite (5 Å) was studied by X-ray diffraction spectroscopy, Fourier-transform infrared spectroscopy *in situ*, transmission electron microscopy (TEM), EPR and using chemical traps.<sup>149, 150</sup> Carbon formation from CH<sub>4</sub> and CO upon its disproportionation was confirmed in experiments with <sup>13</sup>CH<sub>4</sub>, and the contribution of CO increased at higher temperatures. According to TEM data, the bulk of carbon was deposited in the form of carbon nanotubes. Enhanced adsorption of CO<sub>2</sub> was observed in the presence of hydrogen. In experiments with pulsed injection of methane following reduction of the catalyst with hydrogen it was shown that the surface oxygen favoured cracking of CH<sub>4</sub>. The use of chemical traps (CD<sub>3</sub>I) and infrared diffuse reflectance spectroscopy established the formation of CD<sub>3</sub>CO<sub>2</sub>H and CD<sub>3</sub>CHO. In experiments with CH<sub>3</sub>I as a trap, HCO<sub>2</sub> or CH<sub>x</sub>O were detected as intermediates in the formation of CH<sub>3</sub>CO<sub>2</sub>H. The dissociation of the C–H bond in CH<sub>x</sub>O is a slow step, which suggests the formation of reactive intermediates HCO<sub>2</sub> and HCO. The number of converted CO<sub>2</sub> molecules was nearly proportional to the number of hydrogen atoms on the catalyst, which suggests that the activation of CO<sub>2</sub> occurs with the involvement of H<sub>ads</sub>. The larger degree of conversion of CH<sub>4</sub> on a CO<sub>2</sub>-treated catalyst suggests the involvement of oxygen in the cracking of CH<sub>4</sub>. IR spectroscopic studies *in situ* of the CDR mechanism over Rh/Al<sub>2</sub>O<sub>3</sub> revealed<sup>54</sup> that the linear form of the adsorbed CO<sub>2</sub> is the active form that generates the reaction product.

Over Rh/α-Al<sub>2</sub>O<sub>3</sub>, the dissociation of CH<sub>4</sub> proceeds in the same manner as over Ni or Co, but the mechanism of CO<sub>2</sub> activation is different.<sup>151</sup> Unlike carbide or filamentous carbon formed over Ni or Co, the carbon formed over Rh is of a 'graphite' type and possesses low activity. CO<sub>2</sub> is neither activated on such a carbon, nor reacts with it. Presumably, a short-lived carbon, which differs from the graphite-type carbon, is formed initially and reacts with CO<sub>2</sub>. It is this carbon that may represent a true intermediate of CDR. Oxygen acts as a poison over Ni or Co catalysts, whereas over Pt catalysts it activates CDR by eliminating the graphite-type carbon.

The CDR reaction over Pt/ZrO<sub>2</sub> and ZrO<sub>2</sub> was studied in a TAP-reactor using IR spectroscopy.<sup>152, 153</sup> At 700 °C, the adsorption of CH<sub>4</sub> and CO<sub>2</sub> occurred independently of one another. The CH<sub>4</sub> cracking products over Pt/ZrO<sub>2</sub> and ZrO<sub>2</sub> abstract oxygen from ZrO<sub>2</sub>. In an excess of oxygen, CO<sub>2</sub> was formed. The selectivity towards CO or CO<sub>2</sub> is determined by the same reaction:

and depends on the surface concentration of oxygen. Under the reaction conditions, adsorption bands corresponding to carbonates CO<sub>3</sub><sup>2-</sup>, bidentate carbonates, linear CO and OH groups were observed in the IR spectra. After administration of CO<sub>2</sub> pulses, only surface OH groups remained on the catalyst, but those were nonreactive. Obviously, the O<sub>ads</sub><sup>\*</sup> which remained after adsorption of CO<sub>2</sub>, reacted with CH<sub>4</sub>. The nature of the O<sup>\*</sup> species has not been established; O<sub>ads</sub>, OH<sub>ads</sub> and even CO<sub>3ads</sub> groups may have to do with these. Over Pt/ZrO<sub>2</sub>, methane dissociated into C<sub>ads</sub> and H<sub>ads</sub>, but no such dissociation was observed over ZrO<sub>2</sub>. Probably, ZrO<sub>2</sub> is partly reduced to form an alloy Pt<sub>1-x</sub>Zr<sub>x</sub>, where the activation of CO<sub>2</sub> occurs. The following reactions take place on Pt/ZrO<sub>2</sub>:<sup>152</sup>

where [O] is the oxygen vacancy in ZrO<sub>2</sub>. The adsorbed hydrogen atoms form OH groups with surface oxygen, which serve as the sources of H<sub>2</sub> and H<sub>2</sub>O. Substitution of CO<sub>2</sub>, which yields CO [reaction (4) in the scheme above], for the lattice oxygen vacancy, is the limiting step of this process.

A large series of investigations of CDR over Ni/SiO<sub>2</sub>, Ni/La<sub>2</sub>O<sub>3</sub>, Ni/Al<sub>2</sub>O<sub>3</sub>, Ru/SiO<sub>2</sub> and Ru/Al<sub>2</sub>O<sub>3</sub> were carried out using isotope exchange, XPS, IR spectroscopy, ferromagnetic resonance and electron microscopy.<sup>128, 152–164</sup> It was found that cracking of CH<sub>4</sub> over Ni/SiO<sub>2</sub> resulted in the formation of H<sub>2</sub> and accumulation of carbon on the surface. Cracking of <sup>13</sup>CO<sub>2</sub> results in the instantaneous formation of gaseous <sup>13</sup>CO and adsorbed oxygen. The latter reacts with <sup>12</sup>C derived from <sup>12</sup>CH<sub>4</sub> to produce a second molecule of carbon monoxide (<sup>12</sup>CO) (the limiting step). Cracking of CH<sub>4</sub> was the slowest step over Ru, while CO<sub>2</sub> reacted directly with carbon to give two CO molecules. Administration of <sup>13</sup>CO<sub>2</sub> and <sup>12</sup>CH<sub>4</sub> pulses produces two output pulses, *viz.*, <sup>12</sup>CO and <sup>13</sup>CO. Alternating pulses of CO<sub>2</sub> enabled the removal of all the adsorbed carbon as a result of which the reaction rate dropped down to zero. In this case, the amount of oxygen accumulated on the surface was the lowest, which inevitably led to the inhibition of oxidation of H<sub>2</sub>. Silicon dioxide is a rather inert support and does not take part in CDR.

Using the TAP-reactor method, it was proved that the support carbon of the Ru/C catalyst reacted with CO<sub>2</sub>. In Ru/C doped with MgO, MgCO<sub>3</sub> was formed in the vicinity of Ru, which favoured the oxidation of carbon following cracking of methane. The OH groups at the MgO–Ru boundary prevented deactivation of the catalyst.

The following redox mechanism of CDR over Ni-catalysts has been proposed.<sup>114</sup> The oxidation and reduction of the NiO constituent of the catalyst (NiO–Cr<sub>2</sub>O<sub>3</sub>–MgO) occurs *via* a spinel according to the overall stoichiometric equation:

Apparently, cracking of methane and activation of CO<sub>2</sub> occur over Ni or NiC.

Over different catalysts, the mechanisms of CDR differ: over pure metals or over metals on neutral supports of the SiO<sub>2</sub> type, complete cracking of CH<sub>4</sub> and CO<sub>2</sub> is more probable, whereas on metals on basic supports the reaction proceeds *via* intermediate carbonates.

The intermediate formation of methyl radicals in CDR has been proposed. The free radicals CH<sub>3</sub> generated upon decomposition of azomethane were adsorbed on the catalyst (Rh/SiO<sub>2</sub>) in order to elucidate this possibility.<sup>165</sup> Using IR spectroscopy, it was established that CH<sub>3</sub>O<sub>ads</sub> species formed reacted with CO<sub>2</sub> in the gas phase at temperatures above 10 °C. No coke deposition on the catalyst occurred. Under these conditions, the major part of CH<sub>3</sub> was adsorbed on SiO<sub>2</sub>, while Rh took part in further conversions. The presence of CH<sub>3</sub> radicals on the surface of Ni/SiO<sub>2</sub> under conditions of CDR was confirmed by TPR and TPD.<sup>166</sup> In addition, C<sub>2</sub>H<sub>6</sub> was also formed. Surface CH<sub>3</sub> radicals reacted with adsorbed oxygen atoms to give CH<sub>x</sub>O and further CO and H<sub>2</sub>.

The majority of experimental results suggest the double-centred mechanism of CDR where CH<sub>4</sub> is activated on the metal components of the catalyst with cracking into C + 2H<sub>2</sub> (or CH<sub>x</sub> + H<sub>2</sub>), while the activation of CO<sub>2</sub> is mediated by the oxide component. The reaction product (CO) is formed in two ways, *viz.*, by oxidation of the surface carbon and by reduction of CO<sub>2</sub>.

On the surface, carbon is formed by two reactions, *viz.*, cracking of CH<sub>4</sub> and the Boudouard reaction. On transition metal oxides supported on basic oxides, CDR can follow a redox mechanism.

#### d. Technological features

Attempts have been undertaken to separate the steps of CH<sub>4</sub> and CO<sub>2</sub> activation by carrying out CDR in a membrane reactor.<sup>167</sup> A Pd/Al<sub>2</sub>O<sub>3</sub> membrane was prepared by electrodeposition of the metal on the support. At 350–600 °C, the degree of CH<sub>4</sub> conversion was 4%–20% larger than in a conventional process with the same catalyst, and the yield of H<sub>2</sub> increased from 3% to 18%. However, the operation of the membrane is strongly affected by coking and the expediency of its application was not presented.

CDR and POM were carried out using the oxygen-permeable membrane Ba<sub>0.5</sub>Sr<sub>0.5</sub>Co<sub>0.8</sub>Fe<sub>0.2</sub>O.<sup>168</sup> The degree of conversion of CH<sub>4</sub> and the selectivity towards CO exceeded 98% under oxygen conversion at 850 °C and at high CH<sub>4</sub>:O<sub>2</sub> ratios. High activities and selectivities of CDR carried out at 900 °C were achieved. The use of a CH<sub>4</sub> + CO<sub>2</sub> + O<sub>2</sub> mixture for over 100 h ensured stable conversion of CH<sub>4</sub> (90%–92%) and CO<sub>2</sub> (94%–96%) with the selectivity towards CO close to 100%.

The feasibility of membrane isolation of pure hydrogen from synthesis gas in the CDR process over Ni/La<sub>2</sub>O<sub>3</sub>, Ni–Rh/La<sub>2</sub>O<sub>3</sub>,<sup>105</sup> Ni/ZrO<sub>2</sub> and Ni–Rh/La<sub>2</sub>O<sub>3</sub><sup>106</sup> is under study. At 700 °C, bimetallic Ni–Rh catalysts were much more active than monometallic catalysts, but monometallic Rh was found to be more stable.

### 5. Autothermal reforming (ATR)

The combination of two or three routes of oxidative reforming of methane, *viz.*, SRM, POM and CDR, can result in the increase in the efficiency of raw material utilisation, in improvement of the thermal balance and control over the composition of synthesis gas. To this goal, one-pot exothermic deep oxidation of CH<sub>4</sub> and endothermic SRM and/or CDR are often performed. The technological process in ATR reactors includes two consecutive steps, *viz.*, deep oxidation of methane followed by CDR + SRM with subsequent conversion of water gas.

The autothermal reforming of methane at high pressures (4–10 MPa), which meets the demands for subsequent synthesis of methanol and dimethyl ether, is discussed.<sup>169</sup> Its first step consists of combustion of CH<sub>4</sub> in a gas burner, and the second step includes CDR and SRM in a fluidised bed of a catalyst. Calculations show that the outlet temperature should be increased with an increase in pressure, but this may result in sintering of the catalyst and destruction of the fluidised bed. The kinetic calculations made account of 49 intermediates and 277 elementary reactions including those involving C<sub>2</sub> hydrocarbons. Lower yields of C<sub>2</sub>H<sub>2</sub> and reduced soot formation are the beneficial effects of the elevated pressures.

