## Department of Chemistry of the M V Lomonosov Moscow State University

This issue of the Journal is devoted to the 250th anniversary of the M V Lomonosov Moscow State University (MSU), an outstanding event in the history of culture, education and science in Russia. From the very moment of the foundation of Moscow University, studies into various chemical processes and training of students in fundamental chemistry formed a significant part of its educational and research activities. The interest in specific characteristics of substances and their possible interconversions initiated by M V Lomonosov is being realised in the wide-ranging research activities which encompass virtually all areas of modern chemistry. At the beginning, chemical investigations were carried out by the Department of Physics and Mathematics up to the establishment, in 1929, of the Department of Chemistry as an independent structural division of Moscow University.

The structure of the Department of Chemistry developed over decades reflects the evolution of scientific ideas, scientific schools and priorities characteristic of chemical education and science at different stages of its development.

Traditionally, the divisions and laboratories of the Department were grouped around physicochemical, organic and inorganic cycles. The advent and explosive development of a science of macromolecules and polymeric materials resulted in the establishment of a Division of Polymer Science, while the growing interest of chemists in processes occurring in living matter gave an impetus to the establishment and further development of the Divisions of Chemistry of Natural Compounds and Chemical Enzymology.

The indissoluble unity of educational and research processes is the main prerequisite for the fruitful development of the Department of Chemistry and its advancement. Today, the Department of Chemistry admits annually 215 students from various regions of Russia. During the first five semesters, the students receive

fundamental chemical knowledge. In the second semester of the third year, the students are allowed to choose a division, a laboratory and a research group that interests them most. The fourth and fifth years are devoted to specialised lecture courses, practical and research work. The educational cycle is terminated by the defence of a diploma work, which usually represents an expert study in one of the most advanced fields of chemistry. A large (~100 people) contingent of graduates take a postgraduate course at the Department of Chemistry and complete their education by presentation of a Ph.D. thesis. This is actually the end of the eight-year educational cycle, which is aimed at the training of high-level specialists.

The staff members of the Department, being interested in retention of the highest level of teaching chemistry in modern higher school and attraction of the most talented and capable secondary school graduates to the Department, develop high educational standards. In large measure, this task is fulfilled through the involvement of schoolchildren in annual federal and international multilevel chemical olympiads.

The most advanced level of education and research at the Department of Chemistry of MSU is maintained owing to long-standing traditions, rich experience of research work and significant contributions by the most outstanding representatives of Russian chemical science to its development. Academicians A N Nesmeyanov, A V Novoselova, N N Semenov, N M Emanuel, V A Kargin, P A Rehinder, A N Frumkin, V I Spitsin, I P Alimarin and the Corresponding Members I V Berezin, Ya I Gerasimov and many others have worked at the Department of Chemistry of MSU at different times. At present, the divisions of the Department are headed by Academicians V A Kabanov (Division of Polymer Science), N S Zefirov (Division of Organic

Chemistry), V V Lunin (Division of Physical Chemistry), Yu D Tretyakov (Division of Inorganic Chemistry), Yu A Zolotov (Division of Analytical Chemistry), A A Bogdanov (Division of Chemistry of Natural Compounds), A L Buchachenko (Division of Chemical Kinetics) as well as by Professors S D Varfolomeev (Division of Chemical Enzymology), O A Petrii (Division of Electrochemistry), B D Summ (Division of Colloidal Chemistry), S F Dunaev (Division of General Chemistry), E A Karakhanov (Division of Petrochemistry and Organic Catalysis), V M Fedoseev (Division of Radiochemistry), V V Avdeev (Division of Chemical Technology and Novel Materials), Yu A Kuzyakov (Division of Laser Chemistry). Each of the Department's divisions is an independent research-and-educational centre which specialises in a particular branch of modern chemical science.

Academicians N A Plate, I P Beletskaya, N F Bakeev and the Corresponding Members of RAS A B Zezin, A L Volynsky and I V Melikhov are working successfully at the Department of Chemistry of MSU. The Department is one of the leading multidisciplinary research-and-educational establishments in Russia. Over 1000 teachers and researchers are working in the Department. Every year, staff members of the Department of Chemistry publish 1100 scientific papers and participate in 15–20 congresses, conferences and symposia. About 150 Ph.D. and D.Sci. theses are defended at specialised councils of the Higher Attestation Commission.

As regards the quality of research and citation rates of published papers, the highly fruitful research-and-education activities in the Department of Chemistry account for its high prestige both inside the country and abroad.

This issue of the Journal 'Russian Chemical Reviews' comprises reviews reflecting the scientific interests of different research groups working at the Department of Chemistry of MSU.

The review by Academician V A Kabanov 'Polyelectrolyte complexes in solution and in bulk' considers various reactions between oppositely charged polymeric molecules in aqueous solutions which result in the formation of insoluble (stoichiometric) and soluble (non-stoichiometric) interpolyelectrolyte complexes. Thermodynamics, kinetics and mechanisms of reactions of charged polyelectrolytes and the formation of interpolymeric complexes, which represent a special family of polymeric materials, are considered. Some unusual phenomena are described. Thus soluble non-stoichiometric polymeric complexes manifest properties of linear polyelectrolytes, but often behave as amphiphilic block copolymers. The nature of the forces controlling the behaviour of the complexes and properties of multilayer materials obtained by alternation of polycations and polyanions are discussed.

The review by Dr. A A Galkin and Academician V V Lunin 'Subcritical and supercritical water: a universal medium for chemical reactions' is devoted to the discussion of the properties of water in the sub- and supercritical states. The unique properties of water in the aforementioned states as media for chemical reactions are demonstrated. A wide range of problems including some peculiarities of experimenting with water in its sub- and supercritical states, chemical characteristics of reactions of organic compounds in these media, synthesis of nanocrystalline oxides and application of sub- and supercritical water in various waste utilisation processes are discussed.

The review by Academician Yu A Zolotov *et al.* 'Sorption preconcentration of microcomponents for chemical analysis' is devoted to one of the most important trends in analytical chemistry developed by the Division over decades, *viz.*, sorption preconcentration. This procedure is based on the use of various synthetic and natural sorbents and enables a significant increase in the detection limits of analytes. The use of various methodological approaches and design of hybrid and combined variants of analysis allow one to determine, with a high level of efficiency, a broad range of compounds including organic and inorganic substances.

The review by Prof. S D Varfolomeev *et al.* 'Catalytic sites of hydrolases: structures and catalytic cycles' deals with the description of the structures and functions of active sites of enzymes. A detailed analysis of modern computer databases of protein structures is given. Methods for identification of active sites of enzymes based on the analysis of computer databases are considered. The structural paradox of enzymatic catalysis, which suggests that the practically infinite variability of protein structures within the framework of a concrete catalytic task is confined to a limited number of catalytic site structures responsible for the catalytic act, is discussed for the example of a special class of enzymes, *viz.*, hydrolases.

The review by Prof. T S Oretskaya *et al.* 'Covalent binding of modified nucleic acids to proteins as a method for investigation of specific protein–nucleic acid interactions' is devoted to the study of specific interactions between proteins and nucleic acids. Covalent binding of modified nucleic acids to proteins is considered as a method of investigation. Methods for the introduction of modifications in the structures of nucleic acids, synthesis of photoactive derivatives and structures of 'nucleic acid–protein' conjugates formed upon enzymatic reactions are discussed. The development of these methods allows identification of a specific site in a protein bound to a nucleic acid.

The main emphasis in the review by Prof. E A Karakhanov *et al.* 'Design of supramolecular metal complex catalytic systems for organic and petrochemical synthesis' is laid on supramolecular metal-complex systems. The formation of active sites, which involves macrocyclic receptor molecules, opens up prospects, new in principle, for the design of catalysts for hydrogenation, hydroformylation, carbonylation, hydroxylation, *etc.*

The issue includes only some of the reviews prepared by researchers of the Department of Chemistry and dedicated to the 250th anniversary of the Moscow State University. One of the next issues of the Journal will also be devoted to this jubilee event. We are sure that the reviews presented herein as well as those designed for publication in the subsequent issues of the Journal will be interesting for a broad circle of readers and will shed additional light on the main trends and level of research carried out by the Department.

**Abstract.** The review surveys the thermodynamics, kinetics and reaction mechanisms of oppositely charged polyelectrolytes in aqueous solutions giving rise to insoluble stoichiometric or soluble non-stoichiometric interpolyelectrolyte complexes. The mechanisms of polyelectrolyte exchange reactions are discussed. Equilibrated non-stoichiometric interpolyelectrolyte complexes show a dual behaviour in aqueous solutions. On the one hand, they behave as usual linear polyelectrolytes and, on the other hand, they exhibit properties of amphiphilic block copolymers. The addition of low-molecular-weight salts to solutions of interpolyelectrolyte complexes usually leads to redistribution of electrostatically bound chains and phase separation. Analysis of these processes is of key importance in assigning these complexes to a special family of polymeric materials. Selected data on the conformations of polyions in solid interpolyelectrolyte complexes are given and their thermomechanical properties in the swollen state are considered. The bibliography includes 117 references.

## I. Introduction

Interpolyelectrolyte complexes (IPECs) belong to a special family of polymeric compounds<sup>1–6</sup> formed through cooperative electrostatic interactions between polycations with polyanions upon mixing of aqueous solutions of oppositely charged polyelectrolytes. Depending on the charge ratio and the degree of polymerisation of the starting polyelectrolytes, either non-stoichiometric water-soluble or stoichiometric insoluble IPECs exhibiting low swelling in water can be prepared.

An analysis of the state of the art in research on IPECs, which was based essentially on the results of investigations performed over many years at the Chair of High-Molecular-Weight Compounds of the Department of Chemistry of the Moscow State University, has been presented recently in the introductory chapter of Ref. 7. This chapter was used as the basis for the present review.

In the 1930s, researchers working in the field of colloidal chemistry found that, under particular conditions, mixing of aqueous solutions of oppositely charged natural polyelectrolytes

characterised by a relatively low charge density on the macromolecules (for example, gelatins and gum arabic) leads to phase separation and formation of liquid coacervates.<sup>8–10</sup> Further studies of such systems have been aimed primarily at characterising the conditions of phase separation by experimental and theoretical methods.<sup>11,12</sup>

Solid IPECs exhibiting low swelling in water have also been known for many years. Synthetic polyelectrolytes with a high linear charge density have become available at least from the early 1960s.<sup>1,13–15</sup> Later, the practical use of these compounds has attracted attention. For example, insoluble IPECs proved to be highly efficient as ecologically safe hydrophilic binders, which prevent soil erosion by wind and water. Composites based on such IPECs were used, for instance, for suppressing the formation of radioactive aerosols in the contaminated dusting areas of the Chernobyl disaster. Industrial tests showed that insoluble IPECs are much more efficient than individual polyelectrolytes, which are generally used for coagulation of colloidal dispersions, in particular, of metallurgical slags (see, for example, Ref. 16). Insoluble IPECs were also successfully tested as biocompatible coatings for blood-contacting medical materials (including chemisorbents) and other biological liquids (see, for example, Ref. 17).

There also some other promising fields of application of IPECs. One of them is being extensively developed and deals with the preparation of thin films consisting of alternating nano-size polycation and polyanion layers. These films are prepared by successive deposition of oppositely charged polyelectrolytes from aqueous solutions on various surfaces.<sup>7</sup>

The existence of water-soluble interpolyelectrolyte duplexes was supported by several examples<sup>18,19</sup> and the general conditions and criteria for their formation were revealed, which proved to be valid for most pairs of oppositely charged polyions.<sup>3,5,20,21</sup> These are considerable achievements, which marked the onset of a new stage of investigation of IPECs associated with the possibility of employing all modern physical and physicochemical methods generally used in studies of macromolecules in solution (light scattering, analytical ultracentrifugation, viscosimetry, gel-permeation chromatography, *etc.*). Fundamental data obtained by these methods gave a deeper insight into the structural organisation and behaviour of IPECs not only in solutions but also in the bulk. These investigations also opened new fields of application of IPECs, in particular, in biotechnology, medicine, and modelling of biological systems.<sup>22–26</sup> For example, it appeared that interpolyelectrolyte duplexes involving DNA plasmids or single-stranded antisense oligonucleotides as polyanions can penetrate rather easily through biological membranes analogously to viri-

ons. Nowadays, this phenomenon is used for delivering genetic material to cells to transfect or block specified genome regions.<sup>25</sup>

## II. Interpolyelectrolyte reactions and solution behaviour of interpolyelectrolyte complexes

The simplest procedure for the preparation of IPECs involves mixing of two aqueous solutions containing polyanions and polycations, respectively. The reaction of two strong polyelectrolytes can be represented as follows:

where  $\text{A}^-$  and  $\text{B}^+$  are acidic and basic side groups, respectively, and  $\text{a}^-$  and  $\text{b}^+$  are counterions.

An interaction between two weak polyelectrolytes can be described by the following scheme:

The degree of conversion  $\Theta$  in these reactions is determined as the ratio of the number of salt bonds (ion pairs) formed between polyions under particular conditions to their maximum possible number

$$\Theta = \frac{x}{m}, \text{ if } n \geq m,$$

and

$$\Theta = \frac{x}{n}, \text{ if } n < m.$$

The formation of duplexes from weak polyelectrolytes can be controlled by varying pH of the medium.<sup>3,6</sup> In these cases, IPECs can be prepared in equilibrium conditions by gradual acidification or alkalisation of the reaction mixture.

The degree of conversion  $\Theta$  can be calculated from the results of potentiometric titration.<sup>3,6</sup>

For a weak polyacid,

$$\Theta = \frac{m_b/V + [\text{H}^+] - \sqrt{K_a c_0}}{c_0}, \quad (3)$$

for a weak polybase,

$$\Theta = \frac{m_a/V + [\text{OH}^-] - \sqrt{K_b c_0}}{c_0}. \quad (4)$$

In these equations,  $m_a$  or  $m_b$  are the numbers of moles of the acid or base, respectively, added to the mixture,  $V$  is the volume of the reaction mixture,  $K_a$  and  $K_b$  are the characteristic ionisation constants of the polyacid and the polybase, respectively, and  $c_0$  is the concentration of one of the polyelectrolytes.

Typical plots of  $\Theta$  vs. pH, which were calculated from experimental titration curves of weak polyelectrolytes in the presence of oppositely charged polyions, are shown in Fig. 1. Solid lines enclose the pH region where IPECs are formed and

**Figure 1.** Typical plots of the degrees of conversion ( $\Theta$ ) in reactions of weak polyelectrolytes (1, 2) and their starting degrees of ionisation ( $\alpha$ ) (1', 2') vs. pH in aqueous solutions.

exist in the reaction system in the absence of low-molecular-weight salts. If one polyelectrolyte is weak, whereas another polyelectrolyte is strong, the range of existence is limited only by one curve either on the left or on the right, respectively. Figure 1 shows also the plots of the degree of ionisation  $\alpha$  of individual polyelectrolytes vs. pH. It can be seen that polyacids and polybases whose degree of ionisation depends on pH become much stronger in the presence of oppositely charged polyions.

The value of  $\Delta\text{pH}(\Theta, \alpha)$  is a measure of the free energy ( $\Delta G_{cs}$ ), which is a driving force for the complexation process. This parameter characterises a cooperative multicentre interaction between the oppositely charged units of polyion chains at  $\Theta = \alpha$

$$\Delta\text{pH}(\Theta, \alpha) = \frac{\Delta G(\alpha) - \Delta G(\Theta)}{2.3 RT} = \frac{\Delta G_{cs}(\Theta, \alpha)}{2.3 RT}. \quad (5)$$

Here  $\Delta G(\alpha)$  and  $\Delta G(\Theta)$  are the free energies of ionisation of a weak polyelectrolyte in the absence and in the presence of an oppositely charged polyion, respectively.

Equation (3) is written on the assumption that each ionised group of the polyelectrolyte that is titrated forms a salt bond (ion pair) with an oppositely charged polyion. This situation is close to reality if the ratio of the numbers of ionising groups of the components ( $Z = m/n$ ) is equal to unity. For  $Z \neq 1$ , Eqn (3) is valid if the total number of ionising groups in a weak polyelectrolyte is smaller than that in the fully ionised strong polyelectrolyte.

A decrease in the free energy corresponding to the shift of the equilibria (1) and (2) toward IPECs takes place primarily due to an increase in the entropy caused by release of low-molecular-weight counterions, which are initially localised in the vicinity of polyelectrolyte coils. However, depending on the composition and structure of the oppositely charged polyions, other factors, for example, hydrophobic interactions, hydrogen bonds, charge transfer, etc., can contribute substantially to their coupling.

In terms of the commonly accepted classification, the processes (1) and (2) correspond to the ion exchange and neutralisation reactions, respectively. However, in relation to interacting polyelectrolytes, these processes can be considered as coupling reactions of oppositely charged polyions.

Interpolyelectrolyte complexes can also be prepared by polymerisation of ionic monomers on oppositely charged polyions serving as matrices.<sup>27</sup> In this case, the total change in the free energy includes two terms

$$\Delta G_{tp} = \Delta G_p + \Delta G_{cs}, \quad (6)$$

where  $\Delta G_p$  is the free energy of polymerisation in the absence of a matrix. The negative value of  $\Delta G_{cs}$  is thermodynamically favourable for the formation of a polymer. This factor may be of decisive importance if polymerisation of a free monomer is thermodynamically impossible ( $\Delta G_p > 0$ ):  $\Delta G_{tp}$  remains negative if

$|\Delta G_{cs}| > |\Delta G_p|$ . In other words, a polyion matrix, being a potential component of IPEC, shifts the polymerisation–depolymerisation equilibrium toward the oppositely charged polyion.

A factor analogous to  $\Delta G_{cs}$  is responsible for clustering of protein globules with oppositely charged linear polyions upon complexation of polyelectrolytes with proteins<sup>28–30</sup> and for aggregation of ionic surfactants in solutions and hydrogels of oppositely charged polyelectrolytes at surfactant concentrations substantially lower than the critical micelle concentration (CMC).<sup>31–37</sup> In reality, both these processes consist in ‘polymerisation’ of protein globules or surfactant ions on the oppositely charged polymer matrices.

For a particular structure of polyelectrolytes, the ability of IPEC to dissolve or swell in water depends on  $Z$ ,  $\Theta$ , the ratio of the degrees of polymerisation of the oppositely charged polyions and the composition of an aqueous phase (the nature and concentration of low-molecular-weight salts, pH, the presence of organic additives, *etc.*). If  $Z = 1$  and  $\Theta$  is close to unity, the interpolyelectrolyte reaction affords stoichiometric IPECs, which are always insoluble but swell in water to some degree.

Under particular conditions, most pairs of oppositely charged polyelectrolytes give water-soluble IPECs.<sup>3, 5, 20, 21</sup> At  $Z = 1$ , the solubility of duplexes can be achieved only at  $\Theta < 1$ , *i.e.*, for products of the incomplete reaction (2).<sup>20</sup> In this case, free units of polyions (which are not involved in interchain salt bonds) act as hydrophilic fragments, which retain IPEC particles in solution.

Water-soluble duplexes can be prepared also at  $\Theta$  equal or close to unity, provided that  $Z \neq 1$  or that the degree of polymerisation of an excess polyion, *viz.*, a host polyelectrolyte (HPE), is higher than the degree of polymerisation of another polyion present in a deficient amount, *viz.*, a guest polyelectrolyte (GPE). Then the solubility condition can be written as follows:

$$\varphi = \frac{[\text{GPE}]}{[\text{HPE}]} < \varphi_c < 1,$$

where  $\varphi$  is the ratio of the numbers of the charged GPE and HPE units in IPEC particles. In the case of a uniform distribution of GPE over HPE,

$$\varphi = Z.$$

The critical value  $\varphi_c$  is determined by the maximum population of HPE by GPE chains. At  $\varphi$  higher than  $\varphi_c$ , hydrophilicity of excess single-stranded regions of the chains is insufficient to retain all IPEC particles in solution. For most known systems,  $\varphi_c$ , which is determined primarily by the chemical structures of interacting polyelectrolytes, varies from 0.2 to 0.6.

In the pH region, enclosed by the potentiometric titration curves 1 and 2 (see Fig. 1), the cooperative character of multi-centre electrostatic coupling provides high resistance of IPECs to dissociation into the individual starting components. The effective dissociation constant at  $\Theta$  close to unity sharply decreases with increasing degree of polymerisation of GPE and approaches zero even for rather short oligomers. For example, in the case of polymer homologues of quaternised linear ethyleneimine (**1**) interacting with poly(methacrylate) (PMA) polyanions, the degree of dissociation of IPEC has become negligibly small already for octamers.<sup>4, 38</sup> Analogous results were obtained in studies of the reactions of oligophosphates with poly(*N*-dimethylaminoethyl methacrylate) (PDMAEMA)<sup>39</sup> and the reactions of oligo-2,5-ionenes with polyacrylate (PA) polyanions.<sup>40</sup>

Consequently, IPECs produced in the absence of low-molecular-weight salts do not virtually dissociate into individual components once a particular critical length of polyions is achieved.

If one of the polyions can exist in solution in a specific ordered conformation (for example, like ionic polypeptides or DNA), an oppositely charged polyelectrolyte can either stabilise or destabilise this conformation upon complexation.<sup>6, 24</sup> For example, the  $\alpha$ -helical conformation of free poly-L-lysine (PL) is stable only in strongly alkaline media where this compound is uncharged. Upon protonation of amino groups in a mixed aqueous–ethanolic solution, this conformation of PL is transformed into an uncoiled conformation already at pH 9–8.5. It should be noted that even completely protonated PL in the PL–PMA duplex retains the  $\alpha$ -helical conformation in a much broader pH range. The helix–coil transformation occurs only at pH 3.5–4.0, at which IPEC decomposes due to protonation of the  $\text{COO}^-$  groups of PMA.<sup>6</sup> In other words, complexation stabilises the  $\alpha$ -helix of PL. The opposite situation is observed for poly-L-glutamic acid (PGA). The  $\alpha$ -helical conformation of PGA is stable in acidic aqueous solutions and is transformed into a random-coil conformation as pH increases to 6.0–6.5. By contrast, the helix–coil transformation in the PGA–linear polyethyleneimine (PEI) system occurs already at pH 3.0–4.0, *i.e.*, in the pH region where the PGA–PEI polyelectrolyte complex is formed. Consequently, binding of the PEI polycation to the negatively charged  $\alpha$ -helix is thermodynamically less favourable compared to binding to the negatively charged PGA random coil.<sup>6</sup> Another example refers to DNA. It is known that, in an aqueous solution, the double helix of native DNA exists in the B form. Upon the formation of native DNA duplexes with polycations, the B form is transformed into the more compact C or A form.<sup>24</sup>

## 1. Kinetics and mechanisms of polyelectrolyte coupling, exchange and substitution reactions

The course of a coupling reaction of two strong polyelectrolytes in salt-free media can be monitored by any method that allows one to measure the amounts of low-molecular-weight counterions released (elemental analysis, conductometry, ion-specific potentiometry, *etc.*). The limitations of the sensitivity of these methods arise when the interpolyelectrolyte reactions are performed in the presence of low-molecular-weight salts at concentrations substantially higher than the base-mole concentration of interacting polyelectrolytes.

If one polyelectrolyte is a weak polyacid or a weak polybase, the degree of conversion  $\Theta$  can be determined by measuring pH.<sup>6</sup> However, this method is applicable only in a pH range where  $\Theta$  is no higher than 0.4–0.5 (40%–50%).<sup>24</sup>

It is convenient to perform quantitative investigations of the formation and transformations of soluble IPECs by luminescence quenching. For this purpose, it is necessary to label one of the oppositely charged polyions with a chemically bonded luminescence group and to choose the second polyion such that it can interact with the former group and quench luminescence. The portion of labelled polyions interacting with quencher polyions can be calculated at any pH both in the presence and absence of low-molecular-weight salts by measuring the luminescence intensity and using the corresponding calibrations.

Luminescence quenching was used to study the kinetics of the coupling reactions of typical polyelectrolyte pairs. The conditions under which soluble IPECs dissociate into the starting components were determined. Direct experimental evidence for the ability of various soluble IPECs to be involved in competitive exchange and substitution reactions with other polyions was documented and the kinetics of these reactions was quantitatively studied.<sup>41–44</sup> It should be noted that the earlier study of the behaviour of DNA duplexes with poly(*N*-ethyl-4-vinylpyridinium) bromide in aqueous solutions<sup>18</sup> also provided indirect evidence for the possible polyion exchange.

Polyion exchange and substitution reactions can be represented in the general form as follows:

where  $n$  or  $x$  is the number of the GPE chains in IPEC particles. In terms of the above-mentioned approach, this process is a polyion exchange reaction if HPE<sub>1</sub> and HPE<sub>2</sub> are identical and a polyion substitution reaction if HPE<sub>1</sub> and HPE<sub>2</sub> differ in chemical structure. Different HPE segments can also exchange GPE polyions within one IPEC particle. This exchange is, in essence, equivalent to migration of GPE inside the HPE coil and serves as the mechanism of rearrangements within the complex giving rise to an equilibrium inner structure of IPEC particles and resulting in optimisation of their interactions with the environment.

In most kinetic studies,<sup>41–48</sup> fractions of polymethacrylic acid labelled with fluorescent anthryl or pyrenyl groups (PMA\*)<sup>49</sup> (one label per 350–1500 repeated units) (2) served as a polyanionic component. The (*N*-ethyl-4-vinylpyridinium)–vinylpyridine copolymer (PVP) (3) was used as the polycationic component.

This copolymer was prepared by quaternisation of poly-4-vinylpyridine fractions with bromoethane.<sup>50</sup> The number of quaternised units (*i.e.*, the linear positive-charge density) was specified by varying the degree of quaternisation (in %)

$$\beta = \frac{m}{m+n} 100.$$

Most experiments described below (unless otherwise indicated) were carried out with the use of PVP whose degree of quaternisation was close to 100%. Quaternary vinylpyridinium units located in proximity to the anthryl and pyrenyl groups can quench fluorescence.

The kinetics of a typical coupling reaction of polyions was studied using the reaction of NaPMA\* with PVP as an example.<sup>45,47</sup> The formation of the PMA\*–PVP complex leads to a decrease in the fluorescence intensity of PMA\* due to quenching of the pyrenyl labels with the quaternary vinylpyridinium units of PVP. The reaction mixture was prepared by the rapid addition of a calibrated aqueous PVP solution (0.02 ml) into a cell containing a calibrated aqueous NaPMA\* solution (1.5 ml) with continuous stirring in such a way that the reagents were mixed for no longer than 2–4 s. The concentrations of the starting solutions were chosen so as to prepare a complex of the desired final composition. As can be seen from Fig. 2, mixing of the reagents in the absence of a salt is accompanied by a sharp decrease in the fluorescence intensity to a particular constant value. This corresponds to the rapid formation of contacts between PMA\* and PVP (curve 1). However, the decrease in the fluorescence intensity is smaller than that expected in the case of formation of the equilibrated PMA\*–PVP interpolyelectrolyte complex of the desired composition (*cf.* curves 1 and 1'). Moreover, mixing of the same reagents in the presence of NaCl (0.03 mol litre<sup>−1</sup>) leads to a substantially larger initial decrease in the fluorescence intensity (*cf.* curves 2 and 2' in Fig. 2).

**Figure 2.** Typical kinetic curves of interpolyelectrolyte coupling and exchange reactions.<sup>47</sup>

$I$  and  $I_0$  are the current and starting fluorescence intensities, respectively, of PMA\*; (1) NaPMA\* ( $P_w = 4.4 \times 10^3$ , one label per 600 monomer units) + PVP ( $P_w = 2.0 \times 10^2$ ,  $\beta = 95\%$ ) in the absence of a salt,  $[NaPMA^*] = 8.6 \times 10^{-8}$  mol litre<sup>−1</sup> (with respect to the polyion),  $Z = [PVP]/[NaPMA^*] = 0.2$ ; (2) the same reaction in the presence of sodium chloride (0.03 mol litre<sup>−1</sup>); (3) IPEC (PMA–PVP) + NaPMA\*,  $[NaPMA^*] = [IPEC] = 8.6 \times 10^{-8}$  mol litre<sup>−1</sup>,  $P_w = 4.4 \times 10^3$ ,  $\varphi = 0.2$ ,  $T = 20^\circ\text{C}$ , pH 10,  $\Theta \rightarrow 1$ ; (1') the equilibrium limit for the curve 1; (2') the equilibrium limit for the curves 2 and 3; (3) the curve for pure polyion exchange.

Stop-flow measurements demonstrated that the fast step of polyion coupling reactions corresponding to an instantaneous drop observed in the kinetic curves is characterised by the rate constant of  $\sim 10^9$  litre mol<sup>−1</sup> s<sup>−1</sup>. This value is close to the expected bimolecular rate constant of diffusion collisions of polyelectrolyte coils in a dilute solution.<sup>45,47</sup> Diffusion collisions of oppositely charged polyions lead to their association due to formation of random interchain salt bonds, *i.e.*, the formation of IPEC. However, at very low concentrations of simple salts or in their absence, rearrangements of randomly coupled polyions in exchange reactions are hindered. Hence, the resulting IPEC associates are 'frozen' in a non-equilibrium state (see curve 1 in Fig. 2). In the presence of a sufficiently large amount of a salt, the rate of polyion exchange, on the contrary, sharply increases. As a result, the initially non-equilibrated IPEC associates are rearranged with time and reach an equilibrium state, which is characterised by the maximum possible number of salt bonds between the interacting polyions. In other words, primary associates are transformed into equilibrated particles of the PMA\*–PVP interpolyelectrolyte complexes (see curve 2 in Fig. 2). The pyrenyl labels attached to the PMA\* chains give rise to additional hydrophobic interactions, due to which PMA\*–PVP particles become more stabilised than PMA–PVP particles. As a consequence, the PMA\* polyanions replace the PMA polyanions in the complex particles. Therefore, the kinetic curve 2 in Fig. 2 can be qualitatively considered as a superposition of the curves 1 and 3. In other words, the presence of one pyrenyl group per several hundreds of monomer units in the PMA\* chain appears to be sufficiently large for this chain to replace the chain of usual unmodified PMA initially bound to the PVP polycation.

For soluble IPECs, the polyion exchange reaction involving the transfer of one GPE (PVP) chain from HPE<sub>1</sub> (PMA) to HPE<sub>2</sub> (PMA\*) in a dilute solution was demonstrated<sup>46,47</sup> to be characterised by second-order kinetics with respect to the concentrations of the polymers involved in the reaction (IPEC and PMA\*).

The experimental kinetic curves fit well to straight lines in the coordinates of the equation

$$\frac{q}{1-q} = k_2[PMA^*]_0 t, \quad (9)$$

**Table 1.** Rate constants of the exchange reactions between the PMA–PVP interpolyelectrolyte complexes and NaPMA\* at pH 10,  $\theta \rightarrow 1$ ,  $T = 20^\circ\text{C}$ .

**Note.**  $P_w(\text{PMA}) = P_w(\text{PMA}^*)$ , PMA\* contains one pyrenyl label per 350 units.

<sup>a</sup> In litre mol $^{-1}$  s $^{-1}$ .

where  $q$  is the degree of conversion in the reaction (8), and  $[\text{PMA}^*]_0 = [\text{PMA}]_0 = [\text{IPEC}]_0$  are the starting molar concentrations of the reagents. The absolute rate constant ( $k_2$ ) of the transfer of the GPE chain from one HPE chain to another under various conditions can be determined according to Eqn (9). As can be seen from Table 1, the constant  $k_2$  is independent of the concentrations of the compounds involved in the reaction (runs 1–3 and 6), which is consistent with Eqn (9). It should be emphasised that the constant  $k_2$  is also independent of the degree of polymerisation of HPE (PMA) (runs 8 and 9), but this constant decreases substantially with increasing degree of polymerisation of GPE (PVP) (runs 10–13). Under the experimental conditions,  $k_2$  varied in a range of  $10^4$ – $10^6$  litre mol $^{-1}$  s $^{-1}$ , *i.e.*, it is 3–5 orders of magnitude smaller than the estimated rate constant of diffusion collisions between the interacting particles. The results of investigations suggest that the transfer occurs in the intermediate ternary complex (PMA...PVP–PMA\*) generated as a result of the mutual penetration of the chains of the starting IPEC and NaPMA\* upon their random collisions in solution. This complex presented in Scheme 1 serves as a ‘transition state’ in the bi-macromolecular polyion exchange reaction. Under the above-mentioned experimental conditions, only some collisions are productive. There are, on the average,  $10^3$ – $10^5$  ineffective collisions per event of transfer of PVP from PMA to PMA\*. The strong dependence of  $k_2$  on both the salt concentration (runs 4–7)

Scheme 1

and the linear charge density of the PVP chains (runs 14–18) is in complete agreement with the proposed reaction mechanism.

The polyion exchange processes with the involvement of IPEC particles containing more than one GPE chain are described by polychronic kinetics. However, factors governing these more complex reactions are qualitatively similar to the considered above simplest second-order reaction.<sup>43</sup> In particular, their rates also depend substantially on the concentrations of the additives of simple salts. This is confirmed by the following data:

| [NaCl] $\times 10^3$ /mol litre $^{-1}$ | 0                       | 35  | 70 | 100   |
|-----------------------------------------|-------------------------|-----|----|-------|
| Half-life /s                            | reaction does not occur | 240 | 6  | < 1.5 |

$\{P_w(\text{NaPMA}^*) = P_w(\text{NaPMA}) = 3 \times 10^3, P_w(\text{PVP}) = 2 \times 10^2; [\text{NaPMA}^*] = [\text{NaPMA}] = [\text{IPEC}] = 4 \times 10^{-3}$  base-mol litre $^{-1}$ ,  $\varphi = 0.33$ ; pH 10,  $T = 20^\circ\text{C}$ ).

The presence of salts substantially affects the polyion substitution reactions as well.<sup>39, 40, 44, 48, 51–53</sup> The replacement of the PMA\* polyanions in the PMA\*–PVP polyelectrolyte complex with the polyvinyl sulfate (PVS) polyanions is completely hindered in a salt-free solution but it is strongly accelerated in the presence of NaCl, as evidenced by the following results:

| [NaCl] $\times 10^3$ /mol litre $^{-1}$ | 0                       | 2   | 4  | 6  | 8 | 10    |
|-----------------------------------------|-------------------------|-----|----|----|---|-------|
| Half-life /s                            | reaction does not occur | 600 | 60 | 13 | 5 | < 1.5 |

$\{P_w(\text{NaPMA}^*) = 3 \times 10^3, P_w(\text{PVS}) = 1.3 \times 10^3, P_w(\text{PVP}) = 2 \times 10^2; [\text{IPEC}(\text{PMA}^* - \text{PVP})] = 4 \times 10^{-3}$  base-mol litre $^{-1}$ ,  $\varphi = 0.2$ ; [PVS] = [PVP]; pH 10,  $T = 20^\circ\text{C}$ ).

In substitution reactions, not only the kinetics but also the position of equilibrium depend substantially on the chemical nature of polyions. In particular, polyanions containing the sulfonate or sulfate group in the repeated monomer unit (PVS, polyethylene sulfonate, heparin, *etc.*) generally replace polycarboxylates (for example, PA or PMA) in polyelectrolyte complexes containing ammonium as the polycation.<sup>40</sup> The driving force for the substitution is a specific (in addition to Coulombic) affinity of the sulfonate or sulfate group for protonated or quaternary amino groups.

The dramatic influence of the degree of polymerisation of competitive polyelectrolytes and the chemical nature of a low-molecular-weight salt on the equilibrium degree of conversion was observed in the polyion substitution reaction of the PMA\* (HPE)–PVP (GPE) interpolyelectrolyte complexes with polyphosphates (PP) with different degrees of polymerisation<sup>48</sup>

A change in the equilibrium degree of conversion  $q_e$  in the forward reaction (10) with increasing concentration of the additives of simple salts is illustrated by Fig. 3. It can be seen that, all other factors being the same, the curve shape depends substantially on the degree of polymerisation of PP (Fig. 3a) and the nature of the cation of the salt present as an additive (Fig. 3b). At high salt concentrations, these differences are associated with the sign change. For PPs possessing the longest chain (230 monomer units), the equilibrium (10) in a 0.3 M aqueous NaCl solution at fixed base-mole concentrations of all polymers completely shifts to the right, whereas this equilibrium for short-chain PPs (20 monomer units) completely shifts to the left. For PPs with intermediate degrees of polymerisation,  $q_e$  has intermediate values. For PPs with a fixed chain length (70 monomer units), the equilibrium (10) in a 0.3 M LiCl solution completely shifts to the right, whereas this equilibrium in a 0.3 M KCl solution completely shifts to the left. Analogous phenomena were not observed in non-polymer systems. Moreover, this phenomenon can, apparently, be considered as a model of biologically important rearrangements, which occur in cells with the involvement of oppositely charged natural polyelectrolytes. Under the reaction conditions, inter-

**Figure 4.** Kinetics of the interpolyelectrolyte substitution reaction (12) at different concentrations of NaCl (a) and the influence of the salt on the position of equilibrium of this reaction with native and denaturated DNA (b);<sup>31</sup>

(a)  $[NaCl] = 0.25$  (1),  $0.20$  (2) and  $0.125$  mol litre<sup>-1</sup> (3); (b) sodium salt (1), potassium salt (2), lithium salt (3); solid lines refer to native DNA and dashed lines correspond to denaturated DNA.

DNA is involved in the reaction (12). Actually, in the case of native DNA, unlike denaturated DNA, the equilibrium completely shifts to the PVP–PMA\* interpolyelectrolyte complex throughout the LiCl concentration range under study. Apparently, this difference is attributable to the fact that  $Li^+$  cations have a higher affinity for native DNA than for denaturated DNA. This fact is yet another example of the influence of specific interactions superimposed on usual Coulombic attractions.

Not only linear but also dendritic polyelectrolytes (dendrimers),<sup>22–24</sup> globular proteins<sup>28,29</sup> and other charged compact particles, for example, sols of polysilicic acid,<sup>54–60</sup> can serve as GPEs in the formation of IPECs. These IPECs remain in solution provided that the diameter of globules is much smaller than the contour length of linear HPE, and the population of HPE (the charge ratio) is no higher than a particular critical value. The mechanism of their formation is analogous to the above-considered mechanism of linear polyion coupling, and the equilibrium can be reached through rearrangements analogous to the above-described polyion exchange reactions. It should be noted that linear polyions with a rather high charge density on the chain generally replace globular particles, for example, proteins, in the starting IPEC (Scheme 4).<sup>29</sup>

Polyion exchange reactions, which play a decisive role in the establishment of equilibrium in IPEC-containing systems, can be hindered or completely frozen even in the presence of low-molecular-weight salts, if Coulombic interactions between poly-

ions are enhanced due to other types of interactions, such as hydrophobic interactions, donor–acceptor bonds, *etc.* A typical example is the different solution behaviour of two similar non-stoichiometric IPECs containing identical polyanionic components, *viz.*, NaPA or NaPMA, as HPE but different GPEs, *viz.*, either linear PEI polycations or poly(*tert*-butyl aziridine) (PTBA) polycations. The latter has a linear charge density identical to that of protonated PEI (see structure 4). Both interpolyelectrolyte complexes can exchange GPE at room temperature. However, at high temperatures ( $40–60$  °C), at which hydrophobic interactions play a larger role, the PTBA chains, unlike the PEI chains, are fixed within the complex and do not migrate from one particle to another.<sup>61</sup>

Other examples of the critical phenomena typical of polyion exchange reactions are considered below.

## 2. Properties of equilibrated non-stoichiometric interpolyelectrolyte complexes in solution

Nonstoichiometric IPECs can be considered as block copolymers containing free hydrophilic segments of HPE chains and relatively hydrophobic GPE–HPE domains.<sup>3,5</sup> In dilute solution, the behaviour of such equilibrated water-soluble IPECs (see above) is to some extent similar to the behaviour of usual polyelectrolytes. Methods for the preparation of soluble equilibrated non-stoichiometric IPECs composed of various GPE–HPE pairs were documented.<sup>62–64</sup> These methods have been also reviewed in detail in the publication.<sup>3</sup>

Studies by analytical ultracentrifugation,<sup>54,62,63</sup> gel-permeation chromatography<sup>65</sup> and light scattering<sup>3,5,29,64,66</sup> demonstrated that equilibrated water-soluble non-stoichiometric IPECs, which were prepared in dilute solutions from rather narrow molecular-weight fractions of HPEs and GPEs, occur as individual polymer particles. They are characterised by high compositional homogeneity and a narrow molecular-mass distribution. The characteristics of the PDMAEMA–PP polyelectrolyte complexes, which were prepared according to different procedures, are given in Table 2. Figure 5a shows the Zimm plot for a solution of the thermodynamically equilibrated PDMAEMA–PP complex studied by quasi-elastic light scattering. This plot is similar to typical plots constructed by processing the light scattering data for solutions of usual polymers. Analysis of the characteristics given in Table 2 demonstrated that the procedure for the preparation of complexes has virtually no effect on the measured molecular mass ( $M_w$ ), the radius of gyration ( $R_g$ ), the second virial coefficient ( $A_2$ ) and the sedimentation coefficient ( $S_c$ ). However, the above-mentioned characteristics (except for  $M_w$  compensated due to release of counterions) are sensitive to the composition of IPEC. The characteristics of equilibrated non-stoichiometric IPECs in dilute aqueous salt solutions are given in Table 3. It can be seen that  $R_g$  and  $A_2$  decrease, whereas  $S_c$  increases as the GPE/HPE ratio increases, *i.e.*, as the effective charge of HPE decreases in the range of  $0 < \varphi < \varphi_c$ . At  $\varphi < \varphi_c$ , IPECs listed in Table 3 exist in dilute solutions as individual particles: each particle includes one HPE polyion containing a particular number of GPE molecules.

**Table 2.** Characteristics of interpolyelectrolyte complexes prepared by titration methods {HPE = PDMAEMA ( $M_w = 6.3 \times 10^5$ ), GPE = PP ( $M_w = 6.6 \times 10^4$ ),  $\varphi = 0.33$ ,  $[\text{NaCl}] = 0.1 \text{ mol litre}^{-1}$ , pH 4.0}.

| Method of preparation of IPEC                         | $M_w \times 10^{-5}$ | $(R_g^2)^{1/2} / \text{nm}$ | $A_2 \times 10^4$ |
|-------------------------------------------------------|----------------------|-----------------------------|-------------------|
| Titration of HPE with a GPE solution                  | 7.7                  | 38                          | 3.3               |
| Titration of GPE with an HPE solution                 | 7.7                  | 39                          | 2.9               |
| Titration of a HPE–GPE mixture with hydrochloric acid | 7.2                  | 37                          | 2.8               |

However, the situation changes substantially as  $\varphi_c$  is approached. This is manifested primarily in a substantial change in the Zimm plot, which becomes similar to the plots characteristic of polymers in poor solvents. The molecular mass of soluble particles increases. This is indicative of the formation of IPEC aggregates, which do not dissociate upon dilution. Simultaneously, the absolute value of the second virial coefficient  $A_2$  sharply decreases and its sign changes from positive to negative (Fig. 5b, Table 3, run 8).

In dilute solutions, the tendency of non-stoichiometric IPEC particles to aggregation depends on the chemical nature of HPE and GPE. In particular, this tendency increases with increasing hydrophobicity of the starting polyelectrolytes. As an example let us consider the behaviour of IPEC formed by NaPA (HPE) and

**Figure 5.** Zimm plots for a solution of the PDMAEMA–PP interpolyelectrolyte complex at  $\varphi = 0.33$  (a) and  $0.56$  (b) (see runs 6 and 8, respectively, in Table 3).  $K$  is the optical constant,  $c$  is the concentration,  $R_\theta$  is the scattering intensity at the  $\theta$  angle.

5,6-ionene bromide (IB) serving as GPE.<sup>67</sup> Each repeated unit of the IB polycation (5) contains 5.5 methylene groups and two methyl groups per charge.

**Table 3.** Characteristics of equilibrated non-stoichiometric interpolyelectrolyte complexes in dilute aqueous salt solutions (20 °C).<sup>3,5,58</sup>

**Note.** The scattering intensities and refractive index increments were measured by varying the IPEC concentration at a constant concentration of a simple salt using dialysis of solutions of the samples against a solution of a common salt.<sup>64</sup> The molecular mass of IPEC of a given composition was calculated as follows:  $M_c = P_{\text{HPE}}[m_{\text{HPE}} + \varphi(m_{\text{GPE}} - m)]$ , where  $P_{\text{HPE}}$  is the degree of polymerisation of HPE,  $m_{\text{HPE}}$  and  $m_{\text{GPE}}$  are the molecular masses of the repeated units of HPE and GPE, respectively,  $m$  is the molecular mass of the salt eliminated upon coupling of polyelectrolytes;  $S_c$  was determined at a constant IPEC concentration of 0.35 mass %. <sup>a</sup> For all complexes,  $n_{\text{HPE}} = 1$ .

**Table 4.** Characteristics of IPEC formed from NaPA (HPE) and 5,6-ionene bromide (GPE) ( $M_{wHPE} = 1.2 \times 10^5$ ,  $M_{wGPE} = 1.4 \times 10^4$ , pH 7.2,  $[NaBr] = 0.025 \text{ mol litre}^{-1}$ ,  $20^\circ\text{C}$ ).

These groups are not sufficiently hydrophobic to suppress the solubility of the starting IB in water. However, in the presence of these groups, the affinity of IB–PA binary domains of IPEC for each other, apparently, increases. As can be seen from Table 4, the IB–PA particles undergo aggregation at  $\varphi \geq 0.2$  (these values are, however, substantially smaller than  $\varphi_c$ ) in contrast to IPECs listed in Table 3. Apparently, binary domains in aggregated IPECs form a water-insoluble core, while excess PA segments are exposed to water and form a crown, which imparts solubility to a particle as a whole.

Turning back to the experimental values of  $A_2$ , which decrease with increasing  $\varphi$ , recall that, according to the Donnan–Guggenheim theory,<sup>68</sup> the contribution of Coulombic repulsions between the charges of the polyion to the overall value of  $A_2$  can be expressed as follows:

$$A_{2el} = \frac{1000z_c^2\gamma^2}{4M^2I}, \quad (13)$$

where  $z_c$  is the total charge of the polyion,  $\gamma$  is the degree of binding of the counterions to free HPE segments,  $M$  is the molecular mass of the polyion and  $I$  is the ionic strength equal to the concentration of a simple salt in solution. The effective charge of non-stoichiometric IPEC particles in the pH range corresponding to complete ionisation of HPE depends on  $\varphi$

$$\frac{z_c}{M} = \frac{1-\varphi}{M_0}, \quad (14)$$

where  $M_0$  is the molecular mass of the repeated HPE unit. From Eqs (13) and (14) it follows that

$$A_{2el} \sim \frac{(1-\varphi)^2}{I}. \quad (15)$$

Figure 6a shows the dependence of the experimental values of  $A_2$  on  $(1-\varphi)^2$  at a constant ionic strength, which is in good

**Figure 6.** Dependences of the second virial coefficient ( $A_2$ ) of solutions of IPECs prepared from PDMAEMA ( $M_w = 6.3 \times 10^5$ ) and NaPP ( $M_w = 1.7 \times 10^4$ ) on their compositions at a constant ionic strength  $I = [NaCl] = 0.1 \text{ mol litre}^{-1}$  (a) and on the ionic strength at a constant composition (b); (b):  $\varphi = 0.33$ ; pH 4.0,  $T = 20^\circ\text{C}$ .**Figure 7.** Second virial coefficients ( $A_2$ ) in the coordinates of the equation (16) for different systems (see Table 3).

agreement with relation (15). The latter is also applicable for the case where the ionic strength varies, whereas  $\varphi$  remains constant (Fig. 6b). Assuming that the radius of gyration of a polyelectrolyte coil is directly proportional to the radius of the equivalent sphere and that the charge in the vicinity of the polyelectrolyte chain is primarily compensated by counterions and in accordance with the excluded volume theory, we can write

$$A_2 \sim \frac{R_g^3}{M_w^2}. \quad (16)$$

The experimental data given in Table 3 agree well with relation (16) (Fig. 7).

The agreement between the experimental data and the above theoretical relations supports the conclusion that the behaviour of soluble equilibrated IPECs, whose compositions are in a range  $0 < \varphi < \varphi_c$ , in dilute solutions is analogous to that of usual polyelectrolytes with different charge densities.

The solution behaviour of non-stoichiometric IPECs formed upon complexation of linear HPE polyions with relatively small charged globular particles serving as GPE is similar to the behaviour of non-stoichiometric IPECs consisting of linear polyelectrolytes. In particular, this is true for cationic dendrimers,<sup>22–24</sup> which interact with linear polyelectrolytes with rather high degrees of polymerisation.

However, it should be emphasised that the above-described behaviour is untypical of IPECs formed by polyelectrolyte pairs, which are not prone to exchange reactions even if the starting components are taken in a non-stoichiometric ratio and an excess of polyions with a high degree of polymerisation is used. In such systems, the equilibrium is not established for kinetic reasons. Interpolyelectrolyte complexes formed by mixing polyamines or polyammonium salts with polysulfates or polysulfonates are examples of non-equilibrated systems. In such IPECs, interchain ion pairs are additionally stabilised by specific donor–acceptor interactions. In this case, complexation gives rise to relatively large IPEC aggregates containing a large amount of oppositely charged polyions. These aggregates are formed, in particular, in the reactions of sodium poly(styrene sulfonate) (NaPSS) with poly-*N,N*-dimethyl-*N,N*-diallylammonium chloride.<sup>69–72</sup>

### 3. Conversions of interpolyelectrolyte complexes in salt solutions

Typical plots of the reduced turbidity ( $\tau/\tau_{\max}$ ) vs. the ionic strength for HPE–GPE mixtures in water for  $Z < \varphi_c$ ,  $\Theta$  close to unity ( $Z = \varphi$ ) and at a HPE concentration lower than the crossover concentration are presented in Fig. 8a. The homogeneity region *I* corresponds to dilute solutions of equilibrated non-stoichiometric IPECs. These solutions are transparent, and IPEC particles in such solutions behave analogously to individual polyelectrolytes. It should be noted that the smaller  $\varphi$ , i.e., the lower the population of HPE by GPE particles, the wider the region *I*. In region *II*, the system is also homogeneous. However, at these concentrations of

**Figure 8.** Phase behaviour of NaPMA ( $M_w = 2.6 \times 10^5$ )–PVP ( $M_w = 6.0 \times 10^4$ ) mixtures depending on the ionic strength, which was varied by the addition of NaBr (pH 7.5,  $T = 20^\circ\text{C}$ );<sup>71</sup> (a) plots of relative transmittance ( $\tau/\tau_{\max}$ ) vs. the ionic strength ( $I = [\text{NaBr}]$ ) at  $Z = 0.40$  (1), 0.33 (2, 2'), 0.25 (3), 0.40 (4); (b) sedimentograms of the mixtures at  $Z = 0.14$ ; (c) = 0.3 mass %,  $\omega = 56$  100 rpm,  $I = [\text{NaBr}] = 0.2$  (1), 0.35 (2), 0.48 mol litre<sup>-1</sup> (3); NaPMA (4) and PVP (5) at  $[\text{NaBr}] = 0.48$  mol litre<sup>-1</sup>.

low-molecular-weight salts, IPECs do not exist. In solution, they dissociate into the starting components because the oppositely charged polyions are shielded from each other by low-molecular-weight counterions. In the regions characterised by high turbidity, which are observed for different  $Z$  at intermediate salt concentrations, phase separation occurs and the systems become heterogeneous. The sedimentograms of the HPE–GPE system at different salt concentrations (profiles 1–3) are compared in Fig. 8b with the sedimentograms of individual HPE and GPE (profiles 4 and 5). The profiles 1 and 2 are characterised by one sedimentation peak and belong to the homogeneity region I. The profile 3 has two peaks and corresponds to the heterogeneity region.<sup>3, 73</sup>

The phase behaviour of charge-non-stoichiometric mixtures of oppositely charged polyelectrolytes in salt solutions were studied in detail by light scattering methods, analytical and preparative ultracentrifugation, fluorimetry (in systems containing fluorescent-labelled HPE- and GPE-quenchers), phase composition analysis, *etc.*,<sup>73–80</sup> which provided deeper insight into the phenomenon as a whole.

An increase in the salt concentration within the homogeneity region I (see Fig. 8a) deteriorates the thermodynamic quality of the solvent, which, in turn, leads to a decrease in the particle size of dissolved IPECs. The limiting concentration of HPE populated by GPE chains (at higher concentrations, phase separation occurs), which is determined by  $\varphi_c(I)$ , also decreases. Hence, the higher the starting value of  $\varphi$ ,  $\varphi_0 = Z$ , the lower the critical ionic strength ( $I_c$ ), at which  $\varphi_c(I)$  decreases to  $\varphi_0$ , and the broader the region I (see Fig. 8a, curves 1–4). To minimise the free energy of the system as a whole at  $I > I_c$ , the IPEC particles should lose a part of GPE chains. This occurs by redistribution of GPE chains between HPE chains according to the above-described mechanism of interpolyelectrolyte exchange. As a result, the reaction system undergoes disproportionation to give stoichiometric IPEC as an

individual phase, while particles of non-stoichiometric IPEC of composition  $\varphi' = \varphi_c(I) < Z$  (i.e., depleted in GPE compared to the starting particles) remain in solution. A further increase in the salt concentrations within the heterogeneity region leads to an increase in the amount of the stoichiometric complex, which forms an individual phase and remains in equilibrium with soluble IPEC particles of composition  $\varphi'$ . Evidently, under conditions where  $\Theta$  is close to unity,  $\varphi'$  cannot be smaller than the ratio of the degrees of polymerisation of GPE and HPE. Then if  $\varphi_c(I) < P_{\text{GPE}}/P_{\text{HPE}}$ , free HPE chains remain in the supernatant after precipitation of stoichiometric IPEC (Scheme 5).<sup>81</sup> The maximum HPE concentration in the supernatant can be as high as  $[\text{HPE}]_\infty = [\text{HPE}]_0(1 - \varphi)$ , where  $[\text{HPE}]_0$  is its initial concentration.

Scheme 5

It should be noted that this phase behaviour of IPECs in salt solutions is not unambiguously determined by the ionic strength. The critical ionic strength  $I_c$  for each IPEC depends substantially on the nature of the HPE counterions.<sup>73</sup> The turbidimetric titration curves of the NaPA (HPE)–IB (GPE) polyelectrolyte complexes ( $\varphi = 0.33$ ) with various simple salts are presented in Fig. 9. A comparison of the curves 1–4 shows that the critical ionic strength  $I_c$  decreases in the series  $(\text{CH}_3)_4\text{N}^+$ ,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{Li}^+$  as the affinity of the cation for the  $\text{COO}^-$  group increases.<sup>81</sup> At the same time,  $I_c$  is independent of the nature of the coanions of HPE, in particular, of  $\text{F}^-$ ,  $\text{Cl}^-$  and  $\text{Br}^-$  (see Fig. 9, curves 2'–2'''). The above data are consistent with the dependences of the sedimentation coefficients on the ionic strength of a solution for the PMA (HPE)–PVP (GPE) interpolyelectrolyte complexes ( $\varphi = 0.37$ ) and free NaPMA at low concentrations of simple salts (i.e., under conditions where IPECs are still quite stable).<sup>77</sup> It appeared that the addition of NaCl in the ionic

**Figure 9.** Plots of the relative transmittance ( $\tau/\tau_{\max}$ ) vs. the ionic strength for titration of IPEC formed in the NaPMA ( $M_w = 1.8 \times 10^5$ )–IB ( $M_w = 1.4 \times 10^4$ ) mixture ( $Z = \varphi = 0.33$ ) with solutions of LiCl (1); NaX, where X = F (2'), Cl (2''), Br (2'''); KCl (3);  $(\text{CH}_3)_4\text{NCl}$  (4); the concentration of IPEC in the solution was 0.01 mass %, pH 8.5,  $T = 20^\circ\text{C}$ .<sup>73</sup>

strength range  $0 < I < 0.1 \text{ mol litre}^{-1}$  leads to a substantial increase in  $S_c$  for both IPEC (from 1.7 to 4.35 Sv) and free NaPMA (from 1.3 to 2.5 Sv). This indicates that dissolved polymer particles become compact due to binding of the  $\text{Na}^+$  counterions to negatively charged PMA units. The  $(\text{CH}_3)_4\text{N}^+$  cations have a much lower affinity for carboxylate groups compared to the  $\text{Na}^+$  cations. Hence, an equal increase in the ionic strength upon the addition of tetramethylammonium chloride to the system leads to only a slight change in the sedimentation coefficients  $S_c$ . Similar effects were observed also for soluble non-stoichiometric IPECs formed by cationic HPEs and anionic GPEs but in relation to the chemical nature of low-molecular-weight anions. For example, IPEC consisting of poly-*N*-ethyl-4-vinylpyridinium fluoride (HPE) and PMA (GPE) ( $\varphi = 0.33$ ) decomposes at  $[\text{NaF}]_c = 0.2$ ,  $[\text{NaCl}]_c = 0.03$  and  $[\text{NaBr}]_c = 0.01 \text{ mol litre}^{-1}$ . This order corresponds to an increase in the affinity of halides for the pyridinium units of HPE. In this case,  $I_c$  is completely independent of the nature of simple cations.<sup>82</sup>

The salt concentration at which IPEC dissociates into the starting polyelectrolytes, which pass into solution, and the phase-separated systems are again homogenised (*i.e.*, pass into region II, see Fig. 8a) depends on the nature of both shielding counterions.<sup>78, 79</sup>

Figure 10 shows the plots of the relative fluorescence intensities of PMA\* (HPE), which is initially involved into the soluble non-stoichiometric PMA\*–PVP interpolyelectrolyte complex, vs. the concentrations of simple salts. The fluorescence intensity of the starting IPEC is low because of its quenching by the pyridinium rings of GPE. An increase in the fluorescence intensity in the course of titration of an IPEC solution with salts solutions is indicative of a decrease in the number of fluorescent labels in

HPE, which interact with the GPE units. This may be a consequence of dissociation of interpolyelectrolyte duplexes. A sedimentation study of the NaPMA\*–PVP electrolyte complexes in the corresponding salt solutions using a high-speed analytical ultracentrifuge equipped with a UV detector demonstrated that curves presented in Fig. 10 qualitatively describe the degree of cleavage of IPEC into the starting polyelectrolyte components.<sup>80</sup>

A comparison of the fluorimetric titration curves of a PMA\* (HPE)–PVP (GPE) solution with chlorides of various alkali metals and tetramethylammonium (Fig. 10a) demonstrated that the ability of low-molecular-weight cations to shield interacting oppositely charged polyions (thus inducing dissociation of IPEC) decreases in the series  $\text{Li}^+ > \text{Na}^+ > \text{K}^+ \gg (\text{CH}_3)_4\text{N}^+$ . The affinity of the cations for polyanions of polycarboxylic acids decreases in the same order.<sup>81</sup> Figure 10b displays the fluorimetric titration curves of the same IPEC with solutions of various tetramethylammonium halides. It can be seen that decomposition of IPEC can occur at a very low concentration of tetramethylammonium bromide (which determines the ionic strength of the solution), whereas the complex retains stability even at very high concentrations of tetramethylammonium fluoride. Tetramethylammonium chloride occupies an intermediate place. It should be noted that the affinity of halides for the PVP cations decreases in an analogous order.<sup>82</sup>

Analysis of the data presented in Fig. 10a shows that the fluorescence intensity noticeably decreases at concentrations of alkali metal halides substantially lower than those necessary for decomposition of IPECs. Apparently, the formation of compact IPEC particles through specific binding of alkali metal ions to excess PMA units facilitates fluorescence quenching within IPEC particles. Such a decrease is not observed in the presence of tetramethylammonium salts due to a substantially lower affinity of the  $(\text{CH}_3)_4\text{N}^+$  cations for  $\text{COO}^-$  groups.<sup>79</sup>

The threshold concentration of a low-molecular-weight salt necessary for decomposition of insoluble stoichiometric IPECs can be determined from a decrease in turbidity of the reaction mixture. This characteristic is independent of the degree of polymerisation of HPE, but it sharply increases (up to a certain limit) with increasing degree of polymerisation of GPE oligomers (Fig. 11).<sup>80</sup> However, it should be noted that a decrease in turbidity of the reaction mixture is not necessary indicative of the exhaustive cleavage of salt bonds and complete separation of the GPE and HPE chains, particularly, if GPE has a high molecular mass. Analysis of the results of sedimentation measurements demonstrated that a particular number of dynamic contacts between oppositely charged polyions can be retained even in a dilute solution, which appears in going through the clarification point. These contacts are completely broken only at higher salt concentrations.<sup>78</sup>

It should be emphasised that if the exchange of GPE between complex particles are, for one reason or other, forbidden, the

**Figure 10.** Plots of the relative fluorescence intensities ( $I/I_0$ ) of a solution of IPEC formed from NaPMA\* ( $P_w = 2150$ ) and PVP ( $P_w = 390$ ) vs. the concentrations of salts with various cations (a) and anions (b);  $Z = \varphi = 0.3$ ,  $[\text{PMA}^*] = 2 \times 10^3 \text{ base-mol litre}^{-1}$ , pH 9.5,  $T = 20^\circ\text{C}$  ( $I_0$  is the fluorescence intensity of free HPE in an analogous solution of the salt).<sup>77</sup> (a) M = Li (1), Na (2), K (3),  $(\text{CH}_3)_4\text{N}$  (4); (b) X = Br (1), Cl (2), F (3).

**Figure 11.** Change in the threshold concentration of sodium chloride necessary for dissociation of the PVP–PMA\* interpolyelectrolyte complexes at high (a) and low (b) degrees of polymerisation of PVP.  $P_w(\text{PMA}^*) = 3.9 \times 10^3$ ,  $\varphi = 0.30$ ,  $T = 20^\circ\text{C}$ .

addition of salts to solutions of non-stoichiometric IPECs does not lead to phase separation. In particular, the addition of NaCl to the above-mentioned solutions of the PA(or PMA)–PTBA polyelectrolyte complexes leads to phase separation at room temperature, but these solutions remain homogeneous at 40–60 °C because at these temperatures the polycation exchange is suppressed by hydrophobic interactions.<sup>59</sup> In PA (HPE)–PE (GPE) solutions, phase separation does not occur even at high salt concentrations if the HPE and GPE chains are linked not only through Coulombic interactions but also through a particular number of covalent bonds.<sup>74–77</sup> At a salt concentration sufficiently high for interpolyelectrolyte ion pairs to be broken, covalent bonds are retained. Hence, the IPEC particles behave here as graft copolymers present in a solution common to the main chain and grafted branches.

A new family of water-soluble IPECs referred to as block ionomer complexes (BIC) was documented.<sup>83–86</sup> These complexes include a block copolymer composed of an ionic and non-ionic water-soluble blocks. They can retain solubility even at  $Z = \varphi = 1$ , where  $Z$  is the charge ratio of the constituent polyelectrolytes. As an example we refer to the block ionomer complex formed by the diblock copolymer NaPMA ( $P = 188$ )–block-poly(ethylene oxide) ( $P = 176$ ) and PVP ( $P = 100$ ).<sup>83</sup> At  $Z = \varphi = 1$ , the BIC unimer contains a hydrophobic domain of the stoichiometric PMA–PVP interpolyelectrolyte complex covalently bonded to the hydrophilic poly(ethylene oxide) block, *i.e.*, it is virtually a complex amphiphilic macromolecule. The BIC unimers act as surfactants characterised by a particular critical micelle concentration. Actually, at concentrations higher than CMC, the unimers undergo aggregation to form polymer micelles, which contain an insoluble core assembled from IPEC domains and a crown consisting of poly(ethylene oxide) blocks. Due to the presence of the crown, micelles are soluble in water and are resistant to further aggregation. At the same time, BIC micelles can be involved in polyelectrolyte exchange reactions with homopolyelectrolytes (in particular, with NaPSS or NaPMA). Unlike all other polymer micelles, they undergo deaggregation upon the addition of low-molecular-weight salts. Deaggregation occurs due to destruction of the IPEC core caused by electrostatic shielding analogously to that described above for usual IPECs.<sup>83</sup>

Adsorption of polyelectrolytes on large oppositely charged surfaces can also be considered in terms of the IPEC formation. From this standpoint, adsorption of PVP on polystyrene latex particles coated with chemically bonded carboxyl groups was examined.<sup>87–92</sup> The diameter of latex particles ( $5 \times 10^2$  nm) was much larger than the contour line of the polyelectrolyte. The surface density of the carboxyl groups was  $\sim 5$  nm<sup>-2</sup>, and their  $pK_a = 6.8$ . At pH 9, at which all carboxyl groups are ionised, the starting electrophoretic mobility (EPM) of latex particles is negative. The dependence of EPM on  $Z$  is shown in Fig. 12. It can be seen that the surface charge decreases with increasing  $Z$  and becomes equal to zero at  $Z = 1$ . However in this case, in contrast to equilibrated stoichiometric IPECs formed in the reactions of completely ionised oppositely charged linear polyelectrolytes, a noticeable number of surface negative groups and positive units of the adsorbed polycations do not ‘find each other’ at the isoelectric point and, hence, cannot form contact ion pairs because of steric hindrance. The ‘unpaired’ units of the adsorbed polycations remain in loops and ‘free tails’. These units, as well as ‘unpaired’ surface charges, are neutralised by low-molecular-weight counterions. Hence, the surface layer formed at the isoelectric point retains centres, which can adsorb both excess polycations (charge inversion) and polyanions, if they are added to the reaction system.

Actually, charge inversion of latex particles occurs at  $Z > 1$ , which indicates that excess polycations are adsorbed on these particles. At the same time, the dependence of EPM on  $Z$  is insensitive to changes in the latex concentration, which suggests that PVP is strongly bound to the adsorbent surface. Actually, titration of latex with a PVP solution affords the free polyelec-

**Figure 12.** Dependence of the electrophoretic mobility of latex particles – PVP on the composition of their surface layer. The concentration of the latex particles /litre<sup>-1</sup>: (1)  $1.8 \times 10^{12}$ , (2)  $1.8 \times 10^{11}$ , (3)  $9.0 \times 10^9$ ; pH 9.0,  $T = 20$  °C.

trolyte, which is accumulated in solution only once it completely saturates the latex surface. In spite of this fact, the adsorbed polycations are easily exchanged between the latex particles through random collisions. This fact was established experimentally. The starting negatively charged latex (Fig. 12, arrow *a*) was mixed with an analogous latex, which was recharged with adsorbed PVP polycations (Fig. 12, arrow *b*). In the course of mixing, the latex particles bearing opposite charges undergo aggregation followed by spontaneous redispersion of these aggregates to individual particles whose size is identical to the particle size of the starting latex. However, EPM measured after redispersion has an intermediate value (Fig. 12, arrow *c*), which unambiguously indicates that mixing leads to redistribution of the adsorbed PVP polycations between the latex particles in the system.

Negatively charged small monolamellar liposomes (SML) display analogous behaviour in interactions with PVP.<sup>92,93</sup> Upon the addition of a PVP solution to a suspension of SML composed of the zwitterionic lipid, *viz.*, phosphatidyl choline (or dipalmitoyl phosphatidyl choline), and the anionic lipid, *viz.*, cardiolipin, the polycations are strongly adsorbed on the liposome surface. However, the subsequent addition of a NaPA solution leads to rapid removal of PVP from the surface due to formation of the even stronger PA–PVP interpolyelectrolyte complex. The SML–PVP complex, like usual IPECs, dissociates in the presence of low-molecular-weight salts (for example, NaCl). Both transformations are accompanied by complete regeneration of the starting SMLs.

The above examples reflect ‘ideal relations’ between polyelectrolytes and oppositely charged surfaces. This behaviour is typical only of systems, in which the electrostatic component plays the major role in adsorption. A different situation arises when other interactions (hydrogen bonds, hydrophobic or donor–acceptor interactions, *etc.*) are present in the system along with Coulombic attractions. In these systems, the polyion exchange or substitution does not occur, and the addition of low-molecular-weight salts does not cause desorption of polyions bound to the surface. For example, unlike PVP ( $\beta > 90\%$ ), PVP copolymers containing hydrophobic regions are not desorbed from the surface of the above-mentioned SMLs upon the addition of NaCl.<sup>93</sup>

Presumably, nonideal electrostatic or strong non-electrostatic adsorption of a soluble polyelectrolyte on the solid sorbent surface plays the key role in the technology of the preparation of thin monolayer IPEC films.<sup>7</sup> In this case, adsorption gives rise to the

starting interface, which can strongly bind another oppositely charged polyelectrolyte as it comes in contact with its solution. This affords the first starting IPEC nanolayer. The latter serves as a basis for the formation and multiple reproduction of identical layers. These layers are deposited by successive immersion of the sorbent into solutions of oppositely charged polyelectrolytes. The factors suppressing polyelectrolyte exchange reactions are favourable for the retention of the continuity of each newly formed layer and regeneration of a 'sticky' interface necessary for each successive deposition.

### III. Complexation of polyelectrolytes with oppositely charged hydrogels

In the late 1980s, it was found that macroscopic samples of weakly cross-linked polyelectrolyte hydrogels (#PE) can adsorb oppositely charged linear polyelectrolytes from aqueous solutions to form cross-linked interpolyelectrolyte complexes (#IPEC).<sup>94,95</sup> Hydrogels containing 1–2 chemical cross-linkages per 200 repeated monomer units were investigated. In the initial state, their equilibrium degree of swelling was  $\sim 10^3$ . It appeared that complexation giving rise to #IPECs is controlled by the same factors as the reactions between oppositely charged linear polyelectrolytes. In the reactions involving weak polyelectrolytes as components, the pH range where #IPEC are formed and retain stability is bounded by the curves shown in Fig. 1.

Sorption of linear PEs was demonstrated to cause a sharp decrease in the volume of the hydrogel involved in the reaction (by 2–3 orders of magnitude). In the course of the interpolyelectrolyte reaction, a weakly swollen shell of the resulting #IPEC coexists with the strongly swollen core of the starting #PE. The coexisting regions are separated by a pronounced interface presented in Scheme 6.

Scheme 6

The sorption mechanism of soluble #PE involves two independent interpolyelectrolyte reactions. The adsorption-rate-determining step involves a 'relay-race' transfer of polyion segments from one fragment of the #PE network to another (initially vacant) through the interpolyelectrolyte exchange reaction

Each transfer event occurring at the shell/core interface and directed into the hydrogel phase affords a vacancy in the #IPEC shell, which becomes accessible for another segment of the polyion, thus allowing transfer in the same direction (Scheme 7).

As a result, the interface between the shell and the core moves to the centre of the sample involved in the reaction and the shell gradually extends over the whole starting #PE hydrogel. At the same time, charged vacancies together with their neutralising counterions move in the opposite direction and finally reach the interface between the #IPEC shell and the external solution, where they are bound to the oppositely charged polyions coming from the solution.

It is this coupling reaction that is the driving force for migration of polyions to the oppositely charged hydrogel. In other words, the free energy of the reaction (19) is consumed for the transport of polyions in the hydrogel phase, thus pushing the reaction (18).<sup>94</sup>

Scheme 7

Hence, the formation of #IPEC is thermodynamically controlled by the reaction (19), which occurs only under conditions (pH or the degree of ionisation of polyelectrolytes,  $\alpha$ , the ionic strength) where the equilibrium shifts to the left. Correspondingly, #IPEC dissociates if the equilibrium (19) shifts to the right. In this case, linear polyions go back into the solution and the starting #PE hydrogel is completely regenerated. The composition of the final #IPEC is also determined by  $\alpha$ .

The formation of #IPEC can be terminated in any intermediate step by ceasing the supply of polyions from the solution. If the conditions of stability of #IPEC are still met, the sharp interface between the shell and the core in the partially reacted sample (see Scheme 6) is not blurred and remains stationary for as long as desired. Hence, one can easily control the thickness of the #IPEC shell.

At the same time, the formation of #IPEC is kinetically controlled by the reaction (18).<sup>95</sup> The process is accelerated with increasing ionic strength (in the range of stability of IPEC) and with decreasing degree of polymerisation of the linear polyion. If the interpolyelectrolyte exchange reaction is forbidden for one reason or other, linear polyions do not penetrate into the #PE hydrogel. In this case, only a thin #IPEC film (its thickness is close to the diameter of the polyion) is formed on the hydrogel surface.<sup>96</sup> The data given in Table 5 describe the character of complexation of various #PE hydrogels with various linear polyelectrolytes. It can be seen that the factors suppressing the exchange reactions of soluble IPEC with linear polyelectrolytes (the presence of hydrophobic, sulfate or sulfonate groups in polymer chains) hinder the unlimited penetration of linear polyions into cross-linked hydrogels.

Cross-linked polyelectrolyte hydrogels can adsorb not only linear polyions but also oppositely charged globular proteins to form the corresponding #IPECs. This was exemplified for the first time by the reaction of strongly cross-linked sodium polyacrylate (#NaPA) hydrogel with lysozyme.<sup>97</sup> Later on, this phenomenon was studied in detail for sorption of cytochrome *c* and protamine by weakly cross-linked #NaPA hydrogels.<sup>98,99</sup> In particular, it was demonstrated that the number of salt bonds between the  $\text{COO}^-$  groups of #NaPA and the amino groups of the protein globule in salt-free systems is determined by pH, and the equilibrium composition of the final #IPEC formed in the presence of an excess protein in the reaction mixture is identical to the composition of IPEC precipitated by titration of a solution of linear NaPA with a solution of the corresponding protein. In the

intermediate steps of sorption of proteins by hydrogels from salt-free solutions, analogously to sorption of linear polyelectrolytes, the strongly swollen hydrogel core coexists with a well-defined compact shell of the resulting #IPEC, which is gradually thickened and finally takes up the whole starting hydrogel. However, the addition of low-molecular-weight salts to these systems, in contrast to the above-considered #PE/linear polyelectrolyte systems, not only affects the sorption kinetics but also radically changes the protein distribution within the partially reacted hydrogel, and the protein distribution changes from completely heterogeneous to virtually homogeneous.<sup>99</sup>

#### IV. Structures and mechanical properties of interpolyelectrolyte complexes in the bulk

Although IPECs have been studied for many years, their structures and properties in the bulk remain poorly known. Unfortunately, scarce data were published primarily in sources that are difficult to access and, hence, are unknown to a wide range of researchers.

In early studies devoted to analysis of equilibria in coupling reactions of oppositely charged polyelectrolytes, IPECs were interpreted (on the basis of indirect evidence) as polymer compounds, in which polycations and polyanions are separated by more or less extended sequences composed of contact ion pairs coexisting with individual loops and tails. The latter can be considered as structural defects.<sup>100</sup> The higher the degree of conversion  $\Theta$ , the larger the percentage of paired units in such IPECs (see Fig. 1). The percentage of free hydrophilic units in the loops and tails determines the maximum degree of swelling of IPEC in water. Swelling is limited by sequences of ion pairs, which, under the conditions of existence of IPEC, are stabilised by cooperative Coulombic interactions.

Unlike the equilibrated soluble non-stoichiometric IPECs considered above, insoluble stoichiometric IPECs, even those prepared in dilute aqueous solutions, undergo aggregation and form compact globular particles whose sizes are generally no smaller than tens of micrometers.<sup>101–103</sup>

The presence of structural defects in stoichiometric IPECs may be associated with ‘freezing’ of random interchain ion contacts, which appear in early steps of fast coupling reactions of polyions, resulting in the formation of IPEC particles as an individual phase. Then subsequent rearrangements of chains necessary for correction of defects proceed very slowly, partic-

ularly in the absence of low-molecular-weight salts. Slow relaxation of non-equilibrated IPECs prepared by neutralisation of strong polyacids with strong polybases was documented.<sup>14, 103</sup> However, if factors responsible for the formation of non-equilibrium structures are excluded, for example, in the preparation of stoichiometric IPECs by polymerisation of an ionic polymer on an oppositely charged polyelectrolyte matrix, the resulting products can be rather well ordered.<sup>104–107</sup>

Generally, steric incompatibility between the interacting constituent polyelectrolytes is the main reason for the presence of structural defects in IPECs. The majority of known IPECs are coupling products of sterically irregular polyions. Such IPECs are X-ray amorphous. Studies by the ion-exchange equilibrium method demonstrated that at least 20%–30% of pairs of oppositely charged units in these IPECs are spatially separated.<sup>108</sup> In particular, even the product of the completed reaction of linear PEI with atactic PAA, whose chains are characterised by rather good steric compatibility, is X-ray amorphous. The IR spectroscopic study<sup>109</sup> demonstrated that at  $Z = 1$ , about 20% of the carboxy and imino groups in this IPEC are not involved in ion pairs but are located in structural defects. At the same time, domains of the PEI–PA interpolyelectrolyte complexes formed by contact ion pairs have, apparently, good short-range order. This is evidenced by the fact that heating of a dry PEI–PA film leads to the quantitative ‘transformation’ of the interpolyelectrolyte ion pairs into covalent amide bonds to form a ladder structure.

The carboxy and amino groups occupying defect sites are not involved in this reaction.<sup>109–111</sup>

However, the aforesaid does not mean that crystalline IPECs cannot be prepared by direct mixing of oppositely charged polyelectrolytes. In particular, IPECs, which were prepared by mixing solutions of ionene (6) and isotactic NaPA<sup>107</sup> or NaPP,<sup>112, 113</sup>

are characterised by a very high degree of crystallinity. In any case, stereoregularity and particular steric compatibility between oppositely charged polyelectrolytes are, apparently, the necessary conditions for IPEC crystallisation.

Important data on the conformations of individual chains in solid IPEC consisting of high-molecular-weight PMAK and chitosan ( $M_w = 1.9 \times 10^5$ ,  $Z = 1$ ), were obtained by small-angle neutron scattering.<sup>114</sup> A mixture of usual PMAK [PMAK(H),  $M_w = 3 \times 10^5$ ] and 2% deuterated PMAK [PMAK(D),  $M_w = 1.1 \times 10^5$ ,  $M_w/M_n = 1.25$ ] was used as the polyanion. Samples of IPEC as 0.1-mm-thick homogeneous films were prepared from solutions of polyelectrolytes in a common solvent, viz., an aqueous formic acid solution. Films formed after evaporation of the solvent were thoroughly washed with water and dried *in vacuo*, as was described in the study.<sup>115</sup> Samples of PMAK, which were used for measuring unperturbed sizes of the PMAK(D) chains, were prepared as thin films from an aqueous solution containing 2 mol.% PMAK(D) and 98 mol.% PMAK(H). In these experiments, PMAK(H) films were used as reference samples. Small-angle neutron scattering measurements were carried out in the scattering vector ( $Q$ ) range  $4 \times 10^{-5} \leq Q \leq 8 \times 10^{-4} \text{ nm}^{-1}$ , where  $Q = 4\pi(\sin\theta)/\lambda$ ,  $2\theta$  is the scan angle and  $\lambda = 3.03 \times 10^{-2} \text{ nm}$  is the average wavelength of the incident neutron beam. The spectral half-width was  $\Delta\lambda/\lambda = 0.35$ .

In the case of PMAK(D) strongly 'diluted' with PMAK(H), intramolecular interference from PMAK(D) may be ignored. Then, the Debye equation for coil-like chains

$$I(Q)^{-1} = I(0)^{-1} \left( 1 + \frac{Q^2 R_g^2}{3} \right) \quad (21)$$

is fulfilled at  $QR_g < 1$ , where  $I(Q)$  and  $I(0)$  are the scattering intensities at  $Q \neq 0$  and  $\theta = 0$ , respectively.

Since chitosan and PMAK(H) are characterised by virtually equal scattering densities, the radius of gyration of the PMAK(D) chain in IPEC was determined from Eqn (16). Figure 13 displays the plots of  $I(Q)^{-1}$  vs.  $Q^2$  for IPEC and PMAK samples at small scattering vectors  $Q$ . The observed equality of the extrapolated values of  $I(Q)^{-1}$  suggests that the contrast PMAK(D) chains in both samples are uniformly distributed and are not aggregated. For PMAK(D) in the PMAK(H) matrix,  $R_g = 10.2 \pm 0.3$  nm exactly corresponds to the expected unperturbed size. By contrast,  $R_g = 17.5 \pm 0.5$  nm for PMAK(D) in the IPEC matrix, which is indicative of a noticeable elongation of the PMAK coils interacting with chitosan. However, the shape of these elongated coils deviates only slightly from the Gaussian. Processing of the neutron scattering data for PMAK(D) in the PMAK(H) matrix (Fig. 14, curves 1 and 2) at  $QR > 5$  gives  $I(Q) \sim Q^{-2}$ , which is complete agreement with the Gaussian distribution. For PMAK(D) in the IPEC matrix,  $I(Q) \sim Q^{-2.2}$ .

Unfortunately, the above-described experiments are, to my knowledge, the only example of studies of the IPEC structure in the solid state by small-angle neutron scattering. Undoubtedly, further systematic investigations in this field will be highly informative and useful.

Air-dry amorphous IPECs in the bulk are transparent fragile materials. For most of them, water serves as a common plasticiser: IPEC films weakly swollen in water (tens of percentage at  $Z = 1$ ) are flexible and elastic. Homogeneous IPEC films can be formed from solutions of the corresponding polyelectrolytes, if their

**Figure 13.** Initial regions of the small-angle neutron scattering curves for PMAK(D) in the PMAK(H) matrix (1) and for PMAK(D) in the matrix of the PMAK – chitosan interpolyelectrolyte complex (2).

**Figure 14.** Full experimental small-angle neutron scattering curves for PMAK(D) in the PMAK(H) matrix (1) and for PMAK(D) in the matrix of the PMAK – chitosan interpolyelectrolyte complex (2).

premature electrostatic binding to each other in solution is prevented in one way or another. For a pair of strong polyelectrolytes, mixed aqueous-organic solvent containing a shielding low-molecular-weight salt (for example, NaCl or NaBr) and a volatile organic component (for example, acetone or dioxane) are used, which hinders salting-out of the polyelectrolytes from the solution. After evaporation of the mixed solvent, the films are repeatedly washed with water to remove inorganic salts.<sup>1, 15, 116</sup> In the case of weak polyelectrolytes, their premature binding in solution can be prevented by shifting pH for a time from the stability range of IPEC to an acidic or basic region (see Fig. 1). This is achieved by adding a volatile acid (for example, formic or acetic acid) or a volatile base (for example, ammonia or trimethylamine).<sup>115</sup>

The mechanical properties of IPECs formed by pairs of strong polyelectrolytes have not been studied systematically. However, it was noted that the most strong water-swelling IPEC films, which were tested as potential ion-exchange and separating membranes for salting-out of water, are formed at  $Z = 1$ , *i.e.*, when the maximum number of interpolyelectrolyte salt bonds per unit volume are present.<sup>1</sup>

A more complex situation occurs with IPEC membranes involving weak polyelectrolytes,<sup>115</sup> in particular, poly(ethylenepiperazine) (7) (PEP,  $M_n = 3 \times 10^5$ ) and PAA ( $M_n = 3 \times 10^5$ ).

Their mechanical properties were studied in detail.<sup>117</sup> Films of different compositions  $Z = [\text{PAA}]/[\text{PEP}]$  were prepared from 50% aqueous formic acid. Load – deformation curves describing the viscoelastic properties of equilibrium swollen films of PAA – PEP interpolyelectrolyte complexes of composition  $Z \geq 1$  immersed in aqueous solutions are presented in Fig. 15a. The majority of water-swollen PECs are characterised by analogous

**Figure 15.** Viscoelastic properties of the PAA – PEP interpolyelectrolyte complexes;

(a) load – deformation curves for IPECs of various compositions in an aqueous solution, pH 6.0,  $T = 20^\circ\text{C}$ ;  $Z = [\text{PAA}]/[\text{PEP}] = 2$  (1), 1.5 (2), 5 (3), 7 (4), 1 (5); (b) the plot of the initial Young's modulus of IPEC vs. the composition; (c) load – deformation curves for IPEC ( $Z = 1$ ) in water (1), an aqueous NaCl solution (5 mass %) (2) and dioxane (3).

load–deformation curves. However, in contrast to IPECs consisting of a pair of strong polyelectrolytes, the maximum rupture stress (Fig. 15a) and Young's modulus (Fig. 15b) are observed at  $Z = 2$  rather than at  $Z = 1$ . In other words, PAA-rich films are most strong. The minimal equilibrium degree of swelling corresponds to the same composition ( $\sim 35\%$ ). At  $Z < 1$ , the strength of the films is even smaller than that at  $Z = 1$ . Undoubtedly, the role of intermolecular salt bonds, which reinforce a film structure, in these materials is as important as in IPECs formed by strong polyelectrolytes. In particular, this is evident from a consideration of the load–deformation curves presented in Fig. 15c. It can be seen that a sample, which was initially immersed in a solution of a low-molecular-weight salt responsible for shielding of salt bonds between the oppositely charged polyions and then tested in the same medium, is characterised by much smaller initial Young's modulus and yield stress. At the same time, the replacement of water with a water–dioxane mixture or pure dioxane leads to substantial strengthening of IPEC films due to an increase in stability of the ion pairs as a result of a decrease in the polarity of the medium. Nevertheless, analysis of the mechanical behaviour of PAA–PEP films containing excess PAA demonstrates that additional hydrogen bonds also contribute substantially to stabilisation of the IPEC structure. For example, the initial Young's moduli of films of PAA–PEP interpolyelectrolyte complexes decrease with increasing temperature (Fig. 16). For PAA-rich IPECs, the Young's moduli decrease more substantially and are characterised by more pronounced cooperativity.

**Figure 16.** Temperature dependence of the viscoelastic properties of the PAA–PEP interpolyelectrolyte complexes in an aqueous solution, pH 6.0; (a) load–deformation curves measured at 10 (1), 20 (2), 30 (3), 40 °C (4); (b) the temperature dependence of the initial Young's modulus,  $Z = 1$  (1), 3 (2), 5 (3).

## V. Conclusion

Vital functions of any complex biological construction were determined not only by precisely programmed molecular structures of the starting constituent biopolymers but also by the controlled mechanisms of their self-assembly and reorganisation. The structures of supramolecular biological particles are formed as a result of establishment of balance between superimposed

multipoint interactions, some of them being oppositely directed (hydrogen, hydrophobic and donor–acceptor bonds, electrostatic attraction and repulsion). Hence, along with retention of extraordinary stability under particular conditions, biological structures can undergo rearrangements and substantial reorganisation even upon insignificant changes in the environmental medium. These characteristic features are, to some extent, typical also of IPECs constructed from synthetic polyelectrolytes. The phenomena, characteristic features and their interpretation presented in this review may be useful in controlling the synthesis, structure and properties of IPECs prepared for various technical and biomedical applications.

I thank the Corresponding Member of the Russian Academy of Sciences A B Zezin for helpful discussion of some key aspects of the review, researchers, graduate students and students of the Chair of High-Molecular-Weight Compounds of the Department of Chemistry of the Moscow State University, which were engaged in some of the above-cited studies, and Dr. O A Pyshkina for help in preparing the review for publication.

**Abstract.** The results of studies on the properties of subcritical and supercritical water are generalised. The possibility of using such water as a solvent, a reagent or a catalyst in chemical reactions is considered. Primary attention is paid to specific features of experimental research under hydrothermal conditions. Prospects for use of subcritical and supercritical water in heterogeneous catalysis for the preparation of nanocrystalline materials with predictable properties and for solving environmental problems are discussed. The bibliography includes 208 references.

## I. Introduction

Over billions of years subcritical and supercritical water has been involved in the formation of ores and minerals in Earth's depths.<sup>1</sup> The beginning of research on supercritical fluids dates back to 1822. At that time, experiments with different solvents at high temperatures and pressures were first carried out by Cagniard de la Tour who discovered the critical points of substances.<sup>2</sup> The supercritical state of a substance is a state characterised by the disappearance of distinctions between the liquid and gaseous phases. In the nineteenth century, the development of chemistry of supercritical fluids was not so rapid. It was not until 1896 that Villard reported the first detailed review concerning the properties of a group of substances in the supercritical state.<sup>2</sup> In the twentieth century, environmental safety problems and improvement of the efficiency of chemical plants became topical. Because of this, interest increased in studying the properties of substances in the supercritical state. At present, the unique physicochemical properties of supercritical fluids are widely used in extraction and chromatographic separation of substances, in production of various materials and detoxification of liquid waste.<sup>2–4</sup> In addition, intensive research has been carried out on the possibility of using supercritical fluids in organic and inorganic synthesis and in homogeneous and heterogeneous catalysis.<sup>5–9</sup> Table 1 lists the critical parameters, *viz.*, the critical temperature ( $T$ ), pressure ( $P$ )

and density ( $\rho$ ) of the most widely used solvents. The scatter of the numerical values of these parameters for different substances is rather large, from nearly 282 K and 5 MPa for ethylene to almost 647 K and 22 MPa for water.

**Table 1.** Critical point parameters of solvents.<sup>5, 10</sup>

| Solvent                          | $T$ /K | $P$ /MPa | $\rho$ /kg m <sup>-3</sup> |
|----------------------------------|--------|----------|----------------------------|
| C <sub>2</sub> H <sub>4</sub>    | 282.1  | 5.041    | 214                        |
| Xe                               | 289.5  | 5.840    | 1110                       |
| CO <sub>2</sub>                  | 303.9  | 7.375    | 468                        |
| C <sub>2</sub> H <sub>6</sub>    | 305.2  | 4.884    | 203                        |
| N <sub>2</sub> O                 | 309.4  | 7.255    | 452                        |
| NH <sub>3</sub>                  | 405.3  | 11.350   | 235                        |
| C <sub>2</sub> H <sub>5</sub> OH | 513.7  | 6.137    | 276                        |
| H <sub>2</sub> O                 | 646.9  | 22.060   | 322                        |

Chemistry of subcritical and supercritical fluids belongs to the most rapidly progressing fields of chemical science. To date, a great body of experimental data on the properties of tens of substances at near-critical temperatures and pressures has been accumulated. Research on the properties of subcritical and supercritical water and on processes involving this substance occupies a particular place. It should be noted that supercritical water is still of limited use due to the high critical point parameters (see Table 1). However, one should keep in mind that water is the most abundant, cheap, safe and environmentally pure solvent. Because of this, water seems to be of crucial importance for further development of the chemistry of supercritical fluids.

This review summarises the available results obtained in basic and applied studies on the properties of subcritical and supercritical water and corresponding chemical processes. We present a consistent treatment of the physicochemical properties of water at elevated temperatures and pressures, experimental features and problems posed when using subcritical and supercritical water and the possibilities of using subcritical and supercritical water as a solvent, reagent and catalyst of inorganic and organic chemical reactions. The emphasis is placed on the prospects for application of subcritical and supercritical water in heterogeneous catalysis, in the fabrication of nanocrystalline materials with predictable properties and in solving the environmental pollution problem, which belongs to the most important problems of modern times.

## II. Physicochemical properties of subcritical and supercritical water

At a temperature of 295 K and a pressure of 0.1 MPa, water is a polar solvent with a density of  $1000 \text{ kg m}^{-3}$ , a dielectric constant,  $\epsilon$ , of 79.73 and an ionic product,  $K_w$ , of  $10^{-14}$  (see Ref. 11). Raising the temperature and pressure causes significant changes in the properties of water and aqueous solutions. Changes in the thermodynamic parameters are reflected in the phase diagrams of water and corresponding multicomponent systems. The properties of water, as a solvent, vary owing to variation of its dielectric constant, conductivity, ionic product and the structure of the H bond network. Changes in the viscosity, heat capacity, diffusion coefficients and density influence the transport characteristics of aqueous solutions.

It should be noted that the physicochemical properties of water at the critical point are changed continuously rather than in stepwise manner. The characteristics of supercritical water are intermediate between those of the liquid and gas (Table 2).

**Table 2.** Characteristics of water under different conditions.

| Characteristic                                                   | Water under normal conditions | Supercritical water   | Super-heated steam    |
|------------------------------------------------------------------|-------------------------------|-----------------------|-----------------------|
| $T/\text{K}$                                                     | 298                           | 723                   | 723                   |
| $P/\text{MPa}$                                                   | 0.1                           | 27.2                  | 1.4                   |

### 1. The density

At subcritical temperatures and pressures, water can exist in the liquid and gaseous states (Fig. 1). Under isothermal conditions,

**Figure 1.** Phase diagram of water at elevated temperatures and pressures.  $T/\text{K}$ : 553 (1), 573 (2), 593 (3), 623 (4), 633 (5), 647 (6), 653 (7) and 673 (8); G is gas and L is liquid.

the density of water changes continuously in both phases; a density jump occurs only at the gas–liquid interface. At the critical point, this interface disappears and the density of water becomes equal to nearly  $300 \text{ kg m}^{-3}$ . However, in the near-critical region water is characterised by an infinite compressibility, which allows the density of water to be changed over a very wide range by (only slightly) varying the temperature and pressure. For instance, the density of water is halved as the temperature increases by only 6 K at a pressure of 22 MPa.<sup>12</sup> A supercritical water density of  $1000 \text{ kg m}^{-3}$  can also be achieved; however, this requires a pressure of 750 MPa to be applied at 673 K.<sup>13</sup>

Carrying out chemical reactions in aqueous solutions usually requires control of the reagent concentrations, temperature and pressure. On going to subcritical and supercritical water one should also control the density of the medium because minor variations of this parameter can significantly influence the rate constants for reactions and the distribution of reaction products.<sup>10, 14</sup> The reason is that some characteristics of water, *e.g.*, the dielectric constant, ionic product, viscosity and thermal conductivity change in parallel with the density. Using controllable variation of the density of subcritical and supercritical water, one can vary the properties of water, as a solvent, and control the physicochemical processes proceeding in the medium.

### 2. The dielectric constant and ionic product

The temperature dependence of the ionic product of water measured at a constant pressure exhibits an extremum (Fig. 2). In the subcritical region the ionisation constant of  $\text{H}_2\text{O}$  reaches a maximum value, which is three orders of magnitude higher than the value typical of normal conditions. Therefore, subcritical water is a rich source of  $\text{H}^+$  and  $\text{OH}^-$  ions (see Ref. 15); in other words, it can serve not only as a polar solvent but also as a self-neutralising acid–base catalyst. This offers great prospects for carrying out various catalytic reactions and hydrolysis in the subcritical region. As the critical point is approached, the parameter  $\log K_w$  abruptly decreases and then monotonically decreases in the supercritical region (see Fig. 2).

The dielectric constant of water measured at a constant pressure continuously decreases as the temperature increases. At  $T = 573 \text{ K}$  and a density of  $700 \text{ kg m}^{-3}$ , the dielectric constant of water is four times lower than that of acetone.<sup>10</sup> Supercritical water can be treated as a non-polar ‘organic’ solvent because its dielectric constant approaches a value of six.<sup>16</sup>

It should be noted that the subcritical and supercritical states of water are usually attained in various units of steam and nuclear power plants. Corresponding technological processes are thoroughly controlled. Therefore, a great body of experimental data on the properties of water at elevated temperatures and pressures was accumulated. Treatment of these data allowed the equations

**Figure 2.** Temperature dependences of the dielectric constant (1), density (2) and ionic product of water (3) at a pressure of 24 MPa.

for calculation of the ionic product and dielectric constant of water over wide ranges of temperature and pressure to be derived.<sup>17,18</sup>

### 3. Hydrogen bonds

Under normal conditions all water molecules are interconnected by a network of hydrogen bonds. This provides an explanation for many physicochemical properties of water. Association of water molecules leading to formation of hydrogen bonds can be described by the following reaction:

where  $i = 1, 2, \dots, \infty$  and  $K_i$  is the equilibrium constant for association.

At room temperature and atmospheric pressure, the  $(\text{H}_2\text{O})_{i+1}$  aggregates can comprise up to 100 molecules.<sup>19</sup> The formation of hydrogen bonds is an exothermic process; therefore, the equilibrium constant  $K_i$  decreases as the temperature increases.<sup>10</sup> Near the critical point the structure of water changes significantly, namely, an infinite network of hydrogen bonds is destroyed and water exists as separate clusters with a chain structure.<sup>20</sup> In the supercritical region, molecules within these clusters remain hydrogen bonded. At 673 K and a water density of  $850 \text{ kg m}^{-3}$ , up to 50% of the total amount of hydrogen bonds are broken.<sup>21</sup> A computer simulation showed that the number of water molecules in the clusters strongly depends on the density of the supercritical fluid. For instance, in the low density region ( $T = 673 \text{ K}$ ,  $\rho = 167 \text{ kg m}^{-3}$ ) water clusters comprise up to ten molecules, but as the density increases ( $T = 772 \text{ K}$ ,  $\rho = 528 \text{ kg m}^{-3}$ ), the number of molecules in certain clusters can exceed twenty. At a high density of supercritical water ( $T = 680\text{--}771 \text{ K}$ ,  $\rho = 972\text{--}1284 \text{ kg m}^{-3}$ ), all molecules are again interconnected by hydrogen bonds, but there are also a few clusters comprised of less than fifteen molecules that temporarily are not involved in the common infinite network of H bonds.<sup>20</sup>

It is this breakdown of hydrogen bonds on going to the critical point that is responsible for the decrease in the dielectric constant, changes in the dynamic viscosity and an increase in the self-diffusion coefficient of water.<sup>22</sup> Indeed, for a molecule in a liquid to be mobile, free space and weakened interactions with neighbouring molecules are needed. Water molecules not involved in the system of hydrogen bonds are more mobile; this is responsible for the increase in the self-diffusion coefficient of water.

### 4. Solubility of substances in subcritical and supercritical water

The solubility of inorganic and organic compounds in subcritical and supercritical water is governed by the dielectric constant of the medium. A decrease in the dielectric constant on going to the critical point causes an increase in the solubility of organic compounds and a decrease in the solubility of inorganic ionic compounds. Supercritical water can be mixed with oxygen, hydrogen and hydrocarbons in any proportion. Generally, the solubility of substances in water increases with temperature (provided a constant density of water) and with pressure (under isothermal conditions). Since slight variations of the state parameters near the critical point lead to significant changes in all physicochemical characteristics of water, even minor changes in the pressure and temperature can result in complete dissolution or, contrarily, precipitation of oxides and salts from solutions.<sup>1,2</sup>

In the supercritical state, water molecules are clustered round the solute molecules; this causes local density fluctuations. On adding a substance, the density of the system near the critical point can increase to such an extent that the molar volume of the solute decreases by one or two orders of magnitude.<sup>23</sup>

A decrease in the dielectric constant of water at elevated temperature and pressure is responsible for significant changes in the structure of electrolyte solutions. Namely, under subcritical and supercritical conditions water molecules cannot efficiently

screen ions; therefore, rearrangement of hydration shells and ion pairing occur.<sup>24–26</sup> For instance, nearly 50% of water molecules are lost in the first hydration shell of the  $\text{Ni}^{2+}$  ion in a nickel bromide solution at 698 K and 69 MPa.<sup>24</sup> If under normal (not critical) conditions nickel ions in aqueous solutions are octahedrally coordinated by water molecules (coordination number equals six), in supercritical water the  $\text{H}_2\text{O}$  molecules in the hydration shell are replaced by bromide anions and there are only 2.5 water molecules per  $\text{Ni}^{2+}$  cation. A similar ‘ion dehydration’ effect in supercritical water was also observed in sodium chloride<sup>25,27</sup> and strontium nitrate and zinc nitrate solutions.<sup>26,28</sup> A Raman spectroscopy study showed that replacement of water molecules in the hydration shells of ions under near-critical conditions leads to appreciable strengthening of cation–anion interactions and the number of ion pairs (here, cations are tightly bound to anions) increases.

A decrease in the number of water molecules surrounding an ion usually facilitates ion diffusion.<sup>29</sup> However, considering the conductivity of electrolyte solutions in the supercritical region, one should take into account two competing factors, *viz.*, the number of water molecules in the hydration shell of the ion and the strength of the interaction between the ion and water molecules. The former factor dominates in the high-density region while the latter dominates at low density of supercritical water. Because of this, the electric conductivity plots for electrolyte solutions can exhibit extrema.<sup>29</sup>

### 5. Multicomponent systems

Efficient use of subcritical and supercritical water in various chemical and technological processes is impossible without investigating the phase diagrams of corresponding multicomponent systems. First of all, this is necessary in order to determine the temperatures, pressures and component concentrations corresponding to a monophasic system. Indeed, operation with a homogeneous medium allows one to avoid the diffusion-related difficulties associated with mass transfer through the interface. For instance, the rate constant for cellulose hydrolysis increases abruptly on going from subcritical to supercritical water, thus providing an explanation for the transition from a heterogeneous to homogeneous reaction.<sup>30</sup>

Adding substances to water significantly complicates the water phase diagram. Phase equilibria studies in multicomponent systems near the critical point of water face some experimental problems; for this reason, computer simulation is often used.

To date, tens of phase diagrams of binary and ternary systems such as  $\text{H}_2\text{O} - \text{C}_x\text{H}_y$ ,<sup>13,23,31–33</sup>  $\text{H}_2\text{O} - \text{CO}_2$ ,<sup>13</sup>  $\text{H}_2\text{O} - \text{O}_2$ ,<sup>34</sup>  $\text{H}_2\text{O} - \text{NaCl}(\text{NaOH}, \text{KCl})$ ,<sup>35</sup>  $\text{H}_2\text{O} - \text{CH}_4 - x\text{F}_x$ ,<sup>36</sup>  $\text{H}_2\text{O} - \text{Na}_2\text{SO}_4$ ,<sup>37</sup>  $\text{CF}_4(\text{CHF}_3) - \text{H}_2\text{O} - \text{NaCl}$ <sup>36</sup> and  $\text{NaCl} - \text{Na}_2\text{SO}_4 - \text{H}_2\text{O}$ <sup>38</sup> are available. All phase equilibria at high temperatures and pressures can be described by five schematic phase diagrams which were considered in detail in Ref. 2.

In practice, it is convenient to use projections of the  $P - T - x$  diagrams on the  $P - T$  plane. Figure 3 presents the critical curves (lines connecting the critical points of individual components) plotted in the  $P - T$  coordinates for a number of binary systems.<sup>13</sup> If water and the second component have similar properties (as is the case of, *e.g.*, the system  $\text{H}_2\text{O} - \text{NH}_3$ ), the critical curve connecting the critical points of the two pure components in the  $P - T$  diagram is continuous. If the polarity of the solute differs appreciably from that of water, the critical curve will consist of two portions. The upper portion issues from the critical point of the pure component with the higher boiling temperature and then the curve goes either to the region of high pressures and temperatures (as for the systems  $\text{H}_2\text{O} - \text{Ar}$  and  $\text{H}_2\text{O} - \text{H}_2$ ) or initially to the low-temperature region and then, after passing through a minimum, to the region of high temperatures and pressures (as for the systems  $\text{H}_2\text{O} - \text{C}_6\text{H}_6$  and  $\text{H}_2\text{O} - \text{CO}_2$ ). Adding an electrolyte to water appreciably shifts the critical point of water.

The critical curves bound the homogeneity region of binary systems, namely, above the critical curve we deal with a mono-

**Figure 3.** Critical curves for binary systems  $\text{NH}_3\text{--H}_2\text{O}$  (1),  $\text{CO}_2\text{--H}_2\text{O}$  (2),  $\text{C}_6\text{H}_6\text{--H}_2\text{O}$  (3),  $\text{Xe--H}_2\text{O}$  (4),  $\text{CH}_4\text{--H}_2\text{O}$  (5),  $\text{N}_2\text{--H}_2\text{O}$  (6),  $\text{H}_2\text{--H}_2\text{O}$  (7),  $\text{Ar--H}_2\text{O}$  (8),  $\text{HCl--H}_2\text{O}$  (9) and  $\text{NaCl--H}_2\text{O}$  (10).<sup>13</sup> CP( $\text{H}_2\text{O}$ ) and CP( $\text{NH}_3$ ) are the critical points of water and ammonia, respectively.

phase system. At  $T > 673$  K, all hydrocarbons, hydrogen and oxygen can be mixed with supercritical water in any proportion. In particular, adding oxygen to a water–methane (70% : 30%) mixture can lead to combustion ( $T = 723$  K,  $P = 100$  MPa); under these conditions, electrolysis of supercritical water can proceed without formation of the gas phase on electrodes.<sup>13</sup>

## 6. Homogeneous and heterogeneous catalysis

Among the most promising application avenues of subcritical and supercritical water are homogeneous and heterogeneous catalyses. Recently, a few reviews concerning the use of supercritical fluids in catalysis were published.<sup>5,9,39</sup> Unfortunately, subcritical and supercritical water is of limited use in the field so far. We would like to point out some advantages of the use of water in the near-critical region in various catalytic processes. Subcritical and supercritical water can serve as:

- a non-toxic solvent whose physicochemical properties can be ‘tuned’ in an optimised fashion to perform particular catalytic reactions;
- an efficient acid–base catalyst in homogeneous catalysis;
- a reagent and/or medium for preparing nanocrystalline heterogeneous catalysts with specified properties.

All these functions will be discussed below taking particular reactions and processes as examples.

It is convenient to consider the advantages of using supercritical water in catalysis taking a hypothetical heterogeneous reaction of gas A with liquid B on the surface of catalyst C as an example.<sup>5</sup> Figure 4 presents the concentration profiles of gas A for the same reaction carried out in water under normal conditions and in supercritical water. In the former case we deal with a ternary system ‘gas + liquid + solid catalyst’ (Fig. 4a).

The concentration profile of gas A for the same reaction in supercritical water is quite different (Fig. 4b). In this case, the gas and the liquid can be mixed in any proportion and we deal with a binary system ‘supercritical fluid + solid catalyst’. Now, diffusion-related problems associated with mass transfer at the gas–liquid interface (processes 1 and 2) are absent. In addition, diffusion of reagents towards the supercritical fluid/catalyst inter-

**Figure 4.** Concentration profiles of gas A in the course of a heterogeneous catalytic reaction carried out in water under normal conditions (a) and in supercritical water (b).<sup>5</sup>

Process: gas diffusion towards the gas/liquid interface (1), gas adsorption at the interface and gas diffusion in the bulk of the liquid (2), gas diffusion and liquid diffusion towards the liquid/catalyst interface (3), gas diffusion and liquid diffusion in the porous structure of catalyst (4), gas adsorption and liquid adsorption at the surface of the catalyst (5) and reaction between the gas and liquid molecules at the surface of the catalyst, desorption of reaction products and their diffusion in the bulk of the liquid phase (6).

face and in pores of the catalyst (processes 3 and 4) proceeds much faster owing to the low viscosity of supercritical water. Thus, the catalytic reaction in the supercritical water proceeds in the kinetic region and its rate and, hence, selectivity can be controlled by varying the temperature and pressure. Probably, the poisoning and coking rates of the catalyst in supercritical water will be much lower due to the low viscosity of the medium, shorter time of contact between reagents and the surface of catalyst and high diffusion coefficients of reagents and reaction products.<sup>40</sup>

The activity and selectivity of heterogeneous catalysts are complex functions of their chemical compositions and the morphology and macrostructure parameters. Structure imperfection, state of the surface, nature of active centres and the concentration and distribution of impurity phases are governed by the synthesis conditions and heat treatment regime of the catalyst. The use of subcritical and supercritical water for preparing catalysts is quite promising for the design of new efficient nanocrystalline catalytic systems and for modification of the properties of traditional catalysts and supports.<sup>41–44</sup>

## III. Specific features of experimental research using subcritical and supercritical water

Experiments with water at elevated temperatures and pressures require taking particular care and use of tailor-made equipment suitable for operation under extreme conditions. The end products of hydrothermal synthesis as well as the rates and selectivities of processes in subcritical and supercritical water are to a great extent determined by not only the properties of water but also the experimental technique, reactor material, being also dependent on the accuracy of maintenance of the specified temperature (pressure) and other parameters.

### 1. Batch and flow reactors

Reactions in subcritical and supercritical water can be carried out in batch and flow reactors. The simplest batch reactor is an autoclave placed inside a powerful heater and connected to temperature and pressure transducers (Fig. 5). In most cases the pressure in the batch reactor depends on the water filling degree; however, it can also be maintained using an external compressor or a pump. Reactions in these reactors can proceed both isothermally and under temperature gradient conditions.<sup>45</sup>

The vast majority of the studies on subcritical and supercritical media were carried out in batch reactors. However, from our point of view, this reactor design is for some reasons

Figure 5. Scheme of a batch reactor.

inappropriate for experimental research. For instance, if a reaction is followed by a release of gaseous products, it is difficult to maintain the density of the medium at a constant level in the batch reactor. Target organic synthesis in these systems is nearly impossible because variations of the reagent and product concentrations in the course of experiments can change the mechanisms of the processes occurring in the system, thus making the interpretation of the results obtained more difficult.

Batch reactors are appropriate only for carrying out recrystallisation processes and obtaining single crystals and minerals.<sup>46</sup> All other experiments in subcritical and supercritical water can be more conveniently performed in highly efficient flow systems that are also easy to control. In addition, laboratory flow systems can be scaled with ease to commercial plant level.

A scheme of a typical experimental flow system for operation with subcritical and supercritical water is shown in Fig. 6. Using a high pressure pump, water is continuously supplied to the system of powerful heaters at a specified rate and is heated to the desired temperature. A solution of reagents is continuously supplied to the system using the second pump. Mixing of the two flows at the inlet of the reactor is followed by physicochemical transformations of the reagents in subcritical and supercritical water. After passage through the reactor the reaction mixture is cooled to room temperature and then collected at the system's outlet. The pressure in the reactor is maintained by a back pressure regulator. If needed, one can use additional pumps for separate supply of several reagents to the reactor. For instance, oxidation reactions of organic compounds in supercritical water can be designed in such a way that one pump will supply the organic compound and the other pump will supply the oxidiser, *e.g.*, hydrogen peroxide.

Figure 6. Scheme of an experimental flow reactor for operation with subcritical and supercritical water. Heating zone (1) and cooling zone (2).

The duration of a reaction in a flow reactor ( $\tau$ ) depends on the specific volume of water under the experimental conditions ( $v/\text{m}^3 \text{ kg}^{-1}$ ), on the reaction mixture consumption ( $M_f/\text{kg s}^{-1}$ ) and on the volume of the reaction zone ( $V/\text{m}^3$ )

$$\tau = \frac{V}{M_f v}.$$

Typically, the duration,  $\tau$ , is of the order of a few seconds for a flow reactor,<sup>43</sup> being much shorter than for the batch reactors.

Near the critical point the heat capacity of water tends to infinity; therefore, powerful heaters are needed to attain the supercritical state. These can be conventional electric furnaces as well as other heat sources, *e.g.*, microwave radiators.<sup>47</sup>

To establish the mechanisms of the reactions proceeding in subcritical and supercritical water, it is of great interest to study processes *in situ* using various spectral methods. To this end, the reactor can be equipped with a tailor-made optical cell suitable for operation under hydrothermal conditions.<sup>7, 48</sup>

When carrying out reactions in flow systems, the possibility of reactor blockage due to precipitation of various substances (*e.g.*, inorganic salts and oxides) should be taken into account.<sup>49</sup> In order to avoid reactor blockage, it is appropriate to periodically pass a solvent through the reactor to remove organic and inorganic sediments.<sup>50</sup>

Extraction processes used in household and industrial waste management and in modification of the properties of various systems involve treatment of solid materials with subcritical and supercritical water, which can hardly be done in flow reactors. Specific pumps for operation with aqueous suspensions function only if solid particles have a particular size. To solve this problem, a system was designed with simultaneous supply of the solid phase and subcritical or supercritical water to the batch reactor.<sup>51</sup> After a specified time the reaction products are removed from the reactor and a new portion of reagents is supplied to the system. This design combines the advantages of the flow and batch reactors.

## 2. Corrosion problem

Perhaps, the most complicated problem in operating with subcritical and supercritical water is corrosion of experimental setups. Even deionised supercritical water is a highly corrosive medium, which causes destruction of the alloys the reactors are made of.<sup>52</sup> When performing chemical reactions involving organic and inorganic substances under hydrothermal conditions, researchers deal with oxidant, salt, acid and base solutions that are corrosive media even under normal conditions. In this connection, the search for materials that are corrosion stable at high temperatures and pressures is a topical problem in chemistry of subcritical and supercritical water.<sup>53, 54</sup>

Corrosion studies<sup>52, 54–62</sup> of various materials in subcritical and supercritical water showed that stainless steel, nickel alloys, titanium, tantalum, noble metals and ceramics undergo severe destruction in the presence of salts, acids or gases.<sup>61</sup>

The mechanism of water corrosion at high temperatures and pressures is somewhat different from the conventional water corrosion mechanism. Electrochemical corrosion usually involves two or more conjugated redox reactions on different sides of the corroding metal. The low conductivity of supercritical water hampers ion transfer between the centres of the conjugated redox reactions; therefore, in this case corrosion is a result of the one-step reaction of, *e.g.*, oxygen or HCl with the metal.<sup>58</sup>

The corrosion stability of many metals and alloys is due to the formation of passivating oxide films on their surfaces. However, metal oxides become reactive in supercritical water. For instance,  $\text{Cr}_2\text{O}_3$  is dissolved to give chromic acid<sup>57</sup>

Because of this, chromium and some Cr-based alloys corrode in supercritical water. Only the G-30 alloy (29.4% Cr, 40.1% Ni, 14.5% Fe, 5.1% Mo, 2.9% W + Co + Cu) exhibits a high corrosion stability against aqueous solutions containing oxygen and chloride ion at 693 K and a pressure of 40 MPa.<sup>60</sup>

Sometimes, in order to avoid corrosion, the inside of metallic reactors is covered with ceramics. However, often this does not make the situation better, because out of more than thirty investigated ceramic materials only pure alumina and  $\text{Al}_2\text{O}_3\text{--ZrO}_2$  ceramics did not severely corrode in supercritical water containing hydrogen peroxide and hydrochloric acid.<sup>59</sup>

#### IV. Hydrothermal synthesis of nanocrystalline oxide materials

Recently, interest in nanocrystalline materials has been growing increasingly because of the unique physicochemical properties of these objects. It was established that the majority of the properties of solids become size-dependent as the particle size decreases down to a few interatomic distances in one, two or three dimensions. Nanocrystalline metallic and oxide powders with specified morphologies, phase compositions and properties of the bulk phase and the surface are needed to produce a variety of new generation materials such as sensors, semiconductors, fuel cells, high-density ceramics, efficient heterogeneous catalysts and sorbents.

At present, nanocrystalline materials are obtained using the sol–gel technique, codeposition, hydrolysis of alkoxides, organometallic synthesis, pyrolysis, gas-phase methods and detonation synthesis. Most of the methods mentioned above involve a number of stages and are labour-consuming, which complicates the wide use of nanocrystalline materials (even well-studied materials!) in technological processes. In this connection development of new, high-performance methods of fabrication of nanomaterials becomes topical.

Among the most promising methods of fabrication of oxide nanocrystalline materials is hydrothermal synthesis (a heterogeneous reaction in water at  $T > 373$  K and  $P > 0.1$  MPa).<sup>45</sup> When synthesising various oxides, the reaction conditions can be varied over a wide range, *i.e.*, it is possible to carry out hydrothermal synthesis both under mild conditions at moderate temperatures and pressures<sup>47, 63</sup> and in supercritical water.<sup>8, 43</sup> The hydrothermal method is used to obtain nanocrystalline oxide powders with specified particle sizes and phase compositions and well-developed specific surface area, which often cannot be attained using conventional techniques. The method also permits preparation of nanocrystalline metastable phases that cannot be synthesised under normal conditions.<sup>64, 65</sup>

For a long time, single crystals and minerals were mainly obtained by hydrothermal synthesis in batch reactors. The authors of most recent studies on the synthesis of nanocrystalline simple and complex oxide systems in subcritical and supercritical water [*e.g.*, solid solutions with fluorite structures  $\text{Ce}_{1-x}\text{M}_x\text{O}_{2-\delta}$  ( $\text{M} = \text{Eu}, \text{Sm}, \text{La}, \text{Pr}, \text{Ca}, \text{Sr}, \text{Gd}, \text{Y}$ ),<sup>66–70</sup>  $\text{ZrO}_2\text{--CaO}$  (see<sup>71</sup>) and  $\text{ZrO}_2\text{--Y}_2\text{O}_3$ ,<sup>72</sup> perovskites  $\text{BaTiO}_3$ ,  $\text{SrTiO}_3$  and  $(\text{Ba}_{1-x}\text{Sr}_x)\text{TiO}_3$ ,<sup>73–75</sup> simple oxides  $\text{HfO}_2$ ,<sup>76</sup>  $\text{Y}_2\text{O}_3$ ,<sup>77</sup>  $\text{ZnO}$ ,<sup>78</sup>  $\text{Cu}_2\text{O}$  and  $\text{CuO}$ ,<sup>43, 79</sup>  $\text{Fe}_3\text{O}_4$ ,<sup>80</sup>  $\text{CeO}_2$ ] also used batch reactors.<sup>81</sup> These nanocrystalline oxide materials often comprise a number of phases and are characterised by a nonuniform particle size distribution, which is due to the difficulties of control of the experimental conditions in batch reactors. According to published data, the synthesis can take from a few minutes<sup>79</sup> to several days;<sup>72</sup> often, no explanation is given for the choice of a certain duration of the reaction.

To the best of our knowledge, current research on the synthesis of nanocrystalline oxide materials using subcritical and supercritical water in flow reactors is carried out at three research centres, namely, at the Tohoku University (Japan),<sup>8, 82–89</sup> at the University of Nottingham (United Kingdom)<sup>65, 90</sup> and at the M V Lomonosov Moscow State University (Russia).<sup>41–44</sup> Here, researchers developed methods of synthesis of many simple and complex oxide systems and demonstrated the possibility of carrying out one-step syntheses of supported nanocrystalline heterogeneous catalysts in flow reactors (Table 3). The majority of systems synthesised in flow reactors are characterised by a narrow particle

size distribution, a well-developed surface, and by being monophase. The synthesis takes a few seconds and the experimental conditions vary from 503 K and 25 MPa to 673 K and 35 MPa. The physicochemical properties of oxide nanosystems are governed by the synthesis conditions (temperature, pressure, duration) and by the composition and concentration of the reaction mixture.

##### 1. Mechanism of oxide formation

A research group from Japan headed by Prof. K Arai proposed a two-step mechanism of metal oxide formation under hydrothermal conditions.<sup>8, 83</sup> The first reaction stage involves fast hydrolysis of the metal salt solution to give corresponding hydroxides. In the second stage, dehydration of hydroxides results in the formation of oxides.

The overall rate of oxide formation is a function of the temperature, ionic product of water and dielectric constant of the medium. The ionic product of subcritical water is high; therefore, one can expect that in this case hydrolysis will proceed at a higher rate compared to the reaction in supercritical water. At the same time, dehydration of hydroxides and nucleation of oxides require a low dielectric constant of the medium. The solubilities of inorganic compounds in subcritical water are rather high; this hampers attainment of local supersaturations which is necessary for nucleation of crystalline oxides. Owing to the high dielectric constant of the medium, dehydration of hydroxides in subcritical water proceeds at a lower rate compared to the process in supercritical water. In this connection one should choose the experimental conditions with allowance for specific features of a particular system (namely, the tendency of the precursor towards hydrolysis and the solubility of the reaction products). In most cases the maximum rate of formation of nanocrystalline metal oxides under hydrothermal conditions is achieved using supercritical water. For instance, the synthesis of nanocrystalline  $\alpha\text{-Fe}_2\text{O}_3$  (particle size 20 nm) from ferric nitrate in supercritical water takes less than a second.<sup>8</sup>

##### 2. Choice of precursor

The properties of nanocrystalline oxides obtained by the hydrothermal method are to a great extent determined by the choice of precursor, all things being equal. For instance, hydrolysis of  $\text{Fe}(\text{NO}_3)_3$ ,  $\text{Fe}_2(\text{SO}_4)_3$  and  $\text{FeCl}_3$  in supercritical water results in  $\alpha\text{-Fe}_2\text{O}_3$ ; however, the reaction carried out under identical conditions with  $\text{Fe}(\text{NH}_4)_2\text{H}(\text{C}_6\text{H}_5\text{O}_7)_2$  as precursor gives mixed oxide  $\text{Fe}_3\text{O}_4$ .<sup>8</sup> The case in point is that in the latter case thermal decomposition of ammonium citrate leads to carbon monoxide, which reduces  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ .

Usually, nanocrystalline oxides are synthesised in flow reactors from true solutions of metal salts (nitrates, chlorides, sulfates, acetates). Multicomponent oxides are obtained using solutions that simultaneously contain a number of salts in stoichiometric ratios (see Table 3).

The use of solutions for the synthesis of multicomponent oxides in batch reactors is usually precluded owing to different hydrolysis rates of the salts of the metal constituents of the complex oxide because gradual heating of the autoclave leads to formation of individual simple oxides at different instants of time. Therefore, experiments in closed systems are carried out with gels or codeposited metal hydroxides as precursors. For instance, the oxides  $\text{Ce}_{1-x}\text{M}_x\text{O}_{2-\delta}$  ( $\text{M} = \text{Eu}, \text{Sm}, \text{La}$ ) were synthesised<sup>66–68</sup> in autoclaves loaded with gels prepared by coprecipitation of solutions of cerium nitrate and the second metal with ammonia at pH 10, while nanocrystalline solid solutions  $\text{ZrO}_2\text{--CaO}$  were synthesised from amorphous hydrated zirconia, freshly prepared  $\text{CaO}$  and alkali additives ( $\text{LiOH}$  or  $\text{NaOH}$ ).<sup>71</sup> However, synthesis involving alkali and other mineral additives is undesirable because they can contaminate nanomaterials.

**Table 3.** Synthesis conditions and characteristics of nanocrystalline oxide systems obtained under hydrothermal conditions.

| Oxide                                                                                          | Synthesis conditions |               |           | Precursor                                                                                                                                                 | Particle size /nm | Specific surface /m <sup>2</sup> g <sup>-1</sup> | Ref. |

### 3. Particle size and phase composition

By varying the synthesis conditions it is possible to vary the particle size and to change the morphology of the oxides obtained. An increase in the synthesis time causes an increase in the average particle size. A similar effect is also observed with increasing the concentration of reagent solutions.

There is no consensus of opinion as to the influence of the temperature of hydrothermal synthesis on the particle size. Taking TiO<sub>2</sub> as an example, it was shown that an increase in the reaction temperature from 503 to 653 K causes an increase in the particle size from 7–9 to 16–18 nm, respectively, and a decrease in the specific surface area of titania from 200 to 50 m<sup>2</sup> g<sup>-1</sup>, respectively (see Ref. 43). The reverse was observed for ceria, *viz.*, the CeO<sub>2</sub> particle size is 300 nm at 573 K and 18 nm at 673 K (see Ref. 84). Probably, these results could be explained with allowance for specific features of precursors and the ratio of the rates of hydrolysis, dehydration and crystal growth at various temperatures.

In spite of the short times for the synthesis of oxides in flow reactors, these substances are characterised by a high degree of crystallinity. Sometimes hydrothermal treatment leads to stabilisation of phases that are metastable under normal conditions. For instance, hydrolysis of zirconium nitrate in subcritical water results in a mixture of monoclinic and tetragonal ZrO<sub>2</sub> polymorphs.<sup>65</sup> The formation of the metastable tetragonal polymorph is most probably due to the size effect, namely, a decrease in the

particle size to a certain critical size causes preferred formation of the phases with higher symmetry of the crystal lattice.<sup>65,91</sup>

Depending on the composition of the solution used in the hydrothermal synthesis of the oxides Zr<sub>1-x</sub>M<sub>x</sub>O<sub>2</sub> (M = Ce, Y, In), it is possible to obtain systems with specified ratios of the monoclinic, tetragonal and cubic polymorphs. For instance, as the indium content in the system Zr<sub>1-x</sub>In<sub>x</sub>O<sub>2</sub> increases, the tetragonal-to-monoclinic ratio of ZrO<sub>2</sub> phases increases; nanocrystalline solid solutions Ce<sub>0.5</sub>Zr<sub>0.5</sub>O<sub>2</sub> and Ce<sub>0.1</sub>Y<sub>0.1</sub>Zr<sub>0.8</sub>O<sub>2</sub> obtained in supercritical water have cubic lattices.<sup>43</sup>

### 4. Control of the oxidation states of elements

Hydrolysis of metal acetates, formates and oxalates in supercritical water involves partial decomposition of acids formed to CO. At supercritical temperatures and pressures, carbon monoxide can be mixed with water in any proportion, thus forming a homogeneous reducing medium. By varying the experimental conditions one can control the oxidation states of the elements in nanocrystalline oxides and thus obtain systems with specified ratios of the phases containing the same element in different oxidation states.

In supercritical water (*T* = 658 K, *P* = 35 MPa) copper hydroxycarbonate decomposes into copper(II) oxide and oxalic acid decomposes into carbon monoxide. Carrying out these two reactions simultaneously in a batch reactor results in metallic copper, a mixture of copper and copper(I) oxide or a mixture of

copper(I) oxide and copper(II) oxide.<sup>43</sup> The content of each phase is governed by the amount of oxalic acid added and can be controlled with ease. This technique seems to be promising for the preparation of catalysts and magnetic materials with preset concentrations of paramagnetic centres.

Hydrocarbon ligands can also favour the formation of reduced nanocrystalline systems in supercritical water. In particular, hydrothermal treatment of copper(II) nitrate in the presence of hexane-1-thiol affords metallic copper with particle sizes lying between 1.5 and 30 nm (see Ref. 79).

The oxidation states of elements can also be controlled in the course of fabrication of nanocrystalline materials in subcritical and supercritical water using hydrogen, oxygen and hydrogen peroxide. For instance, hydrolysis of cobalt(II) salts under hydrothermal conditions in the presence of  $\text{H}_2\text{O}_2$  involves oxidation of  $\text{Co}^{2+}$  to  $\text{Co}^{3+}$ , which allows phases containing cobalt(III), *e.g.*,  $\text{LiCoO}_2$  to be synthesised.<sup>89</sup>

It should be noted that subcritical and supercritical water can be successfully used for the synthesis of not only oxides but also other nanocrystalline materials. For instance, carbon nanotubes can be obtained by hydrothermal treatment of amorphous carbon at a temperature of 1073 K and a pressure of 100 MPa.<sup>92</sup> The nanotubes are a few hundred nanometres long, have an outer diameter of 10 to 50 nm and contain no amorphous carbon impurities.

Nanomaterials can also be formed under hydrothermal conditions by the rapid expansion of supercritical water containing dissolved oxides and hydroxides (RESS process).<sup>93</sup> Nearly instantaneous transition from supercritical fluid to gas ( $< 10^{-5}$  s) causes the formation of nanocrystalline oxides. However, this is a low-performance technology because of the low solubility of inorganic substances in supercritical water. For instance, the solubility of  $\text{Co}(\text{OH})_2$  and  $\text{Ni}(\text{OH})_2$  in water at 653 K is only  $10^{-6}$  and  $10^{-8}$  mol  $\text{kg}^{-1}$ , respectively.<sup>94</sup> In this connection the RESS process is of limited use.

## V. Organic reactions in subcritical and supercritical water

To date, wide experience in carrying out various organic reactions under hydrothermal conditions has been accumulated.<sup>6,95–97</sup> Unfortunately, most studies are concerned with deep oxidation of organic substances in subcritical and supercritical water. These studies are undoubtedly of importance for solving problems of treatment of toxic industrial and municipal waste. However, water at elevated temperatures and pressures is first of all of interest as a unique solvent and reagent for fine organic synthesis.

Carrying out many organic reactions is preceded by the routine procedure of choosing a solvent with optimum physico-chemical characteristics. Many solvents are toxic, fire-hazardous and explosive, which present severe problems for the industrial application of these compounds. In the case of reactions involving subcritical and supercritical water the choice of solvent is replaced by 'tuning' the temperature and pressure in such a way that the properties of the medium (density, ionic product, dielectric constant, viscosity, *etc.*) be optimised for performing a particular organic reaction.

Differences between the physical properties of subcritical and supercritical water are responsible for the fundamentally different mechanisms of organic reactions proceeding in these media. Typically, acidic and basic catalyses involving charged intermediates proceed in subcritical water while free-radical processes proceed in supercritical water.<sup>98</sup> In the latter case the reactions are initiated by hydrogen atoms and hydroxyl radicals that form in the homolytic decomposition of water molecules. Primary free radicals can also be formed in the system by collisions between the reagent and solvent molecules or as a result of the reactions with  $\text{O}_2$  and  $\text{NO}_2$  molecules having unpaired electrons.

Generally, the organic reactions possible in subcritical and supercritical water are as follows: hydrolysis; hydration/dehydra-

tion; various rearrangements; elimination; formation and cleavage of carbon-carbon bonds; hydrogenation/dehydrogenation and oxidation.

Many of these reactions can proceed under hydrothermal conditions at rather high rates and yields in the absence of catalysts. As to other types of reactions, subcritical water is an efficient acid-base catalyst, which excludes the necessity of neutralisation of large amounts of salts traditionally used as Lewis acids in, *e.g.*, alkylation reactions.<sup>14</sup> Conventional oxide and metallic heterogeneous catalysts can also be employed; however, in this case particular attention should be paid to the stability of catalytic systems in subcritical and supercritical water.<sup>99</sup>

Below we will consider a number of organic reactions that proceed under hydrothermal conditions, are of greatest value for practical use and provide an idea of the features of transformations of organic compounds in subcritical and supercritical water.

### 1. Methanol oxidation

Methanol oxidation is one of the best studied reactions in supercritical water.<sup>100–108</sup> At present, most studies in the field are concerned with analysis of the available experimental data.

Methanol oxidation in supercritical water results in water and carbon dioxide as end products. A detailed kinetic model<sup>100</sup> for this reaction is in good agreement with the experimental data. The model includes one hundred and forty-eight reversible elementary radical stages and twenty-two types of reactive particles. Among the primary products of methanol oxidation is formaldehyde, which is more reactive than methanol under the reaction conditions (773–862 K, 24.6 MPa); therefore, eventually the yield of formaldehyde is at most 24%.<sup>101</sup> Kinetic studies revealed that methanol oxidation is a pseudo-first order reaction with respect to methanol and zero order reaction with respect to oxygen and has an activation energy of  $328 \pm 84$  kJ  $\text{mol}^{-1}$ .

Later,<sup>102</sup> it was shown that the kinetics of methanol oxidation in supercritical water can be correctly described using seventeen fastest radical reactions and fourteen types of reactive particles. The calculated overall rate constant for the reaction and the yields of various oxidation products were in agreement with those obtained using the more complex model (see Ref. 100).

Methanol oxidation under hydrothermal conditions can also be described using the ideal gas model.<sup>101, 102</sup> However, near the critical point of water the equation of ideal gas state is inapplicable owing to the infinite compressibility of the medium. The compressibility of supercritical water can be taken into account using, *e.g.*, the Peng–Robinson semiempirical cubic equation.<sup>103</sup>

### 2. Reactions involving hydrocarbons

The high stability of hydrocarbons at temperatures and pressures near the critical point of water opens great prospects for carrying out target organic synthesis under hydrothermal conditions. Here, methane oxidation reaction has been best studied (Refs 100, 106, 107, 109–112). Most studies were concerned with deep oxidation of methane in supercritical water to carbon oxides and water. The process is characterised by an activation energy of about 180 kJ  $\text{mol}^{-1}$  at  $T = 288–923$  K and  $P = 24.6$  MPa, being a first order reaction with respect to methane and a 2/3 order reaction with respect to oxygen.<sup>109</sup>

Methane oxidation in an excess of oxygen can be theoretically described using both traditional combustion models corrected for high pressure and the ideal gas model. In the latter case the inclusion of reactions involving the  $\text{HO}_2$  radical (probably, the main oxidant under supercritical conditions) has the strongest effect on the results of calculations.<sup>100, 110</sup>

Partial methane oxidation into methanol in subcritical and supercritical water is also possible.<sup>112, 113</sup> Methane conversion in a batch reactor ( $T = 622–754$  K,  $\rho = 150–350$  kg  $\text{m}^{-3}$ ) at a  $[\text{CH}_4]:[\text{O}_2]$  ratio of 10:26 is at most 6%, the greatest selectivity of methanol formation (75%) being attained at low methane conversions.<sup>112</sup> The maximum selectivity of methanol formation in a flow system in the temperature range 673–683 K at a pressure

of 25 MPa is 35%.<sup>113</sup> Among other oxidation products are carbon oxides and hydrogen. Raising the temperature and an increase in oxygen conversion reduces the selectivity. The activation energy for methane oxidation is 400 kJ mol<sup>-1</sup>, the process being a 1.3 order reaction with respect to methane and a 0.3 order reaction with respect to oxygen.

In the course of catalytic cyclotrimerisation of alkynes under supercritical conditions water behaves as a conventional organic solvent.<sup>114,115</sup> Hydration of hydrocarbons to give ketones proceeds only in the presence of acids.<sup>114</sup> In particular, treatment of hex-1-yne at pH 6 affords nearly 10%–14% yields of hexan-2-one in accord with Markovnikov's rule. In the case of salt catalysed ketone hydrolysis the product yields correlate with the acidity of the cation aqua complexes, namely, no hydrolysis proceeds in the presence of NaCl and CaCl<sub>2</sub> and a 100% selectivity of hexan-2-one formation is achieved in the presence of CuCl<sub>2</sub> and SnCl<sub>2</sub>.

Subcritical water (573–628 K) is suitable for selective oxidation of alkylaromatic hydrocarbons with molecular oxygen to the corresponding aromatic acids and carbonyl compounds in the presence of catalysts.<sup>116</sup> The best results were obtained using MnBr<sub>2</sub> and CoBr<sub>2</sub> as catalysts. Reactions in the presence of other salts or in the absence of catalysts are characterised by severe charring and formation of dimerisation products.

### 3. Dehydration of alcohols

Dehydration of alcohols to give alkenes in subcritical water proceeds at high rates even in the absence of catalysts.<sup>6,117</sup> In the supercritical region, the reaction significantly slows down and the process can be accelerated only by adding mineral acids.<sup>98</sup> As a consequence, the selectivity decreases due to the reactions between the catalyst and alcohols. Formation of carbon oxides, methane and ethane in the ethanol dehydration in supercritical water points to a radical character of the reaction.

Subcritical water is a protic solvent; therefore, dehydration under subcritical conditions proceeds following the E2 mechanism with high selectivity.<sup>117</sup> The appearance of small amounts of by-products is due to alkene protonation to give carbocations that undergo rearrangements followed by isomerisation. For instance, dehydration of cyclohexanol results in cyclohexene, 1-methylcyclopentene and 3-methylcyclopentene.

### 4. Ether transformations

Supercritical water possesses no ionic properties; however, reactions catalysed by bases or acids that were added (or formed in the course of reaction) can proceed in this medium at high pressures and moderate temperatures. In particular, diphenyl ether decomposes into typical radical condensation products, diphenyl and phenoxydiphenyl, at a density of water of less than 300 kg m<sup>-3</sup> in the temperature interval 688–753 K.<sup>118</sup> However, as the critical density of water (~300 kg m<sup>-3</sup>) is attained, the conversion of diphenyl ether increases dramatically and only phenol is formed, a product of ether hydrolysis by the S<sub>N</sub>1 cationic mechanism. The reaction is catalysed by protons that appear during heterolytic dissociation of phenol; therefore, the process accelerates with time.

Hydrolysis of ethers in subcritical water has been well studied.<sup>98,119–122</sup> Note that in this case water can act as an efficient acid-base catalyst owing to a high dissociation constant.<sup>6,14</sup> For instance, hydrolysis of 1,3-dioxolane at 623 K and 34.5 MPa proceeds by the following acid-base mechanism:<sup>98</sup>

The degree of conversion is 99.8% and the end products are formaldehyde and ethylene glycol.

Decomposition of dibenzyl ether in supercritical water at 936–961 K and a density of water of 347 kg m<sup>-3</sup> results in benzyl alcohol, benzaldehyde, toluene and a number of by-products.<sup>123</sup> The proposed mechanism of the process includes eight main stages and is in good agreement with experimental data. The rate constant for pyrolysis of dibenzyl ether in supercritical water exceeds the rate constant for hydrolysis of this compound.

### 5. Acetic acid oxidation

The limiting stage of decomposition of various organic substances in supercritical water is oxidation of an intermediate product, acetic acid. Therefore, particular attention is paid to acetic acid oxidation under hydrothermal conditions.<sup>108,124–130</sup>

Depending on the reaction conditions, various products can be formed. For instance, oxidation with oxygen at 698–873 K and a pressure of 24.6 MPa (100% conversion at a residence time of 8 s) leads to the formation of carbon oxides, methane, hydrogen and trace amounts of propionic acid.<sup>124</sup> Oxidation in a batch reactor at long residence times results in carbon dioxide and water; however, in this case the conversion of acetic acid is at most 64% even in a five-fold excess of oxygen.<sup>125</sup> Hydrogen peroxide is a more efficient oxidant; here, the acid conversion increases to 97.7%.

Addition of transition metal cations favours the formation of large amounts of hydroxyl radicals and enhances the oxidising ability of H<sub>2</sub>O<sub>2</sub>. The efficiency of acetic acid oxidants in supercritical water ( $T = 673\text{--}733\text{ K}$ ,  $P = 27.5\text{--}35.0\text{ MPa}$ ) decreases as follows:<sup>126</sup> Cu–H<sub>2</sub>O<sub>2</sub> > Fe–H<sub>2</sub>O<sub>2</sub> > MnSO<sub>4</sub>–H<sub>2</sub>O<sub>2</sub> > H<sub>2</sub>O<sub>2</sub> > O<sub>2</sub>. In this case, the strongest acetic acid oxidant is potassium permanganate; however, its activity decreases in subcritical water.

Acetic acid oxidation reaction in a flow reactor is ~ 1/3 order with respect to oxygen and nearly first order with respect to acetic acid,<sup>124,128</sup> with an activation energy of about 180 kJ mol<sup>-1</sup>.

Acetic acid remains rather stable in supercritical water in the absence of oxidants, namely, the conversion of AcOH at 873 K and 24.6 MPa and a residence time of 8 s is only 35%.<sup>124</sup>

### 6. Phenol oxidation

The chemistry of phenol in supercritical media is interesting in regard to both the utilisation of toxic industrial waste and target organic synthesis, because phenolic type fragments are present in the structures of many organic molecules. A great body of experimental data and results of theoretical studies concerned with phenol transformations under hydrothermal conditions are available.<sup>131–140</sup> However, all of them were obtained for phenol oxidation only. At the same time phenol is rather stable in supercritical water in the absence of oxygen.<sup>135</sup> This suggests the possibility of carrying out more complex reactions involving phenol, such as formylation, sulfonation, amination, *etc.* under hydrothermal conditions.

The majority of the experimental data on phenol oxidation are consistent. The activation energy for this reaction is 100–125 kJ mol<sup>-1</sup> (see Refs 135 and 136). The rate of the reaction in supercritical water is proportional to the phenol concentration<sup>133–137</sup> and oxygen concentration to the 0.4–0.5 power.<sup>133,136</sup> It was experimentally proved that the rate of phenol oxidation is independent of the total pressure in the system, being dependent on the reagent concentrations<sup>135</sup>

$$\frac{d[\text{PhOH}]}{dt} = -k \frac{[\text{PhOH}][\text{H}_2\text{O}]^{1.38}\chi}{2.89 + \chi}$$

where

$$\chi = \frac{[\text{O}_2]}{[\text{PhOH}]}.$$

It is assumed that the mechanism of phenol oxidation involves two parallel reactions, ring opening and dimerisation.<sup>140</sup> The reaction results in carbon oxides as the end products; chain branching in the course of decomposition of an aromatic hydroperoxide and bimolecular initiation have the strongest effect on the kinetics of phenol oxidation. However, the reaction order with respect to oxygen, the activation energy and the rate constant for the reaction calculated using this model are overestimated compared to the experimental data.

More complex kinetic models include the possibility for water to participate in the phenol oxidation as a reagent.<sup>135, 138</sup> Initially, the reaction system contains only phenol, oxygen and water; therefore, the oxidation can be initiated by three monomolecular and two bimolecular reactions<sup>138</sup>

The phenoxyl radical formed in the reaction can then undergo dimerisation, hydroxylation to give cresols and ring opening. Dimerisation leads to 2-phenoxyphenol, dibenzofuran, 4-phenoxyphenol and 2,2'-diphenol as the major products.<sup>138</sup> As an example, we will consider the formation of 2-phenoxyphenol.

Ring opening of the phenoxyl radical can proceed as follows:<sup>138</sup>

Only route 1 resulting in a substituted vinyl radical is possible for the radical bearing the unpaired electron in the *para*-position to the oxygen atom. Phenol dimers can also undergo similar transformations to give formic, glyoxylic, propionic, oxalic, succinic, maleic and acetic acids.<sup>136, 138</sup> Further oxidation of these carboxylic acids results in water and carbon dioxide.

## 7. Reduction of aldehydes and ketones

Reduction of the carbonyl group provides an example of a selective, environmentally safe reaction in subcritical water. Sodium formate reduces aldehydes and a number of ketones in the absence of catalysts and toxic solvents at 523–573 K and a pressure of 7.5 MPa.<sup>141</sup> Environmentally friendly carbon dioxide is produced as a by-product of the reaction. The selectivity of the reaction can be controlled by varying the reaction conditions. An increase in temperature gives higher yields of primary alcohols. In

most cases the reduction proceeds with high yield (up to 74%); only for acyclic ketones does the conversion remain low even at long residence times.

## 8. Diels–Alder reaction

The Diels–Alder reaction is a conventional method of synthesis of organic compounds containing six-membered rings in the chemical structure. However, a significant drawback of this reaction is its low rate. Sometimes, the reaction can take a few days. Raising the temperature accelerates the process; here, subcritical and supercritical water are excellent solvents.

It was established that the non-catalytic reaction of diethyl maleate with cyclopentadiene under hydrothermal conditions at 648 K results in a mixture of 2,3-diethoxycarbonyl-5-norbornene isomers in 86% yield.<sup>142</sup> The reaction time is at most one hour (*cf.* a few hours to a few days for the process in organic solvents under normal conditions).

Not only the rate but also the selectivity of the Diels–Alder reaction changes under hydrothermal conditions. In particular, the reaction of ethyl acrylate with cyclopentadiene in supercritical water results in a mixture of *endo*- and *exo*-isomers of 2-ethoxycarbonyl-5-norbornene in an equimolar ratio. Under normal conditions in the presence of the catalyst  $\text{LiClO}_4$  the yield of the *endo*-isomer is eight times higher. The change in the selectivity is associated with a weakening of hydrophobic interactions in supercritical water.<sup>143</sup>

## VI. Use of subcritical and supercritical water for solving environmental problems

Development of efficient and environmentally safe technologies for treatment of increasing amounts of various toxic inorganic and organic waste (products of anthropogenic activity) is among the most important problems of modern times. A possible way of solving this problem could be the use of subcritical and supercritical water for detoxification of these products. Being an environmentally safe solvent, water can be mixed with oxygen and organic compounds in any proportion near the critical point, it dissolves organic solid substances (but not inorganic salts), has high diffusion and mass transfer coefficients, is of low viscosity and zero surface tension.<sup>144</sup> It is these properties that must be possessed by a solvent appropriate for efficient treatment of industrial wastes.

Traditionally, organic waste detoxification methods involve combustion, liquid-phase oxidation or biodegradation.<sup>145</sup> Each technology has certain drawbacks and can only be used for particular concentration ranges of organic substances. For instance, combustion of highly concentrated organic waste produces toxic substances, *e.g.*,  $\text{CO}$ ,  $\text{NO}_x$ , dioxins and polyaromatic compounds that should be neutralised. Liquid-phase oxidation technology is applicable to moderate concentrations of organic waste. The process is limited by mass transfer phenomena and the solutions formed contain high concentrations of carboxylic acids and ammonia. Biodegradation is only used for neutralisation of waste containing up to 1 mass% of organic substances. This is a rather slow process and simultaneous biodegradation of large amounts of wastewater requires large surface areas.

The expedience of the use of supercritical water for detoxification of organic waste was assessed taking catalytic oxidation of pyridine as an example and this treatment technology was found to be efficient.<sup>145</sup> According to calculations, the amount of investment necessary to build a waste-disposal plant for treatment of pyridine-containing solutions in supercritical water is 1 650 000 US dollars. Building waste-disposal plants for combustion and liquid-phase oxidation treatment requires 1 920 000 and 2 350 000 US dollars, respectively. A plant for catalytic oxidation of pyridine in supercritical water is also cheaper than those employing combustion and liquid-phase oxidation treatment. In addition, supercritical water oxidation imposes almost no limitations on the concentration of the pyridine-containing solutions.

Thus, treatment of organic waste with subcritical and supercritical water could be an alternative to traditional methods.

Studies on the use of subcritical and supercritical water for the detoxification of waste were concerned with dechlorination and dearomatisation of organic solutions,<sup>53, 55, 131, 135, 146–162</sup> treatment of polymers and plastics,<sup>30, 144, 163–167</sup> oxidation of municipal and food waste,<sup>51, 168–173</sup> gasification of biomass,<sup>174–176</sup> oxidation of toxic naval waste,<sup>177</sup> hydrolysis of cellulose and lignin,<sup>3, 178–182</sup> treatment of industrial waste<sup>183</sup> and extraction of heavy-metal compounds from waste water.<sup>30, 49, 184–186</sup> A number of processes are considered below.

### 1. Phenol and heterocyclic compounds

Every year chemical and petroleum industries produce millions of tons of liquid waste containing aromatic and heterocyclic organic compounds and their halogenated derivatives. These substances are highly toxic and are often carcinogenic; however, they are irreplaceable in the production of various pharmaceuticals, vitamins, herbicides and pesticides. Here, dearomatisation, dechlorination and removal of heterocyclic compounds from waste water can be performed using subcritical and supercritical water.

The efficiency of hydrothermal detoxification of pyridine- and phenol-containing waste substantially increases when using heterogeneous catalysts.<sup>131, 151, 152, 159, 187–189</sup> For instance, a 99% conversion is reached in supercritical water oxidation of pyridine in the presence of catalyst (0.5% Pt/Al<sub>2</sub>O<sub>3</sub>).<sup>187</sup> The process is limited by the diffusion of reagents in the pores of the catalyst; it results in CO<sub>2</sub>, N<sub>2</sub>O and nitrate as the major oxidation products.

The use of CuO/Al<sub>2</sub>O<sub>3</sub> catalyst in supercritical water oxidation of phenol permits not only acceleration of the reaction but also reduction of the yield of undesirable polycyclic by-products.<sup>131</sup> Carbon-supported catalysts are more reactive in the phenol oxidations.<sup>151</sup> By reducing the partial pressure of oxygen down to 0.2 MPa it is possible to decrease the oxidation rate of this catalyst in the reaction medium. The use of catalytic systems MnO<sub>2</sub>/CeO<sub>2</sub>, V<sub>2</sub>O<sub>5</sub>/Al<sub>2</sub>O<sub>3</sub>, Cr<sub>2</sub>O<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> and V<sub>2</sub>O<sub>5</sub> in supercritical water oxidation of phenol provides 100% conversion of PhOH to carbon dioxide, the formation of by-products being suppressed.<sup>152, 153</sup> It should be noted that hydrothermal phenol oxidation is also possible at lower temperatures (308–338 K) in the presence of a bimetallic catalyst (20% Pt–5% Ru)/C with a high content of noble metals.<sup>156</sup> The rate of hydrothermal phenol oxidation depends on the temperature and reagent concentrations, being at the same time independent of the pressure in the system.<sup>135</sup>

### 2. Chlorinated organic compounds

Dechlorination in supercritical water is a promising environmentally safe method of decomposition of chlorinated organic compounds.<sup>53</sup> The efficiency of catalytic neutralisation of liquid waste containing chlorophenols increases in the presence of alkali metal and iron cations.<sup>154, 158, 190</sup> The presence of these metals favours chlorine fixation and suppresses the formation of by-products (*e.g.*, trichlorophenols, dibenzo-*p*-dioxin and polycyclic aromatic hydrocarbons).

Zeolite catalysts used for the supercritical water decomposition of chlorophenols do not react with the chlorine released; this was confirmed by X-ray photoelectron spectroscopy data.<sup>149</sup> The highest efficiency of the process is achieved using the CuO/ZSM-48 catalyst.<sup>149, 158</sup> Due to its two-dimensional channel structure, the catalyst ZSM-48 zeolite (in contrast to the ZSM-5 and Y zeolites) suppresses the formation of undesired by-products. Hydrothermal hydrodechlorination and hydroaromatisation of thirteen various chlorophenols under mild conditions ( $T = 298–353$  K,  $P = 0.3–0.5$  MPa) in the presence of industrial catalyst Ru/C was performed.<sup>146</sup> The complete conversion of contaminants into nontoxic cyclohexanol and sodium chloride was achieved.

3-Chlorodiphenol oxidation in supercritical water results in carbon dioxide, water and HCl.<sup>157</sup> Reactions carried out under

similar conditions ( $T = 673$  K,  $P = 30$  MPa, reaction time 72.7–101.7 s) with hydrogen peroxide and molecular oxygen as oxidants were characterised by substantially different conversions, 99.999% in the former and 14.3% in the latter case. The efficiency of hydrodechlorination of polychlorinated diphenyls considerably increases in the presence of methanol,<sup>161</sup> which initiates a radical decomposition of intermediate chlorine-containing products with the formation of diphenyl.

Methylene chloride decomposition in subcritical and supercritical water involves two stages. Initially, hydrolysis of methylene chloride yields hydrogen chloride, formaldehyde and methanol.<sup>55</sup> Then, HCHO and CH<sub>3</sub>OH are oxidised with oxygen to CO and CO<sub>2</sub>. A 99.9% conversion of methylene chloride is achieved if the reaction is carried out in the temperature range 723–873 K at a pressure of 24.6 MPa and residence times of 4 to 9 s. Here, hydrolysis is a first order reaction with respect to methylene chloride, being also the limiting stage. The decomposition rate of methylene chloride increases only slightly in the presence of sodium chloride and does not depend on the amount of oxygen added.<sup>160</sup>

### 3. Polymers and plastics

Production of polymers and plastics is increasing worldwide annually. The amount of polymeric and plastic waste also increases; therefore, the search for new utilisation methods is topical. Nearly 100 000 tons per year of printed circuit board waste are to be disposed of in Taiwan.<sup>144</sup> High bromine content in these wastes hampers utilisation by conventional methods. In supercritical water ( $T = 793$  K,  $P = 24$  MPa,  $\tau = 600$  s) the material printed circuits are made of is oxidised with hydrogen peroxide to water and CO<sub>2</sub>. The degree of conversion is 90% and the bromine released is efficiently bound by sodium cations.

Subcritical and supercritical water can also be used for treatment of other polymers. In particular, polyethylene terephthalate decomposes in supercritical water producing oligomers, ethylene glycol and terephthalic acid.<sup>30</sup> Hydrolysis of polycarbonate in the temperature range 503–703 K results in the formation of phenol, bisphenol A, *p*-isopropenylphenol and *p*-isopropylphenol.<sup>165</sup> Decomposition of polyethylene in supercritical water is characterised by higher conversion and the formation of hydrocarbons with shorter chains compared to pyrolysis in argon.<sup>164</sup> At the same time polyethylene degradation in supercritical water proceeds more slowly than thermal pyrolysis; however, the yield of liquid decomposition products in the former case is higher.<sup>166</sup>

### 4. Municipal and industrial wastes

Efficient treatment of excretory waste and biomass is a severe problem, especially in megalopolises. It could also be solved using subcritical and supercritical water. For instance, a flow reactor for oxidation of excretory and alcohol production waste with hydrogen peroxide in supercritical water (473–873 K) was designed.<sup>168</sup> Two major intermediate oxidation products are acetic acid and ammonia. Further oxidation of ammonia requires a higher temperature compared to the oxidation of acetic acid. The efficiency of ammonia oxidation to nitrogen can be significantly enhanced using heterogeneous catalysts, *e.g.*, MnO<sub>2</sub>/CeO<sub>2</sub>.<sup>191</sup>

Biomass and organic wastes can also be gasified under hydrothermal conditions to produce fuel gas.<sup>174</sup> At  $T = 873$  K and  $P = 25$  MPa, biomass is completely gasified in the presence of KOH and K<sub>2</sub>CO<sub>3</sub>, forming a hydrogen-rich gas containing CO<sub>2</sub> as the main carbon compound. Concentrations of CO, CH<sub>4</sub> and C<sub>2</sub>–C<sub>4</sub> hydrocarbons in the product gas are <1 vol.%, ~3 vol.% and <1 vol.%, respectively.

Surfactant concentrations in waste water can be rather high. These compounds are oxidised with hydrogen peroxide in supercritical water to low-molecular-mass fatty acids (formic acid and acetic acid), sulfur-containing aromatic substances and sulfates.<sup>192</sup>

Phenol-containing olive oil production waste water can be efficiently neutralised in the presence of oxygen or hydrogen

peroxide in the temperature range 653–773 K at a pressure of 25 MPa.<sup>171</sup> The major oxidation products are water and carbon dioxide.

Utilisation of municipal waste in supercritical water can be combined with liquefaction of low-rank coals to produce liquid fuel.<sup>175</sup> The use of organic solvents for liquefaction is inefficient because of the high cost. The physicochemical properties of supercritical water are similar to those of nonpolar organic solvents. Supercritical water can be mixed with liquefaction products in any proportion and provides an efficient separation from liquid fuel on cooling. However, liquefaction of coals in supercritical water produces fuel with high oxygen content compounds, which reduces the heat of combustion. This problem can be solved by adding a source of hydrogen (*e.g.*, excretory waste or cellulose) to water.

In megalopolises solid municipal waste is usually burned out. In the atmosphere, components of the ash formed produce up to 50% of all dioxin-containing contaminants. Ash treatment with supercritical water in the presence of hydrogen peroxide ( $T = 673$  K,  $P = 30$  MPa,  $\tau = 1800$  s) permits oxidation of up to 99.7% of all dioxins to produce non-toxic chemical compounds.<sup>173</sup>

As mentioned above, inorganic compounds are insoluble in supercritical water owing to the low dielectric constant of the medium. This property can be used successfully for detoxification of liquid waste containing inorganic substances. For instance, 96% of sulfates and chlorides are removed from waste at  $T > 773$  K and  $P = 29.8$  MPa.<sup>184</sup> Cobalt and other metals can also be extracted from low-level radioactive nuclear power plant waste under similar conditions.<sup>30, 185, 186</sup>

The possibility of simultaneous neutralisation of several components of industrial waste and waste water using subcritical and supercritical water should be pointed out. For instance, a compact plant was built for the oxidation of toxic naval waste simultaneously containing fuel, hydraulic liquids, lubricants, coolants, dyes and photographic materials.<sup>177</sup> The oxidant used was air; oxidation products obtained at  $T = 870$  K and  $P = 22.5$  MPa were  $\text{CO}_2$ , water, oxides and mineral acids. The plant is compact and can be placed on a ship's board.

## 5. Food waste

Oxidation of food waste (beef suet and carrots) with hydrogen peroxide in supercritical water involves two stages.<sup>169</sup> Fast hydrolysis of polysaccharides with the formation of glucose (in the case of carrots) or glycerides to give glycerol and carboxylic acids (in the case of beef suet) is followed by slow oxidation of the intermediates formed.

Hydrothermal treatment of various types of food waste can be combined with the production of valuable chemicals, *e.g.*, amino acids.<sup>51, 172</sup> For instance, shrimp shells usually contain 17% of chitin and 42% of proteins. Treatment with subcritical water permits extraction of up to 70 mg of valuable amino acids per gramme of dry shrimp shells.<sup>172</sup>

## 6. Cellulose and lignin

Cellulose is one of the most important organic substances on the Earth. At the same time large amounts of cellulose-containing waste have not been treated efficiently. Hydrolysis of various cellulose sources in supercritical water ( $T = 773$  K,  $P = 35$  MPa,  $\tau = 3 - 105$  s) allows one to obtain glucose and its derivatives.<sup>179</sup> The degree of cellulose conversion achieved is as high as in the treatment of corn starch under similar conditions. This result deserves particular attention because the time taken to attain the same conversion in the case of enzymic hydrolysis of cellulose is three orders of magnitude longer than in the case of corn starch. Probably, the water present in the structure of cellulose microfibres goes to a supercritical state at high temperatures and pressure, which appreciably accelerates hydrolysis.<sup>179</sup>

The rates of cellulose hydrolysis in subcritical and supercritical water were compared<sup>180</sup> with the rates of further decom-

position of glucose, fructose and various oligomers formed. Near the critical point the rate of cellulose hydrolysis abruptly increases by more than an order of magnitude; therefore, hydrolysis in supercritical water produces much higher yields of products compared to the process in subcritical water. At temperatures and pressures below the critical point parameters, saccharide decompositions dominate hydrolysis of cellulose. Hence, by varying the temperature and pressure it is possible either to obtain saccharides from cellulose (in supercritical water) or perform a deep treatment of cellulose waste (in subcritical water).

The mechanisms of cellobiose (a cellulose model compound) pyrolysis and hydrolysis in subcritical and supercritical water have been studied in detail.<sup>182</sup> Pyrolysis products are glycosylerythrose and glycosylglycol aldehyde, whereas hydrolysis gives glucose, erythrose and glycolaldehyde.

Gasification of a lignin–cellulose mixture in water at  $T = 623$  K and  $P = 25$  MPa produces hydrogen, methane and carbon dioxide.<sup>193</sup> The amount and composition of the product gas strongly depends on the lignin content; probably, cellulose is a hydrogen donor for lignin hydrogenation, which causes changes in the composition of the gas produced depending on the lignin/cellulose ratio.

## 7. Extraction processes

Such properties of supercritical fluids as low viscosity and zero surface tension open great prospects for the use of these substances in the extraction and impregnation of various materials. At elevated temperatures and pressures, water can be used instead of many toxic solvents such as dichloromethane and acetone traditionally used for the extraction of organics from various matrices. Subcritical and supercritical water was employed in extraction of toxic contaminants from soil,<sup>194–199</sup> sorbent regeneration,<sup>200</sup> impurity desorption from the surface of materials<sup>201</sup> and fuel quality improvement.<sup>202–204</sup>

Usually, detoxification of compounds in soil requires pre-extraction. Petrochemicals, chlorophenols, chloroanilines and methylanilines, nitrotoluene, alkylbenzenes, polychlorinated diphenyls, phosphonium acids and pesticides can be efficiently extracted from natural matrices with subcritical and supercritical water. Subcritical water extraction of polar contaminants (phenols and amines) proceeds at lower temperatures compared to nonpolar contaminants (polycyclic aromatic hydrocarbons).<sup>205</sup> By adding anionic surfactants to water it is possible to substantially shorten the hydrocarbon extraction time.<sup>196</sup>

The solubility of dioxins in subcritical water is 340 times higher than in water under normal conditions.<sup>199</sup> At 523 K, 30% to 100% of dioxins are extracted from soils depending on the type of the matrix; raising the temperature favours an increase in the extent of extraction.

Pesticides are nonpolar compounds well extractable with supercritical water, *i.e.*, at high temperature and pressure.<sup>195</sup> However, the addition of ethanol and some other solvents causes a substantial decrease in the polarity of subcritical water, which permits extraction of pesticides from soils under milder conditions.

In microelectronics, various contaminants must be removed from the surface of silicon. Compounds traditionally used to this end are acidic and basic solutions; as a consequence, utilisation of corrosive waste is required. Subcritical water is a good solvent for ionic inorganic compounds at temperatures below 373 K and for carbonaceous substances at higher temperatures.<sup>201</sup> Thus, subcritical water can be used instead of the corrosive solvents traditionally employed for cleaning the surface of silicon. Adding small amounts of carbon dioxide to water allows (at  $T = 373 - 443$  K and  $P = 1.03 - 13.8$  MPa) not only a silica film and hydrocarbons but also amorphous carbon insoluble in pure subcritical water to be removed from the surface of silicon.

Extraction of gaseous contaminants from air and treatment of waste water and drinking water are usually performed using activated carbon. This sorbent efficiently absorbs even very low

concentrations of toxic substances. However, the rather high cost of activated carbon requires its regeneration. In the case of thermal regeneration the loss of carbon is 5%–10%, bioregeneration is only applicable to biodegradable substances and chemical regeneration is too expensive a process.<sup>200</sup> Treatment of activated carbon with subcritical water ( $T = 573$  K,  $P = 12$  MPa) allows the adsorption properties of the material to be completely regenerated. The process is accompanied by removal of phenol, dyes and pesticides. The properties of carbon do not deteriorate after a few regeneration cycles.<sup>200</sup> Under more severe conditions ( $T = 873$ – $923$  K,  $P = 25.5$ – $34.5$  MPa) carbon reacts with water to give carbon monoxide and hydrogen; however, short-term gasification favours an increase in the specific surface area and improvement of the adsorption characteristics of activated carbon.<sup>206</sup>

Modified subcritical water can be used to improve fuel quality. For instance, treatment of coal with subcritical water containing nitric acid (4 vol.%) causes extraction of Al, Ca, Mg, Na, K and other ash-forming elements.<sup>207</sup> Subcritical water containing  $\text{HNO}_3$  and KCl can also be used for metal extraction from used industrial oils. After treatment of oil for 270 s up to 90% of Cu, V, Pb, Ni, Cd and Cr goes to the aqueous phase.

It should be noted that though traditional extraction techniques are much simpler to use compared to subcritical and supercritical water extraction, they are often of low selectivity. Extraction under hydrothermal conditions requires the use of complex equipment; however, in this case the process selectivity can be controlled by varying the temperature and pressure.<sup>208</sup>

## VII. Conclusion

Subcritical and supercritical water is finding increasing use as a reagent, acid-base catalyst and a unique environmentally safe solvent whose physicochemical properties can be varied over a wide range. In this review we have tried to demonstrate the possibilities and advantages of the use of subcritical and supercritical water for the synthesis of nanocrystalline materials, in organic synthesis and for solution of environmental problems.

Successful practical application of subcritical and supercritical water requires a deep insight into all features of the physicochemical interactions occurring under hydrothermal conditions on the molecular level. Production of efficient industrial plants requires the design of new materials that are corrosion stable under extreme conditions. Systematic basic and applied research on the possibility of use of subcritical and supercritical water for target organic synthesis and in heterogeneous catalysis should be carried out. In the latter case water at high temperatures and pressures should be considered not only as a medium appropriate for performing catalytic reactions but also as a reagent for the one-step synthesis of multicomponent nanocrystalline heterogeneous catalysts with specified properties. One should expect that, in contrast to traditional systems, catalytic systems prepared under nonequilibrium subcritical and supercritical conditions will be sufficiently stable for the operation in supercritical media.

**Abstract.** Data on the methodology of sorption preconcentration are surveyed and the key concepts and quantitative parameters are given. The approaches to the preconcentration are considered, and various sorbents are characterised. Examples of using cellulose, styrene–divinylbenzene sorbents with grafted complexing groups, polyurethane foams and non-covalently modified silica gels, including those prepared by the sol–gel strategy, for preconcentration of inorganic and organic substances and development of combined and hybrid methods of analysis are given. The bibliography includes 357 references.

## I. Introduction

Sorption, in particular, ion exchange, methods for the isolation, separation, and preconcentration of substances are widely used in the chemical and hydrometallurgical processes. The high efficiency of sorption processes in combination with high feasibility ensure the priority development of these methods. Sorption processes are also used on a large scale in analytical chemistry, for example, in chromatography. An essential place is occupied by sorption methods in solving problems of analytical preconcentration.

Preconcentration of microcomponents for determination is used, first of all, in those cases where the sensitivity of direct determination of these components is too low. Preconcentration is also necessary if the component is inhomogeneously distributed in the specimen. In addition, when physical methods of analysis are used, preconcentration makes it possible to manage without a large number of reference samples, in particular, standard samples, because preconcentration provides concentrates on a unified base, for example, in a carbon powder (in the case of atomic-emission analysis). During preconcentration, it is also convenient to introduce so-called internal standards if necessary. Therefore,

preconcentration methods play an exceptionally important role in analytical chemistry.

Development of preconcentration methods, especially during the last two decades, has demonstrated appreciable advantages of sorption preconcentration as a relatively non-laborious process ensuring high preconcentration factors of substances. In particular, of interest is the mobile version of this method, which eliminates the necessity of separating the phases after preconcentration and opens up the way for automation of the whole cycle of analysis including sample preparation.

Thousands of original publications have been devoted to the sorption preconcentration of trace amounts of inorganic and organic compounds. General aspects of this topic have been considered in a number of monographs.<sup>1–5</sup> The sorption preconcentration has been employed to develop combined and hybrid methods for the analysis of environmental objects and industrial, geological, and biological objects. However, the design of new sorbents with specified properties for quantitative recovery of substances from diverse objects remains a topical task. The search for new approaches to determination of compounds after the isolation by sorption, in particular, directly in the sorbent phase, and development of quick, sensitive and simple determination methods are equally important.

This review, based on published data and authors' research, covers the strategy of sorption preconcentration of inorganic and organic compounds and characteristic features of recovery of substances on various sorbents, discusses the approaches to rational coupling of preconcentration methods with methods used for the subsequent determination, and considers the use of sorption preconcentration in the analysis of diverse objects. The review is based on authors' studies carried out together with colleagues at the Preconcentration Laboratory of the Chair of Analytical Chemistry at the Department of Chemistry of the Moscow State University. The purpose of the review is to draw attention to modern sorption preconcentration techniques, to characterise promising sorbents and to reveal their advantages and drawbacks.

## II. Theoretical grounds of the selection of sorption systems for preconcentration under dynamic conditions

Some advantages of dynamic preconcentration have already been noted. To extend the scope of this method, one can also use non-equilibrium conditions for dynamic sorption. For example, the

selectivity of the collection of a component may be increased by using kinetic features of its sorption and the preconcentration efficiency may be increased when non-equilibrium forms of components are recovered. Despite the good prospects offered by the last-mentioned approaches, they have been little developed as yet.

The last 15–20 years have seen vigorous development of flow analysis techniques which include the stage of dynamic sorption preconcentration (so-called on-line version). In this case, sorption, desorption and determination of components are performed in a cyclic mode, which implies repeated use of the sorbent without a change in its properties. However, not any determination method can be implemented in the on-line mode. Despite the attractive features of this approach, it cannot be applied, for example, for neutron activation or X-ray fluorescence determination of chemical elements. It is also noteworthy that the necessity of desorption leads inevitably to dilution of the concentrate and its dispersion in the flow on the way to a flow-type detector. In addition, the use of on-line preconcentration is expedient only provided that the preconcentration time is commensurable with the time of subsequent detection; otherwise, non-productive expenses related to the no-load running of the detector will increase. This is especially tangible when expensive equipment and valuable consumables, for example, inert gases, are used.

Thus, if on-line detectors are inapplicable, it is expedient to use the off-line version of flow preconcentration to attain high preconcentration factors. In this version, the preconcentration and determination steps are independent of each other and are separated in time. The off-line methods are difficult to automate; however, they possess certain advantages and their existence is thus justified. For example, many molecular-spectroscopic, atomic-spectroscopic and electrochemical methods impose similar requirements on the gross composition of the concentrate for determination of toxic elements (heavy metals) in the environmental objects and foodstuffs. In the preconcentration of the elements, it is necessary to separate the major matrix elements of the sample, first of all, alkali and alkaline earth metals, and organic substances, for example, fulvic acids. When effective sorbents are used in the off-line mode, preconcentration methods can ensure the development of unified sample preparation procedures. The practically facile off-line flow sorption preconcentration of water samples of various types, extracts from soils and plants, *etc.*, yields liquid or solid concentrates, which are suitable for long-term storage and transportation and which can be analysed by a variety of methods.

The use of the off-line and on-line options for preconcentration is determined by the sorbent properties or, strictly speaking, by the relationship between the properties of all components of the sorption system, which includes the sorbent, the solvent (most often, water), and the solutes including the trace component to be concentrated. In view of the sorbent inhomogeneity, the large numbers of components in solutions encountered in real-world tasks, and the diversity and complexity of the chemical and mass transfer processes that occur under non-equilibrium conditions of the dynamic preconcentration, one must admit that strict description of sorption systems is a highly complicated problem. However, without solving this problem, it is difficult to choose properly efficient sorbents and preconcentration systems. Most often, these are chosen empirically, taking into account the chemical properties of the functional group of the sorbent, the mechanical properties of the sorbent and other data. This is a labour-consuming procedure that requires screening of properties of sorption systems. This can be confirmed by tens of thousands of publications dealing with the use of various sorbents for the dynamic preconcentration of elements. Since most publications describe preconcentration of a small number of elements from a rather limited range of solutions, it can be stated that hundreds of variants have been proposed for the solution of similar tasks.

Meanwhile, in chromatography and chemical engineering — which have traditionally used sorption processes — mathematical

models have been developed that establish the relationship between the physicochemical properties of the sorbent, the microcomponent to be recovered, and other sorption parameters.<sup>6,7</sup> Vast experimental material on the physicochemical properties of sorption systems has been accumulated. The development of the theoretical grounds of the dynamic sorption preconcentration using these models has allowed researchers to minimise the amount of experimental studies needed to choose sorbents for preconcentration of elements, to outline the ways for the development (synthesis) of new efficient sorbents, and to propose computation methods for the optimisation of experimental conditions.<sup>8</sup>

## 1. Parameters of the dynamic sorption preconcentration

Like any other preconcentration technique, the dynamic sorption preconcentration is described by the following key parameters.<sup>1,4</sup>

1. Preconcentration factor  $K_{\text{conc}}$  defined as the ratio of the component (element) concentration in the concentrate to that in the initial sample. For the case where the sorbent phase functions as the concentrate,  $K_{\text{conc}} = c_s / c_{0\text{liq}}$  ( $c_s$  is the average concentration of microcomponent in the sorbent bulk,  $c_{0\text{liq}}$  is the starting concentration of the microcomponent in the solution).

2. Recovery of the microcomponent ( $R$ ) is the ratio of the amount of the substance in the concentrate  $m_s$  to that in the bulk of the initial solution  $m_{0\text{liq}}$  ( $R = m_s / m_{0\text{liq}}$ ). It is significant that the  $R$  values for preconcentration of a microcomponent from solutions with different compositions should remain constant; otherwise, when determining a component by a combined method including the preconcentration stage, it would be impossible to use calibration dependences plotted for 'pure' solutions.

3. Preconcentration rate. This value is determined by the time of preconcentration stage  $t_{\text{conc}}$ . In the ideal case,  $t_{\text{conc}}$  should not exceed the time of the subsequent instrument determination of the microcomponent. For the use of advanced instrumental methods of analysis, characterised by high sampling frequency (above 100 element determinations per hour), this parameter becomes not less important than the two previous parameters. In some cases, this value determines whether a system is suitable for dynamic preconcentration.<sup>9–14</sup>

4. Factors that describe the enhancement of the analytical signal. In flow analysis, sorption preconcentration is often characterised by parameters that reflect the growth of the analytical signal due to preconcentration, for example, the enrichment factor ( $EF$ ).<sup>9,14,15</sup> The  $EF$  is calculated as the ratio of the analytical signals obtained before and after preconcentration,<sup>16,17</sup> or as the ratio of the higher and lower concentrations of the analyte responsible for the same magnitude of the analytical signal without and after preconcentration.<sup>18</sup> It has also been proposed to define the  $EF$  as the ratio of the sensitivity coefficients of the determination method attained after and without preconcentration, respectively.<sup>19</sup> Note that in flow systems that include desorption and detection steps, the increase in the analytical signal is not determined by the preconcentration factor alone, being an integrated characteristics of the whole analytical cycle. In the last-mentioned case, the  $EF$  should be called more correctly the enhancement factor.<sup>9</sup>

The dynamic sorption preconcentration can also be characterised by an integral criterion, namely, preconcentration efficiency  $CE$ , which was defined as the product of the enrichment coefficient attained through preconcentration and sampling frequency ( $\text{min}^{-1}$ ).<sup>13,14</sup> According to this definition, the  $CE$  value is independent of the preconcentration or detection techniques and can be used to compare the efficiencies of various systems of flow analysis.<sup>9,14</sup>

The sorption preconcentration under dynamic conditions is characterised by a much higher  $CE$  value than that under static conditions. In the static mode,  $CE$  does not usually exceed  $4 \text{ min}^{-1}$ , whereas in flow analysis,  $CE$  reaches  $30–60 \text{ min}^{-1}$  or even more.<sup>9,14</sup> It has been noted<sup>9</sup> that with the use of advanced spectroscopic methods, the minimum  $CE$  value to justify the on-

line preconcentration compared to the off-line preconcentration from the economical standpoint is about 8 min<sup>-1</sup>.

Meanwhile, this definition of the *CE* does not allow one to distinguish the contribution of the proper preconcentration stage to the overall efficiency of the flow analysis. Moreover, *CE* does not take into account the recovery of the microcomponent. We proposed defining the *CE* value for preconcentration as the preconcentration factor attained per unit time at a specified microcomponent recovery.<sup>8</sup> Note that the preconcentration efficiency defined in this way is proportional to the ratio of the solution space velocity (*w*) to the volume of the sorbent layer (*V*<sub>sorb</sub>),

$$CE = \frac{Rw}{V_{\text{sorb}}} \quad (1)$$

Thus, the *CE* value actually characterises the effective productivity of the sorption preconcentration. Note that for a column with a constant cross-section area *S*, the ratio of the liquid phase space velocity to the volume of the sorbent layer is equal to the ratio of the linear velocity of the liquid phase *v* to the length of the sorbent layer *x*<sub>0</sub>. This can be easily seen if the numerator and denominator in expression (1) are divided by the column cross-section area *S*.

## 2. Comparison of the efficiency of sorption systems

For comparison of sorption systems under dynamic conditions and for elucidation of the optimal conditions of sorption, one should choose criteria describing the efficiency of such systems. This is done using a number of parameters, in particular, the preconcentration factor *K*<sub>conc</sub>, the recovery *R*, the dynamic capacity up to breakthrough, *t*<sub>conc</sub> and *CE*. These parameters are not independent;<sup>9</sup> therefore, efficient preconcentration systems and the optimal preconcentration conditions are usually chosen in the following ways.<sup>20</sup>

1. One parameter is varied, while the other are restricted. This method has found application in the design of low-output process units.

2. A unified optimality criterion is composed. In process engineering, this is an economical criterion that takes into account the contributions of all system parameters in terms of the cost per unit.<sup>20, 21</sup>

When elucidating the optimal conditions of the dynamic sorption preconcentration, variable parameters are also distinguished (usually, the length of the layer and the size of sorbent particles, the column diameter, and the solution flow rate). The preconcentration conditions are chosen by experimental or calculation methods proceeding from the particular task and imposing restrictions on most of the parameters. As in the static version of sorption, the first item is to choose the optimal values for the parameters responsible for chemical reactions in the system: functional groups of the sorbent, pH, composition of the solution, etc.<sup>9–14</sup> Equally important are the sorbent weight, the size and the shape of the sorbent layer, the flow rate of the solution (the optimal values of these parameters have been determined in numerous publications).

In flow sorption spectroscopic systems, the signal-to-noise ratio directly related to the *EF* is often used as the optimality criterion.<sup>9–12</sup> This criterion has been used to determine the optimal solution flow rate during the on-line preconcentration of cobalt on alumina modified by nitroso-R-salt;<sup>22</sup> seven elements on a cellulose sorbent with ethylenediaminetriacetic acid groups;<sup>23</sup> antimony on the CPG-8Q sorbent (glass with a controlled pore size and 8-hydroxyquinoline groups).<sup>24</sup> In the last-mentioned case, the recovery *R* provided an additional restrictive criterion. The optimal amount of the sorbent and the diameter of its layer at a constant length were determined for the on-line preconcentration of lead on basic alumina;<sup>25</sup> Cd, Cu, Ni and Pb on the Resin 122 sorbent;<sup>26</sup> the same elements as complexes with diethyldithiocarbamate on C<sub>18</sub> silica gel;<sup>27</sup> and Al, Cr(III), Fe(III), Ti(IV) and

V(IV) on the Muromac A-1 sorbent.<sup>28</sup> A significant contribution of hydrodynamic factors to the formation of the analytical signal has been noted.<sup>29</sup>

In a number of studies,<sup>30–38</sup> the efficiencies of systems with various sorbents under dynamic conditions have been compared using the microcomponent recovery *R*. However, this comparison is legitimate only provided that other conditions (the sorbent layer size and shape, the flow rate of the solvent, and the preconcentration ratio attained) are the same for all systems, which is far from being always the case.<sup>30, 31</sup>

When the efficiencies of dynamic sorption systems were compared as regards the microcomponent recovery, restriction was imposed on *K*<sub>conc</sub>. For example, the optimal flow rates of the samples were determined for the flow preconcentration of eight elements as complexes with 7-iodo-8-hydroxyquinoline-5-sulfonic acid on the BioRad AG MP 1 anion exchange resin;<sup>30</sup> with 8-hydroxyquinoline on Amberlite XAD-2;<sup>31</sup> or with bis(carboxymethyl)dithiocarbamate on Amberlite XAD-4;<sup>32</sup> ten elements on Chelex-100;<sup>33</sup> and Amberlite XAD-2 modified with 1-(2-thiasolylazo)-2-naphthol;<sup>34</sup> six elements from sea water as diethyldithiocarbamates on SiO<sub>2</sub>-C<sub>18</sub>, Amberlite XAD-2 and XAD-7;<sup>35</sup> Mo and W on the anion exchanger Amberlite IRA-93;<sup>36</sup> Pb on the Spheron-oxine sorbent;<sup>37</sup> Mn on the vinyl gel with immobilised 8-hydroxyquinoline.<sup>38</sup>

The microcomponent recovery has been used as the efficiency criterion in the choice of the optimal quantity of the sorbent and the column dimensions.<sup>31, 38</sup> Having determined the recoveries of several elements, the researchers compared the efficiencies of four sorbents under dynamic conditions.<sup>29</sup> This criterion was used to determine the optimal amount of the sorbent, the length and the cross-section of its layer for preconcentration of cadmium from soil extracts<sup>39</sup> and various forms of copper and lead from natural water as dithiocarbamates on SiO<sub>2</sub>-C<sub>18</sub>.<sup>27</sup>

The *R* value is related to the system capacity 'before breakthrough', which stands for the amount of the substance collected by the sorbent up to the instant where the recovery drops below a specified value.<sup>40</sup> For most tasks, it is taken that *R* = 0.95. The ratio of the average attained concentration of the microcomponent *a* to its equilibrium concentration *a*<sub>0</sub> in the solid phase characterises the fraction of the sorbent capacity that has been spent before the breakthrough (the dynamic sorbent capacity before the breakthrough). In other studies,<sup>40–44</sup> this parameter was used to compare the efficiency of different systems. The dynamic capacity before breakthrough depends, in particular, on the size and the shape of the sorbent layer, the solution flow rate (the pattern of this dependence was determined only in a few cases<sup>40</sup>). It has been noted that by using microcolumns with a great length-to-diameter ratio, one can attain fuller recovery of the microcomponent and a larger before-breakthrough capacity, especially at high *CE* values.<sup>40</sup>

The *CE* value was also used as the efficiency criterion; in this case, restrictions were imposed on *K*<sub>conc</sub> and *R*. Thus, the efficiencies of the Chelex-100, CPG-8Q and Resin 122 sorbents in the preconcentration of heavy metals were compared;<sup>45</sup> the optimal flow rate of the solution for gold preconcentration on Amberlite XAD-7 and XAD-8<sup>46</sup> and cobalt and cadmium preconcentration on CPG-8Q<sup>47</sup> were determined. In the latter case, the optimal amount of the sorbent and the layer shape were also found.

In a number of studies, computation techniques were used to optimise the geometric parameters and the hydrodynamic operating conditions of microcolumns-reactors meant for determination of physiologically active compounds based on the reaction products in flow-injection systems. The formation of the analytical signal in flow-injection systems was described using layer-by-layer models.<sup>48–51</sup> The analysis productivity served as the efficiency criterion, the degree of substance conversion served as the analogue of the recovery and the size of the analytical signal served as an approximate analogue of the preconcentration factor. The efficiency of operation of the reactor was estimated

from the magnitude of the analytical signal (determined by the degree of conversion of the analyte and the longitudinal dispersion of its zone); restrictions were imposed on the system productivity. The layer-by-layer model parameters determined experimentally were used to calculate the optimal volume and the inner diameter of the reactor, the grain diameter of the filler, and the solution flow rate.<sup>51</sup> By imposing additional restrictions on the hydrodynamic resistance, the optimal size and the length of the reactor, and the corresponding reagent and sample consumptions were determined. The calculated parameters were employed to compare the efficiency of reactors of different types.<sup>49</sup> The general principles of their construction were formulated.<sup>50</sup> The possibility of influence of the rate of chemical reactions<sup>48, 50, 51</sup> and the substantial contribution of the longitudinal dispersion to the formation of the analytical signal in these systems have been noted. When the analytical signal is used as the criterion of the efficiency for flow injection systems, the last-mentioned factor can become crucial. This indicates that not only the sorption preconcentration stage, but also the subsequent desorption should be considered separately and perhaps optimised.

Modelling of the sorption dynamics was also employed to calculate the amount of the sorbent and sorption time for the dynamic preconcentration of palladium and platinum on the POLIORGS XI-N sorbent<sup>52</sup> on the basis of previously determined physicochemical parameters. The required flow rate of the solution and recovery were specified for the calculation. Good agreement between the calculated and experimental parameters was noted.

Thus, the dynamic sorption preconcentration is characterised by a set of parameters that depend in an intricate manner on one another and on the physicochemical properties of the system. Therefore, when comparing the efficiencies of various dynamic sorption systems, these parameters should be considered together (this was done, in particular, by Fang<sup>9</sup>). The search for the optimal preconcentration conditions (the region of the highest efficiency of a sorption system) has been performed both empirically and using various theoretical models.

To elucidate the legitimate criteria for comparison of the efficiency of dynamic preconcentration sorption systems, we proposed the use of mathematical models of sorption dynamics.<sup>6–8</sup>

### 3. Mathematical models of sorption dynamics

The sorption under dynamic conditions is a complex heterogeneous process consisting of several successive stages:<sup>6, 7</sup> the transport of the substance in the solution to the sorbent surface; the transport of this substance in the sorbent phase to the point where the chemical reaction takes place; the chemical reaction between the substance and functional groups of the sorbent; the transport of the reaction products in the sorbent phase; the transport of the reaction products from the sorbent surface to the solution bulk. The full mathematical description of processes that occur in the system implies taking into account the contribution of each of these stages to the overall rate of mass transfer, which is a fairly complicated task. The mathematical models proposed for describing sorption include three equations: differential material balance and kinetic equations and the equilibrium equation (isotherm) with initial and boundary conditions.<sup>7</sup> Rather detailed models constructed in this way are called deterministic models. In many cases, these can be simplified by averaging the concentrations of the sorbed substance over some volume of the system. The models thus obtained are called aggregated.<sup>7, 20</sup> If the concentration of the microcomponent in the solution is averaged over some volume of the liquid phase, these models are called layer-by-layer ones.<sup>20, 53</sup> The layer-by-layer method is used to describe the dynamics of sorption of substance mixtures when combined allowance for all kinetic parameters is impossible.<sup>7, 20</sup> As applied to chromatographic systems, it is widely used under the name of the method of 'theoretical plates.'

Methods for the solution of sets of partial differential equations describing the dynamics of sorption are well developed and presented in a number of monographs.<sup>54, 55</sup> Analytical solutions have been obtained only for limiting cases, in particular, for linear and rectangular sorption isotherms, external- and internal-diffusion kinetics.<sup>54</sup> In more complicated cases, approximate and numerical methods are used.<sup>56, 57</sup> The developed algorithms have been implemented as software programs. By using them, it is possible to obtain solutions for any case of diffusion kinetics (external, internal and mixed diffusion).<sup>58–64</sup> The numerical solutions of the problem of external diffusion dynamics for the linear sorption isotherms are tabulated.<sup>64</sup>

### 4. The use of the mathematical model of sorption dynamics for description of preconcentration problems

Dynamic sorption is widely used for various purposes, first of all, for the isolation, preconcentration and separation of substances. However, the efficiency criteria of sorption systems differ appreciably in various applications, depending on the task to be solved. For example, in solving most of process engineering problems, the key criterion is represented by the 'specific reduced costs.' During dynamic preconcentration, it is important to quantitatively isolate the microcomponent from the solution using the smallest possible amount of the sorbent (*i.e.*, the capacity before breakthrough should be high) over the shortest period of time (*i.e.*, the flow rate of the solution should be high), which is especially important in flow systems. Thus, of the parameters describing dynamic preconcentration, the preconcentration efficiency *CE* and the preconcentration factor  $K_{\text{conc}}$  are most general.

Note that the *CE* does not reflect in any way the true value of the preconcentration factor  $K_{\text{conc}}$  or, in other words, the dynamic capacity of the sorbent. Thus, the problem of preconcentration, unlike technological problems, can be formulated as follows: in a sorption system, it is necessary to attain the highest possible *CE* value at a specified  $K_{\text{conc}}$  or, *vice versa*, the highest  $K_{\text{conc}}$  at a specified *CE* value. The former version rather applies to the solution of off-line problems where a microcomponent is to be collected from large solution volumes. The latter is more important in on-line systems where the dimensions of the column and the flow rate of the solution are restricted by the system design, the preconcentration being limited by column capacity. In any case, the *CE* and  $K_{\text{conc}}$  values considered simultaneously ensure a well-posed characterisation of the efficiency of the sorption system for preconcentration of the given microcomponent.

Let us consider the mathematical model of sorption dynamics.<sup>8</sup> Let the  $\eta$  value mean the fraction of the total sorbent capacity that has been used by the end of preconcentration,

$$\eta = \left[ \int_0^l a(x, t) dx \right] / \Gamma c_0,$$

where  $a$  is the concentration of the microcomponent in the bulk of the solid phase,  $t$  is time,  $\Gamma$  is a dimensionless distribution coefficient of the microcomponent ( $\text{ml ml}^{-1}$ ),  $\Gamma = K_{\text{conc}}/\eta$ ,  $c_0$  is its initial concentration in the solution. Note that within the bounds of the chosen and substantiated mathematical models, the  $\eta$  value can be calculated as a function of the dimensionless variables,  $X$  and  $T$  (the dimensionless sorption length and time), where  $X = \beta x/v$ ;  $T = \beta t/\Gamma$  ( $\beta$  is the effective mass transfer coefficient for the microcomponent in the solution,  $v$  is the linear velocity of the flow of the liquid phase).

For further calculations, it is convenient to represent  $\eta$  as isolines in the  $X-T$  plane (Fig. 1). The limiting value of  $\eta$  is 1, *i.e.*, the limiting value of  $K_{\text{conc}}$  is  $\Gamma$ . This provides the limitation for the sorbent capacity, namely, the  $\Gamma$  value cannot be lower than the required  $K_{\text{conc}}$ .

The second limitation is related to the allowable breakthrough level  $\chi$ . This means that the substance loss during sorption cannot be higher than a particular fraction of all substance that entered the layer, namely:

**Figure 1.** Theoretical function of the specific cumulative breakthrough  $\chi$  (continuous lines) and fractions of the sorbent used  $\eta$  (dashed lines) in the case of external diffusion dynamics and linear sorption isotherm in the  $X$ – $T$  coordinates used to determine the maximum attainable preconcentration efficiency.

$\chi$ : 0.8 (1), 0.6 (2), 0.4 (3), 0.2 (4), 0.1 (5), 0.07 (6), 0.05 (7), 0.03 (8), 0.01 (9), 0.007 (10), 0.005 (11), 0.003 (12);

$\eta$ : 0.9 (1'), 0.8 (2'), 0.7 (3'), 0.6 (4'), 0.5 (5'), 0.4 (6'), 0.3 (7'), 0.2 (8'), 0.1 (9').

$$\chi = \frac{m_{\text{liq}}}{m_{0\text{liq}}} = \frac{m_{0\text{liq}} - m_s}{m_{0\text{liq}}}.$$

Note that the  $\chi$  value is related to  $R$  by a simple relation  $\chi = 1 - R$ . It can also be calculated as a function of  $X$  and  $T$  for each type of kinetics and is represented as a series of theoretical curves.<sup>64</sup> Like the function  $\eta$ , this function is convenient to depict as isolines in the  $X$ – $T$  plane (see Fig. 1).<sup>8</sup>

The values of  $\eta(X, T)$  and  $\chi(X, T)$  found numerically using appropriate software are tabulated.<sup>64</sup>

A remarkable feature of this way of tackling the preconcentration problem (where it is necessary to attain a specified  $K_{\text{conc}}$  without losing more than  $m_{\text{liq}}$  of the microcomponent weight) is that the problem can be solved in terms of dimensionless variables with the restrictions already made. If metrological requirements have been specified as definite  $\eta$  and  $\chi$  values, the only  $X_{\text{opt}}$  and  $T_{\text{opt}}$  values corresponding to them can be found by a simple graphical operation, in particular, by matching two plots for  $\eta$  and  $\chi$  in the  $X$ – $T$  plane (Fig. 1).

Thus, in terms of dimensionless variables, we have a unique solution for the dimensionless length  $X_{\text{opt}}$  and the sorption time  $T_{\text{opt}}$ . The dimensional expressions for  $x_0$  and  $t_0$  are defined, in the case of external diffusion, by the relations

$$x_0 = \frac{X_{\text{opt}} v}{\beta}, \quad t_0 = \frac{T_{\text{opt}} \Gamma}{\beta}, \quad (2)$$

and for the internal-diffusion sorption kinetics, by the relations

$$x_0 = \frac{X_{\text{opt}} d^2 v}{4D\Gamma}, \quad t_0 = \frac{T_{\text{opt}} d^2}{4D}, \quad (3)$$

where  $d$  is the diameter of sorbent particles,  $D$  is the internal diffusion coefficient.

The  $X_{\text{opt}}$  and  $T_{\text{opt}}$  values determine the corresponding  $CE_{\text{max}}$ , i.e., the maximum preconcentration efficiency attainable in the system with specified  $K_{\text{conc}}$  and  $R$  (because  $\eta$  and  $\chi$  are specified).

Thus, we arrive at an important conclusion — in any sorption system and for specified preconcentration ratio and recovery of the microcomponent, one can calculate the maximum attainable preconcentration efficiency  $CE_{\text{max}}$ , which can serve as a universal criterion for comparison of the efficiency of dynamic sorption systems as regards their application for preconcentration of microcomponents.

The value of  $CE_{\text{max}} = T_{\text{opt}} \Gamma / X_{\text{opt}} t_0$  depends on  $t_0$ , which is determined by expressions (2) and (3); hence, it is related unambiguously to the  $v$ ,  $d$  and  $\Gamma$  parameters. It follows from (2) and (3) that the smaller the grain size of the sorbent and the higher the flow rate of the liquid phase, the higher the preconcentration efficiency. However, it is clear that  $v$  cannot be increased and  $d$  cannot be decreased infinitely if for no other reason than from hydrodynamic considerations.

For analysis of the reasons for different efficiencies of sorption systems in preconcentration processes, it is necessary to estimate the degree to which the thermodynamic and kinetic sorption parameters and the particle size of the sorbent influence the generalised efficiency criterion,  $CE_{\text{max}}$ , for specified  $K_{\text{conc}}$  and  $R$ . To solve this problem,  $CE_{\text{max}}$  values were calculated for various  $\Gamma$ ,  $\beta$ ,  $D$  and  $d$ .<sup>8</sup> The calculations were carried out for different kinetic mechanisms of sorption (Tables 1 and 2).

**Table 1.** Maximum attainable preconcentration efficiency  $CE_{\text{max}}$  ( $\text{s}^{-1}$ ) calculated for the external-diffusion mass transfer mechanism ( $K_{\text{conc}} = 1000$ ,  $R = 95\%$ ).

<sup>a</sup> Here and in Table 2, obtained by extrapolation.

It follows from the data of Table 1 that in the case of external-diffusion sorption kinetics, an increase in the mass transfer coefficient by a factor of 10 results in an identical change in the  $CE_{\text{max}}$ , while the same increase in the distribution coefficient results in an approximately 16-fold increase in the  $CE_{\text{max}}$ , i.e., the thermodynamic sorption parameter impacts  $CE_{\text{max}}$  to somewhat a greater extent than the kinetic one.

In the case of internal-diffusion sorption kinetics,  $CE_{\text{max}}$  depends on the thermodynamic parameter to a markedly greater extent than on the kinetic one. Indeed, an 8-fold increase in  $\Gamma$  induces an increase in  $CE_{\text{max}}$  by more than two orders of magnitude; a similar change in the  $CE_{\text{max}}$  requires an increase in  $D$  (and  $1/d^2$ ) also by two orders of magnitude (Table 2).

The efficiency criterion of sorption systems for preconcentration ( $CE_{\text{max}}$  at specified  $K_{\text{conc}}$  and  $R$  values) and the method for its

calculation allow a legitimate comparison of sorption systems. The following procedure was proposed for the selection of an efficient sorption system for dynamic preconcentration.<sup>8</sup>

1. Published data or experimental results (obtained, for example, by the method of dynamic breakthrough curves) are used to determine the kinetic sorption mechanism and the  $\Gamma$  (or the distribution coefficient  $K_d$ ),  $\beta$  or  $D$  values. This is done using mere matching of the theoretical and experimental curves.

2. Proceeding from the preconcentration factors  $K_{\text{conc}}$  needed to attain the specified detection limit in a combined method involving a sorption preconcentration stage, the required  $\eta$  value is calculated, the allowable breakthrough value  $\chi$  is specified (usually, it is equal to 0.05). Then the intersection point of the calculated  $X_{\text{opt}}$  and  $T_{\text{opt}}$  curves (corresponding to these  $\eta$  and  $\chi$ ) is found in the  $X$ – $T$  coordinates (Fig. 1). These values are used to calculate the maximum preconcentration efficiency  $CE_{\text{max}}$  attainable in this system. The sorption system that ensures the highest  $CE_{\text{max}}$  value, all other factors being the same, is the most efficient.

### III. Preconcentration of metal ions on polymeric sorbents with conformationally mobile aminocarboxyl groups

Complexing sorbents are often used for preconcentration of metal ions from solutions. Sorption in these systems is highly efficient if the solid-state metal compounds are stable and are formed at a high rate. When reacting with a metal ion, the sorbent acts as a ligand whose heteroatoms fill the metal coordination sphere either completely or partially. Various approaches to ensuring the efficiency and selectivity of these sorbents have been proposed and are successfully developing. These approaches are based, first of all, on the formation of a functional group required for optimal filling of the metal coordination sphere.

A traditional way is to design the sorbent taking into account the basicity of the heteroatoms of functional groups and the basicity of the species to be preconcentrated. In this case, the complexing groups are chosen on the basis of extensive knowledge accumulated in the field of monomeric analytical reagents. The geometric (spatial) factors are taken into account to a lesser extent.

#### 1. Development of new sorbents

Complexing sorbents of new types are developed deliberately, proceeding from the expected structure of the complex of an element with the monomeric ligand. The ability of the metal ion to form the optimal coordination polyhedron from a set of heteroatoms offered depends on the basicity of the donor atoms of the functional groups of the ligand and on the conformational mobility of these atoms, the latter being mainly determined by the possibility of bond angle and bond length distortions in these functional groups. Unlike solutions, the mobility of donor atoms in the complexing groups grafted onto a polymer matrix is restricted by both the conformational rigidity of the matrix and the length and the conformational mobility of the spacer, *i.e.*, the fragment that links the polymer matrix to the complexing group. The grafting density of the functional groups on the polymer is also important. (In the case where the polymer matrix is modified by polydentate ligands able to saturate the coordination sphere of the element, the requirement of high density of complexing groups and relatively long spacers become less stringent, because the complexation capacity is determined only by the conformational mobility of the grafted polydentate ligand.) The lower efficiency of interaction of metal ions with grafted groups compared to the corresponding monomeric reagents in solution is due, first of all, to the distortion of the resulting coordination polyhedron. In our opinion, an increase in the coordination mobility of the donor atoms incorporated in the functional groups of sorbents should

reduce the steric hindrance to the formation of the coordination sphere required for the given element.<sup>65</sup>

The complexation scheme considered<sup>65</sup> is not universal and has some limitations. In some cases, an increase in the number of donor atoms and in the spacer length can result in enhanced steric hindrance to complexation. However, generally, this scheme can show the way to the perfection of known and the development of new complexing sorbents.

Within the bounds of the proposed approach, sorbents based on polystyrene and poly(vinyl chloride) containing diethylenetri-aminetetraacetate (DETATA) groups were synthesised. The synthesis was carried out by condensation of chlorine-containing compounds with amines followed by treatment of the aminated products with monochloroacetic acid in an alkaline medium.<sup>66,67</sup> Gel-type chloromethylated polystyrene with a cross-linking degree of 2% (grain diameter 40–80  $\mu\text{m}$ ) and poly(vinyl chloride) fibre with a fibre diameter of 8–12  $\mu\text{m}$  were used. Cellulose-based sorbents were synthesised using a fibre (with a diameter of 10–20  $\mu\text{m}$ ) and ‘blue ribbon’ grade filter paper.

The results of experiments carried out under static conditions showed the advantage of sorbents with conformationally mobile groups over ‘usual’ aminocarboxyl sorbents, caused by the formation of stable coordinatively saturated complexes in the sorbent phase (Fig. 2).<sup>65,66</sup> Thus the equilibrium distribution coefficients  $K_d$  for the sorption of Mn(II), Ca, Co(II), Cu(II) and Zn on the polystyrene-based DETATA sorbent in the pH range most favourable for sorption are 1–1.5 orders of magnitude higher than those for the sorption of the same metals on the widely used Dowex A-1 sorbent (an analogue of Chelex 100) with iminodiacetate (IDA) groups. The dynamic capacity before breakthrough can serve as a criterion for comparison of dynamic sorption systems. As mentioned above, the use of this criterion is not completely legitimate<sup>8</sup> but fairly illustrative, for example, for the comparison of sorption filters (Table 3).<sup>66</sup> All other factors being the same (composition of the solution, solution flow rate, filter size), the capacity of DETATA filters is several times higher than that of the previously synthesised filters with IDA groups or EDTA-type groups in which one nitrogen atom is quaternary.

**Figure 2.** Distribution coefficients of some metals on aminocarboxyl sorbents.

(1) Polystyrene sorbent with DETATA groups; (2) Dowex A-1 sorbent;  $V_{\text{soln}} = 100 \text{ ml}$ ,  $m_{\text{sorb}} = 50 \text{ mg}$ ,  $20^\circ\text{C}$ ;  $t = 0.5$  (I, 2), 1 (I'), 3 h (I'').

**Table 3.** Capacity before breakthrough of some filters with aminocarboxyl groups ( $v = 1.0 \text{ ml min}^{-1} \text{ cm}^{-2}$ , pH 5.0).

| DETATA | 771                                                                                      | 671 | 445    | 340     |

## 2. Preconcentration of elements on DETATA sorbents

Under dynamic sorption conditions, sorbents are used most often in columns (columns, cartridges or cylinders) or as filters. The column version is preferred as regards the subsequent desorption because the dead volume of a column is much smaller than those of devices used for filter locking-up. In our studies, the elements were collected on microcolumns with a sorbent ( $d = 2-3 \text{ mm}$ ;  $l = 10-15 \text{ mm}$ ,  $V_{\text{col}} = 0.03-0.12 \text{ ml}$ ) and on cellulose filters with the same grafted groups (filter diameter, 25 mm; filter thickness, 0.15 mm, diameter of the filtering surface, 22 mm).<sup>68-71</sup>

A study of the mass transfer kinetics for metals during sorption on DETATA sorbents has shown<sup>72</sup> that high thermodynamic and kinetic sorption parameters and small size of sorbent grains and fibres ensure the quantitative recovery of metals even with exceptionally high flow rates of the solution. For example, it was found that Cd, Co, Cu, Fe, Mn, Pb and Zn (in a concentration of  $0.01 \mu\text{g ml}^{-1}$ ) are quantitatively recovered from 100 ml of a 0.1 M solution of ammonium acetate (pH 5) on a 0.03-ml column at a solution flow rate of up to  $20 \text{ ml min}^{-1}$  (see Ref. 73). An increase in the flow rate of the solution through a two-filter tandem to  $4 \text{ ml min}^{-1} \text{ cm}^{-2}$  ( $14 \text{ ml min}^{-1}$  through the filtering surface with  $d = 22 \text{ mm}$ ) does not lead to a loss in Cd, Co, Cu, Fe, Mn, Ni, Pb or Zn at the preconcentration stage ( $V_{\text{soln}} = 100 \text{ ml}$ ).<sup>74</sup> Thus, quick preconcentration of metals from large solution volumes is possible.

### a. Study of the effect of the major inorganic components of solutions on the sorption of heavy metals

It has been found that Cd and Pb are quantitatively collected on a column with a sorbent even in the presence of  $10 \text{ g litre}^{-1}$  of Ca and Mg and  $100 \text{ g litre}^{-1}$  of Na. Similar results have been obtained for Co, Cu, Ni and Zn. Some decrease in the recovery (down to 85%–90%) at high concentrations of alkali and alkaline earth metals was observed only for Mn sorption.<sup>73, 75</sup>

The recovery of Cd and Pb does not decrease either in the presence of iron (up to  $0.1 \text{ g litre}^{-1}$ ), whereas aluminium ( $0.05 \text{ g litre}^{-1}$ ) suppresses appreciably their sorption. With an iron concentration of  $10 \text{ g litre}^{-1}$ , the recovery of lead is equal to 96%. The pronounced influence of aluminium on the sorption of Cd and Pb may be due to the higher stability of complexes of the macrocomponent with respect to those formed by the microcomponents in the sorbent phase. Lead forms more stable complexes with functional groups than cadmium (and, apparently, iron), and is successfully recovered from solutions in the presence of this macrocomponent.<sup>75</sup>

A potential masking reagent for Al, Ca and Fe, namely, the citrate ion almost does not decrease the distribution coefficients or the recovery of Cd and Pb during sorption on DETATA sorbents and, therefore, it can be used to bind the macrocomponents when collecting these elements from solutions of complex composition.<sup>75</sup> For example, in the presence of citrate, the recovery of Cd and Pb from solutions with high contents of Al and Fe increases, quantitative extraction of microcomponents being observed when the citrate concentration is equimolar to the concentration of the macrocomponent.

In order to choose conditions for the preconcentration of lanthanides in the presence of the key matrix components of sedimentary rocks and elements creating noise in determination of

lanthanides by inductively coupled plasma atomic emission (ICP-AES), sorption of Al, Ba, Cr(III), Fe(III), Mo(VI), Sr, Ti(IV), V(V), W(VI) and Zr was studied. It was found that DETATA polymers do not exhibit high selectivity with respect to lanthanides. To reduce sorption of interfering elements, 5-sulfosalicylic acid was proposed as the masking reagent. In the presence of this reagent, sorption of other elements was suppressed and lanthanides can be recovered quantitatively over a broad pH range.<sup>76, 77</sup>

Chromium(III) is recovered quantitatively on the DETATA sorbent at pH 7, while chromium(VI), at pH 3; in addition, these pH values allow almost complete separation of these chromium forms. However, during sorption of this element, the equilibrium is attained slowly. The efficiency of chromium collection under both static and dynamic conditions increases when sorption is carried out in a microwave field.<sup>78</sup>

The sorption of Ag, Bi(III), In and Tl(III) from sea water on microcolumns with the DETATA-sorbent based on polystyrene has been studied under dynamic conditions. An increase in the content of alkali and alkaline earth metal salts in water to  $200 \text{ g litre}^{-1}$  does not decrease the recovery of the target elements.<sup>79</sup>

The experiments dealing with the effect of Na, K, Mg and Ca on the sorption of Cd, Cu(II) and Zn on DETATA filters were carried out over a broad range of concentrations of macrocomponents ( $0$  to  $100 \text{ mg litre}^{-1}$ ), which is fairly typical of the surface fresh water.<sup>74</sup> It was shown that potassium has a minor influence on sorption of copper and cadmium. In terms of their influence on the sorption of copper and cadmium, other macrocomponents can be arranged in the sequence  $\text{Mg} > \text{Ca} > \text{Na}$ .

The sorption of trace amounts of Mn(II) and Zn on DETATA filters as a function of the concentration of the same salt components in natural waters has been studied by the radio-isotopic tracer method.<sup>66, 70</sup> These elements are recovered quantitatively even when the concentrations of macrocomponents exceed markedly the natural level. Similar results have been obtained for the preconcentration of Bi, Cd, Co, Cu, Fe, In, Mn, Ni, Pb, Tl and Zn from sea water.<sup>74</sup> For increasing the recovery of heavy metals at high concentrations of inorganic components, it is better to use a tandem of two or three filters.

### b. Effect of some organic substances on the sorption of heavy metals

Fulvic acids are the major organic components of natural water and soil extracts able to affect the sorption of metals. In fresh water, they account for 60%–90% of the dissolved organic compounds, while in sea water, almost 100%. Fulvic acids are involved in complex formation mainly through the carboxy and hydroxy groups.<sup>74</sup>

The sorption of cadmium and lead on microcolumns with the DETATA sorbent from model solutions containing fulvic acids isolated preliminarily from river water has been studied.<sup>74, 75</sup> The presence of up to  $50 \text{ mg litre}^{-1}$  of fulvic acids barely influences the recovery of the target elements.

The dependence of the recovery of Cu(II) and Cd on filters on the colouring of model solutions caused by the presence of fulvic acids has been studied. The concentration of fulvic acids typical of the superficial land water has little influence on the recovery of Cu and Cd on DETATA filters.<sup>74</sup>

The high stability of heavy metal complexes in the DETATA sorbent phase suggests that these elements could be preconcentrated from juices or wines and other alcoholic beverages. It was found that a key complexing macrocomponent in these solutions, namely, citrate, does not influence the sorption of cadmium and lead on microcolumns up to a concentration of  $0.2 \text{ mol litre}^{-1}$  (Ref. 75). Similar results were obtained in the cadmium and lead preconcentration from tartrate-containing solutions.<sup>72</sup>

The conditions chosen for the dynamic preconcentration of Cd and Pb were applied to study the recovery of Co, Cu, Mn, Ni and Zn from various waters and solutions obtained after auto-clave digestion of some foodstuffs.<sup>80</sup> The recovery of all elements on a 0.03-ml microcolumn at a flow rate of  $6 \text{ ml min}^{-1}$  (200 sorb-

ent volumes per min) or on DETATA filters from solutions containing inorganic and organic macrocomponents amounts to 96%–99%. Quantitative recovery of Cd and Pb from solutions obtained after the autoclave digestion of soil (clay loam) is attained by adding  $0.02 \text{ mol litre}^{-1}$  of citrate.<sup>75</sup>

### 3. Methods for determination of elements that include dynamic preconcentration on DETATA sorbents

The techniques of the dynamic preconcentration of heavy metals have been used to develop highly sensitive combined methods for determination of these elements in various objects. The high efficiency of the chosen preconcentration systems ensured better metrological characteristics of these methods compared not only to direct methods but also to the methods proposed previously that involve sorption preconcentration.