The oxygen–carbon-dioxide reforming of methane over Pt/ZrO<sub>2</sub>, Pt/Al<sub>2</sub>O<sub>3</sub> and Ni/Al<sub>2</sub>O<sub>3</sub> were studied in the temperature range of 550–800 °C.<sup>170</sup> At all temperatures, the yields of CO and H<sub>2</sub> from CH<sub>4</sub> + CO<sub>2</sub> + O<sub>2</sub> mixtures (the content of O<sub>2</sub> varied from 3% to 11%) were higher than in the case of the CH<sub>4</sub> + CO<sub>2</sub> mixture, and carbon deposition was smaller. Besides, these conditions facilitated control over formation of the hot spot on the catalyst. From a mixture containing 11% of O<sub>2</sub>, the yields of CO and H<sub>2</sub> were nearly the same as those achieved upon oxidative reforming, CH<sub>4</sub> + O<sub>2</sub> (95% at 800 °C).

The combination of POM, SRM, CDR and deep oxidation of methane in one reactor is the most promising approach to autothermal reforming of methane. The main problem in the design of such reactors is connected with the differences in temperatures of these reactions, which brings forth the necessity for the spatial separation of heat-evolving and heat-adsorbing sites of the catalyst. One of the possible clues to the solution of this problem came from a group of Japanese investigators who performed the conversion of a CH<sub>4</sub> + CO<sub>2</sub> + O<sub>2</sub> mixture in a

fluidised bed. However, it was not always possible to obtain the target CO + H<sub>2</sub> mixture with the required composition.

It was found<sup>171</sup> that the addition of CO<sub>2</sub> to the CH<sub>4</sub> + H<sub>2</sub>O mixture optimised methanol synthesis. Thus, the use of carbon dioxide reforming of methane instead of steam reforming reduces the cost of the technological process. However, this process is commercially profitable if only large amounts of relatively pure CO<sub>2</sub> are available. The H<sub>2</sub>:CO = 2:1 ratio required for methanol synthesis is achieved at CO<sub>2</sub>:CH<sub>4</sub> = 1:3 in accordance to the stoichiometry of the reaction:

In 2002, a pilot plant for synthetic liquid hydrocarbons (SLH) with the daily capacity of 7 barrels was put into operation in Japan for trials of a novel catalyst for combined CO<sub>2</sub>/H<sub>2</sub>O reforming and assessment of a JNOC (Japan National Oil Corporation) technology based on this catalyst. The process is carried out in a tubular converter that requires no addition of oxygen. Synthesis gas thus produced is well-balanced with regard to the H<sub>2</sub>/CO ratio for manufacture of SLH, methanol and dimethyl ether. The energy consumption is lower than in conventional processes at smaller CO<sub>2</sub> and H<sub>2</sub>O molar ratios with respect to carbon in the supplied gas. It is expected that this technology will be especially efficient for the application to small fields with high content of CO<sub>2</sub> in the natural gas as well as for reprocessing of effluent gases rich in CO<sub>2</sub> and at liquefied gas plants.<sup>172</sup>

A heat-integrated ATR reactor with a Rh/Al<sub>2</sub>O<sub>3</sub> catalyst is described.<sup>173</sup> The catalyst was applied onto the inner and outer surfaces of a ceramic tube. A CH<sub>4</sub> + O<sub>2</sub> flow was first fed inside the tube where deep oxidation of methane occurred and then onto the outer surface of the tube where CDR and SRM took place. This method allows a significant reduction of the ‘hot spot’ temperature in the reactor (below 900 °C). This process can be optimised by varying the number of catalyst layers on the inner and outer surfaces of the tube.

The mechanism of autothermal reforming over Pt/CeO<sub>2</sub>, Pt/ZrO<sub>2</sub> and Pt/CeZrO<sub>2</sub> catalysts has been considered.<sup>174</sup> This reaction proceeds by a consecutive mechanism, *i.e.*, the combustion of methane is followed by steam and carbon dioxide reforming of the unburned gas. Pt/Ce<sub>0.18</sub>Zr<sub>0.82</sub>O<sub>2</sub> is the catalyst of choice, it possesses high oxygen capacity, which is beneficial for the redox process. In the absence of CeO<sub>2</sub>, the catalyst undergoes rapid deactivation.

The interest in the production of synthesis gas and hydrogen from higher hydrocarbons (including liquid hydrocarbons) is steadily increasing in connection with the prospects of broad use of hydrogen in motor transport. Steam and autothermal reforming of n-heptane were carried out over 15% Ni/Al<sub>2</sub>O<sub>3</sub> at 700 °C.<sup>175</sup> At lower temperatures, thermal cracking occurred. An active and selective catalyst for steam reforming of ethanol into synthesis gas was obtained by doping a Cu–Zr-fluorite catalyst with cobalt.<sup>176</sup> Reduction of Co led to the generation of Co nanoparticles able to react with oxides. It was also shown that high (26%–27%) selectivity towards H<sub>2</sub> can be achieved in gas-phase oxidation of methane catalysed by NO<sub>x</sub> (20% CH<sub>4</sub>, 10% O<sub>2</sub>, 0.06% NO).<sup>177</sup> The degree of methane conversion in a flow-through quartz reactor at 700–800 °C and the residence time of 0.6–3.7 s was 34%.

## III. Partial oxidation of methane to oxygenates

### 1. Homogeneous oxidation of methane and ethane

Studies into kinetics and mechanism of homogeneous partial oxidation of methane to methanol (Direct Methane to Methanol, DMTM) and kinetics of partial oxidation of the nearest methane homologues are underway. The key features of the mechanism, optimum reaction conditions and actual yields of oxygenates upon methane oxidation in laboratory flow reactors were established<sup>178–180</sup> and the effects of pressure on partial oxidation of methane to methanol were analysed.<sup>179</sup> The most important

factors include a critical transition to a steady-state chain-branched mode,<sup>8</sup> increasing role of nonlinear gas-phase reactions and change in the relative contribution of heterogeneous processes.

The chain-branched oxidation process has a pronounced nonlinear character, the increase in the overall pressure accompanied by the increase in partial pressures of the reactants not only accelerates the reaction, but also increases the contribution of nonlinear gas-phase methanol-yielding processes. A decrease in the diffusion rate with an increase in pressure decreases the contribution of heterogeneous processes leading to the predominant formation of deep oxidation products. Studies on direct homogeneous oxidation of methane in laboratory-scale stainless steel and quartz flow reactors at 15–80 atm demonstrated the considerable effect of the reactor surface material on the oxidation process.<sup>179</sup>

A complex study of the dependence of the main parameters of the DMTM process on such factors as pressure, temperature,  $\text{CH}_4/\text{O}_2$  ratio and the extent of dilution with the inert gas has been carried out.<sup>181</sup> The experiments were performed in fused-quartz reactors (1–10 mm in diameter) at residence time of  $\sim 10$  s and complete conversion of oxygen. The experimental results are in good agreement with the known data.<sup>8, 181</sup> At pressures around 100 atm and the  $\text{CH}_4:\text{O}_2$  ratio of 16.3 in a gas mixture containing 63% of He, the yields of the major reaction products ( $\text{CH}_3\text{OH}$ ,  $\text{CO}$ ,  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) exceeded 95%. No identification of other reaction products was carried out in this study. At temperatures above 460 °C, the degree of oxygen conversion increased jumpwise to 100%. The degree of methane conversion virtually paralleled the oxygen content in the mixture. The mean selectivity towards methanol was  $\sim 50\%$ , which corresponded to the published data. It is of note that the optimum (in the authors' opinion) selectivity was reached at relatively high ( $\sim 6\%$  with respect to methane) oxygen concentrations. The selectivity towards CO was, on average, 3 times as great as that in  $\text{CO}_2$ . At temperatures above threshold values, the selectivity towards methanol passed through a small maximum at  $\sim 470$  °C with subsequent monotonic decrease with an increase in temperature (35% at 490 °C).

As in the majority of previous studies, the drop in pressure was accompanied by a rapid decrease in the selectivity towards methanol (35% at 17 atm) and an increase in temperature (535 °C at 17 atm) at which the maximum selectivity was reached. Further dilution of the reaction mixture with He resulted in an increase in temperature required for complete conversion of oxygen from 445 °C in the absence of helium to 530 °C in the presence of 80% helium. At a He content of 90%, no reaction occurred even at 554 °C. It is noteworthy that the monotonic increase in the selectivity towards methanol occurred with a decrease in the degree of dilution (from 35% at 80% of He to 63% in the absence of He). The reason should be sought in the drop of the reaction temperature rather than in the dilution itself. As in the previous studies,<sup>178–180</sup> the selectivity towards methanol increased with an increase in the  $\text{CH}_4:\text{O}_2$  ratio.

The tenfold increase in the reactor diameter required an increase in the reaction temperature to 495 °C, which is apparently due to higher activation energy of the homogeneous generation of radicals in comparison with the generation in a heterogeneous reaction. This was accompanied by a slight increase in the selectivity towards methanol, which is quite natural, taking into consideration the role of the catalytic formation of methane deep oxidation products on the catalyst surface. Under these conditions ( $\leq 500$  °C, residence time  $\sim 10$  s), relatively high ( $\leq 25\%$  for CO and  $\leq 8\%$  for  $\text{CO}_2$  with respect to methane) concentrations of carbon oxides had virtually no effect on either the degree of methane conversion or the selectivity towards methanol. This followed from virtually complete coincidence of experimental results obtained after a single passage of the mixture through the reactor and with recirculation of gases after separation of methanol and water.

Among recent studies of the DMTM process, special mention should be made of experiments carried out by Zhang *et al.*<sup>182</sup> Gas-phase oxidation was carried out in a flow reactor with a quartz insertion having an internal diameter of 6.7 mm and a heated area diameter of 270 mm at variable pressures (1.0–5.0 MPa) and temperatures (380–500 °C). Special attention has been given to exclusion of interactions of the reactants and reaction products with the metallic surfaces of the reactor and the thermocouple. The composition of the reaction products ( $\text{CH}_3\text{OH}$ ,  $\text{CO}$ ,  $\text{CO}_2$ ,  $\text{C}_2\text{H}_6$  and  $\text{C}_2\text{H}_4$ ) was quite typical of this reaction except for the absence of formaldehyde.

A sharp increase in the degree of conversion of the reactants with an increase in temperature and the relatively weak effect of temperature on the yield of methanol after complete conversion of  $\text{O}_2$  is consistent with the results of previous studies<sup>8, 180, 181</sup> and is characteristic of temperature dependences of the yield of  $\text{CH}_3\text{OH}$  in the branched-chain partial oxidation of methane. A decrease in the yields and selectivity towards methanol at temperatures above 480 °C at low jet velocities and the residence times in the heated zone of 45–90 s in reactors with small diameters can be attributed to the heterogeneous decomposition of  $\text{CH}_3\text{OH}$ . In any case, noticeable decomposition of methanol over Pyrex was observed under similar conditions even in the temperature range of 475–500 °C (see Ref. 8). The absence, from the reaction products, of formaldehyde, which is normally formed under conditions mentioned but is less resistant to heterogeneous decomposition, seems to be due to the same reason.

The results obtained suggest<sup>182</sup> that the degree of conversion of oxygen becomes smaller than 100% with an increase in temperature. The presence of small amounts of oxygen in the final products was observed in previous studies<sup>8</sup> and seems to be due to heterogeneous decomposition of oxygen-containing products, e.g., peroxides.

The relatively high yield of methanol reported<sup>182</sup> correlates to some extent to the results reported by other authors.<sup>183, 184</sup> It is noteworthy that in these studies the residence time was  $\leq 1$  min at relatively low temperatures, pressures and sizes of reactors with quartz or sapphire surfaces insulating the metallic parts of the reactor. These results are at variance with both those obtained at higher flow rates of the reactants and the results of kinetic simulation of a gas-phase process,<sup>8</sup> which suggests that in this case heterogeneous processes occurring on the reactor surface play a more prominent role. At temperatures and pressures mentioned above, neither quartz nor  $\text{Al}_2\text{O}_3$  can be regarded as inert materials with respect to the reacting methane–oxygen mixture, although the mechanisms and rates of surface processes differ substantially from those occurring on the metal surface. The relatively low temperatures used in these studies also favour an increase in the contribution of heterogeneous reactions into the overall homogeneous–heterogeneous process of methane oxidation.<sup>8</sup> The residence time may be regarded as high, if one takes into account the rates of radial and axial diffusion, and this may rationalise the pronounced effect exerted by the presence of even insignificant metallic parts in any zone of the reactor. If this is true, the experimental results, which seem encouraging at the first glance, give unfortunately no grounds for the favourable assessment of the prospects of implementation of the process on an industrial scale, since it envisages, in principle, the use of very slow flows and high surface-to-volume ratios.