#### a. Methods involving preconcentration and determination of the elements directly in the solid concentrate

The advantage of this combined approach is that high preconcentration factors ( $10^3$ – $10^4$  and more) are attained and, as a consequence, the detection limits are reduced compared to those attained in direct determination. However, the drawbacks of these combined methods are rather significant. As a rule, it is necessary to dry the concentrate and to transfer it from the preconcentration system into the system for determination. In the optimisation of the conditions for element determination by the combined method, it is necessary to take into account the influence of the solid matrix of the sorbent on the formation of the analytical signal; these effects can be more pronounced with solid concentrates than in the case of liquid ones. Methods that include determination of elements in solid concentrates usually cannot be fully automated. Some important analyses carried out by this method are considered below.

1. Sorption coupled with X-ray fluorescence determination of As, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Se, V and Zn in potable, natural and waste waters. X-ray fluorescence analysis (XFA) is known to be a widely used instrumental method for determining the elemental composition of natural and industrial materials, which is due to the simple instrumentation (especially in recent years), the possibility of multiple-element determination, high reproducibility and relatively low cost. However, until recently, this method has found only limited application for determination of minor concentrations of elements, in particular, in environmental objects due to low sensitivity.

For XFA determination of elements, it is useful to employ cellulose filters as substrates, as the fluorescence of the filter elements (C, H, N, O) does not fall in the spectral range covered and the small thickness and low density of the filters minimise the absorption and scattering of the primary and fluorescence emission. The data we obtained on the sorption of elements from solutions of complex composition on the DETATA filters were used to develop simple procedures involving sorption and X-ray fluorescence determination of a number of elements in potable, natural and treated waste waters and in urine.<sup>70, 71, 74, 81</sup>

When developing these procedures, three different spectrometers were used: an energy-dispersive spectrometer (a Si–Li semiconductor detector with a resolution of 180 eV at the  $\text{MnK}_\alpha$  line, a Kevex X-ray tube with an Ag anode and a Link Analytical spectrometer tract) and portable single-crystal diffraction Spark-1M and Spectroscan-001 instruments. The detection limits of elements in solutions were  $1$ – $5 \text{ } \mu\text{g litre}^{-1}$ , the relative standard deviation ( $s_r$ ) of the results did not exceed 0.06 over broad ranges of element concentrations.<sup>70, 74, 81</sup>

2. Determination of chromium forms in water by sorption coupled with atomic-absorption spectrometry (with electrothermal atomisation).<sup>78</sup> The procedure proposed for separate preconcentration of Cr(III) and Cr(VI) on the polystyrene-based DETATA sorbent made it possible to develop a procedure for determination of these species in river water. Chromium(III) and chromium(VI) were extracted from solutions at pH 3 and 7 on a

microcolumn with the sorbent (0.03 ml) placed in a microwave oven. Chromium was determined in solid and liquid concentrates by the atomic-absorption method with electrothermal atomisation at a wavelength of 357.9 nm, the background absorption being corrected based on broadening of the resonant absorption line. The detection limit of chromium (both in the case of determination in an aqueous suspension of the sorbent and after desorption with 6 M HCl) amounted to  $30 \text{ ng litre}^{-1}$  ( $K_{\text{conc}} = 100$ ). The method shows a high reproducibility; the  $s_r$  value did not exceed 0.05 in the region of chromium concentrations of  $0.2$ – $10 \text{ } \mu\text{g litre}^{-1}$ .

3. Determination of Ag, Bi, Cd, In, Pb and Tl in natural waters by sorption coupled with atomic-absorption spectrometry (with electrothermal atomisation).<sup>79, 82</sup> Two-chamber graphite atomisers of the crucible–cell type with independent heating of the vaporisation and atomisation zones, Saturn-2 and AAS-3 spectrometers and an experimental multichannel atomic-absorption/atomic-fluorescence setup were used. The atomiser crucibles with the bottom made of a porous graphite filter (disc) were employed as the microcolumns for dynamic preconcentration of elements. The dynamic preconcentration in the crucible/microcolumn with subsequent electrothermal atomic-absorption determination resulted in the following detection limits of elements:  $0.3$ – $1$  (Ag, Cd) and  $2$ – $10 \text{ ng litre}^{-1}$  (Bi, Pb, Tl). The relative standard deviation for a single determination of elements was  $0.1$ – $0.3$ , which complies with the goals of geochemical and ecological studies.

4. Determination of elements in waters by sorption coupled with neutron activation analysis. It has been demonstrated that the dynamic preconcentration of a broad range of elements can be easily combined with neutron activation determination.<sup>83</sup> For element preconcentration and determination, a special quartz cell acting as a microcolumn was used. The concentrates obtained were exposed to a neutron flux directly in these cells in an IR-8 reactor (the neutron flux density  $n \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ ). The spectra were recorded using an HPGe detector (resolution 1.8 keV on the 1332.5 keV line) connected to a NUC-810 multichannel analyser. Two analysis protocols were used: (1) irradiation of the sorbent with the concentrate for  $5$ – $10 \text{ h}$ , storage the samples for a week after irradiation and determination of Au, Ba, Cd, Co, Cr, Eu, Fe, Hg, La, Mn, Sc, Sr and Zn; (2) irradiation of the sorbent with the concentrate for  $40$ – $60 \text{ s}$  for determination of Cu, In, Mn, V and some lanthanides.

#### b. Flow analysis for determination of elements involving preconcentration on sorbents with aminocarboxyl groups

A decrease in the proportion of human labour in performing analyses is a priority task in analytical chemistry. The extensive use of microprocessor-based units provided the possibility for the development of automated analytical systems characterised by high sampling frequency, good metrological characteristics and relatively low cost. Unfortunately, automated systems are still seldom used in the environment monitoring and quality control of foodstuffs where it may be necessary to take urgent measures on the basis of analysis of large series of samples.

It is relatively simple to automate analytical systems with flow detectors: atomic absorption, atomic fluorescence, inductively coupled plasma atomic emission, spectrophotometric, some electrochemical detectors and so on. A popular and rapidly developing way for automation of the sample preparation in the analysis of solutions is the use of flow-injection devices. Despite the relative simplicity of this equipment (usually this includes one or two peristaltic pumps, one to three injection valves and a simple electronic control device), its use not only ensured automation of numerous methods of analysis but also substantially increased the sampling frequency and improved the metrological characteristics, first of all, the sensitivity and reproducibility of the analysis.

In our opinion, for using sorption systems in flow methods of analysis, it is necessary and sufficient that the following conditions be met:<sup>84</sup>

— the microcomponent should be recovered quantitatively on a sorbent at a high flow rate of the solution (this ensures accumulation on the column of an amount of the analyte needed for reliable detection);

— the microcomponent is desorbed quickly and quantitatively by a desorbing solution suitable for detection; the sorption properties should not change after repeated sorption–desorption cycles;

— the capacity of the sorbent in the column should be sufficient for the recovery of the microcomponent from the solution under analysis in amounts exceeding the absolute limits of the subsequent detection;

— to decrease the dispersion of the concentrate zone in the stream, the dimensions of the column with the sorbent should be as small as possible;

— the sorbent should be sufficiently selective for the recovery of the target microcomponents in the presence of other components of the solution.

In flow analysis systems involving preconcentration, the analytical signal is formed under non-equilibrium conditions — when the concentrate zone resulting from the element desorption passes through the flow detector.<sup>84</sup> Attaining the maximum signal-to-noise ratio under the non-steady-state conditions existing in the flow system requires optimisation of the conditions for the desorption of metals from the column (the composition and concentration of the desorbing solution and the flow rate of this solution), conditions for analytical signal processing and some design factors of the flow system: flow distribution at various stages of the analysis cycle, some pipeline diameters, and the shape and dimensions of the column with the sorbent.

The sorption systems we proposed were chosen to ensure the highest efficiency, and they comply with most of the above requirements. The use of these systems in combination with flow detectors made it possible to develop automated highly sensitive flow techniques for determination of a large number of elements and to extend the range of objects suitable for analysis.

1. Flow sorption coupled with atomic absorption for determination of Cd, Co, Cu, Fe, Mn, Ni, Pb and Zn in potable, natural and waste waters, soil extracts and solutions obtained after digestion of soils and foodstuffs.<sup>75, 80, 84–86</sup> A set of procedures for determination of toxic elements in natural, potable and waste waters, soils and soil extracts, food raw materials, and foodstuffs have been proposed. The procedures were certified by Gosstandart of the Russian Federation. The procedures for determination of Cd, Co, Cu, Mn, Ni, Pb and Zn in potable, natural and treated waste waters and Cd and Pb in soils and soil extracts have been included in the Public Register of the Procedures Approved for the State Environmental Control (PND F 14.1:2:4.59-96 and PND F 16.14-97).

The limits of detection of elements by the flow sorption/atomic-absorption method (a KVANT AGA spectrometer) for preconcentration time of 1 min and atomisation in the propane–butane–air flame were 0.05 (Cd), 0.2 (Cu), 0.5 (Co, Mn, Zn), 1.0 (Pb), 2.0 (Ni)  $\mu\text{g litre}^{-1}$  (see Ref. 85). For the quantification of metals present in amounts 10 times as high as the detection limits, the relative standard deviation was 0.02–0.03. It should be noted that low detection limits of metals and high reproducibility of the results were attained with complete automation of the whole analysis cycle. The duration of the analysis cycle (with preconcentration for 1 min) was 95–105 s (depending on the time of column flushing), and the sampling frequency was up to 37 samples per hour. An increase in the preconcentration time results in lower detection limits of elements and better reproducibility of the determination results.

2. Flow sorption coupled with ICP AES for determination of Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, V and Zn in natural waters.<sup>69, 73</sup> The inductively coupled plasma atomic emission spectrometry (ICP AES) is a highly informational method for solution analysis. The use of a polychromator allows simultaneous determination of a large number of elements (up to 50) for sample consumption of

1–5 ml. In our studies, we have accomplished a combination of the flow sorption preconcentration on the DETATA sorbent and ICP AES determination of metals within a single automated cycle.

The non-stationary signals formed during flow determination by sorption coupled with atomic emission spectrometry of Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, V and Zn have been studied. It was found that desorption of all ten elements takes place simultaneously and requires the same period of time (equal signal widths).

The signal recording in the flow sorption coupled with ICP AES determination of elements requires identification of the zone of the concentrate which enters the spectrometer detector in the flow of the desorbing solution. The integration time of analytical signals determined by the size of the concentrate zone in the flow and the pre-integration time, which corresponds to the time it takes for the desorbing solution moving ahead of this zone to pass through the detector, are the key parameters for optimisation of the determination conditions. In the case of desorption of elements from the polystyrene-based DETATA sorbent, both parameters depend on the concentration of the acid in the desorbing solution and the flow rate of this solution. It was shown that all the ten elements can be desorbed with 2 M  $\text{HNO}_3$ . The optimal flow rate of the desorbing solution is 2  $\text{ml min}^{-1}$ . With this flow rate, the integration time for all the elements to be quantified is 20 s and the pre-integration time is 7 s.

Under the conditions chosen, the limits of detection of the elements in solutions by a flow method were 0.2–1  $\mu\text{g litre}^{-1}$  and the enhancement factors of the analytical signal due to preconcentration (*EF*) with respect to those in the direct ICP AES determination (after preconcentration for 1 min) were 17 (Cu), 15 (Cd, Zn), 14 (Co), 11 (Cr, Mn, Pb) and 10 (Fe, Ni, V). The relative standard deviation in the determination of elements present in concentrations of 10  $\mu\text{g litre}^{-1}$  was 0.02–0.06.

3. Flow sorption coupled with ICP AES for determination of rare earth elements in solutions of complex composition.<sup>76, 77</sup> To attain the highest signal-to-noise ratio, the composition and the flow rate of the desorbing solution were optimised. The range of quantifiable rare earth metal concentrations (for simultaneous determination) in solutions was  $1–1 \times 10^{-4} \mu\text{g ml}^{-1}$ .

4. Flow sorption coupled with voltammetry or with X-ray fluorescence for determination of metals in solutions ('stopped-flow systems'). Coupling of the dynamic sorption preconcentration with the electrothermal atomic absorption, inversion voltammetry and X-ray fluorescence implies a discrete analytical cycle. The specific feature of this approach is that the concentrate zone is identified in the flow of the desorbing solution and stopped in the area of analytical signal measurement. 'Stopped-flow systems' are promising, as they combine the advantages of the dynamic preconcentration and the determination methods involved. In the case where the preconcentration time is commensurable with the detection time, automation of the analysis cycle is expedient. It is especially convenient to combine preconcentration of a group of elements with simple and readily available methods of simultaneous multielement determination. Thus dynamic preconcentration of heavy metals on the DETATA sorbent can be coupled with their determination in the concentrates (solutions) by inversion voltammetry or XFA.<sup>87</sup>

X-Ray fluorescence analysis alone does not ensure determination of elements whose concentrations are at the MPC level. The time of measurement for the simultaneous determination of 9 elements using a Spectroscan spectrometer is about 15 min. A simple calculation shows that a 15-min preconcentration by forcing a solution through a DETATA microcolumn at a flow rate of 6–7  $\text{ml min}^{-1}$  ensures  $K_{\text{conc}} \approx 200$  (the volume of the desorbing solution is 0.5 ml). When the sorption technique is combined with the stopped flow, the time required for element determination remains the same (during the detection, the elements from the next sample are preconcentrated), while the detection limits markedly decrease. The following detection limits were attained for a frequency of 4 samples per h: 0.005 (Co, Ni); 0.02 (Cu, Fe, Mn, Pb, Zn); 0.05 (Cr) and 0.07 (V)  $\mu\text{g ml}^{-1}$  (see

Ref. 87). Owing to the high reproducibility of the results ( $s_r = 0.03-0.06$  over a broad range of element concentrations) and the stability of spectrometer operation with time, this method can be recommended for the monitoring of continuous industrial processes.

#### IV. Preconcentration on polyurethane foams

Polyurethane foams (PUF), an important product of the industrial organic synthesis, are of interest for the sorption preconcentration of substances. These sorbents are distinguished by high efficiency, versatility, chemical and mechanical stability, stability against organic solvents, relatively low cost and ready availability. The sorption properties of these synthetic polymeric materials are largely due to the combination of various hydrophobic (hydrocarbon, aromatic) and hydrophilic (urethane, amide, urea, ester, ether and terminal toluidine) groups, which allows the use of these materials for efficient sorption of both non-polar and polar compounds. A part of the solid phase in PUF is replaced by air,<sup>88</sup> which occurs in the polymer as numerous cells, thus forming an ordered system of solid quasispherical membranes. Owing to the system of cells, the sorbed substance can penetrate inside the sorbent. Thus, the substances are collected not only due to adsorption but also as a result of absorption; therefore, the capacity of PUF is fairly high. Polyurethane foams actually 'dissolve' sorbates in the membranes. This is a unique feature of PUF, which distinguishes them from many other sorbents.

Polyurethane foams have been used in analytical practice since the early 1970s.<sup>89-91</sup> At present, a large body of facts concerning sorption of organic compounds and elements on PUF have been accumulated. The publications generalised in a monograph<sup>92</sup> and reviews<sup>93-98</sup> discuss the reasons for the high efficiency of these sorbents, the factors that influence sorption and the ways of optimisation of the preconcentration and separation conditions of microcomponents. Below we consider (mainly, relying on our data) the characteristic features of sorption of various substances on PUF and discuss the potential of hybrid methods of analysis based on sorption preconcentration coupled with spectroscopic determination directly in the concentrate.

##### 1. Characteristic features of sorption on polyurethane foams

Development of combined and hybrid methods of analysis based on the use of PUF requires study of the laws of sorption processes and elucidation of sorption mechanisms. The knowledge of the chemistry of sorption of substances on PUF can facilitate the selection of practically important sorption systems and to explain (in favourable cases, even to predict) the conditions of sorption in systems not yet studied.

##### a. Effect of the sorbate hydrophobicity

Comparative estimation of the hydrophobicity of six industrial PUF samples based on ethers (PUF-ET) and esters (PUF-ES)<sup>99</sup> indicates that the surfaces of all these polymers are nearly equal in hydrophobicity. Their hydrophobicity proved to be higher than that of sorbents based on cellulose, cellulose triacetate, polyacrylate (Amberlite XAD-8), silicas (Diasorb-C<sub>4</sub>, -C<sub>8</sub>, -C<sub>16</sub>, -phenyl, -carboxyl) but lower than the hydrophobicity of the activated carbon AX-21.

Due to their hydrophobic properties, PUF efficiently sorb molecules containing hydrophobic fragments (for example, polycyclic aromatic hydrocarbons, PAH).<sup>100,101</sup> The distribution coefficients of PAH are linearly related to their hydrophobicity parameters, *i.e.*, the Hansch's parameters (the logarithms of the distribution constant in the *n*-octanol–water system,  $\log P_{ow}$ ), by correlation (4) (Table 4). The correlation equations (4)–(7) describe satisfactorily the sorption on PUF of not only PAH but also other aromatic hydrocarbons: the calculated and experimental distribution coefficients of benzene, toluene, acenaphthene, fluorene and fluoranthene are in good agreement with each other.<sup>101</sup>

**Table 4.** Types of correlations describing the sorption of various organic compounds on PUF.

| Class of compounds                                              | Correlation <sup>a</sup>                    | Correlation coefficient |
|-----------------------------------------------------------------|---------------------------------------------|-------------------------|
| PAH, aromatic hydrocarbons                                      | $\log K_d = a + b \log P_{ow}$ (4)          | 0.980–0.997             |
| Cationic surfactants of the alkyltrimethylammonium series       | $\log K_d = a + b n_C$ (5)                  | 0.970–0.989             |
| Phenols, phenol-carboxylic acids                                | $\log K_d = a + b \log P_{ow} - c pK_a$ (6) | 0.963–0.996             |
| Xanthene dyes, cationic metal chelates with 1,10-phenanthroline | $\log K_d = a + b \Delta H$ (7)             | 0.967–0.997             |

<sup>a</sup> *a*, *b*, *c* are constants.

The sorption of homologues of cationic surfactants of the alkyltrimethylammonium series increases with an increase in the chain length, which is indicative of an important role of hydrophobic interactions of the hydrocarbon parts of the cationic surfactant molecules with the PUF hydrophobic matrix and with one another.<sup>102</sup> The  $\log K_d$  values follow a linear dependence on the number of carbon atoms in the alkyl radical ( $n_C$ ) [relation (5) in Table 4].

For phenols with close  $pK_a$  values, differences in the sorption are also determined by the hydrophobicity difference. In the series phenol–3-cresol–1-naphthol,  $\log K_d$  values follow a linear correlation with the hydrophobicity parameter of the phenol on any of the PUF studied [relation (6) in Table 4].<sup>103,104</sup> Similar regularities are observed in the sorption of phenolcarboxylic acids.<sup>105</sup> The distribution coefficients, the limiting sorption values and the sorption constants of xanthene<sup>106</sup> and sulfophthalein dyes<sup>107</sup> increase with an increase in the hydrophobicity of their molecules in the following sequences: rhodamine 6G < rhodamine 3B < butylrhodamine, thymol blue < bromocresol purple < bromothymol blue < bromocresol green. An important role of hydrophobic interaction in the sorption of dyes was also pointed out in a study.<sup>108</sup>

The sorption of 4-nitrophenylazo derivatives of phenols increases with an increase in the hydrophobicity of the azo component on passing from phenol to 2-cresol and then to 1-naphthol.<sup>109</sup> For the associates formed by cationic surfactants of the alkyltrimethylammonium series with the bromothymol blue (BTB) anion<sup>110</sup> and with phenol and 1-naphthol 4-nitrophenylazo derivatives,<sup>111</sup> it has been shown that sorption increases with an increase in the hydrophobicity of the alkyl radical of the cationic surfactant in the sequence  $C_{10} < C_{12} < C_{14} < C_{16} < C_{18}$ . In the presence of cationic surfactants, the dependence of  $\log K_d$  of ion associates formed by 4-nitrophenylazophenol and 4-nitrophenylazo-1-naphthol on the number of carbon atoms in the alkyl radical of the cationic surfactant is described by linear equations (5) (Table 4).

##### b. The ability to form hydrogen bonds

As a rule, organic compounds containing a hydroxy group are sorbed more efficiently on PUF-ET, which, in the opinion of many researchers,<sup>104,105,112-116</sup> attests to the formation of a hydrogen bond (ether groups are known to be more prone to form hydrogen bonds than the ester groups). In the sorption of compounds containing hydrophobic fragments in addition to a hydroxy group, two factors should be taken into account, in particular, hydrophobicity and the ability to form intermolecular hydrogen bonds. It was shown that the logarithms of the distribution coefficients of phenols<sup>104,111</sup> and phenolcarboxylic acids<sup>105</sup> are related to their hydrophobicity parameters and the

$pK_a$  values by two-parameter correlation equations [relation (6) in Table 4].

### c. The concentration and the nature of the partner ion

Ionised compounds are most often sorbed on PUF as ion associates.<sup>117</sup> The concentration and the nature of the partner ion are important factors influencing their sorption. Typical dependences of the recovery of associates on the concentration of partner ions are curves with saturation.

The sorption of associates of xanthene dyes<sup>106</sup> and cationic metal chelates with 1,10-phenanthroline<sup>118, 119</sup> increases with an increase in the size and hydrophobicity of the anion in the sequence  $Cl^- < Br^- < NO_3^- < I^- < SCN^- < ClO_4^-$ . A linear correlation is observed between  $\log K_d$  and hydration energies of anions ( $\Delta H$ , kJ mol<sup>-1</sup>) [relation (7) in Table 4]. The distribution coefficients of the associates formed by 4-nitrophenylazophenols<sup>109, 111</sup> and sulfophthalein dyes<sup>107, 108, 119</sup> on PUF-ET in the presence of alkali metal ions increase in the sequence  $Li^+ < Na^+ < Rb^+ < K^+$  (the maximum value is observed for potassium). Similar dependences are observed for the sorption of anionic metal complexes (mainly thiocyanate complexes).<sup>120–123</sup> This means that the polyether units of PUF bind selectively alkali metal ions, especially potassium ions. The resulting positively charged fragments of the sorbent promote the recovery of anions.

### d. The structure of the PUF polymer unit

The influence of the structure of the PUF polymer unit shows itself in different ways for different groups of sorbates. The sorption of PAH<sup>100, 101</sup> and hydrophobic ion associates, for example, those of cationic surfactants with 4-nitrophenylazophenols,<sup>111</sup> is the same on PUF having different structures but identical hydrophobicities. As the sorbate hydrophobicity increases, the difference between the sorption properties of PUF differing in the structure of the polymer unit becomes less pronounced.<sup>124</sup> Conversely, the effect of the polymer base is essential when specific interactions are present in the system. As a rule, PUF-ET are more efficient for such compounds. In most cases, PUF-ET sorb more efficiently metal thiocyanate complexes,<sup>120–123</sup> heteropoly acids,<sup>125, 126</sup> singly and doubly charged anions of the sulfophthalein dyes,<sup>107, 108, 119</sup> anionic surfactants<sup>102, 119</sup> and 4-nitrophenylazo phenol derivatives.<sup>109, 111</sup> The recovery increases on passing from propylene oxide-based PUF to ethylene/propylene oxide-based PUF and then to ethylene oxide-based PUF.<sup>124</sup>

### e. The charge of ions, the composition of the aqueous phase and solution acidity

The sorption of ion associates depends on the charge of ions they contain. Doubly charged ions are sorbed less efficiently on any PUF than singly charged ions, all other factors being the same.<sup>117</sup>

The sorption of associates is influenced also by the solution composition and the pH. Depending on the pH, the compounds sorbed can exist as different species, either as singly or doubly charged species or as neutral molecules.<sup>106, 107, 127</sup> In addition, the sorption properties of PUF can change with the acidity and salt composition of the solution, as they can be modified by hydroxonium and alkali metal ions. It is known that PUF are protonated on contact with mineral acid solutions.<sup>124, 128</sup>

Let us consider some examples. The maximum recovery of phenols<sup>103, 104</sup> and phenolcarboxylic acids<sup>105</sup> is observed for  $pH \leq pK_a - 2$ , where the hydroxy group is not dissociated. As the pH increases to  $pK_a + 2$  and further, the recovery of phenol decreases almost to zero. Conversely, the sorption of PAH does not depend on the acidity of the initial solution over a broad pH range (from 4 M HCl to pH 13).<sup>100, 101</sup> The maximum recovery of the oxidised and reduced forms of heteropoly acids on PUF is attained in the range from 4 M HCl to pH 2, which coincide, on the one hand, with the stability region of the corresponding heteropoly anions in an aqueous solution, and on the other hand, with the pH of the maximum extraction of these compounds with oxygen-containing extractants.<sup>124, 125</sup> The quantitative

recovery of thiocyanate complexes is attained in the pH ranges of pH 2–3 (Cu), 5–1 M HCl (Co), pH 2–1 M HCl (Fe) and pH 1–2 M HCl (Ti), which coincides with the regions of quantitative extraction of these compounds with oxygen-containing solvents.<sup>124</sup>

## 2. Chemisorption of polyurethane foams

The chemisorption processes involving the functional groups of macromolecules of polyurethane foams and accompanied by the formation of intensely coloured products have been studied by diffuse reflectance and IR spectroscopy.<sup>129–134</sup> It was found that the terminal toluidine groups of PUF enter into heterogeneous chemical reactions typical of aromatic amines: diazotisation with sodium nitrite, azo coupling with 4-nitrophenyldiazonium tetrafluoroborate, the reaction with active chlorine, and condensation with formaldehyde. The chemisorption of the above-listed substances takes place under relatively mild conditions (aqueous solutions, room temperature, atmospheric pressure), the coloured products are formed rapidly and at rather low concentrations of the compounds in aqueous solutions. The main factors influencing these processes were elucidated, in particular, pH and the acid composition of the aqueous phase, the time of phase contact, the structure of the monomeric unit in the polymer and the concentrations of the reactants. The high efficiency of chemisorption preconcentration of free active chlorine and nitrite and nitrate ions, the intensive colour of the sorbent thus attained, the ready availability and the low cost of the sorbent proved to be attractive for the use of PUF as new polymeric reagents.<sup>129, 130, 133, 134</sup>

## 3. The state of sorbed molecules in the polyurethane foam matrix

Study of the state of the sorbed molecules in the polyurethane foam matrix is important for extension of the analytical potential of hybrid methods of analysis based on sorption coupled with spectroscopy. In a series of studies (Refs 100, 101, 109–111, 118, 119, 122–125, 127, 135) using the diffuse reflectance spectroscopy and luminescence, the spectroscopic characteristics of the coloured and luminescent sorbates have been studied. If hydrophobic (as in PAH)<sup>100, 101</sup> or electrostatic (as in thiocyanate metal complexes) interactions are the predominant type of intermolecular interactions in the sorbed compounds, no pronounced changes in their spectroscopic characteristics take place.<sup>122–124</sup> The normalised fluorescence, fluorescence excitation, absorption and diffuse reflectance spectra for these groups of compounds incorporated in a PUF matrix or occurring in solution are shifted with respect to each other by not more than 10 nm.

For other groups of sorbed compounds, the changes in the spectral characteristics can be more pronounced. For example, the maxima of the diffuse reflectance spectra of oxidised forms of heteropoly acids as sorbates are shifted bathochromically by 55, 45 and 65 nm for molybdosilicic, molybdophosphoric and molybdovanadophosphoric acids, respectively, with respect to the absorption spectra of aqueous solutions, which is indicative of strong interaction between the heteropoly anion and the polymeric matrix.<sup>125</sup>

The diffuse reflectance spectra of 4-nitrophenylazo phenol derivatives<sup>109, 111</sup> or sulfophthalein dyes<sup>119</sup> as sorbates are shifted bathochromically with respect to those in the absorption spectra of aqueous solutions by 50–60 nm, which may be due to the change in the nature of the ionic bond in the associates caused by ionisation processes taking place in the PUF phase and resulting in the separation of ion pairs to give solvated ions. As shown in a study,<sup>136</sup> PUF membranes contain polar microregions in addition to the hydrophobic ones. Similar structural changes have been observed previously for the ion pairs formed by alkali metal ions with hydrophobic anions in the presence of crown ethers.<sup>137</sup>

On storage of some sorbates, for example, 4-nitrophenylazophenols<sup>111</sup> or acridine yellow,<sup>127</sup> in air, the diffuse reflectance spectra change, in particular, the amplitude decreases or new bands appear. Most often, these processes are reversible and are

related to acid–base interactions taking place in the PUF matrix upon the contact of sorbed compounds with acid or ammonia vapour present in the laboratory air. A method for stabilisation of the colour of 4-nitrophenylazo phenol derivatives as sorbates consisting of treating the material with a solution of tetrabutylammonium hydroxide has been proposed.<sup>111</sup>

In some cases, reactions that are impossible in solutions take place in the PUF matrix. Thus the diffuse reflectance spectrum of Cu(II) thiocyanate sorbed on PUF-ET exhibits a broad band with a maximum at 480 nm, which is shifted bathochromically by 130 nm compared to that in the absorption spectrum of the aqueous solution. The Cu(II) thiocyanate complexes in an aqueous solution and in the PUF matrix were compared by EPR. The hyperfine splitting constants and the *g*-factors for aqueous solutions and sorbates were determined. It was shown that the  $\text{Cu}(\text{NCS})_4^{2-}$  complexes in which copper is coordinated by four equivalent nitrogen atoms predominate in aqueous solutions, whereas the PUF matrix incorporates mainly  $\text{Cu}(\text{NCS})_3^-$  complexes whose inner coordination sphere contains one oxygen-containing group of the polymer.<sup>124</sup>

The product formed in the reaction of PUF-immobilised diphenylcarbazide with chromium(VI) in the presence of tetraphenylborate ions  $\text{BPh}_4^-$  differs in spectral characteristics from the product formed in the presence of other anions.<sup>122, 123</sup> In the presence of  $\text{BPh}_4^-$  in highly acidic media (1.5–4.5 M  $\text{H}_2\text{SO}_4$ ), the diffuse reflectance spectra of the sorbate exhibit a bathochromic shift (40 nm) and a hyperchromic effect (~5-fold). The formation of intensively coloured compounds on the PUF surface in the presence of  $\text{BPh}_4^-$  is also typical of other potent oxidants ( $\text{O}_2$ ,  $\text{MnO}_4^-$ ,  $\text{S}_2\text{O}_8^{2-}$ ), which may be used for their combined determination at a level of  $10^{-8}$  mol litre<sup>-1</sup>, the detection limit of chromium being decreased by almost an order of magnitude.

Comparative analysis of the fluorescence spectra of the PAH sorbates allows one to classify all these compounds into two groups.<sup>100, 101</sup> One group includes naphthalene, phenanthrene, acenaphthene and fluorene, for which the fluorescence excitation wavelength ( $\lambda_{\text{ex}}$ ) is smaller than 310 nm. The fluorescence spectra of these compounds coincide with the fluorescence spectrum of PUF; therefore, it is difficult to quantify them by the solid-phase luminescence technique. The second group includes anthracene, pyrene, fluoranthene and 3,4-benzpyrene, for which  $\lambda_{\text{ex}}$  is greater than 310 nm. These compounds develop intensive fluorescence in the PUF matrix in the region where no sorbent fluorescence is observed. The characteristics of the luminescence spectra of binary and ternary mixtures of the PAH sorbates were studied. It was found that the presence of feebly fluorescing naphthalene, phenanthrene, fluorene and/or acenaphthene molecules (even in a 100-fold amount) in the PUF phase together with intensively fluorescing anthracene, fluoranthene, pyrene and 3,4-benzpyrene has virtually no influence on the emission intensity from the latter group. By changing the excitation wavelength, it is possible to distinguish between PAH present as binary or ternary sorbate mixtures in comparable amounts and to identify them on the basis of characteristic bands in the spectrum.<sup>100, 101</sup>

For all the coloured and luminescent compounds, the change in the sorbate concentration does not change either the positions of peaks in the diffuse reflectance or fluorescence spectra or the spectral patterns. Within the linear sections of sorption isotherms, there exists a linear correlation between the Kubelka–Munk function values or the fluorescence intensity and the concentration of the compounds being sorbed in an aqueous solution, which is the reason why these polymers can be used to develop hybrid methods of analysis based on coupling of sorption with photometry or luminescence measurements.<sup>100, 109, 110, 118, 122–124</sup>

#### 4. The technique of preconcentration on polyurethane foams

The technique of preconcentration of elements and organic compounds on PUF differs from that with other sorbents. The sorption preconcentration and separation of PUF can be accomplished in either static or dynamic mode.

The static sorption is performed by two ways. A traditional method is based on shaking (stirring) of the solution under analysis with a known amount of the sorbent, from which air bubbles have been removed. Usually PUF are used as cubes, cylinders, cylindrical discs (tablets) cut or stamped out from a polymer sheet. The PUF cubes or discs occurring in the solution should be squeezed at intervals either manually (for example, by means of the bottom of a glass measuring cylinder) or using special automatic devices.

The dynamic version of sorption implies passing of the solution under analysis through chromatographic column filled with PUF cubes or cylinders. A number of methods for packing of these columns have been developed; a vacuum method is the most popular among them. Yet another specific mode of preconcentration on PUF called the method of ‘pulsating column’ is implemented by pumping the solution through a sorbent layer situated in a glass or plastic medical syringe. Owing to the sorbent elasticity, the cylindrical core of polyurethane foam can be easily compressed and released by movement of the syringe piston. The pulsating column technique suits perfectly for process automation in the sorption–desorption mode. More detailed information concerning various modes of sorption on PUF from aqueous solutions can be found in monographs<sup>92</sup> and reviews;<sup>93, 94</sup> these publications also describe various types of samplers used for sorption preconcentration of organic compounds in air.

The efficiency of preconcentration on PUF can be increased by increasing the sample volume (Table 5), decreasing the sorbent weight within reasonable limits or by performing successive sorption.<sup>138, 139</sup> In the last-mentioned case, the same sorbent tablet is successively brought in contact with fresh portions of the solution to be analysed. Due to the presence of linear sections on sorption isotherms, high recovery values and the ease of separation of the sorbent from the solution, this method provides efficient preconcentration of compounds from dilute solutions. The absolute amount of the substance that has passed to the PUF phase is equal, to a good approximation, to  $nqR$  (*n* is the number of successive sorptions, *q* is the absolute amount of the substance in the sample, µg), and *R* is the recovery.

**Table 5.** Recoveries and preconcentration ratios for the ion associate formed by 4-nitrophenylazo phenol derivative with cetyltrimethylammonium (4-NPA ... CTMA)<sup>138</sup> and for pyrene<sup>139</sup> and sorption time of these compounds from different volumes of aqueous solutions on polyurethane foams.

| <i>V</i> /ml | 4-NPA ... CTMA |                           |               | Pyrene       |                           |               |
|--------------|----------------|---------------------------|---------------|--------------|---------------------------|---------------|
|              | <i>R</i> (%)   | $10^{-2} K_{\text{conc}}$ | <i>t</i> /min | <i>R</i> (%) | $10^{-2} K_{\text{conc}}$ | <i>t</i> /min |
| 25           | 95             | 7.3                       | 40            | 99           | 4.5                       | 10            |
| 50           | 95             | 16.1                      | 50            | 98           | 8.7                       | 15            |
| 100          | 95             | 27.6                      | 60            | 99           | 17.0                      | 20            |
| 200          | 73             | 45.0                      | 90            | 98           | 33.0                      | 30            |
| 250          | –              | –                         | –             | 98           | 41.0                      | 40            |
| 500          | –              | –                         | –             | 96           | 81.0                      | 60            |

The sorbent capacity, *i.e.*, the greatest amount of the preconcentrated component per unit weight of the sorbent is an important parameter as regards the subsequent isolation of the preconcentrated substances in reasonable amounts. Here the advantages of PUF are obvious, as the preconcentration takes place throughout the whole sorbent volume. The sorption capacities with respect to anionic metal complexes vary from 0.2 to 2 mmol per gramme of the sorbent, *i.e.*, they reach 10% of the sorbent weight.<sup>89, 140–146</sup> Taking into account the sorption sites and the limiting sorption values for pyrene and heteropoly acids, the areas occupied by these compounds in the PUF phase have been calculated.<sup>100, 124, 125</sup> They were found to exceed the specific surface area of PUF by factors of 10 to 340.

It has been noted in a number of publication that PUF have a number of advantages over other polymeric sorbents and carbons for preconcentration of polychlorobiphenyls,<sup>147–150</sup> PAH,<sup>139, 150–152</sup> phenols,<sup>113, 114, 138</sup> organophosphorus and chlorinated acaricides and organophosphorus insecticides<sup>153, 154</sup> from waters.

### 5. Polyurethane foams in sorption spectroscopic and test methods of analysis

The methods of analysis combining sorption and spectroscopic determination are based on the sorption preconcentration of the component to be quantified on PUF, the formation of a coloured or luminescent product on the PUF surface, and its subsequent determination directly in the sorbent matrix by measuring the optical density, diffuse reflectance, luminescence intensity or chromatic characteristics. The sorption preconcentration combined with measurement of the analytical signal on the sorbent surface decreases the limit of detection of the target components by several orders of magnitude, while the use of sorbents modified by specific analytical reagents increases the selectivity of analysis.

Depending on the way of measurement of the analytical signal, the methods based on sorption coupled with spectroscopy can be classified into solid-phase spectrophotometry, sorption photometric and sorption luminescence methods and chromaticity measurements.

The solid-phase spectrophotometry is based on direct measurement of light absorption by the sorbent after it has collected the target component.<sup>155–161</sup> To this end, a thin parallelepiped with dimensions matching the cell dimensions ( $2 \times 1 \times 0.1$  cm) is cut out of a PUF plate, a coloured compound is sorbed on it, the sorbent is transferred into the cell filled by an organic solvent and the optical density is measured. The solvent serves as the immersion liquid which decreases light scattering. Methods have been developed for determination of bismuth as the iodide complex,<sup>155</sup> cobalt as the thiocyanate,<sup>156</sup> phosphate ions as the reduced molybdophosphoric heteropoly acid,<sup>157</sup> zinc and bismuth<sup>158</sup> and Hg(II) chloride and phenyl chloride<sup>159</sup> as dithizonates, chromium as blue peroxychromic acid and as the diphenylcarbazide complex.<sup>160, 161</sup> These methods are characterised by a rather narrow ranges of linearity of the calibration plots and relatively low reproducibility of the results.

In the method of analysis where sorption is coupled photometry, the appearance or change of the sorbent colour due to sorption of the component under analysis on its surface can be recorded by measuring the diffusion reflectance (Refs 109–111, 119, 121–124, 129, 130, 133, 135, 162–172). The method involving sorption and luminescence measurement is based on preconcentration of the component by a solid substrate followed by determination directly in the sorbent phase using luminescence spectroscopy.<sup>100, 173–175</sup> The procedural aspects of the quantitative measurement of diffuse reflectance and luminescence intensity for the sorbates on PUF have been considered.<sup>176</sup> The key characteristics of the analysis of organic compounds, anions and elements based on sorption coupled with photometric determination or with luminescent determination are summarised in Table 6.

In the chromaticity measurements, colour coordinates serve as the analytical signal determined in the sorbent matrix. A method including chromaticity measurements and numerical estimation of the colour intensity of substances sorbed on PUF by means of an office scanner and computer software for digital image processing has been proposed.<sup>177</sup>

Test methods of analysis are quick, simple and cheap techniques for detection and determination of substances that do not require any essential sample preparation, the use of complex instrumentation, complex laboratory equipment or highly qualified personnel.<sup>178</sup> The analytical signal used in test methods is the appearance or a change of the sorbent colour upon collection of the analyte on its surface as a coloured analytical form. Most often, this change is detected by sight, although in some cases,

**Table 6.** Characteristics of determination methods of organic compounds, non-metals and metal ions based on sorption on polyurethane foams and spectroscopy.

<sup>a</sup> CTMA is cetyltrimethylammonium bromide, <sup>b</sup> CP is cetylpyridinium chloride, <sup>c</sup> DDC is sodium dodecyl sulfate, <sup>d</sup> the reduction was performed in a microwave field.

recording by simple instruments is also possible.<sup>178</sup> The possibility of using PUF in test methods of analysis was first noted in 1974.<sup>179</sup> Determination was performed after preconcentration of elements on chromofoams (the term was proposed by Braun<sup>179</sup>), i.e., PUF modified by photometric reagents. On contact of these foams (as small cubes) with the solution to be analysed, the initially white polymer acquires a colour typical of the given photometric reaction. These reactions are highly sensitive. The detection limits for sorption under static conditions and for a sample volume of not more than 1 to 2 ml are tenth or even hundredths of a µg (as, for example, for Co,<sup>179</sup> Cu,<sup>179–181</sup> Cd,<sup>180</sup> Pd,<sup>181</sup> Pb,<sup>179</sup> Cr,<sup>182</sup> Mo<sup>183</sup>).

A different way of using PUF in test methods that does not require the preparation of modified PUF has also been proposed. In a number of studies,<sup>110, 118, 129, 130, 138, 163, 164, 184</sup> tablets of non-modified PUF in combination with tubes containing a reagent solution were used as test systems. The reproducibility of the results ( $s_r$ ) of visual determination against a colour scale varies from 0.1 to 0.5. Test systems based on PUF for determination of Co, Ni, Fe(III), nitrite ions, active chlorine, the total content of phenols and anionic and cationic surfactants have passed the metrological certification procedure at the Urals Research Institute of Metrology of the Russian Federation Gosstandart, have been included in the register of test system types and are now manufactured commercially by the ecological and analytical association Ekoanalitika. The test kits based on PUF are easily manufactured, reliable in operation and can be used to determine environmentally toxic compounds in various types of water

including potable and mineral water, soil extracts and juices. If necessary, the test form can be preserved and analysed in a laboratory using diffuse reflectance spectroscopy or (after desorption of the compounds) by HPLC.<sup>138, 139</sup>

## V. Preconcentration on non-covalently modified silicas

Silicas differ favourably from other inorganic and organic sorbents: they do not tend to swell, ensure a rather high mass exchange rate, possess chemical stability and mechanical strength, and in some cases, also fairly high hydrolytic stability.<sup>185–188</sup> On the basis of silica, a large number of diverse modified materials that possess chemical features of the immobilised compound and the properties of silica as a solid have been produced.<sup>185–192</sup> Covalently and non-covalently modified silicas can be distinguished.

For preconcentration and determination of metal ions, a number of chemically modified silicas have been prepared and studied, the chemical modification being performed by mono-, di-, tri- and tetramines,<sup>185, 193–195</sup> eriochrome black T,<sup>196</sup> naphthoquinone,<sup>197</sup> carbazides,<sup>194</sup> purpurogallin,<sup>198</sup> nitrogen-containing heterocycles (1,10-phenanthroline, 2,2'-bipyridine, 8-hydroxyquinoline, *etc.*),<sup>199</sup> iminodiacetic,<sup>185, 200</sup> aminophosphonic<sup>201</sup> and carboxylic<sup>202</sup> acids.

Yet another approach is non-covalent immobilisation of analytical reagents on silicas. Depending on the chemical nature and the structure, analytical reagents can undergo electrostatic, donor-acceptor, hydrophobic and other types of interaction with the silica surface groups and thus become attached to the surface.<sup>203</sup> It has been proposed to use immobilisation both to improve the chemicoanalytical properties of the reagents and to design new organic reagents.<sup>204</sup> The non-covalent modification of silochromes and other silica gels by complexing analytical reagents has been studied fairly comprehensively.<sup>205–235</sup>

Terada *et al.* have prepared and described silica gels modified by 2-mercaptobenzothiazole,<sup>205–207</sup> 2-mercaptobenzoimidazole, 2,5-dimercapto-1,3,4-thiadiazole,<sup>207</sup> thionalide,<sup>208, 209</sup> *p*-dimethylaminobenzylidenerhodanine<sup>210</sup> and 1-nitroso-2-naphthol.<sup>211</sup> Ukrainian researchers immobilised on silica gels dodecylaminoethyl- $\beta$ -triiodoammonium iodide, high-molecular-mass quaternary ammonium salts,<sup>212, 213</sup> 1,10-phenanthroline,<sup>214, 215</sup> dithizone and zinc dithizonate,<sup>216</sup> 1-(2-thiazolazo)-2-naphthol<sup>217</sup> and other reagents<sup>218–221</sup> and found that a substantial contribution to the retention of reagents is made by the formation of hydrogen bonds between the donor atoms of the reagents and the silanol groups on the silica gel surface.<sup>212, 217</sup> For attaching of readily water-soluble organic complexing reagents such as nitroso-R-salt,<sup>222</sup> eriochrome black T,<sup>223</sup> calcion,<sup>224</sup> titanium yellow<sup>225</sup> and zincon<sup>226</sup> to silica gels, Kocjan *et al.* have proposed that the reagent to be fastened should be preliminarily extracted into chloroform as an ionic associate with methyltriethylammonium chloride (Aliquat 336) and, after treatment of silica gel, chloroform was removed by evaporation. Heterocyclic azo compounds were immobilised on silica gels of various brands through sorption from aqueous and water-organic solutions.<sup>227–235</sup> Ivanov and co-workers prepared and characterised silica gels modified by 4-(2-pyridylazo)resorcinol (PAR),<sup>228, 229</sup> 1-(2-pyridylazo)-2-naphthol (PAN),<sup>228–232, 234</sup> 4-(2-thiazolylazo)resorcinol,<sup>233</sup> 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PAAP),<sup>234, 235</sup>

Complexing sorbents based on non-covalently modified silica gels are often used for preconcentration under static conditions to determine metal ions, including radioactive ones.

The few papers dealing with non-covalently immobilised redox reagents show that the redox properties change upon immobilisation.<sup>236–239</sup> Examples of the practical use of redox sorbents are virtually missing. We have prepared and studied a number of complexing and redox sorbents. Diverse analytical reagents were immobilised in two ways, either sorbed on the surface of modified silicas containing hydrophobic and ion

exchange groups or incorporated into xerogels of silicic acid using the sol-gel process.

## 1. Preparation and characteristics of modified silicas

### a. Hydrophobised silicas and capillary columns modified with complexing reagents

In the mid-1990s when we started our studies, only a few examples of non-covalent modification of hydrophobised silicas were known.<sup>240–245</sup> We have studied immobilisation, on reverse-phase silica gels with alkyl (SG-C<sub>1</sub>, SG-C<sub>8</sub>, SG-C<sub>16</sub>), nirtile (SG-CN) and phenyl (SG-P) groups and in capillary columns with hydrophobic inner surface, of the following reagents: hydroxyquinolines [2-methyl-8-hydroxyquinoline (MOx),<sup>246, 247</sup> 8-hydroxyquinoline (Ox),<sup>246–248</sup> 5-phenylazo-8-hydroxyquinoline (PAOx),<sup>246, 247</sup>]; oximes [nioxime (NIO),<sup>246, 247</sup> dimethylglyoxime (DMGO),<sup>246, 247</sup> salicylaldehyde (SAO),<sup>246, 247</sup>];  $\beta$ -diketones [benzoylacetone (BA),<sup>246, 247</sup> thenoyltrifluoroacetone (TTA),<sup>246, 247</sup> 1-phenyl-3-methyl-4-benzoylpyrazolone-5 (PMBP),<sup>246, 247, 249</sup>]; bis(2-ethylhexyl) hydrogen phosphate (BEHHP),<sup>246, 247, 249</sup> azo compounds [PAR,<sup>246, 250</sup> PAN,<sup>246, 251–253</sup> sulfochlorophenolazorhodanine (SCPAR),<sup>246, 250</sup> 1-(6-bromo-2-benzothiazolylazo)-2-naphthol (BBT),<sup>246, 250</sup> lumogallion (LG),<sup>246</sup> cadion (CD),<sup>246, 250, 251</sup> hexaoxacycloazochromium (HOCAC),<sup>246, 253</sup> pyrogallol and bromopyrogallol red,<sup>246, 252</sup>]; triphenylmethane and xanthane derivatives [xylanol orange (XO),<sup>246, 251, 252, 254</sup> crystal violet (CV),<sup>246, 250</sup>]; N,O,S-macrocyclic compounds<sup>246, 255–257</sup> and octaethylporphyrin (EEP),<sup>246, 255</sup> sodium diethyldithiocarbamate (DDTC),<sup>246, 249, 252</sup> sodium rhodizionate,<sup>246, 252</sup> 1-nitroso-2-naphthol (NN),<sup>246, 249, 252, 258, 259</sup> 4-dimethylaminobenzylidenerhodanine (DMABR),<sup>246</sup> 2,2'-dipyridine (D),<sup>246, 252, 258</sup> 1,10-phenanthroline (P),<sup>246, 252, 258</sup> diphenylcarbazone (DPCone),<sup>246</sup> diphenylcarbazide (DPCide),<sup>246</sup> quinalizarin (QL),<sup>246, 260</sup>

We proposed capillary columns with a hydrophobic inner surface for the on-line sorption preconcentration and separation of metal ions. For this purpose, the inner surface of quartz capillary tubes (internal diameter 0.45–1.1 mm, length 1–10 m) was chemically etched and then modified *in situ* with organosilicon compounds (dimethyldichlorosilane S-C<sub>1</sub>, methylhexyldichlorosilane S-C<sub>6</sub>, diphenyldichlorosilane S-P) and their polymeric analogues (S-polyC<sub>1</sub>, S-polyC<sub>6</sub>, S-polyP).<sup>257, 253, 260</sup> It was found that the major contribution to the retention of reagents on hydrophobised surfaces is made by the distribution mechanism, which determines the behaviour of the reagents in organic solvent-water extraction systems. As the reagent and surface hydrophobicities increase, for example, with an increase in the number of atoms in the carbon chain, C<sub>1</sub> < C<sub>8</sub> < C<sub>16</sub>, the capacity increases. All the reagents we studied are strongly held on 'phenyl' hydrophobic surfaces, apparently, due to non-specific  $\pi$ - $\pi$ -interactions between the aromatic systems of the reagents and the surface. In the sorbents we studied, the interaction between the donor atoms of the reagents and the surface silanol groups does not make a substantial contribution to the retention of the reagents (apparently, due to the high density of grafting of hydrophobic groups).<sup>246, 247, 250–253, 260, 261</sup>

The strongest retention of the reagents is observed in slightly acidic and neutral media in which the molecular forms of the reagents predominate.<sup>246–261</sup> In the presence of non-ionic surfactants (Triton X-100 and Bridge 35), the capacity of a hydrophobic surface markedly increases.<sup>246, 262</sup> Probably, a hydrophilically hydrated reagent becomes hydrophobically hydrated in micellar media, which enhances the hydrophobic interactions.<sup>263</sup>

The service life of complex-forming sorbents (the reproducibility of the retention times of metal ions) prepared based on hydrophobised silicas is rather long: for example, the Ox/SG-C<sub>16</sub> sorbent can be used 30 times in the sorption-desorption mode<sup>248</sup> and sorbents based on PAOx, diaza-18-crown-6 (DAC) and OEP withstand up to 100 cycles.<sup>246</sup>

The modification of hydrophobised surfaces under dynamic conditions allows one to obtain complex-forming sorbents within

several minutes. Conditions for modification–regeneration of packed micro and capillary columns in an automated mode have been selected; after modification for 30–120 s, capillary columns can be used in continuous flow analysis systems for up to 15 h.<sup>246, 249, 251, 260</sup>

Dynamic sorption of Ca, Mg, Al, Mn(II), Fe(III), Co(II), Ni, Cu(II), Zn, Cd, Pb and Ag(I) on modified silica gels and capillary columns has been studied in the off-line and on-line modes.<sup>246–261</sup> The key factors affecting the sorption behaviour of metals include the nature of immobilised complexing reagent (first of all, the set of donor atoms) and the sample pH and flow rate.

The conditions for quantitative sorption of metals are virtually the same as the optimal conditions for the reactions of these metals with free reagents in solutions.<sup>246–261</sup> Therefore, the enormous body of data accumulated on the complexation of metal ions with analytical reagents in solutions (in particular, for solvent extraction) can be utilised to design sorbents with specified properties.<sup>246</sup>

To increase the selectivity of sorption, the most selective complexing reagents have been immobilised; mixed sorbents<sup>246, 248, 261, 264, 265</sup> and exchange sorption<sup>249</sup> have been used. Sorbents containing at least two sorts of functional groups (complexing, ion exchange, and so on) are referred to as mixed sorbents. If the compound to be sorbed reacts with both sorts of group, its retention can be smoothly controlled by varying their ratio.<sup>264</sup> Mixed sorbents are used in chromatography to enhance the separation of organic substances<sup>266–269</sup> or metal ions.<sup>270</sup> Examples of modification of the substrate simultaneously by hydrophilic and hydrophobic reagents have been reported.<sup>268, 269</sup> Mixtures of ion exchangers have been used for simultaneous determination of cations and anions from the same sample;<sup>271</sup> and mixed metal hydroxides and phosphates have been used for selective sorption preconcentration of Ca, Mg, Sr and Ba.<sup>272</sup> We have proposed preparing mixed sorbents by modification of hydrophobised surfaces with mixtures of complexing reagents with different sets of donor atoms. The sorption behaviour of metals can be controlled (for example, to ensure that a required metal is eluted first) by mere variation of the ratio of complexing reagents in the modifying solution.<sup>246, 248, 261, 264</sup> Mixed sorbents have been used to increase the selectivity of sorption preconcentration,<sup>246, 248, 261, 265</sup> including that in the on-line mode,<sup>261</sup> and for TLC separation.<sup>264</sup>

Exchange sorption is also employed to increase the selectivity of the sorption process. The immobilised complexing reagent is loaded with a metal ion and then used to recover another metal ion.<sup>249</sup> It is obvious that this approach resembles exchange solvent extraction; however, the sorption version does not require the presence of an organic solvent and implies a much lower consumption of the reagent; this version is faster and can be more easily automated. The metal ion-loaded complexing sorbents based on non-covalently modified hydrophobised silicas ensured a record selectivity of the sorption preconcentration of Cu(II) and Fe(III).<sup>249</sup>

Non-covalently immobilised complexing reagents have been used to develop hybrid methods for metal determination that combine sorption preconcentration and separation.<sup>246–261, 265, 273</sup>

#### b. Hydrophobised silicas and ion exchangers modified by redox reagents

The immobilisation of quinone imines (2,6-dichloroindophenol, 2,6-dibromoindoguaiacol, indophenol blue, Bindschedler's green, variamine blue, phenol blue), thiazine dyes (methylene blue, toluidine blue), *N,N*-diethyl-*p*-phenylenediamine (DPPDA) and benzidine on Silochrome S 80 (SG), reverse-phase silica gels (SG-P, SG-C<sub>16</sub>, SG-CN) and ion exchange resins with sulfo groups (SG-SO<sub>3</sub><sup>−</sup>) and tetramethylammonium groups (SG-TA) has been studied.<sup>274–278</sup> In addition, benzidine was grafted covalently to silica gel and cellulose<sup>278</sup> and quinone imine was immobilised on ion exchangers obtained by modification of SG-CN by solutions of cationic and anionic surfactants.<sup>277</sup>

The retention of reagents depends substantially on the nature of the sorbent and the solution pH. Silica gels retain strongly thiazine dyes (methylene blue, toluidine blue) and DPPDA (apparently, due to the formation of hydrogen bonds between the amine and imine nitrogen atoms of the reagents and the silanol groups of the substrate surface).<sup>274, 275</sup> In weakly acidic and neutral media (when molecular species predominate), quinone imine derivatives are firmly held on SG-P. Indophenols are held on an anion exchanger (SG-TA) in an alkaline medium where indophenolates predominate. The protonated forms of indamines and benzidine are held on cation exchangers (SG-SO<sub>3</sub>H).<sup>276, 277</sup>

The redox equilibrium involving non-covalently immobilised reagents is attained within a few minutes.<sup>276, 278</sup> In the mode of successively repeated oxidation–reduction cycles, indophenol- and indanine-based sorbents are almost completely reversible. Non-covalently immobilised 2,6-dichloroindophenol can be used in 50 cycles and 2,6-dibromoindoguaiacol and Bindschedler's green, in 20 cycles.<sup>277</sup>

The nature of substrates has a pronounced influence on the acid–base and redox properties of the reagents. Whereas sorption on reverse-phase silica gels does not change the acid–base properties, sorption on cation exchangers markedly enhances the acidic properties of reagents.<sup>277</sup> Indophenols and indamines have been used as examples to elucidate the influence of non-covalent immobilisation on the redox properties of reagents. For Bindschedler's green, the greatest difference between the formal redox potentials in a solution and on a sorbent surface was found in the case of SG-P.<sup>277</sup>

The redox sorbents considered were used to develop hybrid methods for determination of sulfur-containing reducing agents, ascorbic acid, free active chlorine and aniline.<sup>274–278</sup>

#### c. Xerogels of silicic acid modified by analytical reagents

The sol–gel process is now widely used to obtain materials with specified properties. Sol–gel materials are characterised by high strength and high thermal and light stabilities, many of these being optically transparent. Using sol–gel process, it is possible to modify materials by various substances, in particular, analytical reagents.<sup>187, 279–285</sup>

Sol–gel materials based on silica (xerogels, XG) are used most often for analytical purposes. The sol–gel process is performed in the presence of catalysts. The porosity and the specific surface area of xerogels depend substantially on both the conditions of the sol–gel process (the composition of the mixture subjected to hydrolysis, the nature of the catalyst, and the pH) and on the drying conditions.<sup>279–284</sup>

Modified sol–gel materials can be prepared either by using functionally substituted alkoxysilanes containing alkyl, amino, vinyl, epoxy, mercapto and other groups<sup>187, 280, 285–287</sup> or by adding the compound to be grafted at the sol formation stage.<sup>286–323</sup> The latter approach is obviously more versatile and has an almost infinite potential, because in this case, retention is mainly provided by the mechanical capture of substances by the network silica structure formed during the gelation.

The immobilisation of an analytical reagent (rhodamine 6G) on a sol–gel material was first accomplished in 1984.<sup>289</sup> However, intensive research along this line started only in 1990 when Avnir and co-workers<sup>290</sup> concluded, based on the data accumulated at that time, that substances incorporated in sol–gel materials can participate in chemical reactions. The materials now obtained include silica-based monoliths and films modified by acid–base indicators (azo, phthalein and sulfophthalein compounds and by porphyrins),<sup>291–295</sup> complexing organic reagents (ethylenediamine, tetraacetic acid, 1,10-phenanthroline, alizarin, quinalizarin, 1-nitroso-2-naphthol, dimethylglyoxime, sodium rhodizonate, hydroturbic acid, cuproin, galloycyanin, morin, eriochrome cyanine, diphenylcarbazine)<sup>286, 290, 296–303</sup> and metal salts.<sup>290</sup> Sol–gel process is a convenient way of immobilisation of biological molecules (proteins, enzymes, antibodies); interesting data concerning this issue have been reported in reviews.<sup>304–306</sup>

The protolytic reactions involving acid–base indicators incorporated in sol–gel materials have been studied fairly comprehensively.<sup>292, 294</sup> Complexation reactions have been less investigated [only the nickel–dimethylglyoxime,<sup>286</sup> iron(II)–1,10-phenanthroline,<sup>287</sup> aluminium–morin,<sup>300</sup> copper(II)–eriochrome cyanine (ECC) systems have been studied in detail].<sup>300</sup> It has been noted that the retention of complexing reagents and their interaction with metal ions depends appreciably on the material porosity.<sup>286, 300</sup>

The sol–gel materials modified by analytical reagents have been used for determination of metal ions by solid-phase spectroscopy<sup>298–300</sup> and by test methods (indicator tubes),<sup>287, 296, 297</sup> for the design of spectroscopic<sup>301–317</sup> and electrochemical sensors<sup>318, 319</sup> and as sorbents.<sup>187, 286, 320–323</sup> A study of affinity sorbents — sol–gel materials modified by polyclonal antibodies — has demonstrated a better selectivity of the antigen–antibody interaction.<sup>322, 323</sup> A substantial limitation hampering the extensive use of sol–gel materials in analysis is the long time it takes for sorption equilibrium to be established (in some cases, up to several days).

Good results have been obtained in gas and liquid chromatography used to separate organic compounds on capillary columns modified by ion exchange or hydrophobic sol–gel films.<sup>324–328</sup> The use of capillary columns containing sol–gel monoliths has been proposed.<sup>327</sup>

Our studies<sup>246, 250, 273, 329–344</sup> have promoted extensive introduction of sol–gel materials modified by analytical reagents into the chemical analysis practice in Russia. We have developed a new method for the preparation of silicic acid xerogel powders with specified physicochemical properties (specific surface area, pore diameter, concentration of the immobilised reagent).<sup>329</sup> These were used to immobilise analytical reagents promising for preconcentration, separation and determination of metal ions, anions and a number of organic compounds including those whose immobilisation had been studied on hydrophobic surfaces: hydroxyquinolines [Ox,<sup>246</sup> 5,7-dibromo-8-hydroxyquinoline (5,7-dibromo-8-Ox)<sup>246, 342</sup>]; azo compounds [PAN,<sup>246, 250, 331, 332</sup> PAR,<sup>246, 250, 333</sup> 4-(2-thiazolylazo)-2-naphthol,<sup>246</sup> SCPAR,<sup>246, 250</sup> BBT,<sup>246, 250</sup> LG,<sup>246</sup> CD,<sup>246, 250</sup> HOCAC,<sup>246</sup> sulfarsazene (SA)<sup>246</sup>]; triphenylmethane and xanthone derivatives [chromazurol (CAZ),<sup>246, 334, 335</sup> sulfochrome (SC),<sup>334</sup> ECC,<sup>246, 334</sup> XO,<sup>246, 331, 336</sup> CV<sup>246, 250</sup>]; 1,10-phenanthroline,<sup>246</sup> bathophenanthroline (BP),<sup>246</sup> DPCide,<sup>246, 335</sup> DPCone,<sup>246, 336</sup> morin,<sup>246</sup> chrompyrazol I (CP I),<sup>246</sup> copper(II),<sup>246</sup> cobalt(II),<sup>246, 337</sup> iron(III),<sup>246, 338</sup> molybdophosphoric acid and its ammonium salt, Vavele reagent (VR) (a mixture of 12- and 18-row molybdophosphoric acids),<sup>246, 339–341</sup> aromatic hydroxy compounds [1- and 2-naphthols, 2,7-dihydroxynaphthalene, *N*-(1-naphthyl)ethylene-diamine, *p*-hydroxydiphenyl],<sup>246, 342</sup> 4-aminoantipyrine (4-AAP),<sup>246, 343</sup> disodium 4,4'-dithiobis(8-chloro-1-hydroxy-2-phenylazonaphthalene)-3,6-disulfonic acid (BAS) and butyrylthiocholine (BTCI).<sup>344</sup> Methods for the synthesis of modified sol–gel materials with a specified concentration of an analytical reagent, in particular, those modified by mixtures of reagents [a complexing reagent and a surfactant,<sup>333, 334</sup> molybdophosphoric heteropoly compound and copper(II),<sup>246, 341</sup> and BAS and BTCI] have been developed.<sup>344</sup>

Data on the thermodynamics and kinetics of heterogeneous reactions involving immobilised analytical reagents have been obtained. It was shown that inclusion of complexing reagents of various classes or 1-naphthol and 4-aminoantipyrine into silicic acid xerogel powders enhances the acid–base properties of the reagents.<sup>246</sup> Apparently, this is due to the reaction of active hydrogen atoms of immobilised compounds with the silanol groups in the bulk of the xerogel matrix. The formation of complexes in xerogels of silicic acid is possible upon immobilisation of both a complexing reagent and a metal ion. Complexes with a metal : reagent ratio of  $\leq 1 : 3$  are formed in the xerogels. The equilibrium constants of heterogeneous reactions vary in parallel with the stability constants of complexes in solutions,

which makes it possible to predict the analytical properties of reagents incorporated in xerogels of silicic acid.<sup>246</sup> Xerogels modified by molybdophosphoric heteropoly compounds (HPC) withstand at least 30 oxidation–reduction cycles. It was found that the oxidative ability of molybdophosphoric HPC is enhanced upon their inclusion into xerogels of silicic acid.<sup>339–341</sup> Various reactions can take place in xerogels of silicic acid: azo coupling, diazotisation–azo coupling and oxidative condensation.<sup>246, 342, 343</sup> For example, in xerogels modified by aromatic hydroxy compounds (the best results were attained with 1-naphthol), reactions with diazotised anilines yield azo dyes.<sup>246, 342</sup> The xerogel modified by a mixture of sulfanilic and chromotropic acids reacts with nitrite ions (diazotisation–azo coupling reactions).<sup>246</sup> The selectivity of oxidative condensation of phenolic compounds in 4-aminoantipyrine substantially increases in xerogels.<sup>246, 343</sup>

The conditions of interaction of choline esterase with BAS and BTCI contained in a xerogel have been selected: first, enzymic hydrolysis of BTCI takes place and then the resulting thiocholine reacts with BAS, which is accompanied by a sharp colour change.<sup>344</sup>

In two publications,<sup>246, 330</sup> reactions of inorganic and organic compounds with modified xerogels have been considered from the standpoint of the general mass transfer theory as sequences of the following processes: diffusion of a reactant from the bulk to the surface of modified xerogel particles (external diffusion), diffusion inside the pores (internal diffusion) and the proper chemical reaction with immobilised reagents. The rate-limiting steps were established and the rate constants for diffusion processes were determined.<sup>246</sup>

Interesting data on the effect of microwave radiation and ultrasound on the rate of heterogeneous processes involving sol–gel materials have been obtained. The microwave radiation intensifies all stages of the heterogeneous process. The time it takes to attain the equilibrium decreases three- to four-fold, while the rate constants for diffusion processes are almost doubled. It was shown that it is expedient to use 200–600 W microwave radiation.<sup>246, 330</sup> To accelerate the processes whose duration is determined by external diffusion, ultrasonic treatment was used. The high intensity of stirring, and apparently cavitation phenomena markedly accelerate heterogeneous reactions by intensification of, most of all, the external diffusion (the rate constants for external diffusion increase by a factor of almost three).<sup>246, 330</sup>

In powders of sol–gel materials, heterogeneous reactions proceed much faster than in monolithic structures: whereas the complexation of copper(II) with the monolith modified by eriochrome cyanine requires 48 h,<sup>300</sup> the reaction with a powder modified with the same reagent (pore diameter 40 Å) takes place over a period of 5 min.<sup>334</sup> An increase in the average pore diameter in the powders from 20 to 200 Å (which can be easily attained by using the method for the preparation of xerogels we developed) results in a higher rate of internal diffusion, which almost halves the time required to reach the equilibrium.<sup>246</sup>

To accelerate the reactions between molybdophosphoric HPC immobilised on xerogels and reducing agents, we synthesised xerogels containing simultaneously molybdophosphoric HPC and copper(II) as the catalyst for their reduction. The results indicate a substantial acceleration of the heterogeneous reaction, *i.e.*, a catalytic reaction takes place.<sup>341</sup>

## 2. The use of non-covalently modified silicas in analysis

Due to the simplicity of preparation of silicas non-covalently modified by analytical reagents with a high concentration of firmly attached reagents and to the high rate of sorption, these materials can be regarded as promising sorbents. They have been used for sorption preconcentration and separation of metal ions, including that in the on-line mode,<sup>246–252, 255, 257, 259–261, 265</sup> and for the solid-state spectroscopic and test determination of metal ions, anions, reducing agents, oxidants and organic compounds.<sup>246, 254, 258, 274–278, 330–344</sup>

### a. Determination of metal ions by sorption coupled with atomic absorption spectrometry or photometry

The sorption preconcentration of metal ions on reverse-phase silica gels and xerogels of silicic acid non-covalently modified by complexing reagents results in high preconcentration factors (up to  $5 \times 10^3$ ). The capacities before breakthrough of the complexing sorbents with respect to metal ions are rather high ( $5\text{--}100\text{ }\mu\text{mol g}^{-1}$ ). The high preconcentration efficiency is determined by rather high flow rates of the sample: from  $3\text{--}4\text{ ml min}^{-1}$  (for complexes) to  $20\text{ ml min}^{-1}$  (for ion associates).<sup>246–248, 250–253, 259, 273</sup>

An obvious advantage of complexing sorbents based on modified silicas is the high selectivity attained by immobilisation of selective complexing reagents, choice of appropriate conditions and by using mixed sorbents<sup>246, 255, 261, 265</sup> or exchange sorption.<sup>246, 249</sup>

For sorption preconcentration of metal ions, the use of cartridges filled with hydrophobic silica gels modified by complexing reagents (XO, PAN, CD, Ox and DMABR) has been proposed. If necessary, modification can be carried out under field conditions on the sampling site.<sup>246, 248</sup>

The procedures proposed for determination of Ag, Cd, Cu(II), Fe(II), Mn(II) and Pb using sorption preconcentration coupled with atomic absorption or photometry allow the use of serial, readily available and cheap spectrophotometers and flame atomic absorption spectrometers to determine traces of metals in natural, potable and waste waters, atmospheric precipitates and industrial solutions at the MPC level (Table 7). The sorption–atomic absorption procedure for determination of Cd, Pb and Zn in atmospheric precipitates or natural and waste water using preconcentrating cartridges filled with reverse-phase silica gel SG-P non-covalently modified by XO has passed the state metrological certification procedure (PND P 14.1:2.81-96) and was approved for the use in the state ecological monitoring.<sup>246</sup>

### b. Continuous flow analysis

Flow analysis of samples has a high sampling frequency and good reproducibility and requires small amounts of samples and

**Table 7.** Characteristics of metal determination by sorption on non-covalently modified silicas ( $n = 3$ ,  $p = 0.95$ ) coupled with atomic absorption spectrometry and photometry.

| Sorbent                                   | Analyte | Quantifiable concentration range /mg litre <sup>-1</sup> | Detection limit /mg litre <sup>-1</sup> |

<sup>a</sup> N<sub>4</sub> is the tetraaza analogue of dibenzo-18-crown-6; <sup>b</sup> joint determination of Cd and Pb; <sup>c</sup> joint determination of Cd, Pb and Zn.

reagents. Currently, the development of flow analysis is related to the possibility of performing sorption preconcentration and separation and solid-state detection under dynamic flow conditions (often, on a micro scale).<sup>345</sup>

The reasonable efficiency ( $CE = 5\text{--}95$ ) and high selectivity of complexing sorbents based on non-covalently modified silicas determine the success in using them for the on-line sorption preconcentration and separation of metal ions.

A study<sup>273</sup> describes a flow distribution system for automated photometric determination of  $0.009\text{--}0.3\text{ mg litre}^{-1}$  of aluminium in waters and beverages including the on-line sorption preconcentration on a microcolumn filled with xerogel of silicic acid modified by chromazurol (50 samples per hour).

We developed a universal flow distribution system for determination of metal ions. The system core is a sorption column. This can be either a microcolumn packed with reverse-phase silica gel or a capillary column with a hydrophobic inner surface, which is modified alternately by various complexing reagents that ensure the retention of different metal ions (Fig. 3). The system allows automated sorption separation of metal ions, preconcentration of one ion and separation of the interfering metal ions; hence, a number of analytical problems can be solved. Automated highly productive procedures for determination of traces of metal ions [Cd, Pb, Co(II), Cu(II), Fe(III)] or for simultaneous determination of two metal ions [Ca–Mg, Co(II)–Fe(III), Pb–Fe(III)] in atmospheric precipitates have been developed. The high selectivity of the flow photometric determination of metal ions with on-line sorption preconcentration is ensured by the appropriate choice of the sorbent and by the sorption–desorption and photometric detection conditions. Advantages of capillary columns over packed microcolumns include higher sampling frequency and better metrological characteristics of the determination. The main reason is the decrease in sample diffusion in the case of capillary columns (Table 8).<sup>246, 251, 259–261</sup>

For determination of Pb(II), Co(II), Mn(II) and Fe(III) traces in natural waters, the versatile gas distribution system was supplemented by a block for on-line sample preparation (destruction of the metal complexes with humic and fulvic acids) in a microwave field (see Fig. 3).<sup>346</sup>

The flow distribution systems for the simultaneous determination of cadmium and zinc, aluminium and manganese(II) have been developed on the basis of on-line sorption separation on

### c. Solid-state spectroscopy and test methods

Due to the simplicity and high sensitivity of the determinations, the title methods are now attracting considerable attention of researchers. The determination is based on a chromogenic heterogeneous reaction carried out under static conditions (as a result of sorption of pre-synthesised coloured compounds by appropriate sorbents or the reaction of the analyte with immobilised chromogenic reagents) and measurement of the spectroscopic characteristics of the solid phase. The spectroscopic characteristics of the indicator powders are recorded, after the sorption equilibrium has

been established, by diffuse reflectance spectroscopy, solid-state spectrophotometry or chromaticity measurements.<sup>347, 348</sup>

When the colour can be estimated by sight or portable instruments can be used, test versions of these methods can be developed.<sup>178, 349</sup>

Solid-state spectroscopy has found the most extensive application for determination of metal ions. To this end, ion exchange resins,<sup>348</sup> fibrous materials and fabrics with ionogenic groups filled by ion exchangers,<sup>350–352</sup> cellulose sorbents,<sup>348</sup> silochromes<sup>212–221, 228–235</sup> and sol–gel materials (monoliths and films)<sup>298–300</sup> have been used.

The high porosity and optical transparency of silicas modified by analytical reagents and the possibility of implementation of various heterogeneous reactions in the solid phase ensured further development of methods based on solid-state spectroscopy. Highly sensitive and simple procedures for determination of Mn(II), Cu(II), Zn, Mo(VI), Cd, Pb; nitrate, nitrite, fluoride and phosphate ions; the total content of sulfur-containing anions, ammonium ions, anionic surfactants, ascorbic acid, hydrazines, asymmetric dimethylhydrazine, anilines, phenols, naphthols and esters have been developed (Table 9, 10). The procedures are fairly quick; it takes only 5–20 min to attain the sorption equilibrium.<sup>246, 274–277, 330–343</sup>

Quantification by these procedures does not imply the use of expensive instrumentation and can be performed by portable photometers and reflectometers; in the test version, this is also done using colour scales. The procedures proved useful in analysis of field samples: water, industrial process solutions, foodstuffs, pharmaceuticals and biological liquids.<sup>246</sup>

Test systems based on indicator powders have passed metrological certification procedure at the State Metrological Scientific Centre based on Urals Research Institute of Metrology; they have been included in the register of test system types, approved for the use and are now manufactured commercially by the limited liability company MedEkoTest (Moscow).

| Anionic surfactants                                   | 0.1 – 150                                                |
| Cationic surfactants                                  | 10 – 150                                                 |

<sup>a</sup> The test system has passed the state metrological certification procedure, registered under the number TS-224.01:11/008-2004 and approved for the use by the Problem Commission of the RF Ministry of Health; <sup>b</sup> the test system has passed the state metrological certification procedure and is registered under the number TS-224.09/009-2004; <sup>c</sup> in mol litre<sup>-1</sup>.

of this approach is the possibility of reliable test determination based on the easily measurable stain length rather than on the degree of colour or tint change (as in most test methods). The method is widely used to analyse gases and aerosols, in particular, in military chemistry.<sup>353</sup>

We have applied the indicator tube method for analysis of solutions (environmental objects, waste waters, foodstuffs and beverages, biological liquids).<sup>246, 252, 254, 258, 274–276, 331, 336, 339, 344</sup> For the preparation of indicator powders, analytical reagents were either non-covalently immobilised on reverse-phase silica gels and silica gel-based ion exchangers directly in the indicator tube<sup>246, 252, 254, 258, 274–276, 354</sup> or incorporated in xerogels of silicic acid.<sup>246, 331, 332, 335, 336, 339, 344</sup>

On the basis of studies of the dependence of determination sensitivity on the physicochemical characteristics of the indicator powders, the flow rate and the mode of supply of the analyte solution to the tube, and the tube length and internal diameter, requirements to the selection of indicator reactions and analysis protocols have been formulated. To ensure high accuracy of determination, the time of passage of the solution through the tube should be 10–20 times longer than the characteristic time of the chemical reaction.<sup>355</sup>

Two modes were employed to feed analyte solutions to the indicator tubes: rising of the liquid due to capillary forces (the 'sinking' mode) and pumping the solution through the tube, for example, by means of a medical syringe (the 'passing' mode). The former mode markedly facilitates and accelerates the procedure of analysis, while the latter ensures a higher determination sensitivity due to the larger solution volume.<sup>246, 254, 258, 274–276, 331, 332, 335, 336, 339, 344, 354</sup>

Indicator tubes for determination of heavy metal mixtures, Al, Cr(VI), Fe, Co(II), Ni, Cu(III), Cd and Sn(III); nitrate, nitrite, chloride and iodide ions; the total content of sulfite, thiosulfate and sulfide ions, ascorbic acid, free active chlorine, cationic and anionic surfactants, sulfur-containing reducing agents, aniline and hydrazines; and the choline esterase activity have been developed (see Table 10). The indicator tubes have been used to analyse environmental objects, industrial process solutions, food-stuffs (after the appropriate sample preparation), beverages, and biological liquids.<sup>246, 254, 258, 274–276, 331, 332, 335, 336, 339, 344, 354</sup>

The metrological characteristics of indicator tube analyses are comparable to those for instrument methods. The relative standard deviation for determination using indicator tubes is 0.02–0.15 and the analysis time is 2–10 min.

Test systems based on indicator tubes have passed metrological certification procedure at the State Metrological Scientific Centre based on the Urals Research Institute of Metrology; they have been included in the register of test system types, approved for the use and are now manufactured commercially by the limited liability company MedEkoTest (Moscow).

Test systems for determination of nitrate, nitrite and chloride ions and Cu(II) and Fe in natural waters have passed state inter-branch tests. The test system for determination of asymmetrical dimethylhydrazine ensures reliable quantification of this toxic substance in soils and in special rinsing solutions.

Indicator tubes are used to determine Sn(II) in the reagents for the preparation of radiopharmaceuticals by the <sup>99m</sup>Tc generator. The test system for determination of nitrate ions is used for clinical urine and blood serum analyses. The indicator tubes for determination of chloride ions in sweat and the choline esterase activity in biological liquids have been recommended for detection of mucoviscidosis in babies and general intoxication in patients.

Thus, non-covalent immobilisation on the surface-modified silicas and incorporation into xerogels of silicic acid has imparted new analytical properties to the fixed analytical reagents, which determined their use in the practice of chemical analysis. In our opinion, silicas modified by analytical reagents can be successfully used to develop flow methods of analysis, in particular, electro-injection<sup>356</sup> and sequential injection analyses and analysis with particle injection.<sup>357</sup> Of particular interest is the design of micro-electrodes and microanalytical systems on microchips.

## VI. Conclusion

The information presented in the review demonstrates the substantial achievements in the development of sorption preconcentration techniques aimed at solving topical tasks of chemical analysis. First, this is the pronounced increase in the number of sorbents that allow quantitative and in some cases fairly selective recovery of trace amounts of metal ions (including complex ions), various ionised and non-ionised organic compounds and simple inorganic anions. Second, this is the appreciable progress attained in the quantitative description of sorption processes, in the investigation of the interaction mechanism, in the development of the strategy for the *a priori* estimation of the sorption conditions and even in the deliberate selection of sorbents for particular purposes. Third, fundamental research has resulted in the development of a large number of combined and hybrid methods for the analysis of diverse objects, including environmental objects. Some of these methods are routinely used in chemical analysis.

A prominent place in the approaches and methods considered belongs to dynamic sorption preconcentration and flow preconcentration. This provides a way to automation of the analysis; numerous examples of automated analyses are currently known, mainly represented by flow injection analysis. A significant contribution to the development of analytical sorption preconcentration was made by the researchers of the Department of Chemistry of the Moscow State University.

**Abstract.** The applications of various bioinformatics methods and databases to the analysis and classification of proteins and search for active sites of enzymes are considered. The published data on the structures of active sites and mechanisms of action of hydrolases are analysed. It is emphasised that all of the known hydrolases can be divided into four groups according to the types of catalytic site which differ in the mechanisms of water activation. The mechanisms of water activation by catalytic groups in the active sites of hydrolases are discussed and the schemes of catalytic cycles characteristic of classical types of active sites of these enzymes are considered. Using glycosyl hydrolases and serine hydrolases as examples, it is demonstrated that different proteins possess common catalytic sites and mechanisms of action. The role of aspartic acid and histidine in the activation of hydrolase substrates and the role of structure-forming acids (glycine, proline, cysteine) in the structural organisation of the catalytic sites are considered. The bibliography includes 195 references.

## I. Introduction

Considerable progress achieved in the study of enzymes in recent decades is caused by the profound fundamental interest in enzymes as highly efficient catalysts of chemical reactions, on the one hand, and by continuously expanding areas of their applications aimed at the solution of numerous practical tasks, on the other hand.<sup>1–13</sup>

The large amount of information on the structures of enzymes has been accumulated over recent years, considerable progress has been observed in the development of concepts of the principles of formation of active sites of enzymes and their mechanisms of action. Tremendous amounts of information concerning amino

acid sequences and spatial structures of protein molecules have been amassed in numerous computer databases. This information demands analysis, systematisation and interpretation from the standpoint of the chemistry of catalytic processes. This review is devoted to applications of bioinformatics methods and databases in the analysis of enzymes and search for their active sites.

Hydrolases, *i.e.*, enzymes catalysing hydrolysis of various compounds, were chosen as the subjects of investigation. This choice was determined by a number of circumstances. Hydrolases constitute about one third of all currently known enzymes (approximately 1100 out of 3700 in the Enzyme Classification). The functional groups in the active sites of many hydrolases that effect their catalytic cycles have been determined. The mechanisms of action of all hydrolases include activation of water by a limited array of functional groups. The fact that many structural elements in the active sites of hydrolases are present in enzymes pertaining to other classes is of no less importance for enzymatic catalysis at large.

## II. Databases of amino acid sequences and three-dimensional structures of enzymes

A considerable body of information on the primary and spatial structures of biopolymers has been accumulated to date. Information on amino acid sequences of enzymes is widely used for their classification, *i.e.*, belonging to one or another family,<sup>†</sup> determination of conserved amino acids and their positions within the families, studies of translated sequences of proteins derived from decoded genomes, *etc.* Spatial structures of enzymes are used for the studies of enzyme-catalysed chemical transformations, rationalisation of substrate specificities, site-directed mutagenesis of enzymes aimed at conferring specific functions on them, *etc.*

Databases containing amino acid sequences or spatial structures of proteins are referred to as primary. Secondary databases comprise elements of the primary databases classified according to their specific features, *e.g.*, databases on alignments of amino acid sequences of proteins or hierarchical databases of protein structures.

<sup>†</sup> The terminology used by different authors may differ.

The Swiss-Prot/TrEMBL (EMBL stands for 'European Molecular Biology Laboratory' database),<sup>14</sup> which further developed into the knowledgebase UniProt,<sup>15</sup> is one of the most popular primary databases of protein sequences. The non-commercial database Swiss-Prot is supported by several research institutes in Europe (e.g., the Swiss and European Institutes for Bioinformatics) and the USA and is accessible through Expasy (Expert Protein Analysis System), the proteomic server of the Swiss Institute for Bioinformatics (<http://www.expasy.org>). Information deposited therein is available through servers in many other countries, which ensures rapid responses to the users' queries.

By the time of writing of this paper (June 2004), the latest version of the Swiss-Prot 43.5 database contained information about 153 017 annotated amino acid sequences with the overall length of 56 301 572 amino acids retrieved from 116 894 publications. It is noteworthy that this database contains only annotated sequences, i.e., sequences of the proteins (including enzymes) with well-established functions. The database TrEMBL, which comprises translated protein sequences, is a supplement to the Swiss-Prot database. The translation is carried out automatically from the nucleotide sequences deposited with the EMBL Nucleotide Sequence Database.<sup>16</sup> For the protein sequences deposited in the database TrEMBL, only the sources are known. The conclusion about their putative functions is made on the basis of their similarities to the sequences of the studied (annotated) proteins. The latest version of the database TrEMBL contained information about 1 062 416 sequences with the overall length of 332 514 237 amino acids. Special mention should be made of a nearly tenfold difference between the number of protein sequences in the databases Swiss-Prot (annotated) and TrEMBL (translated). As a result of their investigation, the proteins from the database TrEMBL pass into the database Swiss-Prot, where they supplement the arrays of sequences of the annotated proteins. The number of sequences in the database Swiss-Prot/TrEMBL increases nearly exponentially with time.

The data deposited with the database Swiss-Prot/TrEMBL encompass several fields; their content can be illustrated by the following example. The amino acid sequence of formate dehydrogenase from *Pseudomonas* sp. strain 101 has the primary accession number P33160 (a unique identifier of this sequence in the Swiss-Prot) and the entry name FDH\_PSESR (the second unique identifier of this particular sequence having a definite semantic meaning): FDH is abbreviated from Formate DeHydrogenase, while the abbreviation PSESR indicates the source, viz., *Pseudomonas* sp. Using the accession number or the entry name, one can obtain available information about the amino acid sequence.<sup>‡</sup> The accession number and the entry name (if it exists) are followed by chronological information (database entry date, latest modification date, annotation modification date, etc.); name(s) of the protein [official, synonyms, Enzyme Classification (EC) number]; origin and taxonomic data; references to the literature sources of the sequence or its corrections; comments on enzyme-catalysed reactions and data on the quaternary structure and relatedness to a protein family. Other information includes cross-references to the corresponding entries of other databases. For formate dehydrogenase used as an example, there are references to the entry in the protein structure database PDB (Protein Data Bank, 2NAC identifier) and two entries in the Protein families database (Pfam).<sup>17</sup> It is of note that the number of cross-references varies for different sequences and depends on the level of investigation of a protein. The cross-references are succeeded by the field 'Features', which provides information about the domain structure and secondary structure elements based on the spatial structure of a protein (if any) and, finally, the amino acid sequence itself.

‡ It is of note that the primary accession number and entry name for each amino acid sequence deposited with the database TrEMBL coincide, since their functions are unknown and the conferment of names reflecting their function or classification is unjustified.

For the overwhelming majority of protein sequences deposited in the database Swiss-Prot, the set of fields is not that big, since the spatial structures are known only for a limited number of proteins including well-studied ones. For protein sequences deposited with the database TrEMBL, the set of fields is even smaller: it is only the sequence source (gene), references and the sequence itself that are reliable. It is of note that the access to the database Swiss-Prot/TrEMBL permits the use of different kinds of search and the user's interface is well thought-out, which significantly facilitates the work.

The Protein Data Bank (PDB)<sup>18</sup> (<http://www.rcsb.org>) represents a primary database of spatial structures of biopolymers. This data bank is supported by the Research Collaboratory for Structural Bioinformatics which comprises three research centres in the USA. By June 2004, this data bank comprised information about 25 882 biopolymer structures (including 23 429 peptide and viral structures) established by X-ray diffraction analysis and multidimensional NMR.<sup>§</sup> It is of note that the number of structures deposited with PDB increases exponentially and so does the volume of data banks of the primary sequences. However, in contrast to amino acid sequence data banks, the structure data bank includes different structures of the same biopolymer obtained under different conditions (e.g., pH) or as a complex with different molecules (e.g., with inhibitors), etc. Some protein structures look very similar. If such 'similar' structures are omitted, the remaining ~ 5 000 structures will differ, in one degree or another, in the fold of their polypeptide chains, the increase in the number of new folding types being far from exponential. It is noteworthy that the difference in the growth rates of the bank of primary sequences and the bank of spatial protein structures makes the simulation of protein structures based on their amino acid sequences a topical task. The development of methods for simulation is progressing rapidly.<sup>19</sup>

Every structure deposited with the PDB is presented as a text file, which includes the coordinates of all of its heavy atoms (these coordinates are read by molecular graphics programs or are used as the starting information for calculations). Some proteins possess spatial elements (groups of atoms) manifesting high lability (these include disordered structures situated on the surface of protein globules or several amino acid residues nearest to the N-/C-ends). The impossibility of determining their coordinates leads to the appearance of gaps in the polypeptide chains or a lack of structural data on the side chains of amino acid residues.

In addition to the atom coordinates, PDB files contain references to the papers with the protein structures, experimental procedures and subsequent processing of the results obtained, amino acid sequences and secondary structures of proteins. High accuracy of determination of spatial structures of enzymes makes quantum-chemical methods applicable to simulation of enzymatic catalytic processes.<sup>20</sup>

The interface of the PDB database allows text searching in different fields. In our opinion, the database PDBsum (<http://www.biochem.ucl.ac.uk/bsm/pdbsum/>) developed and supported by researchers of the European Institute for Bioinformatics is the most convenient tool for object searching.<sup>21–23</sup> This database is secondary according to our classification and contains references to PDB files ordered according to specific features. For example, it allows a rapid search for protein structures on the basis of their EC numbers, determination of all structures containing a specific ligand or a prosthetic group (e.g., heme or NAD) and retrieval of a list of biomolecules isolated from any particular organism. In addition to a large number of cross-references, this database provides a graphical presentation of the secondary structure of a protein with the indication of its conserved amino acids.

§ The term 'biopolymer (particularly, protein) structure' stands for a set of Cartesian coordinates of heavy atoms (of all atoms with the exception of hydrogen atoms) constituting the given biopolymer.

Two databases, *viz.*, CATH (<http://www.biochem.ucl.ac.uk/bsm/cath/>),<sup>24–25</sup> and SCOP (<http://scop.mrc-lmb.cam.ac.uk/scop/>),<sup>26–28</sup> comprise a hierarchical classification of protein structures. The structural domains of the proteins deposited with these databases are clustered according to the fold of the polypeptide chain. The hierarchical nature of these databases is manifested in the stepwise introduction of similarity levels of protein structures. Thus the structures in the database CATH are first combined into homologous superfamilies (Homology), the families are united into topologies (Topology), which form the topology architectures (Architecture); the latter, in turn, form classes (Class). A knowledge of the index of a structure in the database classification allows a rapid search for structural ‘neighbours’ and determination of the qualitative degree of similarity between different protein structures.

The database HSSP (Homology-derived Secondary Structures of Proteins)<sup>29</sup> available at the address <http://www.sander.ebi.ac.uk/hssp/> is a database linking structural information to sequence information. This database comprises pairwise alignment of the amino acid sequence of a protein deposited with the data bank PDB and homologous sequences with the degree of identity of 30% and higher from the data bank Swiss-Prot/TrEMBL. This information can be used for the construction of spatial structure models of proteins using homologous simulation.<sup>19</sup> The database HSSP also contains information about the conservation of the constituent amino acids in the amino acid sequences.

The aforementioned database Pfam is the only secondary database of protein sequences that deserves special consideration.<sup>17</sup> This database comprises multiple alignments of protein sequences from the database Swiss-Prot/TrEMBL, united into families according to the similarity of their amino acid sequences. The protein families deposited with the version 14.0 of this database (June 2004) cover 95% of all known protein sequences. The database Pfam is available at the address <http://www.sanger.ac.uk/Software/Pfam/>. Multiple alignments of protein sequences have made it possible to single out domains manifesting the highest degree of similarity. The amino acid sequence of a real protein may contain several domains. It is therefore important to discriminate between the structural domains of the proteins deposited with the databases CATH and SCOP and the amino acid sequence domains. The former are derived from similar folding of the peptide chains of proteins with the known spatial structures, while the latter were established by multiple alignments of an array of protein sequences. Very often, the boundaries of structural and amino acid sequence domains coincide.

Multiple alignments in the database Pfam were built by the program HMMER (<http://hmmer.wustl.edu>) based on the Hidden Markovian Model.<sup>29</sup> The alignment of sequences by the HMM method is characterised by an extremely high sensitivity in the determination of homologies between evolutionary distant proteins. This method is based on the concept according to which every position in a sequence is determined by a random Markovian process, which results in the generation of an amino acid. In this approach, conserved positions generate only one type of amino acid, while less conserved positions generate two or three such types. In mathematical terms, this fact can be described by the introduction of probabilities of generation of amino acids in all positions. Moreover, it is necessary to introduce probabilities of a transition from one position to another, gap probabilities and so on. The set of such probabilities and the HMM architecture constitute the main principle of the HMM method for the given protein family. Some efficient methods for the determination of a set of probabilities by sequential iteration have been devised. The main advantage of the HMM method over traditional alignment methods is that the penalty of the sequence gap is not an external parameter, but rather is established in a self-consistent mode in the course of HMM construction and varies on going from one position to another. The HMM method is successfully used for predicting structures and hypothetical functions of protein

sequences in the genome annotation.<sup>30</sup> In addition to HMM parameters, the database Pfam contains the multiple alignment itself and the corresponding dendrogram (a phylogenetic tree), *i.e.*, a schematic presentation of the spatial structure of the given domain (if a family comprises at least one domain with a known spatial structure) and a histogram of probabilities of amino acid generation in each position of the protein domain (the higher the column height, the higher the conservation of the given position). This information is extremely important in designing site-directed mutagenesis of enzymes, since it allows rapid localisation of the most significant amino acid residues for the tested sequence.

The list of the aforementioned databases of protein sequences and structures is far from being complete. We have mentioned and discussed only some of these databases which, in our opinion, comprise important information about amino acid sequences and spatial structures of enzymes. This information is displayed in a convenient form and is extremely useful in the different steps of an investigation.

### III. Methods for identification of groups constituting the catalytic site

Information about the involvement of one or another group in the catalytic site and in the catalytic process at large can be derived from different (often complementary) sources. An essential role in the development of concepts on the structure of active sites is played by the methods of chemical modification of amino acid residues, especially if a modifier can be incorporated into a substrate or an inhibitor to be further directed to the active site of the enzyme.<sup>4,11</sup> The use of site-directed mutagenesis with replacement of one or several amino acids in the polypeptide chain of the enzyme enables reliable identification of participants in the catalytic process. This methodological approach is very popular.<sup>31–36</sup> The design and progress in the development of methods for the studies of spatial structures of proteins has provided this branch of enzymology with abundant and highly reliable structural information.<sup>37–40</sup> At the same time, this information is insufficient for identification of groups constituting the active site. It is necessary to isolate a fragment directly involved in the catalytic process. The approaches to the solution of this task are discussed below.

Owing to the decoding of DNA sequences of individual genes and entire genomes, the number of proteins with established amino acid sequences exceeds 1 000 000. However, this diversity is rather apparent, since different organisms often contain similar (homologous) proteins derived from the same evolutionary progenitor. Their amino acid sequences are characterised by an extremely high degree of identity. In the case of enzymes, they possess similar catalytic sites, mechanisms of action, cofactors and inhibitors. Therefore, the bioinformatics methods are often employed to classify enzymes based on the analysis of their primary structures and to unite them into homologous protein families. It should be noted that methods of comparison (alignment of amino acid sequences and detection of the degree of their identity) are fairly well-developed and automated; therefore, this approach allows operation with large amounts of information in an automatic mode. The two main databases using this approach for classification of hydrolases are MEROPS<sup>41–50</sup> and CAZY.<sup>51–59</sup>

The database MEROPS<sup>41–50</sup> (<http://merops.sanger.ac.uk/>) comprises information about peptidases and their inhibitors. Two enzymes are united into a family, if the degree of identity of their amino acid sequences exceeds 30%. In turn, the families are united into clans, *viz.*, groups of families where protein homology cannot be established by analysis of their amino acid sequences, although there is some indirect evidence (*e.g.*, the fold of the polypeptide chains and the sequence order of the active site residues in amino acid sequences), which suggests a relationship between these proteins. The clans are united into classes according to the type of their catalytic mechanisms. For example, serine, thiol, aspartyl

and metal-dependent proteases are known; the serine proteases are divided into 10 clans which in turn are divided into 25 families that comprise altogether 6886 proteins.

The database CAZY<sup>51–59</sup> (<http://afmb.cnrs-mrs.fr/CAZY/>) contains information about glycosidases, glycosyl transferases and other enzymes catalysing the formation and cleavage of the glycosidic bond. Based on the results of analysis of identity of their amino acid sequences, all glycosidases are divided into 14 clans which unite 96 families.

An analysis of identities of amino acid sequences was also employed in the construction of the database Catalytic Site Atlas<sup>60,61</sup> (<http://www.ebi.ac.uk/thornton-srv/databases/CSA/>), although inclusion of enzymes into homologous protein families was not their main goal. The base designers have chosen about 300 most well-studied enzymes with established three-dimensional structures. The data on the amino acid residues constituting the active sites and a list of proteins with amino acid sequences with high degree of identity are given separately for each enzyme.<sup>¶</sup>

The bioinformatics methods of analysis of amino acid sequences and determination of protein functions considered above have become very popular owing to abundant original structures obtained by translation of their nucleotide sequences. However, the functional potentials of proteins are determined primarily by their three-dimensional (rather than primary) structures. Although high degree of identity of amino acid sequences underlies the similarity of spatial structures of active sites of enzymes, in the general case the converse is wrong. Thus the catalytic triad Ser-His-Asp is characteristic of both trypsin and subtilisin. These proteins possess non-homologous amino acid sequences, they differ in the order of amino acid residues within the active site and the fold of the protein globule. Mammalian trypsin and bacterial subtilisin provide examples of convergent evolution of enzymes where enzymes derived from different proteins acquire similar (in all probability, optimum) structures of catalytic sites in the course of evolution. However, a comparison of primary amino acid sequences of such proteins does not allow one to establish a similarity of their catalytic sites.

The methods for analysis of three-dimensional (3D) structures of proteins allow one to cope, in principle, with evolutionally non-related proteins; however, they are much less developed than the methods for the analysis of amino acid sequences and are still at the stage of development rather than at the wide-scale application stage. First, this is due to the complexity of the systems under study and, second, to the lower level of the original data (since proteins with established three-dimensional structures are far less numerous than proteins with established primary structures). It can be assumed that in future the methods of analysis of three-dimensional structures of proteins will play a more significant role, since the number of structures in the database PDB is steadily increasing and so is the accuracy of prediction of the 3D-structures of proteins based on their amino acid sequences. Some methods aimed at a search for functional sites on the basis of structural data have been reviewed.<sup>63</sup>

A convenient method for classification of active sites of enzymes and substrate-binding sites (ligands or cofactors) according to the three-dimensional structure of proteins has been developed.<sup>64</sup> Considering that the active sites of 70% of enzymes are localised in the largest cavity of the protein globule,<sup>65</sup> one can restrict oneself to the analysis of the amino acid sequences of the protein that form the cavity surface. Such residues can be found automatically. The search can culminate in the physicochemical 'image' of the cavity, *viz.*, spatial arrangement of charges, the groups serving as potential donors or acceptors of the hydrogen bond as well as hydrophobic and hydrophilic sites on the protein surface. The presentation of the cavity as a graph with the atoms as vertices and the distances between them as edges allows a

comparison of two proteins irrespective of their amino acid sequences as well as a search for the greatest common elements using an algorithm for the search of the largest common subgraph. This approach was used for identification of substrate-binding sites in subtilisin, trypsin and chorismate isomerase isolated from different sources with the degree of identity of the amino acid residues of < 20%, as well as NADH-binding sites in several non-related oxidoreductases.

Although this method is applicable to the study of substrate-binding sites, it does not seem to be suitable for the search for the catalytic sites themselves. For instance, it is only the serine residue in serine hydrolases with the catalytic triad Ser-His-Asp that is localised on the surface of the protein globule, while histidine and aspartic acid residues are embedded inside the protein.

The so-called method of geometrical invariants was suggested for classification of proteins according to the presence of clusters built of several amino acid residues with similar spatial distributions.<sup>66</sup> All possible combinations of several amino acid residues are sorted out for each protein; the geometrical invariants, *i.e.*, the parameters dependent on the coordinates of the appropriate atoms, but independent of translations and frame rotations are calculated. These include the distance between two atoms, the volume of a tetrahedron formed by four atoms, *etc.* For each group of residues, there is a single point in the *n*-meric space (*n* is the selected number of invariants) and a set of such points for each protein. By applying this procedure to all proteins, one can obtain several domains in the *n*-meric space where the points corresponding to different proteins are concentrated. All these proteins are characterised by a similar arrangement of amino acid residues within the protein structure. This method has made it possible to determine the active site residues for many enzymes including cysteine proteases, xylanases and  $\beta$ -lactamases. The advantage of this method is that it permits an automated search for common structural elements for different proteins and does not require preliminary elucidation of common elements of the tested proteins. Besides, it enables the detection of common elements even in the sites where their occurrence was thought to be hardly probable.

In yet another approach, which is based on expert knowledge and analysis of the published data, a desired spatial arrangement of amino acid residues or individual atoms,<sup>†</sup> which corresponds, *e.g.*, to the active site of the enzyme, is preset, and the search routine finds the corresponding proteins in the structure database.

The graph-theoretic approach based on the use of templates for the classification of proteins has been suggested.<sup>67,68</sup> Each amino acid residue is represented by a vector between two atoms depending on the type of the amino acid residue. The reciprocal spatial arrangement of two vectors is determined by the distances between their initial, final and central points. A template represents an array of the vectors and a matrix of triples of distances between them plotted as a graph; each graph vertex corresponds to an amino acid residue and each edge is a set of distances between the vectors of the residues. One graph isomorphism search algorithm is used as a template in a search for protein structure coincidence. This method has been realised in the program ASSAM, which was successfully used for a correct search of the catalytic triad Ser-His-Asp, the zinc-binding site of thermolysin (and related enzymes) and a great number of other functional sites of proteins.

The transition from the presentation of an amino acid residue as a vector (which imparts an additional degree of axial symmetry to the amino acid residue) is an obvious route to further perfection of the method. This approach was realised in the programs TESS and JESS.<sup>69–71</sup> The coordinates of the atoms from the primary database PDB of amino acid residues with established functional

¶ The search for the appropriate proteins was carried out using the BLAST method (Basic Local Alignment Search Tool).<sup>62</sup>

† The set of limitations for the types of amino acid residues or atoms and their reciprocal spatial distributions is usually referred to as a template, although the terminology used by different authors may differ.

significance were used as templates. This approach resulted in the construction of the database PROCAT<sup>70</sup> (<http://www.biochem.ucl.ac.uk/bism/PROCAT/>), which comprises the data on the active sites in protein structures.

The aforementioned methods make use of the data only on three-dimensional structures of proteins. They seemed opposed to the methods based only on the primary structures data. In actual research practice, both approaches are used to determine the functional significance of amino acid residues.