To date, the mechanism of the gas-phase DMTM process is generally understood. Numerous experiments showed that the selectivity towards methanol can reliably reach the level of 50% in flow-type reactors at  $\sim 450$ –500 °C and pressures  $\geq 70$ –80 atm with a residence time of several seconds where the degree of methane conversion per cycle is 5%–6%.<sup>8, 180</sup> Practical implementation of this process requires apparently that the main efforts are directed at improving the process technology to make use of its obvious benefits (simplicity, stability, non-susceptibility to contaminants) and to compensate for the no less obvious disadvantages (low conversion per cycle and low selectivity). DMTM was

recommended as a part of an integral energochemical process that combines production of methanol with generation of electric power.<sup>185</sup> This provides yet another benefit and allows maximum simplification of the technology and cut of the production cost of methanol with simultaneous reduction of specific emission of  $\text{NO}_x$  in the generation of electric power from natural gas.

Partial oxidation of methane homologues is studied in less detail. The oxidation of ethane and methane–ethane mixtures in a flow reactor at 10–70 atm was studied with variable macrokinetic parameters.<sup>186, 187</sup> The use of ethane and ethane-containing gases for direct gas-phase oxidation is in every respect more advantageous than the oxidation of methane-containing gases. Although this reaction yields similar major products (except for appearance of noticeable amounts of ethylene), their yields and the degree of conversion of the hydrocarbon gas are somewhat higher, while the working pressure and temperature are significantly lower than in methane oxidation. The increase in the yields of such valuable compounds as formaldehyde and ethanol is especially pronounced, although methanol remains to be the main oxidation liquid product. High total yields of oxygenates were achieved at relatively low pressures ( $\sim 30$  atm). The content of formaldehyde in liquid products was  $\sim 30\%$  at the total alcohol content of 45% and the methanol:ethanol ratio of 5:1. Such a ratio is characteristic of fuel alcohol mixtures that can directly be used as high-octane additives to motor fuels. This allows the direct gas-phase oxidation of ethane to be considered as a potential one-step procedure for production of formaldehyde and fuel alcohols. A promoting effect of methane on the formation of methanol and the yield of liquid products in the ethane oxidation was established. Presumably, this is due to the ability of methyl peroxide radicals generated upon methane oxidation to serve as effective branching species, whereas peroxide radicals generated in the oxidation of ethane and higher hydrocarbons can decompose by alternative routes that yield alkenes but do not result in branching.

Experimental studies and kinetic simulation of conversions of methane and ethane in their combined partial oxidation and of conversions of hydrocarbons  $\text{C}_1$ – $\text{C}_4$  in the oxidation of more complex mixtures imitating natural and associated gases have been carried out.<sup>188</sup> Under conditions of partial oxidation of hydrocarbons  $\text{C}_1$ – $\text{C}_4$  to oxygenates, fast burn-out of higher hydrocarbons at the initial  $\text{O}_2$  concentration of 4%–16% is accompanied by an increase in methane concentration, particularly as a result of their oxidative reforming. However, complete conversion of only one of these hydrocarbons in the oxidation of methane–ethane mixtures is impossible in principle, since both are oxidative interconversion products. The changes in the relative concentrations of hydrocarbons upon combined oxidation depend critically on the initial concentration of oxygen in the mixture. At the same time, the effect of temperature is far less pronounced, while the changes in the pressure in the range 25–70 atm have virtually no effect on this parameter.

Short-term catalytic impact on these complex non-linear systems that are far from the thermodynamic equilibrium as a means of the control over the chemical process is a promising trend in the study of partial oxidation of methane and its homologues. The nonlinear, in principle, nature of such systems determined by interconversions of numerous intermediates allows control over the evolution of the system and its transitions into different steady states by applying relatively weak impacts on the system.<sup>189</sup> However, these studies should be based on the use of reliable quantitative kinetic models of relevant homogeneous–heterogeneous processes. The development of such models is a very complicated task if we take into consideration the ambiguity of many kinetic parameters of even key elementary steps.

## 2. Homogeneous promotion of methane oxidation to oxygenates

Attempts to increase the yields of methane partial oxidation products by homogeneous promotion or using heterogeneous

catalysis have been undertaken since the 1920's. Hydrogen peroxide and nitrogen oxides formerly employed in various industrial processes still remain the most popular homogeneous promoters. In the majority of cases, the effects of promoters are apparently confined to the decrease in either the temperature of the process or the induction period, but the yields of the reaction products are unaffected. Presumably,<sup>190, 191</sup> the failure to increase the product yields by promoting the reaction is due largely to the necessity of additional generation of radicals at very high rates comparable to those attainable in homogeneous branched-chain processes. Kinetic simulation showed that promotion of partial oxidation of methane can, in principle, significantly affect the yields of target products. For example, it is expected that the yield of formaldehyde can be increased by nearly an order of magnitude upon promotion of the oxidation of a  $\text{CH}_4:\text{O}_2 = 9:1$  mixture (1 atm,  $T = 753$  K). However, this can be the case provided the promoter ensures the rate of the radical generation more than five orders of magnitude larger than that of their thermal generation in the reaction itself.<sup>8, 189, 190</sup>

The possibility of promoting the DMTM process with different radicals and molecules has been studied experimentally.<sup>192</sup> The concentrations of radicals above 0.1% could not be achieved irrespective of the nature of the radicals, since they readily interconverted in the gaseous phase. The introduction of radicals or  $\sim 2\%$  of different molecular promoters reduced the ignition delay without any effect on the yields of the reaction products. Among molecular compounds tested, the ability of  $\text{H}_2\text{O}_2$  to reduce the ignition delay was the highest and exceeded twofold that of methanol.

The promotion of incomplete methane oxidation by nitrogen oxides can be concomitant with the catalysis of the formation of various oxygen-containing species. One of the pioneering studies in this field has demonstrated<sup>193</sup> that the addition of 2% NO to a  $\text{CH}_4:\text{O}_2 = 9:1$  mixture (1 atm, 560 °C) increased 10-fold the yield of formaldehyde (from 0.35% to 3.96%). Although this increase could be explained by the promoting effect of NO, it was assumed that it was a manifestation of homogeneous catalysis, since the reaction products contained no  $\text{N}_2\text{O}$  and only trace amounts of  $\text{N}_2$ .

The effect of nitric acid vapour ( $\sim 0.26\%$ ) as a potential source of  $\text{NO}_2$  on methane oxidation has been studied.<sup>194</sup> The addition of  $\text{HNO}_3$  increased not only the degree of methane conversion, but also the general selectivity and the yields of organic products (from 0.7 to  $> 2\%$ ), mainly due to the formation of  $\text{CH}_3\text{NO}_2$ . In the presence of  $\text{HNO}_3$  and at similar degrees of methane conversion, the selectivity towards  $\text{CH}_3\text{OH}$  and  $\text{HCHO}$  changed only insignificantly, while the general selectivity and the yields of oxygenates increased due to the presence of  $\text{CH}_3\text{NO}_2$ . The selectivity towards  $\text{HCHO}$  and  $\text{CH}_3\text{NO}_2$  increased with the increase in the degree of methane conversion in the presence of  $\text{HNO}_3$ , while the selectivity towards  $\text{CH}_3\text{OH}$  decreased under these conditions. It was assumed<sup>194</sup> that the effect of  $\text{NO}_2$  is not confined to initiation alone, since the initial reaction temperature ( $\sim 410$  °C) was the same in all experiments with the same oxygen concentration (2.6%). No nitrogen was formed under these conditions, while the major part of  $\text{NO}_2$  (40%–80%) was converted into  $\text{CH}_3\text{NO}_2$ . In the authors' opinion,  $\text{NO}_2$  can be used as a catalyst in partial oxidation of methane provided that the conditions of this reaction or its individual steps favour the conversion of  $\text{CH}_3\text{NO}_2$  into other oxygenates and regeneration of  $\text{NO}_2$ .

The effect of nitrogen oxides on partial oxidation of other lower alkanes is similar. In the gas-phase oxidation of  $\text{CH}_4$ ,  $\text{C}_2\text{H}_6$ ,  $\text{C}_3\text{H}_8$  and iso- $\text{C}_4\text{H}_{10}$ , the introduction of nitrogen oxides not only increased the rates of alkane conversions and reduced the initial temperature of the overall reaction, but also increased considerably the yields of the oxygenates, *i.e.*, aldehydes, ketones and alcohols.<sup>195, 196</sup> The experiments were carried out in a quartz reactor with an internal diameter of 8 mm; the flow rate was  $120 \text{ ml min}^{-1}$ ; the partial pressures of alkanes,  $\text{O}_2$  and NO were

5–10, 2.5–15 and 0.5–4 kPa, respectively.<sup>195</sup> The reaction mixture was diluted with helium to the total pressure of 101 kPa. After addition of NO, the oxidation of ethane and propane occurred at 400 °C, *i.e.*, at 100 °C lower temperature than in the absence of NO, while the activation energies of the reactions were equal to 208 (methane), 138 (ethane) (361 in the absence of NO) and 107 (propane) kJ mol<sup>-1</sup> (275 in the absence of NO). The total yields of oxygenates under optimum conditions were as follows: 6.7% (methane), 11.3% (ethane), 12.9% (propane) and 28.7% (isobutane). Only trace amounts of nitroalkanes and N<sub>2</sub> were formed under these conditions. Thus, the bulk of added NO remained in the gas phase, which favoured its subsequent isolation and reuse as a catalyst for the oxidation of lower alkanes. The reaction between NO and alkanes did not occur in the absence of O<sub>2</sub>, which points to the involvement of NO<sub>2</sub> in the oxidation and poses a question of the role of nitroalkanes as intermediates in this process. The latter were formed in small amounts in the oxidation carried out at low temperatures. However, direct studies of decomposition of nitropropane C<sub>3</sub>H<sub>7</sub>NO<sub>2</sub> established that C<sub>3</sub>H<sub>8</sub> was formed as the main product, *i.e.*, nitroalkanes are not precursors of oxygenate. Contrariwise, the decomposition of iso-C<sub>4</sub>H<sub>9</sub>ONO at 400 °C resulted in the formation of acetone as the main product. The addition of a NO–O<sub>2</sub> mixture to the nitroalkane did not change the rate of acetone formation, but yielded HCOH, CO, CO<sub>2</sub> and CH<sub>3</sub>NO<sub>2</sub> instead of soot. Thus, alkyl nitrite can serve as the oxygenate precursor.

It was suggested<sup>196</sup> that the oxidation of alkanes RH is catalysed by nitrogen oxides and involves the following main reactions:

in particular, at R = CH<sub>3</sub>

whereas at R = iso-C<sub>4</sub>H<sub>9</sub>

NO and NO<sub>2</sub> play the role of homogeneous catalysts, since the nitroalkanes formed fully decomposed at temperatures above 600 °C with simultaneous release of NO<sub>x</sub>.

It should be taken into account that both hydrocarbons themselves and CO strongly promote oxidation of NO to NO<sub>2</sub> even at relatively low temperatures (300 °C). In addition, NO markedly accelerates the oxidation of methanol and ethanol formed, presumably *via* partially oxidised intermediates that are unstable under other conditions.<sup>197</sup>

A simplified system for the reaction of CH<sub>4</sub> with NO<sub>x</sub> (in the absence of O<sub>2</sub>) was analysed theoretically and the activation energies and rate constants for the reactions of nitrogen oxides with methane were calculated.<sup>198</sup> The activation energy of the reaction:

is 65.6 kcal mol<sup>-1</sup>, *i.e.*, higher than the activation energy (59.0 kcal mol<sup>-1</sup>) of the reaction:

This implies that NO cannot play the role of a promoter in this reaction. Contrariwise, the activation energy of the reaction

is equal to 37.6 kcal mol<sup>-1</sup>, *i.e.*, it is this reaction that is presumably the promotor in the process. It is believed<sup>198</sup> that in the presence of oxygen this reaction is accompanied by fast conversion:

with the liberation of NO<sub>2</sub>.

Since the formation of C<sub>1</sub>-oxygenates proceeds *via* CH<sub>3</sub>O as an intermediate, these may be formed at ~800 K because the energy barriers of all steps are below 40 kcal mol<sup>-1</sup>. In terms of the hypothetical mechanism, the increase in NO concentration favours a higher yield of CH<sub>2</sub>O with a corresponding decrease in the yield of CH<sub>3</sub>OH, which is consistent with the above-mentioned data for the CH<sub>4</sub>–O<sub>2</sub>–NO system.