The Evolutionary Trace method<sup>72</sup> consists of the search (usually automated, employing the BLAST method) of a set of homologous proteins, their alignment and construction of a dendrogram (a tree) from the alignment data obtained. Each terminal node in the tree corresponds to a real protein and each intermediate node corresponds to a certain hypothetical protein called 'evolutionary precursor'. In the sequence of the latter, only that part of the amino acid sequence is known which is common for all the proteins of the daughter nodes. Therefore, the amino acid residues of the starting protein can be ranged from the most conserved, identical in all homologous proteins of the set, to the most variable ones, which are different in the original protein and its closest relative. The depth of the node in the dendrogram where the divergence took place is a quantitative measure of amino acid residue conservation. Having removed the residues below a certain degree of conservation, one can isolate clusters of residues which, according to the structural data, are in contact with one another. A correlation exists between the conserved clusters and the functional sites of the protein. The method allows correct determination of 70%–90% of the functional sites.

#### IV. Catalytically important groups and structure-forming amino acids in the active sites of enzymes

The answer to the question: which amino acids constitute active sites in enzymes the most often, was obtained by a comparison of amino acid sequences of proteins united in one large family.<sup>11, 73, 74</sup> The results of the alignment of sequences of large families of enzymes deposited with the database HSSP (<http://www.sander.embl-heidelberg.de/hssp/>) have been analysed.

The alignment is usually presented in the form of tables obtained by superposition of a protein sequence and a basic sequence. Visual detection of the conserved elements of a sequence is possible. Apparently, this method provides insufficient information where more than three to five proteins are to be compared. This can be automated to quantitate the conservation of amino acid positions in a sequence. The statistic criterion in the form of the Shannon entropy can serve as a quantitative measure of the conservation of each amino acid in the amino acid sequence of the protein.<sup>75–77</sup> It is noteworthy that the Shannon entropy is one of the most important functions in the theory of information. This was introduced as a measure of the degree of uncertainty which describes events characterised by a definite probability. In this case, the information can be defined as a measure of the level of uncertainty, which is corrected after the acquisition of information. Formally, the amount of information is presented as a difference between the information entropies before the experiment and upon its completion, *i.e.*, receipt of a message. The information entropy (the Shannon entropy) is the most convenient function for a comparison of related proteins differing in amino acid sequences. The alignment of sequences relative to a reference protein implies arrangement of their amino acid sequences one above the other with fixation of homologous sites, detection and elimination of the inserts. A comparison of a large panel of proteins allows calculation, with a sufficiently high degree of accuracy, of the probability of localisation of amino acids in each position of the protein sequence. This probability is defined as a relative frequency of the appearance of an amino acid of the type *i* in position *j*. The entropy function can be calculated for each position of all the 20 amino acids of the protein sequence.<sup>75</sup>

$$H_j = - \sum_i p_i^j \log_2 p_i^j$$

An important feature of this function is that it is close to zero for both the events occurring with high ( $p_i^j \rightarrow 1$ ) and low ( $p_i^j \rightarrow 0$ ) probabilities. Calculation of the Shannon entropy for a protein sequence may result in the detection of common (*i.e.*, absolutely conserved) sites for the whole large family of proteins. This is a position where the probability of appearance of the given amino acid is close to unity, whereas that in the remaining positions is close to zero. High values of the Shannon entropy are characteristic of amino acids with variable positions in the amino acid sequences, being low for amino acids with conserved positions in the amino acid sequence. At the limit, for  $p_i^j \rightarrow 1$  (absolute conservation),  $H_j \rightarrow 0$  (Fig. 1).

**Figure 1.** A presentation of alignment of the caspase family (PDB code 1cp3) in the form of the Shannon entropies. The amino acid residues of the active site are encircled.

The Shannon entropy criterion was used in the analysis of protein superfamilies with such basic proteins as trypsin/chymotrypsin, subtilisin, lipase, cytochrome C oxidase, pepsin/pepsinogen, enolase, lactate dehydrogenase, DNase, aminoacyl-tRNA synthase and lysozyme.<sup>73, 74</sup> This sample of enzyme families comprises 2281 proteins with the overall length of 249 252 amino acid residues.

This analysis revealed the following regularities.

1. Upon alignment of amino acid sequences in enzymes, the amino acids that form the catalytic site are always detected as conserved elements.

2. A comparison of amino acid sequences shows that glycine and aspartic acid are most commonly detected as absolutely conserved elements.

From our point of view, consideration of the results of the analysis of the most conserved amino acids with  $H_j = 0$  (or close to zero) is of interest. A somewhat unexpected finding was that glycine appeared to be the most common conserved amino acid. The second position was occupied by aspartic acid; in total, glycine and aspartic acid constitute approximately one third of the conserved amino acids altogether.

The rating of amino acids according to their conservation in the protein families studied has been carried out. To this end, the frequency of occurrence of each amino acid as a conserved element ( $H_j \approx 0$ ) was determined relative to the total number of conserved positions for all amino acids in the families. The conservation ratings of amino acids for two enzyme classes, *viz.*, hydrolases and oxidoreductases, are presented in Fig. 2. Despite the differences in the reactions catalysed by these enzymes, the mode of distribution of conserved amino acids virtually coincide.

It can be seen that glycine, aspartic acid, cysteine, proline, arginine and histidine in the amino acid sequences of enzymes usually manifest themselves as conserved amino acids and con-

Distribution of conserved amino acids (%)

**Figure 2.** The rating of conservation of amino acids.

stitute ~ 60% of all conserved positions. Methionine and isoleucine are never conserved.

It seems logical to divide all conserved amino acids into two groups, different in principle, namely, amino acids involved in the elementary acts of activation of substrates as acids and bases (aspartic acid, histidine, arginine) and amino acids responsible for the architectonics of the active site (glycine, cysteine, proline).

A physicochemical interpretation of the role of acids, bases and structure-forming amino acids (glycine, proline, cysteine) in enzymatic catalysis will be given below in the example of hydrolases.

## V. Classification of hydrolases according to the types of catalytic sites and catalytic mechanisms

In discussing the structures of active sites of enzymes, it is necessary to discriminate between two structural components of the active site, *viz.*, a sorption subsite responsible for the binding, fixation and orientation of substrates (its properties determine the specificity of the enzyme),<sup>1–3</sup> and a catalytic subsite responsible for general acid-base catalysed chemical transformations of substrates.<sup>4–6</sup>

The structures and functions of hydrolases are extremely diverse. In addition to traditional involvement in the cleavage of biopolymers (proteins, nucleic acids, polysaccharides) into constituent monomers, hydrolases play a central role in some vital processes, such as regulation of fibrinolysis and thrombolysis,<sup>78–80</sup> apoptosis,<sup>81–83</sup> signal transmission in protein phosphorylation–dephosphorylation systems,<sup>84–88</sup> restriction and modification of DNA,<sup>89,90</sup> resistance against antibiotics,<sup>91,92</sup> regulation of the level of proteins,<sup>93–95</sup> nerve pulse transmission,<sup>96</sup> carcinogenesis,<sup>97</sup> *etc.* Within the framework of a traditional enzyme classification approved by the International Union of Biochemistry and Molecular Biology, hydrolases are classified according to the type of the reaction catalysed by them (hydrolysis) and enzyme specificity (the substrate structure). At present, the imperfection of this nomenclature is becoming more and more evident. On the one hand, the majority of enzymes do not possess absolute specificity and, which is even more important, manifest different types of activity. On the other hand, many enzymes with the same specificity and utilising the same substrate differ essentially in their primary structures, compositions of the active sites and fold of the polypeptide chain.

The analysis of the published data devoted to the mechanisms of action of different hydrolases suggests that despite the great diversity of enzymes, the number of catalytic sites that are different in principle is rather small.<sup>73, 74, 98</sup>

Hydrolases differ in the nature of the catalytic groups activating the water molecule in the course of the catalytic cycle. In principle, this information is imprinted in the spatial structure of a protein. The difficulty consists of an unambiguous identification of the catalytic group and the water molecule underwent activa-

tion. An active site may contain several water molecules among which only one is activated in the catalysis.

A comparative analysis of the compositions of active sites of hydrolases and mechanisms of activation of water revealed four main types of catalytic sites that are directly involved in the activation of water, *viz.*:

(1) hydrolases containing aspartic or glutamic acid in their active sites (pepsin and retroviral pepsins, glycosidases, dehalogenases and epoxide hydrolases);

(2) hydrolases containing histidine in their active sites (ribonucleases including pancreatic ribonuclease and barnase, acid phosphatases, hydrolases containing the Ser-His-Asp triad and its isomorphic substitutions, thiol hydrolases);

(3) zinc-dependent hydrolases containing one (carboxypeptidase A) or two (alkaline phosphatase, organophosphate hydrolase) zinc ion(s) used for the activation of water and the substrate;

(4) magnesium-dependent hydrolases (enzymes of the inorganic pyrophosphatase type, aryl sulfatase).

Taking into account the great abundance and significance of hydrolases containing serine, cysteine or threonine residues and a proton-transfer chain responsible for the activation of a hydroxy or a thiol group, it seemed expedient to group them in an individual subtype [the nucleophile–imidazole–aspartic (glutamic) acid subtype]. These enzymes form stable intermediates identified as acyl-enzymes in the course of catalysis.

The analysis of mechanisms of catalytic reactions shows that aspartic acid and histidine, in principle, play a crucial role in the majority of catalytic sites. The mechanisms of hydrolase catalysis can be illustrated by schemes that, though being rather approximate and not reflecting all the details of the reaction mechanisms, include their main stages, *viz.*, activation of water and substrate hydrolysis.

### 1. Hydrolases containing aspartic or glutamic acid in their active sites

Hydrolases containing aspartic or glutamic acid in their active sites cleave ester, amide and glycosidic bonds. The catalytic sites of these enzymes contain two or more carboxy groups.<sup>4,6</sup> The non-dissociated carboxy group acts as an electrophile and takes part in the activation of the substrate as a generalised acid, while the deprotonated group acts as a nucleophile in the activation of the water molecule.<sup>4,5</sup> Enzymes of this group usually manifest maximum activity at relatively low values of pH. Pepsin (protease) and lysozyme (glycosidase) are typical representatives of this group.<sup>99,100</sup> The essential role of the carboxy groups of Asp-32 and Asp-215 in pepsin consists of formation of a hydrogen bond with each other and with the water molecule attacking the substrate (the spatial arrangement of the Asp-32 and Asp-215 residues is shown in Fig. 3). At optimum pH values, the carboxy group of Asp-32 becomes ionised, whereas the carboxy group of Asp-215 exists in the non-dissociated form. The processes occurring in the active site are shown in Scheme 1.<sup>99–103</sup>

**Figure 3.** The active site of pepsin (PDB code 1flh). The residues of the active site are highlighted.

Human immunodeficiency virus protease (retroviral pepsin) has the same mechanism of action, but its two aspartic acid residues (Asp-25) are localised in two identical subunits. It is assumed that animal pepsin was formed from a protein precursor similar to retroviral pepsin by duplication and concatenation of the corresponding genes. In the course of evolution, the local environments of two aspartic acid residues of pepsin changed, which resulted in the enhancement of its catalytic properties.<sup>104</sup>

The active sites of glycosidases also contain two aspartic (or glutamic) acid residues localised on opposite sides of the bond to be hydrolysed. One of these carboxy groups, *viz.*, the non-ionised group, activates the substrate by a proton-transfer mechanism thus decreasing the electron density on the carbon atom of the bond to be hydrolysed. The second carboxy group activates the water molecule (the mechanism with inversion of configuration of the carbon atom) or attacks the substrate directly resulting in the formation of an intermediate which is further decomposed by the water molecule (the mechanism with retention of configuration).<sup>105, 106</sup> This mechanism operates in the case of lysozyme<sup>107–109</sup> and chitinases.<sup>110, 111</sup>

The three-dimensional structures of dehalogenases were established relatively recently.<sup>112, 113</sup> The interest in this group of enzymes is explained by the possibility of using them for the decomposition of halogen-containing organic environmental pollutants. The active sites of dehalogenases also contain two carboxy groups. One of them (a nucleophile) attacks the substrate with the elimination of the halide ion to give a covalent intermediate. The second carboxy group activates the water molecule involved in the dealkylation of the enzyme.

## 2. Hydrolases containing histidine residues in their active sites

Histidine residues of hydrolases are either involved in the activation of water or react with substrates directly.

According to classical concepts, the mechanism of catalytic cleavage of phosphodiester bonds in ribonucleic acids by pancreatic ribonuclease A (see Ref. 114) is provided by a concerted action of the imidazole groups of two histidine residues (Fig. 4). The imidazole group of His-12 activates the 2-hydroxy group of ribose by a proton transfer in the step involving the formation of a 2,3-cyclophosphate intermediate, whereas the imidazole group of His-119 activates the water molecule that hydrolyses the cyclophosphate.

The active site of barnase contains a glutamic acid residue (Glu-73) instead of His-12. A detailed mechanism of catalysis of barnase has been described.<sup>115, 116</sup>

In acid phosphatases,<sup>117</sup> histidine plays the role of a nucleophile that attacks the phosphorylated substrate. This results in the

Figure 4. The active site of pancreatic ribonuclease (PDB code 1a5q).

formation of phosphohistidine and the liberation of the non-substituted substrate (in the next step, the phosphoenzyme is hydrolysed with water).

It is of note that there is no hydrolase known at present for which the catalytic mechanism includes the formation of substituted histidine with the nitrogen of histidine and the carbon atom of the substrate. Apparently, this can be attributed to the fact that such a bond is relatively stable, so its cleavage would be a limiting step in the catalytic cycle.

## 3. Hydrolases containing a nucleophilic serine, cysteine or threonine residue

Serine proteases (chymotrypsin and trypsin) and cysteine protease (papain) are typical representatives of this group of enzymes. Their catalytic mechanisms include acylation of the hydroxy or thiol group of the enzyme with the formation of an intermediate (acylenzyme) and its subsequent hydrolysis.<sup>4, 118, 119</sup> As the hydroxy group is a weak nucleophile, all the enzymes of this type contain amino acid residues essential for its activation and deprotonation (the proton-transfer chain). The same residues activate the water molecule in the enzyme deacylation step.

Hydrolases containing the catalytic triad Ser-His-Asp seem to be especially well studied. They include proteases (trypsin, chymotrypsin, elastase, subtilisin, carboxypeptidase Y and many others),<sup>4, 120–123</sup> lipase,<sup>124</sup> and acetylcholinesterase<sup>125</sup> (the latter contains a glutamic acid residue instead of aspartic acid). The active site of chymotrypsin contains Ser-195, His-57 and Asp-102 residues (Fig. 5). The catalytic mechanism of chymotrypsin is presented in Scheme 2.

Numerous isomorphous substitutions of the amino acids of the triad are known; this problem has been discussed in detail.<sup>126</sup> Thus thiol hydrolases contain a cysteine residue instead of serine. Since the thiol group is a stronger nucleophile than the hydroxy group, a shorter (in comparison with serine hydrolases) proton-transfer chain can be used. For example, many thiol proteases homologous

Figure 5. The active site of trypsin (PDB code 1fmg).

Scheme 2

**Figure 6.** The active site of organophosphate hydrolase (PDB code 1dpm).

to trypsin proteases contain asparagine able to form a hydrogen bond with histidine instead of aspartic acid, which polarises the imidazole ring of histidine. Some enzymes which do not involve histidine for the activation of the thiol group are known.<sup>127</sup>

Enzymes in which the amino group acts as a proton acceptor<sup>128</sup> in the activation of the hydroxy group constitute a separate group of enzymes. An example is a non-charged amino group in the side chain of lysine ( $\beta$ -lactamase<sup>129</sup> and asparaginase<sup>130</sup>). Serine, threonine or cysteine are N-terminal amino acids in N-terminal hydrolases, which include proteasome<sup>131</sup> and penicillinase components;<sup>132</sup> the free amino group in the main protein chain activates the hydroxy or the thiol group of the same amino acid.

#### 4. Zinc(nickel, cobalt)-dependent hydrolases

This type of hydrolase contains one or several zinc ions (which can be replaced by cobalt or nickel without any loss of activity). Metal ions localised in the active sites of enzymes fulfil two main functions,<sup>4, 133, 134</sup> viz., that of an electrophilic agent activating the reaction centre of the substrate that is being attacked, and that of an electrophilic activator of water as a source of hydroxyl ions.

Enzymes of the carboxypeptidase A type, thermolysin or botulinic toxin,<sup>135</sup> each contains one zinc ion in their active sites; the role of ligands is played by aspartic or glutamic acid, histidine or cysteine residues. The metal ion complexes in the active sites of these enzymes act as electrophilic reagents which activate the reaction centres of the substrates. The activation of the attacking water molecule is induced by the deprotonated carboxy group of glutamic acid that is not involved in the coordination sphere of the zinc ion.

Enzymes of the type of alkaline phosphatase,<sup>136–138</sup> urease,<sup>139</sup> metal-dependent  $\beta$ -lactamase<sup>92</sup> or organophosphate hydrolase<sup>140, 141</sup> contain two zinc ions in their active sites; these ions form structurally similar complexes with the protein (Fig. 6). Aspartic and glutamic acid residues as well as histidine (or cysteine) and N-carboxyllysine residues act as metal-ion ligands. As a rule, one of the zinc ions activates the substrate by reducing electron density on the atoms being attacked, whereas the second zinc ion activates the water molecule or, in the case of alkaline phosphatase, the hydroxy group of serine. For organophosphate hydrolase,<sup>140–144</sup> the enzyme catalysing hydrolysis of organo-

phosphorous pesticides and war gases such as Sarin, Soman or Vx, the catalytic mechanism<sup>145</sup> can be described by Scheme 3.

Scheme 3

#### 5. Magnesium(manganese)-dependent hydrolases

This type of hydrolase contains magnesium or doubly charged manganese ions in the catalytic site.<sup>146, 147</sup> As in the case of zinc-dependent enzymes, the metal complexes in the active sites of hydrolases behave as strong electrophilic reagents which activate the substrates (or the water molecule) by reducing electron density on the reaction centre. Such behaviour of metal ions became especially apparent in the analysis of the structure and catalytic mechanism of inorganic pyrophosphatase.<sup>148–153</sup> The substrate is fixed in the active site of the enzyme due to ionic interactions with

**Figure 7.** The active site of inorganic pyrophosphatase (PDB code 1ipw).

positively charged groups of the protein, Lys-103, Arg-78 or Lys-56. The main catalytic events involve two metal ions ( $Mg^{2+}$  or  $Mn^{2+}$ ).<sup>154</sup> The carboxy groups of the residues Asp-65, Asp-70 and Asp-102 and three water molecules play the role of ligands for the ions in the high-affinity site where the formation of the  $Mg^{2+}$  (or  $Mn^{2+}$ ) complex takes place. The low-affinity site is formed by the metal ion, water molecules and the carboxy group of the Glu-20 residue (Fig. 7). It can be assumed that the high-affinity site functions as the electrophilic activator of water (a generator of hydroxyl ions), while the low-affinity site plays the role of an electrophilic activator of the substrate.

These examples illustrate the role of aspartic acid and histidine in the mechanism of action of enzymes. Obviously, concerted action of nucleophilic and electrophilic components of the active site is the major principle in the functioning of active sites of enzymes.

It seems interesting to follow the transition from enzymes that catalyse hydrolysis of particular bonds to enzymes that catalyse the formation of these bonds. It is known that the active sites of exonucleases, which catalyse hydrolysis of DNA,<sup>155–159</sup> represent complexes of magnesium ions with the carboxy groups of aspartic and glutamic acids and resemble the active site of pyrophosphatase. The active site of DNA polymerase, which catalyses synthesis of DNA, is largely homologous to the active site of this nucle-

ase.<sup>155–159</sup> The same functional groups of DNA polymerase activate the reaction centre and the nucleophile; however, the hydroxy group of the sugar (but not water) becomes activated owing to the abstraction of a proton. The nucleophilic attack on the reaction centre of the phosphate group ensures the growth of the DNA chain.

It should be noted that the structural elements constituting the active sites of hydrolases were also detected in the active sites of other classes of enzymes. Thus the proton-transfer chain, which includes the pair 'imidazole–carboxy group of aspartic acid' is often identified in the active sites of oxidoreductases. In peroxidases and in the protein environment of heme, the pair 'imidazole–carboxy group' plays the role of a generalised nucleophilic reagent which activates the iron ion of heme.<sup>160–162</sup> The same structural element of the proton-transfer system, *viz.*, the imidazole complex with the carboxy group, is identified in the active sites of dehydrogenases.<sup>163–165</sup>

## VI. Glycosyl hydrolases, cellulases

The diversity of structures and fold of the polypeptide chain with simultaneous preservation of the main mechanism of water activation and the structure of the catalytic site can be illustrated in the examples of 1,4- $\beta$ -glycosyl hydrolases and cellulases. Two carboxy groups of these enzymes, which induce concerted cleavage of 1,4- $\beta$ -glycosidic bonds, are involved in the catalytic process.<sup>106, 166</sup> Xylanases, chitinases and lysozyme act in a similar way.<sup>107–111</sup> Cellulases are multidomain proteins, which contain one catalytic and one cellulose-binding domain. These enzymes are represented by a vast array of structures.<sup>167</sup> According to the fold of their polypeptide chains, they are classified into 15 clans, each containing > 90 structural families.<sup>167–173</sup> It is interesting to note that in contrast to 1,4- $\beta$ -glycosidases,  $\alpha$ -glycosidases are represented by only three families.<sup>167, 174</sup> The immense diversity of structural elements of catalytic domains of glycosyl hydrolases, of cellulases, in particular, is determined by the peculiarities of their primary sequences and the folding of their polypeptide chains. The database CAZY offers the most complete structural classification of glycosyl hydrolases. However, the structures of the catalytic sites of the whole array of proteins differing in their primary sequences and secondary structures are rather monotonous. The activation of the water molecule and the hydrolytic catalytic cycle are supported by the concerted action of two carboxy groups.

Enzymes containing two carboxy groups in their active sites, which represent concertedly acting electrophilic and nucleophilic agents, are especially widely occurring in nature. The results of alignment and calculation of the Shannon entropy for pepsin are shown in Fig. 8. As can be seen, Asp-32 and Asp-215 represent

**Figure 8.** A presentation of alignment of the pepsin family (HSSP code 1ps0) in the form of the Shannon entropy. The amino acid residues in the active site are encircled.

conserved amino acids. The activities of other proteases as well as peptidases, lysozymes, chitinases and many other hydrolases (the set of structures is virtually unlimited) are also mediated by the two carboxy groups. All these proteins are built in such a way as to favour the spatial approach and concerted action of two carboxy groups of the catalytic site. These data clearly demonstrate the structural paradox of enzymatic catalysis, namely: the immense diversity of protein structures provides the formation and assembly of a limited number of unique catalytic sites.<sup>91, 175, 176</sup>

## VII. Serine hydrolases. Automatic search for a catalytic triad

We have carried out an automatic search for definite structures in the catalytic site of hydrolases based on an analysis of primary sequences within the framework of 'alignment' studies and calculations of the Shannon entropies using a template of three-dimensional structures of catalytically important residues. In the four classical types of active site structures of hydrolases, identification of catalytic groups of Zn(Co)- and Mg(Mn)-dependent enzymes is the least difficult. The localisation of the metal ion and its environment allows identification, with a high degree of reliability, of the components of the catalytic process. The identification of catalytic sites of hydrolases containing carboxy groups in the active sites was especially difficult because of the limited number of enzymes containing such catalytic sites and the lack of additional criteria characteristic of active sites and differentiating it from other potential structures, the use of an automatic procedure has led to the detection of a large number of false examples. Probably, this task would be solved more successfully in future upon introduction of additional structural limitations. The most adequate results were obtained in the analysis of protein structures containing the catalytic triad serine–histidine–carboxy group.

Serine hydrolases containing the catalytic triad Ser-His-Asp constitute the most well-studied representative group of hydrolases. This type of a catalytic site was first discovered in bovine pancreatic  $\alpha$ -chymotrypsin (for a review see Ref. 177). Later, an identical catalytic site was found in bacterial subtilisin which is not homologous to chymotrypsin. The same triad was also found in lipases, while a similar triad (Ser-His-Glu) was detected in acetylcholinesterases. In more recent studies, new families of hydrolases (brain cortex esterases, virus envelope proteins, *etc.*) non-homologous to the known enzymes and containing the same residues in the catalytic site with the same spatial arrangement were established.<sup>126</sup> Various physiologically active substances, *e.g.*, cocaine<sup>178</sup> or the platelet activation factor,<sup>179</sup> can serve as the substrates.

Serine hydrolases form covalent intermediates with these substrates; in their active sites, the hydroxy group of the serine residue is acylated by the acidic fragment of the substrate (the acyl-enzyme-type intermediate). In the active sites of all enzymes of this type, the spatial localisation of the triad Ser-His-Asp is similar despite the difference in the fold of the polypeptide chain.

The catalytically important groups were identified using the method previously developed for estimating the conservation of residues deposited with the database HSSP, which is based on pairwise alignment and the Shannon entropies and employs the data on the coordinates of individual atoms used for data retrieval in the structural bases of these proteins.

The data on the arrangement of residues in chymotrypsin and subtilisin (for typical arrangement of the residues see Fig. 9) were used for designing a template for the catalytic triad (the constraints on type of the appropriate amino acid residues are listed in Table 1); this was followed by a search on the set of non-homologous hydrolases from the data bank PDB. Over 100 structures with a required arrangement of catalytically important functional groups containing unique primary sequences were found.

**Figure 9.** A typical distribution of catalytic triad residues. The names of amino acid residues are capitalised; the names of individual atoms are given in lower case letters. The dotted lines indicate the distances between the atoms on which certain restrictions were imposed in the search (for explanations see text).

**Table 1.** The criteria of a search for the triads Ser-His-Asp through the protein structures.

<sup>a</sup> The designations of the atoms and amino acid residues coincide with those used in Fig. 9. <sup>b</sup> The names of the atoms correspond to the nomenclature of the Protein Data Bank.

The next step included the use of the database SCOP, where the proteins are systematised according to the fold of the polypeptide chain (see above). The data on the folding of the catalytic domain for each protein were retrieved from the database SCOP. The two upper levels of the hierarchy obtained are shown in Fig. 10. The most characteristic enzymes of each group are listed in Table 2. It was found that all serine hydrolases containing the triad Ser-His-Asp(Glu) are made up exclusively of  $\beta$ -sheets (*e.g.*, chymotrypsin), or irregularly alternating  $\alpha$ -helices and  $\beta$ -sheets (*e.g.*, subtilisin). None of the hydrolases of this type, known so far, are built up exclusively of  $\alpha$ -helices. Considering that primary sequences differ in the types of spatial folding of the peptide chain, all hydrolases can be divided into families according to this particular criterion. By choosing different levels of folding, hydrolases can be divided into families with different levels of similarity. From Fig. 10 it follows that all Ser-His-Asp-containing hydrolases form two clans; it is noteworthy that the clan of proteins built up of  $\beta$ -sheets comprises only one family, while the clan of  $\alpha$ ,  $\beta$ -proteins includes five different families. These families differ not only in the type of chain folding, but also in the order of

**Figure 10.** The classification of protein structures deposited with the database SCOP.

<sup>a</sup> The order of the distribution of the catalytic site residues in the primary protein sequence.

distribution of active site residues in the primary sequence (see Table 2).

It is of note that these results were obtained as a result of an automatic search for proteins in the structural database PDB and were confirmed by independent literature data. Thus, the approach based on the use of automatic bioinformatics methods and databases in the information selection step permits the processing of the tremendous bulk of accessible information.

### VIII. Mechanism of activation of substrates by active sites of hydrolases

Acids and bases of the active sites play a crucial role in enzymatic catalysis by activating the substrates. Aspartic acid and histidine are most often involved in the activation of molecules in the enzymatic catalytic cycles in comparison with other amino acids. Presumably, the catalytic function of aspartic acid and histidine in

the active sites of enzymes is determined by their properties as an acid and a base.<sup>4, 5, 11</sup>

In the non-dissociated form, the carboxy group of aspartic acid represents a proton donor, which manifests pronounced electrophilic properties, whereas in the deprotonated form it plays the role of a proton acceptor (a nucleophilic agent), *viz.*, an electron density donor for the corresponding reaction centre. The imidazole group of histidine is a pronounced nucleophilic reagent able to donate unshared electron pairs of nitrogen atoms.

Several schemes of substrate activation by histidine and aspartic acid residues represent the main reactions occurring in the catalytic site.

1. Nucleophilic activation of the substrate by the imidazole group.

In this case, a negative charge is generated in the reaction centre.

2. Nucleophilic activation of the substrate by the carboxy group of aspartic acid.

3. Electrophilic activation of water. Metal ions ( $\text{Zn}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Mn}^{2+}$ ) present in the active sites of enzymes as complexes with the carboxy groups of aspartic or glutamic acid can take part in the catalytic cycle as both acids and bases. Metal ions can replace the proton in the molecule of water thus inducing a highly reactive and mobile hydroxyl ion.

4. Electrophilic activation of the reaction centre. The electrophilic activation of the reaction centre of the substrate (*e.g.*, the carbonyl group) can be induced by both the carboxy group and the metal ion.

These reactions reduce the electron density on the reaction centre.

For hydrolytic reactions, the water activation steps in the nucleophilic catalysis can be presented as follows:

The reactivity of the water molecule increases  $10^7$ -fold upon its conversion into hydroxyl ions.<sup>5</sup> Assuming that the electrophilic activation of the reaction centre, which proceeds according to the mechanisms (4) and (5), increases its reactivity  $10^6$ – $10^7$ -fold, the high efficiency of the enzymatic catalysis and its ability to increase the reaction rate  $10^{13}$ – $10^{14}$ -fold can be explained in the first approximation. The hypothesis that acids and bases act concertedly in the catalysis was put forward on the basis of an analysis of some independent studies.<sup>5, 180, 181</sup>

The degree of charge transfer in various activation processes occurring in accordance with Schemes (1)–(6) in the transition states of enzymatic reactions is still questionable.<sup>182</sup> It is obvious, however, that the activation of well-oriented fixed (relative to one another) molecules takes place in the reaction centres. Of crucial importance is the fact that acids and bases within the catalytic site form a system of hydrogen bonds with one another, which opens up unique opportunities for the proton transfer. In systems containing hydrogen bonds, acids and bases react much faster than in solution. The interactions of hydroxyl ions with protons in a system of water molecules structured by hydrogen bonds in ice crystals (studied by Eigen<sup>183</sup>) provides an illustrative example. It was found that the reaction rates of the hydroxyl ion with hydrogen ion exceed those of diffusion-controlled processes by 3–4 orders of magnitude. As a matter of fact, the proton transfer and charge neutralisation are complete within a single vibration with a frequency of  $10^{14} \text{ s}^{-1}$ . The precise orientation of reactants and catalytic site components is a salient feature of enzymatic catalysis.<sup>184</sup>

Identification of acids and bases (electrophilic and nucleophilic reagents) within the catalytic site is the primary goal in the elucidation the mechanisms involved in the functioning of catalytic sites of enzymes. The activation mechanisms presented in Schemes (1)–(6) provide an explanation for the high efficiencies of the majority of presently known enzymatic reactions. We described an algorithm for identification of the active groups of the catalytic site. The knowledge of amino acid sequences of the protein allows determination of a group of proteins (enzymes) homologous to the given protein using bioinformatics methods. The alignment procedure and calculation of the Shannon entropies permits one to determine the positions of conserved amino acids. The latter represent, with a high degree of probability, catalytically important residues, which ensure substrate activation and, correspondingly, determine the mechanism of catalytic action.

## IX. Glycine, cysteine and proline as structure-forming amino acids

A comparison of amino acid sequences in homologous families showed that conserved glycine, cysteine and proline residues are essential elements in the active sites of enzymes. The role of glycine in the formation and functioning of active sites is not so apparent as the role of aspartic acid. Evidently, conserved glycine residues do not play any pronounced role in the activation reactions in the catalytic cycle. Nevertheless, this amino acid is a very important structural element of the protein<sup>73, 74, 185–190</sup> as can be evidenced from the results of its site-specific substitution for any other amino acid. As a rule, such a substitution results in a complete loss or a significant decrease of the enzyme activity.<sup>188</sup>

Studies of the substrate specificity of the functional domain of halogenocarboxylic acid dehydrogenases<sup>191</sup> revealed that mutations in the conserved Gly residue localised between the amino acid residues of the catalytic site to Pro, Val or Ala reduce dramatically the catalytic activity. Structural studies of mutants have demonstrated substantial conformational changes in the side chains of the residues forming the catalytic site. It was concluded that the presence of Gly is critical for conferring flexibility on the polypeptide chain in its folding in the vicinity of the active site. The

role of conserved Gly residues in the functioning of gramicidin S synthase has been studied.<sup>192</sup> It was shown that single mutations in three conserved Gly residues to Glu or Asp result in the loss of the valine-adenylate activity of this enzyme.

Apparently, conserved glycine residues are important in principle for the following reasons. First, glycine, being a unique amino acid with the smallest energy of rotation around the C–N and C–C bonds of the polypeptide chain plays the role of a node which determines the direction of the folding of the polypeptide chain in the assembly of the protein globule. Thus, the presence of conserved glycine residues accounts for the structural paradox of enzymatic catalysis, *viz.*, the ‘assembly’ of identical active sites from absolutely different polypeptide chains. The presence of conserved glycine residues and stabilisation factors in the ‘assembled’ structures, *e.g.*, disulfide bonds, are a common feature of these chains.

The substantial effect of conserved glycine residues on structure formation of the active sites of enzymes was established in computer studies.<sup>74</sup> Computer simulation was used to study the changes in the conformations of amino acid residues in the active sites of different types of hydrolases. Two series of calculations were carried out for each representative of the hydrolase family. In the first series, all conserved Gly were replaced by Ala and the corresponding conformational changes in the polypeptide chain in the vicinity of the active site were determined. Similar calculations were performed in the second series except that the non-conserved Gly residues were replaced by Ala. The root-mean-square deviation of the coordinates of the atoms in active site residues (calculated per one substituted amino acid residue) in the structure calculated after the substitutions from the coordinates in the active site of the native enzyme following superposition of these structures was used as a measure of distortion of the geometry of the active sites of these enzymes. It was found that the substitution of Ala for conserved Gly for all types of hydrolase under study caused more significant distortions in the geometry of the active sites of enzymes than the substitution for a greater number of non-conserved Gly. This suggests enhanced ‘sensitivity’ of the geometry of the active sites of enzymes to the presence of Gly residues in conserved positions.

Second, conserved glycine residues can play the role of conformational ‘hinges’ which impart conformational mobility to the catalytic groups. Supporting evidence can be derived from the fact that very often the conserved glycine residues are found in the vicinity of catalytically active groups. For example, the conserved motifs for hydrolases belonging to different families are as follows: Asp-215-X-Gly-217 (pepsin); Asp-170-X-X-Gly-173 (thermolysin); Asp-32-X-Gly-34, His-63-Gly-64, Gly-219-X-Ser-221 (subtilisin); Gly-173-X-Ser-177 (trypsin); His-76-Gly-77, Ser-153-X-Gly-155, Gly-175-X-Asp-177, Gly-X-Ser-X-Gly (lipases).<sup>193</sup> The residues Asp, Ser and His of these enzymes constitute the active sites.

Enzyme-catalysed transformation of the starting substrate into final products is accompanied by the formation of many intermediates with structures different from that of the starting substrate. Glycine residues of the active site can play the role of ‘relaxing’ elements by tuning the conformation of the active site for the subsequent elementary act.

A prominent role in the formation of the active site architecture is played by cysteine and proline residues (the fourth and third positions in the rating list of conserved amino acids). Proline is known to be a unique amino acid responsible for the unfolding of the polypeptide chain.

In all probability, the role of cysteine residues consists in the ‘fixing’ of the required configuration of the active site built up of different, often remote fragments of the polypeptide chain, by forming a chemical bond in the form of a disulfide bridge. For many enzymes, this process completes the formation of the active site architecture.

## X. The rates of conformational changes and proton transfer as the limiting steps

The numeric values of the rate constants ( $k_{\text{cat}}$ ) of the limiting and known elementary steps of catalytic processes involving enzymes are worth analysing and comparing. To date, much is known on  $V_{\text{max}}$ ,  $K_{\text{m}}$  (the Michaelis constant) and  $k_{\text{cat}}$  values.

Figure 11 shows the distribution density curves of different enzymes according to their  $k_{\text{cat}}$ ,  $K_{\text{m}}$  and  $k_{\text{cat}}/K_{\text{m}}$  values and the rate constants for the elementary steps ( $k_1$ ,  $k_{-1}$  and  $k_{\text{conf}}$ ) (see Ref. 11). The shapes of these curves are characteristic of normal logarithmic distribution.

The  $k_{\text{cat}}$  values lie in the range of  $10^1$ – $10^4$  s<sup>−1</sup>. Enzymatic reactions in which the limiting step is of the order of  $10^2$  s<sup>−1</sup> are especially abundant in nature. The distribution patterns of enzymes according to their  $K_{\text{m}}$  values are similar. This parameter changes in the range from  $10^{-2}$  to  $10^{-7}$  mol litre<sup>−1</sup>. The distribution density has a maximum at  $K_{\text{m}} \approx 10^{-4}$  mol litre<sup>−1</sup>. The  $k_{\text{cat}}/K_{\text{m}}$  values for different enzymes lie in the range of  $10^1$ – $10^{10}$  litre mol<sup>−1</sup> s<sup>−1</sup>; enzymes with  $k_{\text{cat}}/K_{\text{m}} = 10^6$  litre mol<sup>−1</sup> s<sup>−1</sup> are especially numerous.

These values define the limiting step of the substrate conversion in the active site of the enzyme. The energy barrier (10–17 kcal mol<sup>−1</sup>) seems to be determined by physicochemical factors. Other reaction steps proceed at faster rates.

Structural isomerisations are substantial steps of the catalytic cycle. If conformational changes affect the active site of the enzyme, this is reflected in the kinetics of the enzymatic reaction. In many cases, binding of the enzyme to the substrate (or the inhibitor) occurs by a two-step mechanism:

where E is the enzyme, S is the substrate,  $\text{X}_1$  is the primary complex and  $\text{X}_2$  is the enzyme–substrate (or enzyme–inhibitor) complex.

As the formation of enzyme–substrate (or enzyme–inhibitor) complexes is not accompanied by the formation of covalent bonds, the second step of the reaction represents a conformational transformation of the primary complex  $\text{X}_1$ . Presumably, this fact provides the strongest evidence in favour of conformational changes in the active site of the enzyme during enzymatic catalysis.<sup>11</sup>

Very often, the conformational changes  $\text{X}_1 \rightleftharpoons \text{X}_2$  occur at faster rates ( $10^3$ – $10^4$  s<sup>−1</sup>) than the limiting step of the catalytic process.

The rate constants of many conformational changes in proteins involved in catalytic transformations have now been established. These data can be used for conducting statistical analyses and revealing ‘typical’ characteristics of the catalytic reaction. Figure 11a shows the curve of the distribution density of rate constants of conformational changes ( $k_{\text{conf}}$ ). The maximum of the distribution density lies around  $10^3$  s<sup>−1</sup>. It can be seen that the distribution density curve  $k_{\text{conf}}$  is very similar to that for the

limiting steps. It may thus be assumed that sometimes the rates of conformational changes determine the rates of enzymatic reactions.

However, in the majority of cases conformational changes occur faster and precede the rate-limiting step. The role of conformational changes in enzymatic catalysis is evident. The mechanisms of enzymatic reactions are rather complex involving rearrangement of numerous bonds. Such processes cannot occur in one elementary step. The mechanisms of action of enzymes include the formation and conversion of a great number of intermediates. The enzyme ensures the reaction pathway with the least energy and entropy expenditures. The mechanism of action of an enzyme can be compared to that of a programmed control machine which operates at the molecular level and its functioning is provided by conformational changes.

In terms of chemical kinetics, this means that the structure similar to the transition state is formed as a result of conformational changes in the ground state. Conformational changes ‘push’ the reactants along the reaction pathway. The formation of a conformer structurally similar to the transition state or the reaction product significantly lowers the potential reaction barrier. The lowering of the reaction barrier the greater the more similar the structure of the conformer to that of the transition state or the reaction product.

Proton transfer is yet another process which limits the rate of an enzymatic reaction. It follows from the above-said that the acid-base nature of enzymatic reactions is their main characteristic feature.

Owing to the classical works by Eigen,<sup>194, 195</sup> the mechanisms of reactions of the proton with bases and of the hydroxyl ion with acids are now well understood. The main conclusion is that these reactions do not depend on the basicity or acidity of the reactants, but represent diffusion-controlled processes ( $k \approx 10^{10}$  litre mol<sup>−1</sup> s<sup>−1</sup>). Correspondingly, the rate constants of reverse reactions are determined by the values of equilibrium constants. In some cases, the proton transfer steps can be limiting for the enzymatic process.

Since in the course of an enzymatic reaction the catalytically active group undergoes both protonation and deprotonation, the proton transfer poses certain restrictions on the efficiency of acid-base catalysis. The reactions occurring in this process can be described as:

Since the reverse steps of these reactions are controlled by the diffusion of the reactants, the rate constants of the direct reactions can be presented as  $10^{10}K_{\text{a}}$  s<sup>−1</sup> and  $10^{10}(K_{\text{W}}/K_{\text{a}})$  litre mol<sup>−1</sup> s<sup>−1</sup> ( $K_{\text{a}}$  is the acid dissociation constant of  $\text{BH}^+$  and  $K_{\text{W}}$  is the ionisation constant of water). The maximum value of the rate constant of the overall reaction is approximately equal to  $10^3$  s<sup>−1</sup> at  $K_{\text{a}} \approx 10^{-1}$  mol litre<sup>−1</sup>. Indeed, for  $K_{\text{a}} < 10^{-7}$  mol litre<sup>−1</sup>, the dissociation rate constant of the acid  $\text{BH}^+$  [reaction (7a)] is

**Figure 11.** The distribution of enzymes according to their  $k_{\text{cat}}$  (a),  $K_{\text{m}}$  (b) and  $k_{\text{cat}}/K_{\text{m}}$  (c) values. (a) First-order rate constant, (b) the Michaelis constant, (c) second-order rate constant.

smaller than  $10^3 \text{ s}^{-1}$ , while at  $K_a > 10^{-7} \text{ mol litre}^{-1}$ , the hydrolysis rate constant of the base [reaction (7b)] is smaller than  $10^3 \text{ s}^{-1}$ . Therefore, the maximum value of the rate constant for an acid-base catalysis involving water is equal to  $10^3 \text{ s}^{-1}$ . This conclusion can be used for interpreting the maximum rates of enzymatic catalysis. The value  $10^3 \text{ s}^{-1}$  is characteristic of the turnover number of many enzymes (see Fig. 11a). Besides, the optimum value of  $\text{p}K_a \approx 7$ , which is necessary for effective catalysis, corresponds to  $\text{p}K_a$  of the imidazole group of the histidine residue.

Analysis of the structures of active sites of enzymes shows that in many cases the imidazole group of histidine participates in the catalytic act as a complex with a stronger nucleophile (proton conjugation), viz., a deprotonated carboxy group of aspartic or glutamic acid. The kinetic significance of such conjugation is obvious. The proton transfer from the protonated imidazole to the carboxy group in the last step of the catalytic cycle enables regeneration of properties of the catalytic site within microseconds. Indeed, the rate constant for the reaction

is equal to  $10^6 \text{ s}^{-1}$ .

Thus, the enzymatic catalysis illustrates the maximum catalytic accelerations which can be realised for the reactions occurring in solutions.

In all probability, the evolution of biocatalysis has long been searching for effective structures by the trial-and-error method. Having fixed these structures at the genetic level, the biosystems have learnt to use them for the formation of various active sites, and not only of the hydrolase type.

**Abstract.** Methods for specific covalent binding of modified nucleic acids to proteins and enzymes with conservation of their native structures are discussed. Possible applications of synthetic nucleic acids containing reactive (nucleophilic and electrophilic) groups and groups that can be photoactivated for testing protein – nucleic acid contacts and studying protein functioning are considered. The structures of protein – nucleic acid conjugates formed in the enzymatic reactions are described. Methods for the isolation and analysis of covalently bound protein – nucleic acid complexes are generalised. The main attention is given to methods for determination of protein sites attached to nucleic acids. The bibliography includes 226 references.

## I. Introduction

Protein – nucleic acid interactions determine numerous processes occurring in cells, *viz.*, replication, transcription and translation of DNA as well as RNA processing. Amino acid residues involved in the formation of protein – nucleic acid complexes are identified by various methods. These can be divided into two groups, *viz.*, instrumental methods (*e.g.*, X-ray diffraction analysis, NMR spectroscopy, *etc.*) and molecular-biological methods (site-directed mutagenesis of proteins, cross-linking, *etc.*).

Undoubtedly, the most reliable information about the structures of NA – protein conjugates can be obtained from X-ray diffraction data, however, isolation and crystallisation of the corresponding complexes are not always possible.<sup>†</sup> In addition, X-ray diffraction analysis often fails to establish the conformational reconstructions of the proteins in their interactions with NA and to determine the effects of the nucleotide sequences of NA flanking the protein-binding sites.<sup>2</sup> The dynamics of protein – nu-

cleic acid complexes in solution is usually studied by NMR spectroscopy, but the latter is often inapplicable to the study of multisubunit complexes and processes associated with significant changes in the structures of biopolymers. Other spectroscopic methods, *e.g.*, fluorescence spectroscopy including stop-flow technique, Raman and small-angle X-ray scattering and electron microscopy, provide little information about the structures of NA – protein complexes.

Among other molecular-biological methods used in the analysis of NA – protein interactions, site-directed mutagenesis and addressed chemical modification of proteins are most popular, but they are rather laborious and sometimes provide incorrect information due to changes in the biopolymer structure caused by the substitution of the functional amino acid residues. Moreover, this demands localisation of the protein domain involved in binding. This group of methods also includes covalent binding of proteins to NA, which is optimum for solution of many problems. In the first place, it allows identification of the protein domain and even particular amino acids interacting with a specific NA fragment within the NA – protein complex.<sup>3–7</sup> It is also used in the study of multiprotein complexes formed upon replication, translation, *etc.* In particular, this can also be employed for identification of a protein component interacting with a specific site in NA.<sup>8</sup> This approach can be used in the study of cell extracts (particularly, for detecting proteins selectively interacting with specific nucleotide sequences) and in the SELEX technology<sup>‡</sup> for selection of oligonucleotides with specific primary structures (*e.g.*, NA aptamers) that bind to proteins irreversibly.<sup>9, 10</sup>

Covalent binding of proteins to NA has been used for the study of NA – protein interactions virtually from the moment of the origin of molecular biology, *i.e.*, since the mid-1960 s.<sup>11</sup> At present, photoaffinity modification of proteins is the most popular; this is based on covalent binding of non-modified nucleic acids to proteins upon UV irradiation.<sup>12</sup> However, it can hardly be regarded as a versatile procedure because of low yields of conjugates, radiation-induced damage of biopolymers and the necessity to identify the nucleotide unit to which the protein is attached. The use of NA analogues that can be photoactivated to generate radicals and biradicals under the influence of UV light seems to be a more promising approach. It excludes the necessity

<sup>†</sup> Considerable progress in crystallisation of covalently bound NA – protein complexes and study of their structures by X-ray diffraction analysis achieved in the past decade is considered in detail in the review by Verdine and Norman.<sup>1</sup>

<sup>‡</sup> SELEX is an abbreviation from 'Systematic Evolution of Ligands by EXponential enrichment'.

to identify the nucleotide unit involved in binding and diminishes the risk of destruction of biopolymers, since in this case irradiation is performed under less destructive conditions (*i.e.*, with longer wavelengths). Several reviews devoted to the synthesis,<sup>13</sup> properties<sup>14</sup> and applications<sup>15–17</sup> of NA analogues that can be photoactivated are available.

Chemical methods for the attachment of proteins to NA are based on either the use of non-specific binding reagents (*e.g.*, formaldehyde<sup>18–20</sup>), or selective introduction of reactive groups into the protein or NA. A novel procedure for the covalent binding of proteins to NA in the presence of metal complexes has been developed recently.<sup>21</sup> It was found that UV irradiation of DNA in the presence of complexes with platinum-group metals results in specific oxidation of guanosine residues within the oligonucleotide.<sup>22–24</sup> When such nucleotides come closer to the protein, cross-linking occurs. However, despite the obvious originality of this technique, it has not found wide application because of low yields of protein–NA conjugates and commercial inaccessibility of the most efficient metal complexes.

The present review is devoted to the use of modified NA for the study of specific protein–nucleic acid interactions (here, we do not consider the methods based on the use of chemically modified proteins).<sup>25–27</sup> The review by Sheflyan *et al.*<sup>3</sup> published in 1996 was devoted to methods for covalent attachment of nucleic acids and their derivatives to proteins; however, many new NA derivatives have been synthesised in the past 7 years and, most importantly, the methodology of determination of amino acid residues covalently bound to NA has been finally stated and brought to practice.

## II. Covalent binding of modified nucleic acids to proteins

### 1. Methods for functionalisation of nucleic acids

Modified NA can be synthesised using chemical or enzymatic methods. The former approach includes preparation of modified nucleosides (as a rule, in the form of 3'-phosphoroamidite derivatives) which are further used in automated oligonucleotide synthesis. These nucleosides have to be stable under conditions of the synthesis and post-synthetic workup, which is not always possible. In addition, this method makes it possible to prepare oligomers having no more than 80–100 nucleotide units.

The enzymatic approach entails incorporation of modified 5'-nucleoside triphosphates into NA using various polymerases. As a rule, C(5)-substituted pyrimidine and C(8)-substituted purine nucleosides are used, the use of cytidine derivatives modified at N(4) has also been described. In this case, the length of the NA synthesised can reach thousands of nucleotides. However, the limitations of the enzymatic chain elongation method consist of impossibility of incorporation of certain modified nucleotides into the chain. The enzymatic method enables statistical functionalisation of NA and if 5'-nucleoside triphosphate terminates the growth of the oligonucleotide, it is the 3'-terminus of NA that is modified.

Substituents can be introduced into NA in the course of post-synthetic workup. Various reactive groups, *e.g.*, aliphatic amino groups, thiol groups, phosphorothionate internucleotide groups, *etc.*, can be used as substituents. An original procedure for the introduction of reactive internucleotide groups by chemical ligation of modified oligonucleotides has been developed in the laboratory headed by Z A Shabarova at MSU (see a review<sup>28</sup> and Section II.3).

### 2. Photoactivatable derivatives of nucleic acids

As mentioned above, the use of photoactivatable derivatives of NA in the study of specific protein–nucleic acid interactions is a promising approach. A comprehensive review by Meisenheimer and Koch<sup>14</sup> published in 1997 dealt with a detailed consideration of the mechanism and selectivity of covalent binding of side groups of amino acid residues of a polypeptide chain to the

modified nucleotide units of nucleic acids containing photoactivatable groups.

Arylazide derivatives have become especially popular among other photoactivatable NA analogues due to their high reactivities.<sup>8</sup> Nucleosides containing arylazido groups can be introduced into NA by both enzymatic and chemical methods.

The main disadvantages of arylazide derivatives of NA include the lack of selectivity in the binding to proteins and large size of the arylazido group, which can lead to disturbances in the local structure of an NA–protein complex and to cross-linking with remote protein fragments. Nevertheless, this type of modified NA is widely used in the study of structures of protein–nucleic acid complexes.

Arylazides can be introduced into NA

— at the internucleotide phosphorothioate bond of modified oligonucleotides:<sup>29–31</sup>

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain;

— at the 5'-phosphate group of oligonucleotides:

R<sup>1</sup> is a fragment of the oligonucleotide chain;

(a) Ph<sub>3</sub>P, ; (b) NH<sub>2</sub>(CH<sub>2</sub>)<sub>3</sub>NH<sub>2</sub>;

— in the course of a polymerase reaction using 5'-nucleoside triphosphates **1–3** modified at the heterocyclic base as one of the reactants (see Refs 32–43).

§ Highly reactive short-living arylnitrene biradicals, which react with the majority of amino acids, are formed upon irradiation of arylazido groups.

The photoactivatable triphosphates **1a–f** were prepared by the acylation of 5-(2-aminovinyl)-2'-deoxyuridine-5'-triphosphate (**4**) with an activated ester of the corresponding azidobenzoic acid (**5a–f**).

X = C<sub>6</sub>F<sub>5</sub>, succinimido.

The electron-withdrawing groups in the benzene ring of the arylazide stabilise the nitrene formed upon irradiation of the azide, as a result of which the yield of the protein–nucleic acid conjugate increases.<sup>44</sup>

The introduction of amino and hydrazide groups at C(4) of pyrimidine and their subsequent acylation or alkylidenylation is yet another approach to the synthesis of triphosphates containing an arylazide group. The synthesis of the corresponding compounds **6** and **7** has been described.<sup>45–49</sup>

The photoreagents **1–3**, **6** and **7** were used for the study of the human replication protein A,<sup>32, 50–53</sup> HIV-1 reverse transcriptase,<sup>54</sup> DNA polymerases,<sup>55, 56</sup> helicase Rep from *E. coli*<sup>35</sup> and excision repair proteins (BER, Base Excision Repair).<sup>57, 58</sup> The previously obtained data on the structures of DNA polymerases have been reviewed.<sup>59</sup> The use of arylazide derivatives of NA for structure–function studies has also been described.<sup>15–18</sup>

Lavrik *et al.*<sup>60</sup> have developed an original procedure for sensitised photomodification of DNA polymerase  $\beta$  which involves the use of an arylazido group. First, a nucleotide containing an arylazido group at the 3'-end was synthesised from a primer using DNA polymerase  $\beta$ . Then, pyrene-containing uridine-5'-triphosphate that binds to polymerase is added to the reaction mixture, and the resulting complex is irradiated with light with the wavelength of 365–450 nm. Irradiation induces the excitation of the pyrenyl residue and the fluorescence-resonance-energy transfer (FRET) to the arylazido group (Fig. 1). The activation of the latter brings about covalent binding of the 3'-end of the primer to the polymerase. Such a binary system allows the use of significantly longer irradiation wavelengths required for the formation of NA–protein conjugates in comparison with those commonly used for the photoactivation of arylazide derivatives (325–350 nm). The use of this approach has made it possible to reduce the photodamage of DNA and proteins and to increase (by an order of magnitude) the initial rate of photomodification. Later, this approach was repeatedly used for the study of functioning of DNA polymerases in both model systems and cellular extracts.<sup>54, 61–65</sup>

Figure 1. Sensitised modification of DNA polymerase.

Among other commonly used photoactivatable NA derivatives, mention can be made of 5-halogenopyrimidine and 8-halogenopurine nucleosides, *e.g.*, 5-bromo- (**8a**)<sup>33, 66–72</sup> and 5-iodo-2'-deoxyuridine (**8b**),<sup>31, 40, 67, 73–95</sup> 5-iodo-2'-deoxycytidine (**9**)<sup>77, 96</sup> and 8-bromo-2'-deoxyguanosine (**10**).<sup>97</sup>

Photolysis of these photoactivatable NA produces stable radicals which react with electron-donor amino acid residues of proteins, particularly, with aromatic and sulfur-containing side groups. In the case of bromo derivatives, the optimum wavelength of the UV light necessary for the abstraction of the halogen atom is 308 nm, while that for iodo derivatives is 325 nm. The increase in the wavelength reduces photoinduced damage of proteins and NA, but decreases the yields of the photoaddition products. By virtue of their small size (the van der Waals radii of iodine and bromine atoms correspond approximately to that of the methyl group), halogen atoms do not induce any significant changes in the structure of NA and do not prevent protein–nucleic acid recognition. This makes halogen derivatives of NA highly attractive tools for probing protein–nucleic acid contacts in the binding sites of biopolymers.

Halogen derivatives of NA were used in the studies of a broad array of NA-recognising proteins, such as the transcription factor NF- $\kappa$ B;<sup>33</sup> the transcription factor binding the CCAAT motif of DNA (CBF);<sup>69</sup> the restriction–modification enzymes EcoP15I,<sup>66</sup> EcoRI,<sup>78,87</sup> EcoRII,<sup>93,94,96</sup> EcoRV,<sup>84,95</sup> SsoII,<sup>88</sup> CviBIII and TaqI,<sup>81</sup> homing endonuclease PI-SceI;<sup>79,80</sup> the eukaryotic ribosome L5 protein;<sup>89</sup> the herpes simplex virus helicase—primase subcomplex;<sup>83,90</sup> the replication terminator Tus;<sup>67</sup> HIV-1 integrase;<sup>74,77</sup> the repair protein MutS;<sup>77</sup> the protein HMG1;<sup>91</sup> the replication protein A;<sup>82</sup> the recombination proteins RAG1 and RAG2;<sup>85</sup> telomerase of *Euplotes aediculatus*;<sup>75</sup> the protein SSB;<sup>92</sup> the fibroblast growth factor (bFGF<sub>155</sub>);<sup>70</sup> vimentine;<sup>71</sup> the phage capsid protein MS2<sup>73</sup> as well as the multiprotein centromeric complex (CBF3).<sup>68</sup>

Nucleoside derivatives in which the oxo group in the heterocyclic base is substituted for the thioxo group, e.g., 4-thiothymidine (**11**)<sup>34,98–100</sup> and 6-thio-2'-deoxyguanosine (**12**),<sup>101–103</sup> belong to yet another class of photoactivatable NA derivatives.

Replacement of the oxygen atom by sulfur induces minimum structural changes in the biopolymer, which, together with the high reactivity of thiones, makes them rather promising compounds. Upon irradiation with light with the wavelengths > 300 nm, these derivatives react with proteins by a free-radical mechanism. They were successfully used in the studies of the binding site of TAR RNA to the Tat-protein of HIV-1<sup>98,103</sup> (testing of NA–protein contacts in the large groove of the double

helix of RNA) as well as of DNA methyl transferase EcoR124I,<sup>102</sup> the transcription factor SRF,<sup>101</sup> integrase of the bacteriophage lambda<sup>100</sup> and the protein Rev of HIV-1.<sup>99</sup>

It is known that the benzophenone residue incorporated into NA<sup>40,104</sup> reacts with the  $\alpha$ -carbon atom of the polypeptide chain upon UV irradiation.<sup>105</sup>

It seemed therefore interesting to consider possible applications of such NA for the study of NA–protein interactions. Thus triphosphates **13** and **14** containing a benzophenone residue were tested as photoreagents for the study of the transcription complex of yeast RNA polymerase III<sup>40</sup> at the RNA-binding site of RNA polymerase T7.<sup>104</sup>

With rare exception, the yields of cross-linked products of such NA derivatives to proteins are extremely low; therefore, they have not found wide application.

Coumarins (**15**) and furocoumarins (**16**, psoralenes)<sup>¶</sup>

are widely used for the introduction of various non-radioactive labels<sup>107,108</sup> and the synthesis of covalently bound NA<sup>109</sup> as well as in the photochemistry<sup>110</sup> and diagnostics of genetic diseases.<sup>111</sup>

Psoralenes contain two photoactivatable double bonds by virtue of which they add to the double bond C(5)=C(6) of thymine to give compound **17** (Scheme 1). This reaction occurs upon UV irradiation ( $\lambda = 300–340$  nm). It was suggested<sup>112–115</sup> to use DNA fragments containing the thymidine residue **18** modified by 4'-hydroxymethyl 4,5',8-trimethylpsoralene for photoaffinity modification of proteins.

Coumarin can be introduced into NA by direct incorporation, into the oligonucleotide chain, of compound **19** with a carbohydrate-mimicking fragment.<sup>111,116</sup>

Psoralene- (or coumarin-) modified NA were used for the study of T7 RNA polymerase,<sup>106,112–114</sup> proteins RecA and Max,<sup>114</sup> as well as complex TFIIH proteins.<sup>115</sup>

¶ Psoralenes are also used for the modification of protein chains *in vivo*.<sup>106</sup>

Scheme 1

$R^1$ – $R^4$  are fragments of the oligonucleotide chain.

The optimum wavelength of UV light triggering the formation of protein–nucleic acid cross-links is 300 nm. The mechanism and selectivity of photoaddition of amino acid residues of proteins to psoralene-containing NA have not been established.

Aryl(trifluoromethyl)diazirine is yet another photosensitive reagent for the modification of NA. Upon UV irradiation, diazirines **20** are converted into reactive carbenes **21**, which react with virtually any molecule.

The review<sup>117</sup> published in 2000 is devoted to the use of aryl(trifluoromethyl)diazirines for the study of NA–protein interactions. Later, three other papers<sup>94, 118, 119</sup> devoted to the use of NA **22** and **23** containing diazirine residues were published.

$R^1$ ,  $R^2$  are fragments of the oligonucleotide chain.

DNA methyl transferase EcoRII<sup>94</sup> and HIV-1B integrase<sup>118</sup> were used as subjects of studies.

Unfortunately, the yields of cross-linked binding products of diazirine derivatives of NA to proteins are low because of side reactions of carbenes with water.

### 3. Chemical modification of nucleic acids

The non-specificity of the above-described photoactivatable NA reagents is their main disadvantage. Besides, their activation requires UV irradiation which can damage biopolymers. In contrast, NA reagents containing reactive groups react selectively with spatially close amino acid residues of the protein without any external factors. The introduction of a reactive group into a preset position of the oligonucleotide chain allows the probing of point contacts between different regions of biomolecules, whereas variations of the chemical nature of the reactive group enable selective binding of a definite type of amino acid residues within the NA–protein complex.

Reactive groups can be introduced into any position of NA, *i.e.*, the heterocyclic base, the sugar–phosphate backbone or the ends of the oligonucleotide chain. The introduction of these groups into the sugar–phosphate backbone of NA is the most promising approach, while modification of heterocyclic bases can disturb complementary interactions of NA and specific interactions within the protein–nucleic acid complex.

The following properties should be characteristic of the NA reagents used for the cross-linking with proteins:

- (1) the possibility to react specifically with spatially close functional amino acid groups of the protein;
- (2) formation of stable conjugates with the protein without any additional activation at physiological values of pH (6.0–8.0);
- (3) retention of stability in neutral aqueous solutions over a long period of time without any loss of reactivity.

#### a. Modification of nucleic acids at the internucleotide phosphodiester bond

It is known that nonspecific interactions make a significant contribution to the structural organisation and stability of virtually all macromolecular complexes including NA–protein complexes. In this connection, modification of the phosphate groups of NA, which are involved in the majority of cases in these interactions, seems to be important for the study of NA–protein contacts. In the early 1990s, Shabarova *et al.*<sup>120–123</sup> proposed to substitute trisubstituted (TSP) groups for the natural 3',5'-phosphodiester bonds in NA.

The trisubstituted pyrophosphate group possesses all the properties necessary for the interaction with proteins, *viz.*, it is stable in aqueous media and is readily cleaved by amines. It was found that oligonucleotides containing TSP groups react exclusively with lysine and histidine residues as well as with the terminal  $\alpha$ -amino group of the protein;<sup>124</sup> the nucleophilic substitution occurs only with the disubstituted phosphate to yield a covalently linked protein–oligonucleotide complex. If the phosphoramidate bond is formed with involvement of the  $\epsilon$ -amino group of Lys or the terminal  $\alpha$ -amino group of the protein, this bond is stable at pH > 4; if the amino group of His is involved, the bond is cleaved in weakly acidic media or under the action of *N*-methylimidazole, which allows discrimination of lysine and histidine residues.<sup>125</sup>

Scheme 2

NuH are Lys and His residues of the protein.

Template-directed condensation of oligonucleotides carrying mono- and disubstituted terminal phosphate groups using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) (Scheme 2, chemical ligation) is employed for the introduction of the TSP group into the predetermined position of the oligonucleotide. The use of chemical ligation for the preparation of various single- and double-stranded TSP-modified oligonucleotides has been described in detail in the reviews.<sup>3, 18, 126</sup>

The formation of two isomeric TSP-containing oligonucleotides **A** and **B** (see Scheme 2) is possible depending on which of the terminal phosphate residues (3'- or 5'-) in the starting oligonucleotide is esterified. It was found that the synthesis of the isomer **B** is far more effective than that of the isomer **A** due to the difference in the reactivities and availabilities of the reacting mono- and disubstituted phosphate residues. At the same time, the isomer **B**, which is formed more easily, reacts more slowly with the amino group of lysine than the isomer **A**.

The human transcription factor NF- $\kappa$ B was used as a target protein.<sup>127, 128</sup> This belongs to the class of multifunctional eukaryotic proteins (the family Rel), which control gene expression and play an important role in such vital processes as immune response,<sup>129</sup> apoptosis,<sup>130</sup> cell growth<sup>131</sup> and proliferation.<sup>130</sup> It has been shown that synthetic DNA duplexes containing TSP groups in different positions of the recognition site of the transcription factor NF- $\kappa$ B differ substantially in the efficiency of their covalent binding to the protein. Thus in the case of isomers **A** the yield of the protein–nucleic acid conjugate was 35%, while for isomers **B** it did not exceed 7%. The observed regularity was taken into consideration in subsequent studies aimed at the design of DNA reagents containing the TSP groups.

A series of DNA duplexes containing *O*-methyl pyrophosphate in different positions of the binding site of the transcription factor HNF-1 was used for the probing of DNA contacts with this protein in nuclear extracts of rat liver<sup>132</sup> and the study of DNA formamido–DNA glycosylase contacts.<sup>133</sup>

The synthesis of TSP-containing oligoribonucleotides has been described by Shabarova *et al.*<sup>134</sup> These were used to confirm the existence of contacts between individual phosphate groups of RNA within the TAR RNA complex with the Tat-peptide<sup>135</sup> predicted on the basis of NMR spectroscopic data. The aim of this study was to specify the architecture of the natural TAR RNA–Tat-protein complex. The amino acids interacting with the RNA duplex were determined using chemical and enzymatic cleavage of the protein fragment in the covalently bound complex with subsequent analysis of the conjugate by mass spectrometry.<sup>135</sup> The natural TAR RNA–Tat-protein complex plays a key role in the activation of transcription of the human immunodeficiency virus. It was found that the Tat-protein after formation of the complex with TAR RNA initiates indirect activation of RNA

polymerase II.<sup>136</sup> This reaction is the determining step in the initiation of transcription of HIV-1, since no elongation of transcription takes place in the absence of the Tat-protein.

The structural polymorphism of proteins including that induced by irradiation and crystallisation has been studied especially intensely in recent years. It remains to be hoped that the use of nucleic acids containing TSP groups will enable a more accurate determination of individual contacts between the biopolymers within the protein–nucleic acid complexes which exist in the native state in aqueous media and a comparison of the results obtained from X-ray diffraction analysis. The main advantages of this approach include selectivity of interaction (Lys or His) and the absence of extended spacers between the phosphate group responsible for the binding and the nucleophilic groups of proteins. Thus some of the contacts of the Lys and His residues in RNA polymerase of bacteriophage T7 with the phosphate groups of the promoter were established<sup>137</sup> with the use of synthetic fragments of the promoter (10–20 b.p.) containing a TSP group in positions that, according to data from X-ray diffraction analysis, are close to particular amino acids. The functional significance of such contacts has been established previously in biochemical studies.

This approach was used in the study of the complex of the transcription factor NF- $\kappa$ B with DNA duplexes with different primary structures.<sup>128</sup> Covalent binding made it possible to establish an important fact that in principle the structure of the NF- $\kappa$ B complex with DNA is determined not only by the nucleotide sequence in the protein-binding site, but also by flanking regions. Later, this fact was confirmed by X-ray diffraction analysis.<sup>138–141</sup>

Studies by Shabarova *et al.*<sup>142</sup> have shown that DNA duplexes containing TSP groups are promising reagents for the probing of conformational changes in the enzyme during functioning of the enzyme–substrate complex. Restriction endonuclease MvaI (R.MvaI) was used as a subject of investigation, while a 14-membered DNA duplex containing a recognition site for the enzyme with a TSP group instead of a hydrolysable phosphodiester bond was used as a substrate.<sup>142</sup> This system was used for the study of conformational changes in the restriction endonuclease MvaI in the enzyme–substrate complex induced by different concentrations of magnesium ions (the latter is a cofactor of the cleavage of DNA). It was found that magnesium ions favour conformational rearrangements in the protein as a result of which one of the nucleophilic groups in the catalytic site of R.MvaI (presumably, histidine) comes closer to the modified bond in the DNA substrate.

In order to enhance the reactivities of internucleotide bonds, it was proposed to replace the TSP groups in DNA duplexes by their sulfur-containing analogues.<sup>143</sup> Oligonucleotides containing thio

analogues of the TSP groups appeared to be more reactive with respect to aliphatic amines, since dialkyl thiophosphoric acid is a stronger acid (in comparison with dialkyl phosphoric acid) and, as a consequence, the better leaving group.

Hairpin DNA duplexes containing a recognition site of the human transcription factor NF- $\kappa$ B, the position of the modified fragment (*i.e.*, the sulfur-containing TSP group) in which corresponded to the position of the group the most close to the lysine residue, were bound covalently to the protein (Scheme 3). In contrast to oxygen-containing TSP, both isomers differing in the position of the trisubstituted phosphorothioate residue reacted with the same efficiency. However, the lability of sulfur-containing TSP groups and the relative difficulty of their incorporation into oligonucleotides prevent large-scale application of this type of DNA reagents.

It was proposed<sup>124,144</sup> to use oligonucleotides containing a reactive acylphosphate group instead of one phosphodiester bond for the study of NA–protein interactions. This group was introduced into the preset position of the sugar–phosphate backbone by template-directed chemical ligation of two oligonucleotides one of which served as a phosphate donor, while the other one was used as a carboxyl donor (Scheme 4).<sup>124</sup> The mixed anhydride formed undergoes cleavage in aqueous solution ( $\text{pH} \geq 8$ ) under the action of amines to give a carboxamide (rather than phosphoramidate) (see Scheme 4).<sup>124</sup> In reactions with amines, such acyl phosphate-containing oligonucleotides play the role of mild acylating reagents. A comparison of the properties of DNA duplexes containing an acyl phosphate or a TSP group in the same position of the recognition site of the transcription factor NF- $\kappa$ B revealed that the yields of the protein–nucleic acid conjugates in the case of acyl phosphate-containing DNA were three times lower than those from TSP-containing DNA.<sup>124</sup> The lower reactivities and the formation of side products in the

synthesis of acyl-phosphate oligonucleotide derivatives are the reasons for their low utility for the covalent binding to proteins.<sup>†</sup>

#### b. Modifications of the terminal phosphate groups of nucleic acids

Oligonucleotide derivatives with activated terminal phosphoester groups are more accessible than other reactive phosphorylating agents. *N*-Hydroxybenzotriazole esters (HOBt-derivatives) of oligonucleotides **24** are the most popular reagents of this type. They are prepared in one step from oligonucleotide-3'- or 5'-phosphates and *N*-hydroxybenzotriazole under the action of water-soluble carbodiimide in water-organic media.<sup>147,148</sup>

R is the oligonucleotide residue.

HOBt-Derivatives of the oligonucleotides **24** manifest phosphorylating properties in reactions with amino acids, peptides and proteins. In this case, the reaction with the protein occurs at the N-terminal  $\alpha$ -amino group, at the  $\epsilon$ -amino group of Lys or at the imidazole residue of histidine.<sup>149</sup>

Reactive *N*-hydroxybenzotriazole esters of oligonucleotides were successfully used in the study of DNA-<sup>125</sup> and RNA-binding<sup>149</sup> proteins. The structure of the complex of RNA polymerase of *E. coli* with a DNA promoter has been studied<sup>125</sup> with the help of a large series of hydroxybenzotriazole derivatives of single- and double-stranded oligonucleotides corresponding to various fragments of the promoter responsible for different transcription initiation steps (–35 and –10 relative to the transcription initiation point). The RNA polymerase subunit of the holoenzyme built up of five subunits and the amino acid residues involved in the binding to each oligonucleotide were determined based on the results of covalent binding.<sup>125</sup> The results obtained with the use of hydroxybenzotriazole derivatives were confirmed by Naryshkin *et al.*<sup>150</sup> who have used photoactivatable arylazide analogues of DNA for the solution of the same task.

The use of hydroxybenzotriazole derivatives of RNA has also been described in the study<sup>149</sup> on the binding of Tat-proteins to the fragment of TAR RNA. The high efficiency of the covalent binding of RNA to the peptide suggests that this type of derivatives can be used for the construction of 'decoys' that slow down the transcription of the immunodeficiency virus in infected cells.

It should be noted that HOBt and TSP derivatives of nucleic acids containing modified phosphate groups both inside the NA chain and at its termini are the only currently available reagents for testing the contacts of Lys and His residues of proteins. The high efficiency of formation of protein–nucleic acid conjugates (yields up to 50%), the high selectivity of binding to proteins and the availability of chemical means of analysis of covalent binding products open up broad opportunities for further applications of these reagents for determination of the structures and analysis of conformational rearrangements in NA–protein complexes during their functioning or upon changes in their environments.

#### c. Modification of sugar moieties of nucleic acids

Only a small number of NA reagents containing reactive groups in the sugar moiety have been obtained so far. At the same time, it is known that NA-recognising proteins react with NA exclusively by generating hydrophobic and van der Waals contacts with the

<sup>†</sup> The methods for the introduction of carboxy groups into DNA and the chemical properties of such derivatives have been studied fairly extensively.<sup>145,146</sup>

ribose residue.<sup>151</sup> Of special interest are NA reagents modified in the 2'-position of ribose which plays a crucial role in the discrimination of DNA and RNA molecules by proteins.

It was suggested<sup>152</sup> that the 2'-iodoacetamide group within DNA duplexes can be used for selective covalent binding of proteins containing a cysteine residue in the active centre. The iodoacetamido group was chosen due to its higher (in comparison with the bromoacetamido group) activity in the alkylation of the thiol group of cysteine.<sup>153</sup> Synthetic oligonucleotides containing 2'-amino-2'-deoxyuridine **25** in the preset position instead of thymidine were used as starting compounds for the directed introduction of the iodoacetamido group (this approach enables easy changes in the position of the reaction centre in the target oligonucleotide sequence). The 2'-deoxy-2'-iodoacetamidouridine derivatives **26** were prepared by acylation of the amino group with an excess of iodoacetic anhydride (Scheme 5).

$\text{R}^1, \text{R}^2$  are fragments of the oligonucleotide chain.

Studies of reactions of DNA reagents containing an iodoacetamide group in position 2' of the uridine residue with various low-molecular-mass nucleophiles (including amino acids and peptides) revealed that they react only with thiol-containing compounds, particularly, with cysteine-containing proteins. It is of note that the iodoacetamide groups at the 2'-position of the sugar-phosphate backbone of DNA react with the cysteine residues of the protein only within specific protein-nucleic acid complexes (*e.g.*, within the duplex **27**, see Scheme 5).

Such DNA duplexes were used for the affinity modification of a series of DNA-recognising cysteine-containing proteins, *e.g.*, the transcription factor NF- $\kappa$ B, the restriction-modification enzyme SsoII and uracil DNA glycosylase.<sup>152</sup> Thus the reaction of the modified DNA duplexes **27** with the transcription factor NF- $\kappa$ B is complete within 15 min at pH 8.1 and yields the covalently bound adducts **28**. These data altogether suggest that this reaction occurs with good efficiency (the yield of the conjugates reaches 25%) and high specificity.

The amino groups of lysine residues of DNA-recognising proteins can also be involved in the interaction with the sugar-phosphate backbone of DNA. To this end, aldehyde groups are to be introduced into the sugar-phosphate backbone. The synthesis and properties of oligonucleotides containing dialdehyde groups are considered in the reviews.<sup>154-156</sup>

Synthesis of oligodeoxyribonucleotides **29** containing a 2-oxoethyl group at the O(2') atom has been described.<sup>157,158</sup> The protected phosphoramidite 2'-O-(2,3-dihydroxypropyl)uridine derivative **30** was used as a starting compound in the oligonucleotide synthesis of such DNA (Scheme 6).

Oxidation of the diol group into the aldehyde group was carried out under mild conditions by treatment with a twofold

DMTr is dimethoxytrityl;

$\text{R}^1, \text{R}^2$  are fragments of the oligonucleotide chain.

excess of sodium periodate. The oligonucleotides **29** obtained react efficiently with different amino compounds.<sup>159</sup> The possibility of covalent binding of DNA containing a 2'-O-(2-oxoethyl)-uridine fragment to the transcription factor NF- $\kappa$ B (see Scheme 6) has been demonstrated.<sup>160</sup> The oligonucleotide **29** appeared to be more efficient in the reaction with NF- $\kappa$ B than the dialdehyde derivatives, since in this case  $\beta$ -elimination is excluded and the small size of the 2'-O-(2-oxoethyl) residue allows the  $\epsilon$ -amino groups of lysine to approach the most close to DNA. The advantage of this methodology is the possibility to vary the position of the modified unit and the number of modifications in the oligonucleotide. The yields of the addition products of the transcription factor NF- $\kappa$ B to DNA ligands were 8% - 10%.

It was proposed<sup>161</sup> that the DNA ligands **29** were used for the study of the mechanism of functioning of DNA methyltransferase SsoII. With a set of duplexes containing one or two modifications in the recognition site, two types of DNA-protein conjugates have been obtained in 70% yields. From determination of molecular masses of such conjugates it was suggested that DNA methyltransferase SsoII interacts with DNA as a dimer.

Oligonucleotides **31** containing a 2-deoxyribonolactone fragment were used for the covalent binding of some repair enzymes.<sup>162,163</sup>

$\text{R}^1, \text{R}^2$  are fragments of the oligonucleotide chain, the protein is endonuclease III or human DNA polymerase.

Such oligonucleotides appeared to be versatile for the covalent addition of various excision repair proteins. It was suggested<sup>164</sup> that the oligonucleotides **31** were used for the synthesis of oligonucleotides **32** containing furan-2(5H)-one at the 3'-end of the chain.

$R^1, R^2$  are fragments of the oligonucleotide chain.

The latter represent substrates for only those BER enzymes that catalyse  $\beta, \delta$ -elimination of the apurine site, which allows selective binding of these proteins, particularly, in cellular extracts.

#### d. Modification of nucleic acids at the heterocyclic bases

It has been noted above that the introduction of reactive groups into heterocyclic bases is seldom used for modification of NA. Nevertheless, such examples are known. In particular, substituents containing  $-\text{SH}$  or  $-\text{SS}$  groups were introduced into the heterocyclic base in order to achieve covalent binding of cysteine-containing proteins to DNA through formation of disulfide bridges. Introduction of these groups into the oligonucleotide allows its covalent binding to the protein either by thiol–disulfide exchange or as a result of oxidation of the thiol groups under the action of atmospheric oxygen.

The thiol–disulfide exchange

proceeds efficiently at room temperature in water at physiological values of pH despite the fact that this reaction includes the cleavage and formation of a stable covalent  $\text{S}—\text{S}$  bond with the energy of  $60 \text{ kcal mol}^{-1}$  (see Ref. 165). The formation of the disulfide bond through the oxidation of thiols by oxygen occurs in two steps.<sup>166</sup>

For the first time, the formation of a disulfide bond in the DNA–protein complex has been used in order to confirm the specificity of binding of a modified oligonucleotide ligand to the active site of (methylguanine)–DNA methyltransferase (MGMTase) of *E. coli* containing a cysteine residue.<sup>167</sup> The action of this key repair enzyme is directed at the removal of the methyl and other alkyl groups from position O(6) of guanine or from position O(4) of thymine by their transfer to the cysteine residue in the active site of the protein. In the ‘dormant’ state, the cysteine residue is localised inside the protein globule.<sup>168</sup> It was assumed that the binding of MGMTase to the substrate or its repair are accompanied by conformational rearrangements; however, the information on the nature of these changes was absent. In order to corroborate this hypothesis, 2-amino-6-cystamino-2'-deoxy- $\beta$ -D-ribofuranosyl purine (**33**) was introduced into the 21-membered oligodeoxyribonucleotide instead of deoxyguanosine by automated synthesis.

The modified oligonucleotide containing the fragment **33** was incorporated into NA and the disulfide bond was reduced by dithiothreitol (DTT). A covalent bond between the double-stranded oligonucleotide and MGMTase was formed under the action of atmospheric oxygen (the yield of the NA–protein conjugate was low). The formation of the disulfide bond between DNA and the protein was confirmed by its cleavage with DTT. Analysis of the primary structure of the polypeptide fragment covalently bound to the oligonucleotide confirmed the fact that it was cysteine that was involved in the formation of the disulfide bridge. Supporting evidence for the involvement of this amino acid residue in the formation of the covalent complex MGMTase–DNA was obtained in the following experiment. The cysteine residue in the active site of the enzyme was methylated by its incubation with an oligomer containing an O(6)-methylguanosine residue. The protein obtained did not form conjugates with reduced DNA substrates containing the nucleoside analogue **33** with a free thiol group. These studies have shown that MGMTase undergoes conformational rearrangements during its functioning which favour the convergence of the cysteine residue to the alkylated guanosine derivative.<sup>167</sup>

A similar approach based on the site-specific attachment of proteins to reactive analogues of DNA aimed at the formation of disulfide bonds was used<sup>169</sup> in order to establish the contacts in the active complex of HIV integrase with viral cDNA. At the beginning, additional cysteine residues were introduced into the predetermined positions of integrase by site-directed mutagenesis and modified fragments of 2'-deoxyadenosine containing a disulfide group at the N(6) atom were introduced into the predetermined positions of DNA by automated synthesis. It was expected that the cysteine residue in the DNA–protein complex would be localised in the vicinity of the modification site of DNA, since thiol–disulfide exchange demands a more ‘close’ arrangement of two interacting groups than photo-induced covalent addition.

The reactivity of DNA **34** containing a disulfide group could be enhanced by converting it into the thiol form by treatment with DTT; the reaction of DNA **35** with the cysteine residue of a protein occurs upon oxidation with atmospheric oxygen. Treatment of DNA **35** with 5,5'-dithiobis(2-nitrobenzoic acid) yields an even more reactive DNA derivative **36**.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain; *n* = 2, 3.

It is of note that the introduction of reactive groups at N(6) of adenine does not influence its ability to form Watson–Crick hydrogen bonds.

It was found that the yields of covalent binding products of the highly reactive substrates **36** to all mutant forms of integrase containing single additional cysteine residues are nearly identical. The use of less reactive substrates **35** or **34** is recommended to increase the specificity of the covalent binding. In fact, the required specificity of the covalent binding was achieved with the least reactive oligonucleotides **34**: a noticeable yield of the conjugate was observed only for one mutant form of integrase. It was shown also that the use of a propylene linker instead of an ethylene linker increases significantly the yields of the protein–nucleic acid conjugates. The effect of 2-mercaptoethanol as an additive on the yields of the protein–nucleic acid conjugates has also been examined.<sup>167</sup> It was shown that high concentrations of 2-mercaptoethanol (> 5 mmol litre<sup>-1</sup>) block completely the formation of the reaction product; however, lower concentrations (2 mmol litre<sup>-1</sup>) enhance the specificity of the covalent binding of HS- and SS-containing DNA. Under these conditions, the formation of the protein–nucleic acid complex is reversible and spatially close arrangement of the reactive groups is the only prerequisite for cross-linking.

These studies have demonstrated the *trans*-interaction between viral cDNA and integrase, *i.e.*, the enzyme–substrate complex represents a DNA bound to the C-terminal domain of one integrase monomer and the catalytic domain of the other integrase monomer. Moreover, site-specific covalent binding revealed conformational changes in the integrase–DNA complex concomitant with the terminal processing reaction.

Oxidation of thiol groups by atmospheric oxygen was successfully used in the synthesis of a covalently bound complex of reverse transcriptase of HIV-1 with a DNA duplex consisting of a matrix and a primer. This reaction was carried out in the presence of deoxynucleoside triphosphates, which provided the formation of a functionally active supramolecular associate.<sup>170, 171</sup> The reactive mercaptoalkyl group was introduced at the amino group in position 2 of guanine (compound **37**). This group was localised in the small groove of DNA and was spatially close to the cysteine residue<sup>‡</sup> of the H helix of reverse transcriptase. One of the conjugates (complex **38**) was crystallised and examined by X-ray

diffraction, which made it possible to determine the structure of the reverse transcriptase complex with the primer, the DNA template and 2'-deoxynucleoside triphosphate.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain; *n* = 2, 3; the protein is HIV-1 reverse transcriptase.

A similar strategy was used for the study of conformational changes in reverse transcriptase during its binding to 2'-deoxynucleoside triphosphate.<sup>172, 173</sup>

He and Verdine<sup>174</sup> used the oligonucleotide **39** containing a cytidine residue modified at the amino group for the study of the N-terminal domain of the mutant Ada-protein from *E. coli*. Studies of specific covalent addition of modified DNA **39** to mutant proteins has made it possible to establish some DNA–protein contacts.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain.

#### e. Miscellaneous examples of modification of nucleic acids

It was suggested<sup>175–178</sup> that oligodeoxyribonucleotides containing phosphoryl disulfide and diphosphoryl disulfide groups in the sugar–phosphate backbone were used for selective binding of cysteine in proteins and peptides. Interaction of DNA methyltransferase SsoII with DNA containing a methylated site was studied using a series of DNA duplexes where one of the phosphodiester internucleotide bonds was replaced by the phosphoryl disulfide (PDS) group (one of the duplex strands represented a modified oligonucleotide **40**).<sup>179, 180</sup> The modified bond was introduced into the positions directly flanking the methylated cytidine residue using thiol–disulfide exchange between the 3'-thiophosphorylated oligonucleotide **41** and the 2-pyridyldithio-substituted oligonucleotide **42**.

<sup>‡</sup> The cysteine residue was introduced instead of glutamine into the native enzyme using site-directed mutagenesis.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain; B<sup>1</sup>, B<sup>2</sup> are heterocyclic bases.

This reaction proceeded with equal efficiency both in the presence and in the absence of the template oligonucleotide.<sup>177, 178, 180</sup> It was shown that PDS-containing DNA duplexes form conjugates with M.SsoII with different degrees of efficiency, which depended on the position of modification.<sup>179</sup>

It is known that the cleavage of the mixed disulfide R<sup>1</sup>SSR<sup>2</sup> by a nucleophilic thiolate ion R<sup>3</sup>S<sup>-</sup> results in the formation of a more stable anion R<sup>1</sup>S<sup>-</sup> and a new mixed disulfide R<sup>3</sup>SSR<sup>2</sup> (see Refs 165 and 181). With regard to PDS-containing DNA duplexes, this suggests that the thiolate ion attacks the sulfur bound to the carbon atom (but not the sulfur bound to phosphorus), since thiophosphoric acid is a much stronger acid than thiol. This was confirmed experimentally by an analysis (PAAG electrophoresis and mass spectrometry) of conjugates of PDS-containing DNA duplexes with M.SsoII (Scheme 7) and glutathione, a simple tripeptide model of cysteine-containing proteins.<sup>179</sup>

Scheme 7

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain.

The internucleotide PDS bond within DNA is selective with respect to the cysteine residues and does not react with the ε-amino group of lysine.<sup>179</sup>

It is of note that the formation of a new disulfide bond between the cysteine residue and the PDS group is only possible where these are spatially close in the supramolecular DNA–protein complex. It has been shown<sup>182</sup> that the formation of the conjugate of the restriction endonuclease SsoII (R.SsoII) and the DNA

duplex containing a PDS group in the recognition site proceeds with an extremely low efficiency. This phenomenon was attributed to the remoteness of the Cys residue from the binding and catalytic sites of R.SsoII. Evidence for this hypothesis can be derived from the fact that the R.SsoII variants in which the Arg-(116, 117, 119) or Lys-122 residues interacting with the sugar–phosphate backbone of DNA were replaced by the Cys residue form conjugates with PDS-containing DNA substrates in high yields.<sup>182</sup>

### III. Natural protein–nucleic acid conjugates formed in the enzymatic reactions

Reactions of certain enzymes with NA yield unstable intermediates which represent covalently bound biopolymer complexes. In some cases, dissociation of these intermediates can be prevented by modification of NA and they can be investigated.

The transfer of the methyl group onto 5-fluoro-2'-deoxyuridine monophosphate by thymidylate synthase is a classical example of an enzymatic reaction which results in the formation of a stable covalently bound protein–nucleic acid complex.<sup>183</sup> Substitution of the fluorine atom for the hydrogen atom in 2'-deoxyuridine monophosphate prevents the cleavage of the nucleotide–enzyme bond.<sup>184</sup> Cytosine-5-DNA methyltransferases and methyltransferases that react with RNA also belong to enzymes that form conjugates with oligonucleotides. Oligonucleotides containing a 5-fluorocytidine or 5-fluoro-2'-deoxycytidine residues (compound 43) are widely used for the stabilisation of such conjugates.

A more detailed description of these processes is given in the reviews;<sup>10, 185</sup> see also Ref. 186.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain, protein is cytosine-5-DNA methyltransferase, SAM is S-adenosyl-L-methionine.

Landy *et al.*<sup>187–189</sup> studied the covalent binding of DNA to recombinases catalysing the homologous recombination of DNA in the cross-like structures A (the Holiday structures) (Scheme 8) resulting in transfer of fragments of one region of a genome into the other region.

Scheme 8

Hereinafter, are the strands of recombining fragments of DNA.

The mechanism of action of recombinases includes an attack of the hydroxy group of tyrosine on the internucleotide phosphate of DNA (Scheme 9) resulting in the cleavage of the phosphodiester bond and the formation of a conjugate between the 5'-terminal site of DNA and recombinase with subsequent ligation

Scheme 9

Scheme 10

of recombining DNA fragments and release of recombinaise. It was suggested that shortened oligonucleotides were used so that cleavage in a single strand resulted in dissociation of the short 3'-terminal fragment of DNA. This prevented recombination in the ligation step and, as a consequence, stabilised the recombinaise–DNA conjugate.

It was suggested<sup>190, 191</sup> that modified DNA containing phosphorothioate internucleotide bonds (Scheme 10) were used for the study of covalent binding of topoisomerases.<sup>8</sup> No ligation took place after the formation of the protein–nucleic acid conjugate **B**, since the replacement of the P–O bond by the P–S bond is energetically unfavourable. This enabled selective inhibition of topoisomerase I and isolation of a conjugate in high yield.

The modified oligonucleotide **44** was used<sup>192</sup> for the study of the mechanism of action of MGMTase. The reaction of the oligonucleotide **44** with MGMTase containing a cysteine residue in the active site gave the conjugate **45**. Even in the presence of a 10-fold excess of the protein this reaction was rather slow (48 h).

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain.

In a review<sup>193</sup> on bifunctional DNA glycosylases, which possess N-glycosylase and β-lyase activities, the formation of the

Shiff base **46** upon reaction of the lysine side amino group of DNA glycosylase with an apurine site of the oligonucleotide was considered as a key reaction; subsequent reduction was aimed at the access to the stable conjugate **47**.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain; the protein is DNA glycosylase.

Strengthening of the bond between the enzyme and the substrate by the reduction of the Schiff base has also been used elsewhere.<sup>194–197</sup> Detailed studies of the mechanism of this reaction were carried out using model peptides.<sup>198</sup> Virtually all studies on glycosylases<sup>193</sup> made use of MutY from *E. coli*<sup>194–196</sup> and human endonuclease III.<sup>197</sup> Study of 8-oxoguanine-DNA glycosylase made it possible, for the first time, to establish the involvement of one of the reaction products, viz., 8-oxoguanine, in the cascade of reactions triggered by the β-lyase activity of this enzyme.<sup>199</sup>

It is of note that this approach cannot be applied to monofunctional DNA glycosylases, since they function according to a different mechanism which includes cleavage of the N-glycosidic bond with the participation of the water molecule.

R<sup>1</sup>, R<sup>2</sup> are fragments of the oligonucleotide chain; the protein is DNA glycosylase

#### IV. Identification of protein sites covalently bound to nucleic acids

Amino acid residues in the proteins involved in the complex formation with NA can be identified by direct and indirect methods. The former entail isolation of the NA–protein conjugate, partial cleavage of the protein, isolation of an oligonucleotide–peptide fragment and elucidation of the primary structure of the peptide and identification of the amino acid involved in the formation of the covalent bond. The latter make use of mutant proteins and X-ray diffraction analysis. The amino acid residue of the protein, which is thought to react with DNA, is replaced by a non-reactive residue with subsequent analysis of whether the covalent bond is formed between the protein and the oligonucleotide.<sup>162, 163</sup> Obviously, this method is inapplicable to photoactivatable NA, which react with any amino acids. Data from X-ray diffraction on the arrangement of side groups of amino acid residues are used as evidence of proximity of definite amino acids of the protein to the specific fragment of NA.

Let us consider the direct method used for the analysis of protein–nucleic acid conjugates in more detail. The conjugates are usually isolated by polyacrylamide gel (PAAG) electrophoresis under denaturing conditions (Table 1).

The analysis of the data presented in Table 1 suggests that the conditions of isolation of protein–nucleic acid conjugates are analogous or are much the same as those used for the separation of

proteins by PAAG electrophoresis according to Laemmli (12.5% PAAG, 250 mM Tris–HCl, 0.1% sodium dodecyl sulfate, pH 8.8).<sup>202</sup> The conjugate is eluted from the gel using a buffer in which subsequent partial cleavage of the protein is carried out. In some cases, the isolated product is desalted, dialysis being the most efficient and versatile procedure.

Medium-pressure ion-exchange chromatography (FPLC MonoQ HR5/5)<sup>203</sup> and anion-exchange HPLC (Porous HQ, PerSeptive Biosystems),<sup>204</sup> which permit separation of the DNA–protein conjugate from the nonbound protein, are also used for the isolation of conjugates.

The protein and the covalently bound biopolymer complex were precipitated with 10% trichloroacetic acid or antibodies, which made it possible to separate the bulk of the nonbound NA.<sup>69, 74, 205</sup> Dialysis of the reaction mixture can also be used for this purpose.<sup>100</sup> Nucleic acid–protein conjugates could be separated from excess protein if oligonucleotides carrying biotin at the 3'-end were used with subsequent immobilisation of the oligonucleotide (both free and within the conjugate) on avidin-coated magnetic particles.<sup>74</sup> Isolation of NA and the NA–protein conjugate by affinity chromatography was described.<sup>76</sup> To this end, an oligoadenylate sequence (oligo-dA) was attached to the 3'-end of a modified oligonucleotide followed by chromatography on a microcolumn with oligothymidylate-cellulose (oligo-dT). In this case, the separation of the complex from NA was achieved due to the formation of the oligo-dA · oligo-dT duplex.

It should be noted that the purification of the covalently bound protein–NA complex is not compulsory and in some cases<sup>12, 79, 88, 206</sup> the covalent binding is immediately followed by the next stage, *viz.*, partial chemical or enzymatic cleavage of the protein.

The methods for the cleavage of the protein within the protein–nucleic acid complex are summarised in Table 2.

The data listed in Table 2 suggest that such proteases as trypsin and chymotrypsin are most commonly used for partial cleavage of the protein component of the conjugate. Enzymatic treatment is carried out in weakly alkaline solutions under

**Table 1.** Isolation of a NA-protein conjugate by gel electrophoresis.

| Protein                                       | Composition of gel <sup>a</sup>                                                              | Conditions of isolation from gel                                                                                             | Desalting conditions                                                               | Ref.    |

<sup>a</sup>The concentration of the reagent ( $c_A$ ) or the enzyme:substrate ratio (A : B). <sup>b</sup>Preliminary denaturation of the protein–nucleic acid conjugate.

<sup>c</sup>Functionalisation with 3-bromo-3-methyl-2-(2-nitrophenylsulfenyl)-3*H*-indole. <sup>d</sup>Preliminary denaturation of the protein–nucleic acid conjugate and treatment with iodoacetic acid. <sup>e</sup>Preliminary treatment of the protein–nucleic acid conjugate with iodoacetamide.

denaturing conditions. In some cases, preliminary denaturation of the protein, reduction of the disulfide bonds and alkylation of the thiol groups of cysteine with iodoacetic acid or iodoacetamide are performed in order to reduce the proteolysis time and to obtain more homogeneous protein–nucleic acid conjugates. Proteinase K is often used for the treatment of analytical amounts of protein–nucleic acid conjugates; however, this enzyme is not used in a large scale due to its low specificity, which results in the formation of a mixture of peptide–nucleic acid conjugates and, as a consequence, prevents the identification of the covalently bound site of the protein. Nevertheless, the use of proteinase K permits a comparison of stabilities of DNA–protein conjugates and of the original protein, which facilitates the selection of conditions for the trypsinolysis of a conjugate in subsequent studies.

Partial cleavage of the protein is followed by purification of the peptide–oligonucleotide conjugate. This is achieved by

reversed-phase HPLC, gel filtration, anion-exchange HPLC and PAAG electrophoresis (Table 3). Elucidation of the primary structure according to Edman or using mass spectrometry demands preliminary isolation and desalting of the conjugates. The most efficient chromatographic procedures make use of buffer solutions based on volatile salts, *e.g.*, ammonium formate or triethylammonium acetate. In this case, multiple evaporation with water or aqueous ethanol is sufficient to desalt the conjugate isolated by HPLC. However, in some cases protein admixtures cannot be removed by reversed-phase HPLC and gel filtration, and a two-step purification procedure of a conjugate seems to be more reliable, first, by anion-exchange HPLC or electrophoresis in PAAG with subsequent desalting by microcolumn gel filtration or reversed-phase chromatography or ultracentrifugation. The transfer of a conjugate to poly(difluorovinylidene) (PVDF) membrane (blotting) with subsequent determination of the primary

**Table 3.** Isolation of peptide–oligonucleotide conjugates.

<sup>a</sup> Abbreviations: SP, spectrophotometric detection (the wavelengths, nm, are indicated in parenthesis); RA, autoradiographic detection; MS, mass-spectrometric detection. <sup>b</sup> HEPES is 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid.

structure of the peptide in the immobilised NA–peptide complex has been described. The transfer of conjugates onto anion-exchange filters is also used.<sup>207</sup>

The final step includes determination of the primary structure of the covalently bound peptide using chemical or enzymatic sequencing. In some studies,<sup>37, 67, 74, 76, 79, 81, 87, 88, 96, 100, 201, 205</sup> the primary structures of the proteins were determined by sequencing

which included chemical degradation according to Edman.<sup>208</sup> This procedure is usually performed on automatic sequencers, which demands significant amounts of the conjugate (50–150 pmol). The substituted amino acid is determined by the absence of a standard *N*-phenylthiocarbonyl derivative (the so-called ‘blank’ sequencing cycle). In the case of incomplete purification of the conjugate, *i.e.*, when a mixture of oligonucleotide–

peptide conjugates differing in one or two amino acids is present in the solution, the use of this approach is significantly complicated.

An interesting approach to determination of the primary structure of a cross-linked peptide was proposed by Mucke *et al.*<sup>96</sup> These authors carried out a comparative analysis of trypsinolysis products of free restriction endonuclease EcoRII and its conjugate with an oligonucleotide using reversed-phase HPLC. A short protein–nucleic acid conjugate was not absorbed on the column and the ‘extra’ fragment present in the tryptic hydrolysate of the free protein could unambiguously be determined. Sequencing of this peptide allowed identification of the amino acid that reacted with the 5-iodopyrimidine residue of NA. Unfortunately, this method is not versatile, since the presence of several reactive residues in the peptide under study casts doubts on the structure of the conjugate.

Sequencing of peptides can also be performed using mass spectrometry.<sup>209–215</sup> A comparison of several approaches to the determination of substituted amino acids using mass spectrometry has been carried out.<sup>92</sup> Currently, determination of molecular masses and sequencing of biopolymers are usually performed using matrix-assisted laser desorption/ionisation (MALDI)<sup>209</sup> and electrospray ionisation (ESI) mass spectrometry.<sup>210</sup> In MALDI MS, the biomolecule is separated from the neighbouring molecules using matrices, *i.e.*, various low-molecular-mass aromatic compounds excitable under the action of laser irradiation. Irradiation of samples is accompanied by ionisation of a biomolecule with the predominant formation of a single-charged ion. In ESI MS, the solution containing the biopolymer is fed into the ionisation chamber of the mass spectrometer through a capillary. Application of a strong electrostatic field results in the formation of ionised aerosol at the capillary tip. The ionisation of the biopolymer occurs after evaporation of the solvent.

In the analysis of proteins, it is positively charged ions that are registered, while negatively charged ions are recorded in the analysis of oligonucleotides, which is the main problem in the use of MS for the characterisation of protein–nucleic acid conjugates. Nevertheless, some authors believe<sup>216–218</sup> that MALDI MS and ESI MS can be used for detecting and sequencing of these conjugates. The choice of an effective matrix in the sequencing of protein–nucleic acid conjugates by MALDI MS is a central task, since no versatile matrices for the detection of both peptides and oligonucleotides exist. The mass-spectrometric analysis of protein–nucleic acid conjugates by ESI MS is facilitated by removal of the nucleic acid component using enzymatic degradation of NA.<sup>70, 83, 87, 219, 220</sup> The advantage of the ESI MS is the possibility of its application for the analysis of fractions after high-performance liquid chromatography or electrophoresis.

In the study,<sup>92</sup> the structure of a DNA–protein conjugate was determined by mass spectrometry. After partial trypsinolysis of the isolated conjugate, the reaction mixtures were analysed by MALDI TOF (time-of-flight) MS and the data obtained were compared with the analogous data for the free protein. This enabled determination of the peptide fragment covalently bound to DNA. The use of proteinase K instead of trypsin has made it possible to diminish the peptide fragment to four amino acid residues. However, the amino acid covalently bound to the oligonucleotide could only be determined after complete degradation of DNA by phosphodiesterase and alkaline phosphatase and subsequent sequencing of the resulting DNA–protein conjugate by tandem nanoESI MS.<sup>†</sup>

Tandem MS entails the presence of two consecutively arranged detectors with an ionisation chamber in-between. The first detector permits the passage of only ions with a definite mass/charge ratio into the ionisation cell. These undergo fragmentation in the ionisation chamber. The ionisation products (the so-called

daughter ions) pass into the second detector for determination of the primary structure of the peptide. As a rule, this method allows determination of amino acid sequences in proteins containing up to 30 amino acids.

Tandem ESI MS is the most efficient method for the determination of the structures of peptide–oligonucleotide conjugates and, hence, of the target amino acid. The use of tandem nanoESI MS<sup>92</sup> has made it possible to determine the structure of a protein at its content in the solution of about  $10^{-10}$  moles. However, low yields of the conjugates and inevitable losses in numerous intermediate steps require femtomolar amounts of the protein. The sensitivity of mass-spectrometric methods was found to exceed significantly those of traditional sequencing methods based on the Edman procedure, since they permit direct determination of the attached amino acid from its molecular mass (tandem MS) and direct sequencing of both the oligonucleotide and the peptide and do not require thorough purification of the samples.

The use of mass-spectrometric techniques for the determination of the structures of the attached peptides has also been considered elsewhere.<sup>206, 207, 219, 221, 222</sup> However, despite the obvious merits of mass spectrometry in the analysis and determination of structures of peptide–oligonucleotide conjugates, this method has not found wide application due to low accessibility of tandem mass spectrometers.<sup>†</sup>

Hybrid instruments, *e.g.*, quadrupole time-of-flight (Q-TOF) and Fourier-transform ion-cyclotron resonance mass spectrometers,<sup>92</sup> (FTICR) and quadrupole ion traps<sup>92</sup> (QIT), are used along with traditional time-of-flight mass spectrometers with a linear detector designed for the study of biomolecules. The use of FTICR MS ensures a much higher accuracy in the determination of molecular masses ( $> 10$  kDa) in comparison with TOF MS; however, its high cost and complexity of calibration for the analysis of peptide–oligonucleotide conjugates make them unclaimed, at least at present. Mass spectrometers supplied with quadrupole ion traps do not ensure the resolution comparable to that of TOF MS. A more detailed description of various mass-spectrometric techniques used in the study of structures of protein–nucleic acid complexes and conjugates can be found in the reviews.<sup>224–226</sup>

<sup>†</sup> The prefix ‘nano’ designates that the solution in the capillary is fed at the rate of  $\text{nl s}^{-1}$  (this enables to reduce the amount of the protein and to increase the sensitivity of the detector).

<sup>†</sup> In the past decade, significant investments were made to investigations in the field of proteomics,<sup>223</sup> which made it possible to increase significantly the number of tandem mass spectrometers.

**Abstract.** The state-of-the-art in investigations into the supramolecular catalysis by metal complexes using macrocyclic receptor molecules is surveyed. The emphasis is placed on issues related to the design of novel metal complex catalysts capable of molecular recognition and to their applications in organic synthesis, in particular, in such reactions as hydrogenation, hydroformylation, carbonylation, hydroxylation, Wacker oxidation, biomimetic oxidation, and some others. The factors affecting the activity, stability and selectivity of such catalytic systems are discussed. The bibliography includes 159 references.

## I. Introduction

Nowadays, the vast majority of industrial processes are based on catalytic reactions. Catalysts are utilised in diverse fields ranging from large-scale processes, such as petroleum refining, hydro-treatment, production of ammonia, *etc.*, to the synthesis of drugs and chemical reagents and sewage and exhaust gas purification. In this respect, catalysis is a key element of technological progress, since development and implementation of new highly efficient and selective catalysts will stimulate production and contribute to the solution of global problems, such as rational exploitation of natural resources and environmental protection.

Although numerous homogeneous and heterogeneous catalysts for oxidation, hydrogenation, hydroformylation, carbonylation, *etc.* are known, these catalysts do not always possess high selectivity for reactions involving substrates with several active sites. Furthermore, if the substrates contain heteroatoms, systems of conjugated bonds and functional groups, the reactions should be carried out under conditions as mild as possible in order to avoid side reactions, *e.g.*, isomerisation or decomposition. Ordinary catalysts often exhibit low activities or selectivities under mild conditions. Metal complex catalysts represent an important alternative.

The application of principles of supramolecular chemistry, which deals with studies of ordered molecular ensembles secured

by intermolecular forces,<sup>1–5</sup> to catalysis has an enormous potential in the design of novel highly selective catalysts. The design of compounds capable of molecular recognition of cations, anions or neutral molecules is the main area of progress in the chemistry of molecular ensembles and intermolecular bonding. When such compounds are used as catalysts, the conversion of reactants into reaction products is preceded by formation of a ‘supramolecule’ due to selective binding of a substrate molecule by the respective receptor molecule.<sup>1,6,7</sup> This approach enables development of catalysts whose activity and selectivity is governed by the intermolecular interactions of a substrate with the catalyst.

Among molecules capable of molecular recognition, macrocyclic receptors (*e.g.*, cyclodextrins and calixarenes) are of primary interest. These can form host–guest complexes with substrates due to intermolecular interactions, such as van der Waals forces or H bonds.<sup>1–7</sup> These molecules possess hydrophobic cavities with diverse shapes enabling selective binding of the substrates that match the size and shape of the cavity, which implies molecular recognition.<sup>1,8,9</sup>

The present review is devoted to issues related to the design of novel metal complex catalytic systems containing macrocycles, primarily cyclodextrins and calixarenes.

It is of note that, despite intense development of investigations into supramolecular catalysis,<sup>8</sup> it is only recently that macrocyclic receptor molecules capable of molecular recognition have started to be exploited as components of metal complex catalytic systems, predominantly as models of enzymes.<sup>7,10–13</sup> The number of publications on this subject is relatively small as compared to, for instance, supramolecular catalysis with the use of dendrimers, which has been thoroughly surveyed.<sup>14–20</sup>

Cyclodextrins are cyclic oligomers built up of 1,4-linked D-glucopyranose residues.<sup>21–27</sup>

**Figure 1.** The arrangement of the hydroxy groups in cyclodextrins (a), the sizes of cyclodextrin molecules and of their internal cavities (b).

The most common representatives of this class are  $\alpha$ -,  $\beta$ - and  $\gamma$ -cyclodextrins containing, respectively, 6, 7 and 8 glucose residues. The size of the cavity inside the macrocycle increases from 5.7 Å to 9.5 Å on going from  $\alpha$ - to  $\gamma$ -cyclodextrin (Fig. 1). The hydrogen atoms H(3) and H(5) are always directed inward, toward the molecular cavity, whereas the hydroxy groups are directed outward. As a result, a hydrophobic cavity is formed, which is capable of accommodating fragments of molecules with suitable sizes and polarities to yield respective host–guest complexes. In the case of calixarenes, which represent cyclic oligomers of phenol and formaldehyde with different numbers of aromatic units, the non-polar cavity formed by several monomeric units has a bowl-like shape.<sup>28–32</sup> An increase in the number of these units from 4 in calix[4]arene to 8 in calix[8]arene substantially increases the sizes of the macrocycle and the cavity (Fig. 2a). Both cyclodextrins and calixarenes can readily be functionalised with various complex-forming groups, which allows synthesis on their base of metal complex catalysts capable of molecular recognition.

**Figure 2.** Calixarenes (a) and ‘molecular clips’ (b).

A few examples of metal complex catalysts based on other macrocycles, *e.g.*, modified ‘molecular clips’ [synthesised from diphenylglycoluril (Fig. 2b)] and cyclophanes will also be given.

The review is subdivided into two sections. The first considers catalytic systems involving non-coordinated macrocyclic receptors. The second section is devoted to metal complex catalysts where the corresponding receptor molecules act as ligands.

## II. Metal complex catalytic systems based on non-coordinated receptor molecules

Catalytic systems based on metal complexes can include compounds capable of forming host–guest complexes as their components. In the first step, the formation of an inclusion complex of the macrocyclic receptor with either the metal complex or the substrate occurs. Thus, the macrocyclic receptor can affect the mechanism of a catalytic process in two ways that are depicted in Figs 3 and 4.

**Figure 3.** Formation of a host–guest complex with the substrate. A is a substrate; B<sup>1</sup> and B<sup>2</sup> are inclusion complexes with the substrate; L<sub>x</sub>M is a metal complex; C is an inclusion complex with the product; D is a reaction product.

**Figure 4.** Formation of a host–guest complex with the metal complex L<sub>x</sub>M.

A is an inclusion complex, B is a substrate, C is the inclusion compound metal complex–substrate, D is a reaction product.

In the first case, which is postulated in the majority of studies, the substrate inclusion complex rather than the substrate itself is involved in the catalytic cycle. The selectivity of the reaction with respect to the substrate is determined by the stability of the respective host–guest inclusion complex, which in turn depends on the size and structure of the host molecule (see Fig. 3).

The host molecule acts as a ‘microreactor’ and can stabilise the transition state of the reaction thus increasing its rate.<sup>1,6,7</sup> Furthermore, the formation of the inclusion complex can significantly affect the regio- and stereoselectivity of the process by favouring a specific orientation of the substrate (complexes B<sup>1</sup> or B<sup>2</sup>). Some parts of the substrate molecule can be shielded and thus escape reaction. The reaction product can also form an inclusion complex with the receptor (C). This leads to a decrease in the concentration of the receptor molecules and to deceleration of the reaction [the so-called product inhibition effect (see Fig. 3)].

In the second of the two above cases, it is a ligand or the metal complex itself that acts as a guest in the formation of the inclusion complex (see Fig. 4). The role of the macroligand-host can consist of stabilisation of a catalytically active complex and the respective

activated complex or of the ligand environment of the metal atom. The regioselectivity and stereoselectivity of the reaction are governed by the orientation of the substrate in the metal complex.

The stability of the host–guest complex strongly depends on the nature of the solvent used for the reaction. In aqueous media, it is the hydrophobic interactions that make the dominant contribution to the energy of formation of the complex and thus substantially enhance its stability. In this respect, the use of calixarenes and cyclodextrins as components of biphasic catalytic systems based on water-soluble metal complexes is of particular interest.<sup>13, 33–35</sup> An advantage of this approach is that the water-soluble catalyst can easily be separated from insoluble products and recycled.

It should be stressed that the activities of traditional catalysts in the case of substrates poorly soluble in water are low. Owing to the formation of the host–guest inclusion complexes, the macrocyclic receptors can both affect the activity and the selectivity of the reaction and act as phase-transfer carriers of the substrate from an organic medium to the aqueous phase.

### 1. Oxidation

Catalytic systems involving cyclodextrins and calixarenes have been tested for Wacker oxidation, hydroxylation, oxidative coupling and oxidation of hydrocarbons (Table 1).

Biphasic Wacker oxidation of unsaturated compounds to ketones, catalysed by systems based on palladium and copper salts in combination with different cyclodextrins, has been studied.<sup>36–42</sup> In this case, a complex of cyclodextrin and alkene is formed and transferred to the aqueous phase, where the oxidation reaction occurs (Fig. 5).

Figure 5. Cyclodextrin-assisted Wacker oxidation of alkenes.

The addition of  $\beta$ -cyclodextrin at the optimum concentration accelerates oxidation of dec-1-ene more than 20-fold.<sup>36, 37</sup> The activity of the catalytic system for the oxidation of linear alkenes and dienes depends on the nature of the cyclodextrin. Generally, systems containing  $\beta$ -cyclodextrin are somewhat more active than those containing  $\alpha$ -cyclodextrin and substantially (by several times) more active than  $\gamma$ -cyclodextrin systems. In particular, the initial rate of the oxidation of dec-1-ene in the case of  $\beta$ -cyclodextrin is virtually the same as in the case of  $\alpha$ -cyclodextrin and more than three times higher than in the case of  $\gamma$ -cyclodextrin.<sup>36</sup>

Table 1. Oxidation and hydroxylation reactions catalysed by systems containing receptor molecules.

| Catalytic system                                                                                                                                                                          | Reaction                                                                                                                                                                                                                  | Ref.      |

Presumably, the difference in the activity is due to different stabilities of the respective host–guest inclusion complexes with the substrates. For  $\alpha$ -cyclodextrin, complex formation is hampered by the relatively small volume of its cavity; for  $\gamma$ -cyclodextrin, the entrance to the cavity is too wide such that the resultant complex becomes unstable.<sup>43</sup>

It should be emphasised that the oxidation in the cases where terminal alkenes and isomeric alkenes with internal double bonds were present in the reaction mixture proceeded regioselectively: methyl ketones were the single carbonyl products. The rate of oxidation of non-terminal alkenes is too low due to the structure of the respective inclusion complexes: for such substrates, the double bond occurs inside the cyclodextrin cavity and thus is unavailable for reaction.<sup>36, 38–40</sup> Isomeric ketones were detected as the oxidation products of dec-1-ene in the presence of  $\alpha$ - or  $\gamma$ -cyclodextrins only where the reaction was conducted in a homogeneous solution (water–propan-2-ol), *i.e.*, when no formation of the inclusion complexes occurred.<sup>36</sup>

The substrate selectivity has been revealed for the oxidation of a number of linear alkenes in the presence of the catalytic systems listed in Table 1.<sup>38, 39</sup> In the case of systems containing  $\alpha$ -cyclodextrin, the maximum reactivity at atmospheric pressure of oxygen was found for non-1-ene whereas the system based on  $\beta$ -cyclodextrin is most active towards dec-1-ene.<sup>40</sup> Apparently, these two substrates provide the optimum matches to the sizes of the respective cyclodextrin molecules. This suggestion is further supported by data on the stability of complexes of  $\beta$ -cyclodextrin with linear alcohols: the complex with decan-1-ol is the most stable.<sup>44</sup> At elevated oxygen pressures, hept-1-ene manifested the highest rate of oxidation among alkenes studied.<sup>42</sup> With an increase in the cyclodextrin concentration, the reaction rate first abruptly increases and then remains virtually constant, which could be due to diffusion-limited formation of the complex.<sup>35</sup>

The rate of substrate interphase transfer can be substantially increased if modified  $\beta$ -cyclodextrins are used, in which methyl [2,6-dimethyl- $\beta$ -cyclodextrin (**1**)] or hydroxypropyl (the compounds **3**, **4**) groups substitute some of the hydrogen atoms of the hydroxy groups.<sup>35, 39</sup>

R = Me:  $k + m = 14$  (**1**),  $k + m = 21$  (**2**);  
 R =  $\text{CH}_2\text{CH}(\text{OH})\text{Me}$ :  $k + m = 4$  (**3**), **6** (**4**);  
 R =  $\text{SO}_3^- \text{Na}^+$ :  $k + m = 6$  (**5**);  
 R = Ac:  $k + m = 6$  (**6**), **14** (**7**), **21** (**8**);  
 R =  $(\text{CH}_2\text{CH}_2\text{O})_n\text{H}$ :  $k + m = 8$ ,  $n = 2-5$  (**9**);  
 R =  $\text{CH}_2\text{CH}_2\text{OH}$ :  $k + m = 5$  (**10**).

This gives rise to enhanced activity with retention of the substrate selectivity. The maximum activity with respect to oxidation of alkenes was observed for the system containing  $\beta$ -cyclodextrin **1**, which is well soluble in water and partly soluble in organic solvents thus providing fast phase transfer of the substrate. If respective sulfate (**5** (which is insoluble in the organic phase) is used instead of  $\beta$ -cyclodextrin, the activity drops. Similar results were obtained for permethylated  $\beta$ -cyclodextrin **2** and partially or fully acylated  $\beta$ -cyclodextrins **6–8** that are virtually insoluble in water. A decrease in the binding constant of a methyl ketone, *i.e.*, the reaction product, to the respective cyclodextrins is yet another factor that enhances the activity of catalytic systems containing substituted cyclodextrins. Indeed, no additional stabilisation of the complex of substituted cyclodextrins with the reaction product is possible, whereas for non-substituted cyclodextrins it is achieved through the H-bonding with the hydroxy groups.<sup>35, 41</sup>

The catalytic activity of water-soluble sulfonated and glycidylated calixarenes **11–15** in the Wacker oxidation of alk-1-enes has also been studied<sup>34, 45, 46</sup>

R<sup>1</sup> = R<sup>2</sup> =  $\text{SO}_3^- \text{Na}^+$ :  $n = 1$  (**11**), **3** (**12**), **5** (**13**);  
 R<sup>1</sup> = R<sup>2</sup> =  $(\text{CH}_2\text{CH}_2(\text{OH})\text{CH}_2\text{O})_m$ :  $n = 1$ ,  $m = 2-4$  (**14**),  
 $n = 3$ ,  $m = 2-4$  (**15**); R<sup>1</sup> = R<sup>2</sup> =  $\text{CH}_2\text{NMe}_2$ :  $n = 1$  (**16**);  
 R<sup>1</sup> =  $\text{CH}_2\text{NMe}_2$ , R<sup>2</sup> = Bu<sup>t</sup>:  $n = 3$  (**17**), **1** (**18**).

These systems are characterised both by high chemoselectivity (as regards formation of the respective methyl ketones) and substrate selectivity, which is governed by the correspondence between the sizes of the cavity within the host molecule and the substrate molecule, as for cyclodextrins considered above. In the oxidation of hex-1-ene, the reaction rate is a maximum in the case of water-soluble calix[4]arenes **11** and **14** and calix[8]arene **13**. Similarly, in the oxidation of oct-1-ene, calix[6]arenes **12** and **15** were the most active (Fig. 6).<sup>47</sup> The catalytic activity correlates with the stability constants of the respective host–guest complexes.<sup>44</sup>

| Calixarene                                             | Stability constant ( $k_s$ ) / litre mol <sup>-1</sup> |           |
|--------------------------------------------------------|--------------------------------------------------------|-----------|
|                                                        | hex-1-ene                                              | oct-1-ene |
| Tetrasodium calix[4]arene-tetrasulfonate ( <b>11</b> ) | 280                                                    | 50        |
| Hexasodium calix[6]arene-hexasulfonate ( <b>12</b> )   | 20                                                     | 85        |

In the oxidation of different styrenes, the maximum yield of products was observed where the size of the substrate matched the size of the calixarene cavity: *p*-methylstyrene is the optimum substrate for calix[6]arene **12** whereas styrene is the optimum for calix[4]arene **11**.<sup>47</sup>

Modified  $\beta$ -cyclodextrins have been used as components of catalytic systems for the oxidation of aromatic hydrocarbons. Hydroxylation of benzene with hydrogen peroxide, catalysed by iron ions in a phase-transfer system containing  $\beta$ -cyclodextrin, gave rise to phenol in 29% yield. The yield increased to 69% with

**Figure 6.** The substrate selectivity of the catalytic system  $\text{PdSO}_4\text{--CuCl}_2\text{--water-soluble calixarene}$  in the Wacker oxidation as a function of the nature of the calixarene and the number of carbon atoms in the alk-1-ene.<sup>44</sup>

oxyethylated  $\beta$ -cyclodextrin **9**, which is well soluble both in water and benzene.<sup>34, 48–50</sup>

Upon similar hydroxylation of phenol in the system dichloroethane–water, products with the hydroxy group in the *para*-position, *i.e.*, quinone and hydroquinone, are predominantly formed. The selectivity of hydroquinone formation was >95% with oxyethylated cyclodextrin. The reaction proceeds through the host–guest complexes,<sup>50, 54–57</sup> in which all the carbon atoms of the benzene ring except for that at the *para*-position are shielded, which results in the high selectivity (Fig. 7). Oxidation of alkyl-substituted aromatic hydrocarbons in the presence of oxyethylated cyclodextrins involves the alkyl groups yielding the corresponding ketones as the major products. In these cases, the whole aromatic moiety in the host–guest complexes is shielded against attack, and the reaction has been used in the synthesis of (hydroxyphenyl)acetic acids.<sup>58</sup>

**Figure 7.** Orientation of the phenol molecule in the cavity of cyclodextrin **9** in the hydroxylation (a) and orientation of the hex-1-ene molecule in the cavity of  $\beta$ -cyclodextrin upon oxidation by PhIO (b). The arrows indicate positions available to attack by the active species.

It has been shown that the formation of host–guest complexes with cyclodextrin can also affect the direction of the oxidative oligomerisation of alkylphenol derivatives.<sup>51</sup> In particular, in the

oxidation of *p*-cresol by iron ions, the addition of  $\alpha$ -cyclodextrin substantially increases the yield of a trimer whereas the addition of  $\gamma$ -cyclodextrin favours formation of a dimer. In the latter case, the complex of the dimer and  $\gamma$ -cyclodextrin is insoluble in the reaction medium, which prevents further oligomerisation.

In the oxidation of cyclohexane by a PhIO–iron(III)tetrakis(n-hexadecyloxyphenyl)porphyrin chloride catalytic system, the yield of cyclohexanol (relative to the oxidant consumed) increased from 0.8% to 9% and 14% upon addition of  $\beta$ -cyclodextrin and methylated cyclodextrin **1**, respectively.

In the oxidation of n-hexane by the same catalytic system, an abrupt increase in the comparative reactivity of the methyl groups was observed. This was explained by partial shielding of the secondary C–H groups of the substrate in the host–guest complex that is formed in a biphasic system. The relative reactivity per terminal C–H bond in benzene as a solvent is 0.01 [the unity reactivity corresponds to that of the C(3)–H bond in hexane], whereas the use of catalytic systems containing  $\beta$ -cyclodextrin or 2,6-dimethyl- $\beta$ -cyclodextrin increases this reactivity up to 0.59 and 0.77, respectively.<sup>52</sup>

The oxidation of bicyclic [1-benzyl-1-(3-dimethylamino-propoxy)cycloheptane fumarate] represents yet another example of the influence of  $\beta$ -cyclodextrin on the reaction selectivity.<sup>53</sup> Only C–H bonds of the cycloheptane ring in the molecule undergo oxidation in the presence of  $\beta$ -cyclodextrin whereas the aromatic moiety, being incorporated in a host–guest complex, is shielded and thus does not react. In a biphasic water–substrate system, the ratio of *cis*- and *trans*-isomers of  $\gamma$ -hydroxybicyclic is 7 : 1, while without the receptor, the respective ratio is  $\sim 1 : 1$ . Presumably, this increase in the stereoselectivity is due to specific orientation of the substrate in the inclusion complex.

## 2. Reactions with hydrogen and carbon monoxide

Receptor molecules were also employed as components of metal complex catalytic systems for such reactions as hydrogenation, hydroformylation and hydrocarboxylation (Table 2).

**Table 2.** Catalytic systems containing receptor molecules for reactions with hydrogen and carbon monoxide.

| Catalytic system                                                                                                        | Starting compound | Reagent             | Reaction product                                                    | Ref.      |

**Note.** 1,3-HD is cyclohexa-1,3-diene, COD is cycloocta-1,5-diene, TPPTS is trisodium tris(*m*-sulfophenyl)phosphine, TPPMS is monosodium (*p*-sulfophenyl)diphenylphosphine.

The use of supramolecular catalytic systems for selective hydrogenation and reduction of substrates containing functional groups (*e.g.*, alcohols, aromatic carbonyl compounds, linear aldehydes, dienes, *etc.*) enhanced the activity of metal complex catalytic systems and selectivity of the reactions.<sup>59–72</sup>

Hydrogenation of aromatic aldehydes and ketones by hydrogen in THF in the presence of rhodium(hexa-1,3-diene) chloride results in complete deoxygenation to yield alkylbenzenes. The addition of  $\beta$ -cyclodextrin accelerates the process more than fourfold and enhances the selectivity of hydrocarbon formation.<sup>59</sup> It was demonstrated<sup>75</sup> that alkyl aryl ketones form 1 : 1 inclusion complexes with  $\beta$ -cyclodextrins. In these complexes, the benzene ring is located inside the cavity and thus is protected from the attack by the reagent. This leads to enhanced selectivity of the reaction of the carbonyl group. If  $\alpha$ -cyclodextrin is used instead, the reaction rate drops due to the low stability of the complexes formed by this receptor with aromatic ketones in THF.

Similar effects were observed in the hydrogenation of aromatic ketones catalysed by Ir/Al<sub>2</sub>O<sub>3</sub> and Pt/C.<sup>76,77</sup> In these cases, the addition of  $\beta$ -cyclodextrin to the catalytic system abruptly decreased the yield of the hydrogenation product of the aromatic fragment. Hydrogenation of substituted pyridines catalysed by Pd/C is also decelerated in the presence of cyclodextrins.<sup>78</sup>

The rate of reduction of normal aldehydes by formate anions in the presence of ruthenium(II), rhodium(I) or iridium(I) complexes with sulfonated triphenylphosphine ligands is abruptly decreased upon addition of  $\beta$ -cyclodextrin, which is explained by steric hindrance associated with formation of the inclusion complexes of the aldehyde with cyclodextrin.<sup>60</sup> However, in the case of hydrogenation of the same aldehydes by hydrogen in biphasic systems (water–aldehyde) catalysed by ruthenium complexes with trisodium tris(*m*-sulfophenyl)phosphine (TPPTS), the addition of cyclodextrin significantly increases the yield of the product, *i.e.*, normal alcohol, as in the case of the aforementioned Wacker oxidation. Substituted  $\beta$ -cyclodextrins, *viz.*, hydroxypropyl- (**3**, **4**), hydroxyethyl- (**10**) and 2,6-dimethylcyclodextrins (**1**) are even more active. The latter compound provides the maximum reaction rate, which was explained by the lowest stability of the complex with the reaction product and faster formation of the host–guest complexes.<sup>61,62</sup>

The RhCl<sub>3</sub>–TPPTS system containing  $\beta$ -cyclodextrin is highly active in the hydrogenation of unsaturated acids in aqueous media. The use of  $\beta$ -cyclodextrin both accelerates the reaction and affects its selectivity due to structural features of the inclusion complexes formed. For instance, complete reduction of maleic and fumaric acids in the absence of  $\beta$ -cyclodextrin required 83 h and 104 h, respectively. Meanwhile, in the presence of cyclodextrin, 100% conversion of maleic acid was achieved in 17 h whereas the level of conversion of fumaric acid was still as low as 45% after 96 h. Hydrogenation of acrylic acid was slower than that of cinnamic acid in the absence of cyclodextrin. The opposite situation was observed after the receptor was added to the catalytic system. Presumably, this difference was due to formation of the inclusion complex, where the double bond of the substrate is located inside the cyclodextrin cavity and the active rhodium sites interact with the hydroxy groups of the host molecule. This suggestion also explains the fact that the difference in the hydrogenation rates for the two substrates is substantially decreased if methylated cyclodextrin **1** is used instead of  $\beta$ -cyclodextrin. Furthermore, the degree of hydrogenation of cinnamic acid using the catalytic system containing  $\beta$ -cyclodextrin was 2% after 50 h as compared to 80% after 24 h in the case of cyclodextrin **1**.<sup>63</sup>

Lee and Alper showed<sup>64</sup> that the use of cyclodextrins for the reduction of allylic alcohols to alkenes by hydrogen, catalysed by a system containing aqueous potassium hydroxide and the complex HCo(CN)<sub>5</sub><sup>3–</sup> generated *in situ*, allows one to significantly increase the activity of the catalyst and change the selectivity of the reaction. Without cyclodextrin, a mixture of *cis*- and *trans*-alkenes is obtained whereas *trans*-isomers are exclusively produced in its

presence. However, in the case of those allylic alcohols that should yield terminal alkenes, virtually no reaction occurs. Presumably,<sup>64</sup> the *trans*-selectivity of the reaction is due to formation of a host–guest complex of cyclodextrin and the catalytically active anion HCo(CN)<sub>5</sub><sup>3–</sup>, with subsequent reaction inside the cavity of cyclodextrin. Thus, it represents one of a few examples of a reaction proceeding according to the scheme depicted in Fig. 4. As in the previous cases, the activity of the system depends on the size of the cyclodextrin ring. The yields (%) of the reduction products of cinnamic alcohol in the presence and in the absence of cyclodextrins are listed below.

|                        |    |    |
|------------------------|----|----|
| No cyclodextrin        | 62 | 12 |
| $\alpha$ -Cyclodextrin | 70 | 26 |
| $\beta$ -Cyclodextrin  | 80 | 11 |
| $\gamma$ -Cyclodextrin | 3  | 15 |

Hydrogenation of dienes in a water–benzene system, like reduction of allylic alcohols, yields only *trans*-alkenes, the reaction occurs mainly as 1,2-addition due to shielding of one of the double bonds in the inclusion complex.<sup>65</sup> Hydrogenation of  $\alpha,\beta$ -unsaturated carboxylic acids and of their derivatives gives rise to the products of the C=C bond reduction.<sup>66</sup> It is noteworthy that the use of catalytic systems containing  $\beta$ -cyclodextrin made it possible to achieve high yields of reduction products in the cases of acrylic acid (81%) and methacrylonitrile (80%). Furthermore, in these cases, no dimerisation occurred due to the formation of the inclusion complexes.

Asymmetric hydrogenation of  $\alpha$ -keto esters to *R*-isomers of  $\alpha$ -hydroxy esters is catalysed by a complex of *N,N'*-dimethyl-(1*R*,2*R*)-diphenylethylenediamine with rhodium cyclooctadiene chloride.<sup>71</sup> The addition of  $\beta$ -cyclodextrin to the catalytic system enhances both the reaction rate and the selectivity. It was suggested<sup>71,79</sup> that it is the complex of cyclodextrin and the substrate that reacts; this changes the polarity of the micro-environment and increases the yield of the *R*-product.

The addition of cyclodextrins to catalytic systems containing TPPTS and palladium dichloride substantially increases the rate of hydrocarboxylation of alkenes by carbon monoxide in aqueous media.<sup>35,72</sup> A comparison of different modified cyclodextrins as regards their activities in the hydrocarboxylation of dec-1-ene showed that hydroxypropyl- (**3**, **4**) and poly(oxyethyl)cyclodextrin (**9**) are nearly as active as  $\beta$ -cyclodextrin. Meanwhile, the activity and selectivity of methylated cyclodextrin **1**, as in other reactions studied, were significantly higher. In all cases, the effect of inhibition by the reaction product was observed due to the formation of H bonds between the carboxy group of the substrate and the oxygen atoms of cyclodextrin.<sup>35</sup>

In the example of the hydroformylation reaction catalysed by rhodium complexes in biphasic systems, it was shown that the influence of cyclodextrin on the reaction rate and selectivity can differ substantially depending on the structure of the host–guest complex involved. In the case of the hydroformylation of hex-1-ene by a rhodium complex with monosulfonated triphenylphosphine [(4-NaO<sub>3</sub>SC<sub>6</sub>H<sub>4</sub>)Ph<sub>2</sub>P], *viz.*, HRh(CO)(TPPMS)<sub>3</sub>, the addition of  $\alpha$ -cyclodextrin gives rise to a decrease in the yield of aldehydes from 55% to 11%.<sup>72</sup> A similar effect was observed upon addition of  $\alpha$ -cyclodextrin to the catalytic system based on the complex HRh(CO)(PPh<sub>3</sub>)<sub>3–n</sub>(TPPMS)<sub>n</sub>. Presumably,<sup>67</sup> in this case, a complex of cyclodextrin with TPPMS is formed, which inhibits the reaction.

In contrast, in the hydroformylation catalysed by a rhodium complex with trisulfonated phosphine (TPPTS), the addition of  $\beta$ -cyclodextrin, acylated cyclodextrin **7** or 2,6-dimethylcyclodextrin **1** increased the yield of aldehydes from 6% to 19%, 45% or even 80%, respectively.<sup>35,68–70</sup> The selectivity of aldehyde formation is also enhanced from 60% (without cyclodextrin) to 95% (in the presence of cyclodextrin **1**). This system also manifests the substrate selectivity related to different stabilities of the respective

inclusion complexes: the reaction rate in the case of dec-1-ene is significantly higher than that for undec-1-ene or dodec-1-ene. Vinylcyclohexane, styrene, propenyl- and butenylbenzenes react faster than *n*-alkenes. Finally, alkenes with an internal double bond are virtually inert in this reaction since such a bond is shielded in the inclusion complex.

The increase in the activity of the catalytic system Rh–TPPTS in hydroformylation upon addition of cyclodextrins is explained by the formation of not only host–guest complexes of the substrate with the receptor molecule, but of analogous complexes of  $\beta$ -cyclodextrin with TPPTS as well.<sup>35,80</sup> The existence of the latter complexes was confirmed by several methods.<sup>73,81–84</sup> The stability constant of the complex is  $7110 \text{ M}^{-1}$  at 298 K and decreases to  $610 \text{ M}^{-1}$  with an increase in temperature to 348 K. In the case of cyclodextrin **1**, the stability constant of the 1 : 1 complex with TPPTS is  $2800 \text{ M}^{-1}$  (see Refs. 82, 84). Structural studies of these complexes revealed that the phosphorus atom therein is arranged in a way that prevents its coordination to the metal ion. The addition of cyclodextrin changes the equilibrium between the rhodium complexes in the solution thus facilitating formation of the complex with an alkene, which leads to acceleration of the reaction. It is of note that this effect is weakened with an increase in the concentration of TPPTS. Meanwhile, the activity of the catalytic system significantly increases with an increase in the concentration of cyclodextrin up to a cyclodextrin : rhodium molar ratio of 30 : 1. It was shown that at elevated temperatures, the reaction rate is limited by diffusion of the inclusion complex into the aqueous phase. The activation energy of the reaction above  $60^\circ\text{C}$  is slightly more than  $5 \text{ kJ mol}^{-1}$  (see Ref. 80).

In the hydroformylation of alkenes catalysed by  $\text{Rh}_2(\mu\text{-SBU})_2(\text{CO})_2(\text{TPPTS})_2$ , the addition of  $\beta$ -cyclodextrin to the catalytic system significantly increases their conversion into aldehydes but decreases the fraction of linear isomers.<sup>74</sup> In particular, the selectivity with respect to *n*-nonanal is 98% in the absence of cyclodextrins and decreases to 76% in the presence of  $\beta$ -cyclodextrin. With cyclodextrin **1**, the selectivity with respect to *n*-nonanal under identical conditions is 92%.

The decrease in the selectivity was rationalised assuming specific orientation of the substrate in the cavity of cyclodextrin, which favours an attack on the terminal  $\text{CH}_2$  groups of the alkene by the rhodium hydride species.<sup>74,85</sup> If cyclodextrin **1** was used, the rates of the hydroformylation were equally high for alkenes  $\text{C}_8\text{--C}_{12}$ .<sup>84,85</sup>

It should be noted that the rate of hydroformylation in the presence of  $\beta$ -cyclodextrin decreases with an increase in the number of carbon atoms in the alkene (the rate for dodec-1-ene was only 2% of the value observed for oct-1-ene).

In the case of cyclodextrin **1**, the activity of the catalytic system in an aqueous phase increases upon repetitive use. Dessoudeix *et al.*<sup>85</sup> explained this fact by the formation of supramolecular associates composed of two cyclodextrin molecules and the active rhodium complex in the solution.

### 3. Miscellaneous reactions

Decomposition of allyl carbonates catalysed by palladium complexes with sulfonylated triphenylphosphine in the presence of various modified cyclodextrins has been studied by Monflier and co-workers<sup>86,87</sup>

(a)  $\text{Pd(OAc)}_2$ –TPPTS, modified cyclodextrins,  $\text{NEt}_3$ ,  $\Delta$ .

The activity of these catalytic systems is several times higher than that of systems containing unsubstituted  $\beta$ -cyclodextrin. The maximum activity was found for the system containing methylated cyclodextrin **1**, then the activity decreases in the following series: permethylated  $\beta$ -cyclodextrin **2**, hydroxypropyl- (**3**, **4**) and hydroxyethyl- $\beta$ -cyclodextrin **10**. For this reaction, the depend-

ence of the reaction rate on the substrate structure was elucidated in detail. It was found that, among alkyl allyl carbonates with linear substituents, the maximum activity is manifested by the derivative having 12 carbon atoms in the alkyl chain. For allyl decyl and allyl dodecyl carbonates it was shown that the introduction of additional methyl groups into the alkyl radical virtually did not affect the reaction rate whereas the introduction of bulkier substituents decelerated the reaction. The activity of allyl  $\beta$ -naphthylbenzyl carbonate was two times higher than that of allyl  $\alpha$ -naphthylbenzyl carbonate; a similar situation was observed for allyl *p*-phenylbenzyl carbonate in comparison with allyl *o*-phenylbenzyl carbonate. These results can be rationalised in terms of correspondence between sizes of the cyclodextrin cavity and of the substrate molecule.<sup>87</sup>

Isomerisation of *p*-allylanisole to anethole catalysed by iridium trichloride in a water–substrate system was studied by Barak *et al.*<sup>88</sup> The addition of either  $\alpha$ - or  $\beta$ -cyclodextrin led to acceleration of isomerisation several-fold and to a decrease in the energy of activation of the process. Presumably, a complex of iridium trichloride with the substrate and cyclodextrin is formed in this case.

(a)  $\text{IrCl}_3$ – $\beta$ -cyclodextrin.

Hydrosilylation of alkenes on platinum- or palladium-containing catalysts represents yet another example of an increase in the product yield upon addition of  $\beta$ -cyclodextrin to a catalytic system. Thus, the rate of hydrosilylation of styrene by triethoxysilane or trimethylvinylsilane on Pt catalysts is increased in the presence of  $\beta$ -cyclodextrin by a factor of two and more than three, respectively. In the case of Pd-containing catalysts, the rate of the last mentioned reaction is negligibly low. The increase in the reaction rate can be explained by stabilisation of the transition state due to the formation of the host–guest complex. These reactions are nearly completely inhibited by decane, which itself forms stable complexes with  $\beta$ -cyclodextrin.<sup>89</sup>

Water-soluble calixarenes (**11**, **12**, **16–18**) and  $\beta$ -cyclodextrin have been tested as components of catalytic systems for the cross-coupling of iodobenzene with phenylboronic acid (the Suzuki reaction), catalysed by a palladium complex with sulfonylated triphenylphosphine.<sup>90</sup>

(a)  $\text{PdCl}_2$ –TPPTS,  $\beta$ -cyclodextrin or modified calixarenes.

The addition of the receptors increased the yield of biphenyl more than twofold. Amino-containing calixarenes manifested the maximum activity. The stability constants for the respective inclusion complexes as well as the rates of their formation were substantially higher than those for non-substituted calixarenes (Table 3).

**Table 3.** The stability constants ( $k_s$ ) of calixarene complexes with iodobenzene and yields of products in the Suzuki reaction.<sup>90</sup>

| Calixarene                                                           | $k_s$ of the 'guest–host' complex / $\text{M}^{-1}$ | Relative yield |
|----------------------------------------------------------------------|-----------------------------------------------------|----------------|
| Tetrasodium calix[4]arene-tetrasulfonate ( <b>11</b> )               | 60                                                  | 2.4            |
| Hexasodium calix[6]arene-hexasulfonate ( <b>12</b> )                 | 56                                                  | 2.9            |
| Tetrakis( <i>p</i> -dimethylamino-methyl)calix[4]arene ( <b>16</b> ) | 402                                                 | 5.8            |

**Note.** Relative to the yield obtained in the absence of the receptor molecule.

### III. Catalysis by metal complexes with ligands based on receptor molecules

The catalysts that combine, within one molecule, properties of a metal complex and a phase-transfer reagent together with capabilities of molecular recognition, attract special attention from researchers.<sup>12, 13, 23, 26</sup> Such catalysts include a metal centre and a ligand containing one or several macrocyclic receptors (*e.g.*, cyclodextrin, calixarene, *etc.*) (Fig. 8).<sup>91–93</sup>

**Figure 8.** Different types of binding of a substrate by a metal complex containing fragments of receptor molecules.

L is a ligand bound to the receptor molecule; M is a metal ion; A is a group accessible for reaction; B is a group in the guest molecule.

(a) binding of two fragments of a guest molecule; (b) additional coordination of the group B in the guest molecule to the metal atom.

This combination of a host and a metal centre in one molecule not only retains all the features typical of catalytic systems discussed in the previous section but also confers new catalytically important properties. First of all, binding of a substrate by the cavity of the receptor ligand strictly defines its orientation with respect to the metal centre, which can strongly affect both the product distribution and the substrate selectivity of the reaction. The most interesting examples of this approach are enzyme models containing several host fragments in one ligand (Fig. 8 a).

It has to be emphasised that if the substrate embedded into the host–guest complex is additionally coordinated to the metal centre in the course of reaction (Fig. 8 b), the stability of this inclusion complex, as well as of the transition state of the reaction, can be enhanced by several orders of magnitude. This effect is referred to as ‘double recognition’.<sup>92, 93</sup> Due to concerted binding of the substrate, no additional step of the interaction of the substrate inclusion complex with the metal ion (which was typical of all catalytic systems considered in Section I) is necessary. As a consequence, such catalysts provide a substantial decrease in the energy of activation and the entropy of the reaction and thus increase its rate.<sup>13, 94</sup>

Complexes with receptor molecules were initially tested as models of hydrolytic enzymes.<sup>12, 92, 93, 95–101</sup> Up to now, issues related to the design and catalytic activities of such complexes have been elucidated in biomimetic oxidation, epoxidation, hydroxylation, Wacker oxidation, oxidation of sulfides and alcohols, hydroformylation, hydrogenation and other reactions.

#### 1. Oxidation

Breslow *et al.*<sup>102–107</sup> demonstrated the possibility of selective oxidation of different compounds on manganese porphyrinate complexes capable of selective substrate binding due to the presence of two or more cyclodextrin fragments.

The manganese complexes **19**, **20** enable epoxidation of unsaturated compounds by iodosylbenzene in aqueous media. The product yield is strongly dependent on the matching of the structures of the substrate and the metal complex.<sup>102</sup> In particular,

CD is cyclodextrin; R = H (**19**), F (**20**).

in the presence of complex **19**, the substrate **22** is epoxidised 50 times faster than the substrate **21** due to the presence of nitrophenyl groups, which are strongly bound by the cyclodextrin fragments. The activity of the complex **23**, in which the substrate is cooperatively bound by two cyclodextrin fragments simultaneously, is comparable to that of **19**. The activity of the catalyst **24** (where the arrangement of the receptor fragments does not correspond to the substrate shape and one of the cyclodextrin units does not take part in the substrate binding) is significantly lower.

R = H (**21**), 4-NO<sub>2</sub>C<sub>6</sub>H<sub>4</sub> (**22**).

**23:** R<sup>1</sup> = H, R<sup>2</sup> = C<sub>6</sub>H<sub>4</sub>SCH<sub>2</sub>CD; **24:** R<sup>1</sup> = C<sub>6</sub>H<sub>4</sub>SCH<sub>2</sub>CD, R<sup>2</sup> = H.

The iron porphyrinate complex **25**, containing two cyclodextrin fragments above and below the porphyrin plane, manifests

selectivity in the epoxidation of unsaturated compounds: in the case of cyclohexene, the reaction rate is several times higher than that of styrene. Furthermore, in the presence of a similar porphyrinate complex containing no cyclodextrin fragments, cyclohexene reacts significantly slower than in the presence of the complex **25**.<sup>108</sup>

The selectivity of the oxidation of C–H bonds with PhIO, catalysed by cyclodextrin-containing manganese porphyrinate **19**, also depends on the matching of the arrangement of binding centres within the ligand and the substrate structure.<sup>103–107</sup> In particular, in the oxidation of substituted 1,2-diphenylethanes, the aromatic moieties are not affected while the benzylic sites are selectively oxidised.

R = OCH(CO<sub>2</sub>H)C<sub>6</sub>H<sub>4</sub>Bu<sup>t</sup>-4.

Manganese porphyrinate complexes modified by cyclodextrins can catalyse selective oxidation of specific C–H bonds in steroids **26–30**. It was demonstrated that the selectivity is governed by the orientation of the substrate in the host–guest complexes due to specific binding of aromatic fragments of auxiliary groups in the steroid molecule.<sup>102–104</sup>

R<sup>1</sup> = 4-Bu<sup>t</sup>C<sub>6</sub>H<sub>4</sub>CHCH<sub>2</sub>C(O)O; R<sup>2</sup> = CONHCH<sub>2</sub>CH<sub>2</sub>SO<sub>3</sub>H.

For instance, oxidation of steroid **26** catalysed by the complex **19** yields exclusively the 6- $\alpha$ -hydroxy derivative. Meanwhile, compound **27** devoid of one substituent R<sup>1</sup> yields a mixture of nine components.<sup>102</sup> The activity of manganese porphyrinates **20**, **31** and **32** containing tetrafluorophenyl groups is significantly higher.<sup>105–107</sup>

Selective oxidation of steroid **28**, catalysed by the complexes **20**, **33** and **34**, yields the 9-hydroxy derivative as the major product.<sup>107</sup> This could be due to involvement of all three cyclodextrin fragments in steroid binding. A minor hydroxylation product at C(15) is formed due to involvement of only two cyclodextrin fragments in binding. Therefore, oxidation of steroid **29** catalysed by porphyrinate **20** yields oxidation products at C(9) and C(15) in nearly equal proportions. The catalysts **31** and **32** enable strictly selective hydroxylation at C(9).

It is of note that substrate binding by only one cyclodextrin fragment allows selective introduction of a hydroxy group into a steroid molecule. In particular, oxidation of compound **30** catalysed by porphyrinate **20** yields mainly the hydroxylation product

R<sup>1</sup> = R<sup>2</sup> = H, X = C (**31**); R<sup>1</sup> = F, X = N, R<sup>2</sup> is absent (**32**).

R = NO<sub>2</sub> (**33**), (**34**).

at C(15) whereas neither the double bond nor the hydroxy group are affected.

Manganese porphyrinate **35** containing cyclophane fragments<sup>109</sup> catalyses oxidation of compound **26** but the selectivity is significantly lower compared to that of the analogous complex containing cyclodextrin fragments [the ratio of the hydroxylation products at C(6) and C(15) is 3 : 1]. In the case of steroid **28**, the selectivity of hydroxylation at C(9) is only 60%. Apparently, the substrate, even bound by the cyclophane fragments, retains sufficient mobility resulting in non-oxidation.

Similar effects of the 'rigidity' of substrate binding are observed for the oxidation of  $\beta,\beta$ -carotene **36** and its analogue **37** by *tert*-butyl hydroperoxide catalysed by ruthenium porphyrinate **38** containing two cyclodextrin fragments.<sup>110–113</sup>

In this case, the stability constant of the host–guest complex is very high ( $2.6 \times 10^6 \text{ M}^{-1}$ ) due to cooperative binding of the carotene molecule by the cyclodextrin fragments. Nevertheless, oxidation of carotene proceeds non-selectively: the cleavage products of the C(15)–C(15'), C(11')–C(12') and C(9')–C(10') bonds are formed, although the two former products prevail. At the same time, if one of the cyclohexene fragments is replaced by an aromatic one (compound **37**), the cleavage product of the C(15)–C(15') bond is selectively formed. Probably, in this case both the structural 'rigidity' of the inclusion complex and binding constant are increased, the latter is  $5.6 \times 10^6 \text{ M}^{-1}$ .

The iron complex **39**, containing  $\beta$ -cyclodextrins modified by catechol groups, proved active with respect to phenol hydroxylation. Abnormally high regioselectivity was achieved in this system: the yield of catechol exceeded 90%. The use of the metal complexes results in a significant increase in the binding constant of phenol; its specific orientation in the host–guest complex owing to additional coordination provides selectivity for *ortho*-hydroxylation (Fig. 9).<sup>34, 49, 50, 114</sup> It was shown<sup>115, 116</sup> that the

**Figure 9.** Formation of a complex of the catalyst with phenol in the hydroxylation of the latter by hydrogen peroxide. The arrow marks the site available to hydroxylation.

iron complexes formed at pH 2.5, which contain two ligands per iron ion, manifest the highest activity. The quantitative selectivity as regards catechol formation was achieved in the reaction with copper complexes containing ethylenediamine-modified cyclodextrins and, noteworthy, non-modified  $\beta$ -cyclodextrin. In the latter case, the catalytic activity is probably due to binuclear copper complexes with  $\beta$ -cyclodextrin, which, in turn, form stable complexes with phenol.<sup>117–121</sup>

Catechol is also formed as the main product in hydroxylation of benzene by hydrogen peroxide, catalysed by the complex **39**. The yield of phenol, *i.e.*, the primary hydroxylation product, being about four times lower.<sup>34, 50, 115</sup> This is explained by the fact that phenol formed upon hydroxylation of benzene remains in the cyclodextrin cavity due to cooperative binding to the metal atom and thus undergoes further oxidation to catechol. With iron complexes containing  $\beta$ -cyclodextrin modified by catechol at the primary hydroxy group, hydroquinone is predominantly formed.<sup>115, 116</sup>

Copper complexes with cyclodextrins were used in the oxidation of isoborneol and borneol by peracetic acid and hydrogen peroxide in a acetic acid–pyridine mixture.<sup>122, 123</sup> The yield of camphor, the main product, and selectivity of the reaction were much higher than those in the process catalysed by copper sulfate. The catalytic effect is explained by specific orientation of the substrate molecule in the inclusion complex due to coordination of the alcohol group to the copper ion.

The copper complex of pyridine-modified calix[6]arene **40**<sup>124–128</sup> is active in the oxidation of benzene to quinone *via* phenol and hydroquinone. It is of note that no catechol is formed in this case. The same complex is active in the oxidation of ethylene to acetaldehyde and acetic acid.<sup>129</sup> A similar copper complex of calix[4]arene modified by the imidazole groups **41** catalyses oxidation of 3,5-di-*tert*-butylcatechol, benzene and ethanol by hydrogen peroxide to the corresponding quinone, benzoquinone and acetaldehyde, respectively.<sup>129, 130</sup>

Interesting examples of supramolecular oxidation catalysts are given by compounds based on 'molecular clips'.<sup>131–136</sup> The copper complexes **42** and **43** of such molecules proved to be selective catalysts for biomimetic oxidation of alcohols to the respective aldehydes.<sup>132–134</sup> The analogous porphyrinates were efficient in the epoxidation of stilbene and pinene by hypochlorite.<sup>135</sup>

The rate of oxidation of 3-hydroxy- and 3,5-dihydroxybenzyl alcohols catalysed by the complex **42** was substantially higher than that of benzyl alcohol. Presumably, H bonds are formed between oxygen atoms of the oxy groups in the cavity and the hydroxy groups in the aromatic ring of the substrate, in addition to coordination of the benzyl group to the copper ions.<sup>132</sup> Oxidation of phenols by air in the presence of the copper complexes **43** and **45** with pyridine-containing ligands yields only polymeric products of oxidative coupling.<sup>133</sup> Martens *et al.* proposed<sup>132</sup> analogous catalysts **44** that are soluble in fluorinated solvents.<sup>134</sup> Manganese porphyrinates **46** containing pyridine as an axial ligand are unstable. The use of 4-(*tert*-butyl)pyridine made it possible to stabilise the catalyst owing to another type of ligand coordination in the active complex: in contrast to pyridine, it cannot be accommodated in the cavity of the receptor and thus is coordinated from the outer side.<sup>135, 136</sup>

R = H (43), SiMe<sub>2</sub>R<sub>F</sub> (44) (R<sub>F</sub> is perfluorinated hydrocarbon fragment).

The palladium complex **47** with  $\beta$ -cyclodextrin modified by cyanoethyl group manifested significantly higher activity than the catalytic system PdCl<sub>2</sub>(PhCN)<sub>2</sub>– $\beta$ -cyclodextrin in the Wacker oxidation of higher alk-1-enes. Its activity is due to cooperative binding of the substrate and the increased stability constant of the catalyst–substrate complex. It was shown that the stability constants of the inclusion complexes significantly increase on going from non-modified cyclodextrin to the metal complexes of the type **47**. The energy of activation of the reaction decreases approximately twofold, which is explained<sup>42</sup> by additional coordination of an alkene to the palladium atom in the inclusion complex. The activity of the catalyst depends on the chain length of the alkene and is a maximum for hept-1-ene.<sup>42</sup>

The catalyst **47** demonstrates higher activity in reactions with aromatic substrates, *e.g.*, styrene, than with linear alkenes.<sup>34, 42, 50, 137</sup> Oxidation of styrene catalysed by a system containing the palladium complex and non-modified cyclodextrin, yields acetophenone as the major product. If the cyclodextrin in the catalytic system is modified by nitrile groups, phenylacetaldehyde is formed in about the same proportion as acetophenone. This means that the regioselectivity of the reaction is altered.

Palladium complexes with sulfocalixarenes modified by nitrile-containing groups manifest higher activities in the biphasic Wacker oxidation of alk-1-enes compared to systems composed of non-modified sulfocalixarenes. The catalytic activity strongly depends on the size of the calixarene cavity: calix[4]arene and calix[6]arene are most active towards hex-1-ene and oct-1-ene, respectively.<sup>45</sup>

Catalysts based on cyclodextrins are very promising for performing enantioselective catalytic reactions. Oxidation of a mixture of (*S*)- and (*R*)-pinenes by oxygen under irradiation with visible light, catalysed by the iron complex with porphyrin modified by 2,6-dimethyl- $\beta$ -cyclodextrin (**48**), is an example of this approach.<sup>138, 139</sup> Under these conditions, the (*S*)-isomer was more reactive and the enantioselectivity was above 60%.

Only a few studies were aimed at the synthesis of macrocyclic receptors as catalysts of enantioselective reactions. Oxidation of aromatic sulfides to sulfoxides catalysed by the molybdenum complexes **49**–**51**, containing modified cyclodextrins as ligands, yields predominantly (*R*)-isomers. The yield of sulfoxide in the oxidation of thioanisole by hydrogen peroxide in biphasic systems, catalysed by the molybdenum complex **49** containing cyclodextrin with ethylenediamine as a substituent of one of the primary hydroxy groups, was 91% [*ee* 59% (*R*)]. In the case of the complexes **50**, containing  $\beta$ -cyclodextrin, and **51**, containing  $\beta$ -cyclodextrin with ethylenediamine as a substituent of a secondary hydroxy group, the enantioselectivities were substantially lower (from 17% to 24%).<sup>140</sup>

## 2. Hydrogenation and hydroformylation

A series of rhodium complexes **52–59** with cyclodextrins modified by various phosphine groups have been synthesised as potential catalysts for hydrogenation and hydroformylation reactions.

Reetz *et al.*<sup>94, 141, 142</sup> showed that these complexes possess substrate specificity in the hydrogenation of aromatic unsaturated compounds. Furthermore, rhodium complexes with cyclodextrin ligands are active in the hydroformylation of alkenes<sup>13, 34, 142</sup> and similar platinum, rhodium and iridium complexes are efficient catalysts for the hydrogenation of aromatic chloronitro compounds<sup>143</sup> (Table 4).

**Table 4.** Complexes with cyclodextrin-containing ligands catalysing hydroformylation and hydrogenation reactions.

| Ligand           | Reaction                        | Conditions                                                                                 | Ref.                     |
|------------------|---------------------------------|--------------------------------------------------------------------------------------------|--------------------------|
| <b>52</b>        | Hydrogenation of nitrobenzenes  | toluene – water, 20 °C, H <sub>2</sub> , 2 MPa                                             | 143                      |
| <b>52–55, 57</b> | Hydrogenation, hydroformylation | 25% DMFA in water, H <sub>2</sub> , 0.1 MPa or synthesis-gas under 10 MPa, 25 °C and 60 °C | 12, 13, 34, 94, 141, 142 |
| <b>56</b>        | Hydroformylation                | DMFA, synthesis-gas, 2 MPa, 80 °C                                                          | 144                      |
| <b>59</b>        | Hydroformylation                | methanol : water = 6 : 4, synthesis-gas, 4 MPa, 60 °C                                      | 145                      |
| <b>60</b>        | Asymmetric hydrogenation        | methanol, ethanol, THF, acetone, H <sub>2</sub> , 0.1 MPa                                  | 146                      |

The use of rhodium complexes with the ligands **52–55** as catalysts for hydroformylation increases the rates of the reactions compared to those for catalytic systems containing non-modified  $\beta$ -cyclodextrin and  $\text{H}(\text{CO})\text{Rh}(\text{TPPTS})_3$ . Furthermore, the selectivity of formation of linear aldehyde is also increased, which is explained by specific orientation of the substrate in the supramolecular complex with the cyclodextrin fragment. In contrast to the catalytic systems based on  $\text{H}(\text{CO})\text{Rh}(\text{TPPTS})_3$ , rhodium complexes with the ligands **52–55** enable conversion, in biphasic solvent systems, of alkenes even with an internal double bond [*e.g.*, (*E*)-oct-3-ene]. The catalyst remains in the aqueous phase and can be recycled. Hydrogenation of aromatic compounds on the rhodium complexes with the ligands **52–55** and **57** is characterised by much higher reaction rates than those of linear alkenes, which suggests molecular recognition of the aromatic substrates.

In the hydrogenation of chloronitrobenzene, a platinum complex with the ligand **52** provided the best selectivity. The yield of aminochlorobenzene was > 95%. Virtually no hydrodechlorination products were observed due to shielding of the chlorine atom within the inclusion complex.<sup>143</sup> Rhodium complexes with methylated  $\alpha$ -cyclodextrin (**58**) modified by phosphine

groups and with  $\beta$ -cyclodextrin (**56**) modified by phosphite groups, have been tested as catalysts for homogeneous hydrogenation.<sup>144, 145</sup> In this case, substrate selectivity was also observed: hydrogenation of aromatic compounds proceeded much faster than that of alkenes due to the higher stability of the respective host – guest complexes.

A rhodium complex with the permethylated  $\beta$ -cyclodextrin **59** modified by two triphenylphosphine groups at adjacent glucose fragments, was active in the enantioselective hydrogenation of various substituted  $\alpha, \beta$ -unsaturated acids. The enantioselectivity ranged from 49% to 92% depending on the substrate and solvent. Apparently, in this case, cooperative binding of the substrate by the ligand cavity and the metal atom defines its specific orientation and favours formation of the *R*-isomer.<sup>146</sup>

Nolte and co-workers<sup>147</sup> synthesised the rhodium phosphite complex **60** with a non-polar cavity using molecular receptors based on diphenylglycoluril. Aromatic allylic compounds can be selectively hydrogenated in the presence of this complex with a rate much higher than that in the case of catalytic systems without host fragments, due to binding of the substrate in the cavity. The activity of the catalyst towards hydrogenation of *p*-allylcatechol could be increased by addition of resorcinol, probably owing to cooperative binding of both molecules, *viz.*, the substrate and resorcinol, in the cavity of the host.<sup>147, 148</sup>

A macromolecular rhodium complex containing modified calixarene **61** as a ligand, was tested as a catalyst for hydroformylation in biphasic systems.<sup>149</sup> Hydroformylation of oct-1-ene was conducted in an alkene – water system without other organic solvents; rhodium(I) acetylacetonatodicarbonyl served as a precursor of the catalyst.

At the pressure of synthesis-gas of 4.0 MPa and 100 °C, the substrate was converted into aldehydes with normal and *iso*-carbon skeletons in a ratio of 2 : 1. The degree of conversion was 70% – 95% after 12 h. It is of note that the catalyst is active in the hydroformylation of not only alk-1-enes (*e.g.*, oct-1-ene) but of

such relatively inert substrates as oct-2-ene and oct-4-ene as well. In the latter case, the reaction yielded a mixture of aldehydes.<sup>150</sup>

Complexes with calixarenes modified by phosphine and phosphite groups were also tested as catalysts for reactions with synthesis-gas under homogeneous conditions.<sup>151–159</sup> It should be noted that in this case the fragment of the receptor molecule served primarily as a template for the design of sterically hindered phosphine and phosphite ligands. Unfortunately, the process of formation of the inclusion complexes was not discussed by the authors.

Hydroformylation of styrene and oct-1-ene using rhodium complexes of calixarenes **62**, **63** was described by Bagatin *et al.*<sup>153</sup> and by Fang *et al.*<sup>154</sup> Loeber *et al.*<sup>155</sup> have employed the complex **64** in the same reaction. Quantitative conversion of styrene into 2-phenylpropanal with a selectivity of 95% took 48 h at 40 °C and 4.0 MPa.

Calixarenephosphite **65** ( $R = H$ ) with a non-protected hydroxy group was used as a ligand for the rhodium-catalysed hydroformylation of hex-1-ene.<sup>156</sup> Virtually complete conversion of the starting alkene was achieved in 3 h; the yield of aldehydes was 80%–85%. Unfortunately, the selectivity was rather low: the reaction mixture contained equal amounts of linear and branched aldehydes. A series of analogous phosphites have been tested<sup>157</sup> as components of catalytic systems for the hydroformylation of oct-1-ene. It was shown that the nature and steric volume of the substituent  $R$  insignificantly affects the major characteristics of the process. In particular, the degree of conversion was 80%–90% in all cases and the selectivity of nonanal formation about 60%.

The use of chelate biphosphonite **66** gave rise to a significant increase in the regioselectivity of nonanal formation to 90%–92%.<sup>151</sup>

Hydroformylation of oct-1-ene in the presence of Rh complexes with phosphorus-containing calixarenes **67–74** was studied by Kunze *et al.*<sup>158, 159</sup> The maximum activity was observed for complexes with the ligand **73**, however, the presence of a calixarene fragment in the ligand did not enhance the catalytic activity. For instance, catalysts containing the ligands **67**, **69** and **71** provided the same activity as their analogue without calixarene whereas for complexes with the ligands **68** and **70**, the activity was even lower.

The data summarised in the present review demonstrate the rapidly growing interest of researchers in the design of supramolecular metal complex catalytic systems based on macrocyclic receptors. The number of publications in this area steadily increases.

Since it is high selectivity that becomes an increasingly important factor in chemical processes, there is no doubt that catalysts capable of molecular recognition will find broad applications in chemo-, regio- and stereoselective reactions.

## Chemical research at the Saint-Petersburg State University

This issue of the Journal is compiled from reviews written by researchers of the Department of Chemistry and the Research Institute for Chemistry of the Saint-Petersburg State University.

The Department of Chemistry, which celebrated its 75th anniversary in 2004, descends from the Division of Chemistry of the Physico-Mathematical Department of the Imperial Saint-Petersburg University. Teaching chemistry at the University began in the 1830s, and in 1868 the Division of Chemistry, which had expanded considerably by that time, was split into three sectors, *viz.*, inorganic, organic and analytical chemistry, headed by D I Mendeleev, A M Butlerov and N A Menshutkin, respectively. Academicians D P Konovalov, V E Tishchenko, A E Favorsky, S V Lebedev, V G Khlopin, B P Nikolsky, I I Chernyaev, A A Baikov, the Corresponding Members of the RAS M S Vrevsky, I I Zhukov, Professors L A Chugaev, S A Shchukarev, R L Müller, Ya V Durdin, A V Storonkin and other outstanding representatives of Russian science had been working at the Institute at different times.

In 1934, the Educational-and-Research Centre for Chemistry (RECC) was established on the base of the Department of Chemistry and the newly founded Research Institute for Chemistry. In 2003, the Institute for Laser Research acceded to them.

To date, the staff of the Department and the Institutes comprises Academicians A I Rusanov and M M Shults, Corresponding Members of the RAS N A Smirnova and V B Aleskovsky, 70 professors and Doctors of Science and about 300 Ph.Ds. The results of investigations carried out in the past decade and documented in more than 2400 articles and reviews in Russian and foreign periodicals, 38 monographs, 84 manuals and 33 transactions have been published and 13 patents have been granted; over 200 grants from RFBR, RFBR-DFG, RFBR-INTAS, CRDF, DAAD, INTAS, the Volkswagen Foundation, NWO, INCO-COPERNICUS and various research programmes including the NATO Science Programme, Universities of Russia and programmes of the Ministry for Education and Science and the Ministry of Defence of the Russian Federation have been obtained.

The Department of Chemistry is collaborating successfully with many classical Russian universities, institutes of the RAS, academies of sciences, research establishments and manufacturing companies in the USA, Canada, Japan, China, Korea, SAR and the majority of European countries and takes an active part in organising various conferences, symposia and seminars.

The research activities at the Department are inseparably joined with educational work. The Department is carrying out large-scale training of specialists in virtually all chemical specialties. The Department admits annually 150 students from various regions of Russia. Many of its graduates take a post-graduate course to get a Ph.D. degree and some of these continue to work for a D.Sci. degree.

At present, the Department of Chemistry and its two Institutes comprise 13 divisions and 17 sectors on quantum chemistry, colloid chemistry, physical chemistry, chemical thermodynamics and kinetics, electrochemistry, general and inorganic chemistry, analytical chemistry, organic chemistry, physical organic chemistry, polymer chemistry, chemistry of natural compounds, radiochemistry, chemistry of solids, semiconductors and laser research.

The main areas of research at the *Division and Sector of Quantum Chemistry* include development of theoretical-group methods for the study of electronic and vibrational structures of complex molecules and crystals; studies into the nature of chemical bonds in crystalline solids (transition metal oxides, high-temperature superconductors, fullerenes); studies of vibrational characteristics of complex crystals; development of methods for calculation of electronic structures, electronic spectra, valence structures and magnetic characteristics of complex transition metal derivatives; further development of the theory of atomic structures with special reference to relativistic, quantum-electrodynamic and environmental phenomena; non-empirical calculations of potential energy surfaces of ground and excited states of metastable and excimeric cations; development of the theory on atomic valence in molecules, radicals and crystals; quantum chemistry of organic compounds.

**The Division and Sector of Colloid Chemistry** are among the world leaders in many fields, *e.g.*, electrokinetic phenomena, thermodynamics of surface effects, physicochemical hydrodynamics of capillary systems, micelle formation and surface separation of compounds. The discoveries in these fields are related to the behaviour of surface layers, mechanochemistry, wetting and nucleation. Fundamental results have been obtained in the theory of micelle formation, the theory of wetting of rough surfaces taking account of linear phenomena, the theory of foams, capillary waves and currents as well as computer simulation of minor systems including clusters of polar compounds. Considerable progress has been achieved in the study of structural, adsorption, electrokinetic and filtration characteristics of real and model disperse systems and membranes of various chemical origin including porous glasses; also in the study of surface tension, surface electric charge and surface potential, surface conductivity and surface separation processes. The theory of the equation of state has been developed in recent years. This line of research has been described in the review by Academician A I Rusanov 'Novel approach to the equation of state for fluid systems, based on the concept of the exclusion factor'.

Studies on ion-exchange, ionometry and redoxometry are among the main areas of research at **the Division and Sector of Physical Chemistry**. Other trends include thermodynamics and molecular-statistical simulation of fluid systems [study of quantitative relationships between molecular characteristics of compounds and macroscopic properties of their solutions (fluid phases)]; development of novel versions of quasi-chemical models of solutions; development of a *p*-type quasi-chemical model of the fluid phase in a group variant; experimental studies and simulation of phase equilibria of fluid systems using the Monte Carlo method; thermodynamics of liquid-crystalline systems, *etc.* The review by the Corresponding Member of the RAS N A Smirnova 'Phase behaviour and self-assembly patterns of surfactant mixtures in solutions' is an overview of the state-of-the-art in solutions of surfactant mixtures.

**The Division and Sector of Chemical Thermodynamics and Kinetics** are carrying out research on heterogeneous equilibria in multicomponent systems, thermodynamics of reaction-mass-exchange processes, thermodynamics and kinetics of processes in high-temperature oxide systems, phase diagrams of water-salt systems, *etc.* Other trends include simulation of the thermodynamic behaviour of electrolyte solutions at high concentrations; thermodynamics of membrane processes; kinetics of liquid-phase reactions in strongly non-ideal concentrated media; complex intermolecular interactions (bifurcated hydrogen bonds, general acid-base catalysis, *etc.*); multimolecular intermediate reactive associates; structure and thermodynamics of aqueous solutions of organic compounds and their reactivities in aqueous media.

Studies on equilibria and kinetics of electrode processes in electrolyte solutions of variable compositions are traditional subjects of investigation at **the Division and Sector of Electrochemistry**. These include analysis of the effects of double electrical layer structures on the rates of electrode reactions and processes complicated by chemical reactions in bulk. An entirely new trend, *viz.*, electrochemistry of modified electrodes coated with conducting polymeric inorganic or organic films with mixed ion-electronic conductivities, has been developing successfully in the past decade.

Studies on coordination and cluster compounds and molecular complexes occupy a prominent place in the research carried out at **the Division and Sector of General and Inorganic Chemistry**. A general theory of the electronic structures of transition-metal clusters with weak- and strong-field ligands has been developed together with the methodology for structural-and-dynamic simulation of intramolecular electron transfer in polynuclear organo-metallic transport chains. The most important in principle achievements include the discovery of novel classes of conversions of unsaturated organic ligands on polynuclear coordinating centres; development of a model of vibrational quantum tunnel-

ling of electrons and the theory of a redoxonic mechanism for solid-phase vibrational redox reactions; rationalisation of high-temperature superconductivity, giant magnetoresistivity, electron-ionic conductivity of oxides with heterovalent atoms, *etc.* Studies on the structures and properties of aqueous solutions of salts, thermodynamics and kinetics of gas-phase reactions, nature of the donor-acceptor bonds in molecular complexes, *etc.*, are under way.

The studies at **the Department and Sector of Analytical Chemistry** are developing along several lines, *viz.*, separation methods and hybrid methods of analysis, spectroscopic methods, studies of reactivities of complexes, *etc.* The main achievements include the development of novel chromatographic methods of analysis, such as gas-liquid and gas-liquid-absorption chromatography, chromatomembrane flow techniques for continuous separation of substances, detection methods based on Zeeman modulation polarisation spectroscopy, Mössbauer and X-ray low-angle dispersion spectroscopy and discovery of new ligand reactions in complexes. Researchers at the Division are actively developing luminescent and electrochemical methods along with methods for flow-injection, vapour-phase and capillary-electrophoretic analysis including those based on the use of microchips. Each of these trends has found practical application: on-line ecological monitoring of waters has been substantiated methodologically and novel technologies for flow-injection, spectral analysis and oxygenation of blood, deoxygenation of water and homogeneous catalysis have been developed. The review by A L Moskvina and L N Moskvina 'Water and aqueous environments: on-line chemical analysis, problems and solutions' is devoted to flow-through methods of analysis, while the review by N A Bokach and V Yu Kukushkin 'Addition of HO-nucleophiles to free and coordinated nitriles' deals with novel reactions of ligands within complexes.

The main attention among other research trends developed at **the Division and Sector of Organic Chemistry** is given to the chemistry of unsaturated compounds, strained carbo- and heterocycles, study of rearrangements (including tautomeric conversions), reactions involving carbenes and reactivities of organic compounds. Novel five- and seven-membered oxygen- and nitrogen-containing heterocyclic compounds with potential biological activities have been prepared and novel approaches to the synthesis of unnatural or hardly accessible natural amino acids have been developed. The review by A F Khlebnikov, M S Novikov and R R Kostikov 'Iminium ylides from carbenes and carbeneoids: generation and synthetic applications' is devoted to various reactions of carbenes.

The main areas of research at **the Division and Sector of Physical Organic Chemistry** are studies of the mechanisms of various hetero- and homolytic reactions. Considerable progress has been achieved in the theoretical and experimental design of principles and models for identification of mechanisms of chemical reactions and control over their selectivity; in-depth studies of tautomeric conversions in the synthesis of novel anion-selective ligands, *etc.* Such areas as metal-complex catalysis, directed synthesis of heterocyclic systems and especially the novel promising trend, chemistry of ecotoxicants, *etc.*, are also developing successfully.

The activities at **the Division and Sector of Polymer Chemistry** are aimed at the synthesis and investigation of novel types of polymers with miscellaneous functions (*e.g.*, biodegradable polymers, dendritic macromolecules, *etc.*). The principles and methods for the preparation of dendritic polymers based on natural trifunctional amino acids that are promising for chromatography and the study of transport processes in biosystems have been developed. The self-assembly of dendritic macromolecules based on electrostatic interactions of a polyelectrolyte core with dendrons oppositely charged at the focal point has been carried out for the first time. A new method for the formation of porous polymeric materials for tissue engineering has been developed on the basis of biodegradable polymers.

Methods for the preparation of practically important peptides, *e.g.*, human insulin, bradykinin, vasopressin, oxytocin and its analogues, luliberin and its analogues,  $\delta$ -sleep peptide, angiotensins I and II, somnogenic peptides, neurotensin, cholecystokinin, bombesin and its analogues, *etc.*, have been developed at ***the Division and Sector of Chemistry of Natural Compounds***. Schemes for the total synthesis of steroid estrogen analogues have been developed and their crystal and solution structures have been investigated. Novel compounds manifesting selective biological activities (predominantly, antisclerotic, osteoprotective or immunosuppressive) together with low hormonal activities have been prepared; the biological properties of many natural compounds have been investigated.

***The Division and Sector of Radiochemistry*** are carrying out research in various fields of the physicochemistry of radionuclides. These investigations include studies of the nuclear prehistory and its effect on the nature of radiation-induced damage of metals; structures and migration of admixture 'hot' atoms (admixture radiation defects) formed in metals and alloys upon nuclear fission and transmutation induced by charged species, neutrons or upon radioactive decay; diffusion-thermal methods for isolation of radionuclides in the absence of substrates. Tracer methods were used to study the properties of membranes of chemical sensors [diffusion, electroconductivity, ion exchange (solution/solids) and novel chemical sensors for detecting heavy metals, *etc.*] and sensory systems of the 'electronic language' type have been developed.

Research at ***the Division and Sector of Chemistry of Solids*** is being carried out in such fields as ionics of solids, chemistry of highly organised substances, chemistry of surfaces and surface compounds, chemistry of nanostructures and nanostructured materials, UV-Vis and IR spectroscopy of surfaces and nanostructures, precision synthesis of highly organised solids and nanostructured materials, *etc.* A new line of research, *viz.*, chemistry of highly organised compounds, has appeared. Methods for the synthesis of solids and materials based on the 'backbone hypothesis' have been devised. The molecular layering method was used as a basis for the development of sorbents, catalysts, luminophores, dispersely reinforced composite materials, thin-film structures for electronic engineering, *etc.*

Medium-order studies of various processes occurring in glasses and glass-forming melts, 'semiconductor-metal' transitions and of the nature of the superionic state are being carried out at ***the Sectors for Semiconductors and Laser Investigations***. Highly effective materials for IR optical amplifiers, which represent nanostructured chalcogenide glass films doped with rare-earth ions, have been prepared for the first time by UV-laser sputtering in the framework of a novel direction of investigations, *viz.*, laser materials science. Special attention is given to the interaction of laser irradiation with a material and concomitant chemical reactions. The effect of fundamental photo-induced changes in the optical width of the forbidden gap and the refraction indices of chalcogenide films prepared by laser sputtering have been determined.

This issue includes only some of the reviews prepared by researchers of the Department of Chemistry of SPbSU. The reviews summarising the results of investigations in other areas of research will be published in the next issues of the Journal.

**Abstract.** The review summarises the achievements in the theory of the equation of state. Novel approaches and new high-precision equations of state for one- and multicomponent fluid systems are considered. The results are given for both bulk phases and surface monolayers including two-dimensional equations. In the framework of the theory based on the exclusion factor, a hierarchy of approximations is formulated, incorporating both well-established and relatively new equations of state. The bibliography includes 79 references.

## I. Introduction

A physicochemical state of matter is characterised by some state parameters such as temperature, pressure, density and chemical composition. The significance of the equation of state consists in that it relates these parameters to one another (usually, in explicit form). Finding the equation of state is one of the central problems of the knowledge of matter, which has been under discussion in the scientific literature since 1662 (the Boyle–Mariotte law). Research on the properties of gases took two centuries but the search for a general equation of state for gases and fluids began only after proposal of the idea of continuous transition from gas to fluid (van der Waals, 1873). Interest in this problem is unabated so far. To date, a great body of experimental data has been accumulated. Complete histories of the first fifty equations of state are known<sup>1</sup> but it is impossible to count the total number of the equations of state proposed. The matters in hand are various types (cubic, logarithmic, *etc.* equations), models (*e.g.*, lattice models) and aspects of the equation of state, which have been the subject of particular reviews. The results obtained in this field by the end of the twentieth century are summarised in an incomplete collection of such reviews.<sup>2</sup> The present review is devoted to the major aspect of the equation of state, namely, the use of the concept of the exclusion factor (excluded volume or surface area).

The first equations of state for fluids were based on the Boltzmann and van der Waals concepts of excluded volume, *i.e.*,

the volume that must be subtracted from the actual volume of a system due to the fact that particles in the system have their own volumes. It is easy to understand that in an ideal gas a spherical particle of radius  $r$  and volume  $v_0 = 4\pi r^3/3$  creates an excluded (inaccessible to the centres of other identical particles) volume  $v^{\text{ex}} = 4\pi(2r)^3/3 = 8v_0$ . Now if we write the van der Waals equation

$$p = \frac{k_{\text{B}}T}{v - 4v_0} - \frac{\alpha}{v^2}, \quad (1)$$

( $p$  is the pressure,  $k_{\text{B}}$  is the Boltzmann constant,  $T$  is temperature,  $v$  is the volume per gas particle,  $\alpha$  is the attraction constant), we surprisingly see the coefficient 4 instead of 8, which contradicts van der Waals' idea. Replacement of the numerical factor 4 by 8 in this equation leads to an incorrect value of the second virial coefficient. Van der Waals tried to avoid this contradiction by assuming that collisions always occur between two molecules. This argumentation is no longer valid after Planck's equation of state.<sup>3</sup>

$$p = -\frac{k_{\text{B}}T}{8v_0} \ln \left( 1 - \frac{8v_0}{v} \right) - \frac{\alpha}{v^2}, \quad (2)$$

which contains the excluded volume  $8v_0$  in explicit form. Undoubtedly, Eqns (1) and (2) are different equations of state. But even Planck who expanded the logarithm in a series thought that he confirmed the van der Waals equation which dominated over many decades and was in essence treated as a law of nature; parameters of this equation for particular substances were published in handbooks as physical constants.

The late 1950s and early 1960s were the period when the statistical theory of scaled particles<sup>4,5</sup> was created and methods of computer simulation (molecular dynamics) of the equation of state were elaborated.<sup>6</sup> The new theory provided much more accurate equations of state, introduced a number of additional geometric notions (*e.g.*, the notion of accessible volume, which is immediately related to the equation of state). Over the years it has become a broad field which was called by Reiss (creator of the theory) statistical geometry.<sup>7–12</sup> Elaboration of methods of computer simulation permitted experiments with exactly the same models for which theory was created. By the early 1980s research on the equations of state reached a stage of steady rework, refinement and generalisation. The subject of most recent publications is generalisation of the equations of state for multicomponent systems<sup>13–24</sup> or modelling of systems comprised of aspherical particles.<sup>25</sup>

The two-dimensional van der Waals equation

$$\Pi = \frac{k_B T}{a - 2a_0} - \frac{\alpha}{a^2} \quad (3)$$

[ $\Pi$  is two-dimensional pressure;  $a$  is the surface area per particle;  $a_0$  is the parking area of the particle; the attraction constant,  $\alpha$ , is of course different from that which appeared in Eqn (1)] has dominated since the mid-20th century, as follows from a well-known monograph by de Boer,<sup>26</sup> which is to a great extent based on this equation. However, the scaled particle theory also provided more accurate equations in this field (they are given below). In addition, experimenters working with dense surfactant monolayers began using the logarithmic Frumkin equation (at  $\alpha = 0$ , it is known as the van Laar equation)

$$\Pi = -\frac{k_B T}{a_\infty} \ln \left( 1 - \frac{a_\infty}{a} \right) - \frac{\alpha}{a^2}, \quad (4)$$

where  $a_\infty$  is the surface area per particle at the maximum degree of coverage of the monolayer. Initially, the van Laar equation<sup>27</sup> and recently also the Frumkin equation<sup>28, 29</sup> were extended to multi-component systems.

A reference database for the two-dimensional equation of state for hard disks was created (using the molecular dynamics method and Monte Carlo simulation<sup>30</sup>) twenty-five years later than for the three-dimensional equation of state for hard spheres, being, however, characterised by the highest accuracy (0.01%). The last decade was a period of continuous research in the field of computer simulation<sup>31–33</sup> of two-dimensional systems and, as a supplement, of the scaled particle theory.<sup>34</sup> The availability of the high-accuracy database gave impetus to the development of the theory of the two-dimensional equation of state. Quite accurate but rather complex equations (*e.g.*, the Padé and Levin approximations<sup>30</sup>) based on a set of initial virial coefficients were derived. At the same time it was demonstrated that at present derivation of simple and accurate equations for hard disks<sup>35, 36</sup> using the Boltzmann concepts presents no significant difficulties.

Recently, a new approach has been elaborated to the theory of the equation of state based on the exclusion factor (excluded volume or surface area) for both bulk<sup>37–46</sup> and surface<sup>47–54</sup> systems. The approach is based on new thermodynamic relations and on a general relation of statistical mechanics for the chemical potential of a particle (molecule, ion or nanoparticle) of the  $i$ th component rather than the scaled particle theory

$$\mu_i = \mu_i^0 + k_B T \ln(c_i \Lambda_i^3), \quad (5)$$

where  $\mu_i^0$  is the chemical potential of the particle with centre of mass at rest,  $c_i$  is the concentration (particle number per unit volume) and  $\Lambda_i$  is the average de Broglie wavelength (temperature function). A traditional term including the activity coefficient is allowed for by the quantity  $\mu_i^0$ , which differs from  $\mu$  only in that it corresponds to the particle at rest.

The main parameter of the new theory is the exclusion factor (reduced excluded volume or surface area) determining the solution to the master equation that generates the equations of state. This parameter varies over a narrow range, thus providing a good accuracy of solution in different approximations. The adequacy of the approach is quite surprising. Not only does the method allow new accurate and simple (the simplicity condition is included in the computational algorithm) equations of state to be derived but it also permits reproduction of known equations that are seemingly not interrelated and establishment of some hierarchy of approximations involving these equations. On the one hand, this permits better understanding of conventional relations (we will see it below taking the van der Waals and Planck equations as examples). On the other hand, this provides a way to systematise the most important available data on the equation of state. Because of this, in the text below we use the formalism of the new approach.

## II. The equation of state for bulk phases

Now we introduce some notions and definitions used in the new theory. First of all, this is a new and rigorous thermodynamic definition of the excluded volume  $v_i^{\text{ex}}$  as the partial volume of a particle of component  $i$  with a resting centre of mass in the absence of all interactions except for the short-range interactions related to the volume of the own particle

$$v_i^{\text{ex}} \equiv v_i^0 \equiv \left( \frac{\partial V}{\partial N_i^0} \right)_{T, p, N_j, N_{j \neq i}^0}. \quad (6)$$

Here  $v_i^0$  is the partial volume of a resting particle of component  $i$  defined as the derivative of the system volume  $V$  with respect to the number,  $N_i^0$ , of particles at rest in the system provided that the temperature, pressure and the numbers,  $N_j$ ,  $N_{j \neq i}^0$ , of other particles are constant. A similar definition of the partial volume,  $v_i$ , of ordinary (moving) particles known in thermodynamics obeys the relationship

$$v_i = \left( \frac{\partial \mu_i}{\partial p} \right)_{T, \{x_i\}}, \quad (7)$$

where  $\{x_i\}$  is the set of mole fractions  $x_i$  symbolising the constancy of composition. An analogous expression for particles at rest

$$v_i^0 = \left( \frac{\partial \mu_i^0}{\partial p} \right)_{T, \{x_i\}}, \quad (8)$$

was derived as a new thermodynamic relation.<sup>38</sup> For both resting and moving particles the partial volume differs from the own particle volume  $v_{i0}$ . For instance, in gases  $v_i$  is incomparably larger than  $v_{i0}$ . Moreover, in contrast to the own particle volume, the partial particle volume can be of any sign because of competition between attractive (long-range) and repulsive forces. In the absence of long-range forces the partial volume of a particle at rest is positive and equals the excluded volume. The excluded volume is always positive, being comparable with the own particle volume. Indeed, the excluded volume is usually treated as a space inaccessible to the centres of mass of moving particles. Assuming particles to be spherical (because of Brownian rotation or simply as a model) and their concentration to be low (rarefied gas), the excluded volume can be estimated as follows. For mobile particles of the  $k$ th component of radius  $r_k$ , a resting particle of component  $i$  of radius  $r_i$  creates an excluded volume  $v_{ik}^{\text{ex}}$  in the form of a sphere of radius  $r_i + r_k$  (Fig. 1). From here it follows

$$v_{ik}^{\text{ex}} = \left( v_{i0}^{1/3} + v_{k0}^{1/3} \right)^3, \quad (9)$$

where  $v_{i0} = 4\pi r_i^3/3$  and  $v_{k0} = 4\pi r_k^3/3$  are the corresponding particle volumes [for particles of the same size relationship (9) gives  $v^{\text{ex}} = 8v_0$ , as mentioned above]. Averaging of relation (9) gives the excluded volume for a gas mixture

$$v^{\text{ex}} = \sum_{i,k} x_i x_k \left( v_{i0}^{1/3} + v_{k0}^{1/3} \right)^3. \quad (10)$$

**Figure 1.** The excluded volume (shaded by gray) created by a resting particle (1) with respect to a moving particle (2).

Similarly, for the average particle volume and the average partial particle volume in a mixture one gets

$$v_0 \equiv \sum_i x_i v_{i0}, \quad (11)$$

$$v^0 = \sum_i x_i v_i^0.$$

The exclusion factor  $f$ , the most important parameter of the theory, is defined as the ratio of the average excluded volume to the average particle volume in the system

$$f \equiv \frac{v^{\text{ex}}}{v_0}. \quad (12)$$

From Eqns (10) and (11) it follows that the exclusion factor  $f_0$  for a rarefied gaseous mixture can be calculated using the relationship

$$f_0 = \frac{v^{\text{ex}}}{v_0} = \frac{\sum_{i,k} x_i x_k (v_{i0}^{1/3} + v_{k0}^{1/3})^3}{\sum_i x_i v_{i0}}. \quad (13)$$

From here for a one-component system we again get  $f_0 = 8$  (for mixtures, the  $f_0$  value can be much smaller, remaining, however, greater than two).

Passage from rarefied to the condensed state is accompanied by clustering of matter, which causes a decrease in the exclusion factor.<sup>38, 39, 42</sup> The minimum value,  $f = 1$ , is only possible for 'soft' particles capable of filling the space without cavities; for hard particles the exclusion factor is always larger than unity and depends on the packing type. Generally, the excluded volume factor varies within the limits

$$f_0 \geq f \geq \frac{v_\infty}{v_0}, \quad (14)$$

where  $v_\infty$  is the limiting volume per particle. Equality of  $v_\infty$  and  $v_0$  is only possible for 'soft' particles; otherwise, usually one has  $v_\infty > v_0$ . For instance, one gets  $v_\infty/v_0 = 6/\pi \approx 1.91$  for a cubic packing of hard spheres and  $v_\infty/v_0 = 6/\pi\sqrt{2} \approx 1.35$  for hexagonal packing. In any case the excluded volume factor varies in some narrow region within the interval  $8 \geq f \geq 1$ , whereas the pressure varies in a nearly unbounded interval. This makes the excluded volume factor a convenient tool in deriving the equation of state.

The formulation of theory begins with derivation of the master equation, that is, a rigorous thermodynamic relation to generate equations of state. We start from the Gibbs–Duhem equation

$$dp = -s dT + \sum_i c_i d\mu_i, \quad (15)$$

where  $s$  is the entropy density and  $c_i$  is the concentration of the  $i$ th component. Integration of Eqn (15) is performed at constant temperature and chemical composition (this limitation is removed after integration), so the concentration,  $c_i$ , of each component can be expressed through the overall concentration of all components

$c = \sum_i c_i$ , which becomes the exclusive integration variable.

Substitution of expression (5) into relation (15) with allowance for Eqn (8) gives

$$\frac{dp}{dc} = \frac{k_B T}{1 - cv^0}, \quad (16)$$

where  $v^0$  is the average partial volume of the particle at rest according to definition (11). As mentioned above, the behaviour of the quantity is complex owing to competition between the attractive and repulsive forces, which precludes integration of Eqn (16) in the general form. To get around this problem, we first integrate Eqn (16) in the absence of long-range interactions [in this case, according to definition (6),  $v^0$  is 'automatically' transformed

into  $v^{\text{ex}}$ ] and then add the long-range contribution  $p_1$  to the final expression. This gives the master equation in the form

$$p = k_B T \int_0^c \frac{dc}{1 - cv^{\text{ex}}} + p_1. \quad (17)$$

Expressions for  $p_1$  can be found in the literature. In particular, for the van der Waals forces one has

$$p_1 = - \sum_{i,k} \alpha_{ik} c_i c_k, \quad (18)$$

where  $\alpha_{ik}$  is the constant of attraction between particles of components  $i$  and  $k$ .

For simplicity, the master Eqn (17) can be written in a dimensionless form

$$\tilde{p} = \int_0^\varphi \frac{d\varphi}{1 - f\varphi} + \tilde{p}_1, \quad (19)$$

where  $\tilde{p} \equiv pv_0/k_B T$  and  $\tilde{p}_1$  are respectively the dimensionless pressure and its long-range part and  $\varphi$  is the total volume fraction of all components as the sum of individual volume fractions  $\varphi_i$

$$\varphi \equiv cv_0 = \sum_i c_i v_{i0} = \sum_i \varphi_i.$$

Correspondingly, Eqn (18) is transformed into

$$\tilde{p}_1 = - \sum_{i,k} \tilde{\alpha}_{ik} \varphi_i \varphi_k, \quad (20)$$

where  $\tilde{\alpha}_{ik} \equiv \alpha_{ik} v_0/k_B T v_{i0} v_{k0}$  is the dimensionless image of the constant  $\alpha_{ik}$ . In modern literature, the reduced density

$$y \equiv \frac{\sigma^3}{v} = \frac{6}{\pi} \varphi,$$

rather than the volume fraction  $\varphi$  (here,  $\sigma$  is the particle diameter) is often used. Clearly, this value corresponds to cubic packing of spheres, which, however, is not the closest packing. Having defined the reduced density in a more general form as follows

$$y \equiv \frac{v_\infty}{v},$$

(where  $v_\infty$  can also belong to hexagonal packing), one gets an alternative dimensionless form of the master equation

$$\tilde{p}' = \int_0^y \frac{dy}{1 - gy} + \tilde{p}'_1. \quad (21)$$

Here

$$\tilde{p}' \equiv \frac{pv_\infty}{k_B T},$$

$g \equiv v^{\text{ex}}/v_\infty$  is yet another exclusion factor. Correspondingly, the second dimensionless form of Eqn (18) is as follows:

$$\tilde{p}'_1 = - \sum_{i,k} \tilde{\alpha}'_{ik} y_i y_k, \quad (22)$$

where  $\tilde{\alpha}'_{ik}$  is the dimensionless attraction constant

$$\tilde{\alpha}'_{ik} \equiv \frac{\alpha_{ik} v_\infty}{k_B T v_{i\infty} v_{k\infty}}.$$

For the most dense state the exclusion factor  $g$  equals unity; therefore, it is convenient to use Eqn (21) for the condensed state. But if one starts from the gaseous state, it's better to work with Eqn (19).

To calculate the integral in Eqn (19), one must know the function  $f(\varphi)$ . Information on this function for one-component systems can be extracted from virial coefficients. If we express the exclusion factor in terms of virial expansion<sup>37, 38</sup> and restrict to the ten known virial coefficients for the system of hard spheres,<sup>55</sup> the dependence of  $f$  on  $\varphi$  is characterised by a decreasing concave

**Figure 2.** Exclusion factor plotted vs. volume fraction (solid lines) and the limits of applicability for the corresponding equations of state (dashed lines) with allowance for the short-range part only. Planck equation (1), van der Waals equation (2), Eqn (38) (3) and the line obtained from the virial expansion for hard spheres with ten known virial coefficients (4).

curve (curve 4, Fig. 2). The general form of the function  $f(\varphi)$  is still unknown. However, taking into account that the exclusion factor can vary within narrow limits, one can hope for derivation of rather accurate equations of state using realistic approximations for the function  $f(\varphi)$ .

The simplest (zeroth) approximation is to use a constant exclusion factor  $f$ . Here, the equation of state is immediately derived from Eqn (19)

$$\tilde{p} = -\frac{\ln(1-f\varphi)}{f} + \tilde{p}_1. \quad (23)$$

Particular cases of this equation are well known.

For a non-ionised monatomic gas with  $f = 8$  and allowance for Eqn (20) one has

$$\tilde{p} = -\frac{\ln(1-8\varphi)}{8} - \tilde{\alpha}\varphi^2. \quad (24)$$

This is neither more nor less than the Planck equation (2) written in a dimensionless form.

For the condensed state, taking into account Eqn (21) with  $g = 1$  and Eqn (22), we get

$$\tilde{p}' = -\ln(1-y) - \tilde{\alpha}'y^2. \quad (25)$$

This type of equation of state was derived by Temperley<sup>56,57</sup> who applied the Ising model to the lattice gas condensation theory. Later, it was often used in lattice models.<sup>58</sup>

The next (first) approximation takes into account that the exclusion factor must decrease with an increase in density (a linear dependence is assumed)

$$f = f_0 - k\varphi. \quad (26)$$

Here,  $f_0$  is the exclusion factor for rarefied gas and  $k$  is the a positive coefficient whose magnitude imposes limitations on the range of changes in  $\varphi$ . Substituting Eqn (26) into Eqn (19) gives the lattice gas equation of state in the first approximation

$$\tilde{p} = \int_0^\varphi \frac{d\varphi}{1-f_0\varphi+k\varphi^2} + \tilde{p}_1. \quad (27)$$

The form of the function resulting from the integration depends on the numerical value of the constant  $k$ ; therefore, expression (27) in fact defines a family (namely, three types<sup>37-39,41</sup>) of equations of state rather than a single equation of state. When using this approximation and higher approximations, we are guided by the principle of maximum simplicity of the solution. In this case, we take  $k = (f_0/2)^2$  and the equation of state has the form:

$$\tilde{p} = \frac{\varphi}{1-(f_0/2)\varphi} + \tilde{p}_1. \quad (28)$$

With allowance for Eqn (20) and  $f_0 = 8$ , Eqn (28) for a one-component system with van der Waals forces takes the form

$$\tilde{p} = \frac{\varphi}{1-4\varphi} - \tilde{\alpha}\varphi^2. \quad (29)$$

This is neither more nor less than the van der Waals equation (1) written in a dimensionless form.

Now we can clearly see the sense of the coefficient 4 in Eqn (1) and resolve the apparent contradiction between the van der Waals and Planck equations. Namely, the factor  $4v_0$  in the van der Waals equation is not the excluded volume. This equation does not include a constant excluded volume at all; rather, the excluded volume in this equation is variable. The van der Waals equation ranks higher than the Planck equation in the hierarchy of approximations, though the place occupied by the former is not the place of honour.

In the second approximation<sup>37-43</sup> we model the concavity of the  $f(\varphi)$  curve using a fractional-linear function

$$f = \frac{f_0 - k_1\varphi}{1 + k_2\varphi} \quad (30)$$

with two positive constants  $k_1$  and  $k_2$ . Yet another positive constant  $K$  is introduced to characterise the initial (negative) slope of the curve  $f(\varphi)$

$$\left(\frac{df}{d\varphi}\right)_{\varphi \rightarrow 0} = -K. \quad (31)$$

To calculate  $K$ , it is sufficient to know the second and third virial coefficients. For a one-component system, one has  $K = 34$ . From Eqns (30) and (31) one gets the relation

$$k_1 + k_2 f_0 = K \quad (32)$$

connecting the coefficient  $k_1$  to  $k_2$ ; as a result, only one of them can be chosen independently.

Substituting Eqn (30) into the master equation (19) leads to

$$\tilde{p} = \int_0^\varphi \frac{(1-k_2\varphi)d\varphi}{1-(f_0-k_2)\varphi+k_1\varphi^2} + \tilde{p}_1, \quad (33)$$

and its simplest form after integration meets the condition

$$k_1^{1/2} = \frac{f_0 - k_2}{2} \equiv \beta. \quad (34)$$

Taken together, this relationship and Eqn (32) unambiguously determine the coefficients  $k_1$  and  $k_2$

$$k_1 = (f_0 - K^{1/2})^2, \quad (35)$$

$$k_2 = 2K^{1/2} - f_0.$$

With  $k_1$  and  $k_2$  thus determined, the equation of state in the second approximation has the form

$$\tilde{p} = \frac{f_0 - \beta}{\beta} \frac{\varphi}{1 - \beta\varphi} + \frac{f_0 - 2\beta}{\beta^2} \ln(1 - \beta\varphi) + \tilde{p}_1, \quad (36)$$

where

$$\beta = f_0 - K^{1/2}.$$

Using Eqn (20), Eqn (36) for a nonionic system with van der Waals forces can be written in a more detailed form

$$\tilde{p} = \frac{f_0 - \beta}{\beta} \frac{\varphi}{1 - \beta\varphi} + \frac{f_0 - 2\beta}{\beta^2} \ln(1 - \beta\varphi) - \sum_{i,k} \tilde{\alpha}_{ik} \varphi_i \varphi_k. \quad (37)$$

For a one-component system, one has  $f_0 = 8$ ,  $K = 34$  and  $\beta \approx 2.169$ . In this case Eqn (37) takes the form

$$\tilde{p} = \frac{2.688\varphi}{1 - 2.169\varphi} + 0.778 \ln(1 - 2.169\varphi) - \tilde{\alpha}\varphi^2. \quad (38)$$

Equation (38) looks like a combination of the van der Waals and Planck equations, being much more accurate than both of them and provides exact values of the first three rather than two virial coefficients. This equation describes a gas–liquid phase transition and the critical point. A comparison of the critical parameters of the three equations<sup>37–39, 41</sup> revealed their improvement on going up in the hierarchy of approximations. One of the critical parameters of Eqn (38) can be treated outstandingly, *viz.*, the ratio of the Boyle temperature ( $T_B$ ) to the critical temperature ( $T_c$ ) is 2.74 (*cf.* a value of 2.75 determined from experiments).

Figure 2 shows how the range of applicability of the equation of state extends in the hierarchy of approximations. Indeed, one has  $\varphi < 0.125$  for the Planck equation,  $\varphi < 0.25$  for the van der Waals equation and  $\varphi < 0.461$  for Eqn (38); but this is much smaller than  $\varphi = 0.74$  for the closest packing of hard spheres. Therefore, all three equations are applicable to gases. Nevertheless, Eqn (36) can be adapted to the whole density range. The case in point is that this equation gives the correct value of the second virial coefficient irrespective of the parameter  $\beta$ , which thus is responsible for the correctness of the value of the third virial coefficient. Losing quality of the equation, it is possible to use a fitting parameter  $k$  instead of  $\beta$  and write the equation of state for a system of hard spheres of the same size as

$$\tilde{p} = \frac{8-k}{k} \frac{\varphi}{1-k\varphi} + \frac{8-2k}{k^2} \ln(1-k\varphi), \quad (39)$$

and then determine the  $k$  value assuming the best correspondence between Eqn (39) and the results of a molecular dynamics simulation.<sup>6</sup> This procedure can be illustrated by Fig. 3; the  $k$  and cross-correlation square  $R^2$  (this parameter characterises the quality of computer fitting) values are listed in Table 1. As can be seen, while the curve plotted using Eqn (39) passes near the ‘experimental’ points, the amplitude of deviations (1%–10%) is too large to meet modern requirements.

The third and higher approximations were derived by successively adding the terms next in order of smallness to the numerator of expression (30) while the principle of maximum simplicity was realised by choosing the coefficients reducing the denominator of the first term of the equation of state to an integer power of the difference. All coefficients were expressed through the same

**Figure 3.** Dimensionless pressure isotherms for a fluid of hard spheres obtained in the zeroth (Planck equation, curve 1), first (van der Waals equation, curve 2) and second [Eqn (38), curve 3] approximations of the equation of state for a gas derived in the framework of the theory of excluded volume and using Eqn (39) (curve 4) for the entire density range. Points denote the results of molecular dynamics simulations reported by Alder and Wainwright.<sup>6</sup>

**Table 1.** Coefficient  $k$  and cross-correlation square  $R^2$  obtained in different approximations of the equation of state for the whole range of densities in fitting the Alder and Wainwright<sup>6</sup> and Erpenbeck and Wood<sup>59</sup> databases.

| Approximation number | Database <sup>6</sup> |          | Database <sup>59</sup> |          |
|----------------------|-----------------------|----------|------------------------|----------|
|                      | $k$                   | $R^2$    | $k$                    | $R^2$    |
| 2                    | 1.592960              | 0.994418 | 1.597202               | 0.989454 |
| 3                    | 1.283681              | 0.997342 | 1.299441               | 0.998856 |
| 4                    | 1.070709              | 0.999457 | 1.077599               | 0.999684 |
| 5                    | 0.918766              | 0.999847 | 0.921284               | 0.999920 |
| 6                    | 0.805259              | 0.999945 | 0.805372               | 0.999988 |
| 6'                   | 0.803025              | 0.999952 | 0.802941               | 0.999994 |
| 7                    | 0.717260              | 0.999946 | 0.715955               | 0.999998 |
| 8                    | 0.563023              | 0.998591 | 0.608111               | 0.999611 |

constant  $k$ . The third and higher approximations contain no logarithms and can be expressed using a general relationship

$$\tilde{p}^{(n)} = \frac{1}{(1-k\varphi)^{n-1}} \left\{ \varphi + \frac{f_0 - 2k(n-1)}{(n-1)(n-2)k^2} \times \right. \quad (40)$$

$$\left. \times \left[ (1-k\varphi)^{n-1} - 1 + (n-1)k\varphi \right] \right\} + \tilde{p}_1,$$

where  $n$  is the approximation number ( $n \geq 3$ ). It is acceptable to write the equation of state in terms of a compressibility factor (especially for the model of hard spheres)

$$Z \equiv \frac{pv}{k_B T} = \frac{\tilde{p}}{\varphi}. \quad (41)$$

Using this technique, we rewrite relationship (40) for a fluid of hard spheres of the same size ( $f_0 = 8$ ,  $\tilde{p}_1 = 0$ ) in the form

$$Z^{(n)} = \frac{1}{(1-k\varphi)^{n-1}} \left\{ 1 + \frac{8-2k(n-1)}{(n-1)(n-2)k^2\varphi} \times \right. \quad (42)$$

$$\left. \times \left[ (1-k\varphi)^{n-1} - 1 + (n-1)k\varphi \right] \right\}.$$

In this category the Carnahan–Starling equation<sup>60</sup>

$$Z = \frac{1 + \varphi + \varphi^2 - \varphi^3}{(1-\varphi)^3}, \quad (43)$$

obtained by summing the virial expansion with coefficients rounded to integers is thought to be the most accurate. Before this equation (at first, in the framework of scaled particle theory<sup>4</sup>), the Percus–Yewick equation<sup>61, 62</sup>

$$Z = \frac{1 + \varphi + \varphi^2}{(1-\varphi)^3}, \quad (44)$$

$$Z = \frac{1 + 2\varphi + 3\varphi^2}{(1-\varphi)^2}, \quad (45)$$

(in the form of the compressibility and pressure equations, respectively) and the Guggenheim equation<sup>63</sup>

$$Z = \frac{1}{(1-\varphi)^4}. \quad (46)$$

were derived. Here, we don't present well-established, more complex equations of state (Padé approximants,<sup>64</sup> Le Fevre equation,<sup>65</sup> Woodcock equation,<sup>66</sup> *etc.*) because they are not related to the approach in question and are inconsistent with the concept of maximum simplicity.

Returning to Eqn (42), we will make some comments concerning particular approximations. For the third, fourth and fifth approximations we get the following equations of state:

$$Z^{(3)} = \frac{1 + (4 - 2k)\varphi}{(1 - k\varphi)^2}, \quad (47)$$

$$Z^{(4)} = \frac{1 + (4 - 3k)\varphi + k(k - 4/3)\varphi^2}{(1 - k\varphi)^3}, \quad (48)$$

$$Z^{(5)} = \frac{1 + (2/3)(1 - k)(6\varphi - 4k\varphi^2 + k^2\varphi^3)}{(1 - k\varphi)^4}. \quad (49)$$

With  $k = 1$ , Eqn (47) is a truncated Percus–Yewick equation (45), relationship (48) is similar to the Carnahan–Starling equation (43) and the Percus–Yewick equation (44), while equation (49) coincides with the Guggenheim equation (46).

The reader can assure himself that Eqn (42) gives the correct value of the second virial coefficient irrespective of the value of  $k$ . In other words, Eqn (42) can be applied to a gas of hard spheres at any value of the constant  $k$  that can be used as a parameter of fitting to the results of numerical experiments for all densities; this is the best way to refine Eqn (42). This was done<sup>67, 68</sup> using the first database by Alder and Wainwright<sup>6</sup> (see above) and the highly accurate but covering the range of lower densities database by Erpenbeck and Wood<sup>59</sup>. Table 1 lists the  $k$  values thus found for each approximation and the cross-correlation squares  $R^2$ . As can be seen, the highest accuracy of equation (42) is achieved in the seventh approximation. Passage to higher approximations is pointless because starting from the eighth approximation the results of fitting become much poorer owing to the use of only one parameter. It should be noted that already in the third approximation the region of formally admissible changes in the volume fraction,  $0 \leq \varphi \leq 0.779$ , is broader than the region of formally admissible changes for a system of hard spheres,  $0 \leq \varphi \leq 0.74$ , which ensures coverage of all possible densities.