Somewhat unexpected results have been reported concerning the effects of nitrogen oxides on incomplete oxidation of methane.<sup>199,200</sup> The experimental conditions were similar to those described.<sup>195,196</sup> In the majority of cases, reaction mixtures contained 55.6% CH<sub>4</sub>, 27.7% O<sub>2</sub>, 0.5% NO<sub>x</sub> and 16.2% He. The reaction was carried out in a quartz reactor with an internal diameter 7 mm and the length of 200 mm at 1 atm, ~800 K and a space velocity of 120 ml min<sup>-1</sup>. The product yields were determined at the same degree of methane conversion (10%). Under these conditions, the reaction of CH<sub>4</sub> with NO<sub>2</sub> in the absence of oxygen yielded predominantly formaldehyde, whereas the reaction with NO yielded no oxidation products at all. The introduction of NO<sub>x</sub> to the system CH<sub>4</sub>–O<sub>2</sub> enabled high selectivity towards formaldehyde (24.5%) and even higher selectivity towards methanol (27.3%), although in all previous studies no methanol was formed at all or it was formed in only trace amounts. Nitromethane CH<sub>3</sub>NO<sub>2</sub> was isolated together with methanol and formaldehyde and its final concentration correlated quantitatively with the initial concentration of added nitrogen oxides.

The effects of various parameters on the temperature of partial oxidation of methane and the product yields have been studied.<sup>199–201</sup> At 0.1 and 5 MPa, the increase in the initial concentration of NO to 1% caused a significant (by ~100 K) reduction of the reaction temperature, although the maximum degree of methane conversion did not change. However, further increase (up to 1.5%) of NO concentration had no effect. At the indicated pressure, the selectivity towards oxygenates (methanol, formaldehyde, nitromethane) reached a maximum at [NO] ≈ 0.5%, which is considered as the optimum concentration. The selectivity towards ethane dropped down quickly to a nearly zero level with the increase in the NO concentration. Dilution of the reaction mixture with helium, at least to the concentration of 60%, had little effect. Even the dependence of the product yields on such a critical parameter as the CH<sub>4</sub>:O<sub>2</sub> ratio shows that the yields of methanol and formaldehyde did not change appreciably with the increase in this ratio to 10 despite the presence of a maximum around CH<sub>4</sub>:O<sub>2</sub> = 2. At CH<sub>4</sub>:O<sub>2</sub> < 2, the yield of methanol decreased with a concomitant increase in the yield of formaldehyde. However, neither the increase in the space velocity (from 1000 to 4000 h<sup>-1</sup>), nor the addition of water (up to 16%) had any pronounced effect on the yields of oxygenates. On the whole, NO<sub>2</sub> exerted approximately the same effect as NO.

The consistently high yields of methanol (and nitromethane) in a broad range of experimental conditions call into question the arguments put forward by Suzuki *et al.*<sup>199–201</sup> as a plausible reason for the considerable discrepancies between their experimental results and those obtained under virtually identical conditions.<sup>195,196</sup> Since these works differ from one another by a large number of parameters, the actual dependence of the product yields on reaction conditions is impossible to establish without the use of kinetic simulation.

As for the mechanism of this reaction, it was suggested<sup>199,200</sup> that the interaction of methane with NO<sub>2</sub> not only favours the generation of radicals, but the nitrogen oxides formed thereupon

promote the formation of an alkoxy radical as the oxygenate precursor:

Supporting evidence in favour of these experimental results<sup>199–201</sup> was obtained in the simulation of  $\text{NO}_x$ -promoted oxidation of methane using a CHEMKIN III software.<sup>202</sup>

It is noteworthy that the beneficial effect of  $\text{NO}_x$  promotion is manifested exclusively at low pressures, whereas at pressures above 1 MPa this effect is less pronounced.<sup>201</sup> Thus at 1 MPa, the decrease in the reaction temperature at 4% methane conversion did not exceed 25 K. The selectivity towards oxygenates did not depend on  $\text{NO}_x$  concentration, while the selectivity towards methanol in the absence of  $\text{NO}_x$  amounted to 30%. This suggests that promotion makes no sense at pressures above 1 MPa. This is consistent with the hypothesis according to which the role of promotion in this reaction becomes insignificant when the oxidation process goes to the branched-chain regime with an increase in pressure.<sup>8</sup> This circumstance notwithstanding, the catalytic effect of  $\text{NO}_x$  on oxygenate formation at high pressures is likely. The same group of investigators<sup>203</sup> demonstrated the possibility of a slight increase in the yield of methanol in the system  $\text{CH}_4\text{--O}_2\text{--NO}$  ( $T = 550^\circ\text{C}$ ,  $P = 0.4$  MPa) due to a virtually complete conversion of formaldehyde upon introduction of a catalyst ( $\text{Cu--ZnO/SiO}_2$ ).<sup>203</sup>

Partial oxidation of methane upon combined use of nitrogen(I) oxide and a heterogeneous catalyst has been described.<sup>204</sup> In such reactions, the catalyst usually fulfils several functions: not only does it induce the generation of radicals and catalyse the formation of the reaction products, but it also favours their subsequent decomposition. Separation of these functions was effected with NO as a radical promoter, subsequent reaction was carried out over  $\text{V}_2\text{O}_5/\text{SiO}_2$  with small specific surface ( $\sim 1\text{ m}^2\text{ g}^{-1}$ ). Low decomposition rates of the partial oxidation products over this catalyst enabled a much higher yield (7%) of the  $\text{C}_1$  oxygenates (methanol and formaldehyde) than over catalysts with well-developed surfaces. In more recent studies,<sup>205</sup> the total yields of oxygenates were even higher (up to 16%), which can be considered as the maximum level currently attainable.

Although in the majority of studies devoted to the promotion of methane oxidation by nitrogen oxides at atmospheric pressure, the total yields of oxygenates did not exceed 4%–7%, it was reported<sup>206</sup> that their yields were 11% upon methane oxidation, 16% upon methane oxidation in the presence of trace amounts (0.7%) of ethane and 24% upon ethane oxidation. However, in contrast to the studies<sup>204,205</sup> where methanol was formed as the main product, in the latter case it was formaldehyde that was virtually exclusively formed.

### 3. Physical methods for promoting oxidative conversions of lower alkanes

Oxidative processes are promoted not only by chemical, but also by physical methods, in the first place, by electric discharge, plasma and molecular beams. Gas-discharge plasma is widely used for the initiation of chemical reactions, which can be exemplified by direct conversion of methane into acetylene upon thermal arc discharge. This method developed 50 years ago is also employed for the production of  $\text{H}_2$ . The possibility of applying non-equilibrium plasma to low-temperature conversion of methane into synthesis gas, oxygenates and higher hydrocarbons is under intensive study. The creation of non-equilibrium plasma is an effective approach to promoting chemical reactions due to interaction of electrons and ions accelerated in the electric field with molecules and radicals. In contrast to heterogeneous catalysis, such a promotion occurs in the bulk of the reactor. Plasma is generated using different kinds of electric discharges, *e.g.*, corona, electric arc, barrier, glow, microwave, pulsed, *etc.* In some studies, this technique was used in combination with heterogeneous

catalysis. Taking into account the tremendous number of investigations in this area, here we shall confine ourselves to the consideration of only some of the most recent studies.

Corona discharge was successfully employed for efficient preparation of synthesis gas and  $\text{C}_2$  hydrocarbons from methane and air.<sup>207</sup> The effects of various parameters (*e.g.*,  $\text{CH}_4:\text{O}_2$  ratio, addition of ethane, dilution with inert gases, residence time, power and frequency of the discharge, the pulse form) on the reaction rate were investigated. The conversion of methane and of oxygen increased with an increase in the discharge power, but decreased with the increase in the  $\text{CH}_4:\text{O}_2$  ratio, flow rate and interval between the pulses. In the absence of oxygen, the degree of methane conversion did not exceed 3%, *i.e.*, under these conditions, as in the case of the barrier discharge, methane did not undergo any conversions. This is apparently associated with the low average electron energy of the barrier discharge equal to 5 eV, which is sufficient for the formation of negative oxygen ions, but insufficient for the activation of methane having the ionisation potential of  $> 12$  eV. Negative oxygen ions activate methane, likely owing to abstraction of hydrogen atoms and formation of methyl radicals. Hydrogen and ethane are formed as a result of discharge-induced conversion of pure methane. The minimum energy required for the conversion in a methane–air system at the optimum discharge frequency of 300 Hz is 21 eV per carbon atom.

The selectivity towards ethane upon discharge-induced oxidative methane dimerisation was inversely proportional to methane conversion; subsequent dehydrogenation of ethane yielded ethylene and acetylene. The degree of discharge-induced conversion of ethane added to the reaction mixture is more than fivefold larger than that of methane due to the lower activation energy for hydrogen abstraction from this molecule.<sup>207</sup>

The addition of water vapour significantly enhanced the conversion of methane and oxygen and increased the efficiency in energy at low  $\text{O}_2$  content. At a  $\text{CH}_4:\text{O}_2$  ratio of 5:1, the increase in the concentration of water vapour from 0% to 50% reduced power consumption per methane molecule in the corona discharge from 68 to 13 eV. The percentage of the reaction products showed a stronger dependence on the composition of the gas mixture than on the discharge power or frequency.<sup>208</sup>

Joint conversion of two essential greenhouse gases, *viz.*,  $\text{CH}_4$  and  $\text{CO}_2$ , *e.g.*, by dimerisation of methane in the presence of  $\text{CO}_2$ , is a promising trend in plasmachemistry. This problem has been documented in numerous publications. Thus the use of pulsed microwave discharges in a flow of the reactants  $\text{CH}_4:\text{CO}_2 = 1.5:1$  ( $200\text{ ml min}^{-1}$ ) at ambient pressure and the microwave amplitude of 120 W enabled virtually equal (70%) degrees of conversion of  $\text{CH}_4$  and  $\text{CO}_2$  with the selectivities in CO,  $\text{C}_2\text{H}_2$  and  $\text{C}_2\text{H}_4$  of 75%, 17.8% and 4.1%, respectively.<sup>209</sup> The  $\text{H}_2:\text{CO}$  ratio in the reaction products was 1.5.

Joint conversion of  $\text{CH}_4$  and  $\text{CO}_2$  into synthesis gas as well as methane conversion into acetylene was carried out using different types of pulse discharge.<sup>210</sup> The reactions were performed at atmospheric pressure in the absence of catalysts. The analysis of the reaction products and selectivities of their formation revealed that the chemical features of the processes varied widely depending on the discharge type. The compositions and ratios of the compounds formed in the methane plasma depended critically on the pulse energy.  $\text{C}_2\text{H}_6$  was almost exclusively formed at low energies, as the energy increased, the reaction products contained also  $\text{C}_2\text{H}_4$  and  $\text{C}_2\text{H}_2$ , while at high energies  $\text{C}_2\text{H}_2$  became the predominant and then the only plasmachemical reaction product.

The low temperature of the process, lack of thermodynamic restrictions and possibility of achieving the required  $\text{H}_2:\text{CO}$  ratios by simply varying the  $\text{CH}_4:\text{CO}_2$  ratio in the original mixture, are the attractive features for the production of synthesis gas by  $\text{CH}_4$  and  $\text{CO}_2$  conversion in non-equilibrium plasma. The  $\text{H}_2:\text{CO}$  ratio is virtually independent of the reactor temperature or the specific power of the electric discharge. The maximum degree of conversion of  $\text{CH}_4$  and  $\text{CO}_2$  ( $> 70\%$  and  $> 60\%$ ,

respectively) was reached at the specific energy of the discharge of 60–70 kJ litre<sup>-1</sup>. This value obtained in the electrode discharge<sup>210</sup> was much lower than that in the dielectric barrier discharge, which was probably less efficient in the conversion of electrical energy into chemical energy. Nevertheless, low efficiency of this conversion (nearly two orders of magnitude lower than in the thermal arc discharge) is the main obstacle to the practical application of non-equilibrium plasma for conversion and reforming of methane.

The potential of different devices making use of gas discharge (plasmotrons) in the production of synthesis gas in combined oxidative-steam reforming of methane was compared with that of thermal processes.<sup>211</sup> Although the use of plasmotrons enables a nearly complete conversion of methane at relatively low temperatures (820–900 K) and much lower capital investments (~65 per 1 m<sup>3</sup> H<sub>2</sub> per hour) in comparison with processes conducted in chemical reactors (750–900 per 1 m<sup>3</sup> H<sub>2</sub> per hour), the overall economic assessments are not in favour of plasmochemical technologies. The cost of hydrogen exceeds that produced in conventional reactors 3–5-fold. Therefore, such attractive features of plasmochemical reactors as simple and compact design and low cost can only find application in the design of small-sized units, e.g., for hydrogen fuel cells in motor vehicles.

Direct conversion of methane into C<sub>2</sub> hydrocarbons was studied in cold plasma in the presence of catalysts at 20 °C and at ambient pressure.<sup>212</sup> The effects of such factors as the reactor shape, input power, flow rate, the N<sub>2</sub>:CH<sub>4</sub> ratio and catalyst type, on the selectivity towards these hydrocarbons were investigated. The selectivity was above 98% at a methane conversion of up to 60%, i.e., the yields of these hydrocarbons exceeded 50%. V<sub>2</sub>O<sub>5</sub> manifested the highest efficiency among the catalysts assayed. Since the ordinary catalysts of oxidative dimerisation of methane did not manifest any activity in the plasmochemical process, the role of a catalyst under cold plasma conditions was considered to differ from that in oxidative dimerisation.<sup>212</sup> This consists of fast recombination of radicals generated in the plasma and rapid desorption of H<sub>2</sub> and C<sub>2</sub> hydrocarbons from the surface, which likely prevents the formation of higher hydrocarbons. The combined effect of microwave irradiation and a catalyst on the conversions of methane into hydrogen, synthesis gas, acetylene and carbon has been studied<sup>213</sup> with special reference to direct microwave excitation of separate grains of the catalyst and electric discharge in the gas near the catalyst surface.

The majority of approaches to the conversion of hydrocarbons by plasmochemical methods envisage, in one way or another, the attainment of equilibrium concentrations of the reaction products, at least in the discharge zone. However, due to the non-selectivity of the discharge action (and often due to multiple cleavage and recombination of the same bonds), the transformation of even one molecule requires very high energy that exceeds significantly that of the chemical bonds that undergo transformations. Taking into account the real efficiency factor of transformation of the primary energy into the high-potential discharge energy, the energetic and, as a consequence, the economic value of the matter remains inadmissibly high. The use of plasmochemical methods for potent promoting effects on non-equilibrium chemical systems, e.g., branched-chain processes including those coupled with heterogeneous catalysis, seems to hold much more promise in this respect. Here one can expect significant changes in the chemical behaviour of systems upon relatively weak energetic impact.

#### 4. Catalytic oxidation of methane to methanol

Both heterogeneous-catalytic and homogeneous oxidation of methane to methanol have been the subject of active investigations over the past 100 years. Studies by Nalbandyan, Mukhlenov, Gomonaya *et al.* (for details see Ref. 8) demonstrated high selectivity of these reactions (which in some cases amounted 100%!), attained however at low degrees of conversion. Methanol and formaldehyde formed in yields > 3%–4% under conditions

of essentially heterogeneous mechanism of the process. Our studies have shown<sup>190, 191</sup> that the generation of methyl radicals in the presence of catalysts is a characteristic feature of mechanisms of catalytic oxidation of methane to methanol, formaldehyde and ethylene. Their subsequent conversions in the gas phase or over the surface yield the reaction products. The highest yields of CH<sub>3</sub>OH and CH<sub>2</sub>O were 2%–4% and those of C<sub>2</sub> hydrocarbons were ~25%. A scheme of radical-chain oxidation of methane was proposed to rationalise these yields.<sup>8, 190, 191</sup>

The so-called reductive activation where the oxidation is carried out by an H<sub>2</sub>+O<sub>2</sub> mixture or H<sub>2</sub>O<sub>2</sub> is a novel procedure for converting methane to methanol. Apparently, the oxidation involves the OH radicals generated. The selectivity towards methanol formed from the CH<sub>4</sub>+O<sub>2</sub>+H<sub>2</sub> mixture over Fe<sub>0.5</sub>Al<sub>1.5</sub>O<sub>3</sub> at > 330 °C and atmospheric pressure was 28% at the degree of conversion of 0.4%–1.5%.<sup>214</sup> The IR spectra recorded over the catalyst surface *in situ* manifested the presence of peroxide adsorption bands at 895 cm<sup>-1</sup>. In the absence of hydrogen, formaldehyde was formed at *T* > 530 °C in small amounts. It is suggested that the role of the active site is played by the Fe(III) ion with tetrahedral coordination:

Iron derivatives were found to be the most selective catalysts in the partial oxidation of methane to methanol. The selectivity towards CH<sub>2</sub>O over FePO<sub>4</sub> (2%–16%) supported over Al<sub>2</sub>O<sub>3</sub>, ZrO<sub>2</sub> and TiO<sub>2</sub> reached 63% at low degrees of conversion; the reaction over FePO<sub>4</sub>/SiO<sub>2</sub> gave additionally CH<sub>3</sub>OH.<sup>215</sup> In the authors' opinion, the high selectivity of this catalyst can be attributed to the formation of pentacoordinate Fe as can be evidenced from the pattern of the Mössbauer spectra.

Iron molybdate over a mesoporous support (MSM-41) was more selective in the oxidation of methane by N<sub>2</sub>O in CH<sub>2</sub>O and CH<sub>3</sub>OH (300–500 °C) than non-supported FePO<sub>4</sub> (see Ref. 216). The oxidation of methane by oxygen proceeded with 60% selectivity and afforded CH<sub>2</sub>O and CO (yields 1%–2%). The selectivity towards CH<sub>3</sub>OH and CO<sub>2</sub> increased when N<sub>2</sub>O was used instead of O<sub>2</sub> in the oxidation of methane over V<sub>2</sub>O<sub>5</sub>.<sup>217</sup>

In a series of investigations,<sup>218–220</sup> the oxidation of methane to methanol was carried out over Pd powder dissolved in oleum. The yield of methanol reached 20%. The following reactions took place:

The oxidation of methane to methanol with a H<sub>2</sub>SO<sub>4</sub>+SO<sub>3</sub> mixture in the presence of mercury salts was carried out at 150–200 °C and at CH<sub>4</sub> pressures of 4–10 MPa; the yields were up to 39%.<sup>221</sup> The yield of methanol increased with the increase in both pressure and temperature.

The yield of CH<sub>3</sub>OH in the oxidation of a CH<sub>4</sub>+O<sub>2</sub>+NO mixture also increased in the presence of Cu–ZnO/Al<sub>2</sub>O<sub>3</sub>.<sup>222</sup> This process involved several reactions: 1) formation of CH<sub>3</sub>OH from CH<sub>2</sub>O and H<sub>2</sub>; 2) conversion of water gas at 350 °C and higher temperatures; 3) selective oxidation of methane with an O<sub>2</sub>+NO mixture at 550 °C. At 5.5% conversion, the selectivity towards CH<sub>3</sub>OH was 39%.

In addition to the ongoing studies into the mechanism of this reaction, the possibility of increasing the yields of methanol and other oxygenates is being studied under various reaction conditions. Two of the most obvious trends include the maintenance of constant (or quasi-constant) low concentrations of oxygen in the course of the reaction and continuous or periodic elimination of the target products from the reaction zone (or their binding).

The feasibility of countercurrent adsorption of the reaction products was studied under laboratory conditions using the so-

called Simulated Countercurrent Moving Bed Chromatographic Reactor (SCMCR) previously developed for the oxidative dimerisation of methane.<sup>223</sup> This method has been used for the isolation of methanol in the partial homogeneous oxidation of methane.<sup>181</sup> The nonconsumed methane was separated from the reaction products by consecutive cyclic switching of the gas flow from the homogeneous reactor to one of the three parallel chromatographic columns filled with an adsorbent. Then the column was blown with helium and desorbed methane and carbon oxides were injected into the reactor. After that, liquid products (methanol and water) were collected from the reactor outlet. To a certain extent, such a system simulated the operation of a reactor with a countercurrent adsorbent, its substantial difference being that the optimisation of oxidation and adsorption–desorption was performed under different conditions and the choice of the adsorbent was arbitrary. A typical adsorbent for such a system is, *e.g.*, Supelcoport (80/100 mesh) impregnated with 10% (w/w) Carbowax. However, direct extrapolation of this technology to industrial conditions is hardly justified due to its complexity and vast expenditure of the purge gas. Nevertheless, it presents interest as an illustration of combined application of DMTM and adsorptive methods. Under optimum conditions ( $P = 10$  MPa,  $T = 477$  °C,  $\text{CH}_4:\text{O}_2 = 16.3$ ), the selectivity towards methanol in this cyclic process was 50% at 50% conversion, which corresponds to 25% yield of methanol.

Studies of ‘ $\alpha$ -sites’ of Fe-containing zeolites that can be involved in methane activation are currently underway.<sup>224–227</sup> According to data from Mössbauer spectroscopy, such a site consists of oxygen (the so-called  $\alpha$ -oxygen) bound to two Fe atoms. Such an active site effects the catalytic oxidation of benzene into phenol by  $\text{N}_2\text{O}$ . Zeolite Fe–ZSM-5 manifests higher reactivity in comparison with Fe-mordenite, Fe-chabazite and Fe–CIT-5. It was found that  $\alpha$ -sites are formed upon thermal activation of the zeolite and their formation involves Fe atoms protruding from the lattice. Presumably, they are localised in the intersection points of zeolite Fe–ZSM-5 channels and their maximum concentration is virtually the same as that of the intersection points of zeolite channels ( $\sim 10^{19} \text{ g}^{-1}$ ). The properties of  $\alpha$ -sites are similar to those of the free-radical species  $\text{O}^-$ .

The reaction of methane with the  $\alpha$ -sites of Fe-containing zeolites yields methanol:

and occurs at a very fast rate even at  $-30$  °C, but is not catalytic. Heating causes decomposition of methanol and release of CO and  $\text{H}_2$  into the gas phase. Methane reacts with  $\alpha$ -oxygen in a stoichiometric ratio 1:1.8. Heating of the zeolite results in the release of the excess oxygen in the form of  $\text{O}_2$ .

Kinetic simulation of the hydroxylation of methane to methanol under the action of methane monooxygenase and Fe-containing complexes has been carried out.<sup>228</sup> The activation proceeded *via* pentacoordinate carbon. Binuclear sites  $\text{Fe(III)}-\text{O}-\text{Fe(III)}$  played the role of active sites.

In summary, it may be said that novel promising catalytic reactions have recently been developed for the oxidation of methane to methanol, particularly, with the involvement of alternative oxidants ( $\text{N}_2\text{O}$ ,  $\text{H}_2\text{O}_2$ ,  $\text{H}_2 + \text{O}_2$ ). Many of these reactions are catalysed by Fe-containing oxides or zeolites. The highest yields (up to 40%–50%) are achieved in a liquid-phase procedure developed by Catalytica Ltd. for the oxidation of methane to methanol. In this procedure, Hg, Pt and Pd salts are used as catalysts and concentrated  $\text{H}_2\text{SO}_4$  is used as an oxidant.<sup>218</sup>

### 5. Catalytic oxidation of methane to formaldehyde

Similar to the oxidation of methane to methanol, the yields in the oxidation of methane to formaldehyde pass through a maximum that amounts to 2%–4%. In our studies,<sup>190,191</sup> the existence of maximum yields was interpreted in terms of a heterogeneous–homogeneous mechanism that involves the intermediate formation of methyl radicals released into the gas phase. The selectivity

of this reaction at low ( $\sim 2\%$ ) degrees of conversion may reach 100%.

Selective (or relatively selective) catalysts usually contain oxide forms of several elements, *e.g.*, V, Si, Mo and Fe. The addition of a minor amount of Co enhances the activity and selectivity of partial oxidation, but a large amount brings about deep oxidation of methane. The analysis of IR spectra recorded in the interaction of oxidised surfaces  $\text{MoO}_3(100)$  and  $\text{MoO}_3(110)$  with methane revealed the formation of  $\text{CH}_3\text{O}$  groups;<sup>229</sup> their decomposition yielded the radicals  $\text{CH}_3$ .