The sixth approximation of Eqn (42) deserves particular attention. With the  $k$  value listed in Table 1, which nearly coincides for both databases, this approximation has the numerical form

$$Z^{(6)} = \frac{1 - 0.026(\varphi - 0.805\varphi^2 + 0.324\varphi^3 - 0.052\varphi^4)}{(1 - k\varphi)^5}. \quad (50)$$

The smallness of the coefficient 0.026 allows the numerator to be truncated to unity. Having done this, one gets an approximation (denoted by 6')

$$Z^{(6')} = (1 - k\varphi)^{-5}, \quad (51)$$

which combines a very simple form with high accuracy. Indeed, after repeating the fitting procedure using Eqn (51) and getting somewhat different  $k$  values (see Table 1) we find that Eqn (51) is the most accurate among all approximations (with a maximum deviation of less than 1%) evaluated using the Alder and Wainwright database. A comparison of the accuracy of Eqn (51) with the accuracy of the Carnahan–Starling equation (43) and other equations of state (even complex equations including the most accurate Woodcock equation<sup>66</sup>) shows the advantage of Eqn (51).<sup>45, 46</sup> Evaluated with the highly accurate Erpenbeck and Wood database, Eqn (51) occupies an intermediate position between the sixth and seventh approximations, being characterised by a maximum deviation of 0.45%. Here, the Carnahan–Starling equation provides a maximum deviation of 0.31% while Eqn (42) in the seventh approximation is characterised by a deviation of only 0.20% (see Ref. 68) (the Woodcock equation was evaluated using another database and was characterised by a deviation of 0.59%).

Thus, at present Eqn (42) at  $n = 7$  is one of the most accurate equations of state (maybe, the most accurate one). It should be noted that in comparing the equations of state a question of the accuracy of the database is posed.<sup>6</sup> As it is improved, the procedure can be repeated for any other set of reference data, which allows the coefficient  $k$  in Eqns (42) and (40) to be refined.

### III. Equation of state for surface monolayers

A technique similar to that considered above was applied to the analysis of a surface monolayer formed on adsorption or spreading of a substance on the surface. The surface area was considered instead of volume. However, it is incorrect to reason that transition from the equation of state for bulk systems to the equation of state for a monolayer is reduced to trivial reduction of the equation dimension. The volume,  $v_0$ , of anisometric particles is independent while their parking area,  $a_0$ , depends on the spatial orientation, which complicates the computational procedure. The necessity of taking into account the effect of the substrate also goes beyond the two-dimensional approach. Thus, strictly speaking, description of a monolayer requires a three-dimensional theory based on the same expression (5) for the chemical potential of matter in the bulk system.

Consider a multicomponent monolayer on a planar (solid or liquid) substrate. Since only the surface characteristics are important for the equation of state, the monolayer will be thought insoluble; this will permit a rigorous treatment in terms of equilibrium thermodynamics. The main relationship in this theory is the Gibbs adsorption equation

$$d\gamma = -\bar{s}dT - \sum_i \Gamma_i d\mu_i, \quad (52)$$

where  $\gamma$  is the surface tension,  $\bar{s}$  is the entropy excess per unit surface area and  $\Gamma_i$  and  $\mu_i$  are the adsorption (excess of substance per unit surface area) and the chemical potential of particles (molecules, ions or nanoparticles) of component  $i$  in the monolayer. Summation is performed over all components of the monolayer but does not involve the substrate whose influence is included in all other parameters. For insoluble monolayers the adsorption  $\Gamma_i$  coincides with the actual amount of matter per unit surface area of the monolayer. In other words,  $\Gamma_i$  is the surface concentration of particles of the sort  $i$ , related to conventional (three-dimensional) concentration as follows

$$c_i = \frac{\Gamma_i}{h_i}, \quad (53)$$

where  $h_i$  is the average size of particles of the sort  $i$  in the direction perpendicular to the plane of the monolayer. Clearly, if we deal with aspherical particles, the parameter  $h_i$  is sensitive to their orientation.

According to the Gibbs equation of adsorption, the presence of a substrate causes a decrease in the surface tension of the monolayer. The difference

$$\Pi_0 \equiv \gamma_0 - \gamma, \quad (54)$$

( $\gamma_0$  is the surface tension of the substrate in the absence of a monolayer) is called the surface pressure; this is the main characteristic of the monolayer. Substituting Eqn (54) into Eqn (52) gives the equation

$$d\Pi = \bar{s}dT + \sum_i \Gamma_i d\mu_i, \quad (55)$$

which is similar to the Gibbs–Duhem equation (15). Equations (5), (53) and (55) serve as the basis of a theory which also operates with some geometric characteristics considered below.

The most important geometric characteristics of the particles of component  $i$  in the monolayer are the parking area  $a_{i0}$ , the minimum possible surface area per particle  $a_{i\infty}$  at  $\Pi \rightarrow \infty$ , the partial surface area  $a_i$ , the partial surface area of a particle at rest  $a_i^0$  and the excluded surface area  $a_i^{\text{ex}}$  defined as the partial area of a particle at rest in the absence of long-range forces<sup>47–49</sup>

$$a_i^{\text{ex}} \equiv a_i^0 \equiv \left( \frac{\partial A}{\partial N_i^0} \right)_{T, \Pi, N_j, N_{j \neq i}^0}, \quad (56)$$

where  $A$  is the surface area of the monolayer. The partial surface areas obey the following relations

$$a_i = \left( \frac{\partial \mu_i}{\partial \Pi} \right)_{T, \{x\}}, \quad (57)$$

$$a_i^0 = \left( \frac{\partial \mu_i^0}{\partial \Pi} \right)_{T, \{x\}},$$

where  $\{x_i\}$  is the set of mole fractions of the components

$$x_i \equiv \frac{\Gamma_i}{\Gamma}, \quad (58)$$

$$\Gamma \equiv \sum_i \Gamma_i.$$

Out of two relations (57) the latter was derived recently.<sup>47</sup>

The multicomponent monolayer is also characterised by the average geometric parameters:

$$a_0 \equiv \sum_i x_i a_{i0}, \quad (59)$$

$$a_\infty \equiv \sum_i x_i a_{i\infty}, \quad (60)$$

$$a \equiv \sum_i x_i a_i, \quad (61)$$

$$a^0 \equiv \sum_i x_i a_i^0, \quad (62)$$

$$a^{\text{ex}} \equiv \sum_i x_i a_i^{\text{ex}}, \quad (63)$$

$$h \equiv \sum_i x_i h_i. \quad (64)$$

The parameter  $h$  can be treated as the average monolayer thickness.

Integration of Eqn (55) assuming constant temperature and composition taking into account Eqns (5), (53) and (56)–(64) gives the master equation

$$\Pi = k_B T \int_0^\Gamma \frac{1 - cdh/d\Gamma}{1 - \Gamma a^{\text{ex}}} d\Gamma + \Pi_1, \quad (65)$$

where  $\Pi_1$  is the long-range part of the surface pressure. For instance, in the case of the van der Waals interaction one has

$$\Pi_1 = - \sum_{i,k} \alpha_{ik} \Gamma_i \Gamma_k. \quad (66)$$

Equation (65) is an analogue of the master Eqn (17) for bulk phases but has a more complex form owing to the orientation effect ( $dh/d\Gamma$  derivative). At a specified particle orientation or in the case of spherical particles, the derivative  $dh/d\Gamma$  vanishes and the master equation takes the two-dimensional form

$$\Pi = k_B T \int_0^\Gamma \frac{d\Gamma}{1 - \Gamma a^{\text{ex}}} + \Pi_1, \quad (67)$$

suitable for the derivation of two-dimensional equations of state.

Using  $a_0$  or  $a_\infty$ , Eqn (67) can be written in a dimensionless form in two alternative ways. The first form is

$$\tilde{\Pi} = \int_0^\varphi \frac{d\varphi}{1 - f\varphi} + \tilde{\Pi}_1, \quad (68)$$

where  $\tilde{\Pi} \equiv \Pi a_0 / k_B T$  and  $\tilde{\Pi}_1$  are respectively the dimensionless surface pressure and its long-range part,  $\varphi \equiv \Gamma a_0$  is the total surface fraction of components of the monolayer and  $f \equiv a^{\text{ex}} / a_0$  is the exclusion factor. The second form is as follows

$$\tilde{\Pi}' = \int_0^\theta \frac{d\theta}{1 - g\theta} + \tilde{\Pi}'_1, \quad (69)$$

where the dimensionless surface pressure is given by  $\tilde{\Pi}' \equiv \Pi a_\infty / k_B T$ ,  $\theta \equiv \Gamma a_\infty$  is the surface coverage degree and  $g$  is the second exclusion factor

$$g \equiv \frac{a^{\text{ex}}}{a_\infty} = \frac{f a_0}{a_\infty}. \quad (70)$$

In the case of van der Waals interactions the long-range part of the surface pressure in Eqns (68) and (69) has the form

$$\tilde{\Pi}_1 = - \sum_{i,k} \tilde{\alpha}_{ik} \varphi_i \varphi_k, \quad (71)$$

$$\tilde{\Pi}'_1 = - \sum_{i,k} \tilde{\alpha}'_{ik} \theta_i \theta_k, \quad (72)$$

where  $\tilde{\alpha}_{ik} \equiv \alpha_{ik} a_0 / k_B T a_{i0} a_{k0}$  and  $\tilde{\alpha}'_{ik} \equiv \alpha_{ik} a_\infty / k_B T a_{i\infty} a_{k\infty}$ . Of course, Eqns (68) and (69) are equivalent and the use of a particular equation is governed by convenience. Equation (68) is more appropriate for the gaseous state while Eqn (69) is better for the condensed state.

The functions  $f(\varphi)$  and  $g(\theta)$  in Eqns (68) and (69) are still unknown, but the ranges of their changes are available.<sup>48, 52–54</sup> For a gas, the average exclusion factor in the multicomponent monolayer can be calculated with ease using the relationship

$$f_0 = \frac{\sum_{i,k} x_i x_k (a_{i0}^{1/2} + a_{k0}^{1/2})^2}{\sum_i x_i a_{i0}}. \quad (73)$$

Equation (73) gives  $f_0 = 4$  for one-component and even smaller  $f_0$  for multicomponent monolayers. This is the maximum value of the exclusion factor in the absence of clustering. Analysis of two-dimensional clustering<sup>48, 52–54</sup> defines the minimum value of the exclusion factor as  $f_\infty = a_\infty / a_0$  (packing type dependent parameter). Then, in accord with Eqn (70), the minimum value of  $g$  must be  $g_\infty = 1$ . In any case the exclusion factor varies within the interval  $4 > f$ ,  $g > 1$ , which is narrower than for three-dimensional systems. Correspondingly, one can also expect a higher accuracy of the equation of state when using approximations for the functions  $f(\varphi)$  and  $g(\theta)$ .

Consider two-dimensional equations of state that follow from Eqns (68) and (69). In the zeroth approximation the exclusion factor is thought to be constant, which is possible only for a narrow interval of gas or fluid states. In this case, Eqns (68) and (69) take the form

$$\tilde{\Pi} = - \frac{\ln(1 - f\varphi)}{f} + \tilde{\Pi}_1, \quad (74)$$

$$\tilde{\Pi}' = - \frac{\ln(1 - g\theta)}{g} + \tilde{\Pi}'_1. \quad (75)$$

Equation (74) for a rarefied non-ionised gas with  $f = f_0 = 4$  and allowance for expression (71) is transformed to

$$\tilde{\Pi} = - \frac{\ln(1 - 4\varphi)}{4} - \tilde{\alpha}\varphi^2. \quad (76)$$

This is a two-dimensional analogue of the Planck equation (24), which also gives the exact value of the second virial coefficient of two-dimensional virial expansion. By replacing the factor 4 in Eqn (76) by  $f_0$  in accord with Eqn (73) we get a general expression for a two-dimensional gaseous mixture.

Equation (75) with  $g = 1$  gives two famous equations. At  $\tilde{\Pi}'_1 = 0$ , it represents the van Laar equation of state for an ideal monolayer

$$\tilde{\Pi}' = - \ln(1 - \theta), \quad (77)$$

whose form is independent of the number of components.<sup>27</sup> If (again with  $g = 1$ ) the parameter  $\tilde{H}'_1$  is expressed in the form (72), Eqn (75) represents the generalised Frumkin equation<sup>28, 29</sup> written in a dimensionless form

$$\tilde{H}' = -\ln(1 - \theta) - \sum_{i,k} \tilde{\alpha}'_{ik} \theta_i \theta_k. \quad (78)$$

For one-component systems the equation of state (78) takes the form

$$\tilde{H}' = -\ln(1 - \theta) - \tilde{\alpha}' \theta^2. \quad (79)$$

It corresponds to the Frumkin equation (4) written in a dimensionless form, which is transformed into the van Laar equation at  $\tilde{\alpha}' = 0$ .

Starting from the gaseous state, we must assume that the exclusion factor decreases as the surface density increases. To a first approximation, the exclusion factor  $f$  is a linear function of  $\varphi$

$$f = f_0 - k_1 \varphi, \quad (80)$$

where  $k_1$  is a positive constant. Substituting the dependence (80) into Eqn (68) gives a family of equations of state. The simplest of them meets the condition  $k_1 = f_0^2/4$  and has the form

$$\tilde{H} = \frac{\varphi}{1 - (f_0/2)\varphi} + \tilde{H}_1. \quad (81)$$

Substituting expression (71) into Eqn (81), we get the generalised van der Waals equation written in a dimensionless form

$$\tilde{H} = \frac{\varphi}{1 - (f_0/2)\varphi} - \sum_{i,k} \tilde{\alpha}_{ik} \varphi_i \varphi_k. \quad (82)$$

For a one-component system ( $f_0 = 4$ ) Eqn (82) takes the dimensionless form of the two-dimensional van der Waals equation (3)

$$\tilde{H} = \frac{\varphi}{1 - 2\varphi} - \tilde{\alpha}\varphi^2. \quad (83)$$

In the second approximation, a new equation of state is derived.<sup>47, 48, 51, 52</sup> The procedure is the same as that employed in the case of three dimensions [see Eqns (30)–(36)]. Starting from condition (30), we get the two-dimensional equation of state

$$\tilde{H} = \frac{f_0 - \beta}{\beta} \frac{\varphi}{1 - \beta\varphi} + \frac{f_0 - 2\beta}{\beta^2} \ln(1 - \beta\varphi) + \tilde{H}_1, \quad (84)$$

where again  $\beta = f_0 - K^{1/2}$ . Equations (84) and (36) have the same form, but all coefficients are different. In the case of van der Waals forces, substitution of Eqn (71) provides a more detailed equation of state

$$\tilde{H} = \frac{f_0 - \beta}{\beta} \frac{\varphi}{1 - \beta\varphi} + \frac{f_0 - 2\beta}{\beta^2} \ln(1 - \beta\varphi) - \sum_{i,k} \tilde{\alpha}_{ik} \varphi_i \varphi_k. \quad (85)$$

A one-component monolayer is characterised<sup>47, 48, 51, 52</sup> by  $f_0 = 4$ ,  $K = 6.616$  and  $\beta = 1.428$ . Substituting these values into Eqn (85) leads to

$$\tilde{H} = \frac{1.801\varphi}{1 - 1.428\varphi} + 0.561 \ln(1 - 1.428\varphi) - \tilde{\alpha}\varphi^2. \quad (86)$$

This is a two-dimensional equation of state in the second approximation. Unfortunately, the two-dimensional gaseous state has been studied much less than the three-dimensional state. Equation (86) can be evaluated in two ways, by comparison with the van der Waals equation (83) and by comparing the values of the virial coefficients.<sup>16, 69</sup> The applicability range of Eqn (86) ( $0 < \theta < 0.7$ ) is much broader compared to the van der Waals equation ( $0 < \theta < 0.5$ ), the former being much more accurate. If the van der Waals equation gives exact values of the first and the

second virial coefficients only, Eqn (86) exactly reproduces the first, second and third virial coefficients and provides a nearly exact value of the fourth virial coefficient (overestimated by 9%) and the fifth virial coefficient overestimated by 28%.

It is of interest to compare Eqns (38) and (86). As was expected, the two-dimensional equation is more accurate. Until recently, only the van der Waals equation simultaneously covered the three-dimensional and two-dimensional cases. Making use of the situation, de Boer showed<sup>26</sup> that for the same substance the two-dimensional critical temperature  $T_c^{(2)}$  must be half the three-dimensional critical temperature  $T_c^{(3)}$ . Evaluation<sup>49</sup> using Eqns (38) and (86) revealed that

$$\frac{T_c^{(2)}}{T_c^{(3)}} \approx 0.455. \quad (87)$$

The ratio (87) shows that the de Boer estimate  $T_c^{(2)}/T_c^{(3)} \approx 0.5$  is quite correct, being at the same time somewhat rough.

Higher approximations are derived using the same algorithm as for the bulk phases. A general formula for the  $n$ th approximation ( $n \geq 3$ ) is as follows

$$\begin{aligned} \tilde{H}^{(n)} = & \frac{\varphi}{(1 - k\varphi)^{n-1}} \left\{ 1 - \frac{2nk - 2k - f_0}{(n-1)(n-2)k^2\varphi} \times \right. \\ & \left. \times [(1 - k\varphi)^{n-1} - 1 + (n-1)k\varphi] \right\} + \tilde{H}_1. \end{aligned} \quad (88)$$

It is easy to verify that Eqn (88) gives correct values of the first and second virial coefficients irrespective of the choice of the constant  $k$ . This assures applicability of Eqn (88) to the gaseous state of the monolayer at any  $k$  value and allows  $k$  to be used as a fitting parameter for the whole density range. Here, it is convenient to use an ultrahigh-precision (to 0.01%) data array obtained by Monte Carlo simulation and molecular dynamics.<sup>30</sup> Let us demonstrate the procedure taking a model of hard disks as an example.

Let the disks be of the same size,  $\tilde{H}_1 = 0$  and  $f_0 = 4$ . Rewrite Eqn (88) using the compressibility factor  $Z = \tilde{H}/\varphi$ ,

$$\begin{aligned} Z^{(n)} = & \frac{1}{(1 - k\varphi)^{n-1}} \left\{ 1 - \frac{2nk - 2k - 4}{(n-1)(n-2)k^2\varphi} \times \right. \\ & \left. \times [(1 - k\varphi)^{n-1} - 1 + (n-1)k\varphi] \right\}. \end{aligned} \quad (89)$$

In accord with expression (89), the equation of state in the third approximation has the form

$$Z^{(3)} = \frac{1 - 2(k-1)\varphi}{(1 - k\varphi)^2}. \quad (90)$$

With  $k = 1$  Eqn (90) reproduces the equation of state known in scaled particle theory<sup>70, 71</sup>

$$Z^{(3)} = (1 - \varphi)^{-2}. \quad (91)$$

In addition, Eqn (91) is a two-dimensional analogue of the Carnahan–Starling equation (43) for hard spheres, *i.e.*, it is obtained by summing the two-dimensional virial expansion in which all coefficients are rounded to integers. Equation (91) is also similar to the Henderson equation<sup>72</sup>

$$Z = \frac{1 + (b_3 - 3)\varphi^3}{(1 - \varphi)^2} \quad (92)$$

with  $b_3 - 3 \approx 0.128$ . Equation (90) best fits the reference database<sup>30</sup> at  $k \approx 1.0145$  (cross-correlation squared is 0.999908 with a maximum deviation of  $\sim 1\%$ ) and the form of Eqn (90) is as follows

$$Z^{(3)} = \frac{1 - 0.029\varphi}{(1 - 1.0145\varphi)^2}. \quad (93)$$

Since the  $k$  values found do approach unity, expression (91) can be used as the equation of state in the third approximation. In this case a small decrease in accuracy (maximum deviation increases to 3%) is compensated for by the simplicity of the equation. Thus, we can say that scaled particle theory reproduces the third approximation to the theory of excluded area.

Going to the fourth approximation from Eqn (89) gets

$$Z^{(4)} = \frac{1 - (3k - 2)\varphi + k(k - 2/3)\varphi^2}{(1 - k\varphi)^3}. \quad (94)$$

Equation (94) best fits the database<sup>30</sup> at  $k \approx 0.876677$  (cross-correlation squared is 0.99999 with a maximum deviation of  $\sim 0.46\%$ ). With this  $k$  value Eqn (94) takes the form

$$Z^{(4)} \approx \frac{1 - 0.63\varphi + 0.184\varphi^2}{(1 - 0.876677\varphi)^3}. \quad (95)$$

The next (fifth) approximation gives somewhat poorer results (cross-correlation squared is 0.99993), which can be explained by the use of a sole fitting parameter.

Among the studies reported in the last decade, a simple equation of state<sup>35,36</sup> based on the Boltzmann concept of excluded volume must be pointed out. In our notation, the equation has the form

$$Z = \left(1 - 2\varphi + \frac{2\varphi_\infty - 1}{\varphi_\infty^2} \varphi^2\right)^{-1} = \left[1 - 2\varphi_\infty \theta + (2\varphi_\infty - 1)\theta^2\right]^{-1}, \quad (96)$$

where  $\varphi_\infty = a_0/a_\infty = 3^{1/2}\pi/6 \approx 0.9069$  is the upper limit for  $\varphi$ , which corresponds to the closest hexagonal packing, and  $\theta = \varphi/\varphi_\infty$  is the surface coverage degree. The authors of the study<sup>35</sup> compared the accuracy of their equation with the available simple and complex equations including, except for expressions (91) and (92), the equations of state by Andrews,<sup>73,74</sup> Woodcock,<sup>66</sup> Baram and Luban<sup>75</sup> and the Levin<sup>30</sup> and Padé<sup>76</sup> approximants. It was concluded that Eqn (96) is the most accurate among the simple equations. However, a comparative analysis<sup>53</sup> of Eqns (95) and (96) showed that expression (95) is even better, being the best among the simple equations; only the Levin approximant (the most accurate among the complex equations) ranks above it in accuracy.

#### IV. The orientation equation of state

Let us return to Eqn (65) and discuss the role of orientation characterised by the derivative  $dh/d\Gamma$ . To state that an increase in the surface density of a substance must lead to thickening of a monolayer as the main trend probably requires the mass balance only. But from Eqn (65) it is seen that if  $dh/d\Gamma > 0$  and the derivative is rather large in absolute value, then, possibly, the perfect derivative  $d\Pi/d\Gamma$  will be of negative sign, which means stability violation. As a result, a van der Waals loop corresponding to the first-order phase transition can appear in the two-dimensional pressure isotherm. Thus, the first important conclusion that follows from Eqn (65) is that orientation of the particles of the monolayer can induce two-dimensional first-order phase transitions. It is remarkable that this prediction is also valid in the absence of attractive forces between anisometric particles. The effect of orientation on two-dimensional condensation was demonstrated in the experiments with surfactant monolayers.<sup>77</sup>

To make Eqn (65) complete, one should know the dependence of the monolayer thickness  $h$  on the surface density  $\Gamma$ . In the general case the functional dependence

$$h = h(T, \Gamma_1, \Gamma_2, \dots) \quad (97)$$

can be called the orientation equation of state. Neither theoretical nor experimental data on such an equation are available at the moment but the first steps towards formulation of a theory have been made recently.<sup>47,51–53</sup> Of course, the cases in point are general considerations because the orientation effects strongly depend on the specific geometry of particles in the monolayer.

Apparently, the orientation effect arises in the gaseous monolayer. Since particles change their orientations by collisions, one can assume that the increase in the thickness,  $h - h_0$ , is proportional to the collision rate, which in turn is proportional to the square of the particle concentration and to the collision diameter that is determined by the linear dimension of the particles along the surface. If the parking area of particles is proportional to the square of the linear dimension mentioned above and its product by  $h$  (particle volume) is a constant, the linear dimension is proportional to the square root of the thickness. Then, one gets the orientation equation of state

$$h - h_0 = \frac{K\varphi^2}{h^{1/2}}, \quad (98)$$

where  $h_0$  is the minimum thickness of the monolayer at zero surface pressure and  $K$  is the coefficient of proportionality. Analysis and refinement of Eqn (98) should be set aside until experimental data in the field is obtained.

A model of elastic behaviour can also be applied to a condensed monolayer. This approach was used in the membrane theory<sup>78</sup> by introducing a ‘tilt modulus’ which has not been determined experimentally so far. Using the variable  $\theta$ , which is more convenient for description of the condensed state, expression (65) can be replaced by an equivalent equation

$$\tilde{\Pi}' = \int_0^\theta \frac{1 - d \ln h / d \ln \theta}{1 - g\theta} d\theta + \tilde{\Pi}'_1, \quad (99)$$

where  $\tilde{\Pi}'$  and  $\tilde{\Pi}'_1$  have the same sense as in expression (69). In particular, for a non-ionised monolayer one has

$$\tilde{\Pi}'_1 = -\tilde{\alpha}'\theta^2,$$

where  $\tilde{\alpha}' \equiv \alpha/k_B T a_\infty$  is the dimensionless attracting constant. It is reasonable to assume that the monolayer acquires elastic properties after exceeding a threshold degree of coverage  $\theta_t$ . The action of tangential stress,  $\Pi/h$ , causes the monolayer to thicken. Let us introduce the transversal elasticity modulus

$$\varepsilon = \frac{d(\Pi/h)}{d \ln h}. \quad (100)$$

Integrating relationship (100) gives the equation of state

$$\Pi = \frac{\Pi_t h}{h_t} + \varepsilon h \ln \left( \frac{h}{h_t} \right), \quad (101)$$

where the particular  $\Pi_t$  and  $h_t$  values correspond to  $\theta_t$ , i.e., to the transition to elastic orientation. Such a transition usually manifests itself as a kink point in the surface pressure isotherm (Fig. 4), so the  $\Pi_t$  can be readily determined in the experiment. In addition to the minimum thickness  $h_0$  it is also convenient to introduce the maximum thickness  $h_\infty$  corresponding to the closest packing of the monolayer at an infinite pressure. Then, Eqn (101) can be written in a dimensionless form

$$\Pi' = \frac{\tilde{\Pi}'_t \tilde{h}}{\tilde{h}_t} + \tilde{\varepsilon} \tilde{h} \ln \left( \frac{\tilde{h}}{\tilde{h}_t} \right), \quad (102)$$

where  $\tilde{\varepsilon} \equiv \varepsilon a_\infty h_\infty / k_B T$  and  $\tilde{h} \equiv h/h_\infty \leq 1$  are the reduced elastic modulus and monolayer thickness, respectively.

**Figure 4.** Surface pressure isotherm for the case of an orientation two-dimensional second-order phase transition.

For a dense monolayer we can assume  $a^{\text{ex}} = a$  and correspondingly

$$g^{\text{ex}} = \frac{a}{a_{\infty}} = \frac{h_{\infty}}{h} = \frac{1}{\tilde{h}}. \quad (103)$$

Substituting expression (103) into Eqn (99) with  $\tilde{\Pi}'_1 = -\tilde{\alpha}'\theta^2$  gives the equation of state for a monolayer with van der Waals interactions

$$\tilde{\Pi}' = \int_0^{\theta} \frac{1 - d \ln \tilde{h} / d \ln \theta}{1 - \theta / \tilde{h}} d\theta - \tilde{\alpha}'\theta^2. \quad (104)$$

The system of Eqns (102) and (104) completely describes the state of a non-ionised monolayer with variable orientation of particles. A general solution to this system of equations is problematic but analysis of these equations in the differential form<sup>47,51–53</sup> revealed a trend for the kink points in the surface pressure isotherm. Namely, if the kink point corresponds to an orientation phase transition, the slope of the curve must be smaller in the region of greater  $\theta$  values (see Fig. 4).

## V. Conclusion

The proposed procedure for deriving the equation of state based on the exclusion factor exhibits high creativity. This approach allows not only new highly accurate equations to be derived but also permits a better understanding of the well-established equations of state (a remarkable example is provided by the van der Waals equation). As to the use of the fitting parameter in refining the equation for the whole density range, it is appropriate to make the following comments. First, many equations of state include unknown constants that are more precisely determined in experiments. This is common practice. Second, in order to pass a curve through ten points with high accuracy using only one fitting parameter, one must have a very good equation. Eventually, third, this is a specific trick due to the fact that the problem of dependence of the exclusion factor on the density of matter is still to be solved. To solve this problem, one must know how the degree of particle clustering depends on the particle concentration. At present, this problem has been intensively studied by the researchers working in the field of physical chemistry of solutions.

It should be emphasised that the theory considers the short-range forces related to the particle size but not the long-range forces (the corresponding part of the equation of state has its traditional form). Note that in experimental studies on the role of the attraction and repulsion constants researchers deal with their combination, so knowledge of one constant facilitates determination of the other. Thus, finding the repulsion constants is also of great importance for the attractive part of the equation of state. What kind of force is more important? It is known that at temperatures above the Boyle temperature the attractive forces are insignificant so the behaviour of the gas is governed by the repulsive forces. However, recently it was suggested that near the

triple point the decisive role in molecular systems is played by the repulsive forces, the attractive forces serving to keep particles together.<sup>79</sup>

**Abstract.** Modern trends in studies of solutions of surfactant mixtures are discussed. The emphasis is placed on thermodynamic and molecular-statistical modelling of the phase behaviour and self-assembly patterns. The methods for prediction of properties of mixed micellar solutions based on the data for solutions of individual surfactants and the methods for calculation of the size, shape and composition distribution of micelles using the quasi-chemical models that take into account the molecular characteristics of components are analysed. Recent studies of surfactant solutions using computer experiments are surveyed. Theoretical approaches to the description of self-assembly phenomena in solutions of amphiphilic polymers and of their mixtures with low-molecular-mass surfactants are discussed. The bibliography includes 309 references.

## I. Introduction

Self-organised solutions of surfactants are the most common nanostructured liquid systems; their studies started in 1913 with the discovery of micelles by McBain. Over the last decades, the substantial progress in understanding the nature of phenomena occurring in such systems and diversity of their behaviour has been made owing to the development of novel experimental techniques, methods of theoretical simulations and computer-assisted calculations.<sup>1–3</sup> The range of surfactants under study has extended significantly. Surfactants with complex molecular architectures attract ever increasing interest, in particular, the gemini surfactants that combine two polar head groups and two non-polar tail groups linked through a bridge in one molecule.<sup>4</sup> Surfactants with fluorocarbon and siloxane hydrophobic chains, biological surfactants<sup>5</sup> and surfactants with head groups modified by introduction of specific substituents bearing chemical or biological functions<sup>6,7</sup> are the subjects of intense investigations. For instance, the self-assembly of surfactants designed by introduction of peptides and oligopeptides gives rise to structures that mimic

natural objects, such as biological membranes. Solutions containing two or more surfactants are of particular interest<sup>3,8–10</sup> since mixtures rather than individual surfactants are most abundant in practice. By combining different surfactants one can deliberately adjust properties of the system without recourse to the synthesis of new substances. Another important factor is that technological processes adopted in industry typically afford surfactant mixtures. Isolation of individual components from such mixtures can prove too time-consuming and costly and thus it is desirable to learn the effect of different admixture surfactants on the main component in order to produce formulations with optimum properties.

Mixtures of surfactants with water-soluble polymers have been attracting growing interest over the last two decades. The majority of industrial and household surfactant compositions contain polymers. Amphiphilic water-soluble polymers can be considered as modified surfactants. Such polymers can substantially reduce surface tension of the solution, be adsorbed at interfaces, form micelles in the solution, solubilise non-polar species and be assembled into liquid-crystalline structures. Furthermore, they tend to form mixed micelles with low-molecular-mass surfactants.<sup>1</sup>

The recognition of the similarity between the self-assembly phenomena in colloid systems, polymers and biological structures stimulated emergence of an interdisciplinary field of science that, in terms of physics, chemistry, materials science, biochemistry and engineering, deals with soft matter, *i.e.*, diverse systems manifesting an intermediate degree of ordering between crystalline solids and ordinary liquids. These include micellar solutions, gels and liquid crystals. Hamley, the author of one of the first books devoted to soft matter, expressed confidence that the soft-matter materials will play an ever increasing role and largely replace solid nanostructured materials in the future due to development of new design methods, which can now be only dreamed about.<sup>11</sup>

The modern applications of surfactant solutions encompass production of detergents, drugs, cosmetics, nutrition products and dyes, oil production technologies, chemical, biochemical and pharmaceutical industries where surfactants can control the rate and direction of chemical processes, perform syntheses of mesoporous materials, nanocrystals and periodic composites, produce gels with desired morphology, etc. Furthermore, surfactants are applied to affect colloids stability, emulsification, flocculation, structuring, suspension formation and rheological properties. Micellar and vesicular polymeric systems acquire growing importance in pharmacology (in particular, for encapsulation of drugs)

and chemical catalysis. Polymer gels with different structures are being actively investigated and widely used.

Strictly speaking, mixed micellar surfactant solutions are systems composed of two or more surfactants with each component capable of micelle formation in its own solution. In a broad sense, these are solutions where mixed micelles are formed. This definition also includes the case where only one component is capable of micelle formation, whereas the second diphilic component (*e.g.*, a fatty alcohol or acid) does not form micelles in its individual solution but can penetrate into micelles of the first component. The mixed micellar systems considered in the present review fall into the latter, extended definition. The emphasis is placed on the self-assembly in aqueous solutions of low-molecular-mass surfactants; studies of similar phenomena in solutions of block-copolymers and of their mixtures with surfactants are also cited. The review discusses results of experimental studies as well as problems of the thermodynamic and molecular-statistical modelling of mixed micellar systems.

Over the last few years, micellar solutions of surfactant mixtures have been the subject of extensive investigations, especially, in the USA, Japan and Germany. Many combinations of non-ionic, anionic and cationic surfactants have been studied as well as their mixtures with zwitter-ionic ones. The major results obtained prior to the mid-1990's have been surveyed in several monographs.<sup>2, 3, 8, 12</sup> Of particular interest are synergistic effects, which occur upon mixing of surfactants and result in an increase in the surface activity and viscosity of the solution, decrease in the critical micelle concentration (CMC) and growth of micelles.<sup>9</sup> Recent years are characterised by the increased attention of researchers to the internal structure of aggregates; the capabilities of the experimental elucidation thereof has expanded dramatically due to the modern instrumentation. Novel types of self-assembly in surfactant solutions have been discovered (for instance, formation of multilamellar vesicles). The bulk and quality of the experimental data on the sizes and shapes of aggregates,<sup>13–16</sup> micellar dynamics<sup>17</sup> and, more important, composition of micelles<sup>18–21</sup> have increased substantially. The experimental techniques of structural studies include light scattering, small-angle neutron scattering, electron microscopy, NMR and ESR spectroscopies. Of fundamental importance in the directional search for systems with desired properties is the establishment of the relationship between the molecular structure of a surfactant and its aggregation behaviour in a solution. The progress in this field relies on the achievements in the thermodynamic and molecular-statistical studies of solutions of individual surfactants,<sup>22–26</sup> but additional complications appear due to a variable composition of the micelles and complex patterns of the interparticle interactions. Computer simulation methods play an increasingly important role in studies of micellar solutions.<sup>27, 28</sup> The prediction of properties of mixed solutions based on the data for individual surfactants is of great applied significance. Semiempirical thermodynamical models are often useful in solving this problem.<sup>29</sup>

The present review does not pretend to a comprehensive coverage of the molecular-thermodynamical investigations into the aggregation and phase behaviour of surfactant mixtures. Still, it reflects the major directions of studies and the progress in the field and illustrates the interrelations between the experimental and the theoretical methods.

## II. Forms of aggregation. Synergistic effects

Highly dilute solutions of surfactant mixtures as well as solutions of individual surfactants contain the monomeric forms of the surfactant molecules. At the CMC surfactant aggregates. The region of the isotropic micellar solutions extends up to the boundary corresponding to the transition into the liquid-crystalline (mesomorphic) state (Fig. 1). Within the isotropic region, substantial structural transformations can occur, such as transition of spherical micelles to globular (ellipsoidal) and cylindrical ones (Fig. 2*a–c*), growth of the latter, emergence of worm-like

**Figure 1.** A fragment of a schematic phase diagram composition – temperature for a system surfactant – water.

*L* is a micellar solution, *S* is a solid phase, *E* is a liquid-crystalline phase, *L*<sub>1</sub> and *L*<sub>2</sub> are isotropic liquid phases.

**Figure 2.** The most typical shapes of aggregates in surfactant solutions: a spherical (*a*), a globular (*b*) and a spherocylindrical (*c*) micelles; a bilayer vesicle (*d*).

micelles that form a network. Furthermore, vesicles can form, which represent closed (typically, spherical) bi- or multilayer structures with solvent incapsulated (Fig. 2*d*). Sometimes, especially in the case of non-ionic surfactants, liquid–liquid phase splitting can occur (the solubility diagram has a lower critical point). In the liquid-crystalline region, various structures, such as hexagonal, lamellar, nematic or cubic, can be realised, depending on the nature of the system, concentration of the surfactant and additives, temperature and other parameters (Fig. 3).<sup>1, 2, 30, 31</sup> In some specific cases, a bicontinuous phase is observed. The lower-temperature boundary of existence of a homogeneous surfactant solution is determined by crystallisation of the surfactant (the so-called Krafft boundary) or water. Sometimes, cooling of a micellar solution initiates gelation rather than crystallisation, but such a state is usually unstable.

**Figure 3.** Cubic (a), lamellar (b) and hexagonal (c) liquid-crystalline structures; a bicontinuous structure (d).

In overall, the phase and aggregation behaviour of solutions containing two or more surfactants is characterised by diversity and complexity, although their major features can be observed in solutions of individual surfactants. The methods for the determination of CMC, phase boundaries and structures of aggregates and mesomorphic phases for mixed micellar systems are the same as for solutions of individual surfactants.<sup>3</sup> What is problem specific to mixed systems is the compositional analysis of aggregates. To solve the problem, such techniques as NMR,<sup>32,33</sup> small-angle neutron scattering,<sup>18</sup> ESR,<sup>34</sup> potentiometry with electrodes selective to the surfactant ions,<sup>35,36</sup> ultrafiltration through a membrane that allows monomeric molecules to pass but traps micelles,<sup>37,38</sup> etc. are typically applied.

The specificity of the behaviour of mixed solutions of two or more surfactants as compared to solutions of individual surfactants is related to the entropy of mixing (which is observed even for ideal solutions) and non-ideality effects due to differences in the interactions between identical and different molecules. The first models of micellar solutions of surfactant mixtures suggested by Lange<sup>39</sup> and Shinoda<sup>40</sup> postulated that mixed micelles behave as an ideal solution. Within the ideal solution approximation, Clint derived an equation that related the CMC of a surfactant mixture to the relative content of the individual surfactants and their CMC.<sup>41</sup> Mixtures of two surfactants belonging to one type, *i.e.*, both ionic<sup>39,40,42,43</sup> or both non-ionic,<sup>41,44</sup> behave in a way similar to that expected for an ideal solution. However, many mixtures demonstrate substantial deviations from ideality with the negative deviations due to synergistic effects. These are manifested in additional reduction of the surface tension, a decrease in the CMC, an increase in the viscosity and some peculiarities of the ternary phase diagrams (*e.g.*, extension of the region of a lyotropic liquid-crystalline phase towards lower concentrations of the surfactant, crystallisation of a 1:1 compound from surfactant mixtures with a nearly equimolar ratio of components). For instance, synergistic effects are observed in mixtures of an ionic and a non-ionic surfactants due to the fact that polar groups of the latter become incorporated between the similarly charged heads of the former thus reducing their electrostatic repulsion.<sup>45</sup> The most pronounced effects are typical of

mixtures of a cationic and an anionic surfactants, which form ionic pairs resembling a zwitter-ionic surfactant with a double tail.<sup>3,9,46</sup> This is accompanied by liberation of formerly bound counterions, which increases the ionic strength of the solution and produces the positive entropy effect. In solutions of such mixtures (commonly referred to as catanionic) at nearly equimolar concentrations, precipitation or segregation often occur at temperatures where solutions of individual surfactants are homogeneous.<sup>47</sup> Such solutions often manifest viscoelasticity. Mixtures of an anionic and a weakly basic surfactants that can be protonated (*e.g.*, alkylamine oxides, alkylamines or alkylethoxyamines) reveal strong synergistic effects that are enhanced upon acidification.<sup>48–58</sup> In an acidic medium, such a system becomes similar to a mixture of a cationic and an anionic surfactants and is characterised by very low values of CMC. For instance, CMC of aqueous solutions of sodium dodecyl sulfate and dodecyltrimethylamine oxide at 323.2 K are  $9.5 \text{ mol m}^{-3}$  and  $1.6 \text{ mol m}^{-3}$ , respectively, whereas their 1:1 mixture is characterised by CMC of  $0.65 \text{ mol m}^{-3}$  and  $0.003 \text{ mol m}^{-3}$  at normal acidity of the solution and at pH 2, respectively.<sup>58</sup> Among systems manifesting positive deviations from ideality, mixtures of hydrocarbon and perfluorinated surfactants having hydrocarbon similar polar groups are most studied. These surfactants are poorly compatible, their mixing can yield two types of micelles.<sup>59–62</sup>

Micelles with non-classical shapes (*i.e.*, other than spherical, globular and spherocylindrical) attract significant attention. In particular, tablet-shaped micelles were found in some catanionic systems using small-angle neutron scattering, although this shape is rarely encountered and sometimes appears to be non-equilibrium.<sup>63</sup> An interesting phenomenon is the network formation by long worm-like micelles. Due to this the solution can become viscoelastic (see Section VI). Vesicles are yet another type of aggregates frequently occurring in surfactant mixtures. These are also observed in solutions of many individual surfactants (*e.g.*, phospholipids, other surfactants with two tails or some surfactants with fluorocarbon radicals). The formation of vesicles is particularly typical of mixtures of a cationic and an anionic surfactants,<sup>9,64</sup> which occurs not only in water but in other polar solvents as well.<sup>65</sup> Typical vesicles are characterised by bilayer structures and sizes from *ca.* 100 nm to a few micrometers. In their local properties, vesicles are similar to planar bilayers and thus can serve as convenient models of biological membranes. For a number of surfactant mixtures, it was found that relatively small vesicles (15–40 nm) are formed in dilute solutions, which convert into multilayer onion-like vesicles with an increase in the surfactant concentration.<sup>66</sup> Another type of behaviour has recently been observed in a system sodium oleate–octanol–water: at a high surfactant concentration, small monodisperse bilayer vesicles are assembled into a hard gel that represents a densely packed ordered cubic-like phase.<sup>67</sup> According to studies of mixtures of an ionic and a non-ionic surfactants, an increase in the fraction of the ionic component favours the formation of vesicles, which is in accord with the theoretical predictions indicating the stabilisation of vesicular structures with respect to planar lamellar ones with an increase in the charge density of the bilayers.<sup>68,69</sup> The influence of the ratio of two surfactants, their total concentration, presence of additives and other factors on the transformation of vesicles into micelles and *vice versa* is currently under investigations. The conversion of vesicles into micelles can be promoted by shear stress.<sup>70</sup> For a mixture of tetradecyldimethylamine oxide with dodecylethoxysulfonic acid [ $\text{C}_{12}\text{H}_{25}(\text{CH}_2\text{CH}_2\text{O})_{2.5}\text{SO}_3\text{H}$ ], shear induced the transformation of a lamellar structure into a vesicular one.<sup>71</sup> Evidently, an assessment of the role played by the thermodynamical and kinetic factors in the formation of vesicular systems requires further investigations. Vesicular systems with polymer additives are of special interest. In particular, such additives can stabilise vesicular structures.<sup>72</sup>

The liquid crystal structures and phase boundaries were studied for a number of surfactant mixtures.<sup>2,42,55,73–79</sup> Mixing of different types of surfactants can result in the emergence of new

phases. For instance, upon mixing of tetradecyldimethylamine oxide with sodium dodecyl sulfate, the region of isotropic solutions becomes narrower and an extended region of a nematic phase appears (the total surfactant concentration at the phase boundary is less than 10 mass % at a component ratio of 1 : 1).<sup>55</sup> The available data suggest that the transition of the micellar solution into the liquid-crystalline state can be strongly affected by salts.<sup>2</sup> The phase behaviour in aqueous ethanol solutions of surfactant<sup>80</sup> and mixtures surfactant–water–oil<sup>2,81</sup> have been considered in numerous publications but these systems are beyond the scope of the present review.

### III. The critical micelle concentration and the Krafft boundary. The pseudophase model of micellar solutions

The critical micelle concentration and the Krafft boundary are two important characteristics of surfactant solutions. The former defines the tendency of a surfactant towards aggregation and the concentration of monomeric molecules in the aqueous environment of micelles. The latter represents the lower-temperature boundary of stability of homogeneous surfactant solutions, which is determined by the equilibrium between the surfactant solution and the solid phase. The temperature, at which the solid phase starts to precipitate should be sufficiently low for detergents, cosmetics, micellar solutions employed in oil production, *etc.* Therefore, a typical problem of the design of industrial surfactant formulations consists of lowering the Krafft boundary with various additives. At the same time, crystallisation is an efficient means of purification and isolation of individual surfactants from mixtures. In this case, the knowledge of the diagrams of crystallisation is required for optimising the corresponding processes. Thus, the determination of CMC and precipitation temperature for systems containing two or more surfactants based on the respective data for solutions of individual surfactants represents a topical problem. This problem can be solved within a relatively simple model that approximates a homogeneous micellar solution as a combination of two pseudophases, *viz.*, an aqueous and a micellar.<sup>82</sup> Although the pseudophase model has limitations<sup>22</sup> it appears quite useful in the description of effects of mixing. Holland and Rubingh derived the following equation for the CMC of a non-ideal mixture of two surfactants based on the pseudophase model:

$$\frac{1}{\text{CMC}} = \frac{y_1}{f_1 \text{CMC}_1} + \frac{y_2}{f_2 \text{CMC}_2},$$

where  $y_i = C_i/(C_1 + C_2)$  is the relative molar fraction,  $C_i$  is the molar concentration of the  $i$ th surfactant in the solution,  $f_i$  is its activity coefficient in a micelle ( $f_i = 1$  for a micelle composed of only the  $i$ th surfactant);  $i = 1, 2$ .<sup>83</sup>

Starting from the late 1970's, the concept of a regular solution, which enabled approximate consideration of deviations from ideality in the behaviour of mixed micelles has become widely adopted.<sup>12,83</sup> One of the basic parameters within the regular solution theory is interchange energy, which characterises the difference between the interaction energies of identical and different surfactant molecules. Typically, one uses a dimensionless parameter  $\beta$  defined as the interchange energy divided by  $kT$  ( $k$  is the Boltzmann constant and  $T$  is the temperature). For a binary regular solution, the dependence of the activity coefficients on the mole fractions ( $x_i$ ) of the components in mixed micelles is symmetrical:

$$f_1 = \exp[\beta(1 - x_1)^2]; f_2 = \exp[\beta x_1^2].$$

The value of  $\beta$  is estimated based on the CMC values for individual surfactants and at least one solution containing both surfactants. Such estimates have been obtained for many micellar systems.<sup>12,84,85</sup> Calculations of  $\beta$  using the molecular-statistical

model of mixed micelles<sup>86,87</sup> are in satisfactory agreement with the respective estimates from the experimental data. In particular, data on CMC and adsorption of aqueous solutions containing dodecylpyridinium bromide and a non-ionic surfactant have been interpreted within the regular solution model and compositions of the micelles and adsorption layers were calculated.<sup>88</sup> However, recent investigations have shown that the simple one-parameter regular solution model fails in many cases. Several two- and multi-parameter models of non-ideal mixed micelles have been proposed<sup>10,89,90</sup> that allowed the description of non-symmetrical dependences of the activity coefficients on the surfactant ratios. However, the increased number of fitting parameters diminishes the attractiveness of these, virtually empirical, models since they possess only limited predictive power.

It has been known for a long time that micelle formation in surfactant solutions is affected by the addition of salts. This effect appears as a decrease in the CMC of an ionic surfactant due to shielding of the electrostatic repulsion between the likely charged polar groups of the surfactant molecules. The dependence of CMC of an ionic surfactant on the salt concentration follows approximately the Corrin–Harkins rule, which establishes the linear correlation between the logarithms of CMC and the counterion concentration  $C$ :

$$\log \text{CMC} = -k_{\text{CH}} \log C + b_{\text{CH}}, \quad (1)$$

where  $k_{\text{CH}}$  and  $b_{\text{CH}}$  are constants specific to the surfactant.<sup>91</sup> This presumes that the surfactant and the salt contain identical ions. If both electrolytes are 1 : 1-charged, then  $C = C_s + \text{CMC}$ , where  $C_s$  is the salt concentration; the coefficient  $k_{\text{CH}}$  is taken equal to the degree of counterion binding by a micelle in the salt-free solution. Equation (1) is valid at relatively low salt concentrations. At higher concentrations, the slope of the function  $\log \text{CMC}$  vs.  $\log C$  is altered, which can be due to the change in the mean activity coefficient of the dissociated surfactant ( $f_{\pm}$ ). Taking into account the activity coefficient, the following expression can be written for a mixture of two 1 : 1-charged surfactants and a salt:

$$\log \text{CMC} + 2 \log f_{\pm}(\text{CMC}) \approx -\log(C_s + \text{CMC}) + b,$$

where the parameter  $b$  is determined by the aggregation number and the micelle formation constant.<sup>92</sup> However, this expression neglects the possibility of an incomplete binding of counterions by the micelles, *i.e.*, it assumes that the degree of counterion binding [ $k_{\text{CH}}$  in (1)] is equal to unity. A similar approximation was elaborated for surfactants and salts with arbitrary stoichiometries.<sup>22,92</sup> Simultaneous treatment of the non-ideality effects (*i.e.*, changes in the activity coefficients) and an incomplete binding of ions remains a current challenge. The validity of the Corrin–Harkins rule was discussed<sup>93</sup> on the basis of the Poisson–Boltzmann equation within the approach developed by Evans, Mitchel and Ninham.<sup>94</sup> The dependence of the degree of counterion binding on the ratio of a non-ionic and an anionic surfactants in the solution was analysed in the context of deviations from the linear equation (1).<sup>95,96</sup> Some systems, such as solutions of alkyltrimethylammonium halides with alkali-metal halides as additives, reveal an abrupt change in the slope of the  $\log \text{CMC}$  vs.  $\log C$  lines at a certain salt concentration, which is normally interpreted as the coincidence of two CMC corresponding to the starting point of micelle formation and the transition sphere  $\rightarrow$  cylinder, respectively.

A modification of the ideal pseudophase model, which takes into account the electrostatic contribution into the change in the Gibbs energy upon transfer of a surfactant ion (*e.g.*, a dodecyl sulfate anion) from the solution onto the charged surface of a micelle, was proposed to describe CMC of mixtures of anionic surfactants containing different counterions.<sup>97</sup> This approach was applied to calculate CMC of individual surfactants in the absence and in the presence of a salt as well as of mixtures of two anionic surfactants having singly and doubly charged counterions in the absence of a salt. The model was also extended to mixtures of two surfactants and a salt.<sup>98</sup> The calculations show that the depend-

ence of the CMC on the counterion concentration is mainly affected by the charge of the counterions whereas their nature is of low significance, which is in agreement with the experimental data. According to a recently suggested scheme of estimating CMC for a surfactant mixture based on the pseudophase model using the Gibbs–Duhem relation and the Poisson–Boltzmann equation, the synergistic effects upon mixing of an ionic and a non-ionic or of two ionic surfactants are dominated by the entropic contribution.<sup>99</sup> A description of CMC for mixtures of a cationic and an anionic surfactants, where the charge density on the surface of mixed micelles is strongly reduced as compared to that for the respective one-component micelles and synergistic effects are strong (within the regular solution model, the values of the parameter  $\beta$  for such systems lie between  $-20$  and  $-30$ ), remains a current challenge. The systems manifesting strong pH-dependent changes in CMC are of significant interest.<sup>100</sup>

The majority of published data concerning crystallisation from mixed surfactant solutions dealt with the phase boundaries at constant temperature (*i.e.*, the concentration of an additive as a function of the surfactant concentration in a concentrated solution). The main attention was paid to the effects of additives on the precipitation of anionic surfactants.<sup>101–112</sup> Until recently, data on the precipitation temperature as a function of the relative fraction of one of the surfactants at a constant total surfactant content, which corresponds to the Krafft boundary, were scarce and predominantly related to relatively low total surfactant concentrations, often just slightly above CMC.<sup>47, 113–116</sup> A solid phase that crystallises from a micellar solution typically has constant stoichiometry (*e.g.*, pure surfactant, its hydrate, a complex of two surfactants or ice) whereas solid solutions of surfactants are rarely formed.<sup>117</sup> Therefore, the most common type of the phase diagrams are eutectic diagrams. In the simplest case, such a diagram has two branches corresponding to precipitation of a pure surfactant (or ice) (Fig. 4a). Recently, equilibria of a variety of micellar solutions (aqueous solutions of two non-ionic, two ionic or an ionic and a zwitter-ionic surfactants, solutions of surfactants with addition of salts or alcohols) with solid phases have been elucidated.<sup>29, 44, 58, 118–125</sup> Mixtures of sodium or magnesium dodecyl sulfate [NaDS or Mg(DS)<sub>2</sub>, respectively], which are anionic surfactants, with alkyldimethylamine oxide (AO),

which is a non-ionic surfactant that undergoes protonation and acts as a cationic surfactant in acidic media, were shown to behave anomalously: a strong dependence of the solubility diagrams on pH was observed for the first time (Fig. 4b).<sup>58</sup> In the case of acidic solutions, the diagram precipitation temperature *vs.* mole fraction of AO (for a constant total surfactants content) reveals a maximum corresponding to the composition 1:1. According to chemical analysis and X-ray diffraction studies, a 1:1 cation-anionic complex (AOH<sup>+</sup>DS<sup>−</sup>) is crystallised from solutions with nearly equimolar ratios of the two surfactants, while the nature of the cation of dodecyl sulfate is not important. In addition to the 1:1 compound, complexes with other stoichiometries are likely formed at higher relative concentrations of AO.

Models allowing prediction of solubility diagrams for ternary systems based on the data for aqueous solutions of individual surfactants (*e.g.*, precipitation temperature at constant concentration of the solution, enthalpy of dissolution) are of great interest, in particular, from the practical viewpoint. The problem can be solved using the pseudophase model of a micellar solution. Equilibrium conditions can be expressed in variables of any of the two pseudophases, *viz.*, aqueous ( $x_i^W$ ) and micellar ( $x_i^M$ ). For ionic surfactants, variables describing the composition of the aqueous pseudophase and a concept of the solubility product are traditionally applied.<sup>101</sup> For instance, the solubility product ( $K$ ) of the salt A(DS)<sub>*n*</sub> can be written as

$$K = a_{A^{n+}} a_{DS^-}^n,$$

where  $a_i$  is the activity of free ions  $i$  in the saturated solution ( $i = A^{n+}, DS^-$ ). However, the application of this approach to compositions far from CMC faces difficulties in estimating the concentrations of free surfactant ions and their counterions. It was established that the applicability of the pseudophase model for predicting the phase behaviour of mixed solutions in the range of relatively high concentrations based on the data for solutions of the individual surfactants can be extended making use of the concentration variables of the micellar pseudophase (this is valid for both non-ionic and ionic surfactants).<sup>29, 118–125</sup> Since the micellar pseudophase is composed of only two surfactants (components 1 and 2) and the water (component 3) content may be neglected, the condition of the equilibrium between the ternary

**Figure 4.** Precipitation temperature as a function of the surfactant relative content.<sup>29</sup>

(a) Water–salt solutions of NaDS and Mg(DS)<sub>2</sub>;  $x_2' = x_{MgDS} / (x_{NaDS} + x_{MgDS})$ ;  $C_{NaCl} / \text{mol litre}^{-1}$ : 0 (1); 0.1 (2); 0.3 (3); (b) aqueous solutions of NaDS and dodecyltrimethylamine oxide (AO) with variable acidities;  $x_{AO}' = x_{AO} / (x_{NaDS} + x_{AO})$ ;  $x_{HCl}' = x_{HCl} / (x_{HCl} + x_{AO})$ : 0 (1); 0.3 (2); 0.6 (3).

solution and the solid surfactant can formally be reduced to equations of the biphasic equilibrium for the two-component system 1–2. For the line of crystallisation of the surfactant 1:

$$\Delta T = \frac{RTT_0}{\Delta H_1} \ln a_1(x_1^M), \quad (2)$$

where  $\Delta T = T - T_0$ ,  $T_0$  and  $T$  are precipitation temperatures of the surfactant from its individual and mixed (at identical total surfactants concentration) aqueous solutions, respectively,  $R$  is the gas constant,  $\Delta H_1$  is the enthalpy of dissolution,  $a_1$  is the activity in a mixed micelle ( $a_1 = 1$  provided that  $x_1^M = 1$ ). If the micellar phase behaves as an ideal solution, then:

$$\Delta T = \frac{RTT_0}{\Delta H_1} \ln x_1^M. \quad (3)$$

Equations (2) and (3) are also valid for surfactant solutions containing additives that do not form micelles on their own (*e.g.*, low-molecular-mass alcohols). These equations suggest that a substantial decrease in the precipitation temperature can be induced by additives that form mixed micelles with the main surfactant, and it is the distribution coefficient of the additive between the micellar and aqueous phases that plays a decisive role. For salt-free solutions of mixtures of two non-ionic or ionic surfactants at concentrations substantially above CMC, the composition of micelles is very close to the composition of the surfactant mixture without taking solvent into account:  $x_1^M = x_1/(x_1 + x_2)$ , therefore,  $\Delta T$  depends only on the relative concentrations of the two surfactants but is independent of their total content. The eutectic-type diagrams precipitation temperature–relative concentration of the surfactant for salt-free mixtures of ionic surfactants as well as for mixtures of non-ionic surfactants can be modelled in a similar way. In the case of ionic surfactants, this approach is simpler than that based on the concept of the solubility product. For solutions of ionic surfactants in the presence of salts or low-molecular-mass amphiphilic additives, the ion exchange (for the former) or distribution coefficient (for the latter) between the micelles and the aqueous environment should be taken into account. An account for the non-ideality of mixed micelles and the aqueous pseudophase is a significant aspect of the modelling. For this purpose, approximate models developed for molecular solutions (*e.g.*, the regular solution model, the Flory–Huggins model, *etc.*) are applied.<sup>126</sup> The strong dependence of the solubility diagram for the system sodium dodecyl sulfate–alkylamine oxide–water on pH can be reproduced within a model taking into account protonation of alkylamine oxide and formation of a cation-anionic complex.<sup>29, 58</sup>

In addition to the practical importance, studies of the solubility diagrams represent an efficient means of gaining information on the thermodynamical properties of micellar solutions, the degree of non-ideality in the behaviour of mixed micelles and specific interactions between components of the mixtures. The major difficulties in the calculations of the solubility diagrams for micellar solutions of surfactant mixtures relate to the description of the non-ideality and often to the lack of data on the temperatures and enthalpies of dissolution for individual surfactants. Definitely, the extension of the experimental database is an important task.

#### IV. Molecular-thermodynamical models of aggregation

Starting from pioneering works by Tenford,<sup>23, 127</sup> Israelachvili, Mitchell and Ninham,<sup>24</sup> Ruckenstein and Nagarajan<sup>128</sup> published in the 1970's, strenuous efforts have been put into development of approximate models establishing relationships between the molecular properties of components and their aggregation behaviour (this is often referred to as the molecular-thermodynamic approach). The formation of a micelle is described as a chemical reaction, the equilibrium concentrations of monomers

and aggregates are calculated from the Gibbs energy of the aggregate formation according to the law of mass action. A detailed analysis of the quasichemical approach has been performed by Rusanov.<sup>22</sup> Numerous studies were devoted to estimating different contributions of micelle formation into the Gibbs energy, elucidation of their relationships with the molecular characteristics of the components as well as with the shapes and sizes of the aggregates.<sup>127–137</sup> The dependence of the stability of aggregates having specific shapes (spheres, cylinders or planar bilayers) on the packing of the surfactant molecules has been analysed.<sup>24</sup> Each type of the aggregates is characterised by its own range of values of the so-called packing factor  $P = v/al$ , where  $a$  is the surface area of the hydrocarbon core per surfactant molecule in the aggregate,  $v$  is the volume of the hydrocarbon radical and  $l$  is its length. The packing factor is equal to the mean cross-sectional area of the radical divided by the area occupied by a polar head of the surfactant on the surface of the hydrocarbon core. The packing factor increases in the order spherical micelles → rod-like micelles → planar bilayers ( $1/3 \rightarrow 1/2 \rightarrow 1$ ). The values of the packing factor larger than unity correspond to inverse micelles that form in non-polar media. The packing conditions were generalised to the case of aggregates with concave surfaces and vesicles with a convex and a concave surfaces simultaneously.<sup>138</sup> The effective cross-sectional area of a polar head is affected not only by the structure of the surfactant molecule but by other factors as well. In particular, addition of a salt to a micellar solution of an ionic surfactant gives rise to a decrease in the area of the polar head. This occurs because the degree of counterion binding increases, the electrostatic repulsion between likely charged heads is partially screened and thus they approach closer to each other. As a result, the addition of a salt promotes transition of spherical micelles to rod-like. If the additive forms mixed micelles with the primary surfactant, the packing conditions are mainly affected by the sizes and shapes of polar and non-polar parts of the additive molecule.

The quasichemical model for a solution of two surfactants A and B considers the process:

where  $g_A$  and  $g_B$  are the numbers of the monomers of A and B within a micelle. The following relation between the mole fractions of aggregates ( $X_g$ ) and monomers ( $X_{1A}$ ,  $X_{1B}$ ) can be obtained from the condition of thermodynamic equilibrium:

$$X_g = X_{1A}^{g_A} X_{1B}^{g_B} \exp \left[ - \left( \frac{g \Delta \mu_g^\circ}{kT} \right) \right]. \quad (4)$$

Here,  $g = g_A + g_B$  is the aggregation number;  $\Delta \mu_g^\circ$  is the standard Gibbs energy of micelle formation per molecule. The term  $\Delta \mu_g^\circ$  relates to the standard chemical potential of a mixed micelle  $\mu_g^\circ$  and the standard chemical potentials of the monomeric molecules in the solution  $\mu_{1A}^\circ$  and  $\mu_{1B}^\circ$  in the following way:

$$\frac{g \Delta \mu_g^\circ}{kT} = \frac{\mu_g^\circ - g_A \mu_{1A}^\circ - g_B \mu_{1B}^\circ}{kT}. \quad (5)$$

Equation (4) links the concentrations of the monomers and the aggregates having a specific size and composition. The value of  $\Delta \mu_g^\circ$  depends on temperature, the aggregation number  $g$ , composition and shape of the micelle. If  $\Delta \mu_g^\circ(T, \text{shape } 1, g) < \Delta \mu_g^\circ(T, \text{shape } 2, g)$ , then the aggregates with the shape 1 are more stable than those with the shape 2 at the same aggregation number. Estimating  $\Delta \mu_g^\circ$  taking into account the structure of the surfactant molecules and parameters of aggregates (*i.e.*, their sizes and shapes) is the key problem in modelling the aggregation behaviour of the system. Typically, micelles are represented as spheres, globules (ellipsoids) or rod-like aggregates (spherocylinders). The term  $\Delta \mu_g^\circ$  is expressed as the sum of several contributions:

$$\begin{aligned} \Delta \mu_g^\circ = & (\Delta \mu_g^\circ)_{tr} + (\Delta \mu_g^\circ)_{def} + (\Delta \mu_g^\circ)_{int} + (\Delta \mu_g^\circ)_{st} + (\Delta \mu_g^\circ)_{dip} + \\ & + (\Delta \mu_g^\circ)_{ion} + (\Delta \mu_g^\circ)_{mix}, \end{aligned}$$

where  $(\Delta\mu_g^\circ)_{tr}$  is the chemical potential of transfer of a hydrocarbon tail from the solution to the aggregate core, which is considered as a structureless liquid hydrocarbon;  $(\Delta\mu_g^\circ)_{def}$  is the potential of deformation of the hydrocarbon tail due to configurational confinement of the carbon skeleton imposed by the shape of the aggregate;  $(\Delta\mu_g^\circ)_{int}$  is the contribution of the surface tension at the interface between the hydrocarbon core of the micelle and aqueous environment;  $(\Delta\mu_g^\circ)_{st}$  is the term describing the steric repulsion of hydrophilic groups of the surfactant molecules located at the surface of the aggregate;  $(\Delta\mu_g^\circ)_{dip}$  is the contribution of dipole–dipole interactions between the polar groups;  $(\Delta\mu_g^\circ)_{ion}$  is the contribution of electrostatic interactions between charged hydrophilic groups and surrounding solution (for ionogenic surfactants);  $(\Delta\mu_g^\circ)_{mix}$  is the contribution due to mixing of A and B within one micelle (applicable only to mixed micelles whereas all other terms apply to both individual and mixed micelles).

The first term from the above list (the transfer potential) does not depend on the size and shape of the aggregate whereas other terms (in particular, the electrostatic contribution) are to a certain extent affected by these parameters. Expressions for the individual terms were obtained based on the theoretical estimates and some experimental data. Two of the most thoroughly developed and widely approved variants are Ruckenstein–Nagarajan<sup>26, 130–132</sup> and Blankschtein<sup>25, 86, 87, 133–137</sup> models. Their advantages include detailed assessment of the methods used to estimate the aforementioned terms, parametrisation of the model for a variety of surfactants, applicability of the models not only to description of properties of various systems but to their prediction as well, in particular, for solutions of surfactant mixtures.

The number of carbon atoms ( $n_C$ ) is an important parameter characterising a hydrocarbon radical. In addition to  $\Delta\mu_g^\circ$ ,  $n_C$  determines geometrical characteristics of the hydrophobic part of the surfactant molecule (*i.e.*, its volume and length), which in turn govern possible sizes of aggregates and, importantly, surface area of the hydrocarbon core per surfactant molecule. Several of the aforementioned contributions into the Gibbs energy of micelle formation are affected by the value of  $n_C$  through the geometrical characteristics.

The Gibbs energy of transfer of a hydrophobic tail from the aqueous solution into the hydrocarbon core (which is the major driving force of micelle formation) can be estimated from the experimental data on the solubility of hydrocarbons in water assuming the additivity of contributions from groups constituting the molecule. In the case of *n*-alkyl radicals:

$$(\Delta\mu_g^\circ)_{tr} = (n_C - 1)(\Delta\mu_g^\circ)_{tr(CH_2)} + (\Delta\mu_g^\circ)_{tr(CH_3)},$$

where  $(\Delta\mu_g^\circ)_{tr(CH_2)}$  and  $(\Delta\mu_g^\circ)_{tr(CH_3)}$  are contributions of a methylene and a methyl group estimated from solubilities of alkanes in water.<sup>26, 127</sup> Within this homologous series,  $(\Delta\mu_g^\circ)_{tr}$  is linearly dependent on  $n_C$ . The potential of transfer of a hydrocarbon with one double bond can be written as follows:

$$(\Delta\mu_g^\circ)_{tr} = (n_C - 3)(\Delta\mu_g^\circ)_{tr(CH_2)} + (\Delta\mu_g^\circ)_{tr(CH_3)} + 2(\Delta\mu_g^\circ)_{tr(CH)}.$$

The contribution of a CH group, which is significantly smaller than that of a CH<sub>2</sub> group in absolute value, was estimated from solubilities of saturated and unsaturated hydrocarbons.<sup>139</sup> According to the model estimates, a decrease in the absolute value of the negative transfer potential  $(\Delta\mu_g^\circ)_{tr}$  is the primary reason for an increase in CMC upon introduction of multiple bonds in hydrocarbon radicals whereas other contributions change only insignificantly.<sup>140</sup> When estimating the transfer free energies, the above formulas are sometimes modified by reduction of the number of carbon atoms by 1–2 with respect to the actual number to account for partial penetration of water molecules into the hydrocarbon core of micelles.

Within the model, a polar group is characterised by two parameters. The first one is the effective cross-section  $a_{eff}$ , which is used in the expression for the steric repulsion of head groups of the surfactant molecules:

$$(\Delta\mu_g^\circ)_{st} = -kT \ln \left( 1 - \frac{a_{eff}}{a} \right),$$

where  $a$  is the surface area of the hydrocarbon core per surfactant molecule. The second parameter is screening cross-section  $a_{scr}$ , which represents the surface area of the micelle core screened by the polar group from contacts with the solution. This parameter influences the term  $(\Delta\mu_g^\circ)_{int}$  according to the following relation:

$$(\Delta\mu_g^\circ)_{int} = \sigma_{wc}(a - a_{scr}),$$

where  $\sigma_{wc}$  is the surface tension at the interface between a solution and the hydrocarbon core.

The deformational contribution relates to the conformational confinement of the hydrocarbon tail with one end connected to the polar group located at the surface of the aggregate, while the distribution of segments inside the core corresponds to a density of liquid hydrocarbon. The value of  $(\Delta\mu_g^\circ)_{def}$  depends on the length of the hydrocarbon chain, the shape of the micelle and its composition (in the case of a surfactant mixture). The estimate of the deformational contribution adopted in the Blankschtein model is based on the conformational characteristics of individual and mixed aggregates with various shapes (*e.g.*, bilayers, spheres and cylinders) analysed within the mean-field approximation.<sup>141, 142</sup> Within such an approach, distribution functions of segments for chains with different lengths in a mixed aggregate were obtained by minimising the free conformational energy of the system. In particular, it was found that longer chains tend to stretch towards the centre of the hydrophobic core with an increase in the fraction of short chains. The conformational entropy of flexible hydrocarbon chains in curved films of surfactants can be related to their elasticity constants.<sup>143</sup> The energy required to bend a film is substantially reduced when short-radical molecules within the film are replaced by longer ones. Nagarajan and Ruckenstein derived expressions for the deformational contribution in the cases of spheres, globules and spherocylinders using the theoretical results obtained by Semenov for microdomains of copolymers.<sup>144</sup>

The difficulties in estimating the electrostatic term, which depends on the sizes and shapes of the aggregates and is strongly affected by the salt background, are due to the fact that no exact analytical solution of the non-linearised Poisson–Boltzmann equation has been obtained for curved charged surfaces in a salt solution. Typically, an approximate solution of the Poisson–Boltzmann equation for spherical and cylindrical surfaces obtained by Evans and Ninham is used in the aggregation models to describe the electrostatic term.<sup>145</sup> The nature of the polar group of the surfactant molecule and counterion is normally taken into account through the parameter  $\delta$  that characterises the distance from the surface of the hydrophobic core to the centre of a bound counterion. A serious drawback of this approximation is that it fails in the region of low surfactant and salt concentrations (*i.e.*, for large radii of the ionic atmosphere). The influence of curvature on the profile of the electrostatic potential have been considered more stringently by Mitchell and Ninham.<sup>146</sup> However, the necessity of numerical integration impedes applicability of this approximation to calculations of the size and shape distribution of micelles. An approximate analytical solution of the Poisson–Boltzmann equation for spherical colloidal particles in a salt-free solution has been obtained by Ohshima.<sup>147</sup> MacKintosh, Safran and Pincus<sup>148</sup> proposed a method for estimating the electrostatic term, which enabled successful description of the influence of the surfactant and salt concentrations on the growth of rod-like micelles including the region of dilute solutions.<sup>149, 150</sup> Other approximations have also been considered,<sup>137</sup> a search for new solutions<sup>151</sup> and refinement of the existing description of the electrostatic term for mixed micelles composed of an ionic and a non-ionic or a zwitter-ionic surfactants<sup>86</sup> are currently underway. The nature of a counterion is usually taken into account through the hydrated ion radius. This approach gives satisfactory results in many cases, which was demonstrated, in particular, for a number

of mixtures of an ionic and a non-ionic surfactant. However, it neglects a specific binding of counterions, which should also be taken into consideration.<sup>152, 153</sup> The specific binding increases according to the Hoffmeister series (for instance, in the case of cationic surfactants, the specific binding strengthens in the series  $\text{AcO}^- < \text{NO}_3^- < \text{Br}^- < \text{ClO}_3^- < \text{Sal}^- < \text{HNC}^-$ ). An increase in the degree of binding favours growth of micelles. The specificity of ions depends largely on dispersion forces; thus, the dispersion contribution has to be included into the potential of mean force when estimating the Boltzmann distribution of ions around an ionic micelle.<sup>154</sup> Differences in CMC for different pairs surfactant ion – counterion can also be due to polarisation of the boundary between the hydrocarbon core and the polar outer shell of a micelle.<sup>155</sup> However, the aforementioned factors were considered only in a few studies. A number of possible methods to account for the influence of the counterion nature on the transition sphere  $\rightarrow$  cylinder through the electrostatic term have been discussed elsewhere.<sup>156</sup>

The calculations performed within the Nagarajan – Ruckenstein and Blankshtein models for solutions of various types of individual surfactants and mixed systems have been reported.<sup>44, 140, 157</sup> The models adequately describe the influence exerted by the size of the hydrophobic part of the surfactant molecule on CMC and micelle growth. Furthermore, they make it possible to take into account the nature of the polar groups and effects of salt additives, describe solubilisation and reproduce synergistic effects in mixed systems. Model estimates of CMC are more successful than the estimates of concentrations of transitions sphere  $\rightarrow$  cylinder or of mean aggregation numbers in the micelle growth since changes in the sizes and shapes of micelles depend on finer effects than CMC. Determination of model parameters requires experimental data on CMC for a system of the type under study. However, as soon as the model is parametrised, it can be used for predicting properties of systems based on other surfactants with the same polar group. The Nagarajan – Ruckenstein model was applied to systematic studies of relationships between the molecular parameters of surfactants and characteristics of their aggregation (including CMC, mean aggregation number and polydispersity).<sup>140</sup> In particular, factors favouring the micelle growth (elongation of the hydrocarbon radical, addition of a salt, the size of the polar group) were evaluated. A modification of the Nagarajan – Ruckenstein model was used in the development of a colloidal model describing precipitation of asphaltenes from oil.<sup>158–160</sup> Different versions of the molecular-thermodynamic models have been proposed to describe surface tension of solutions of surfactant mixtures and adsorption.<sup>161, 162</sup> Model approaches to the study of stability of vesicles with respect to planar bilayer and micellar structures in catanionic systems have been developed.<sup>163–166</sup>

The interactions between aggregates, which become significant at high surfactant concentrations, can be accounted for using the virial equation of state or more rapidly converging  $y$ -expansion.<sup>167</sup> The McMillan – Mayer theory and calculations of the potential of mean force were used to describe non-ideal solutions of non-ionic micelles. The repulsive interactions between micelles were estimated through the excluded volume.<sup>168</sup> The electrostatic repulsion between micelles strongly affects deviations of solutions of ionic surfactants from the ideal behaviour. The experimental light scattering and viscosity data for a number of solutions composed of mixtures of an ionic and an anionic surfactants were interpreted with consideration of only the electrostatic contribution calculated according to the Derjaguin – Landau – Verwey – Overbeek theory.<sup>136</sup> A variant of the osmotic equation that takes into account the van der Waals and long-range electrostatic interactions has been proposed to describe micellar solutions, emulsions and microemulsions in a wide range of compositions.<sup>169</sup>

The molecular-thermodynamic approach gives optimal possibilities of using modern theoretical achievements in the search of regularities in relationships between the chemical architecture of

surfactants and aggregation behaviour. This approach is mostly suitable for solving applied problems in the field of surfactant systems. In this regard, it can be considered as the optimum theoretical tool. Meanwhile, further developments and improvements of the models are currently needed. In particular, this relates to evaluation of various contributions into the Gibbs energy of micelle formation. The factors complicating correct estimates of the electrostatic term and thus representing a challenge to modern theories have already been mentioned. Furthermore, a correct account of penetration of water molecules into the micelle core (which is typically neglected), the effects of the surface curvature and salt background on the surface tension at the interface between the hydrocarbon core and aqueous environment is highly desirable. A problem of an adequate description of the mixing functions arises in the case of mixed micelles, the systems revealing specific interactions being particularly interesting.

Several issues of interest were considered in the drop and quasidrop models developed by Rusanov *et al.*<sup>170–173</sup> for spherical micelles of individual surfactants. The canonical drop model, which assumes flexibility of the hydrocarbon chains and their complete immersion into the aggregate core, like the Nagarajan – Ruckenstein model, accounts for the surface effects in a more rigorous way. The electrostatic term is estimated according to the model of a spherical capacitor, while the deformational term is calculated using the Semenov formula.<sup>144</sup> The quasidrop model allows partial exit of undistorted hydrocarbon chains from the core. These models were applied to study the dependence of the work of formation of premicellar and micellar aggregates on the aggregation number and concentration of the surfactant monomers in the solution; the analytical approximations were derived.

The lattice theories are often used in studies of micellisation.<sup>174–181</sup> The self-consistent field lattice theory originally developed by Scheutjens and Fleer for polymer adsorption<sup>174, 175</sup> was generalised by Leermakers for the case of surfactant aggregation.<sup>176, 177</sup> In particular, this approach successfully reproduces the diffuse structure of the micellar core – corona boundary. Nevertheless, the Gaussian statistics of chains adopted in the model can give rise to errors in the estimation of the density profiles of micelles for relatively short diphilic molecules.<sup>178</sup> The lattice theories in the single-chain mean-field (SCMF) variant are free of this drawback. A simple model ‘a diphilic molecule (a diblock-chain composed of two types of units) – solvent (one unit)’ correctly reproduced the dependence of CMC on the length of the hydrocarbon chain and changes in the morphology of aggregates.<sup>180, 181</sup> The molecular structure of aggregates obtained from the theoretical calculations is in qualitative agreement with that found by computer simulations, yet the model represents surfactant molecules in a quite simplified manner.

Studies combining the molecular-thermodynamic modelling and computer simulations for evaluation of certain characteristics of micelles are of special interest.<sup>182–187</sup> This approach was applied to study solutions of cetyltrimethylammonium bromide containing sodium salicylate and describe penetration of salicylate anions inside micelles.<sup>182</sup> The molecular packing, structure and interactions within the corona of a micelle as well as the contribution of the corona to the Gibbs energy of micelle formation were obtained using the Monte Carlo method whereas other contributions were calculated according to the Blankshtein model.<sup>133, 134</sup> The computer experiments (*e.g.*, Monte Carlo and molecular dynamics) can prove extremely useful in parametrisation of model theories based on the molecular structure of surfactants.

## V. Computer simulations of surfactant solutions

Results of computer simulations of surfactant solutions have recently been surveyed.<sup>27, 28, 188</sup> Computer simulations of biological lipid membranes are especially numerous, but these studies represent a special field. The structure and interactions between the particles constituting a surfactant solution can be described at different levels, depending on the purpose of the study. All atoms

or ions constituting the system and interactions between them are explicitly taken into account in the atomistic models, although several atoms can be combined into one pseudoatom, such as methyl group. In the so-called coarse grain models, atoms are grouped into larger species, *i.e.*, represented more roughly. Furthermore, the electrostatic and torsion potentials are normally neglected, in contrast to the atomistic approach. Simulations commonly referred to as mesoscopic are undertaken using various methods including dissipative particle dynamics, calculations within the lattice gas model and dynamic mean-field density functional approach. The time scales of different events occurring in solutions of aggregated surfactants are estimated as follows:  $10^{-10}$  s for shape fluctuations,  $10^{-6}$  s for exchange of surfactant molecules between micelles and the surrounding solution, hundreds of seconds or longer for such macroscopic events as shear-induced changes. The typical time and spatial scales for the atomistic calculations are 1 ns and 1 nm, respectively. So far, simulations of the equilibrium structures of ordered surfactant solutions are impossible at this level, but still computer experiments can yield detailed information on the local structure and some kinetic aspects of the self-assembly process. In the majority of cases, it is the premicellar surfactant aggregates that are the subject of the studies, and the conformations and arrangement of the molecules at a distance scale on the order of 1 nm are obtained as outcome. As a rule, solutions of individual surfactants are studied.<sup>27, 28, 183, 189–193</sup>

Extended molecular dynamics (MD) calculations at the atomistic level have been performed for aqueous solutions of nonyltrimethylammonium chloride and erucylbis(2-hydroxyethyl)methylammonium (50 surfactant molecules and 3000 water molecules);<sup>191</sup> the mechanism and kinetics of micelle formation were studied for time scales up to 3 ns and the effects of sodium salicylate addition were simulated (the salicylate anions can incorporate into micelles between the polar groups of the cationic surfactant and thus promote growth of rod-like aggregates). Among other systems, for which atomistic calculations have been accomplished, mixtures of surfactants with lipids are worth noting.<sup>194</sup> Computer simulations of inverse micelles,<sup>195</sup> hexagonal and lamellar phases and interface layers in surfactant-containing systems have been performed. MD-simulations of bilayers of cationic surfactants in water using the software package GROMACS<sup>196, 197</sup> were reported. The simulations included 242 and  $\sim 4000$  surfactant and water molecules, respectively. The radial distribution functions, density profiles, surface areas per surfactant molecule and diffusion coefficients were estimated; it was revealed that water molecules and counterions penetrate into the hydrophobic core to a significant extent,<sup>198</sup> which was not observed for anionic surfactants.<sup>199</sup>

The coarse grain models enable calculations in wider time and spatial ranges as compared to the atomistic approach, which makes it possible to investigate equilibrium sizes of aggregates, growth of rod-like micelles, formation of vesicles, kinetics of the aggregation processes, solubilisation, phase transitions in two- and three-component systems and adsorption. However, these calculations take into account the chemical nature of the system under study only qualitatively, and their main goal consists of establishing general regularities in the aggregation and phase behaviour (in particular, for systems surfactant–water–oil)<sup>200, 201</sup> and verification of the results of approximate analytical theories, such as the mean-field theory.<sup>202</sup> The models can be formulated in the lattice and non-lattice versions.<sup>203</sup> Implementation of the latter is usually based on the methods proposed by da Gama, Gubbins and Smit *et al.*<sup>204, 205</sup> A model proposed by Larson<sup>206, 207</sup> is a prototype for many lattice models. Within the lattice approach, the Monte Carlo method was applied to study films of diphilic compounds<sup>208, 209</sup> and simulate conformational transitions in a three-component mixture solvent–diphilic compound–polymer.<sup>210</sup> Capabilities of the theoretical description of the self-assembly processes in surfactant solutions and prediction of the phase diagrams and dynamical properties can be extended

by utilisation of mesoscopic simulations using the dissipative particle dynamics method<sup>211, 212</sup> and the lattice gas model<sup>213, 214</sup> as well as dynamic mean-field density functional approach.<sup>215</sup> Many aspects of the behaviour of real systems and specific influence of the molecular structure on the macroscopic parameters have been successfully reproduced by relatively simple models at the coarse grain and mesoscopic levels. However, only qualitative matching has been reached so far and further developments of the models are required to adequately reflect the chemical identity of the components constituting the system under study. Bridging the gaps between the models of different levels, including atomistic, is a current challenge.

## VI. Viscoelastic surfactant solutions

Surfactant solutions manifest diverse rheological properties owing to the self-assembly of diphilic molecules in aqueous solutions and formation of various mesoscopic structures. The viscosities of many solutions even at high concentrations is only slightly larger than that of water so that they behave as ordinary Newtonian liquids. On the other hand, some solutions reveal viscoelastic properties at low surfactant concentrations.<sup>51, 53, 216–222</sup>

Dilute solutions where micelles are independent of each other are characterised by small changes in viscosity as a function of the surfactant concentration. In the case of spherical micelles, this dependence is represented by the Einstein formula:

$$\eta = \eta_0 (1 + 2.5 \varphi), \quad (6)$$

where  $\eta_0$  and  $\eta$  are viscosities of the pure solvent and the solution with a volume fraction of micelles  $\varphi$  (calculated with account of hydration of the surfactant molecules), respectively. The nearly linear correlation (with a slightly different coefficient) is also held for dilute solutions of monodisperse ellipsoids of revolution. The contribution of the intermicellar interactions into the viscosity of dilute solutions is proportional to the concentration squared and is relatively small. Even in the case of strong hydration of micelles (which can give rise to an increase in their apparent volume fraction by a factor of 2–3), the viscosity of a 10% solution will not exceed that of pure solvent more than twice, according to (6). This however is valid only provided the dilute solution approximation remains applicable. There are many systems manifesting a dramatic change in the viscosity vs. composition and a transition into the viscoelastic state, at a certain (sometimes low) concentration. As a rule, the reason for such a transition is the emergence of long worm-like micelles forming a network. In a sense, worm-like micelles are analogous to polymer macromolecules, although the size distribution of the latter is constant for a specific sample whereas the micelles are dynamic entities of a changing size and shape. These structural parameters of micelles strongly depend on the surfactant concentration, nature of counterions, presence of electrolytes and temperature. Growth of micelles can result in their branching under certain conditions. Long micelles can easily break down or coalesce with each other. These properties of micellar systems determine their more complex behaviour as compared to polymeric systems and make additional difficulties in the interpretation of the experimental data.<sup>223, 224</sup> Viscoelastic systems can be prepared by mixing two ordinary dilute micellar solutions (say, of a cationic and an anionic surfactants) or a micellar and a salt solutions with viscosities close to that of water, whereas the resultant solution resembles a gel. Solutions of some non-ionic and zwitter-ionic surfactants also manifest the viscoelastic behaviour. An increase in viscosity can be caused by addition of salts, especially with hydrophobic counterions capable of incorporating between the polar groups of the surfactant.<sup>53, 222, 225–228</sup> For instance, this is typical of mixtures of cetyltrimethylammonium bromide (CTAB) and sodium salicylate, the maximum effect is observed upon mixing of equal volumes of CTAB and the salicylate with concentrations of  $0.05 \text{ mol litre}^{-1}$  and  $0.03 \text{ mol litre}^{-1}$ , respectively (see Ref. 51).

Solutions of some cationic surfactants with unsaturated hydrocarbon tails manifest the viscoelastic properties (even at high temperatures) in the presence of salts.<sup>218</sup> An intense search for new surfactants and mixed systems forming viscoelastic solutions is currently underway. These studies are to a large extent stimulated by strong practical demand, since viscoelastic surfactant solutions are widely employed in the production of cosmetics and detergents, in some oil production technologies, as thickening agents and lubricants. It is often desirable to have viscoelastic behaviour appearing already at low surfactant concentrations and persisting over a wide temperature range. Numerous recent publications and reviews<sup>219–221</sup> devoted to viscoelastic surfactant solutions clearly demonstrate an increasing interest of researchers in this field.

According to the experimental results, the viscosities of surfactant solutions beyond the point of viscoelastic transition (at concentration  $c^*$ ) change with concentration ( $c$ ) obeying a power law  $\eta \propto (c/c^*)^x$  with  $x = 1.5–8.5$ ; higher values of  $x$  are typical of systems containing charged non-shielded micelles whereas lower values are observed for shielded or non-ionic micellar systems near the liquid-crystalline region. The power law usually holds in a wide composition range. In some systems the viscosity passes through maximum and then starts to decrease with increasing surfactant concentration or upon salt addition. For instance, such a behaviour is observed for solutions of cetylpyridinium chloride upon an increase in the concentration of sodium salicylate.<sup>53</sup> The non-monotonic dependence of viscosity on composition can be due to a decrease in the contour length of linear micelles or formation of branched aggregates.<sup>224, 229–231</sup> Theoretical approaches to the description of viscoelastic micellar solutions postulate two basic mechanisms ensuring flexibility of rod-like aggregates, *viz.*, reptation<sup>232–234</sup> and scission–recombination.<sup>223, 229</sup> Probably, both mechanisms can operate simultaneously. Exponents in the scaling correlation viscosity *vs.* volume fraction of the surfactant ( $\phi$ ) for the two mechanisms are different:  $\eta \propto \phi^{5.25}$  if the reptation prevails and  $\eta \propto \phi^{3.5}$  if the scission–recombination plays the dominant role (see Ref. 223).

In the analysis of factors favouring the micelle growth, the molecular-thermodynamical models described in Section IV are useful as well as alternative approaches, which allows estimation of the concentration of a transition sphere  $\rightarrow$  cylinder (the second CMC), growth of rod-like micelles and dependence of the mean aggregation number on composition. According to the general equations (4) and (5), long rod-like micelles can form spontaneously only if the decrease in the combinatorial entropy corresponding to the process is exceeded by the decrease in the Gibbs energy associated with the transfer of a surfactant molecule from the spherical cap to the cylindrical part of the micelle. The tendency of micelles to transform from spheres to spherocylinders is quantified by the parameter  $K$ , which is defined as:

$$\ln K = g_{\text{cap}} \left( \frac{\Delta\mu_{\text{cap}}^\circ - \Delta\mu_{\text{cyl}}^\circ}{kT} \right). \quad (7)$$

Here,  $g_{\text{cap}}$  is the number of surfactant molecules in the terminal spherical caps of a rod-like micelle,  $\Delta\mu_{\text{cap}}^\circ$  and  $\Delta\mu_{\text{cyl}}^\circ$  are the Gibbs energy of micelle formation per surfactant molecule in the spherical cap and infinite cylinder, respectively. The right part of Eqn (7) can be defined as a dimensionless free energy (expressed in  $kT$  units) of scission of a rod-like micelle. The values of the parameter  $K$  have been estimated experimentally for a number of systems,<sup>156, 235, 236</sup> their dependences on temperature and salt content have been measured ( $K$  increases with an increase in the salt concentration). Typical values of  $K$  for systems that form rod-like micelles lie in the range of  $10^8–10^{12}$ . If long micelles are abundant and the solution concentration significantly exceeds CMC, the dependence of the number-average ( $g_n$ ) and weight-average ( $g_w$ ) aggregation numbers on the total mole fraction of the surfactant in the solution ( $X$ ) are given as:

$$g_n \approx K^{1/2} X^{1/2}; g_w \approx 2 K^{1/2} X^{1/2}.$$

The size distribution of rod-like micelles is broad in contrast to that of spherical aggregates. In the case of non-ionic surfactants or strongly screened ionic micelles (*i.e.*, at high salt concentrations), the dependence of  $K$  on the solution composition can be neglected. Therefore, the dependence of the average aggregation number (and, respectively, the average micelle length) on the surfactant concentration under conditions of growth of rod-like micelles obeys a power law. Two other distinct modes are possible for ionic surfactants at low salt concentrations, *viz.*, the dilute mode where the micelle growth is insignificant and the semidilute mode, which is characterised by a rapid growth. Only with a further increase in concentration, the growth starts to obey the power law typical of strongly screened micelles.<sup>148, 149</sup>

According to the formula (7), the parameter  $K$  characterising the transition sphere  $\rightarrow$  cylinder is determined by the difference in the Gibbs energy between the two parts of a micelle having different geometries. The difference is substantially smaller than the energies themselves since it is caused by relatively weak effects.<sup>152</sup> Thus the results of modelling of the micelle growth are substantially more sensitive to errors in  $\Delta\mu_{\text{cap}}^\circ$  and  $\Delta\mu_{\text{cyl}}^\circ$  determination than estimates of CMC. Although the values of  $K$  calculated within theoretical aggregation models differ from the experimentally measured ones,<sup>26</sup> the model calculations make it possible to follow the effects of the chemical structure of the surfactant and the composition of the solution on the micelle growth. A model proposed for worm-like polymer molecules in solutions<sup>237–239</sup> adopted to long micelles in a combination with a micelle formation model. Calculations fairly reproduced viscosities of dilute solutions of hexaethylene glycol *n*-dodecyl ether (a non-ionic surfactant) and afforded an estimate for the concentration of the transition to semidilute solutions where long micelles start to form a network.<sup>240</sup> However, recent calculations for solutions of ionic surfactants accomplished within a similar model were only in qualitative agreement with the experiment.<sup>241</sup> The major difficulties associated with the simulations relate to the adequate description of the size distribution of worm-like micelles and to estimates of their flexibility.

## VII. Self-assembly phenomena in solutions of amphiphilic polymers and of their mixtures with low-molecular-mass surfactants

The self-assembly phenomena giving rise to mesostructures of various morphologies occur in many polymeric solutions and melts and strongly affect the behaviour of these systems. Properties of many polymeric materials and nanocomposites are determined by the structures of the intrinsic microheterogeneities.<sup>242</sup> Investigations into self-assembled polymeric structures represent a huge independent field and thus we mention here only a few relevant directions.

Self-assembly processes in solutions of low-molecular-mass surfactants bear a remarkable resemblance to those of amphiphilic polymers. A prerequisite to self-assembly of macromolecules (as well as of low-molecular-mass surfactants) is the presence of chemically different groups. A simple example is a diblock-copolymer AB composed of a sequence of monomer units A covalently bound to a sequence of units B. There are diverse more complex systems, such as linear triblock copolymers of the types ABA or ABC, multiblock copolymers (AB)<sub>*n*</sub>, comb-like polymers (in which side chains B are grafted to the backbone chain A), star-like polymers and various mixed structures. Polymeric melts or solutions composed of poorly compatible copolymer blocks can undergo microphase segregation resulting in the formation of nanosized areas having various morphologies and containing predominantly blocks of only one type. However, the self-assembly of low-molecular-mass surfactants is only possible if the molecules have a non-polar and a polar (or charged) groups simultaneously, whereas the self-assembly of a macromolecular system can occur even at small differences in the polarity of

blocks. In particular, copolymers of two low-polar organic blocks (*e.g.*, copolymers of styrene and butadiene) form micelles in organic solvents. A difference between micelles formed by high- and low-molecular-mass compounds consists of the larger size of the former. The radius of a micelle often increases with the length of the block that forms the micelle. Flexibility of long chains imparts a number of features (which are, in particular, manifested in dilute solutions) to micelles formed by macromolecules.

Nanostructures that can be formed by amphiphilic polymers in solutions and melts are diverse, they include spherical, cylindrical and disk-shaped micelles, vesicles, several types of liquid-crystalline microphases and complex bicontinuous structures.<sup>1,243</sup> Many amphiphilic block copolymers form micelles in dilute aqueous solutions with cores composed of non-polar blocks and polar coronas.<sup>244–246</sup> Other structures (*e.g.*, cylinders or disks) can be formed, depending on the polymer concentration, solvent nature and presence of additives. Comb-like copolymer macromolecules with strongly self-attracting side chains can form associated networks above a certain concentration and collapse in dilute solutions.<sup>247,248</sup> Mixtures of a hydrophobically modified polymer and a low-molecular-mass surfactant tend to form mixed micelles, like mixtures of two surfactants. With an increase in the solution concentration, a spatial network (*i.e.*, a micellar gel) can form due to binding of one polymeric chain to many micelles simultaneously. A similar phenomenon, which leads to an abrupt increase in the viscosity, is observed upon mixing of a polyelectrolyte solution with an oppositely charged ionic surfactant. The addition of a non-ionic surfactant yields a significantly smaller increase in viscosity whereas the addition of a similarly charged ionic surfactant does not virtually affect the viscosity. This can be illustrated with experimental data on the addition of cationic, non-ionic and anionic surfactants to hydrophobically modified polyacrylate.<sup>249</sup> Copolymers containing ionic hydrophilic blocks bind the oppositely charged low-molecular-mass surfactant and assemble into small vesicles with a neutralised polyion surrounded by the hydrophilic blocks of the copolymer.<sup>250–255</sup> In micellar solutions of copolymers with additives solubilisation can occur. The experimental data on the solubilisation capacity of micelles formed by different copolymers have recently been surveyed.<sup>256</sup>

In theoretical studies of the self-assembly phenomena in solutions of polymers the dominant role is played by the self-consistent mean-field theories<sup>144,242,257–277</sup> and the phenomenological scaling approach.<sup>278,279</sup> The driving force of the microphase segregation is a difference in the interaction energies of identical and different blocks  $\varepsilon_{ij}$  ( $i, j = A, B$ ), which is quantified by the Flory–Huggins parameter:

$$\chi_{AB} = \frac{z}{kT} \frac{\varepsilon_{AB} - (\varepsilon_{AA} + \varepsilon_{BB})}{2}.$$

The parameter  $\chi_{AB}$  (expressed in the  $kT$  units) determines the change in the free energy upon formation of  $z$  mixed contacts A–B between the monomeric units instead of identical contacts A–A and B–B;  $z$  is the number of the nearest monomer neighbours in the configurational cell of the copolymer. Positive values of  $\chi_{AB}$  suggest the tendency of the blocks A and B to segregate, whereas negative values indicate their tendency to mix with each other. Systems revealing no specific interactions are typically characterised by small (significantly smaller than unity) positive values of  $\chi_{AB}$  (for instance,  $\chi \approx 0.1$  for a pair styrene–isoprene). The degree of segregation (weak or strong) is characterised by the product  $\chi_{AB}N$ , where  $N = N_A + N_B$  is the total number of units in the polymeric chain. Since the blocks within a copolymer are bound by covalent bonds, a copolymer melt with a negative value of  $\chi_{AB}$  can undergo only microphase rather than macrophase segregation. The tendency of the blocks A and B to segregate is opposed by the entropy factor since the formation of microphases imposes restrictions on possible configurations of the polymer chains with concomitant decrease in entropy. The

changes in entropy due to configurational restrictions are associated with the elasticity of polymeric chains and networks. Within an approximation that the elasticity is of the purely entropic origin, it can be calculated from the configurational statistics of independent Gaussian chains.<sup>280,281</sup> The balance between the energetic and entropic factors (*i.e.*, between the interface tension and the entropy expenses to straightening of polymeric coils) determines the equilibrium sizes and geometries of the microdomains. In the case of a copolymer AB with similar volume fractions of blocks A and B, the microphase segregation gives rise to a lamellar structure formed by straightened polymer chains. According to estimates made within the mean-field theory, the transition from a completely disordered structure to the lamellar one occurs for a copolymer containing  $N$  units at  $\chi_{AB}N \approx 10.4–10.5$  (see Ref. 242). In the case of a diblock copolymer with the compositional asymmetry (*e.g.*, due to different degrees of polymerisation of the two components), the interface tends to bend thus giving rise to different morphologies of the microphases. A transition of a diblock copolymer from the lamellar structure to hexagonal or cubic structures depending on the composition was predicted in early analytical mean-field theories developed by Semenov<sup>144</sup> within the strong segregation limit ( $\chi_{AB}N \rightarrow \infty$ ) and by Leibler<sup>258</sup> within the weak segregation limit ( $\chi_{AB}N$  slightly exceeds the threshold for the order–disorder transition). A spectral method for the numerical solution of equations of the self-consistent mean-field theory developed later<sup>260–269</sup> made it possible to describe microphases with quite complex structures and demonstrate the diversity of possible patterns of the phase behaviour in the intermediate segregation regime. For instance, a change in the fraction of the units A in the diblock copolymer AB from 0.5 to 0 or 1 at  $\chi_{AB}N = 20$  gave rise to the following sequence of microphases: lamellar L, bicontinuous G (gyroid), hexagonal C (hexagonally packed cylinders), cubic S (spheres packed into a body-centred cubic lattice). According to the calculations, a perforated lamellar phase (PL), in which layers composed of the blocks present in the copolymer in a lower concentration are perforated with hexagonally arranged channels, becomes nearly stable in the proximity of the phase boundary L–G, which is supported by the experimental results. The enhanced segregation between blocks of a diblock copolymer gives rise to a change in the shape of the micellar structures formed from spherical to cylindrical and disk-like.<sup>271,272</sup> The stable gyroid phase of block copolymers was successfully described within the self-consistent field theory corrected for fluctuations either in the weak<sup>270,273</sup> or strong<sup>274</sup> segregation limit. A theory of the microphase segregation in mixtures of block copolymers and homopolymers was developed;<sup>275,276</sup> another theory predicting formation of secondary-domain structures in disordered multiblock copolymers was proposed.<sup>277</sup>

Birshtein *et al.*<sup>282</sup> performed extensive theoretical investigations into the so-called polymeric brushes (*i.e.*, grafted polymeric monolayers). A numerical self-consistency procedure for the mean-field equations originally proposed by Scheutjens and Fleer<sup>175</sup> and developed in further studies<sup>174,283</sup> proved to perform well for various systems. The scaling method was used to elucidate the influence of the solvent selectivity on the morphology of microphases and sizes of domains.<sup>282,284–286</sup> In particular, bicontinuous structures were considered. The self-consistent field theory was applied to concentrated solutions of copolymers in low-molecular-mass solvents,<sup>287,288</sup> although concentrated solutions remain less explored as compared to dilute ones. A model for the analytical description of swelling of a bicontinuous gel in a selective solution was formulated based on the mean-field theory in the strong segregation limit.<sup>289</sup> A theory of gelation of associating polymers was developed.<sup>290,291</sup>

Important regularities of the influence exerted by the structures of macromolecules, their lengths and rigidities, the character of the segment–segment and segment–solvent interactions and component concentrations on the self-assembly processes were

established within the framework of the mean-field theories and scaling approach. Nevertheless, these approaches afford a qualitative picture rather than quantitative description of the behaviour of specific systems taking into account the chemical structures of components and potentials of the interparticle interactions. A description at the microscopic level is required to solve the problems. This level of detailisation is approached in the theory of associating polyelectrolytes developed by Khokhlov *et al.*<sup>292,293</sup> for macromolecules composed of a hydrophilic backbone and hydrophobic side chains that are distributed along the backbone and can aggregate with each other in polar solvents. Within this theory viewing various contributions into the free energy of association such phenomena as stabilisation of finite-size aggregates, abnormal gelation upon a decrease in the number of associating groups, microphase segregation in semidilute solutions, shear-induced thickening of solutions, adsorption of polyelectrolytes on oppositely charged surfaces, *etc.* can be described.

The method of integral equations opens wide prospects in explicit accounting for structural features of specific macromolecules and intermolecular interactions. The integral equation RISM (Reference Interaction Site Model) proposed by Chandler and Andersen as a generalisation of the Ornstein–Zernike equation for systems with multi-site interactions<sup>294</sup> was applied to various self-assembling polymer-containing systems (the RISM equation applied to polymers is referred to as PRISM). Systems containing macromolecules and disperse particles,<sup>295–297</sup> charged copolymers with different types of distribution of monomeric units over a macromolecule (protein-like and statistical copolymers composed of two types of monomeric units, *viz.*, associating neutral hydrophobic and charged ones),<sup>298,299</sup> self-assembling comb-like polymers, polyelectrolytes in bad solvents, *etc.* were studied.

Substantial progress has been achieved in computer simulations of the aggregation in polymeric systems using the Monte Carlo, molecular dynamics and Brownian dynamics methods.<sup>234,300–305</sup> Simplified models of molecules are often used in numerical simulations of polymeric systems. An amphiphilic polymer can be represented as a sequence of two types of beads (hydrophilic and hydrophobic ones). Specific arrangements of the beads mimic a block copolymer or a comb-like copolymer. Using such a model, it has been shown that a collapse of comb-like macromolecules with associating side chains is accompanied by the microphase segregation.<sup>306</sup> The side chains then form spherical micelles and the backbone is located at the surface of these micelles twining between them. A combination of the Brownian dynamics (*i.e.*, a variant of the mesoscopic approach) and self-consistent mean-field algorithms applicable to polymeric brushes was developed.<sup>307,308</sup> Simulations of the microphase segregation in the brushes capable of liquid-crystalline ordering<sup>300</sup> confirmed the major conclusions of the analytical study accomplished earlier.<sup>282</sup> The results of calculations of the thermodynamic parameters for a simple model system, *viz.*, a rigid-chain polymer, obtained using the integral equations RISM and the Monte Carlo method were systematically compared. A self-consistent hybrid approach combining the atomistic Monte Carlo method and the numerical solution of the integral equation RISM was elaborated and adopted to the description of polymer chains in the presence of colloidal particles.<sup>309</sup>

\* \* \*

There is no doubt that investigations into the solutions of surfactant mixtures will develop intensely and converge with studies devoted to the self-assembly processes in other soft-matter systems. A substantial progress in the field might be anticipated owing to combined application of the theoretical studies, physical and computer experiments.