The reactions of methyl radicals generated upon decomposition of azomethane over  $\text{V}_2\text{O}_5/\text{SiO}_2$ , which affords high yields of formaldehyde, were used to study the heterogeneous–homogeneous mechanism of partial oxidation of methane to oxygenates.<sup>213</sup> The formation of  $\text{CH}_3\text{O}^-$  groups upon introduction of the  $\text{CH}_3$  radicals was established by IR spectroscopy. According to EPR data, under these conditions  $\text{V}^{5+}$  is reduced to  $\text{V}^{4+}$ . The  $\text{CH}_3\text{O}$  groups can further be converted into  $\text{CH}_2\text{O}$  or react with  $\text{H}_2\text{O}$  to give  $\text{CH}_3\text{OH}$ . The formation of methanol at 300 °C and of formaldehyde at 400 °C over  $\text{V}_2\text{O}_5/\text{SiO}_2$  (*i.e.*, at lower temperatures than over  $\text{V}_2\text{O}_5$ ) suggests possible involvement of the interactions of  $\text{CH}_3\text{O}^-$  with water or surface OH groups, which increases the yields of  $\text{CH}_3\text{OH}$ . Thus, the main reactions are as follows:

The oxidation of methane to formaldehyde over  $\text{SiO}_2$  and  $\text{V}_2\text{O}_5/\text{SiO}_2$  has been studied.<sup>230–236</sup> The yield of  $\text{CH}_2\text{O}$  over  $\text{SiO}_2$  was increased to 15%–25% where the reaction was carried out in a recycling system at 650–690 °C. In the authors’s opinion,<sup>232</sup> the oxidation to  $\text{CH}_2\text{O}$  occurred due to the presence of reduced sites on  $\text{SiO}_2$ . The 5%  $\text{V}_2\text{O}_5/\text{SiO}_2$  catalyst exceeded pure  $\text{SiO}_2$  in activity, but was less selective. The yield of  $\text{CH}_2\text{O}$  over this catalyst was 16.1%–24.6% at 670 °C, the selectivity was 30.1%–56%, while the efficiency was 240 g per kg of the catalyst per hour. No deactivation of the catalyst was observed over 3000 h.

The mechanism of partial oxidation of methane to formaldehyde over the same catalyst ( $\text{V}_2\text{O}_5/\text{SiO}_2$ ) was studied *in situ* using Raman spectroscopy.<sup>237,238</sup> At low concentrations of  $\text{V}_2\text{O}_5$ , the activity of the catalyst increased linearly with the increase in vanadium content. This suggests that the role of active sites is played by isolated  $\text{V}^{5+}$  ions. The Raman spectra recorded after the termination of the reaction demonstrated that no reduction of vanadium took place. The stability of  $\text{V}^{5+}$  is the main reason for the high selectivity towards  $\text{CH}_2\text{O}$ . The unique properties of  $\text{SiO}_2$  as a support were attributed to its low acidity, which favours deep oxidation.

The oxidation of methane to formaldehyde over  $\text{V}_2\text{O}_5/\text{SiO}_2$  was studied in a recycling reactor at 570–630 °C with freezing-out. At the degree of conversion of  $\text{CH}_4$  of 89%, the selectivity remained at the level of 56%, and the yield of  $\text{CH}_2\text{O}$  amounted to  $\sim 50\%$ . Without recycling, the yield was 2% in a single run.

The oxidation of methane to the oxygenates  $\text{CH}_2\text{O}$  and  $\text{CH}_3\text{OH}$  in the presence of water vapour was studied at 600 °C using  $\text{MoO}_3/\text{SiO}_2$  as a catalyst.<sup>239</sup> The increase in water vapour pressure enhanced the selectivity towards oxygenates, while the selectivity towards CO and  $\text{CO}_2$  decreased. This was attributed to the formation of silicomolybdic acid ( $\text{H}_4\text{SiMo}_{12}\text{O}_{40}$ ) on the surface of  $\text{SiO}_2$  (IR spectroscopic data). In the absence of water vapour, the acid is decomposed at 600 °C. In the presence of 60%  $\text{H}_2\text{O}$ , the conversion of  $\text{CH}_4$  was 25%, while the selectivity towards the target products was as high as 90%. Stable conversion of methane lasted 350 h at the optimum value of the  $P_{\text{CH}_4}:P_{\text{O}_2} = 3:2$  ratio.

A comparison of the catalytic properties of Mo–ZSM-5 (0.3%–3.0% Mo) and H–ZSM-5 revealed<sup>240</sup> that the former

was more reactive, while the latter was more selective in the oxidation of CH<sub>4</sub> to CH<sub>2</sub>O. At 600 °C, the selectivity towards formaldehyde over Mo–ZSM-5 was 10.6% at the 6.5% conversion of CH<sub>4</sub>.

SiO<sub>2</sub>-supported molybdates of various metals were used as catalysts in this reaction.<sup>241</sup> Rb<sub>2</sub>MoO<sub>4</sub>/SiO<sub>2</sub> manifested the highest activity at 580–660 °C. CO, H<sub>2</sub>, CH<sub>2</sub>O, C<sub>2</sub>H<sub>6</sub> and CO<sub>2</sub> were produced over this catalyst. The maximum amount of CH<sub>2</sub>O was formed over MoO<sub>3</sub>/SiO<sub>2</sub>. Thus at 550 °C the selectivity was 20%–30% at the conversion of 3%–5%. A mechanism was proposed implying the involvement of surface O<sup>–</sup> sites and the reduction of Mo<sup>6+</sup> to Mo<sup>5+</sup>.

A relatively high yield of formaldehyde was obtained upon oxidation of methane over W–ZSM-5 (0.3%–11.9% W) at 650 °C.<sup>242,243</sup> The selectivity towards CH<sub>2</sub>O reached 11.0% at the 51.2% conversion. The formation of WO<sub>3</sub> monomers, octahedral polymers and WO<sub>3</sub> crystals was observed on the surface of the catalyst. The W–ZSM-5 catalyst was more selective than MoO<sub>3</sub> and WO<sub>3</sub>.

Partial oxidation of methane was also studied over zeolites containing no transition metals.<sup>244</sup> The oxidation of methane and ethane was carried out over Na–ZSM-5 and H–ZSM-5 at 670–700 °C in a system with CH<sub>2</sub>O and CH<sub>3</sub>OH freezing-out. The selectivity towards CH<sub>3</sub>OH + CH<sub>2</sub>O reached 30% at the 4% conversion. The following oxidation scheme was proposed:

The high efficiency of the H–ZSM-5 catalyst is due the high reactivity of the lattice oxygen as can be judged from the results of <sup>18</sup>O tracer experiments. Hydrogen binds to CH<sub>2</sub>O on the catalyst surface to yield CH<sub>3</sub>OH, while CH<sub>2</sub>O is a direct dehydration product of CH<sub>3</sub>OH. IR spectroscopic studies have shown<sup>245</sup> that the siloxane (Si–O–Si) bonds are involved in partial oxidation of CH<sub>4</sub> over SiO<sub>2</sub>. Probably, these bonds are strained since no signals were observed in the EPR spectra.

Methyl formate can be prepared from methane by a two-step reaction over Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub>, TiO<sub>2</sub>, ZrO<sub>2</sub> and SO<sub>4</sub>/ZrO<sub>2</sub>.<sup>246</sup>

The maximum degree of conversion of CH<sub>2</sub>O over ZrO<sub>2</sub> in the second step (170 °C) was 97% at the selectivity of 94%. The total yield of the reaction product over two steps was 7%–12%, which is one of the highest presently attainable in the oxidation of methane to oxygenates.

## 6. Production of formic acid

Reductive oxidation of the CH<sub>4</sub> + O<sub>2</sub> + H<sub>2</sub> mixture over a heteropolyacid catalyst Pd<sub>0.08</sub>Cs<sub>2.5</sub>H<sub>0.34</sub>PVMo<sub>11</sub>O<sub>40</sub> was proposed for the production of HCOOH from methane.<sup>247</sup> At 150–300 °C, the reaction rate reached 1.2 × 10<sup>–4</sup> mol h<sup>–1</sup> (g cat.)<sup>–1</sup>, *i.e.*, it was 700 times higher than over the previously investigated FePO<sub>4</sub> catalyst. The conversion was 8% at 300 °C, while the selectivity towards formic acid was 60%. The addition of H<sub>2</sub>O accelerated the reaction.

## 7. Production of acetic acid

A new method for the production of acetic acid from methane bypassing the formation of synthesis gas has been developed.<sup>248</sup> In the gas phase, methane undergoes direct oxidation to methanol which is further carbonylated over a supported catalyst.

The conversion of methane per cycle was 6%–12%. Usually, oxygen was consumed totally at temperatures above 400 °C. The reaction was carried out at ~7 MPa. The water vapour formed is utilised for technological purposes. At the indicated pressure and temperatures (200–250 °C), methanol undergoes carbonylation over Pd/C in the presence of CH<sub>3</sub>I to afford CH<sub>3</sub>CO<sub>2</sub>H and CH<sub>3</sub>CO<sub>2</sub>CH<sub>3</sub>. The fact that the catalytic activity is retained over 600 h suggests that the carbonylation takes place in the gas phase. According to estimates, the production cost of acetic acid produced by this method is lower than in conventional procedures.

## IV. Oxidative coupling of methane and related processes

### 1. Oxidative coupling of methane

Oxidative coupling of methane (OCM) resulting in C<sub>2</sub> hydrocarbons was discovered in the early 1980's. A great number of catalysts of this reaction have been investigated; more than 500 relevant papers are cited in the monograph.<sup>8</sup> The most reactive and selective catalysts afford C<sub>2</sub> hydrocarbons in up to 25% yield. The reaction kinetics were studied and the heterogeneous–homogeneous reaction mechanism, which is now universally acknowledged, was developed. However, in recent years the number of publications devoted to oxidative coupling of methane decreased substantially. The principal details of the reaction mechanism are now well established, but economic reasons obviate large-scale production of ethylene by this method.

#### a. Catalysts

The search for novel OCM catalysts is still in progress, but the yields of C<sub>2</sub> hydrocarbons have never exceeded the critical level of ~25%. Active catalysts usually contain oxides of alkaline-earth or rare-earth metals. The OCM reaction over substituted hydroxyapatite Ca<sub>10–x</sub>Pb<sub>x</sub>(PO<sub>4</sub>)<sub>6</sub>(OH)<sub>2</sub> (x = 0.10) was studied at 675–800 °C. This catalyst manifested the highest activity and higher thermal stability than non-substituted Pb-apatite. The maximum yield of C<sub>2</sub> hydrocarbons at 750 °C was 22%.

When OCM was carried out over the active catalyst SrO/La<sub>2</sub>O<sub>3</sub> at 800–850 °C, the maximum conversion of methane was 30.1% at 85.6% selectivity.<sup>249,250</sup> Its catalytic properties were attributed to the basicity of the oxide.

The addition of Na to a 10% PrO<sub>x</sub>/MgO catalyst decreased its activity in OCM, but sharply increased its selectivity.<sup>251</sup> At 750 °C, the conversion was 10.2%, while the selectivity reached 80.2%. The addition of SrF<sub>3</sub> and BaF<sub>2</sub> to Ln<sub>2</sub>O<sub>3</sub> and LnOF (Ln stands for any rare-earth element) resulted in the enhancement of their activities.<sup>252</sup> Presumably, in this case the two phases interact with one another. At 800 °C, the highest yield (19%) was obtained over 50% SrF<sub>2</sub>/Sm<sub>2</sub>O<sub>3</sub>: the conversion was 34%, the selectivity towards C<sub>2</sub> products was 55.8%. In the authors' opinion,<sup>252</sup> the O<sub>2</sub><sup>–</sup> ion on LnOF is the active site in this reaction, as can be evidenced from the appearance of a band at 1090 cm<sup>–1</sup> in the IR spectrum at 750 °C. Its intensity decreased upon interaction of the catalyst with CH<sub>4</sub>.

The addition of Ce to Na/CaO resulted in an eightfold increase in its activity in OCM at 750 °C.<sup>253</sup> The role of active sites was played not only by Na<sup>+</sup>O<sup>–</sup>, but also by peroxides. Cerium oxide enhanced the regeneration of O<sup>–</sup> and Na<sub>2</sub>O<sub>2</sub> active sites.

The selectivity towards C<sub>2</sub> products reached 80% at 10.5% conversion.

α-Al<sub>2</sub>O<sub>3</sub> was found to be the best support for a Pb–Sn–O catalyst.<sup>254,255</sup> At 800 °C, the conversion of methane was 14.9%, the selectivity towards C<sub>2</sub>H<sub>6</sub> was 35.7%, while that towards C<sub>2</sub>H<sub>4</sub> was 15.7%.

Novel active catalysts were prepared from the superacids  $\text{WO}_3/\text{ZrO}_2$  as supports.<sup>256</sup> The latter were impregnated with Eu or Ce together with  $\text{Li}_2\text{CO}_3$  or with Ce or Mn together with NaCl. The former manifested long-lasting (100 h) albeit moderate activities (the yield of  $\text{C}_2$  was 18%), while the latter manifested exceptionally high activity (the product yields were >30%), but rapidly deactivated.