The present review is written with a partial financial support from the Russian Foundation for Basic Research (Project No 04-03-33050) and the programme ‘Leading Scientific Schools of the Russian Federation’ (grant NSh-676.2003.3).

**Abstract.** General approaches to the automation of chemical analysis and to the design of systems for on-line monitoring of aqueous environments are considered. The advantages of flow analysis techniques in the development of these systems are substantiated. Merits and demerits of the existing versions of flow analysis, namely flow-injection and sequential injection analysis, as well as continuous flow analysis and combined versions of these two methods, are discussed. The bibliography includes 108 references.

## I. Introduction

The chemical control of aqueous environments is needed in many branches of human activity. The most important include the environmental monitoring of natural waters and the monitoring of industrial processes that use water as the operating environment (for example, in thermal and nuclear power engineering). Unfortunately, most researchers still have to consider data obtained in the laboratory analyses of samples taken at intervals. An important drawback of such off-line arrangements of analytical control is the substantial time delay before the information on the monitored object is obtained and, hence, late decisions concerning the intervention into the monitored process for preventing an undesirable development. This is especially important for the monitoring of potentially hazardous engineering processes.

The ecological monitoring of natural waters brings about specific problems, as sampling and sample transportation require more time and labour. This is responsible for errors caused by contamination of samples or degradation of the analytes during sampling, transportation, and storage. When abnormal values are obtained for the parameters under control, verification of the results requires additional time and facilities or may not be

possible at all, because one cannot take two identical samples even from the same water area. The selection of the spatial and temporal coordinates of sampling points is largely random. Therefore, the results are scattered and often do not allow one to draw correct conclusions even on the basis of repeated observations.

The need for alternative ways of monitoring the processes taking place in aqueous environments whose composition changes spontaneously is obvious. The purpose of this review is to analyse the general trends in the development of on-line methods for continuous analysis of water environments which appeared recently.

## II. Alternatives to the traditional off-line analysis scheme

The search for alternative solutions has resulted in new schemes of chemical analysis. In medicine, '*in situ*' analysis is used most often, i.e., determination of the analyte directly within the analytical control object. This is done by monitoring easily measurable physical parameters: temperature, pressure and flow rate.<sup>1</sup> The '*on site*'<sup>2</sup> plan has found application in the solution of ecology-related analytical problems. This analysis is performed directly on the site where the monitored object is located. Both schemes imply the development of special methods of analysis as applied to the conditions under which they are performed. In the case of the '*in situ*' analysis, these are chemical sensors, while in the case of '*on site*' analysis, they are test methods.

The most versatile scheme is on-line analysis, which implies creation of a continuous sampling line from the monitored environment and installation of continuously functioning analyser(s).<sup>3</sup> In the on-line scheme, the range of applicable methods of analysis is virtually endless. Algorithms for the selection of an adequate analytical method and, correspondingly, the appropriate analyser have been proposed.<sup>4</sup> To date, up to a hundred methods can be used for continuous ecological and in-process monitoring of aqueous environments.<sup>5</sup> Information on the commercially available analysers has been covered in the *Anadata Analyser Encyclopedia*;<sup>6</sup> and a system of priorities has been outlined.

If it is necessary to monitor simultaneously a large number of impurities, high performance liquid chromatography (HPLC) is a convenient choice. However, the instrumental complexity of liquid chromatographs and, hence, their higher cost for lower reliability, and also the necessity of using flammable and toxic

solvents as eluents hamper broad use of HPLC in the automated systems for continuous in-process monitoring. During the period of vigorous development of HPLC, forecasts were made concerning fast extension of the scope of its application in in-process control, and special liquid chromatographs were manufactured for this purpose (for example, the Optichrom series produced by the Applied Automation company).<sup>5</sup> However, liquid chromatographs, except for ionic ones, have not found wide use in in-process control.<sup>7</sup> Whereas gas chromatography is almost irreplaceable in analysis of hydrocarbon mixtures, in the case of liquid chromatography, there exist alternative solutions. In those rare cases where HPLC is still used for in-process control, conventional laboratory instruments are employed in automated systems. For example, SAMOS (System for the Automatic Measurement of Organic micropollutants in Surface water) designed for the monitoring of organic pollutants in the Rhine collecting area is based on HP 1090 liquid chromatographs.<sup>8–10</sup>

In recent years, rapid separation-free methods of analysis have appeared in the optical and electrochemical technology (for example, those using rapid-scanning spectrophotometers on photodiode lines with computer processing of the spectra).<sup>11</sup> When photodiode lines are used as detectors, a full spectrum composed of 200–1000 points is recorded in several milliseconds.<sup>12,13</sup>

Ion chromatography, which does not require hazardous solvents and operates at much lower pressures, is still used in thermal and nuclear power engineering. Actually, one can hardly propose equally efficient and relatively inexpensive methods for determination of anions.<sup>14–18</sup>

After a period of moderately successful attempts at the development of on-line automated monitoring systems based on HPLC, flow-injection analysis (FIA) has now become the method of choice for the design of such systems.<sup>19</sup>

### III. How can chemical analysis be automated?

The problem of automation of chemical analysis involves two aspects: the automation of proper analytical procedures in the traditional off-line chemical analysis and the integrated automation of the analytical control including sampling, sample processing and data collection and display stages. The problem of integrated automation of the in-process monitoring where the composition of the monitored material spontaneously varies includes automation of analytical procedures for particular methods as a part of continuous on-line analysis.

A monograph<sup>20</sup> presents an attempt to describe the general approaches to the automation of laboratory analysis based on electrochemical, colorimetric, spectroscopic, thermal, radiometric (X-ray) and chromatographic analysis and sample preparation procedures involving separation techniques. The technical solutions proposed for any of the above methods and especially for the processing of analytical information, described in the monograph, are now essentially out-of-date. However, everything concerning the general concepts of automation of chemical analysis remains actual.

In solving the problem of automation of proper chemical analysis, two basically different approaches are possible. The first one, robotic, implies the design of mechanical devices that copy the operation of an analytical chemist when performing analyses. These devices are to measure the required amounts of samples and reagent solutions, mix them, fill the measuring cell or take aliquot portions and inject them into the analyser, measure the analytical signal, and so on. The major advantage of this approach is versatility. Almost any chemical analysis technique (for example, laboratory liquid chromatographs operating in the automated mode<sup>10</sup>) can be automated using the robotic approach. However, analysers of this type have a common drawback: high cost and low reliability caused by complexity of mechanical units.<sup>20</sup> The design of these analysers does not comply with an important requirement of automated systems for chemical analysis, in particular, the principle of minimisation of the number of moving parts.<sup>5</sup>

The second approach implies, instead of the direct imitation of the operator's action, its mimicking under conditions most susceptible to automatic control. This approach is embodied in flow analysis.

### IV. Flow analysis as a general approach to the automation of chemical analysis

This group of methods opens up the most extensive opportunities for the automation of analysis. They were first implemented as continuous flow analysis (CFA) whose history and key principles have been outlined in certain books.<sup>21,22</sup> The hydraulic flow diagram of CFA is presented in Fig. 1a. The flows of the sample and a solution of a reagent capable of producing an 'analytical form' with the analyte detectable by the flow detector are continuously pumped by a peristaltic pump, mixed in the mixing helix, and routed to the detector. This version is used if the detector cannot catch the analytical signal directly from the analyte. Otherwise, the reagent and the mixing helix are not required. A drawback of this flow chart is the fact that correctness of the detector reading cannot be checked during the measurements. This is due to elimination of the boundary between the consecutive samples of different compositions in hydraulic lines caused by mixing; this precludes the possibility of checking the detector readings due to mixing of the test and reference samples.

Figure 1. Hydraulic block diagrams of CFA (a) and FIA (b).

(1) Peristaltic pump, (2) mixing helix, (3) flow detector, (4) measuring valve. Inlet lines: s — for the sample, r — for the reagent, c — for the carrier solution; d — for the discharge.

The FIA scheme<sup>23</sup> implies the introduction of discrete batches of the sample into a moving laminar flow of the carrier solution to form a controlled concentration gradient of the analyte (Fig. 1b). The flow of the carrier solution is combined with the flow of the reagent solution in the mixing helix and the mixture enters the flow detector, which records concentration peaks, the peak width being determined by the dispersion of samples as they move along the hydraulic lines. Thus, FIA is the flow analysis with a 'controlled sample dispersion'.<sup>24</sup> The carrier solution, the flow of which carries the test sample, can serve additionally as the correcting medium, which creates conditions (for example, stabilises the pH) needed for the formation of 'analytical forms' of the analyte upon mixing with the sample. The amplitude and the area of the obtained peaks are related to the analyte concentration. The FIA principles and equipment have been described in the literature.<sup>23,25–27</sup> Specific problems of the application of FIA for the continuous on-line process control have been considered.<sup>28–33</sup>

The major advantage of FIA is the possibility to perform almost all known operations included in the sample preparation<sup>†</sup> — dilution,<sup>35</sup> preconcentration and isolation of the analyte by extraction,<sup>36–42</sup> dialysis<sup>43–47</sup> and sorption<sup>27, 41, 46, 48</sup> in the on-line mode. In addition, quantification can be carried out using almost any of the known detection techniques ranging from simple sensors to mass spectrometers.<sup>19, 27, 49</sup>

Yet another important advantage of FIA is the possibility of calibrating instruments with a specified scale unit directly under operating conditions,<sup>50–56</sup> which is especially important for monitoring systems. The automated taking into account of the drift of the base line and the possibility of correcting the calibrating curves ensures the reliability of the results.

Flow-injection analysis can be considered as a set of instrumental techniques that ensure the automation of the routine analytical procedures of sample preparation and measuring of the analytical signal for most methods used to quantify the analytes. The indisputable advantages of this approach resulted in a growth of the number of companies engaged in the manufacture of flow-injection analysers for process control. The information on the equipment for FIA can be found in the publication.<sup>57</sup> Flow analysers and automated multichannel systems for the on-line analytical control based on them have now been developed.<sup>58</sup>

To eliminate the loss of information concerning the monitored process during the periods between FIA cycles, a combined flow method joining the advantages of CFA and FIA has been proposed.<sup>59</sup> This approach implies alternation of different modes of operation of a flow analyser according to a specified algorithm. To obtain analytical information on even short-term fluctuations of the sample composition, if spontaneous changes are possible, the analyser operates most of the time in the CFA mode, and to verify the detector readings, the analyser is switched to the FIA mode with periodic supply of reference solutions to the inlet. This provides the opportunity to check the position of the detector base line and the response to a particular analyte concentration. Figure 2 shows the form of the analytical signal recorded with alternation of the CFA and FIA modes. During the time period from 0 to  $t_1$ , the analyser operates in the CFA mode with the supply of the test sample to the inlet. At the instant  $t_1$ , the analyser is switched to the FIA mode with the same sample being supplied to the inlet, as indicated by equal amplitudes of the peaks and the magnitudes of the continuous signal. At time instant  $t_2$ , a standard solution of the analyte starts to be supplied, and at time instant  $t_3$ , the analyser is switched again to the CFA mode and the test sample moves through the system.

**Figure 2.** Form of the analytical signal recorded upon consecutive operation of the flow analyser in the CFA and FIA modes.

<sup>†</sup> It should be noted that in automated on-line monitoring systems, the most critical problems arise at the sample preparation stage.<sup>34</sup>

## V. Extension of the analytical potential of flow-injection analysis

Among the advantages of FIA as a versatile method for performing chemical analysis in the on-line mode, worthy of note is the possibility of incorporation of preconcentration and isolation of analytes into the analysis sequence; in some cases, this compensates for the insufficient sensitivity of widely used detectors. The separation and preconcentration methods used in FIA have been surveyed in a collection of papers<sup>28</sup> and in a monograph.<sup>46</sup> The most widely used methods include gas diffusion through porous hydrophobic membranes, extraction and sorption.

In flow analysis, the separation methods based on gas diffusion through a membrane perform two functions in sample preparation.<sup>60</sup> The first one is the isolation of analytes in the aggregative state most convenient for the subsequent determination by flow detectors. Depending on the aggregative states of the source and receiving phases, the analyte can be converted from a gas into a liquid and *vice versa*. Liquid absorption is normally used in FIA and CFA for the analysis of atmospheric air,<sup>46, 61</sup> while gas extraction is used more often in vapour analysis of aqueous media.<sup>62</sup> Another study describes<sup>63</sup> the use of membrane gas diffusion cells for the reaction gas extraction in FIA in which the analyte is intentionally transferred into a volatile form (for example, in the determination of  $\text{NH}_4^+$  in sewage water).

The second function of gas diffusion methods in FIA is to change deliberately the composition of the test medium (for example, the pH) in order to create the optimal conditions for the formation of 'analytical forms' of the substances to be determined.<sup>64–66</sup>

Liquid extraction, like gas diffusion, is used in FIA not only as a preconcentration method but also for the isolation of substances in the aggregative state most convenient for their subsequent determination. An example is extraction of petroleum products and phenols into hexane or carbon tetrachloride.<sup>67</sup> The use of extraction in FIA has required the development of special flow extraction apparatus. Extraction in segmented flows has gained the widest use.<sup>39–42, 68</sup> For this purpose, portions of an extractant are introduced at intervals into the flow of the test solution (after pre-adjustment of the composition of this solution to ensure the optimal conditions for extraction). As a result, the homogeneous flow of the solution is converted into a two-phase segmented flow in which segments of the aqueous solution alternate with segments of the extractant whose length in the capillary tube (about 0.5 mm in diameter) is 1–6 mm. The segmented flow passes through the extraction helix, which intensifies the phase transfer, and enters the separator in which the phases are separated. The organic phase is routed to the flow reactor.

The most severe drawback of these systems is the fact that it is impossible to control the ratio of phase volumes over broad ranges, which stipulates a limitation for the attainable preconcentration factor even when the distribution coefficient in the extraction system used is high.

### 1. New methods in liquid and gas flow extraction

New possibilities for the flow extraction appeared owing to the chromatographic-membrane mass exchange processes in liquid–liquid and liquid–gas systems.<sup>69</sup> The idea of chromatographic-membrane processes is based on the use of capillary effects in hydrophobic porous media.<sup>70</sup> The mass exchange between two phases differing in polarity takes place in a capillary porous medium from a hydrophobic material containing two types of pores with different sizes. The capillary pressure arising in micropores prevents water and aqueous solutions from getting inside. In turn, the aqueous solutions that enter, according to experimental conditions, the biporous system under a higher pressure fill macropores and prevent non-polar phases from entering the macropores. Thus, the two phases can move independently within the mass exchange space formed by the hydrophobic biporous medium. The diagram of a chromatographic-membrane cell

(CMC), shown in Fig. 3, corresponds to the case where the flows of two phases intersect at right angle. The mass exchange takes place in conformity with the rules of a chromatographic process, as the porous structure of the mass exchange layer in the CMC is similar to the structure of a stationary non-polar packing in an extraction-chromatographic column. The differences are manifested only as an increase in the phase transfer rate compared to that in a conventional chromatographic process (in which one phase is stationary) due to the convective movement of both phases at the interface.

**Figure 3.** Block diagram of a chromatographic-membrane cell. (1, 2) Polar liquid inlet and outlet; (3, 4) non-polar liquid or gas inlet and outlet; (5) biporous hydrophobic matrix (microporous filler); (6) macro-pore space; (7) microporous hydrophobic membranes; (8) cell casing.

A flow of a non-polar liquid or a gas is introduced into the mass exchange space and leaves this space through hydrophobic microporous membranes, in which the pore size is close to the size of micropores in the biporous matrix. The material of the membranes and the pore size should ensure the impermeability of the membrane for the aqueous phase under conditions of the mass exchange process.

The chromatographic-membrane liquid or gas extraction is an alternative to not only extraction in segmented flows but also to the isolation by gas diffusion, because it provides intensification of phase transfer both in the liquid-liquid and liquid-gas systems. Instead of the slow diffusion through a porous membrane, the gas-diffusion membrane processes involve the delivery of phases to the interface.

Numerous examples of the use of the chromatographic-membrane liquid and gas extraction in FIA have been reported.<sup>60</sup> A number of combined protocols of sample preparation are possible. For example, for the determination of arsenic, the chromatographic-membrane reaction gas extraction is combined with gas liquid chromatography;<sup>71</sup> petroleum products and phenols are determined in water using an extraction chromatographic column for the preconcentration and isolation of the analytes into the organic phase.<sup>67</sup> After these have been eluted by the extractant, the resulting two-phase flow is separated in a chromatographic-membrane separating vessel.

## 2. Sorption preconcentration in the flow-injection analysis

Sorption techniques for sample preparation actively compete in FIA with the extraction methods and, in some occasions, the former are even preferred.<sup>27, 46, 48</sup> This is the case where it is necessary to attain the limiting preconcentration factors (for example, to determine beryllium in natural water<sup>72</sup>) or to exclude the use of organic solvents. Sorbents with chelating functional groups have found the most extensive use in FIA.<sup>48</sup> As regards minimising the time required for the sorption preconcentration, sorbents with fibrous structure are most efficient, as they ensure the highest rate of sorption equilibration.<sup>72</sup> In this case, it is expedient to incorporate a high-speed peristaltic pump into the

hydraulic circuit for sample filtration through a column containing the sorbent (Fig. 4). When the position of the switching valve corresponds to the route shown by the continuous lines, a mixed flow of the sample and a buffer solution is filtered through a column at the highest permissible rate. Simultaneously, the eluent is mixed with the reagent solution and passes through the flow detector, which records the base line. After the valve has been switched into the position corresponding to the dashed lines, the sample is routed to the discharge and the eluent is fed to the sorption column. At the column outlet, the eluate is mixed with the reagent solution and flows to the detector, which records the analyte peak against the base line obtained in the previous cycle.

**Figure 4.** Hydraulic diagram of FIA with sorption preconcentration on a fibrous sorbent.

## VI. Practical use of on-line chemical analysis based on the principles of flow-injection analysis

Most publications devoted to FIA describe procedures of off-line analysis in stationary laboratories. Much fewer papers have been devoted to the applications of FIA in the on-line mode. The attention is focused on the continuous determination of products either formed in the processes of biotechnology (during operation of fermenters) or supplied to the reaction medium. The publications consider both the general aspects of the on-line analytical monitoring of biochemical processes<sup>73–79</sup> and particular issues of continuous monitoring of the concentration of separate components: proteins,<sup>80</sup> enzymes,<sup>81</sup> amino acids,<sup>82</sup> antibiotics,<sup>83, 84</sup> glucose,<sup>85, 86</sup> lactate and so on.

The publications devoted to analysis of various types of water — subsurface, rain, river, sea and potable water — refer mainly to procedural aspects of the off-line determination of particular impurities. The data on flow-injection analysers operating in the on-line mode on real water environments are summarised in Table 1. Most of them provide monitoring of some single parameter of water contamination, *i.e.*, making use of automated single-channel analysers adjusted to determination of one analyte in the on-line mode.

Among interesting, although disputable solutions,<sup>‡</sup> worth noting is the SCANNER analyser, which is an example of using FIA for *in situ* control.<sup>100</sup> It is designed for determination of  $\text{SiO}_3^{2-}$  and  $\text{S}^{2-}$  in sea water directly from the ship and can operate at depths of up to 2500 m.

To perform automated chemical monitoring of several quality parameters of a water medium in the on-line mode, two systems are possible: (i) the design of *n* independent parallel channels, each

<sup>‡</sup> The point that seems disputable is overcoming of sealing problems when working under high pressures, instead of using (designing) a simple and more reliable system for continuous sampling of water from a required depth.

**Table 1.** Application of FIA for impurity analysis in the aqueous environments of real objects (in the on-line monitoring mode).

| Impurity                                         | Object of analysis                          | Detector                                                     | Detection limit<br>/ $\mu\text{g litre}^{-1}$ | Range of linearity<br>/ $\mu\text{g litre}^{-1}$ | Operation time <sup>a</sup><br>/day | Ref. |

being tuned for determination of one of  $n$  monitored parameters, and (ii) the design of a system containing additional units for switching the flows in order to adjust channels for determination of one or another parameter.

The experience of design and operation of an automated system according to the principle of  $n$  parallel channels to monitor the quality of the outside water from a moving ship <sup>58</sup> has shown that such a system ensures a sufficient reliability when up to 14 parameters are simultaneously determined (Table 2). Therefore, in the design of a ship system for real-time ecological analytical monitoring, an  $n$ -channel system was preferred over the adjustable system. This provides higher reliability of the equipment due to minimisation of the number of mechanical units <sup>5</sup> and elimination of the necessity of combining units of flow-injection analysers that implement different methods of analysis. Evaluating objectively the potential of FIA, the authors <sup>101</sup> noted that these devices function efficiently in a laboratory but are not always suitable for industrial conditions. The need to use sets of different units for each analytical method and the relative complexity of operation of peristaltic pumps are the general drawbacks of FIA as regards the design of on-line monitoring systems. The former drawback is

important for the  $n$ -channel configuration of a multiparametric control system, <sup>58</sup> which is less favourable for economic reasons than a system with adjustable analysers.

## VII. Sequential injection analysis as the next step in the automation of on-line chemical analysis

The search for an alternative to FIA has given rise to a new approach in the flow analysis techniques, namely, sequential injection analysis (SIA). <sup>101</sup>

In flow-injection analysis, the analytical process takes place in a system of tubes along which the sample or calibrating solutions and solutions of reagents move in one direction. After combination of the flows, the sample or the calibration solution is mixed with the reagent, and the flow of the carrier with the reaction products moves toward the detector. Therefore, for inducing the flow along each inlet tube (the sample, the reagent solution, and auxiliary solutions), a separate pump is required. The multi-channel peristaltic pump, which is usually employed for this purpose, is actually a set of pumps operating in parallel. In addition, a measuring valve is required for introducing aliquot portions of the sample or a reagent solution into the flow of the carrier.

In the sequential injection analysis, a single liquid line is used, instead of the set of tubes, in which a syringe pump operating according to a definite schedule induces a flow of solutions moving alternately into two directions (Fig. 5). The piston of the syringe pump moves in discrete strokes in order to suck in the wash solution (1), the solution of the sample (2) and the solution of the reagent (3) into the liquid channel composed of the reaction helix, flow detector and the holding helix. The distributive valve ensures the sequential injection of solutions into the channel by switching the valve outlets synchronously with pumping. During the reverse stroke of the piston, the mixed solution of the sample and the reagent passes through the detector to the discharge and the hydraulic line is washed. Among the important advantages of SIA, noteworthy is the option to stop the flow, which allows this method to be used for measuring the rates of chemical reactions. <sup>102</sup> The possibility of stopping the flow is also useful for adjusting the conditions of analysis as regards the time for the formation of the 'analytical forms' of the analyte.

**Figure 5.** Block diagram of the sequential injection analysis.

(1) Wash solution, (2) a solution of the sample, (3) a solution of the reagent, H is the holding helix, R is the reaction helix, D is detector, (4) standard solution, (5) discharge.

The authors of SIA<sup>101</sup> stipulated the use of a pump having a 'zero time lag' and a 'zero elasticity,' which requires replacement of a peristaltic pump by a computer-controlled plunger pump. The MilliGAT plunger pump,<sup>103</sup> which completely rules out flow pulsation, is the most successful engineering solution. However, peristaltic pumps are also used in some cases.<sup>104</sup>

Sequential injection analysis has a number of advantages over FIA (especially in the on-line mode), in particular, minimisation of the consumption of the reagent solution and a better adaptability to computer control in the case of SIA.<sup>101</sup> Moreover, the SIA version no longer requires the measuring valve (which is considered to be a trouble spot in FIA instruments),<sup>105</sup> the selection of every next solution being accomplished by means of a multiway valve. The authors of the method believe that the replacement of the measuring valve eliminates the problems related to the operation of mechanical units of the analyser; however this is not self-evident. The description of the software for the automation of flow analysis systems in SIA is documented.<sup>106</sup>

The attraction of SIA as a new approach to the automation of chemical analysis is indicated by numerous publications: more than 200 papers, several patents and a review<sup>105</sup> have now been published on this topic.

The discussion of on-line analysis would be incomplete without considering the problem of continuous sampling. According to different estimates, 70% to 85% of malfunctions in on-line analysis systems refer to this stage.<sup>107</sup> The sampling problem is solved rather easily in the case of the in-process control of the aqueous media circulating or occurring in the controlled object under an elevated pressure. Connection of the sampling line requires a choke with a controlled flow rate made of an inert material.

The information on the development and functioning principles of continuous sampling systems (CSS) for natural and sewage water is very limited. The Fathom Oceanology Ltd company (Canada) has designed a CSS having a fluoroplastic hose 8 mm in diameter and a pump for water supply to the ship (with a productivity of up to 40 dm<sup>3</sup> min<sup>-1</sup> at a ship velocity of up to 12 knots). Similar systems have also been designed by the Japanese companies Morikawa and Progress Trading. Direct measurements of contaminants in a sea water flow are also performed.<sup>108</sup> Determination of nitrates and nitrites was carried out by reverse flow-injection analysis (with injection of reagents); sea water was pumped directly through the tubes of a flow-injection analyser. Later, analyses of sea water for sulfates, phosphates, silicates and a number of metals (cobalt, manganese, copper, iron) have been carried out. Analyses were performed from a drifting ship, i.e., no monitoring of water basins, which requires on-line analysis, was involved.

All the CSS systems mentioned above are meant for taking representative samples into sampling vessels for their subsequent chemical analysis in the laboratory (off-line mode). However, an experience in the design and operation of CSS in combination with

a multiparametric system of on-line analysis has been reported.<sup>58</sup> The block diagram of the CSS is shown in Fig. 6. To minimise the time delay between obtaining the data on the sample composition and the real time, a two-step pattern of sample supply to the analyser was chosen. The first step is a main channel with a membrane pump operating for the discharge of the main bulk of water overboard. The main channel includes a unit for splitting of the sample flow, some of the flow being routed to the inlet of analysers. To ensure the sample representativity, polytetrafluoroethylene and stainless steel were chosen as the main structural materials for the CSS. The removal of mechanical impurities was attained by three-step filtration. The design of water intake devices includes coarse filters manufactured from a stainless-steel grid, which separate particles larger than 1 mm. The flow splitting unit installed in the main channel of the CSS includes a fine filter for water with a filter cell made of porous stainless steel for separating particles larger than 0.1 mm. At the inlet of each analyser, except that for petroleum products, fine filters made of porous polytetrafluoroethylene are installed additionally. The filters are expected to protect the hydraulic lines and flow measuring cells of the analysers from plugging with coarse suspensions of either mineral or organic origin, which are always present in natural waters. At the same time, the filters do not influence the chemical composition of the sample.

**Figure 6.** Block diagram of the continuous sampling system for natural water: (1) water intake device; (2) main pump; (3) coarse filter; (4) manometer; (5) controlled choke; (6) fine filters; (7) sample inlet channels of the monitoring system; (8) discharge line.

The presented block diagram of CSS and the diverse types of flow analysers considered above demonstrate the presence of a methodical and instrumental base for the design of automated on-line chemical analysis systems for the industrial process control and ecological analytical control of aqueous environments.

**Abstract.** The review surveys data on the addition of HO-nucleophiles (water, oximes, hydroxylamines, hydroxamic acids, alcohols) to nitriles. Main methods for  $C\equiv N$  bond activation in nucleophilic addition reactions are discussed. Particular attention is given to activation of nitriles through coordination to metal centres. The bibliography includes 191 references.

## I. Introduction

Nitriles are widely used in preparative chemistry due to their ability to be involved in nucleophilic and electrophilic addition and  $[2+3]$ -cycloaddition reactions. In particular, these reactions are used to synthesise amides and carboxylic acids [for example, acrylamide, nicotinamide and *S*-(+)-ibuprofen], which are of considerable practical importance, and a wide range of heterocyclic compounds containing one or more nitrogen atoms. The addition of various nucleophiles at  $C\equiv N$  bonds giving rise to compounds containing new  $C-N$ ,  $C-O$ ,  $C-S$ ,  $C-C$  or  $C-P$  bonds is most generally employed in nitrile chemistry.

Nitriles containing activating electron-withdrawing groups, for example, perfluoroalkyl groups, can react with various nucleophiles without additional  $C\equiv N$  bond activation, whereas the addition reactions to nitriles containing electron-donating or weak electron-withdrawing groups require that the electrophilicity of the carbon atom in the RCN molecule be additionally enhanced. In organic chemistry, activation of nitriles and nucleophilic addition reactions are often carried out with the use of acid catalysis (Pinner reaction;<sup>1</sup> see also Refs 2–10) or alkylation giving rise to nitrilium salts.<sup>11–13</sup> Another efficient method for activation is based on coordination of  $RC\equiv N$  to the metal centre. Nowadays, numerous reactions involving the activated  $C\equiv N$  bond are known: metal-mediated and metal-catalysed hydrolysis and alcoholysis of nitriles,<sup>†</sup> nucleophilic addition reactions of amines, imines and sulfimides and addition reactions of halo- and

aminoalcohols.<sup>14–24</sup> Coordination to metal can not only activate the  $C\equiv N$  bond but also promote reactions accompanied by  $\alpha-C-H$  and  $C-C$  bond cleavage in nitriles.<sup>25–28</sup>

The body of literature on metal-mediated reactions of nitriles published in recent years is too large to be reviewed here. Hence, this review covers the reactions of nitriles with one particular group of nucleophiles, *viz.*, HO-nucleophiles, accompanied by their addition at the  $C\equiv N$  bond to form imidoates  $HN=C(R)O-$ . HO-Nucleophiles include a wide range of compounds of various classes, which differ in reactivity.

In the last few years, data on reactions of nitriles with particular classes of HO-nucleophiles have been summarised in several publications (for example, hydrolysis of RCN involving various metals was considered in the reviews,<sup>19,29–38</sup> reactions with nitrile hydratases and mimetic complexes of these enzymes were surveyed in publications<sup>33–48</sup>). However, in none of these publications were the addition reactions of different classes of HO-nucleophiles with nitriles compared. Moreover, abundant new data on the reactions of nitriles with such HON-nucleophiles as oximes, hydroxylamines and hydroxamic acids have been reported in the very recent past.

The aim of the present review is to survey the available data and perform comparative analysis of the data on interactions of the  $C\equiv N$  group of free and coordinated nitriles with HO-nucleophiles. The review provides an overview of recent studies of the reactions of nitriles with water and alcohols in the presence of metal centres and reveals the main factors responsible for these reactions. Considerable attention is given to reactions with poorly known nucleophiles (in particular, with HON-nucleophiles), which have been investigated rather recently. It should be noted that the present review is a continuation of a series of articles published in this journal<sup>12,13,49–52</sup> and devoted to reactions of nitriles in organic and coordination chemistry.

## II. Metal-mediated and metal-catalysed hydrolysis of nitriles

Hydrolysis of nitriles proceeds in two steps to form carboxamide, which is then transformed into acid. In most cases, the rate of the second step of hydrolysis is higher than that of the first step.<sup>53</sup>

<sup>†</sup> Hydrolysis and alcoholysis of nitriles with stoichiometric (metal-mediated) or catalytic (metal-catalysed) amounts of metal complexes.

Hence, the reaction affords carboxylic acid as the major transformation product (Scheme 1, path *a*).<sup>53, 54</sup>

Scheme 1

A specific feature of metal-mediated hydrolysis is that, as a rule, the reaction stops at coordinated amide  $[M]-NH=C(OH)R$  (Scheme 1, path *b*). This reaction pathway is favoured by mild reaction conditions, under which the resulting free or coordinated amide is not subjected to the transformation into  $RCO_2H$ .

Metal-mediated and metal-catalysed transformations of nitriles into amides were examined in numerous experimental studies, which have been surveyed in sufficient detail in several reviews.<sup>11–24, 32</sup> Hence, here we consider only the main factors responsible for hydrolysis and give selected examples of unusual hydrolytic transformations of coordinated nitriles, which have been reported in the last few years.

**The intra/intermolecular character of the reaction.** The rate of hydrolysis of metal-coordinated nitriles by an intramolecular mechanism (unlike hydrolysis proceeding by an intermolecular mechanism) was found<sup>55–70</sup> to be substantially higher than that of uncoordinated nitriles. In this case, the reaction can be accelerated by a factor of  $10^{18}$  (the rate of reactions proceeding by the intermolecular mechanism increases by a factor of  $10^6–10^9$ ).<sup>55–70</sup> Apparently, the efficiency of the reaction proceeding by the intramolecular mechanism is achieved mainly due to an increase in the 'local' concentration of an  $H_2O/OH^-$  nucleophile in the vicinity of coordinated nitrile.

**The nature of the metal.** The position of the metal in the Periodic table influences substantially the reaction rate and is also responsible for the either catalytic or stoichiometric character of the process. Analysis of the reactivities of related complexes with metals varying within a single subgroup allows one to compare adequately the results of investigations and reveal the corresponding correlations. For example, the rate of hydrolysis of coordinated benzonitrile in the  $[M(NH_3)_5(NCPh)]^{3+}$  complexes ( $M = Co, Rh, Ir$ ) increases with decreasing ionic radius in the series  $Co(III) > Rh(III) > Ir(III)$ .<sup>65</sup> The same tendency is observed for hydrolysis of nitriles in  $Pt(II)$  and  $Pd(II)$  complexes [ $Pd(II) > Pt(II)$ ].<sup>71</sup> If the metal has several oxidation states a higher rate of hydrolysis is observed in complexes, in which the central atom exists in a higher oxidation state. For example, hydrolysis of acetonitrile coordinated to the  $Ru^{III}(NH_3)_5$  group proceeds  $10^8$  times more rapidly than hydrolysis of uncoordinated nitrile, whereas coordination to  $Ru^{II}(NH_3)_5$  has virtually no effect on the reaction rate.<sup>66</sup>

In most cases, metal-mediated hydrolysis of nitriles affords stoichiometric amounts of amide complexes, whereas examples of catalytic reactions are scarce.<sup>18, 19, 32, 54, 72–106</sup> Systems based on platinum(II) phosphinite complexes (see Section VI)<sup>32, 54, 72, 73</sup> and zinc(II) salt–oxime systems (see Section III)<sup>74</sup> proved to be most efficient in metal-catalysed hydrolysis. In both cases,<sup>32, 54, 72–74</sup> hydrolysis involves nitrile activation in one of the initial steps followed by the intramolecular reaction with  $HOP-$ ,<sup>32, 54, 72, 73</sup> or  $HON$ -nucleophiles.<sup>74</sup> Among other catalytic systems used in hydrolysis of nitriles, let us mention  $Ni(II)$  and  $Cu(II)$  complexes with ethylenediamine,<sup>75, 76</sup>  $Co(III)$  sulfenato complexes,<sup>77, 78</sup>  $Hg(II)$  salts in acidic solutions,<sup>79, 80</sup> low-valent ruthenium<sup>27, 81–84</sup> and iridium<sup>26, 27</sup> hydride complexes, systems based on  $[Rh(\mu-Cl)(cod)]_3$  and  $P(C_6H_4SO_3Na-m)_3$ ,<sup>85</sup>  $Ir(I)$  phosphine complexes,<sup>86</sup> mixtures of  $Rh(III)$  or  $Ir(III)$  halides with  $(PhO)_3P$  or

$Ph_3P$  and their derivatives,<sup>87–89</sup> mixtures of  $RuCl_3$  with phenanthroline or  $Na_2[PdCl_4]$  with 2,2'-bipyridyl,<sup>90</sup>  $Pd(II)$  aqua and hydroxo complexes,<sup>91–97</sup>  $Pd(II)$  thiolate complexes,<sup>98, 99</sup>  $Pt(0)$  and  $Pt(II)$  phosphine complexes<sup>100–104</sup> and clusters with a  $Pt_4$  core.<sup>105, 106</sup>

It should be noted that hydrolysis of nitriles in the coordination sphere of the metal affords not only amides but also other products of hydrolytic transformations, for example, the metallacycles  $[RuCl(CO)\{NH=C(p-MeC_6H_4)N=C(p-MeC_6H_4)O\} \cdot (PPh_3)_2]$ ,<sup>107</sup>  $[PtCl\{O=C(CCl_3)NC(CCl_3)=O\}(Me_2SO)]$ <sup>108</sup> and  $[PtCl_4\{NH=C(NR_2)OC(NR_2)=NH\}]$  ( $R = Me, Et$ ;  $R_2 = C_5H_{10}, C_4H_8O$ )<sup>109</sup> (hereinafter, atoms bound to metals are underlined). These complexes are generated in multistep processes involving hydrolysis of one of the nitrile molecules in the coordination sphere of the metal followed by the reaction of the hydrolysis product with another nitrile. The formation of amidines and coordinated imidoyl amidines is considered in Section III. It is believed that these transformations also involve hydrolysis of nitrile in the coordination sphere of the complex as one of the initial steps.

Therefore, the use of metal complexes in reactions of nitriles with water leads to a substantial increase in the rate of the first step of hydrolysis (due to electrophilic activation of the nitrile through its coordination) and provides the possibility of stopping hydrolysis selectively at the formation of amide (due to its stabilisation as a result of coordination and milder reaction conditions).

### III. Reactions of oximes with free and coordinated nitriles

#### 1. Nucleophilic addition of oximes to free nitriles and nitrilium salts

In organic chemistry, only a few examples of the nucleophilic addition of oximes to nitriles are known. These reactions proceed exclusively with activated nitriles, for example, with those containing a perfluoroalkyl group.<sup>110, 111</sup> The reactions of perfluorocarbonitriles with acetone oxime were investigated.<sup>110</sup>

$R_F = CF_3, C_3F_7$ .

These reactions are reversible: *O*-imidoyl oxime that formed in good yield is unstable and decomposes on heating to give the starting compounds.<sup>110</sup> Kabakchi *et al.*<sup>111</sup> prepared 1,2,4-oxadiazoles by the reaction of perfluorocarbonitriles [ $R_F = C_6F_{13}, CF_3O(CF_2CF_2O)_4CF_2, (O(CF_2)_3CF)CF_2$ ] with aromatic amidoximes  $HON=C(NR_2)R^2$  (benzamidoxime, substituted and unsubstituted terephthalamidoximes).

$R^1 = H$ ;  $R^2 = Ph, p-HON(NH_2)CC_6H_4$ ;

$NR_2 = N(CH_2)_4, N(CH_2)_5, R^2 = p-HON(NH_2)CC_6H_4$ .

The first step of the synthesis of 1,2,4-oxadiazoles also involves the formation of *O*-imidoyl oximes. In the study,<sup>111</sup> the authors noted that, although the addition of unsubstituted amidoximes to nitriles could, in principle, occur in two different ways, *viz.*, the addition of either the amide or oxime group could take place, exclusively the latter situation was experimentally observed. It should be noted that *O*-imidoyl oximes were prepared

under mild conditions in good yields. In the reactions with perfluorocarboxylic acid fluorides, *O*-imidoyl oximes are transformed into 1,2,4-oxadiazoles with elimination of ammonia.

Activation of nitriles with electron-withdrawing groups, such as  $\text{CCl}_3$  and  $\text{CCl}_2\text{CN}$ , is also sufficient for them to react with oximes. For example,  $\text{Cl}_3\text{CC}\equiv\text{N}$  and  $(\text{N}\equiv\text{C})\text{Cl}_2\text{CC}\equiv\text{N}$  readily react with oximes to give unstable *O*-imidoyl oximes.<sup>112, 113</sup> Imines **1** produced by the reactions with ketoximes  $\text{R}^2\text{R}^3\text{C}=\text{NOH}$  can be isolated, whereas unstable *O*-imidoyl oximes **2** formed in the reactions with aldoximes  $\text{R}^4\text{CH}=\text{NOH}$  are rearranged to give halogenated carboxamide and nitrile  $\text{R}^4\text{CN}$  as a dehydration product of the corresponding aldoxime.<sup>113</sup>

$\text{R}^1 = \text{CCl}_3, \text{CCl}_2\text{CN}$ ;  $\text{R}^2 = \text{Me}$ ;  $\text{R}^3 = \text{Me, Ph, 4-HOC}_6\text{H}_4$ ;  
 $\text{R}^2 = \text{R}^3 = \text{Ph}$ ;  $\text{R}^4 = 2\text{-C}_4\text{H}_7\text{O, Pr}^n, \text{Pr}^i, \text{Ph, 4-MeC}_6\text{H}_4$ ,  
 $3,4\text{-(MeO)}_2\text{C}_6\text{H}_3$ , 1-naphthyl,  $\text{PhCH}=\text{CH}$ .

In the study,<sup>112</sup> dehydration of aldoximes with trichloroacetonitrile was proposed for use for the preparation of aromatic nitriles, which are difficult to synthesise (dehydration of aldoximes with coordinated nitriles is considered in Section III.3).

Nitriles can be activated also by alkylation of the nitrogen atom of the nitrile group to form nitrilium salts.<sup>114, 115</sup> For example,  $[\text{R}^1\text{C}\equiv\text{N}^+\text{R}^2][\text{SbCl}_6]^-$  salts can be involved in the addition reactions to oximes  $\text{R}^3\text{R}^4\text{C}=\text{NOH}$ . The initiating role of nitrilium salts in the Beckmann rearrangement in anhydrous aprotic solvents was examined in the studies.<sup>114, 115</sup> The reactions of the  $[\text{R}^1\text{C}\equiv\text{N}^+\text{R}^2][\text{SbCl}_6]^-$  salts with oximes were demonstrated to afford imidoyl compounds as unstable intermediates.

$\text{R}^1 = \text{Me, Pr}^i, \text{Ph}$ ;  $\text{R}^2 = \text{Pr}^i$ ;  $\text{R}^1-\text{R}^2 = \text{Me}_2, (\text{CH}_2)_5$ ;  
 $\text{R}^3-\text{R}^4 = \text{Me}_2, (\text{CH}_2)_n$  ( $n = 4-7, 12$ ),  $\text{Ph}_2$ .

Addition products **3** exist in solution as mixtures of *E* and *Z* isomers. Compounds with  $\text{R}^1 = \text{R}^2 = \text{Me}$ ,  $\text{R}^3-\text{R}^4 = (\text{CH}_2)_4$  (**3a**) and  $\text{R}^1 = \text{Ph}$ ,  $\text{R}^2 = \text{Pr}^i$ ,  $\text{R}^3 = \text{R}^4 = \text{Me}$  (**3b**) were characterised by X-ray diffraction. It was established that compounds **3a** and **3b** have *Z* and *E* configurations, respectively.

Iminium salts **3** can be subjected to the Beckmann rearrangement to form the corresponding carboxamides **4**.<sup>114, 115</sup>

Hence, for the nucleophilic addition of oximes to nitriles to occur, it is necessary either to use nitriles  $\text{RCN}$  containing strong electron-withdrawing *R* groups or to activate nitriles by alkylation of the nitrogen atom of the nitrile group. A considerable drawback of the first method is that the field of its application is limited to a relatively small set of perfluorocarbonitriles and some other nitriles containing the chlorine atoms and/or a pseudohalide group in the activating fragment. This method can be used to prepare only derivatives containing electron-withdrawing groups at the carbon atom. The second method can be employed to synthesise nitrile derivatives containing electron-donating groups at the carbon atom (in this case, acylation of oximes affords salts). It was noted<sup>110-115</sup> that imidoyl compounds formed upon addition of nitrilium salts to oximes are unstable. In some cases, they were characterised only in a reaction mixture and were not isolated as individual products.

## 2. Reactions of 'simple' oximes with coordinated nitriles

The nucleophilic addition of 'simple' ‡ oximes to coordinated nitriles was investigated in much more detail. The reaction of oxime with nitrile in the presence of a metal centre giving rise to a stable imino complex was described for the first time in 1990.<sup>116</sup> In this study, the authors performed the reaction of the palladium complex  $[\text{PdCl}_2(\text{PhCN})_2]$  with  $\text{HON}=\text{CMeBu}^t$  to prepare the  $[\text{PdCl}_2\{\text{NH}=\text{C}(\text{Ph})\text{ON}=\text{CMeBu}^t\}]$  complex as one of products and characterised the latter. More than ten studies devoted to the addition of oximes to nitriles in the presence of V(IV), Re(IV), Rh(III), Ni(II), Pt(II) and Pt(IV) complexes were published by the mid-1990s.<sup>117-132</sup> In all these studies (see below), the reactions of oximes with nitriles proceed under mild conditions to give coordinated imines  $\text{HN}=\text{C}(\text{R}^1)\text{ON}=\text{CR}^2\text{R}^3$ . It was reported that even nitriles containing electron-donating substituents, such as  $\text{MeCN}$  and  $\text{EtCN}$ , which do not react with oximes in the free state, are involved in nucleophilic addition to oximes in the presence of metal complexes (see Section III.1).<sup>117-126</sup> Evidently, the metal centre plays a decisive role in these reactions. The metal centre not only activates nitrile but also stabilises the resulting imino ligand.

In spite of the diversity of the starting compounds and reaction conditions, there are several factors influencing the nucleophilic addition of oximes to nitriles in the presence of metal.

### a. Effect of the central metal atom on the reactivity of nitrile

*The nature of the central atom.* In accordance with the logic of the discussion, let us first consider the role of the central metal atom in activation of nitrile followed by consideration of the role of the metal centre in stabilisation of coordinated imines  $\text{HN}=\text{C}(\text{R}^1)\text{ON}=\text{CR}^2\text{R}^3$ .

The way of performing the reaction and the character of the reaction products depend on the nature of the central atom. For example, the reactions of oximes  $\text{R}^1\text{R}^2\text{C}=\text{NOH}$  with nitrile complexes of platinum(IV)<sup>117-119</sup> and rhenium(IV),<sup>120</sup> viz., *trans*- $[\text{PtCl}_4(\text{R}^3\text{CN})_2]$ ,  $[\text{PtCl}_5(\text{EtCN})]^-$  and *cis*- $[\text{ReCl}_4(\text{MeCN})_2]$ , respectively, proceed under mild conditions to give complexes **5** with monodentate imino ligands in nearly quantitative yields (Scheme 2, path *a*). These complexes exist in the *E* form stabilised by hydrogen bonding between the hydrogen atom of imine and the nitrogen atom of oxime.

It was demonstrated<sup>117-120</sup> that free nitrile is not involved in these reactions even under more drastic conditions (on refluxing and/or in the presence of a large excess of  $\text{R}^3\text{CN}$ ).

Another way of performing metal-mediated reactions of nitriles with oximes is based on the use of relatively labile V(IV), Rh(III), Ni(II) and Pd(II) complexes (Scheme 2, paths *b* and *c*). Imines  $\text{NH}=\text{C}(\text{R}^3)\text{ON}=\text{CR}^1\text{R}^2$  formed in the course of the reaction are coordinated to the metal atom in a bidentate fashion

‡ By 'simple' oximes is meant compounds containing only one functional (oxime) group.

Scheme 2

through two nitrogen atoms. In the presence of 'labile' metal complexes,<sup>8</sup> the addition of oximes to nitriles can occur by two mechanisms, *viz.*, either as the addition of the nitrile complex to free oxime (path *b*) or as the addition of the oxime complex to free nitrile (path *c*)<sup>¶</sup> giving rise to the same product **6**. It is believed that the first step of the reaction of an oxime complex with nitrile involves coordination of nitrile at the *cis* position with respect to complexed oxime followed by the reaction of the adjacent oxime and nitrile ligands, the latter being activated as a result of its coordination.

Dissolution of the oxovanadium oximate complexes [VOL<sub>2</sub>] (L is salicylaldehyde or analogous ketoxime and salicylamidoxime) by heating in nitriles<sup>121, 122</sup> affords complexes **7** with the tridentate imino ligand.

$\text{X} = \text{H, Me, Et}; \text{R}^1 = \text{Me, Ph, C}_6\text{H}_4\text{NO}_2\text{-}p, \text{C}_6\text{H}_4\text{Me-}p, \text{MeC}(\text{O})\text{CH}_2;$   
 $\text{R}^2 = \text{H, Cl, Bu}^t;$   
 $\text{X} = \text{NH}_2, \text{R}^1 = \text{Me}, \text{R}^2 = \text{H}.$

§ The metal centre is labile with respect to substitution reactions.

¶ It should be noted that the reaction does not occur in the presence of Pt(IV) or Re(IV) complexes.<sup>117, 118</sup>

In both studies,<sup>121, 122</sup> the authors noted that the imino ligand cannot be prepared by the direct reaction of oximes with nitrile and, consequently, the reaction is promoted by metal. It was suggested<sup>121</sup> that the reaction mechanism involves coordination of nitrile to V(IV) as the initial step followed by nucleophilic addition of oxime to the nitrile to form a tridentate ligand. In addition, the reaction is accompanied by oxidation of the central atom to V(V). It was hypothesised that one of the inner-sphere oximes in the starting complex serves as the oxidiser.<sup>121</sup> The structure of complex **7** (X = NH<sub>2</sub>, R<sup>1</sup> = Me, R<sup>2</sup> = H) is shown in Fig. 1.

Figure 1. Molecular structure of complex **7** (X = NH<sub>2</sub>, R<sup>1</sup> = Me, R<sup>2</sup> = H).

In the studies of the reactions of R<sub>2</sub>C=NOH with the rhodium(III) nitrile complexes *mer*-[RhCl<sub>3</sub>(R<sup>2</sup>CN)<sub>3</sub>] (R<sup>2</sup> = Me, Ph) (Scheme 3, paths *a* and *b*), several imino complexes were isolated and characterised: [RhCl<sub>3</sub>{NH=C(R<sup>2</sup>)ON=CR<sup>1</sup>}]<sub>3</sub>·[HON=CR<sup>1</sup>]<sub>2</sub> (**8**, R<sup>2</sup> = Me) and [RhCl<sub>2</sub>{NH=C(R<sup>2</sup>)ON=CR<sup>1</sup>}]<sub>2</sub>·[ON=CR<sup>1</sup>]<sub>2</sub>Cl (**9**, R<sup>2</sup> = Me, Ph).<sup>123, 124</sup>

Scheme 3

R<sup>1</sup> = Me<sub>2</sub>, (CH<sub>2</sub>)<sub>4</sub>; R<sup>2</sup> = Me, Ph.

In the resulting compounds **8** and **9**, the imino ligand is coordinated to Rh(III) through two nitrogen atoms. The rhodium complexes [RhCl<sub>2</sub>{NH=C(R<sup>2</sup>)ON=CR<sup>1</sup>}]<sub>2</sub>Cl (**9**, R<sup>1</sup> = Me<sub>2</sub>, (CH<sub>2</sub>)<sub>4</sub>; R<sup>2</sup> = Me) were also prepared by independent synthesis by the reaction of the rhodium oxime complexes [RhCl<sub>3</sub>{HON=CR<sup>1</sup>}]<sub>3</sub> with acetonitrile (Scheme 3, path *c*).<sup>123</sup> It was suggested that the reaction proceeds in two steps and involves the initial coordination of MeCN and its activation followed by

**Figure 2.** Molecular structures of complexes **8** (a) and **9** (b) [ $R_2^1 = (CH_2)_4$  and  $R^2 = Me$ ].

nucleophilic addition of oxime to nitrile. The molecular structures of complexes **8** and **9** are shown in Fig. 2.

Nickel(II) complexes promote the addition of sulfur-containing dioxime  $HON=C(Me)CH_2S(CH_2)_2SCH_2C(Me)=NOH$  to nitriles (see Section III.3).<sup>125, 126</sup> In the absence of metal the oxime does not react with nitriles.

It was found<sup>127</sup> that  $PdCl_2$  (which is consistent with the results of the study<sup>116</sup>) promotes nucleophilic addition of oximes  $R^1R^2C=NOH$  to nitriles  $R^3CN$  on heating in a solution of the corresponding nitrile to form the  $[PdCl_2\{NH=C(R^3)ONCR^1R^2\}]$  complex. The reaction proceeds through the formation of the oxime complex  $[PdCl_2\{HON=CR^1R^2\}_2]$ , whose heating in a solution of nitrile affords an imino complex. Garnovskii *et al.*<sup>127</sup> demonstrated that the reaction is accelerated under microwave irradiation.

$R^1 = R^2 = Me$ ;  $R^3 = Me, Et, Ph$ ;  $R^3 = Me$ ;  $R^1 = Me, R^2 = Me, Et$ ;  $R^1 - R^2 = (CH_2)_5$ .

The above data show that the nature of the imidoylation product of oxime (which can be coordinated to  $[M]$  in either monodentate or bidentate fashion), as well as the possibility of the independent synthesis of an imino compound by the reaction of an oxime complex with nitrile proceeding in the presence of labile metal complexes, depends on the nature of the central metal atom.

The oxidation state of the central atom has a substantial effect on nitrile activation, which is clearly demonstrated by comparing the reactivities of the related platinum(II and IV) nitrile complexes

$[PtCl_n(RCN)_2]$  ( $n = 2, 4$ ). Nitriles in the platinum(IV) complexes easily react with oximes at room temperature to give addition products. By contrast, for the platinum(II) complexes, the addition products were neither isolated nor detected in the reaction mixtures even in attempting to perform the reaction under much more drastic conditions (prolonged heating) or under microwave irradiation.<sup>117, 118</sup> The reaction of oximes with the dialkylcyanamide complex  $[Pt(PPh_3)_2(NCNR_2)_2](BF_4)_2$  is the only example of the addition of oximes to nitriles involved in a Pt(II) complex.<sup>128</sup> However, this reaction also proceeds due to additional activation of the ligand with yet another Lewis acid.

**The charge of a complex.** The effect of the charge of the complex on the addition of oximes to nitriles was examined in the study of the reactions of the neutral and anionic Pt(IV) complexes, *viz.*,  $[PtCl_4(MeCN)_2]$  and  $[Ph_3PCH_2Ph][PtCl_5(EtCN)]$ , respectively, with oximes  $R^1R^2C=NOH$  ( $R^1 = H$ ;  $R^2 = Ph$ ,  $o-HOC_6H_4$ ;  $R^1 = R^2 = Me$ ;  $R^1 - R^2 = (CH_2)_4, (CH_2)_5$ ). No substantial difference in the reaction rate for these compounds was revealed. Apparently, this provides evidence that activation of nitrile through coordination to Pt(IV) was sufficiently strong for the reaction to proceed in both cases.<sup>117–119</sup> For compounds of other metals, an analogous comparison was not performed, although it has been *a priori* assumed that the charge of a complex can also affect the rate of nucleophilic addition of oximes to coordinated nitriles.

#### b. Electron-withdrawing properties of R in RCN

As mentioned above (see Section III.1), the rate of the reaction of oximes with free nitriles depends substantially on the nature of the R group in RCN. This phenomenon is also observed for coordinated nitriles. Nitriles containing electron-withdrawing groups R are more active in addition reactions with oximes. It was demonstrated<sup>122</sup> that compound **7** is more easily formed by the reaction with the use of PhCN than with the use of MeCN (the yield of the product was estimated after 48 h at 20–25 °C). By contrast, the reactivity of nitriles in the platinum(IV) complexes  $[PtCl_4(RCN)_2]$  depends only slightly on the character of the R group (electron-donating Me, Et, Bn or electron-withdrawing Ph).<sup>117, 118</sup> Apparently, this is associated with the fact that stronger activation by the central atom masks the less significant effect of the R group in RCN.

#### c. Nature of oxime

Variations in the nature of the R and X groups in the  $RXC=NOH$  molecule can change the rate of nucleophilic addition and determine both stability of the reaction product and the probability of occurrence of side reactions. For example, the reactions of imidoyl chlorides  $ArC(Cl)=NOH$  with nitriles in the  $[PtCl_4(MeCN)_2]$  complex are substantially more difficult to perform than the reactions of alkyl(aryl)- or dialkyl oximes,<sup>129</sup> whereas the reactivity of methyl *N*-hydroxyimidoate  $Me_3C_6H_2.C(OMe)=NOH$  in the addition reactions to coordinated nitrile is higher than the reactivities of ketoximes containing alkyl, aryl and electron-withdrawing groups.<sup>130</sup>

Aldoximes  $R^1(H)C=NOH$ , like ketoximes, readily react with coordinated nitriles in the platinum(IV) complexes  $[PtCl_4(R^2CN)_2]$ , but the resulting imino complexes **10** are unstable and undergo further transformations to give the carboximide complex  $[PtCl_4\{NH=C(OH)R^2\}_2]$  and nitrile  $R^1CN$ . The latter is formed as a result of dehydration of aldoxime.

$R^1 = \text{Me, Ph, PhC(O)}; R^2 = \text{Alk, Ar.}$

The molecular structure of the product obtained upon the addition of aldoxime  $\text{PhC(O)CH=NOH}$  to nitrile  $\text{EtC}\equiv\text{N}$  in the  $[\text{PtCl}_4(\text{NCEt})_2]$  complex is shown in Fig. 3.

**Figure 3.** Molecular structure of complex **10** [ $R^1 = \text{PhC(O)}$ ,  $R^2 = \text{Et}$ ].

This transformation is the first example of dehydration of aldoximes with coordinated nitriles.<sup>131</sup> Derivatives of aliphatic aldoximes were found to be more reactive than derivatives of aromatic aldoximes, particularly if the aryl group contains bulky substituents.<sup>131</sup>

#### d. Concentration of reagents

In the study of the reaction of salicylaldoxime  $o\text{-HO}\cdot\text{C}_6\text{H}_4\text{C=NOH}$  with the anionic platinum(IV) complex  $[\text{Ph}_3\text{PCH}_2\text{Ph}][\text{PtCl}_5(\text{EtCN})]$ ,<sup>132</sup> the addition of oximes to coordinated nitriles was demonstrated to depend on the concentrations of the reagents. The addition of oxime to coordinated nitrile was found to compete with the replacement of nitrile with salicylaldoxime. In dilute solutions, one of these reactions becomes the major process. If the concentration of the  $[\text{Ph}_3\text{PCH}_2\text{Ph}][\text{PtCl}_5(\text{EtCN})]$  complex in  $\text{CH}_2\text{Cl}_2$  is  $0.36 \text{ mmol ml}^{-1}$ , the reaction follows the path *a* to form imino complex **11**.

The reaction in a 50-fold diluted solution in wet  $\text{CH}_2\text{Cl}_2$  affords substitution product **12** (path *b*) and the  $[\text{Ph}_3\text{PCH}_2\text{Ph}]_2[\text{PtCl}_6]$  complex. The addition of a small amount of  $\text{EtCN}$  to a dilute reaction mixture suppresses the formation of product **12** and facilitates the formation of compound **11**. The 'switching' of the reaction from the addition (path *a*) to substitution (path *b*) by dilution of the reaction mixture was explained by an increase in dissociation of the  $\text{EtCN}$  ligand in a dilute solution and, correspondingly, by promotion of the replacement of nitrile.<sup>132</sup>

#### e. Activation of two donor centres in dialkylcyanamide

To understand the mechanism of the nucleophilic addition of oximes to nitriles, let us consider the reaction of oxime with dialkylcyanamide  $\text{NCNR}_2^1$  involved in platinum(II) complex **13** (Scheme 4).

Scheme 4

$R^1 = \text{Me, Et}; R^2 = \text{Me, } R_2^2 = (\text{CH}_2)_4.$

The dialkylcyanamide complexes  $[\text{Pt}(\text{NCNR}_2)_2](\text{PPh}_3)_2 \cdot (\text{BF}_4)_2$  (**13**) were found to react with oximes in the presence of a catalytic (10%) or stoichiometric amount of  $\text{AgBF}_4$  to form chelate **14**.<sup>128</sup> The reaction of the dialkylcyanamide complex with oxime in the absence of  $\text{Ag}^+$  affords complex **15**, in which the nitrile and oxime ligands do not interact with each other. Therefore, the presence of a silver salt is necessary for the reaction of coordinated dialkylcyanamide with oxime to proceed. A catalytic amount of  $\text{Cu}(\text{OAc})_2$  can be used instead of  $\text{AgBF}_4$ . It is believed that in this case metal additionally activates the nitrile group due to coordination of Lewis acid ( $\text{Ag}^+$  or  $\text{Cu}^{2+}$ ) to amide nitrogen resulting in an increase in electrophilicity of the carbon atom of the nitrile group.

$M = \text{Ag}^+, \text{Cu}^{2+}.$

All attempts to perform the addition of oximes to nitriles in analogous platinum complexes with alkanonitrile

ligands instead of dialkylcyanamide  $\{[\text{Pt}(\text{RCN})_2(\text{PPh}_3)_2](\text{BF}_4)_2$ ;  $\text{R} = \text{Et}$ ,  $\text{C}_6\text{H}_4\text{OMe-}p$ \} and in complexes of another type  $\{[\text{PtCl}_2(\text{RCN})_2]$ ;  $\text{R} = \text{Me}$ ,  $\text{Ph}$ \} with nitrile ligands in the presence or absence of an  $\text{Ag}^+$  catalyst failed.<sup>117, 128</sup> This fact suggests that nitrile is insufficiently activated by platinum(II) for the nucleophilic addition of oxime to occur (addition at the  $\text{C}\equiv\text{N}$  bond becomes possible only for dialkylcyanamide complexes in the presence of Lewis acids, which additionally activate the nitrile group).

#### f. Role of the central atom in stabilisation of imino ligands

In most studies of nucleophilic addition of oximes to nitriles, it was noted that coordinated imines produced in these reactions are resistant to hydrolysis.<sup>117–120, 123, 124, 128</sup> For example, platinum(II) and rhodium(III) imino complexes,<sup>117–119, 123, 124</sup> which were prepared by the reactions in wet solvents, can be stored for a long period of time without changes. Storage of the rhodium imino complex  $[\text{RhCl}_2\{\text{NH}=\text{C}(\text{Me})\text{ON}=\text{CMe}_2\}_2]\text{Cl}$  (**16**) in 0.1 M HCl at 80 °C for several days was demonstrated to lead to hydrolysis of the  $\text{C}=\text{N}$  bond of oxime giving rise to products **17** and **18**, while the imine  $\text{C}=\text{N}$  bond remains intact.

It is also known that the  $\text{C}=\text{N}$  bond in oximes is rather stable, whereas the  $\text{C}=\text{N}$  bond in imines is readily hydrolysed. In this case, coordination to metal stabilises the imino group and destabilises the oxime group resulting in selective hydrolysis of the latter. This procedure was used to prepare the *O*-imidoylated hydroxylamine complex, whereas the reaction of free hydroxylamine with coordinated nitrile afforded a mixture of unidentified products.<sup>124</sup>

Stabilisation of a ligand through coordination is also evident from the fact that known free imidoxyated oximes are rather unstable (see Section III.1). Liberation of imines, which are generated through metal-mediated addition of oxime to nitrile, from metal complexes gave the decomposition products  $\text{HN}=\text{C}(\text{R}^3)\text{ON}=\text{CR}^1\text{R}^2$ .<sup>117, 118</sup> The imino ligand was liberated in the free state from the  $[\text{PtCl}_2\{\text{NH}=\text{C}(\text{Et})\text{ON}=\text{C}(\text{Me})-\text{C}(\text{Me})=\text{X}\}_2]$  complex ( $\text{X} = \text{O}$ ,  $\text{NNH}_2$ ) in the presence of 1,2-bis(diphenylphosphino)ethane in a  $\text{CDCl}_3$  solution.<sup>133, 134</sup> Although such imines can exist as ligands of platinum complexes during a long period of time even in wet solvents, free imines decompose in solution within a few hours to form the starting oxime and nitrile.<sup>133, 134</sup>

$\text{X} = \text{O}$ ,  $\text{NNH}_2$ .

Therefore, the central metal atom stabilises the resulting coordinated imine  $\text{HN}=\text{C}(\text{R}^3)\text{ON}=\text{CR}^1\text{R}^2$ , whereas the free imine is either unstable or does not exist at all. Coordination of nitriles favours  $\text{C}\equiv\text{N}$  triple bond activation in addition reactions of oximes, the reaction pathway and the character of the product being dependent on numerous factors, among which the nature of the metal and its oxidation state are of most importance. Coordination also provides stabilisation of the addition product of oxime.

#### 3. Reactions of functionalised oximes

Functionalised oximes (with sulfide groups,<sup>125, 126</sup> *vic*-dioximes,<sup>118, 120</sup> ketoximes,<sup>133</sup> hydrazone oximes<sup>134</sup>), like 'simple' oximes, are involved in nucleophilic addition to metal-activated nitriles. For example, treatment of sulfur-containing dioxime  $\text{HON}=\text{C}(\text{Me})\text{CH}_2\text{S}(\text{CH}_2)_2\text{SCH}_2\text{C}(\text{Me})=\text{NOH}$  ( $\text{DtoxH}_2$ ) with nickel perchlorate in acetonitrile afforded two compounds, *viz.*, the trinuclear complex  $[\text{Ni}_3(\text{Dtox})(\text{DtoxH})_2](\text{ClO}_4)_2 \cdot \text{MeCN}$  and the imino complex  $[\text{Ni}\{\text{NH}=\text{C}(\text{Me})\text{ON}=\text{C}(\text{Me})\cdot\text{CH}_2\text{S}(\text{CH}_2)_2\text{SCH}_2\text{C}(\text{Me})=\text{NO}-\text{C}(\text{Me})=\text{NH}\}](\text{ClO}_4)_2$  (**19**, Fig. 4a).<sup>125</sup>

In the absence of a metal centre, dioxime  $\text{DtoxH}_2$  does not react with  $\text{MeCN}$ . Hence, it was suggested<sup>125</sup> that, on the one hand, the reaction is determined by activation of nitrile through coordination to  $\text{Ni}(\text{II})$  and, on the other hand, the reaction of oxime with nitrile is facilitated by the close arrangement of the reacting molecules upon coordination (the reaction product is stabilised through chelation).

More recently, unusual dinuclear complex **20** with a macrocyclic ligand (Fig. 4b) was prepared by the reaction of the dioxime complex  $[\text{Ni}(\text{DtoxH}_2)(\text{H}_2\text{O})_2](\text{ClO}_4)_2$  with *o*-phthalonitrile  $\text{C}_6\text{H}_4(\text{CN})_2$ .<sup>126</sup> The presence of additional functional (sulfide) groups in the oxime molecule is favourable for stabilisation of the macrocyclic ligand, which forms a stable complex with nickel.

The extremely reactive nitrile ligands in the rhenium(IV) and platinum(IV) complexes  $[\text{MCl}_4(\text{R}^1\text{CN})_2]$  react with *vic*-dioximes  $\text{HON}=\text{C}(\text{R}^2)\text{C}(\text{R}^3)=\text{NOH}$ ,<sup>118, 120</sup> ketoximes  $\text{HON}=\text{C}(\text{R}^2)\cdot\text{C}(\text{O})\text{R}^3$  (see Ref. 133) and hydrazone oximes  $\text{HON}=\text{C}(\text{R}^2)\cdot\text{C}(\text{R}^3)=\text{NNH}_2$  (see Ref. 134) to give imino complexes **21**.

**Figure 4.** Structures of imino complex **19** (a) and dinuclear complex **20** with a macrocyclic ligand (b).

X = NOH; M = Re, Pt; R<sup>1</sup> = Me; R<sup>2</sup> = R<sup>3</sup> = Me,

R<sup>2</sup>–R<sup>3</sup> = (CH<sub>2</sub>)<sub>n</sub> (n = 4–6);

X = O; M = Pt; R<sup>1</sup> = Me, Et; R<sup>2</sup> = Me; R<sup>3</sup> = Me, Ph, C<sub>6</sub>H<sub>4</sub>F;

X = NNH<sub>2</sub>; M = Pt; R<sup>1</sup> = Me, Et; R<sup>2</sup> = Me; R<sup>3</sup> = Me, Ph.

Imino complexes **21** are of interest because the ligand formed upon nucleophilic addition of oxime to nitrile contains a remote free functional group, which can be involved in further reactions.<sup>134</sup> For example, reduction of imino complex **21** (M = Pt, X = NNH<sub>2</sub>, R<sup>1</sup> = Et, R<sup>2</sup> = Me, R<sup>3</sup> = Ph) with phosphorus ylide Ph<sub>3</sub>P=CHCO<sub>2</sub>Me afforded the corresponding platinum(II) complex **22** containing peripheral NH<sub>2</sub> groups, which undergo Schiff condensation with aromatic aldehydes RCHO (R = 2-HO-5-NO<sub>2</sub>C<sub>6</sub>H<sub>3</sub> and 4-NO<sub>2</sub>C<sub>6</sub>H<sub>4</sub>) to give complexes **23** containing the newly formed free remote functionalised groups. Compound **23** with R = 2-HO-5-NO<sub>2</sub>C<sub>6</sub>H<sub>3</sub> was used as a metal-containing ligand for subsequent complexation with Cu<sup>2+</sup> and Co<sup>2+</sup>.<sup>134</sup>

R = 2-HO-5-NO<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, 4-NO<sub>2</sub>C<sub>6</sub>H<sub>4</sub>; M = Cu<sup>2+</sup>, Co<sup>2+</sup>.

To summarise, a new type of reactivity of *vic*-dioximes, dione monooximes and hydrazone oximes with respect to nitriles was revealed in the studies of nucleophilic addition reactions.<sup>118, 120</sup>

#### 4. Transformations of nitriles promoted by 3d-metal–oxime systems

Reactions of nitriles with 'simple' oximes in the presence of complexes and salts of labile 3d metals afford products (free carboxamides **24**, amidinium salts **25** and coordinated imidoyl amidines **26**) different from those described in Sections III.2 and III.3. For example, catalytic hydrolysis of a series of nitriles R<sup>1</sup>CN in the presence of the ZnX<sub>2</sub>–R<sub>2</sub>C=NOH system produces the corresponding carboxamides R<sup>1</sup>C(O)NH<sub>2</sub> (Scheme 5, path a).<sup>74</sup>

Scheme 5

R<sup>1</sup> = Me, CH<sub>2</sub>Cl, Et, Pr<sup>n</sup>, Pr<sup>i</sup>, Bu<sup>n</sup>, Bu<sup>t</sup>, *p*-MeOC<sub>6</sub>H<sub>4</sub>CH<sub>2</sub>, Ph;  
R<sub>2</sub><sup>2</sup> = Me<sub>2</sub>, (CH<sub>2</sub>)<sub>4</sub>, (CH<sub>2</sub>)<sub>5</sub>; M = Co, Ni; X = Cl, NO<sub>3</sub>.

This system containing the zinc salt and oxime in a molar ratio of 1 : 4 (which is optimal for hydrolysis of RCN) allows one to transform nitriles into carboxamides under mild conditions with a

catalyst turnover number of about 100 for the majority of nitriles and up to 1000 for the conversion of *p*-MeOC<sub>6</sub>H<sub>4</sub>CH<sub>2</sub>CN into *p*-MeOC<sub>6</sub>H<sub>4</sub>CH<sub>2</sub>C(O)NH<sub>2</sub>. It should be noted that, taken separately, the zinc salt and oxime do not exhibit catalytic activity. The intermediate [ZnX<sub>2</sub>(R<sub>2</sub>C=NOH)<sub>2</sub>] was isolated and its catalytic activity in hydrolysis was experimentally confirmed, which provide evidence that this complex is directly involved in the catalytic cycle.<sup>74</sup> It is believed<sup>74</sup> that one step of the process involves the reaction of the [ZnX<sub>2</sub>(R<sub>2</sub>C=NOH)<sub>2</sub>] complex with R<sup>1</sup>CN, resulting in its electrophilic activation followed by the formation of the imino complex. The ZnX<sub>2</sub>–R<sub>2</sub>C=NOH reagent system is the most readily accessible and inexpensive catalytic system for the transformation of R<sup>1</sup>CN into the corresponding carboxamides R<sup>1</sup>C(O)NH<sub>2</sub>.<sup>135</sup>

In the presence of salts MX<sub>2</sub>·6H<sub>2</sub>O (M = Co, Ni) and an excess of oxime R<sub>2</sub>C=NOH, sterically unhindered nitriles are quantitatively transformed into amidinium salts R<sup>1</sup>C(NH)NH<sub>2</sub>·HNO<sub>3</sub> (Scheme 5, path *b*).<sup>136, 137</sup> The optimal conditions for the formation of R<sup>1</sup>C(NH)NH<sub>2</sub>·HNO<sub>3</sub> are those where salt M(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O and oxime R<sub>2</sub>C=NOH are used in a molar ratio of 1:4. A change in the ratio to 1:2 leads to a substantial decrease in the yield of the target product and an increase in the reaction time. The results of investigation of the reaction products and intermediates suggested<sup>136, 137</sup> the following mechanism: initial metal-mediated hydrolysis of nitrile giving rise to R<sup>1</sup>CO<sub>2</sub>H and ammonia followed by the reaction of the latter with metal-activated nitrile to produce amidine (Scheme 6). It is believed that all steps of the process yielding amidines require the involvement of a metal centre, and some steps are additionally catalysed by oxime.

Scheme 6

The reaction of nitriles with oximes in the presence of nickel salt NiCl<sub>2</sub>·2H<sub>2</sub>O, which is less hydrated than M(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O (M = Ni, Co), follows a different pathway.<sup>137</sup> For example, the reaction of R<sup>1</sup>CN with a NiCl<sub>2</sub>·2H<sub>2</sub>O–Me<sub>2</sub>C=NOH mixture affords the imidoamidinium complexes [Ni{N=CH(R<sup>1</sup>)}<sub>2</sub>]<sup>2+</sup> (Scheme 5, path *c*).

Although the mechanism of this process is not entirely understood, it was hypothesised<sup>137</sup> that the initial step affords coordinated amidines according to Scheme 6, which are then involved in transformations to give chelating imidoamidinium.

The resulting imidoamidinium ligand was isolated in the free state by the reaction with ethylenediamine or as a salt by the reaction of HBF<sub>4</sub>·Et<sub>2</sub>O with a solution of complex **26** in MeCN.<sup>137</sup> The reaction of ethylenediamine with complex **26** in an aqueous methanolic solution produced acylamides R<sup>1</sup>C(O)NHC(O)R<sup>1</sup> through hydrolysis of intermediate imidoamidinium

amidines **27**. This is a new procedure for the preparation of imidoamidinium **27**, which are used in the synthesis of triazines and triazine-containing polymers.

Therefore, 3d-metal salt–oxime systems can be employed to activate nitriles in the reactions giving rise to carboxamides, amidines, imidoamidinium and acylamides, which are of great commercial and/or preparative importance. It should be noted that variation of the metal salts in the activating system allows one to prepare selectively and in good yield different products from the same starting nitriles.

#### IV. Reactions of hydroxylamines and hydroxamic acids

Other HON-nucleophiles (along with oximes), such as substituted hydroxylamines and hydroxamic acids, can be used in addition reactions to coordinated nitriles. Although hydroxamic acids are formally hydroxylamine derivatives, the nitrogen atoms in these compounds are in different hybridisation states and, consequently, act as nucleophiles of different types.

Unsubstituted hydroxylamine, being an ambidentate N,O-nucleophile, can be involved in the addition to free nitriles at both centres. In most cases, the addition occurs at the nitrogen atom. These reactions produce amidoximes.<sup>11</sup> The addition of unsubstituted hydroxylamine NH<sub>2</sub>OH to complexed nitriles has not been documented. Several studies were devoted to reactions of alkylated hydroxylamines R<sub>2</sub>NOH with coordinated nitriles.<sup>138–140</sup> For instance, N-addition of alkylated hydroxylamines to Mo and W nitrile complexes was described.<sup>138, 139</sup> Only one example of addition of hydroxylamines R<sub>2</sub>NOH to coordinated nitrile in *trans*-[PtCl<sub>4</sub>(MeCN)<sub>2</sub>] involving the OH group is known.<sup>140</sup>

R = Me, Et, Bn.

Hydroxamic acids ArC(O)NHOH also show unusual reactivity with respect to the nitrile complex *trans*-[PtCl<sub>4</sub>(EtCN)<sub>2</sub>].<sup>141</sup> In this case, hydroxamic acids, which are known in chemistry primarily due to chelation reactions giving rise to stable five-membered metallacycles, act as nucleophiles and react with a coordinated nitrile.

Hydroxamic acids exist as two tautomeric forms **A** and **B**. Both forms can potentially act as HO-nucleophiles (Scheme 7).

Their contribution to the addition reactions was elucidated in the study of the reactions of *trans*-[PtCl<sub>4</sub>(EtCN)<sub>2</sub>] with hydroxamic acid PhC(O)N(Me)OH (corresponds to the form **A** in Scheme 7) and methyl *N*-hydroxyimidoate Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>.C(OMe)=NOH (corresponds to the form **B** in Scheme 7), which are 'frozen' through N- or O-alkylation.<sup>130</sup>

The reaction of the platinum(IV) nitrile complex with methyl *N*-hydroxyimidoate is completed at room temperature in a few minutes, whereas the reaction with hydroxamic acid requires more drastic conditions (heating to 50 °C) and longer reaction time (2–3 h), which is indicative of the difference in the reactivity of

R = Alk, Ar; Ar = Ph, *o*-HOC<sub>6</sub>H<sub>4</sub>, *p*-ClC<sub>6</sub>H<sub>4</sub>, *p*-MeC<sub>6</sub>H<sub>4</sub>, *p*-MeOC<sub>6</sub>H<sub>4</sub>.

these forms. This suggests that the form **B** makes a greater contribution to the nucleophilic addition of unsubstituted hydroxamic acids to coordinated nitriles.

## V. Reactions of alcohols with coordinated nitriles

The reaction of free nitriles with alcohols is involved in the two-step Pinner synthesis used for the preparation of amidines **28**. In the first step, the reaction of nitrile R<sup>1</sup>CN with alcohol R<sup>2</sup>OH in the presence of an excess of dry HCl (Scheme 8, path *a*) affords the salt [R<sup>1</sup>C(OR<sup>2</sup>)=NH<sub>2</sub>]<sup>+</sup>Cl<sup>−</sup>, which (in the second step) reacts with two moles of amines to form amidines **28** and with alkali to give imidoates **29**.

In this process, nitrile is activated through protonation. The main drawback of the Pinner synthesis of amidines is that it requires a large excess of HCl.

The reactions of alcohols with coordinated nitriles proceed analogously to the Pinner reaction with the difference that the metal centre serves as an activator (Scheme 8, path *b*). The nucleophilic addition of alcohols to nitriles affords imidoates, which are stabilised through coordination to the metal and, in the coordinated state, are resistant to hydrolysis. Since the nucleophilic addition of alcohols to nitriles has been surveyed in the reviews,<sup>17, 18</sup> we do not consider this reaction in detail. Table 1 gives examples of these reactions.<sup>93, 102, 142–188</sup>

In summary, it should be noted that the conditions of the reactions of alcohols with nitriles depend substantially on the oxidation state of the metal. The addition of R<sup>2</sup>OH to R<sup>1</sup>CN present in low-oxidation-state metal complexes [Pt(II),<sup>102, 143–146</sup> Pd(II),<sup>158</sup> Ni(II),<sup>165</sup> Ir(III),<sup>171</sup> Cu(II)<sup>177</sup>] requires that the nucleophilicity of R<sup>2</sup>OH be additionally increased by adding alkali or another base (for example, NR<sub>3</sub>; see Refs 158 and 165) in a catalytic or stoichiometric amount. Nitrile ligands in high-oxidation-state complexes [Pt(IV), Re(IV)]<sup>157, 174</sup> can react with alcohols in a neutral medium under rather mild conditions. The reaction is influenced by the nature of the R<sup>1</sup> group in the R<sup>1</sup>CN molecule, and the reactions with nitriles containing electron-withdrawing groups (for example, R<sup>1</sup> = Ph) proceed more readily.<sup>165, 167, 168</sup> The addition of alcohols to nitriles also depends substantially on the steric parameters of the R<sup>2</sup> group in the alcohol molecules. Alcohols containing unhindered groups (R<sup>2</sup> = Me, Et) react more readily, whereas sterically hindered alcohols or phenols (R<sup>2</sup> = Ph, Bu<sup>t</sup>) do not react at all.<sup>102, 142, 165, 167, 168</sup>

Imidoate complexes are of interest because they contain imine in the 'frozen' coordinated form, which provides stability of imidoates R<sup>1</sup>C(OR<sup>2</sup>)=NH. In the free state, the latter are generally easily subjected to hydrolysis. Imines can be isolated by decoordination under anhydrous conditions and used in subsequent reactions. An example of the use of this methodology was given in the study,<sup>189</sup> where imidoates were involved in subsequent reactions with nitriles included in platinum(IV) complexes in non-aqueous solutions.

Imidoates are better ligands than nitriles and they are more tightly held in the inner sphere of the metal, which, in most cases, excludes the possibility of a catalytic process. Nevertheless, several examples of catalytic alcoholysis of nitriles in the presence of Pd(II),<sup>93</sup> Re(III)<sup>175</sup> and Ir(III)<sup>171</sup> complexes have been documented. Unfortunately, the available data on the catalytic transformations of RCN into imidoates are insufficient for an understanding of the general features of this process.

## VI. Reactions of other HO-nucleophiles

Examples of the addition of HOP-nucleophiles to coordinated nitriles are scarce. For instance, heating of complex **30** with nitrile *p*-MeC<sub>6</sub>H<sub>4</sub>CN for two days afforded compound **31** containing a new five-membered ring formed through nucleophilic attack of the oxygen atom of the P–OH group on the coordinated nitrile.<sup>190</sup>

**Table 1.** Examples of nucleophilic addition of alcohols to coordinated nitriles.

Otf =  $\text{O}_3\text{SCF}_3$ .

The structure of compound **31** was confirmed by elemental analysis,  $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{31}\text{P}$ ,  $^{19}\text{F}$  and  $^{15}\text{N}$ – $^1\text{H}$  COSY NMR spectroscopy and FAB mass spectrometry.<sup>190</sup>

Several of the most efficient systems for catalytic hydrolysis of nitriles giving rise to amides are based on the platinum phosphinite complexes  $[\text{PtX}(\text{R}_2\text{PO}\cdots\text{H}\cdots\text{OPR}_2)(\text{PR}_2\text{OH})]$  ( $\text{X} = \text{H}, \text{Hal}$ ;  $\text{R} = \text{Alk}, \text{Ar}$ ).<sup>32</sup> It was hypothesised that the initial step involves dissociation of the complex to form the  $[\text{Pt}(\text{R}_2\text{PO}\cdots\text{H}\cdots\text{OPR}_2)(\text{PR}_2\text{OH})]^+$  cation followed by coordination of nitrile.<sup>32</sup> Hydrolysis of coordinated nitrile involves the intramolecular attack of the oxygen atom of hydroxy phosphine on RCN to give an intermediate analogous to that described in the study.<sup>190</sup>

Systems based on the  $[\text{PtX}(\text{R}_2\text{PO}\cdots\text{H}\cdots\text{OPR}_2)(\text{PR}_2\text{OH})]$  complexes allow one to perform efficient transformations of various nitriles into amides, including the synthesis of acrylamide, which is of great commercial importance.<sup>32, 73</sup>

The platinum phosphinite complexes  $[\text{PtH}(\text{R}_2\text{PO}\cdots\text{H}\cdots\text{OPR}_2)(\text{PR}_2\text{OH})]$  catalyse the formation of *N*-substituted amidines from nitriles and primary (or secondary) amines. Presumably,<sup>191</sup> the mechanism of this reaction is analogous to the mechanism of hydrolysis of nitriles involving these complexes.

## VII. Conclusion

The present review surveys recent data on the addition of HO-nucleophiles to nitriles. In most cases, additional electrophilic activation of the  $\text{C}\equiv\text{N}$  group is required for these reactions to occur. Analysis of the published data shows that coordination to a metal centre is one of the most efficient ways of activating nitriles. Since the nucleophilic addition to nitriles provides the basis for the synthesis of a series of compounds of commercial value, the determination of optimal conditions for these reactions is an important problem in preparative chemistry.

Coordination of nitriles leads to a substantial increase in electrophilicity of the  $\text{C}\equiv\text{N}$  group, which substantially influences their reactivity. A comparative evaluation of the rates of hydrolysis of free and coordinated nitriles shows that the reaction constant increases by 6–8 orders of magnitude in metal-mediated processes. Nitrile ligands in high-oxidation-state metal complexes can bind nucleophiles. These reactions with free nitriles do not occur even under drastic conditions. In some cases, the resulting imino ligands can be isolated.

Metals not only increase the reactivity of the  $\text{C}\equiv\text{N}$  group but also influence the course of the reaction of nitriles with HO-nucleophiles. For instance, metal-mediated hydrolysis of nitriles, unlike hydrolysis of free RCN, generally stops at the formation of carboxamides, which do not undergo transformations into carboxylic acids. The latter fact is associated with a change in the ratio of the rate constants of the first and second steps of hydrolysis and stabilisation of the product formed in the first step (carboxamide) through coordination. In the presence of metal complexes, the reactions of nitriles with HO-nucleophiles proceed by mechanisms distinct from those observed in the absence of metal complexes (for example, nitriles are hydrolysed in the presence of nickel and cobalt salts to amidinium salts and imidoil imidates).

In the addition of HO-nucleophiles to nitriles, metal often serves as a stabiliser of the reaction product. In most cases, metal-mediated reactions of HO-nucleophiles with nitriles produce coordinated imino compounds, which are generally unstable in the free state or do not exist at all (for example, the addition products of oximes and hydroxamic acids at the  $\text{C}\equiv\text{N}$  bond). Coordination to the metal centre stabilises these compounds and allows one to isolate such imino complexes in individual form. Coordination can also lead to stabilisation of the reaction products in a tautomeric form different from that in which the free compounds exist.

Due to the possibility of varying the nature of the metal, its oxidation state and ligand environment over wide ranges, a large number of nucleophiles of different strength can be used in addition reactions to coordinated nitriles and a broad spectrum of products can be synthesised. For example, complexes with imino and imidoilamidate ligands, as well as amidinium salts and free carboxamides, can be prepared by metal-mediated reactions of nitriles with oximes by varying the nature of the metal atom. In addition, the nature of the metal atom is responsible for the stoichiometric or catalytic character of the process. It should be noted that most known metal-mediated transformations of nitriles and HO-nucleophiles afford coordinated imines and require a stoichiometric amount of metal. The transformation products can be isolated in the free state as an additional step of the synthesis.

Examples of catalytic transformations of nitriles (hydrolysis and alcoholysis) are described in the literature. These reactions are of interest for the synthesis of compounds of commercial and/or pharmaceutical importance. Intermediates in catalytic systems are often too labile for preparative isolation and investigation. Model systems are used to understand the mechanisms of these reactions. Nitrile complexes of kinetically inert metals (for example, platinum) can serve as such models. The reactions of these complexes with nucleophiles give stable analogues of intermediates of catalytic processes. Studies of systems involving kinetically inert complexes would contribute to the design of new catalytic systems.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 05-03-32140 and 03-03-32362) and the Competition Center for Basic Natural Science (Grant No. PD03-1.3-28).

**Abstract.** The carbene method for the synthesis of iminium ylides based on reactions of carbenes and metallocarbenoids with compounds containing a C=N bond is considered. Special attention is given to the use of iminium ylides in the synthesis of various classes of nitrogen-containing compounds. The bibliography includes 163 references.

## I. Introduction

In recent years, iminium ylides have found wide application in organic synthesis. This is associated with the discovery of new transformations of these compounds, on the one hand, and the perfection of methods for their generation, on the other hand. About ten different procedures for the preparation of iminium ylides are known. To date, the so-called carbene method based on reactions of electrophilic carbenes or metallocarbenoids with compounds containing a C=N bond (an attack at an unshared electron pair of the nitrogen atom) is the most dynamically developing procedure.

This approach allows the introduction of synthetically useful functional groups (e.g., halogen atoms, alkoxy-carbonyl groups) into ylides and their use in domino reactions. Recent reviews<sup>1–6</sup> that touch upon, to a certain degree, the problems of generation of ylides from carbenes and carbenoids cover the literature published more than ten years ago. The present review is a generalisation of the data from the last 15 years devoted to the carbene methods for the generation of iminium ylides and their successful synthetic applications.

## II. Spectroscopic methods for identification of iminium ylides

With rare exception, nitrogen ylides represent unstable intermediates that can nevertheless be identified by spectroscopic methods. Thus ylide species were detected by spectroscopy upon reactions of carbenes with various nitrogen-containing compounds<sup>7</sup> such as amines,<sup>8–10</sup> nitriles<sup>8, 11–13</sup> and pyridine.<sup>14, 15</sup> Carbenes react with pyridine at the maximum rate; therefore, this reaction is considered to be ideal for measuring absolute rates of carbene reactions and was used as a basis for the so-called 'pyridine probe technique'.<sup>16, 17</sup> A vast array of ylides **1** have been prepared from pyridine and diverse carbenes in the past 15 years.

Ylides **1** are prepared in solutions or on matrices using flash vacuum thermolysis (FVT) or laser flash photolysis (LFP) of various compounds such as diazirines **2**, aliphatic diazo compounds **3**, tricyclo[4.3.1.0<sup>1,6</sup>]deca-2,4-diene derivatives **4**, the adduct of dichlorocarbene with phenanthrene (**5**), bicyclo[4.2.0]octa-1,3,5-triene-7,8-dione (**6**), substituted 1,3,4-oxadiazolines **7**, etc.

The ylides **1** formed manifest a characteristic absorption in the UV or the visible region of the spectrum related to the  $\pi \rightarrow \pi^*$ -transition similar to the *B*-band in benzene derivatives. The wavelength of the absorption band depends on the type of the substituents R<sup>1</sup> and R<sup>2</sup> in the ylide **1**:  $\lambda_{\max} = 340–380$  nm for dialkyl- or monochloro-substituted ylides,  $\lambda_{\max} = 390–450$  nm for dihalogeno ylides and  $\lambda_{\max} = 430–480$  nm for phenyl- or carbonyl-substituted ylides. The absorption maxima of pyridi-

nium ylides in the UV region and the absolute rate constants for the formation are listed in Table 1 (for comparison, the rate constants for the reactions of carbenes with tetramethylethylene are given). These data suggest that carbenes react with pyridine several times (from 2 to 30) faster than with tetramethylethylene. The majority of carbenes react with pyridine with the rate constants ranging from  $10^8$  to  $10^{10}$  litre mol $^{-1}$  s $^{-1}$ . Lower activities are characteristic of methoxy carbenes (presumably, by virtue of their nucleophilic nature) as well as of adamantylidene and chloro(2,2-dimethylcyclopropyl)carbene, which can be attributed to steric factors.

The activation parameters of the addition reaction of the singlet carbenes RCIC: to pyridine have been determined:

| R          | $E_a$ /kJ mol $^{-1}$ | log $A$       | Ref. |
|------------|-----------------------|---------------|------|
| Ph         | $5.4 \pm 2.0$         | $9.7 \pm 0.2$ | 66   |
| PhOCH $_2$ | $5.8 \pm 0.8$         | 10.9          | 67   |
| MeOC(O)    | $11.1 \pm 0.8$        | $9.1 \pm 0.2$ | 40   |

The rates of formation of ylides ( $\lambda_{\max} = 540$  nm) in the reactions of phenyl- and (4-chlorophenyl)chlorocarbenes with some substituted pyridines have been determined.<sup>68</sup>

**Table 1.** The rate constants for the reactions of singlet carbenes R<sup>1</sup>R<sup>2</sup>C: with tetramethylethylene (TME) and pyridine (Py) and the absorption bands of ylides **1** in the UV region at room temperature.

| Carbene source | R <sup>1</sup>           | R <sup>2</sup>                                                                    | $k_{\text{TME}}$ /litre mol $^{-1}$ s $^{-1}$ | $k_{\text{Py}}$ /litre mol $^{-1}$ s $^{-1}$ | $\lambda_{\max}$ /nm | Ref.   |

In the reaction of chloro(phenyl)carbene with *trans*-1-phenyl- and 1,5-diphenyl-4-azapenta-1,3-diene, the corresponding ylides ( $\lambda_{\text{max}} = 550 \text{ nm}$ ) are formed with the rate constants of  $(1.0 \pm 0.1) \times 10^9$  and  $(3.6 \pm 0.2) \times 10^8 \text{ litre mol}^{-1} \text{ s}^{-1}$  (see Ref. 68).

R = Me, Bn.

In all these cases, the C=C bond is inactive with respect to carbene.

Studies on matrix photolysis of 2-(diazooacetyl)pyridine (**8**) ( $\nu_{\text{C=O}} = 1652 \text{ cm}^{-1}$ ) using time-resolved infrared spectroscopy (TRIR) have shown that compound **8** yields carbene **9**, which undergoes intramolecular cyclisation into ylide **10** with a characteristic band  $\nu_{\text{C=O}}$  at  $1759 \text{ cm}^{-1}$ . Upon subsequent photolysis at  $\lambda_{\text{max}} > 320 \text{ nm}$ , the ylide **10** is converted into (2-pyridyl)ketene ( $\nu_{\text{C=C=O}} = 2123-2132 \text{ cm}^{-1}$ ).<sup>69</sup>

Studies of reactions of triplet carbenes with pyridine revealed that in this case ylide intermediates are also formed, but the rate constants for their formation are significantly lower (by more than an order of magnitude) than the rate constants for ylide formation from singlet carbenes (Table 2). This is especially noticeable in the case of sterically hindered carbenes (e.g., with a trypticyl substituent).<sup>71</sup> Since the ylide formed exists in the singlet state, it was assumed that the triplet carbene first passes into the singlet state and then reacts with pyridine. Hence, the rate constant for the reaction of a triplet carbene with pyridine comprises the equilibrium constant between the triplet and the singlet carbenes. These considerations were employed for the calculation of the energies of the triplet–singlet conversions of aryl carbenes.<sup>52, 53</sup>

It is known that the triplet diphenylcarbene is 12–16 kJ mol<sup>−1</sup> more stable than the singlet one. Studies of the reaction of diphenylcarbene with pyridine have shown that the activation barrier for the formation of ylides from the triplet diphenylcarbene is equal to 8–12 kJ mol<sup>−1</sup>, which is smaller than the aforementioned difference in the stabilities of states. Thus, it was suggested<sup>69</sup> that the mechanism of the reaction of diphenylcarbene with pyridine does not include preliminary conversion of the triplet carbene into the singlet carbene. Presumably, the triplet and singlet potential reaction surfaces are crossed in this case.<sup>69</sup>

### III. Ylides from metallocarbenoids

Reactions of diazo compounds with imines form the basis of an important procedure for the preparation of aziridines and aziridine-2-carboxylic acid derivatives in particular. Let us consider two main types of catalytic reactions of diazo compounds with imines leading to aziridines. The first, so-called ‘carbene’ type reaction (Scheme 1) consists of the reaction of a diazo compound with a metallocarbenoid catalyst that gives an unstable metallocarbenoid **11**. The reaction of the latter with the unshared electron pair of an imine results in the complex **12**, which either undergoes cyclisation into aziridine **13** or is converted into

**Table 2.** Rate constants for reactions of the triplet carbenes  $R^1R^2C:$  with pyridine, and absorption bands of ylides **1** in the UV region at room temperature.

Scheme 1

azomethine ylide **14** the cyclisation of which also yields aziridine **13**. If the formation of aziridines occurs *via* the complex **12**, the use of a catalyst with chiral ligands yields optically active products. In contrast, the formation of aziridines *via* free azomethine ylide **14** would result in a racemate. In the presence of dipolarophiles  $X=Y$ , azomethine ylide **14** yields the [3 + 2]-cycloaddition products **15** which can probably be formed *via* the intermediate **12**.

The second, 'non-carbene' type reaction (Scheme 2) includes the reaction of the unshared electron pair of an imine with a Lewis acid (LA) to give a complex **16**; in certain cases, this is stable. Increased electrophilicity of the latter in comparison with the free imine favours the addition of a nucleophilic diazo compound (e.g., diazoacetates) to give the intermediate **17**, which eliminates the nitrogen molecule to give aziridines **13** (the use of chiral Lewis acids  $LA^*$  affords optically active products). Compounds **18** and **19** are obtained as side products in this reaction.

Many papers were devoted to the search for efficient catalysts for the reactions of diazoacetates ( $N_2CHCO_2R$ ) with imines resulting in aziridines, especially optically active aziridines. It was shown<sup>72</sup> that it is upon Cu-catalysed thermolysis of ethyl diazoacetate that ethoxycarbonylcarbene formed reacted with  $Bu^tCH=NMe$ ,  $PhCH=NBu^t$  and  $PhCH=NPh$  to give the corresponding 2-ethoxycarbonylaziridines (yields 15%–30%). It was found that diazoacetates reacted *cis*-diastereoselectively to give predominantly *cis*-**13**, if Lewis acids [e.g.,  $BF_3$ ,<sup>73–77</sup>  $AlCl_3$ ,<sup>73,76</sup>  $TiCl_4$ ,<sup>73,76</sup>  $SnCl_4$ ,<sup>74,76,78,79</sup>  $TiCl_2(OPr^i)_2$ ,<sup>77</sup>], salts  $[Cu(OTf)_2]$ ,<sup>77,80</sup> 1-butyl-3-methylimidazolium tetrafluoroborate,<sup>81</sup>  $Ln(OTf)_3$ ,<sup>82,83</sup>  $Yb(OTf)_3$ ,<sup>75,77,82</sup>  $Zn(OTf)_2$ ,<sup>77</sup>] and the metal complexes  $\{[Cu(PF_6)(MeCN)_4]$ ,<sup>84</sup>  $[(\eta^5-C_5H_5)Fe(CO)_2]$ .

Scheme 2

$\cdot(\text{THF})]^+[\text{BF}_4]^-$  (Ref. 85) and  $\text{W(II)}^{86}$  were used as catalysts. Cu(II) salts that represent catalysts for carbene reactions of diazo compounds, on the one hand, and Lewis acids, on the other hand, direct the reactions with imines along the non-carbene pathway. Chiral catalysts<sup>84, 87, 88</sup> and reaction conditions have been found that allow preparation of the corresponding aziridines with a high enantiomeric excess.<sup>87, 88</sup>

At the same time, one cannot assert, with a full degree of confidence, that in the presence of rhodium<sup>89–92</sup> and rhenium<sup>93–95</sup> derivatives as efficient catalysts for carbene reactions of diazoesters, those resulting in aziridinecarboxylates proceed through the carbene pathway. In some cases, where the carbene pathway was suggested, the reaction was *trans*-diastereoselective<sup>90, 93–95</sup> and was accompanied by the formation of fumarates and maleates as side products. This is considered as indirect evidence for the involvement of carbene (carbenoid) intermediates. Dirhodium acetate is especially popular,<sup>89, 92</sup> while other derivatives, *e.g.*,  $[\text{Rh(III)-K10-alumina}, \text{Rh/C}]$ , are used less frequently.<sup>90</sup>

The reaction of ethyl diazoacetate with imines catalysed by the mononuclear rhodium catalyst **20**,<sup>91</sup> results in aziridines **21** and **22**.

The reaction with *N*-benzylideneaniline ( $\text{R}^1 = \text{R}^2 = \text{Ph}$ ) proceeds stereoselectively with the predominant formation of the *cis*-isomer **21** (3 : 1). The diastereoselectivity and the product yields are comparable with those achieved<sup>84</sup> with the copper complex  $[\text{Cu}(\text{PF}_6)(\text{MeCN})_4]$  as a catalyst with addition of a chiral ligand (*S,S*)-2,2-bis(4-phenyl-2-oxazolin-2-yl)propane. As to the enantioselectivity, this is significantly lower (*ee* ≤ 11%) than that reported<sup>84</sup> (*ee* = 35%–44%). The substitution of other ligands in the chiral Rh-catalyst results in the disappearance of the catalytic activity. The yields of products for the reaction carried out in THF are higher than those in dichloromethane.

Aziridine **23** containing *cis*-aryl groups in positions 2 and 3 (see Ref. 92) is the reaction product of methyl diazophenylacetate with *N*-benzylideneanilines catalysed by  $\text{Rh}_2(\text{OAc})_4$ . This reaction occurs stereoselectively. It is believed that aziridine is formed as a result of cyclisation of the intermediate azomethine ylide.

$\text{R}^1 = \text{R}^2 = \text{H}$  (79%);  $\text{R}^1 = \text{NO}_2$ ,  $\text{R}^2 = \text{H}$  (64%);  
 $\text{R}^1 = \text{H}$ ,  $\text{R}^2 = \text{NO}_2$  (89%).

Unfortunately, in the majority of studies aimed at the synthesis of aziridine-2-carboxylates, the possibility of interconversion of aziridines of the type **13** and ylides of the type **14** under reaction conditions (especially upon heating), which might influence significantly the stereoselectivity, was not analysed. The same is true of studies devoted to the synthesis of [3 + 2]-cycloaddition products of azomethine ylides of the type **14** generated in catalytic reactions of diazo compounds with imines in the presence of dipolarophiles.

The porphyrin ruthenium complexes  $[\text{Ru}^{\text{II}}(\text{TDCPP})(\text{CO})]$

(0.1 mol.%) catalyse a three-component coupling of  $\alpha$ -diazo esters with *N*-benzylideneanilines and activated alkenes (or alkynes) resulting in the stereoselective formation of 2,5-*trans*-disubstituted pyrrolidines (**24**) or dihydropyrroles (**25**).<sup>96</sup>

Considering the fact that porphyrin ruthenium(II) complexes form ruthenium–carbene complexes with diazo compounds, Li *et al.* suggested<sup>96</sup> that this reaction occurs *via* azomethine ylides, which undergo 1,3-dipolar cycloaddition with activated alkenes. In the case of non-symmetrical activated alkenes as dipolarophiles, one of two possible regioisomers was isolated. An increase in the steric crowding at the nitrogen atom of the imine hinders the reaction: *e.g.*, *N*-benzylidene-3-chloroaniline yields the cycloadduct with a lower yield than *N*-benzylidene-4-chloroaniline, whereas *N*-benzylidene-2-chloroaniline does not react at all.

Copper(I) triflate catalyses the reactions of various α-diazo esters with imines and alkenes (or alkynes) in dichloromethane to yield polysubstituted pyrrolidines (or dihydropyrroles) **26** (see Ref. 97). This reaction is stereo- and regioselective. It is suggested that the reaction of copper(I) with a diazo compound yields a metalcarbenoid, which forms an azomethine ylide with the imine, the ‘carbenoid’ carbon being in the *cis*-position relative to the substituent R<sup>2</sup>. It is noteworthy that no isomerisation of the ylide takes place, since only 2,5-*trans*-adducts are formed.

Dirhodium acetate Rh<sub>2</sub>(OAc)<sub>4</sub> also catalyses this reaction, but the yield of the adduct of ethyl diazoacetate with dimethyl acetylenedicarboxylate (DMAD) and *N*-benzylideneaniline is lower than in the case of copper(I) triflate. Dichloromethane appeared to be the solvent of choice; in other solvents, the yields were lower and no reaction occurred in THF or DME. The effects of the substituents in *N*-benzylideneanilines on the yields of the corresponding adducts were studied in reactions of ethyl diazoacetate with dimethyl acetylenedicarboxylate and various *N*-benzylideneanilines. It was found that nitrophenyl-substituted imines do not react. It was assumed that THF or DME as the solvent and

the nitro group in the imine decrease the activity of the catalyst due to complex formation.