$\text{Mn}/\text{Na}_2\text{WO}_4/\text{SiO}_2$  was found to be one of the most active catalysts,<sup>257</sup> which retained stability for 97 h.  $\text{Mn}/\text{Na}_2\text{WO}_4/\text{MgO}$  was less stable: its activity decreased gradually due to the presence of a hot spot. The hot spot temperature exceeded the temperatures in other parts of the layer by 150 °C. A series of novel efficient catalysts, *viz.*,  $\text{SiO}_2$ -supported  $\text{Mn}(\text{NO}_3)_2$  and  $\text{Y}_2\text{WO}_4$  or  $\text{X}_2\text{MoO}_4$  ( $\text{X} = \text{Li}, \text{Na}, \text{K}, \text{Rb}, \text{Cs}$ ;  $\text{Y} = \text{K}$  and  $\text{Ca}$ ), were prepared.<sup>258–260</sup> The alkali oxide decreased the quartz  $\rightarrow$   $\alpha$ -cristobalite transition point, which is prerequisite for the preparation of active and stable catalysts. The active sites of the supported tungsten catalyst contained W–O clusters stabilised by alkalis. K/W/Mn and Rb/W/Mn were the systems of choice. In the authors' opinion,<sup>260</sup> the tetrahedral coordination of tungsten on the surface is a prerequisite for the manifestation of catalytic activity. The maximum yield of the  $\text{C}_2$  products (29.0% at 66.6% selectivity) was achieved over  $\text{K}_2\text{WO}_4\text{--Mn}/\text{SiO}_2$  at 800 °C. At high temperatures, the  $\text{Na}_2\text{WO}_4/\text{SiO}_2$  catalyst was also active in the absence of Mn.<sup>261</sup>

$\text{C}_2$  Hydrocarbons can be prepared from methane over  $\text{MgO}/\text{C}$  and  $\text{Sm}_2\text{O}_3/\text{C}$  catalysts in the presence of  $\text{N}_2\text{O}$  as an oxidant.<sup>262</sup> Without  $\text{N}_2\text{O}$ , the conversion of  $\text{CH}_4$  at 850 °C was very low, while in its presence the conversion over  $\text{MgO}/\text{C}$  and  $\text{Sm}_2\text{O}_3/\text{C}$  reached 21.2% and 21.3%, respectively. The selectivity towards  $\text{C}_2\text{H}_6$  in the presence of  $\text{N}_2\text{O}$  increased to 80% at 12% conversion. Hydroxyapatite was used as a catalyst in  $\text{N}_2\text{O}$ -assisted OCM.<sup>263</sup> At 700–750 °C, the selectivity towards the products reached 80% at 80% conversion of  $\text{N}_2\text{O}$  and at ~4% conversion of  $\text{CH}_4$ . At Mn:Si = 0.1, the selectivity towards  $\text{C}_2$  was 88%, the yield was 4.5%.

A combination of  $\text{MnO}_x$  and  $\text{SrCO}_3$  allows one to prepare a selective catalyst for OCM<sup>264</sup> with  $\text{CO}_2$  as an oxidant. The activation of  $\text{CO}_2$  and methane includes the electronic transitions  $\text{Mn}^{2+} \rightleftharpoons \text{Mn}^{3+} + e^-$ .

## b. Mechanism

The Lansford catalyst ( $\text{Li}/\text{MgO}$ ) for OCM was studied by X-ray phase analysis, XPS, EXAFS and XANES (X-Rays Absorption Near Edge Structure).<sup>265</sup> At the concentration <2.5%, lithium penetrated into the bulk of  $\text{MgO}$  as a result of which its crystallinity diminished. Defects in the near-surface layers of  $\text{MgO}$  and  $\text{Li}/\text{MgO}$  are detected after termination of the reaction. The  $\text{Li}/\text{MgO}$  catalyst manifested much higher activity in OCM than  $\text{MgO}$ .

Studies of OCM over  $\text{Na}_2\text{O}/\text{CaO}$  by conductivity and contact potential difference methods showed<sup>266</sup> that  $\text{Na}_2\text{O}$  induced appearance of anionic vacancies in the  $\text{CaO}$  lattice. These vacancies can be localised on the surface and thus decrease the selectivity towards  $\text{C}_2$  products. Experiments with TAP reactors revealed<sup>267</sup> that enhanced activity of  $\text{Na}_2\text{O}/\text{CaO}$  in OCM reflected the low degree of saturation of its surface with oxygen. A kinetic scheme that takes into account only surface reactions was proposed.

The use of Raman spectroscopy for the study of oxidative coupling of methane over  $\text{Nd}_2\text{O}_3$ ,  $\text{BaO}$  and  $\text{BaX}_2$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}$ ) revealed the presence of various oxygen species ( $\text{O}^{2-}$ ,  $\text{O}_2^-$ ,  $\text{O}_3^{2-}$ ,  $\text{O}_2^{\delta-}$  and  $\text{O}^-$ ).<sup>268</sup> The radical ions  $\text{O}_2^-$ ,  $\text{O}_2^{\cdot-}$  and  $\text{O}_3^{\cdot-}$  were also detected in the oxidative coupling of methane over  $\text{BaCO}_3/\text{LaOF}$  and  $\text{Th--LaO}_x/\text{BaCO}_3$  catalysts using the same method (see

Ref. 269).<sup>270</sup> The radical ions  $\text{O}_2^{\cdot-}$  are formed in the presence of large amounts of carbonates. In this state, oxygen is an intermediate species in OCM. The  $\text{O}_2^-$ ,  $\text{O}_2^{\cdot-}$  and  $\text{O}_3^{\cdot-}$  ions are stabilised in anionic vacancies. A reactive oxygen precursor induces abstraction of hydrogen from  $\text{CH}_4$  to be converted into  $\text{OH}^-$  and  $\text{O}_2^-$ , or add an electron from the oxide lattice to yield the  $\text{O}^{2-} + \text{O}^-$  couple.

The radical anions of  $\text{O}_2$  were also detected in the study of OCM over  $\text{LaOF}$  and  $\text{BaF}/\text{LaOF}$  by IR spectroscopy *in situ*.<sup>271</sup> The  $\text{O}_2^{\cdot-}$  ions formed in the presence of oxygen react with  $\text{CH}_4$  to give  $\text{C}_2\text{H}_6$ . It was thus concluded that the  $\text{O}_2^{\cdot-}$  radicals rather than  $\text{O}^-$  species that have not been detected played the role of active sites in the oxidative coupling of methane.

A detailed kinetic model of OCM involving heterogeneous and homogeneous reactions has been described.<sup>272</sup> The calculations were carried out for one of the most well-studied OCM catalysts, *viz.*,  $\text{Li}/\text{MgO}$ , at 650–700 °C,  $\text{CH}_4:\text{O}_2 = 2-12$ , 200–1000 kPa and at the degree of  $\text{CH}_4$  conversion of 10%–100%. This model comprised 10 catalytic and 39 gas-phase reactions. Some values of the constants for the elementary steps were taken from another study.<sup>126</sup> The model allowed a qualitative description of the pronounced increase in the degree of methane conversion with the increase in pressure from 200 to 1000 kPa. Under these conditions, the catalyst not only generated  $\text{CH}_3$  radicals, but also acted as a radical trap. Presumably, the recovery of the active sites occurred through desorption of  $\text{H}_2\text{O}$ . Over  $\text{Li}/\text{MgO}$  the degree of conversion of the  $\text{CH}_4 + \text{O}_2$  mixture at atmospheric pressure amounted to about 90%, while over  $\text{Sn}/\text{Li}/\text{MgO}$  it was only ~30%. According to this scheme, the conversion of methane into  $\text{C}_2$  hydrocarbons is limited by heterogeneous-catalytic oxidation of  $\text{CH}_3$  (see Ref. 273) rather than by gas-phase reactions. The reactions

occur on the surface of  $\text{Li}/\text{MgO}$ .

The symbol  $[\bullet]$  designates the free-radical state.<sup>272</sup>

Valuable information for the elucidation of the mechanism of oxidative coupling of methane can be derived from the study<sup>274</sup> devoted to the formation of methyl radicals on the surface of  $\text{O}/\text{Mo}(110)$ . Injection of oxygen onto the  $\text{Mo}(110)$  surface resulted in the formation of a two- or three-dimensional oxide layer. Subsequent injection of methane vapour resulted in the formation of  $\text{CH}_3\text{O}^-$  fragments, which retained stability at temperatures up to 200 °C over two-dimensional layers and withstood temperatures up to 430 °C over three-dimensional layers. At higher temperatures, the decomposition of  $\text{CH}_3\text{O}^-$  afforded  $\text{H}_2$  and  $\text{CH}_3$ . This prompted a conclusion that methyl radicals are generated from  $\text{CH}_4$  upon oxidative coupling of methane which proceeds *via* the methoxyl radical.

Using HREELS (High Resolution Electron Energy Loss Spectroscopy) and DSE (Diffraction of Slow Electrons), it was shown that it is the  $\text{Mo--CH}_3$  layer rather than the  $\text{Mo--OCH}_3$  layer that was formed as a result of injection of the methyl radicals onto the oxidised facet of  $\text{Mo}(100)\text{--O}$  (the degree of coverage was 0.8).<sup>275</sup> Decomposition of  $\text{Mo--CH}_3$  yielded  $\text{Mo=CH}_2$  and  $\text{OH}$  groups as could be evidenced from the results of spectral analysis.

A comparison of the results obtained in experiments where OCM was carried out in empty reactors and in reactors filled with  $\text{CaO}$ ,  $\text{La}_2\text{O}_3/\text{CaO}$  or  $\text{SrO--La}_2\text{O}_3/\text{CaO}$  led the authors to conclude<sup>276</sup> that the reason for the enhanced yields of the reaction products is the inhibition of the gas-phase oxidation due to quenching of free radicals that play the role of chain carriers in gas-phase reactions. At  $T > 750$  °C, the intensity of inhibition and the yields of  $\text{C}_2$  hydrocarbons decrease in the order:  $\text{SrO--La}_2\text{O}_3/\text{CaO} > \text{La}_2\text{O}_3/\text{CaO} > \text{CaO}$ , which parallels the order of basicities of the oxides. The role of the  $\text{La}_2\text{O}_3$  component

of the catalyst consists of quenching  $\text{CH}_3$  radicals or oxidation of  $\text{CO}$ , while that of  $\text{CaO}$  is dehydrogenation of  $\text{C}_2\text{H}_6$  and that of  $\text{SrO}$  is inhibition of the gas-phase oxidation of  $\text{CH}_4$ .

A ten-step model of methane oxidation has been developed based on the analysis of numerous experimental data concerning OCM over various catalysts.<sup>277</sup> The interaction of  $\text{Sn/Li/MgO}$  with  $\text{C}_2\text{H}_4$  and  $\text{C}_2\text{H}_6$  is limited by abstraction of the hydrogen atom. The formation of  $\text{HO}_2$  and its surface reactions should be taken into consideration in the heterogeneous–homogeneous process. The general scheme includes the following reactions:

(the active site on the surface of the catalyst is designated by the symbol \*).<sup>277</sup>

The mechanism of the reaction  $\text{CH}_4 + \text{O}_2 + \text{CO}_2$  over one of the best OCM catalysts, *viz.*,  $\text{Na}_2\text{WO}_4\text{--Mn/SiO}_2$  was studied.<sup>257</sup> At 800 °C, the selectivity was 25% at 5% conversion. The role of  $\text{CO}_2$  consisted of a decrease in the content of reactive oxygen responsible for deep oxidation. The following reaction mechanism was proposed:

### c. Technological features

The attention of investigators is presently focused not so much over the search for novel OCM catalysts as over the technological design. The technological schemes of  $\text{CH}_4$  conversion into  $\text{C}_2\text{H}_4 + \text{C}_2\text{H}_6$  and aromatic products were described in a study by Lansford, one of the pioneers of OCM.<sup>278</sup>  $\text{C}_2$  hydrocarbons were obtained over the active catalyst  $\text{Mn/Na}_2\text{WO}_4/\text{SiO}_2$ . The resulting mixture from the flow circuit entered first a quartz tube for dehydrogenation of  $\text{C}_2\text{H}_6$  to  $\text{C}_2\text{H}_4$  and then a reactor filled with  $\text{Pd/Al}_2\text{O}_3$  for hydrogenation of admixtures of  $\text{C}_2\text{H}_2$ . After freezing-out  $\text{CO}_2$  and  $\text{H}_2\text{O}$ , the mixture was fed onto a membrane impregnated with  $\text{AgNO}_3$ . The interaction of ethylene with silver yielded a  $\pi$ -complex able to penetrate through the membrane and decomposed in the second flow circuit with liberation of ethylene. When aromatic hydrocarbons were to be prepared from methane, the silver membrane in the flow circuit was replaced by a reactor with the  $\text{Ga/HZSM-5}$  catalyst over which the conversion of  $\text{C}_2\text{H}_4$  into benzene took place. Benzene was removed by cooling to  $-78$  °C. The yields of  $\text{C}_2$  hydrocarbons made up to 70%.

Combined two-step one-pot synthesis of  $\text{C}_2\text{H}_4$  has been described. Its first step included exothermic oxidative coupling

of methane over  $\text{La}_{0.1}\text{Ba}_{0.9}\text{O/CaO}$  at 750 °C; the second step represented an endothermic reaction of ethane with  $\text{CO}_2$  over  $\text{MnO/SiO}_2$  at 800 °C:

The yield of  $\text{C}_2\text{H}_4$  in this combined two-step process was much higher than the yields from these two steps carried out in separate reactors. Continuous (130 h) operation analysis revealed stably high (27%) yield of ethylene.

When OCM was carried out over a 20%  $\text{PbO}$ –80%  $\text{SnO}_2$  catalyst, which manifested sufficiently high stability, the yields of  $\text{C}_2$  hydrocarbons did not exceed 8%.<sup>255</sup>

In some studies of OCM, oxygen-permeable membranes were used in order to increase the yields of  $\text{C}_2$  hydrocarbons. Thus 1%  $\text{SrO/La}_2\text{O}_3$  was used as a catalyst in a membrane reactor,<sup>279</sup> while  $\text{Ag-Y-SrO}$  was used for the preparation of oxygen-permeable membranes.  $\text{Li/MgO}$  was employed in an OCM reactor with an oxygen-permeable  $\text{BaCe}_{0.8}\text{Gd}_{0.2}\text{O}_3$  membrane.<sup>280</sup> The yield of  $\text{C}_2$  was 16.2%, *i.e.*, higher than the yields from flow reactors under identical conditions. In yet another reactor with a 25%  $\text{Y}_2\text{O}_3\text{--Bi}_2\text{O}_3$  membrane, the yield of  $\text{C}_2$  products reached 16% at up to 90% selectivity, *i.e.*, exceeded those obtained in conventional flow reactors by 30%.<sup>281</sup> The experimental value of the activation energy of oxygen diffusion was 70  $\text{kJ mol}^{-1}$ . In a study<sup>282</sup> where  $\text{La}_{0.2}\text{Sr}_{0.4}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_x$  was used as an active stable catalyst, methane and oxygen flows were fed onto the opposite sides of the  $\text{Y-Zr-O}$  membrane. Two different types of OCM membrane reactors were tested,<sup>283</sup> *viz.*, disc-type membranes and cylindrical membranes based over  $\text{Bi}_{1.5}\text{Y}_{0.3}\text{Sm}_{0.2}\text{O}_3$ . The oxygen flow was passed through the disk-type membrane at 900 °C at a rate of  $1\text{--}3 \times 10^{-8} \text{ mol cm}^{-2} \text{ s}^{-1}$ . The maximum yields of  $\text{C}_2$  products from tubular and disc-type membranes were 22% and 10.4%, respectively.

In yet another study,<sup>284</sup> OCM was carried out in the millisecond interval of the reaction times  $\tau$ . Platinum and rhodium catalysts were supported over  $\alpha\text{-Al}_2\text{O}_3$  monoliths. The selectivity towards  $\text{C}_2$  products was extremely low (0%–5%) where the reaction was carried out over  $\text{Rh}/\alpha\text{-Al}_2\text{O}_3$  at  $\tau \approx 1$  ms and somewhat higher over  $\text{Pt}/\alpha\text{-Al}_2\text{O}_3$ . The inlet temperature was below 200 °C, but it increased up to  $\sim 1500$  °C at the outlet of the reactor, which favoured homogeneous reactions. At  $\tau < 0.5$  ms, the selectivity towards  $\text{C}_2\text{H}_6$  increased considerably (to 40%). With an increase in  $\tau$ , the relative yields of  $\text{C}_2\text{H}_6$  decreased, while the selectivity towards  $\text{C}_2\text{H}_4$  passed through a maximum ( $\sim 40\%$ ) at  $\tau = 0.5$  ms. A further increase in  $\tau$  to 1–2 ms caused a decrease in the selectivity towards  $\text{C}_2\text{H}_2$  to 20%.

The progress achieved in the past two decades poses a question about practical implementation of the OCM technology. Joint investigations carried out by researchers of the Institute of Chemical Physics of the RAS and the Institute of Organic Synthesis (VNIOS)<sup>285</sup> were aimed at elucidating the potentials of catalytic OCM reactions in gas chemistry. Based on the results obtained, it was concluded that production of ethylene from natural gas by OCM is technologically more efficient than of other products. Such a technology is especially attractive for Russia with its large reserves of inexpensive natural gas. Pilot-plant studies carried out in 120-ml reactors demonstrated the economic expediency of the development of OCM-based industrial technologies, especially in countries possessing cheap sources of natural gas (Russia and Iran). The production cost of ethylene obtained by this method can further be reduced owing to simultaneous production of water vapour and pure  $\text{CO}_2$ .

### 2. Oxidative dehydrogenation of ethane

Studies into oxidative dehydrogenation of ethane in reactors with millisecond residence times in the presence of  $\text{Pt-Sn}$ -catalysts supported over porous aluminium oxide monolith evoked substantial interest.<sup>286,287</sup> Apparently, the role of a catalyst consisted of the promotion of oxidation of  $\text{H}_2$  to  $\text{H}_2\text{O}$  without noticeable oxidation of ethane and ethylene and, as a consequence, without

any formation of significant amounts of CO and CO<sub>2</sub>. The heat of oxidation of H<sub>2</sub> is sufficient for conducting endothermic dehydrogenation of C<sub>2</sub>H<sub>6</sub> with high selectivity:

On the whole, this process is exothermic, since hydrogen is formed in amounts exceeding those required for autothermal reactions and no additional fuel is needed. The catalyst effects the oxidation of hydrogen, while pyrolysis occurs in the gas phase, which is typical of homogeneous–heterogeneous reactions. Equally high selectivities at a similar degree of ethane conversion are attainable owing to very fast heating of ethane. Presumably, the high degree of conversion concomitant with short contact times can be attributed to enhanced release in the gas phase of reactive radicals generated by the catalyst surface.

These studies stimulated the development of a similar homogeneous process where ethane is injected directly into the diffusion flame of a hydrogen burner.<sup>288</sup> This made it possible to avoid the problems connected with the poisoning of the catalyst and to increase the process safety, since diffusion hydrogen flames are usually generated with conventional gas-jet burners in which hydrogen, ethane and oxygen are fed separately. The reaction temperature can be reduced to the level optimum for pyrolysis by feeding steam into the system. According to theoretical estimates, very high (>85%) selectivity towards ethylene at >70% conversion of ethane can be achieved. High efficiency of heat transfer is the main advantage of this process. Although an increase in temperature increases the rate of conversion (*i.e.*, reduces the reaction time), the selectivity towards ethylene decreases due to formation of acetylene. Moreover, at the degree of ethane conversion higher than 60%, the selectivity of the reaction drops drastically due to simultaneous competing coupling reactions yielding heavier molecules. However, this problem can be circumvented by the addition of steam.

### 3. Oxidative methylation

Relatively few papers devoted to oxidative methylation first discovered by Khcheyan<sup>289</sup> about 25 years ago have recently been published. Oxidative methylation of acetonitrile into acrylonitrile has been studied.<sup>290</sup> The well-known Lansford catalyst (Li/MgO) containing 25% of lithium was found to be the most efficient by virtue of its ability to produce the maximum number of active sites [Li<sup>+</sup>O<sup>−</sup>]. Other known catalysts of oxidative coupling of methane (Sm<sub>2</sub>O<sub>3</sub>, La<sub>2</sub>O<sub>3</sub>, CaO and Bi<sub>2</sub>O<sub>3</sub>) did not manifest any activity in the oxidative methylation and only deep oxidation took place. The basicity of the catalyst surface was not important in this case. At 750 °C, the degree of conversion reached 50% with 35% selectivity.

Zeolites impregnated with CsCl manifested high activity in the oxidative methylation of toluene.<sup>291</sup> The activities of zeolites did not depend on their structures. The activities of Cs-substituted catalysts of oxidative methylation of toluene increased in the following order: CsX < CsY < Cs–ZSM-5 < CsAlPO<sub>4</sub>-5.<sup>291</sup> The most active catalyst, *viz.*, CsAlPO<sub>4</sub>-5, afforded C<sub>6</sub>H<sub>5</sub>C<sub>2</sub>H<sub>5</sub> + C<sub>6</sub>H<sub>5</sub>CH=CH<sub>2</sub> in 16% yield with 75% selectivity at 750 °C. Halides supported over zeolite KY were also tested as catalysts; their activities decreased in the following order: NaBr/KY > KBr/KY > NaCl/KY.

### 4. The Andrussov reaction

Oxidative ammonolysis of methane resulting in HCN was discovered in the 1930's by Andrussov who was working in Germany at that time. The reaction

was carried out in the autothemic regime (~1000 °C) over Pt gauzes in the millisecond range of residence times. It was assumed<sup>292</sup> that this process includes the following reactions:

The thermodynamic equilibrium yield of HCN (8.5%) was obtained at a contact time of  $4 \times 10^{-5}$  s. The parameters could be improved by increasing the rate of supply of the starting mixture to 9000–10 000 m<sup>3</sup> h<sup>−1</sup>, forced reduction of the reaction temperature from 980 to 850 °C and cooling of the exit gas to 300 °C within no more than 0.01 s. A special reactor for non-equilibrium processes has been designed.<sup>293</sup> The addition of small amounts of hydrogen to the CH<sub>4</sub> + NH<sub>3</sub> + O<sub>2</sub> mixture that reacted on a Pt–Rh gauze increased the selectivity towards HCN from 74% to 82%, whereas after addition of air the increase in the selectivity was even greater (86%), but the conversion of NH<sub>3</sub> was lower.

### 5. Cold-flame and nonlinear phenomena associated with oxidation of lower alkanes

Studies of nonlinear phenomena associated with oxidation of lower alkanes, such as the generation of cold flames and region of negative temperature coefficient (NTC), are currently underway. Simulation of NTC in the low-temperature oxidation of propane and butane has been described.<sup>294</sup> An extended mechanism of low-temperature oxidation of hydrocarbons from C<sub>1</sub> to C<sub>4</sub>, which is based on the well-known GRI-Mech mechanism (see Ref. 295), has been proposed. Propyl peroxide radicals and their isomers are the main species that induce the appearance of NTC in the oxidation of propane. Based on the results of simulation, it became possible to obtain a virtually quantitative (with the accuracy of 10 K) agreement with the experimentally determined values of minimum and maximum temperatures in NTC and very good coincidence of the shapes of the temperature dependences of the induction period. The rationale for this phenomenon<sup>295</sup> is consistent with the widely accepted notion of an increased contribution of abstraction of the nonreactive radical HO<sub>2</sub> from the propyl peroxide radical at elevated temperatures:

which is equivalent to the decay of the radicals under the given conditions. This results in a decrease in the rate of the overall branching-chain reaction. With further increase in temperature, the hydrogen peroxide formed by recombination of HO<sub>2</sub> radicals becomes itself a source of OH radicals, which is equivalent to elimination of this channel of the chain termination.

\* \* \*

The analysis of the published data suggests that in-depth studies of oxidative conversion of methane are underway, especially in those areas where their industrial potential is especially high. The level of activities in the field of catalytic oxidation of methane to synthesis gas is steadily expanding against the decreasing number of publications devoted to oxidative coupling of methane or its oxidation to oxygenates. The most recent trend is towards deletion the distinctions between heterogeneous catalysis and homogeneous processes, which are being more often considered as an integral homogeneous–heterogeneous process, and increasing the role of kinetic simulations and modern physical methods of analysis *in situ*.

This work has been supported by the Russian Foundation for Basic Research (Project No. 04-03-07004).