Diazostrylacetate (**27**) is an efficient reagent for the generation of azomethine ylides containing unsaturated fragments; their cyclisation affords dihydropyrroles or dihydroazepines with a high degree of stereocontrol and in high yields.<sup>98</sup> The reaction of diazostrylacetate with *N*-benzylidene-4-nitroaniline catalysed by Rh<sub>2</sub>(OAc)<sub>4</sub> yields dihydropyrrole derivatives predominantly as the *trans*-isomer, which can be attributed to the relative configurational stability of the ylides leading to particular stereoisomers (Scheme 3).

The catalytic reaction of the ester **27** with azadienes yields a mixture of dihydroazepine **28** and dihydropyrrole **29**. The presence of a methyl group in position 3 of the azadiene strongly affects the dihydroazepine : dihydropyrrole ratio. It is assumed that the introduction of a methyl group decreases the stability of

ylide **30** in comparison with ylide **31** resulting in the exclusive formation of dihydroazepine.

| H  | C <sub>6</sub> H <sub>4</sub> NO <sub>2</sub> -4 | 78                                 | 68 : 32                        |
| Me | C <sub>6</sub> H <sub>4</sub> NO <sub>2</sub> -4 | 73                                 | 100 : 0                        |

The reactions of alkenyl-substituted diazo compounds **32** with imines **33** (Scheme 4) in the presence of various catalysts including Rh<sub>2</sub>(OAc)<sub>4</sub>, CuPF<sub>6</sub>, CuOTf and Cu(OTf)<sub>2</sub> have been studied.<sup>99</sup> It was found that the reaction of diazostyrylacetate (**32**, R = Ph)

with *N*-cinnamylidene-4-nitroaniline (**33a**, Ar = Ph) catalysed by dirhodium(II) acetate yields the corresponding dihydropyrrole **34**, whereas a similar reaction catalysed by copper salts with copper(II) triflate as the catalyst of choice affords dihydropyrrole **35**. This dependence of the reaction route on the catalyst was demonstrated for a broad range of compounds (Table 3). The results obtained prompted a conclusion that dihydropyrrole **34** is formed from ylide **A** derived upon addition of the imine **33** to the metallocarbenoid, whereas dihydropyrrole **35** is formed from the intermediate **B** resulting from electrophilic addition of the activated imine **33** to the diazo compound **32**.

The reaction of *N*-methylbenzylideneamine with dimethyl diazomalonate catalysed by Rh<sub>2</sub>(OAc)<sub>4</sub> in the presence of *N*-phenylmaleimide yielded 1,3-dipolar cycloaddition products.<sup>100</sup>

Metallocarbenoids obtained from diazo compounds reacted with heterocyclic compounds containing C=N bonds to give iminium ylides; the 1,3-dipolar cycloaddition of the latter to fumarates or DMAD is a convenient approach to the synthesis of fused heterocyclic compounds. Some examples of these reactions are given below.<sup>101, 102</sup>

**Table 3.** Ratios and yields of catalytic reaction products of diazo compounds **32** with imines **33**.

| R                  | Ar                                              | Reaction catalysed by Rh <sub>2</sub> (OAc) <sub>4</sub> |                                             | Reaction catalysed by Cu(OTf) <sub>2</sub> |                                             |

| Me                 | Ph                                              | 42                                                       | 90 : 10                                     | 0                                          |                                             |
| CO <sub>2</sub> Me | Ph                                              | 51                                                       | 93 : 7                                      | 0                                          |                                             |

*N*-Ylides generated as a result of an intramolecular attack of a metalcarbenoid on the unshared electron pair of the nitrogen atom of the *N*-alkoxyimino group either yield 1,3-dipolar cycloaddition products with dipolarophiles<sup>103</sup> or undergo cyclisation to the corresponding aziridines.<sup>104</sup>

The decomposition of phenyldiazomethane in the presence of imines results in azomethine ylides which undergo conrotatory cyclisation to give *cis*-aziridines in low yields. This cyclisation competes with the 1,3-cycloaddition of the ylide ( $R^1 = H$ ,  $R^2 = Me, Et$ ; CuBr as the catalyst) to the imine, which results in the corresponding imidazolidine.<sup>105</sup>

$R^1 = H, Me$ ;  $R^2 = Me, Et, Pr^i, Bu^t$ .

## IV. Ylides from halogeno carbenes

### 1. Ylides from alkyl- and aryl(chloro)carbenes

#### a. 1,3-Dipolar cycloaddition

Photolysis or thermolysis of aryl chlorodiazirines in the presence of pyridine is a method for the generation of chloro-substituted pyridinium ylides **36**. Earlier studies have demonstrated the possibility of using these non-stabilised intermediates in the synthesis of indolizines by 1,3-dipolar cycloaddition to dimethyl acetylenedicarboxylate<sup>16</sup> and  $\alpha$ -chloroacrylonitrile.<sup>37</sup> The absolute rate constants for these reactions have recently been determined. Thus the rate constant for the reaction of dimethyl acetylenedicarboxylate with the ylide **36** (Ar = Ph) is equal to  $(1.57 \pm 0.06) \times 10^6$  litre mol<sup>-1</sup> s<sup>-1</sup> (see Refs 16 and 66).  $\alpha$ -Chloroacrylonitrile reacts with ylides **36** regioselectively; the absolute rate constants for various Ar are equal to  $(1.88 \pm 0.03) \times 10^7$  (Ar = 4-MeOC<sub>6</sub>H<sub>4</sub>),  $(1.46 \pm 0.04) \times 10^7$  (Ar = 4-MeC<sub>6</sub>H<sub>4</sub>),  $(7.7 \pm 0.4) \times 10^6$  (Ar = Ph) and  $(2.3 \pm 0.1) \times 10^5$  litre mol<sup>-1</sup> s<sup>-1</sup> (Ar = 4-NO<sub>2</sub>C<sub>6</sub>H<sub>4</sub>).

These results suggest that ylides behave as nucleophiles in the 1,3-dipolar addition.<sup>37</sup> The ylide prepared from 1-naphthylcarbene and pyridine undergoes cycloaddition to dimethyl fumarate [the rate constant for this reaction is equal to  $(5.3 \pm 1.0) \times 10^5$  litre mol<sup>-1</sup> s<sup>-1</sup>].<sup>8</sup> The rate constants for the ylide formed from chloro (methyl)carbene and pyridine with acrylonitrile or  $\alpha$ -chloroacrylonitrile are equal to  $(2.06 \pm 0.02) \times 10^7$  and  $(1.60 \pm 0.15) \times 10^8$  litre mol<sup>-1</sup> s<sup>-1</sup>, respectively.<sup>21</sup>

#### b. 1,5-Cyclisation

A multistep reaction of aryl(chloro)carbenes with 2-alkenylpyridines **37** and diazines, which involves ylide formation, 1,5-cyclisation and dehydrochlorination, is an alternative approach to the synthesis of indolizines and their hetero analogues.<sup>68,106</sup> Kinetic studies have shown that 1,5-cyclisation under conditions of vacuum flash photolysis of aryl(chloro)diazirines in isooctane in the presence of 2-vinylpyridine (**37**, R<sup>2</sup> = H) is characterised by

R<sup>1</sup> = Ar, Bn; R<sup>2</sup> = H, Ar, 2-pyridyl.

a noticeable activation barrier ( $E_a \approx 50$  kcal mol<sup>-1</sup>), which suggests that the transition state is somewhat compressed.<sup>107</sup> A phenyl substituent on the double bond favours the cyclisation by lowering this barrier to 33–37 kcal mol<sup>-1</sup>. Presumably, the dehydrochlorination step is fast, since in none of the cases studied were the primary cyclisation products (*viz.*, the corresponding dihydro-indolizines) detected even in trace amounts.

It was shown that the addition of chloro(phenyl)carbene derived upon photolysis of 3-chloro-3-phenyldiazirine to 1-(2-pyridyl)-2-(4-pyridyl)ethylene (**37**, R<sup>2</sup> = 4-pyridyl) is directed to the nitrogen atom of the *para*-, rather than the *ortho*-substituted pyridine ring.<sup>68</sup> No target indolizine could be obtained from this substrate. However, ylides generated from 4-vinyl- and 4-styrylpyrimidines where both reactive nitrogen atoms are localised in the same ring, do undergo 1,5-cyclisation resulting in pyrrolo[1,2-*c*]pyrimidines **38**.<sup>108</sup>

Ylides generated from azadienes **39** and aryl(chloro)carbenes represent acyclic analogues of 2-alkenylpyridinium ylides. These intermediates undergo cyclisation to give 1,2,3-trisubstituted pyrroles in yields exceeding those of the corresponding indolizines in an analogous reaction of pyridines.<sup>68,109</sup> The activation parameters of the 1,5-cyclisation of the 'azadiene' ylides are as follows:  $E_a = 47.0$ – $51.5$  kJ mol<sup>-1</sup>,  $\log A = 12.1$ – $12.9$ .

This reaction occurs smoothly both upon thermolysis in boiling benzene and in the photolysis in hexane and affords pyrroles in comparable yields. This method can also be used for the preparation of 2-heteryl-substituted pyrroles starting from (chloro)-2-pyridyl- and -2-thienylcarbenes, but in this case the yields of the reaction products do not exceed 15%.<sup>110</sup>

The azo compound **40** contains two sites reactive with respect to aryl(chloro)carbene, however, only one of the two ylides formed affords pyrazole as a result of 1,5-cyclisation. Indeed, thermolysis of some aryl(chloro)diazirines in the presence of the azo compound **40** yields the ylide intermediate **A**; cyclisation of the latter and subsequent elimination of HCl afford the tetraaryl-substituted pyrazoles **41** in high yields.<sup>108</sup>

## 2. Ylides from dichlorocarbene

### a. Azomethine ylides from dichlorocarbene

Dichloro-substituted azomethine ylides formed upon reaction of azomethines with dichlorocarbene undergo three types of conversions: (1) 1,3-cyclisation, (2) 1,3-dipolar cycloaddition to dipolarophiles and (3) 1,4-H-shift. Which particular 'stabilisation' pathway occurs depends on the structure of the ylide which, in turn, depends on the structure of the starting imine.

**1,3-Cyclisation.** The analysis of the dependence of the chemical behaviour of *gem*-dichloro-substituted ylides on their geometry calculated by the MNDO method has demonstrated that cyclisation to *gem*-dichloroaziridines is more typical of ylides in which the dichloromethylene fragment is turned appreciably relative to the C=N=C plane (the angle  $\theta_1$  is equal to 34–50°). This type of ylide comprises intermediates generated upon reactions of dichlorocarbene with benzophenone *N*-alkylimines and benzaldehyde *N*-aryl- and *N*-alkylimines (the latter should contain secondary or tertiary alkyl substituents at the nitrogen atom). Reactions of *N*-arylbenzylideneamines with dichlorocarbene have long been known as a convenient method for the synthesis of aziridines;<sup>2, 111, 112</sup> however, experimental evidence in favour of the ylide mechanism of this conversion was obtained as late as 1993.<sup>113</sup>

Substitution of the primary alkyl substituent at the nitrogen atom for an aryl substituent results in resinification of reaction mixtures (no aziridines could be obtained from such imines).<sup>114</sup> Sterically more crowded imines **42** containing an isopropyl, a cyclohexyl or a *tert*-butyl group on the nitrogen atom yield the desired aziridines **43** with dichlorocarbene generated upon treatment of chloroform with an alkali.<sup>114</sup> These are easily hydrolysed to the corresponding amides **44** (16%–95%) during column chromatography on silica gel. Nevertheless, some aziridines can be isolated in an analytically pure state in up to 80% yields.

R = Pr<sup>i</sup>, Bu<sup>t</sup>, cyclo-C<sub>6</sub>H<sub>11</sub>.

Much more stable aziridines were prepared from benzophenone *N*-alkylimines. Thus *N*-benzhydrylidene-*N*-benzylamine reacts with dichlorocarbene to give *gem*-dichloroaziridine **45** in 72% yield.<sup>115</sup>

Aziridination of *N*-benzhydrylideneamino acid derivatives<sup>114, 115</sup> yields functionalised aziridines, which represent valuable building blocks for the synthesis of multifunctional amino acids, certain heteropolycyclic systems<sup>116</sup> and functionalised ketene imines, and is preparatively the most efficient among other reactions of benzophenone imines.<sup>117</sup> It has been found<sup>115</sup> that the nature of the transformation products of benzhydrylidene derivatives of glycine esters, alanine esters and related systems

depends significantly on the method used for the generation of dichlorocarbene. The reaction of dichlorocarbene generated in a KOH–CHCl<sub>3</sub>–Et<sub>3</sub>N<sup>+</sup>CH<sub>2</sub>Ph Cl<sup>–</sup> (TEBA) system with imines **46** was used for the preparation of *gem*-dichloroaziridines **47**.

R<sup>1</sup> = Me, Et, Bn, CH<sub>2</sub>=CHCH<sub>2</sub>; R<sup>2</sup> = Me, Et.

Benzophenone imines **48** and **49** yield the corresponding aziridines **50** and **51** under identical conditions.

In contrast to the alanine derivatives **46**, **48** and **49**, the glycine derivatives **52** do not yield *gem*-dichloroaziridines with dichlorocarbene generated from chloroform upon alkaline treatment. Presumably, compounds **52** manifesting higher CH-acidity undergo deprotonation under the action of KOH, which changes the direction of the reaction. However, the use of a 'neutral' method of decomposition of sodium trichloroacetate for the thermocatalytic generation of dichlorocarbenes affords the desired *gem*-dichloroaziridines **53**.

R = Me, Et.

This method is also suitable for the synthesis of aziridines from sterically more crowded imines **54**; however, azetidinone **55** is formed as a side product; the relative yield of azetidinone increases with an increase in the steric volume of the substituents at the C=N bond. Studies using labelled compounds have shown that azetidine derivatives are formed through a non-carbene pathway.<sup>118</sup>

R<sup>1</sup> = H, R<sup>2</sup> = Alk, R<sup>3</sup> = CO<sub>2</sub>Me; R<sup>1</sup>–R<sup>2</sup> = CH<sub>2</sub>CH<sub>2</sub>, R<sup>3</sup> = CN.

Reactions of dichlorocarbene with substrates containing an endocyclic C=N bond have found applications in the synthesis of fused aziridine compounds. Thus benzoxazines **56** and substituted 3,4-dihydroisoquinolines **57** yield aziridinobenzoxazines **58**.<sup>119</sup>

and aziridinoisoquinolines **59**, respectively, upon reaction with dichlorocarbene.<sup>114</sup>

$\text{R}^1 = \text{H, Alk, Ar}$ ;  $\text{R}^2 = \text{H, Alk}$ ;  $\text{R}_2^2 = (\text{CH}_2)_n$  ( $n = 4, 5$ );  $\text{R}^3 = \text{H, OMe}$ .

Approaches to the cleavage of either of the non-equivalent bonds in the aziridine ring in 1,1-dichloro-1,3,4,8b-tetrahydroazirino[2,1-*a*]isoquinolines (**59**) have been developed.<sup>120</sup> This opens a convenient way to the synthesis of substituted 3-benzazepin-2-ones (**60**), *N*-formyltetrahydroisoquinolines **61** as well as isoquinoline-1-carboxylic acid derivatives, *viz.*, esters **62**, amides **63** and cyclic amidines **64** of the imidazole and pyrimidine series.

It should be noted that 1,3-cyclisation of the aforementioned chlorinated azomethine ylides occurs at a rather fast rate, since the addition of dipolarophilic reagents containing activated double bonds to the reaction mixtures does not change the direction of the reaction with the carbene.

**Cycloaddition.** *gem*-Dichloro-substituted azomethine ylides with the dichloromethylene fragment slightly deviated from the  $\text{Cl}_2\text{C}-\text{N}=\text{C}$  plane [the dihedral angle ( $\theta$ ) between the  $\text{Cl}_2\text{C}-\text{N}=\text{C}$  and  $\text{Cl}_2\text{C}$  planes is equal to  $0-30^\circ$ ] are not prone to yield 1,3-cyclisation products. Intermediates having such geometry are formed in reactions of dichlorocarbene with benzaldehyde *N*-alkylimines only if  $\text{R} = \text{n-Alk}$ . The cycloaddition to the electron-deficient  $\text{C}=\text{C}$  bond is the most characteristic reaction of these azomethine ylides; this can be used as a convenient method for the synthesis of some pyrrolidine and pyridine derivatives.

Thus *N*-alkylimines yield the corresponding 2-chlorodihydropyrroles **65** in reactions with dichlorocarbene generated from trichloroacetate or under alkaline phase-transfer conditions and maleates or fumarates.<sup>114</sup> These compounds are hydrolysed to lactams **66** and **67** upon isolation by column chromatography on silica gel (the yields of the isomers vary from 27% to 66%).

$\text{R} = \text{Me, Et, Bn}$ .

Pyridone **68** was prepared in 32% yield from *N*-benzylidene-*N*-methylamine using an excess of the source of dichlorocarbene.

Fused cyclic compounds **71** and **72** containing a tetrahydropyrrole fragment can be prepared in this way from cyclic analogues of benzaldehyde *N*-alkylimines, *viz.*, dihydropyrrole **69** and 3,4-dihydroisoquinolines **70**.<sup>114</sup>

$\text{R} = \text{H, Me}$ .

**1,4-H-Shift.** Chlorinated ylides generated from imines of aliphatic ketones manifest specific chemical behaviour. It has been found<sup>121</sup> that the reaction of dichlorocarbene generated by decomposition of sodium trichloroacetate with ketone anils **73** yields predominantly enamides **74**, while the corresponding *gem*-dichlorocyclopropanes **75** (35%–42%) are formed when an

excess of the source of the carbene is used. Cyclopropanes **75** are prepared in good yields by a reaction of dichlorocarbene with isolated enamides **74** (56%–83%).<sup>121</sup>

$R^1 = \text{Me, Et, cyclo-C}_3\text{H}_5$ ;  $R^2 = \text{H, Me}$ .

Studies of reactions with deuterated compounds corroborated the formation of enamides **74** *via* ylides **76** with a subsequent intramolecular 1,4-H-shift with a six-electron transition state rather than by a reaction of carbene with an enamine tautomer of imine.

#### b. Azinium and diazinium ylides from dichlorocarbene

Ylides generated by a reaction of dichlorocarbene with azines, diazines and their benzoannulated derivatives are convenient synthons for the chloro-substituted indolizines and their heteroatomic and benzoannulated analogues. Two different approaches to the formation of the indolizine system on the basis of azinium ylides **77** are known (Scheme 5).

One of them represents a domino reaction that includes intermolecular cycloaddition of dichloroylide to an alkene-type or an alkyne-type dipolarophile. For example, the generation of dichlorocarbene using the alkaline or the trichloroacetate method in the presence of pyridines and dimethyl maleate results in unstable tetrahydroindolizines **78**, which are converted into substituted indolizines **79** (28%–90%) upon treatment with mild oxidants (see Scheme 5).<sup>122</sup> The intermediate tetrahydroindolizine **78** could be identified by its adduct with benzonitrile oxide (the adduct **80**).<sup>123</sup>

A series of substituted indolizines have been synthesised by the reaction of 4-picoline with dichlorocarbene in the presence of various electron-deficient unsaturated compounds.<sup>123</sup> Indolizine **81** can be prepared from 4-picoline using methyl phenylpropiolate or methyl cinnamate (in the latter case, the product yields are significantly lower).

As a rule, the reactions of 3-substituted pyridines **82** yield both regioisomeric indolizines **83** and **84** with the predominance of the isomer **83** [(2–2.5):1].

No indolizines are obtained in the reactions of 2-substituted pyridines with dichlorocarbene in the presence of dimethyl maleate.<sup>123</sup>

The above-described approach can be used in the synthesis of chlorinated aza-analogues of indolizines, *e.g.*, pyrrolo[1,2-*b*]pyridazines, pyrrolo[1,2-*c*]- and pyrrolo[1,2-*a*]pyrimidines.<sup>124</sup>

The chemical behaviour of benzoannulated analogues of azines and diazines in the above reaction has a number of specific features. Quinoline reacts slowly with dichlorocarbene in the presence of dimethyl maleate to give substituted pyrrolo[1,2-*a*]quinoline **85** in very low yield (~5%); 8-methylquinoline reacts even more slowly. The reaction of 1,8-naphthyridine with dichlorocarbene and dimethyl maleate gave pyrrolo[1,2-*a*]naphthyridine **86** (11%). Isoquinoline is more reactive than quinoline with respect to dichlorocarbene. Besides, it produces only one of two possible structural isomers. Interestingly, in this case the use of dimethyl maleate as a dipolarophile has made it possible to isolate the intermediate chlorodihydropyrrole derivative **87** (30%), the dehydrohalogenation product of the primary cycloadduct, compound **87**, was converted into pyrroloisoquinoline **88** (80%) under the action of oxidants.

X = CH (85), N (86).

The syntheses of chloro-substituted pyrrolo[2,1-*a*]phthalazine, pyrrolo[1,2-*c*]quinazoline, pyrrolo[1,2-*a*]quinoxaline and pyrrolonaphthridine systems based on analogous reactions of phthalazines, quinoxalines, quinoxalines<sup>124, 125</sup> and benzo[*h*]naphthridines with dichlorocarbene have been described.<sup>126</sup>

On the whole, intermolecular cycloaddition reactions of dichloro-substituted azinium and diazinium ylides occur regioselectively with respect to both the non-symmetrical ylide and the non-symmetrical dipolarophile. The calculation of ylides formed in reactions of pyridine, 3- and 4-substituted pyridines and isoquinoline with dichlorocarbene by the MNDO method revealed that these molecules are planar. At the same time, the plane of CCl<sub>2</sub> in ylides based on 2-substituted pyridines and quinoline is turned relative to the plane of the pyridine ring (26–34°). The data obtained suggest that non-planar ylides are less stable and their formation is energetically less favourable. Considering that concerted processes are sensitive to the spatial characteristics of the reactants, it can be assumed that the inertness of 2-substituted pyridines and low degree of conversion of quinolines in this reaction are due to the fact that the presence of *ortho*- and *peri*-substituents in the azine makes the corresponding ylide non-planar.

An alternative approach to the synthesis of chloro-substituted indolizine and related systems is based on the 1,5-cyclisation of the azinium dichloroylide **89** containing an unsaturated substituent in the *ortho*-position. 3-Chloro-substituted indolizines **90** can be prepared from compound **37** under conditions of generation of dichlorocarbene.<sup>127, 128</sup>

R = H, Ar, CO<sub>2</sub>Et.

The reaction of dichlorocarbene with 2-(arylideneamino)pyridines **91** does not affect the azomethine bond C=N, but includes an attack of carbene at the nitrogen atom of pyridine, which yields pyridinium ylide **92** and makes this reaction suitable for the

synthesis of 3-chloroimidazo[1,2-*a*]pyridines **93**.<sup>129</sup> If the aryl group in compound **91** contains no electron-withdrawing substituents, the synthetic chain can be elongated owing to the addition of carbene to the C=C bond of the imidazole ring of compound **93** with the subsequent ring expansion and the formation of chloro-substituted pyridopyrimidones **94**.

Chloro-substituted heterocycles formed as a result of above-described conversions of azinium ylides are valuable intermediates for organic synthesis. Their synthetic potential has increased considerably after the discovery of a simple and efficient method for the amination of the chloropyrrole fragment,<sup>124</sup> which opens an access to 3-aminopyrrolo[1,2-*a*]azine-1,2-dicarboxylates **95**, which represent convenient building blocks for the synthesis of miscellaneous fused heterocyclic systems.

X = CH, N.

### c. Azolium ylides from dichlorocarbene

Benzazoles afford 2,2'-bis(benzazoly)ls under conditions of generation of dichlorocarbene from CHCl<sub>3</sub> and NaOH in the presence of TEBA.<sup>130</sup> Although the reaction products do not contain fragments that might be generated from carbene, it was assumed that the putative mechanism involves the intermediate formation of benzazolium ylides. This mechanism was later confirmed by performing a reaction of dichlorocarbene with benzoxazole or benzothiazole in the presence of dimethyl acetylenedicarboxylate.<sup>131</sup> This reaction occurs through cycloaddition

X = O (a), S (b).

of benzazolium ylide to the triple bond of the dipolarophile with subsequent elimination of HCl, and can be employed for the preparation of pyrrolo[2,1-*b*]benzoxazoles (**96a**) and pyrrolo[2,1-*b*]benzothiazoles (**96b**).

#### d. Ketene imine ylides from dichlorocarbene

Calculations suggest that ketene imine ylides (alkylidene azomethine ylides) formed upon reaction of dichlorocarbene with ketene imines represent azomethine ylides with reversed polarity.<sup>4</sup> This difference in the electronic structure is manifested in different chemical behaviour of ketene imine ylides and ylides generated from azomethines, azines and azoles and, as a consequence, in significant changes in the array of products that might be synthesised therefrom.

The result of the reaction of ketene imines with dihalocarbenes depends on the method used for the generation of the carbene, since its choice determines the presence or the absence of other reagents in the reaction mixture (*e.g.*, water, trichloromethyl anion, *etc.*). For example, the reaction of triphenylketene imine with dichlorocarbene generated upon thermocatalytic degradation of sodium trichloroacetate in the presence of TEBA yields three main products, *viz.*, compounds **97–99** (Scheme 6). Rational choice of reaction conditions (method for the generation of carbene, phase-transfer catalysts, *etc.*) allows direction of the reaction towards the formation of one of these products.<sup>132</sup> Thus trichloroacetamide **98** is predominantly formed upon addition of an equimolar amount of sodium trichloroacetate, while the use of an excess of trichloroacetate yields dichloroacetamide **99**. Carbamoyl chlorides **97** are the main products if dichlorocarbene is generated from  $\text{CHCl}_3$  and  $\text{Bu}^t\text{OK}$  or if the phase-transfer procedure is used.<sup>133, 134</sup>

| Conditions                                     | Product yield (%) |    |    |
|------------------------------------------------|-------------------|----|----|
|                                                | 97                | 98 | 99 |
| $\text{Cl}_3\text{CCO}_2\text{Na}$ , TEBA      | 8                 | 57 | 9  |
| $\text{Cl}_3\text{CCO}_2\text{Na}$ (excess)    | —                 | 4  | 43 |
| $\text{CHCl}_3$ , KOH, TEBA                    | 58                | —  | 10 |
| $\text{CHCl}_3$ , $\text{Bu}^t\text{OK}$       | 45                | —  | —  |
| $\text{CHCl}_3$ , KOH, $\text{Me}_4\text{NBr}$ | 78                | —  | 2  |

A convenient one-step procedure for the synthesis of *N*-(2,2-dichlorovinyl)carbamoyl chlorides **100** from the simplest compounds, *viz.*, primary amines and chloroform, has been developed.<sup>135</sup> The conversion of an amine into a carbamoyl chloride is an example of an unusual iterative tandem reaction successively occurring *via* isocyanide, ketene imine and ketene imine ylide, it is noteworthy that three molecules of dichlorocarbene take part in the construction of dichlorovinylcarbamoyl chloride **100**. Thus, this reaction demonstrates the feasibility of ‘one-pot’ assembly of the carbon skeleton from dihalogeno carbene.

A three-step synthesis of *N*-alkynylcarbamoyl chlorides **101** from benzyldeneamines is yet another example of the successful application of dihalogeno carbene as a building block for the elongation of the carbon skeleton.<sup>136</sup> The reaction of *C*-halogeno ketene imine with dichlorocarbene generated upon thermolysis of sodium trichloroacetate in the presence of TEBA yields a trihalogeno-substituted ketene imine ylide and is the final step of this synthetic sequence. The unusual stabilisation of the latter and the formation of a triple carbon–carbon bond result in terminal *N*-alkynylcarbamoyl chlorides **101** as the final products.

$\text{R} = \text{Ar}, \text{Bu}^t; \text{X} = \text{Cl}, \text{Br}.$

The carbamoyl chlorides with unsaturated substituents on the nitrogen atom thus prepared are valuable intermediates in the synthesis of various derivatives of carbamic acid (*e.g.*, ureas **102**,<sup>133</sup> carbamates **103**<sup>132, 133, 137</sup>) and heterocycles (*e.g.*, isoquinolinone **104**<sup>134</sup>).

$\text{R}^1, \text{R}^2, \text{R}^3, \text{R}^4 = \text{Alk}, \text{Ar}.$

Carbamates can be prepared from the corresponding ketene imines without isolation of carbamoyl chloride.<sup>132, 133, 137</sup>

Dichlorovinyl-substituted carbamoyl chloride **100** was used for the preparation of various heterocyclic systems.<sup>138</sup> In these syntheses, compounds **100** can be regarded as synthetic equivalents of the bielectrophilic synthons  $O=C^+N(R)C^+(H)CHCl_2$ .

Cycloaddition of ketene imine ylides to electron-deficient alkenes<sup>131, 139</sup> and alkynes<sup>131, 139, 140</sup> occurs rather smoothly and can be used as a convenient method for the preparation of some pyrrole and pyridine derivatives.

The relative yields of the reaction products, *viz.* pyrrole (**105**) and 2-pyridone (**106**), in the last-mentioned reaction can be changed by varying the ketene imine:dipolarophile ratio. Thus the use of a twofold excess of dimethyl fumarate has made it possible to obtain pyrrole (**105**) and pyridin-2-one (**106**) in 21% and 28% yields, whereas the use of a 20-fold excess afforded these compounds in 34% and 5% yields, respectively.

### 3. Ylides from chlorofluorocarbene

Iminiochlorofluoromethanides, *i.e.*, the intermediates in the addition of chlorofluorocarbene to the unshared electron pair of the nitrogen atom, have been studied less thoroughly. The data available suggest that the substitution of one fluorine atom for chlorine in dichloroazomethine ylides does not exert any noticeable changes in the properties of the intermediate ylides. Thus chlorofluorocarbene generated upon alkaline treatment of dichlorofluoromethane in the presence of TEBA is added to benzylideneaniline to give the corresponding *gem*-chlorofluoroazomethine ylide, which is easily cyclised to chlorofluoroaziridine **107**.<sup>141, 142</sup> Ethyl *N*-benzhydrylidene alaninate reacts similarly with chlorofluorocarbene to give aziridine **108** in 79% yield.<sup>115</sup>

Aziridine can also be prepared from the less nucleophilic imine **109**; however, in this case more drastic conditions should be used for the generation of fluorochlorocarbene, *i.e.*, thermolysis of (dichlorofluoromethyl)phenylmercury.<sup>143</sup>

The reactions of chlorofluorocarbene with ketene imines, which proceed *via* the intermediate ketene imine ylides **110** (chlorofluorocarbene was prepared from  $CH_2Cl_2$  and  $Bu^4OK$ ), are related to synthetically valuable reactions. The yields of carbamoyl fluorides **111** formed upon hydrolysis of ylides **110** are usually high, which makes these compounds, along with the above-mentioned carbamoyl chlorides, attractive for the synthesis of carbamic acid derivatives and various polynitrogenous heterocycles.<sup>144</sup>

### 4. Ylides from difluorocarbene

#### a. Acyclic azomethine ylides from difluorocarbene

It is known that difluorocarbene is much less reactive than dichloro- and chlorofluorocarbenes.<sup>145</sup> Nevertheless, it is reactive enough for the addition to benzaldehyde and benzophenone *N*-alkyl- and *N*-arylimines to give the corresponding difluoromethylides. The presence of two highly electronegative fluorine atoms at the ylide carbon atom is the reason for the significant changes in the chemical properties of these intermediates in comparison with dichloro- and chlorofluoro-substituted analogues. The dependence of the reactivities of iminodihalogeno methanides on the nature of the halogen atoms is especially noticeable in the conversions of ylides generated from the corresponding dihalogeno carbenes and benzhydrylidene derivatives of amino acids (Scheme 7).<sup>146, 147</sup>

Scheme 7

Dichloro- and chlorofluoro-substituted ylides **112** undergo cyclisation into aziridines **113** irrespective of the substituent R; the direction of the reaction does not change even in the presence of a 'dipole trap' (a dipolarophile). This conversion route is not characteristic of the difluoroylide from ethyl *N*-benzhydrylidene-glycinate, which undergoes ylide–ylide isomerisation in the absence of a dipolarophile with subsequent cyclisation to aziridine **114**, whereas in the presence of dimethyl maleate it undergoes cycloaddition reaction to give pyrrolidinone **115** after hydrolysis.

According to quantum-chemical calculations (B3LYP/6-31G\*), the presence of two geminal fluorine atoms in the ylide influences its geometry significantly, which changes from nearly planar (*i.e.*, characteristic of classical iminium ylides) to pyramidal (characteristic of ammonium ylides) on going from dichloro-substituted to difluoro-substituted ylides (Table 4). These results are consistent with the experimental results and *ab initio* calculations, which suggest that the presence of fluorine atoms brings about pyramidalisation of the radical centre.<sup>148</sup>

For this reason, difluoroylides do not cyclise to aziridines irrespective of their structures, while 1,3-dipolar cycloaddition reactions to multiple bonds, which will be considered below, are the main pathways of their conversions.

**Table 4.** The sum of angles  $\varphi_1 + \varphi_2 + \varphi_3$  and bond lengths in ylides A–C calculated by the B3LYP/6-31G\* method.

| Parameters                                       | A    | B    | C    |
|--------------------------------------------------|------|------|------|
| $\varphi_1 + \varphi_2 + \varphi_3 / \text{deg}$ | 349  | 339  | 328  |
| C(2)–N(1) / Å                                    | 1.35 | 1.36 | 1.39 |
| N(1)=C(3) / Å                                    | 1.33 | 1.33 | 1.32 |

**Addition of iminodifluoromethanides to the C=C bond.** Ylides **116** prepared by the reaction of difluorocarbene generated upon reduction of dibromodifluoromethane by lead in the presence of tetrabutylammonium bromide with benzaldehyde or benzophenone *N*-alkylimines add easily to electron-deficient alkenes, such as maleic acid esters and imides and fumaric acid esters (Scheme 8).<sup>149–151</sup> Primary cycloadducts formed from ylides

Scheme 8

R<sup>1</sup> = H, Ph; R<sup>2</sup> = Bn, CH<sub>2</sub>CO<sub>2</sub>Me, CH<sub>2</sub>SiMe<sub>3</sub>.

**116**, viz., pyrrolidines **117**, and their dehydrofluorination products, viz., dihydropyrroles **118**, are unstable and can only be detected by GC/MS. Only their hydrolytic products, viz., diastereomeric pyrrolidinones **119**, could be isolated.

Cycloaddition of difluoroylides prepared from benzaldehyde imines and difluorocarbene to *cis*-alkenes, e.g., *N*-phenylmaleimide, occurs *endo*-stereoselectively and gives predominantly pyrrolidinones of the type **120**, whereas *trans*-alkenes largely generate products of the type **119a**.<sup>151</sup> It should be noted that similar reactions with dichlorocarbene afford exclusively adducts of the type **119b**.<sup>114</sup>

$R^1 = \text{H, Ph; } R^2, R^3 = \text{Alk, Ar.}$

Fluorodihydropyrroles **121** prepared from benzophenone imines using fumaronitrile or dimethyl maleate as dipolarophiles are more stable and can be isolated in 63%–84% yields.<sup>152</sup>

$R^1 = \text{H, Bn, CO}_2\text{Me; } R^2 = \text{CN, CO}_2\text{Me.}$

This methodology is applicable not only to Schiff bases, but also to substrates containing an endocyclic C=N bond. In the latter case, the reaction products represent cyclic systems that can be *ortho*-fused with fluorodihydropyrrole.<sup>152</sup>

Ylides of the type **122** react easily even with alkenes containing one electron-withdrawing group; the cycloaddition may occur with either complete regioselectivity, as in the case of methyl methacrylate (where isomer **A** is formed in 77% yield), or formation of both regioisomers **A** (62%) and **B** (21%), as in the case of ethyl acrylate.<sup>149</sup>

$R^1 = \text{H, } R^2 = \text{Et; } R^1 = R^2 = \text{Me.}$

Intramolecular cycloaddition of difluoro-substituted ylides of the type **123** to the monoactivated multiple bond always gives only one regioisomeric difluoropyrrolidine **124**, which can be hydrolysed to the corresponding lactam **125**. In some cases, relatively stable fluorodihydropyrrole derivatives **126** can be isolated.<sup>153</sup>

$R = \text{Ph, Me, Bu}^t.$

Complete *cis*-stereoselectivity is a distinguishing feature of the synthesis of compounds of the type **125** by intramolecular cycloaddition of difluoro-substituted ylides **123** generated by the carbene method, which leads to the formation of systems with only *cis*-fused rings.<sup>†</sup> An explanation of such stereoselectivity is the specificity of the carbene method for the generation of azomethine ylides, which enables preparation of *Z*-configured dipoles, this configuration, in turn, being determined by the *E*-configuration of the starting imines.

This reaction was successfully used for the synthesis of the derivative **127** containing no alkoxy carbonyl group, from imine **128** containing a terminal double bond.<sup>153</sup>

**Addition of iminodifluoromethanides to the C≡C bond.** Addition of difluoroylides to dimethyl acetylenedicarboxylate can be employed in the synthesis of substituted 2-fluoropyrrole-3,4-dicarboxylates **129**.<sup>158, 159</sup>

<sup>†</sup> The intramolecular cycloaddition, to the C=C bond, of non-halogenated azomethine ylides generated by non-carbene methods leading to chromeno[4,3-*b*]pyrrole derivatives has been studied.<sup>154–157</sup>

$R^1 = \text{Ar}$ ,  $R^2 = \text{Ar}$ , furyl, alkenyl, alkynyl.

Stabilisation of the addition products, *viz.*, difluorodihydropyrrole **130**, results from abstraction of HF to give a stable aromatic pyrrole system. This method was successfully used for the synthesis of compounds **131** and **132** containing two fluoropyrrole rings and the formation of a fluoropyrrole fragment in a fused polycyclic system.<sup>159</sup>

The addition of difluoroylides to non-symmetrical acetylenes occurs with both complete regioselectivity, as in the case of ethyl propiolate and methyl tetrolate, and the formation of both regioisomers, as in the case of methyl phenylpropiolate.<sup>159</sup> All these reactions include exclusive or predominant formation of 5-fluoropyrrole-3-carboxylic acid derivatives. It should be noted that the yields of the products of difluoroylide cycloaddition to this kind of monoactivated acetylene are significantly lower than those on addition to the diactivated triple bond (*e.g.*, dimethyl acetylenedicarboxylate). Difluoroylides do not add to non-activated triple bonds (*e.g.*, phenylacetylene). The situation is different on going to systems containing simultaneously an ylide and an acetylenic fragment. Thus the intramolecular cycloaddition of ylide **133** to a non-activated triple bond yields chromenopyrroles **134** in preparative yields.

**Addition of iminodifluoromethanides to the C=O bond.** Studies of intermolecular cycloaddition of iminodifluoromethanides generated from imines and difluorocarbene to the C=O bonds of

various substrates have shown that these reactions usually give good yields only with aldehydes.<sup>160</sup> In this case, the process is characterised by complete regioselectivity and affords oxazolidin-4-one derivatives **135**, which represent hydrolysis products of the primary cycloadducts **136**. The stereoselectivity of the cycloaddition step is determined by the nature of the radical  $R^3$  in the aldehyde: acetaldehyde reacts non-stereoselectively, while aromatic aldehydes react with the predominant formation of the *trans*-product.

$R^1 = \text{H}$ , Ph;  $R^2 = \text{Bn}$ ,  $\text{CH}_2\text{CO}_2\text{Me}$ ,  $\text{CH}_2\text{SiMe}_3$ ;  $R^3 = \text{Alk}$ , Ar.

The reaction of ethyl *N*-benzhydrylidene glycinate with difluorocarbene in the presence of benzaldehyde yields, along with the expected cycloaddition product (oxazolidinone **137**), also aziridine **138**; it was assumed<sup>160</sup> that its formation includes a nucleophilic attack of the ylide on the carbon atom of the carbonyl group of benzaldehyde followed by a 1,5-H-shift and cyclisation (Scheme 9). This suggests a non-concerted cycloaddition mechanism of sterically crowded *C,C*-diphenyl-substituted *gem*-difluoroylides to strongly polarised multiple 'carbon–heteroatom' bonds containing a zwitter-ionic intermediate of the type **140**.

Scheme 9

Ketones are significantly less active in the reaction with difluoro-substituted iminium ylides than aldehydes. Thus an oxazolidinone of the type **135** ( $R^1 = \text{H}$ ,  $R^2 = \text{Bn}$ ,  $R^3 = \text{Me}$ ), the addition product of the intermediate ylide to acetone, was prepared in as low yield as 3%, whereas the carbonyl group of benzophenone is generally inactive with respect to difluoroylides.<sup>160</sup> The data on the chemoselectivity of the cycloaddition of difluoroylide **141** to the C=O and C≡C bonds of phenylpropionaldehyde and methyl phenylethynyl ketone<sup>159</sup> suggest a higher reactivity of the aldehyde C=O group than the mono-activated C≡C group in the 1,3-dipolar cycloaddition. Substitution of the ketone for the aldehyde causes changes in the reaction

centre: thus the  $C\equiv C$  bond in methyl phenylethynyl ketone becomes more reactive.

The data from competitive cycloaddition of ylide **141** to various substrates containing  $C=O$  and  $C\equiv C$  bonds allowed the arrangement of dipolarophiles as regards their activities with respect to iminodifluoromethanides (generated upon reactions of difluorocarbene with aromatic imines) in the following series: the  $C=O$  bond of ketones  $<$  the monoactivated  $C\equiv C$  bond  $<$  the  $C=O$  bond of aldehydes  $<$  the deactivated  $C\equiv C$  bond.<sup>159</sup>

The carbonyl groups of esters are non-reactive with respect to difluoro-substituted ylides. However, the ester carbonyl can be involved in intramolecular cycloaddition reactions with a difluoroylide fragment as a dipolarophilic component. Thus azomethine ylides generated upon reaction of difluorocarbene with *N*-arylimines of the *O*-acylated salicylaldehyde **142** undergo intramolecular 1,3-dipolar cycloaddition with the ester carbonyl group. This reaction is completely regioselective and yields the 2,5-epoxy-1,4-benzoxazepine derivatives **143**.<sup>161</sup> The direction of a cycloaddition reaction is not changed in the presence of an alkenyl fragment on the acyl group as a competitive dipolarophile. Moreover, it has been shown that the rate of the intramolecular cycloaddition to the  $C=O$  bond of ylide **144** is comparable to the rate of intermolecular cycloaddition to one of the most reactive dipolarophiles, *viz.*, dimethyl acetylenedicarboxylate.<sup>162</sup>

## b. Cyclic ylides from difluorocarbene

Various conversions of cyclic nitrogen ylides, in particular intermolecular 1,3-dipolar cycloadditions, underlie an approach to the synthesis of *ortho*-fused nitrogenous heterocycles. At present, only three-, six- and seven-membered cyclic systems containing an endocyclic  $C=N$  bond are known; ylides could be generated from these systems under conditions of generation of difluorocarbene.

The formation of strained azirinium ylides **145** upon reaction of 3-aryl-2*H*-azirines with difluorocarbene obtained by reduction of  $CF_2Br_2$  with active lead was confirmed by 1,3-dipolar cycloaddition to dimethyl acetylenedicarboxylate.<sup>163</sup> Difluoro-substituted dihydroazirino[1,2-*a*]pyrroles **146** were isolated as the reaction products. An important feature of these unusual bicyclic compounds is that they can undergo either ring expansion to give quantitative yields of 2-fluoro-substituted pyridines as valuable intermediates for the preparation of miscellaneous pyridine derivatives or transformations with the retention of the bicyclic skeleton, *e.g.*, with the formation of diaminodicarboxylic acid derivatives **147**.

The reaction of ylide **145** ( $Ar = Ph$ ) with benzaldehyde does not stop at the step of formation of the bicyclic derivative **148**. Presumably, in the course of the reaction, the opening of the aziridine ring takes place with the formation of 3-fluorooxazine derivative **149**, which is easily hydrolysed upon chromatographic isolation to yield lactam **150**.<sup>163</sup>

This approach does not allow preparation of the corresponding fused *gem*-difluorodihydropyrrole derivatives similar to compounds **146** starting from six- and seven-membered heterocycles containing a  $C=N$  bond. Nevertheless, reactions of these heterocyclic compounds with difluorocarbene in the presence of but-2-enoic and acetylenedicarboxylic acid derivatives can be used for the synthesis of polycyclic systems containing fluorodihydropyrrole and fluoropyrrole fragments, respectively.<sup>152</sup>

## V. Conclusion

Considerable progress has been achieved in the past decade in the chemistry of 1,3-dipoles and in the study of reactivities and synthetic applications of unstable iminium ylides in particular. The perfection of the methods for matrix isolation of reactive intermediates (LFP and FVT) has made it possible to expand considerably the range of unstable ylides detected by spectroscopic methods. Recently, only analysis of 1,3-dipolar cycloaddition products to dipolarophiles has been used as indirect evidence for their existence. This trend will undoubtedly be developed in the near future, predominantly with respect to azomethine ylides; their spectral, kinetic and thermodynamic characteristics are not documented anywhere.

The great diversity of products of domino reactions of carbenes and ylides points to the high potential of this approach for designing the synthesis and assembly of the skeletons of nitrogen-containing molecules. The intramolecular 1,3-dipolar cycloaddition reaction is one of the most interesting synthetic approaches to the synthesis of polycyclic nitrogen-containing compounds and a potent tool for the stereoselective construction of complex polycyclic and bridged systems. This methodology will certainly find application in the syntheses of natural compounds and their analogues. In this context, a search for novel types of iminium ylides containing different combinations of synthetically important structural fragments (*e.g.*, functional groups, small and chemically labile rings, *etc.*) is becoming a topical task. Their conversions will lead to intermediates with high synthetic potentials, which can undergo further selective chemical transformations.

This work has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-32735a) and the RF Ministry for Education and Science (Project No. E02-5.0-30).

**Abstract.** Data on the tautomerism of classical chelating ligands, *viz.*,  $\beta$ -diketones and nitrogen- and sulfur-containing analogues, are surveyed. The possibilities of the stabilisation of specific tautomers of these organic compounds due to coordination with metals are discussed. The bibliography includes 455 references.

## I. Introduction

Investigations into tautomerism<sup>1–6</sup> and complex formation<sup>1,7–10</sup> is an important direction of the research activity of the Rostov school of chemists headed by V I Minkin. Proto- and elementotropic tautomerism<sup>1–3,11</sup> was elucidated, the acylotropy phenomenon (*i.e.*, the intramolecular transfer of a COMe group)<sup>5,12</sup> was discovered, and stereochemically non-rigid structures in their ground and electronically excited states were studied<sup>13,14</sup> using  $\beta$ -diketones and functionalised aliphatic, aromatic or heterocyclic azomethines **1** as examples of typical chelating ligands.

R = H, Alk, Ar; X, Y = O, S; Z = H, COR', MR', MR'\_2, MR'\_3  
(R' = Alk, Ar; M = Hg, B, Ga, Tl, In, Si, Sn, Sb).

V I Minkin and co-workers<sup>7,8</sup> developed original methods for the synthesis of azomethine intracomplex compounds with metal-lacycles containing chalcogen atoms (S, Se), and undertook fundamental investigations into the stereochemistry, stereodynamics<sup>13,14</sup> and photochemistry<sup>15,16</sup> of the type **2** metal chelates.

X = O, S, Se; Y = NR'; M = Be, Cd, Hg, Pb, Co, Ni, Cu, Zn.

The above aspects served as a background for the development of an important direction in modern coordination chemistry, *viz.*, the coordination-dependent stabilisation of specific tautomeric forms of organic compounds.<sup>6</sup>

The present review surveys the state-of-the-art structural studies of free and coordinated tautomeric chelating ligand systems, which are of great importance for the chemistry of not only complex compounds but of organic and organometallic compounds as well.

## II. $\beta$ -Diketones and their coordination compounds

The problem of stabilisation of a specific tautomeric form of  $\beta$ -diketones upon complexation with metal ions was discussed for the first time by Kukushkin.<sup>17</sup> It is known that  $\beta$ -diketones exist in two tautomeric forms, *viz.*, ketoenol (**3a**) and diketone (**3b**) with the former predominating.<sup>2–5</sup>

R = Alk, Ar.

Coordination compounds of these chelating ligands are widely represented by intracomplex compounds  $ML_n$  ( $L^-$  is an anionic ligand). Contributions of specific tautomeric forms of the ligands to the solid-state or solution structures of such complexes cannot be estimated due to the equality of the intrachelate bonds M—O (from X-ray diffraction data<sup>18–24</sup>).

In those cases where  $\beta$ -diketones act as neutral proton-containing ligands (LH),<sup>19–30</sup> the ketone form **3b** is realised (for instance, in complex **4**). This has been proved using X-ray

<sup>†</sup> Dedicated to Academician Vladimir Minkin on the occasion of his 70th birthday.

diffraction studies with the objective localisation of all hydrogen atoms.<sup>18, 25, 26</sup>

An is a monocharged anion.

The same structure is typical of mono- (compounds **5**)<sup>18, 25, 26</sup> and polynuclear (compounds **6** and **7**)<sup>31, 32</sup> complexes as well as of compound **8**, in which two β-diketone fragments are differently bound to a metal atom.<sup>18</sup>

**5a:** M = Hg, X = Cl, OAc;  
**5b:** M = Au, X = Ph<sub>3</sub>P.

Unusual C,O-coordination of the β-diketone ligands was observed in complex **9**.<sup>33</sup>

The type **2** (X = Y = O), **4** and **5** β-diketone complexes can be prepared by both chemical (from metal salts)<sup>34, 35</sup> and electrochemical (from zero-valent metals)<sup>34–37</sup> methods. The structures of coordination compounds **2**, **4**–**9** were unequivocally established by X-ray diffraction studies.

Studies of the tautomeric forms of heterocyclic β-diketone ligands **10** showed<sup>6, 21, 38, 39</sup> that the tautomeric equilibrium (3) in solution is shifted towards the formation of the ketoenol form **A**, which is typical of these ligand systems in the crystalline phase as well.<sup>6, 21, 38–44</sup>

(3)

A = NR<sup>2</sup>, O, S, Se; B, D = CR<sup>3</sup>, N; R<sup>1</sup>, R<sup>2</sup>, R<sup>3</sup> = H, Alk, Ar.

4-Acylpyrazol-5-ones **11** are the most studied ligands.<sup>6, 21, 38</sup> Characteristic types of their coordination with different metals are shown below. Different tautomeric forms of these ligand systems (complexes **12**–**18**) are realised depending on the nature of the metal atom.<sup>21</sup>

R<sup>1</sup>, R<sup>2</sup>, R<sup>3</sup> = Alk, Ar.

Studies devoted to β-diketones **12** with equalised intrachelate bonds are most numerous.<sup>6, 21, 39–43, 45–48</sup>

Nearly identical M–O bond lengths in complexes **19**–**21** confirm the delocalisation of the intrachelate bonds within the ligands.<sup>48, 49</sup>

**19:** M = Sn, R<sup>1</sup>, R<sup>3</sup> = Alk, R<sup>2</sup> = 4-MeC<sub>6</sub>H<sub>4</sub>;

**20:** M = Zn, R<sup>1</sup> = R<sup>2</sup> = Ph, R<sup>3</sup> = DMF;

**21:** M = Cu, R<sup>1</sup> = CF<sub>3</sub>, R<sup>2</sup> = Ph, R<sup>3</sup> =

A similar type of coordination was also revealed in the monochelate complex **22** using X-ray diffraction.<sup>50</sup>

According to the X-ray diffraction data, the β-diketone ligand in the organometallic derivative **23**<sup>51, 52</sup> and in polymeric complex compounds **24** exists in the enol form.<sup>53</sup>

Of particular interest is complex **25** where the chelate form and the diketone form of the molecular ligand (LH) are simultaneously present.<sup>21</sup>

### III. Hydroxy-, amino-, thio- and seleno-substituted aromatic azomethines and their metal complexes

It is known that azomethines with the general formula  $o\text{-HXArC(R}^2\text{)=NR}^1$  can exist in three tautomeric forms **A**, **B** and **C** [equilibrium (4)].

X = O, NR<sup>4</sup>, S, Se.

The tautomeric equilibrium (4) is strongly affected by the nature of the donor atom X.

#### 1. Schiff bases with one OH group

Among such tautomeric systems, azomethines of salicylaldehyde and *o*-hydroxynaphthaldehyde **26** are the most abundant.<sup>1–5, 8, 11, 54–58</sup>

R<sup>1</sup> = Alk, Ar, Het; R<sup>2</sup> = H, Alk, Ar; R<sup>3</sup> = H, 5,6-benzo.

The existence of the tautomeric equilibrium (4) in solutions of azomethines **26** and of their derivatives has been confirmed by diverse physical methods,<sup>1–6, 8, 11, 54–56</sup> whereas its involvement in crystalline phases has been observed only in a few examples. The large body of X-ray diffraction studies on the structures of this class of compounds published in 1990–2000 (compounds **27–51**, Table 1) suggested that it is form **A** of the ligand that is virtually always realised in the crystalline phases.<sup>59–86</sup> It is of note that the presence of bulky substituents (compounds **31–36**)<sup>63–67</sup> or

coordinatively active fragments (compounds **37–49**)<sup>68–84</sup> at the nitrogen atom of the imino group does not affect the type of tautomeric form of the azomethine ligand.

The enolimine tautomeric form is also retained in other modifications of the imine; for instance, this was found in *o*-hydroxyazomethine *N*-oxide **52**.<sup>87</sup>

The structures of the Schiff bases of *o*-hydroxynaphthaldehyde are of particular interest.<sup>68, 88–94</sup> As has been established using <sup>1</sup>H, <sup>13</sup>C and <sup>15</sup>N NMR spectroscopy, UV and IR spectroscopy in solution,<sup>11, 55, 56, 68</sup> equilibrium (4) is shifted towards the formation of tautomer **B** (X = O)<sup>88</sup> with an increase in the bulk of the aromatic fragment annulated to the azomethine system of the aromatic fragment (*i.e.*, on going from salicylaldehyde to *o*-hydroxynaphthaldehyde). Meanwhile, tautomeric form **A** prevails<sup>89, 92–94</sup> in crystals (*e.g.*, in compounds **34**, **53**, **54**).

The study by Nazir *et al.*<sup>68</sup> is worth a special note: they synthesised both tautomers of the Schiff base of 2-hydroxy-1-naphthaldehyde and 2-aminopyridine and proved their co-existence in the crystalline phase using X-ray diffraction.

Substituted 2,6-diformylphenol diimines **55** are of significance as alterdentate<sup>13, 95, 96</sup> ligands.<sup>97–99</sup>

R<sup>1</sup> = Ph, Pr<sup>i</sup>, *p*-Tol, cyclo-C<sub>6</sub>H<sub>11</sub>; R<sup>2</sup> = Me, Bu<sup>n</sup>, OMe, Br, NO<sub>2</sub>.

A study of the photo- and thermochromic properties of compounds **55** with consideration of the character of the R<sup>1</sup> and R<sup>2</sup> substituents and the solvent nature has shown that equilibrium (5) is shifted towards the formation of the enolimine tautomer **55A**<sup>97</sup> (this form is also present in the crystalline phase according to X-ray diffraction data<sup>99</sup>) in nonpolar solvents, whereas it is shifted towards the formation of the quinomethide tautomer **55B** in polar solvents (*e.g.*, in DMSO). An increase in temperature shifts equilibrium (5) in a similar way. Alkyl substituents R<sup>1</sup> at the nitrogen atom shift the equilibrium towards the formation of tautomer **B**, whereas aryl substituents shift it towards tautomer **A**. The presence of donor substituents R<sup>2</sup> in the aldehyde fragment stabilises the enolimine form of ligand **55A**, whereas acceptor substituents shift equilibrium (5) to the right.

#### 2. Schiff bases with two and more hydroxy groups

Many mono- and binuclear metal complexes containing Schiff bases with several OH groups as ligands are known.<sup>34, 35, 100, 101</sup> Among them, ligands with two hydroxy groups where two azomethine fragments are bound to each other by a bridge Z through the imine nitrogen atoms (compounds **56–65**),<sup>102–111</sup> or the carbon atoms of the aldehyde moieties (compounds **66a,b**,

**Table 1.** Azomethines of salicylaldehyde and 2-hydroxynaphthaldehyde (type **26**) and their derivatives with known crystal structures.

R = NMe<sub>2</sub> (a), OH (b).

$n = 3, 4$ .

*etc.* can act as the bridges. The hydroxyimine tautomeric form of these ligands predominates in both solution and crystalline phases.

Salicylaldehyde derivatives with OH-containing substituents at the nitrogen atom, *e.g.*, compounds **70** and **71**,<sup>118, 119</sup> represent another class of azomethine ligands with two OH groups. They also exist as the enolimine form.

In these derivatives, the formation of intramolecular H-bonds can involve both OH groups giving rise to five- or six-membered rings. X-Ray diffraction studies have shown that six-membered rings are formed in bishydroxy imines **70** and **71**.

In the recently synthesised and structurally characterised<sup>120</sup> derivative **72**, only one of two possible H-bonded rings<sup>11, 58</sup> is formed, which involves the OH group of salicylaldehyde; the substituent at the nitrogen atom is rotated in such a way that the OH group is far from the nitrogen atom.

A similar situation occurs in the case of 2,3-dihydroxyazomethine **73**,<sup>121</sup> which exists in the ketoenamine form in the crystal. One of the OH groups of this compound, *viz.*, in the *ortho*-position with respect to the imino group, is involved in the intramolecular H-bonding (closure of a six-membered ring), while the second one forms H-bonds with the carbonyl oxygen atom of a neighbouring molecule. This gives rise to dimers with a ten-membered H-bonded pseudocycle. According to <sup>1</sup>H and <sup>13</sup>C NMR spectroscopy, fast exchange between the ketoenamine and enolimine forms is observed in solution at room temperature.<sup>121</sup>

Macrocyclic azomethines (*e.g.*, compounds **74** and **75**)<sup>122–124</sup> and Schiff bases containing crown-ether fragments (*e.g.*, com-

pounds **68** and **69**)<sup>112, 115–117</sup> exist in the enolimine tautomeric form in both solution (as evidenced by <sup>1</sup>H NMR data) and the crystalline phase (according to X-ray diffraction).

**74**: R<sup>1</sup> = F, R<sup>2</sup> = Bu<sup>t</sup>; **75**: R<sup>1</sup> = H, R<sup>2</sup> = Me.

The crystal structure of compound **76** is of considerable interest; this has been determined using X-ray diffraction and the positions of all hydrogen atoms have been revealed objectively. Two tautomeric forms, *viz.*, enolimine and ketoenamine, co-exist in molecules of **76** at 200 K.<sup>125</sup>

The co-existence of two tautomeric forms in one molecule of **76** is also supported by IR spectroscopy (KBr pellets): two bands at 1605 cm<sup>-1</sup> and 1622 cm<sup>-1</sup> are observed in the region 1600–1700 cm<sup>-1</sup>. Although Popovic *et al.*<sup>125</sup> attributed both bands to vibrations of the C=N bond (see Refs 126–129), there are reasons to re-assign the higher-frequency band to vibrations of the C=O group involved in the formation of the intramolecular H-bond. There is some experimental evidence that both of the above tautomeric forms also occur in solution (according to <sup>1</sup>H NMR spectroscopy). Nevertheless, the use of dimethylformamide, which is a strong donor, as a solvent in these spectral studies makes their results doubtful. In particular, a strict assignment of the signals to the fragments OH...N and O...HN is hardly possible.

Prototropic tautomerism is also observed for Schiff bases containing a larger number of OH groups. Typically, these compounds exist in the enolimine tautomeric form. Several Schiff bases containing three (compounds **77–80**)<sup>130–132</sup> and four (compounds **66b**, **81**, **82**)<sup>113, 133–135</sup> OH groups are listed below.

R<sup>1</sup> = H, R<sup>2</sup> = Cl (**78**); R<sup>1</sup> = Bu<sup>t</sup>, R<sup>2</sup> = H (**79**);

R<sup>1</sup> = CHO, R<sup>2</sup> = Me (**80**).

Macrocyclic compounds (e.g., ligands **83**, **84**, etc.)<sup>112, 114, 136–138</sup> constitute another group of tetrahydroxyazomethine derivatives.

**83**:  $R^1 = \text{C}_6\text{H}_4$ ,  $R^2 = \text{Bu}^t$ ;

**84**:  $R^1 = -(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{O}(\text{CH}_2)_2-$ ,  $R^2 = \text{Me}$ .

To our knowledge, no pentahydroxyazomethine structures have been characterised so far; Schiff bases with six OH groups are represented by single macrocyclic structure **85**.<sup>139</sup>

Derivatives **86**<sup>140</sup> and **87**<sup>141</sup> are worth a special note among the Schiff bases with four OH groups; their molecules contain two different tautomeric forms simultaneously, which co-exist both at room temperature and at 116 K (according to X-ray diffraction data). The reported <sup>1</sup>H NMR data (in CDCl<sub>3</sub>) concerned only the possibility of the existence of compound **86** in the open or cyclic forms rather than tautomeric equilibrium.

### 3. Tosylamino- and mercaptoazomethines

Tosylaminoazomethines ( $X = \text{NTs}$ ) exist predominantly in the benzenoid form **A** [like the hydroxyazomethines ( $X = \text{O}$ ) consid-

ered above], i.e., equilibrium (4) is shifted to the left.<sup>142–144</sup> This form is typical of the majority of tosylaminophenyl imines **88**<sup>143–146</sup> and bis-*o*-tosylaminobenzylidene derivatives **89** with various bridges **Z**.<sup>147–149</sup>

$R = \text{Ph}$ ,<sup>142</sup>  $\text{Bn}$ ,<sup>143</sup>  $\text{Bu}^t$ ,<sup>144</sup>  $\text{C}_6\text{H}_4\text{OH}-o$ ,<sup>145</sup> (see <sup>146</sup>).

$Z = \text{C}_2\text{H}_4$ ,<sup>147</sup> (see <sup>148</sup>), (see <sup>149</sup>).

In contrast, in the case of sulfur-containing analogues of hydroxyazomethines ( $X = \text{S}$ ), equilibrium (4) is shifted towards tautomer **B**, as evidenced by data from UV, IR and <sup>1</sup>H NMR spectroscopy and supported by quantum-chemical calculations.<sup>150, 151</sup> The fraction of tautomer **B** increases with an increase in the polarity of the solvent, nucleophilicity of the substituent at the nitrogen atom ( $R^1$ ) and acceptor properties of the substituent  $R^3$  (see Ref. 150). In particular, it was established<sup>151</sup> that the thio-derivative **90** exists virtually exclusively in the tautomeric form **B** in solution (DMSO, ethanol).

$R = \text{H}, \text{Me}, \text{Cl}, \text{OMe}, \text{NO}_2$ .

### 4. Coordination compounds of azomethines

Coordination compounds of hydroxyazomethines can be subdivided<sup>1, 8, 22, 27, 28, 34, 35, 57, 58</sup> into traditional chelates **91** and non-standard molecular complexes **92A** and **92B**.

$R^1 = \text{Alk}, \text{Ar}$ ;  $R^2 = \text{H}, \text{Hal}, \text{NO}_3$ ;  $A = \text{Hal}, \text{NO}_3$ ;  $n = 3, 4$ .

There is experimental evidence<sup>58, 152, 153</sup> that interconversion is possible between the chelate (**91**) and molecular (**92**) complexes.<sup>‡</sup>

Intracomplex compounds of type **91** were the subject of numerous monographs<sup>34–37</sup> and reviews,<sup>8, 22, 58, 154–159</sup> thus only compounds with crystal structures established over the last five years will be considered below. The respective copper, zinc and cobalt intracomplex compounds (structural data published in 2000–2004)<sup>63, 152, 160–169</sup> are listed in Table 2.

<sup>‡</sup> In the majority of schematic drawings of chelate structures, the enol-imine tautomeric form **A** [equilibrium (4)] is depicted, although the bonds in anionic azomethine ligands (complex **91**) are substantially delocalised.

**Table 2.** Mononuclear chelate complexes of 3d metals with hydroxy-azomethine ligands of the type **91**.

| M  | R <sup>1</sup>                                                                    | R <sup>2</sup>                   | Ref. |

A series of copper complexes **93–97** containing azomethines of naphthaldehyde as ligands have been characterised structurally.<sup>165, 170–173</sup>

Monochelates **98–102**<sup>176–179</sup> are of great potential importance as catalysts of polymerisation processes.<sup>174, 175</sup>

In complexes **101** and **102**, trimethylsilyl derivatives of salicylideneaniline are used as ligands.<sup>179</sup>

In complexes of hydroxyazomethines containing coordinatively active fragments with N-, P-, O- or S-donor centres at the nitrogen atom of the imino group,<sup>180–186</sup> additional coordination with the metal atom is observed. For instance, this is typical of complexes **103–108**.<sup>181, 184, 186–188</sup>

The dependence of the coordinative activity of the nitrogen atom of the pyridine fragment on the size of the metallacycle formed was analysed by several authors.<sup>34, 35, 57, 58</sup> It was found that five-membered rings are more stable than four-membered ones. The molecular structures of compounds **107** and **108** support this conclusion.

Protonation of the amino group in the coordinatively active substituent at the nitrogen atom of the imino group (compound **109**)<sup>189</sup> suppresses the donor properties of the substituent.

Among phosphorus-containing azomethine compounds, we are aware of only one complex **110** with the coordination core NiNPOCl.<sup>190</sup>

Intracomplex compounds of azomethines with coordinatively active oxygen-containing fragments<sup>57, 58, 191</sup> include mononuclear complexes with a protonated (compound **111**)<sup>192, 193</sup> or deprotonated (compound **112**)<sup>194</sup> OH group.

In the case of hydroxyazomethine ligands with sulfur-containing coordinatively active substituents, both mono- (compound **113**)<sup>195–197</sup> and polynuclear (compound **114**)<sup>198</sup> complexes have been synthesised.

The structures of chelates **115** for the Group III elements of the Periodic Table have recently been reviewed<sup>199</sup> and structures of complexes of 3d metals (copper, nickel, cobalt) are considered in Refs 200–204.

**115a:** M = Cu, Z = (CH<sub>2</sub>)<sub>3</sub>, X = O, R = H;<sup>200</sup>

**115b:** M = Ni, Z = (CH<sub>2</sub>)<sub>3</sub>, X = O, R = 6-OMe;<sup>201</sup>

**115c:** M = Ni, Z = (CHPh)<sub>2</sub>, X = O, R = H;<sup>202</sup>

**115d:** M = Ni, Z = (CHPh)<sub>2</sub>, X = O, R = NEt<sub>2</sub>;<sup>203</sup>

**115e:** M = Co, Z = , X = O, R = 3,5-Bu<sub>2</sub>;<sup>204</sup>

If the bridge Z contains coordinatively active donor atoms, the dentate numbers of ligands and coordination numbers of the complex-forming metal atoms increase (complexes **116**<sup>205</sup> and **117**<sup>206</sup>).

M = Co, Cu; R = H, Pr<sup>n</sup>, SiMe<sub>3</sub>, Si(OMe)<sub>3</sub>.

Azomethine compounds with three OH groups (*e.g.*, **78–80**) form complexes with lanthanides with the composition LnL (Ln = La, Ce, Sm, Tb, Y or Lu) where triply deprotonated molecules act as the ligands L<sup>3-</sup>. In these complexes, a complex-forming metal atom binds three nitrogen atoms of the C=N groups and a nitrogen atom of the amino group (according to X-ray diffraction data).<sup>132</sup>

Coordination of ligand **86**, which exists in two tautomeric forms, gives rise to a series of chelates **115** (M = Mn, X = O, R = H, Z = CH<sub>2</sub>OH–CH<sub>2</sub>OH) with structures typical of bis-salicylideneiminates.<sup>140</sup>

Similar complexes are formed upon coordination of ligands **89**.<sup>207–211</sup> In particular, metal chelates with the coordination core MN<sub>4</sub> [Z = (CH<sub>2</sub>)<sub>3</sub>, M = Cu;<sup>208</sup> Z = (CH<sub>2</sub>)<sub>2</sub>CHOH, M = Zn;<sup>209</sup> Z = 1,2-C<sub>6</sub>H<sub>4</sub>, M = Ni;<sup>210</sup> Z = 1,2-C<sub>6</sub>H<sub>10</sub>, M = Ni;<sup>149</sup> Z = 1,2-C<sub>6</sub>H<sub>4</sub>, M = Cu (see Ref. 211)] analogous to **115** (X = NTs) have been prepared.

The ligands **89** (Z = C<sub>2</sub>H<sub>4</sub>) can form binuclear chelates in some specific cases as well (*e.g.*, complex **118**).<sup>212</sup>

The Schiff bases with N,N,O,S- and N,N,S,S-donor centres form intracomplex compounds **119**<sup>213</sup> and **115** (X = S, M = Cu, Z = C<sub>2</sub>H<sub>4</sub>).<sup>214</sup> which are characterised by the *cis*-planar configuration of the coordination core.

The mercaptoazomethine ligand with the substituent (CH<sub>2</sub>)<sub>2</sub>S(CH<sub>2</sub>)<sub>2</sub>(C<sub>5</sub>H<sub>4</sub>N-2) with coordinatively active N and S atoms at the nitrogen atom of the imino group forms a nickel complex with the NiN<sub>2</sub>S<sub>2</sub> coordination core (complex **120**, X-ray diffraction data).<sup>215</sup>

Numerous mono- (**121**) and binuclear (**122**) structures with tetra-, penta- and hexa-coordinated metal sites have been synthesised based on bishydroxyazomethines **70** (O,N,O-) and related N,N,N-, N,N,O-, N,N,S- and N,O,S-tridentate azomethines.

The structures of these complexes have been surveyed in several monographs<sup>34–37</sup> and a review<sup>58</sup>. Recently, the structures of nickel, copper and zinc complexes with tosylaminoazomethine ligands (X = NTs, L = 2-aminopyridine, L' = MeOH) have been reported.<sup>216–218</sup>

Compound **123**<sup>120</sup> containing six- and seven-membered metallocyclic fragments represents an interesting example of complex formation involving a tridentate azomethine ligand.

The presence of two OH groups in positions suitable for double chelation does not guarantee the realisation of structures **121** or **122**. For instance, ligand **71** afforded mononuclear intracomplex compounds due to coordination of only one hydroxy group of the hydroxyazomethine fragment.<sup>119</sup> An unusual structure of tungsten complex **124** was suggested by El-Medani.<sup>219</sup> Unfortunately, no reliable X-ray diffraction data confirming this structure are available for this compound.

124

Complexes based on the alterdentate ligand systems **55** or on their sulfur-containing analogues<sup>220–222</sup> have predominantly binuclear structures. The metal atom is coordinated by both imine nitrogen atoms and an oxygen (complex **125**)<sup>221</sup> or sulfur (complex **126**) atom.<sup>222</sup> Similar complexes are formed with macrocyclic Schiff bases.<sup>158, 159, 220</sup>

125

126

Sometimes, both imine nitrogen atoms of the alterdentate ligands **55**<sup>13, 14, 97</sup> cannot be involved in coordination with a metal atom simultaneously due to spatial restrictions. In these cases, intermediate structures (**127**) are formed with equally probable involvement of any of the two nitrogen atoms in coordination with the metal.

127A

127B

M = B, Ga, In; R<sup>1</sup> = H, 5-NO<sub>2</sub>, 5,6-benzo;

R<sup>2</sup> = Me, Pr<sup>i</sup>, Bn; R<sup>3</sup> = OMe, OPr<sup>i</sup>, OBn; R<sup>4</sup> = Ph, C<sub>6</sub>H<sub>4</sub>OMe-4.

Similar coordination is typical, for instance, of organoboron derivatives.<sup>223</sup>

The intrachelate bonds in complexes **91** with anionic ligands are delocalised. Meanwhile, according to X-ray diffraction studies with objective localisation of all hydrogen atoms, the ligand exists in molecular complexes **92** in the ketoenamine (quinomethide) form.<sup>34, 35, 58</sup> This form was also revealed in complexes of salicylidene imines (**92**: R<sup>1</sup> = Ar, R<sup>2</sup> = H)<sup>152</sup> and hydroxynaphthylmethylidene (**92**: R<sup>1</sup> = Ph, R<sup>2</sup> = 4,5-benzo)<sup>89</sup> with zinc dichloride. Although the proton is reliably localised at the nitrogen atom and the coordination of the oxygen atom with the metal atom is confirmed in such complexes, the formation of enolimine<sup>224</sup> and

zwitter-ionic<sup>152</sup> structures cannot be totally ruled out. In particular, a zwitter-ionic structure was suggested for the molecular complex **128**.<sup>225</sup>

128

Compound **129**<sup>226</sup> manifests the N,O-chelate coordination that is unusual for molecular complexes of hydroxyazomethines.

129

The structure of **130**<sup>227</sup> confirms the possibility of the co-existence of two tautomeric forms in one molecule of bishydroxyazomethine.

130

The tautomeric metallotropic equilibrium (6) involving organometallic derivatives of azomethines was studied using spectroscopic<sup>228</sup> and X-ray diffraction<sup>229</sup> methods. It was established that coordination of the oxygen atom with a metal atom stabilises the enolimine (benzenoid) form **A**, whereas coordination of the nitrogen atom stabilises the ketoenamine (quinomethide) tautomeric form **B**.

(6)

R<sup>1</sup> = H, Me, C<sub>6</sub>H<sub>4</sub>OMe-*p*; R<sup>2</sup> = H, 5,6-benzo; R<sup>3</sup> = Me, Ph; M = Hg, Tl; n = 1, 2.

The fraction of the latter increases with an increase in the solvent polarity (*e.g.*, DMSO) and with a lowering of the temperature.<sup>228</sup> Apparently, both tautomeric forms occur in crystalline phases.<sup>229</sup> Although the tautomeric equilibrium (6) has not been studied in detail with other organometallic derivatives of hydroxyazomethines, X-ray diffraction data indicate the predominance of the enolimine tautomers **A**. The enolimine form of the ligand is also realised in complexes **131–135**<sup>230–235</sup> where substituents at the nitrogen (compounds **131–133**) or carbon (compound **134**) atoms of the imino group or at the carbon atom of salicylaldehyde (compound **135**) contain metal-bearing fragments.

Compounds similar to **131–135** can be used as metal-containing ligands for the synthesis of heteronuclear complexes, such as the copper–platinum complex **136**.<sup>236</sup>

Thus, functionalised azomethines exist predominantly in the enolimine tautomeric form independently of the nature of the substituents. Intracomplex compounds **91** containing this ligand system are characterised by delocalised intrachelate bonds, whereas the ketoenamine tautomeric form of ligand **92** is stabilised in molecular complexes due to metal coordination.

#### IV. $\beta$ -Aminovinyl ketones, thiones, imines and their complexes

In contrast to the functionalised aromatic Schiff bases, the tautomeric equilibrium (7) in solutions of enamino ketones ( $X = O$ ), thiones ( $X = S$ ) and imines ( $X = NR^4$ ) **137** is shifted towards form **B**, as evidenced by data from NMR and electronic spectroscopy and supported by quantum-chemical calculations.<sup>11, 55, 56, 237, 238</sup>

$X = NR^4, O, S; R^1 - R^4 = H, \text{Alk}, \text{cyclo-Alk}, \text{Ar}.$

X-Ray diffraction studies<sup>239–253</sup> of enamino ketones ( $X = O$ ) **138–153** confirmed the existence of form **B** in the crystalline phases as well (Table 3).

This form is also typical of bisenamino ketones containing various bridges  $Z$  (compounds **154–159**).<sup>254–261</sup>

**154–157**

**154:**  $Z = C_2H_4$ ,  $R^1 = R^2 = \text{Me}, \text{Ph}, \text{Bn}$ ; **155:**  $Z = o\text{-}C_6H_4$ ,  $R^1 = \text{Me}$ ,  $R^2 = \text{Ph}$ ; **156:**  $Z = p\text{-}C_6H_4$ ,  $R^1 = \text{CO}_2\text{Et}$ ,  $R^2 = (\eta^5\text{-}C_5H_4)\text{FeCp}$ ;

**157:**  $Z = (\eta^5\text{-}C_5H_4)_2\text{Fe}$ ,  $R^1 = R^2 = \text{Me}$ .

**158, 159**

**158:**  $Z = (CF_2)_4$ ,  $R^1 = \text{Pr}^i$ ,  $R^2 = \text{Me}$ ;

**159:**  $Z = (\eta^5\text{-}C_5H_4)_2\text{Fe}$ ,  $R^1 = \text{Ph}$ ,  $R^2 = \text{CO}_2\text{Et}$ .

**Table 3.**  $\beta$ -Aminovinyl ketones (type **137**) with known crystal structures.

| Compound    | $R^1$                                                               | $R^2$                                           | $R^3$                          | Ref. |

Metal chelates **160** are the most common complex compounds of  $\beta$ -aminovinyl ketones; their structures have been considered in numerous publications, including reviews,<sup>8, 27, 58, 262</sup> theses<sup>263–265</sup> and monographs.<sup>35, 36</sup> Metal chelates of the type **160** are widely used for the deposition of metal films; thus they attract undying interest. For instance, the structures of copper and palladium metal chelates have recently been reported.<sup>266–268</sup>

In addition to intracomplex compounds **160**, the deprotonated ligands also form mononuclear complexes **161**<sup>269, 270</sup> and binuclear bridged complexes **162**.<sup>264</sup>

Organopalladium compounds **163** and **164**<sup>269, 270</sup> can be considered as examples of mono- $\beta$ -aminovinylketonate complexes.

R = CHMePh (**163**), Ph (**164**).

Neutral  $\beta$ -aminovinylketonate ligands (LH) form molecular adducts **165** with the stoichiometry  $(\text{LH})_2 \cdot \text{MA}_n$ .<sup>8</sup> As in the case of free molecules of these enamino ketones, the amino ketone form of the ligands was found<sup>271–276</sup> in these complexes.

**165a**:  $\text{MA}_n = \text{TiCl}_4$ ,  $\text{R}^1 = \text{Ph}$ ,  $\text{R}^2 = \text{R}^4 = \text{Me}$ ,  $\text{R}^3 = \text{H}$  (taken from Ref. 8);

**165b**:  $\text{MA}_n = \text{ZnI}_2$ ,  $\text{R}^1 = \text{Bu}^i$ ,  $\text{R}^2 = \text{R}^4 = \text{Me}$ ,  $\text{R}^3 = \text{H}$  (see Ref. 271);

**165c**:  $\text{MA}_n = \text{MoO}_2\text{Cl}_2$ ,  $\text{R}^1 = \text{Ph}$ ,  $\text{R}^2 = \text{R}^4 = \text{Me}$ ,  $\text{R}^3 = \text{H}$  (see Refs 272 and 273);

**165d**:  $\text{MA}_n = \text{ZrCl}_4$ ,  $\text{R}^1 = \text{Pr}^i$ ,  $\text{R}^2 = \text{R}^4 = \text{Me}$ ,  $\text{R}^3 = \text{H}$  (see Ref. 274).

A spectroscopic study of the adduct **165a** has been performed<sup>8</sup> in order to determine the type of ligand coordination (*i.e.*, through the N or O atom). A decrease in the frequency of the stretching vibrations of the carbonyl group in the range 1610–1650  $\text{cm}^{-1}$  (which can be due to the formation of a M–O bond) was used as the criterion for localisation of the coordination bond. Notwithstanding, it should be taken into account that the absorption band of the azomethine group shifted to higher frequencies due to M–N coordination can also fall in the same range. This problem was unambiguously solved by X-ray structural investigation of the adducts **165**.

For the first time, coordination of the neutral ligand LH through the oxygen atom was established for a mixed-ligand complex **166**.<sup>271</sup>

The bisenaminoketone adduct **167**<sup>276</sup> reveals similar coordination of the ligand.

Complex **168** is of particular interest since it contains the ligand system in the anionic and neutral forms simultaneously.<sup>277</sup>

Like enamino ketones, their sulfur-containing analogues, enamino thiones **137** (X = S), exist in the  $\beta$ -aminovinylthione tautomeric form **B**.<sup>278–281</sup> Metal salts and deprotonated ligands yield complex compounds **169** and **170** with delocalised chelate bonds.

Depending on the nature of the metal atom and the substituent  $\text{R}^1$  at the nitrogen atom, the metal cores in chelates **169** adopt the *cis*-planar (M = Ni;  $\text{R}^1 = \text{Me}$ , Et),<sup>281</sup> tetrahedral (M = Zn,  $\text{R}^1 = \text{cyclo-C}_6\text{H}_{11}$ )<sup>8, 282</sup> or square-pyramidal (M = Cu,  $\text{R}^1 = 8\text{-quinolyl}$ )<sup>283</sup> configurations. Despite the fact that octahedral coordination of the copper atom might be expected for copper complex with the  $\beta$ -aminovinylthione ligand containing a coordinatively active quinoline fragment, X-ray diffraction data indicated that only one nitrogen atom of the azine substituent is involved in coordination.<sup>264</sup>

The nickel complex **169** ( $n = 2$ ) possesses the *cis*-planar structure, whereas analogous copper ( $n = 2$ ) and zinc ( $n = 2, 4$ ) complexes are characterised by tetrahedral chelate structures.<sup>8</sup>

It was assumed that neutral  $\beta$ -aminovinylthione ligands form molecular complexes of the type **165** with metal salts (*e.g.*, with  $\text{MoO}_2\text{Cl}_2$ ).<sup>8</sup> The formation of an Mo–S bond therein was suggested based on IR data (which cannot be considered reliable since the frequency of the stretching vibrations of the C=S bond is not characteristic), thus this requires independent confirmation using X-ray diffraction.

According to X-ray diffraction studies,<sup>284–287</sup> the tautomeric forms **A** and **B** for  $\beta$ -aminovinyl imines **137** (X =  $\text{NR}^4$ ) can hardly

be distinguished, especially in the case of similar types of substituents  $R^1$  and  $R^4$ ; form **C** has never been detected.

A series of coordination compounds synthesised from  $\beta$ -aminovinyl imines ( $X = NR^1$ ) has been analysed by Bourget-Merle *et al.*;<sup>288</sup> they proposed that their structures can be classified into several types with **171**–**173** being the most interesting.

Examples of metal chelates of anionic  $\beta$ -aminovinylimine ligands with delocalised coordination bonds include both mono- (types **171** and **174**) and binuclear (type **175**) structures.<sup>288–291</sup> Recently reported synthesis<sup>292</sup> of a non-symmetrically substituted  $\beta$ -aminovinyl imine [2-(2-methoxyphenylimino)-4-(2,6-diisopropylphenylimido)pent-2-ene, BDI] and its magnesium and zinc complexes  $(BDI)_2Mg$ ,  $(BDI)MgPr^i$ ,  $(BDI)MgNPr_2^i$ ,  $(BDI)ZnN(SiMe_3)_2$  and  $(BDI)ZnEt$  are worth a special note. The structures of the bischelatate magnesium complex (**176**) and two monochelate zinc complexes were determined using X-ray diffraction.

$R = C_6H_3Pr_2^{i-2,6}$ .  $R = C_6H_3Pr_2^{i-2,6}$ ;  $L = Et$  (**a**),  $N(SiMe_3)_2$  (**b**).

It was found that the two BDI ligands in the bischelatate magnesium complex are coordinated differently to the metal atom.

Since the number of publications devoted to monochelate anionic complexes **174** is very large, we mention here only recent structural studies of tricoordinated iron [ $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Bu^t$ ,  $L = Me$ ;<sup>293</sup>  $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $C_6F_5$ ,  $Mes$ ,  $2,6-Me_2C_6H_3$ ,  $2,6-Cl_2C_6H_3$ ,  $R^2 = Me$ ,  $L = N(SiMe_3)_2$ ;<sup>294</sup>  $R^1 = Ar$ ,  $R^2 = Alk$ ,  $L = Et$ ,  $CH_2Bu^t$ ,  $Pr^i$ ;<sup>295</sup>  $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Me$ ,  $Bu^t$ ,  $L = Et$ ,  $Bu^i$ ,  $Bu^t$  (see Ref. 296)], cobalt [ $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Bu^t$ ,  $L = Cl$ ,  $Me$ ;<sup>293</sup>  $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Me$ ,  $L = N(SiMe_3)_2$ ;<sup>294</sup>  $R^1 = 2,6-Cl_2C_6H_3$ ,  $R^2 = Bu^t$ ,  $L = Cl$ ,  $THF$ ;<sup>293</sup>  $R^1 = 2,6-Cl_2C_6H_3$ ,  $R^2 = Me$ ,  $L = Cl$ ,  $N(SiMe_3)_2$  (see Ref. 297)], manganese [ $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Me$ ,  $L = N(SiMe_3)_2$  (see Ref. 294)], copper [ $R^1 = Mes$ ,  $R^2 = H$ ,  $L = OAc$ ;<sup>298</sup>  $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Me$ ,  $L = SCPh_3$ ,  $Py$  (see Ref. 299)] and zinc [ $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = Me$ ,  $L = NPr_2$ ,  $OBu^t$  (see Ref. 300)] complexes and tetracoordinated nickel  $(Dipp)NiR(2,4-Lut)$  ( $Dipp = CH[CMEN(C_6H_3Pr_2^{i-2,6})_2]$ ,  $2,4-Lut = 2,4-lutidine$ ,  $R = Me$ ,  $Et$ ,  $Pr$ ),<sup>301</sup> zinc  $(Dipp)Zn(OSiPh_3)(THF)$ <sup>300</sup> and magnesium  $(Dipp)Mg(NPr_2)(THF)$  and  $(Dipp)Mg(OBu^t)(THF)$ <sup>300</sup> complexes.

Compounds **174** can form binuclear complexes **175** containing two monoatomic bridges  $Z$  [ $Z = H$ ,<sup>302</sup>  $Hal$ ,<sup>297, 301–304</sup>  $O$ ,<sup>305</sup>  $OR$

( $R = H$ ,  $Alk$ ,  $Ac$ ),<sup>303, 305–308</sup>  $NR_2$ , *etc.*]. For instance, monochelate zinc  $\beta$ -aminovinyliminates with the composition  $(BDI)ZnL$  [ $BDI$ :  $R^1 = 2,6-Pr_2^iC_6H_3$ ,  $R^2 = H$  or  $R^1 = 2,6-Et_2C_6H_3$ ,  $R^2 = H$ ;  $L = Br$ ,  $Cl$ ,  $Et$ ,  $N(SiMe_3)_2$ ,  $OH$ ,  $OMe$ ,  $OPr^i$ ,  $OAc$ ] were studied.<sup>303</sup> It was established that all these complexes except for ones with  $L = Et$  and  $N(SiMe_3)_2$  exist in the dimeric form  $(BDI)Zn(\mu-L)_2Zn(BDI)$ .

Furthermore, other binuclear chelates with longer bridges are known. In particular, two monochelate fragments are linked through one diatomic bridge  $N_2$  in the iron complex **178**,<sup>309</sup> through two triatomic bridges  $O=C(Me)=O$  in the zinc complex **179**<sup>310</sup> and through one triatomic and one monoatomic bridge in complex **180**.<sup>311</sup>

Complexes with unusual structures were obtained instead of the expected  $\beta$ -aminovinyliminates in the reaction of 1,3-bis(2,6-diisopropylphenylimido)-2-phenylpropane with  $Cu^{2+}$  salts in methanol or ethanol. In particular, copper bis- $\beta$ -diketonate and the dimer **181** were obtained from  $Cu(ClO_4)_2 \cdot 6H_2O$  and  $CuCl_2 \cdot 2H_2O$ , respectively; the structure of the latter was established using X-ray diffraction.<sup>312</sup>

Yet another large class of binuclear metal complexes with  $\beta$ -aminovinyl imines as ligands is represented by compounds where two metal atoms linked through a bridge have different ligand environments. For example, complexes **182**–**185**<sup>313, 314</sup> fall into this class.

Ar = C<sub>6</sub>H<sub>3</sub>Pr<sub>2</sub><sup>i</sup>-2,6.

L = OEt (**184**), THF (**185**);

Ar = C<sub>6</sub>H<sub>3</sub>Pr<sub>2</sub><sup>i</sup>-2,6.

The complexes considered above contain a  $\beta$ -aminovinylimine ligand in the deprotonated form. In addition, complexes are known with the ligands in neutral form; coordination with a metal stabilises the diimine tautomeric form **172**, which is not typical of free enamino imines.<sup>288</sup> This form of the ligand was found both in mononuclear (**186–192**<sup>315–321</sup>) and binuclear (**193**<sup>317</sup> and **194**<sup>286, 322</sup>) complexes.

**186:** M = Ir, X = CO, Y = PPh<sub>3</sub>, R<sup>1</sup> = H, R<sup>2</sup> = CF<sub>3</sub>, R<sup>3</sup> = Allyl;<sup>315</sup>

**187:** M = Rh<sup>+</sup>, X = Y = CO, R<sup>1</sup> = R<sup>3</sup> = H, R<sup>2</sup> = Me;<sup>316</sup>

**188:** M = Ni, X = Y = Br, R<sup>1</sup> = C<sub>6</sub>H<sub>3</sub>Pr<sub>2</sub><sup>i</sup>-2,6, R<sup>2</sup> = Me, R<sup>3</sup> = H.<sup>317</sup>

R = Me (**191**), Ph (**192**);

A = ClO<sub>4</sub><sup>-</sup>, PF<sub>6</sub><sup>-</sup>.

R = C<sub>6</sub>H<sub>3</sub>Pr<sub>2</sub><sup>i</sup>-2,6.

Apparently, this form of the ligand is also typical of complex **195**, where the  $\beta$ -aminovinylimine ligand is tridentate.<sup>323</sup>

The structures of adducts of  $\beta$ -aminovinyl imines with MCl<sub>4</sub> (M = Sn, Ti)<sup>263</sup> are of interest. Although formation of the M–N-coordinated forms **A** or **B** was suggested for them, the question remains open due to a lack of X-ray diffraction data.

## V. Heterocyclic azomethines and their complexes

Amino-, hydroxy(oxo)- and thio-substituted heterocyclic azomethines can be subdivided into two groups depending on the type of imine bond, viz., compounds with exo- (**196**) and endocyclic (**197**) C = N bonds.<sup>6, 8, 11, 38, 55, 56, 324–327</sup>

X, A = NR<sup>3</sup>, O, S.

The best studied class of chelating ligands of type **196** is the pyrazole derivatives **198**. Compounds with X = NR<sup>3</sup> exist exclusively in the imine form **A**, whereas those with X = O and S exist in the amine form **B** [equilibrium (10)].

X = NR<sup>4</sup>, O, S; R<sup>1</sup> = H, Alk, Ar, Het; R<sup>2</sup>, R<sup>3</sup>, R<sup>4</sup> = H, Alk, Ar.

The latter form is realised in both solution and the crystalline phase, as evidenced by X-ray diffraction data. For instance, this form was found in a series of hydroxypyrazoles **198** (X = O) with coordinatively active substituents R<sup>1</sup> (R<sup>1</sup> = C<sub>6</sub>H<sub>4</sub>SMe-2,<sup>328</sup> COCH<sub>2</sub>Cl,<sup>329</sup> 8-quinolyl,<sup>330</sup> C<sub>6</sub>H<sub>4</sub>NH<sub>2</sub>-2,<sup>331</sup> C<sub>6</sub>H<sub>4</sub>OH-2<sup>332</sup> and antipyril<sup>333</sup>) and for pyrazolethione **199** derivatives.<sup>334</sup>

Complex compounds synthesised based on compounds **198** include exclusively chelates **200** with anionic ligands<sup>6, 8, 58, 324, 326, 335</sup> that are characterised by virtually delocalised intrachelate bonds.

Only a few metal complexes with hydroxypyrazole ligands ( $X = O$ ) have been studied (*e.g.*, compounds **201**<sup>336</sup> and **202**<sup>337</sup>).

Meanwhile, mercaptopyrazole complexes are quite numerous.<sup>8, 158, 264, 338–353</sup> These include bischelate structures **200** ( $R^1 = Alk, Ar, Ph, cyclo-C_6H_{11}, pyridyl, crown-ether$  substituent), tricyclic chelates **203** with ethylene,<sup>8, 349, 350</sup> trimethylene<sup>8, 349</sup> or tetramethylene<sup>8</sup> bridges, bicyclic complexes **204** formed due to additional coordination of the metal atom with a coordinatively active substituent  $R^1$  and heteronuclear structures **205**.<sup>352, 353</sup>

$M = Ni, Cu; n = 2, 3, 4.$

Investigations into the tautomeric equilibrium (8) of azomethines of the pyrrole, furan, thiophene, their benzo-analogues<sup>10, 11, 55, 56</sup> (compounds **206**)<sup>354</sup> and benzothiazinone (compounds **207**)<sup>355</sup> series indicate that they predominantly exist in the enaminothione (thione) tautomeric form.

$A = NR^2, O, S; X = O, S;$   
 $R^1 = H, Alk, Ar.$

$R^1, R^2 = Alk, Ar; R^3 = Ar,$   
 8-quinolyl, 4-antipyril.

This suggestion is supported by the X-ray diffraction data for the respective complexes.<sup>8, 356–360</sup>

The possibility of the coordination-dependent stabilisation of specific tautomeric forms was deduced from the data on the tautomeric equilibrium (elementotropy)<sup>2–4</sup> of organometallic derivatives of ligands of the type **206** ( $A, X = O, S$ ). It was

found<sup>55, 361–363</sup> that the interaction of enaminothione **206** ( $X = S$ ) with a soft acid (in terms of the Hard and Soft Acids and Bases, or HSAB, principle)<sup>34, 35, 364–366</sup> stabilises the imine form of the ligand (compound **208**), whereas the similar reaction of enamino ketone **206** ( $X = O$ ) gives rise to the amine form **209**.<sup>55, 56</sup>

The tautomers formed possess the maximum stability within the HSAB principle.<sup>34, 35, 365</sup>

Ligands of the type **197** manifest photo(thermo)-activated tautomerism [equilibrium (9)] with the tautomeric form **A** prevailing (see reviews<sup>6, 367</sup>). According to X-ray diffraction data, this form is also observed in the crystalline phase.

Among compounds **197**, benzoxazole ( $A = O$ ;  $R^1 - R^2 = benzo$ ),<sup>368</sup> oxazoline<sup>369, 370</sup> and imidazole [ $A = NH$ ;  $R^1 = R^2 = H$ ;<sup>371</sup>  $R^1 = Ph, R^2 = NO_2$  (see Ref. 372)] derivatives have been studied using X-ray diffraction. The structures of benzimidazoles **210** and **211**,<sup>373</sup> spiro- (**212**)<sup>374</sup> and polyheterocyclic (**213a,b**) imidazoles<sup>375, 376</sup> have been determined.

**213a:**  $R^1 = 2-C_5H_4N, R^2 = OMe; n = 1;$

**213b:**  $R^1 = N\text{-methylimidazol-2-yl}, R^2 = H; n = 2.$

The tautomeric form **A** is also typical of benzothiazoles **214**,<sup>377</sup> **215**<sup>378</sup> and thiazolines **216**.<sup>379</sup>

$R = H$  (**214**); 5,6-benzo (**215**).

Ligand systems of the type **197** form chelates **217** with delocalised chelate bonds in nearly all cases; this prevents an analysis of the tautomeric forms of the ligands, as in the systems discussed above. The first complexes of this type<sup>380</sup> were synthesised based on 2-tosylaminophenylbenzoimid(ox)azole.<sup>381</sup>

Structural data on complexes **217** ( $X = NTs$ ) with the coordination core  $MN_4$  are rather scarce.<sup>369, 370, 382</sup>

$A, X = NTs, O, S, Se.$

Complexes based on 2-hydroxyphenylazole systems similar to **217** ( $X = O$ ) are more numerous. These include chelates **217** with  $A = NH$ ,  $M = Cu, Co$ ,  $R^1 = R^2 = Ph$ ; <sup>383</sup>  $A = NH$ ,  $M = Cu, Co$ ,  $R^1 - R^2 = benzo$ ; <sup>384, 385</sup>  $A = O$ ,  $M = Cu, Co, Ni, Zn$ ,  $R^1 = H$ ,  $R^2 = H, Me, Ph$ ; <sup>386–388</sup>  $A = O$ ,  $M = Cu$ ,  $R^1 - R^2 = benzo$ ; <sup>389, 390</sup>  $A = S$ ,  $M = Cu$ ,  $R^1 - R^2 = benzo$  <sup>391, 392</sup> and the thiazoline complex **218**. <sup>393</sup>

Several complexes based on mercaptophenylazoles (**217**,  $X = S$ ,  $M = Zn$ ,  $A = O$ ,  $R^1 = H$ ,  $R^2 = Me$ ) <sup>394</sup> and their hydro-seleno-derivatives (**217**,  $X = Se$ ,  $M = Zn$ ,  $A = O$ ,  $R^1 = H$ ,  $R^2 = Me$ ) <sup>395</sup> have been reported.

IR spectroscopic studies of molecular complexes of metal halides **219** produced in the following reaction: <sup>6, 396, 397</sup>

$A = NH, O$ ;  $X = NTs, O$ ;  $M = Sn, Ti, Co, Cu, Zn$ ;  $n = 2, 4$ .

suggest stabilisation of the non-typical quinoid form **197B** due to coordination. However, this suggestion requires more reliable X-ray diffraction confirmation, since the enol form of the ligand was shown to be retained in analogous structurally characterised complexes **220** and **221** with N- (**220**) <sup>398, 399</sup> or N,O-coordination (**221**). <sup>400</sup>

$M = Pd, Pt$ .

The structure of compound **221** is of note; the metal atom therein replaces the hydrogen atom at the endocyclic nitrogen atom rather than the exocyclic phenolic proton.

The stabilisation of specific tautomeric forms of azomethine ligands can be achieved not only for proto- and elementotropic tautomerism but for the ring-chain tautomerism of azole ligand systems **222** <sup>6, 401–403</sup> as well.

$R = Ar, Het$ .

Compound **222** in the free state (in both solution and the crystalline phase) exists predominantly in the closed tautomeric form **A**. Coordination stabilises form **B** (complex **223**). <sup>6, 8, 34, 35, 58, 157</sup>

$M = Ni, Pd, Pt$ ;  $R = Ar, Het$ .

Recently, five-membered chelates with the coordination core  $MN_2S_2$  [compounds **223** ( $R = Ar$ ), <sup>404–406</sup> **224** <sup>407</sup> and **225** <sup>408</sup>] have been synthesised based on benzothiazolines.

$M = Co, Ni, Zn, Cd$ .

One binuclear mercaptoazomethine chelate **226** with an S-bridge and the coordination core  $MNS_3$  has been characterised structurally. <sup>409</sup>

## VI. Hydroxy(mercapto)azo-compounds and metal chelates based on them

Tautomeric transformations occur also in diazo-analogues of azomethines, viz., hydroxy(mercapto)-derivatives of aromatic **227** and heterocyclic **228** azo-compounds. <sup>6, 34, 35, 410, 411</sup>

$R^1 = Ar, Het$ ;  $R^2 = benzo, OAlk, Hal, NO_2$ ;

$X = O, NR^3$  ( $R^3 = Alk, Ts$ ).

$X = NR^4, O, S, Se$ ;  $R^1 = Ar, Het$ ;  $R^2 = R^3 = R^4 = H, Alk, Ar$ .

Ligands **227** and **228** manifest the azo–hydrazone tautomerism [equilibrium (11)]. The equilibrium is shifted towards the azo-tautomer **A** in the case of aromatic amino- (**227**,  $X = \text{NR}^3$ ,  $\text{R}^1 = \text{Ar}$ ) and hydroxyazo-compounds (**227**,  $X = \text{O}$ ,  $\text{R}^1 = \text{Ar}$ ) **A**.<sup>411–414</sup> Pyrazole compounds **228**<sup>6, 34, 35, 38, 411, 415</sup> exhibit a more complex equilibrium (12) with the tautomer **B**<sup>6, 38, 411, 412</sup> prevailing. According to a combined <sup>15</sup>N NMR (in CDCl<sub>3</sub>) and X-ray diffraction study,<sup>416</sup> complexes **227** exist predominantly in the azophenol form (**227A**), whereas compound **228** exists in the oxohydrazone (**228B**) tautomeric form. A similar situation is observed in the crystalline phases of compounds **227** and **228**.

In particular, compounds **228** ( $X = \text{O}$ ) exist in the solid phase exclusively in the form **228B** ( $\text{R}^1 = \text{C}_6\text{H}_3\text{Me}_2\text{-2,4}$ ,  $\text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{Me}$ ;<sup>417, 418</sup>  $\text{R}^1 = \text{C}_6\text{H}_4\text{NO}_2\text{-4}$ ,  $\text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{Me}$ ;<sup>419</sup>  $\text{R}^1 = \text{C}_6\text{H}_4\text{Cl-4}$ ,  $\text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{Me}$ ;<sup>420</sup>  $\text{R}^1 = \text{C}_6\text{H}_3\text{Cl}_2\text{-2,4}$ ,  $\text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{Me}$ ;<sup>421</sup>  $\text{R}^1 = \text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{COOPr}$ ;<sup>422</sup>  $\text{R}^1 = \text{R}^2 = \text{C}_6\text{H}_4\text{OMe-4}$ ,  $\text{R}^3 = \text{CO}_2\text{Et}$ <sup>423</sup>); the same form is typical of mercaptopyrazole derivatives ( $X = \text{S}$ ,  $\text{R}^1 = \text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{Me}$ ).<sup>424</sup> Meanwhile, amino-derivatives exist in the azo-form (**228A**,  $X = \text{NR}^4$ ).<sup>6, 425</sup>

The oxohydrazone tautomeric form is also typical of hydroxy-azo-derivatives of isoxazole **229**.<sup>426</sup>

A large number of metal complexes of the types **230** and **231** with hydroxy(mercapto)azo-ligands have been reported, which are characterised by virtually delocalised intrachelate bonds.

$X = \text{NR}^4$ ,  $\text{O}$ ,  $\text{S}$ ;  $n = 2, 3$ ;  $\text{R}^1 = \text{Ar}$ ,  $\text{Het}$ ;  $\text{R}^2, \text{R}^3, \text{R}^4 = \text{H}$ ,  $\text{Alk}$ ,  $\text{Ar}$ .

According to a suggestion by Price,<sup>427</sup> two five-membered metallacycles are realised in a newly synthesised cobalt complex **230** ( $X = \text{NH}$ ,  $\text{R}^1 = \text{Ph}$ ,  $\text{R}^2 = \text{H}$ ,  $\text{M} = \text{Co}$ ). This suggestion needs to be verified, since it was two six-membered metallacycles that were revealed in a similar nickel complex using X-ray diffraction,<sup>428</sup> while five- and a six-membered metallacycles were shown to co-exist in a chelate with  $X = \text{NTs}$ .<sup>429</sup> Six-membered metallacyclic structures are also realised in coordination compounds based on hydroxyaromatic azo-compounds **230** ( $X = \text{O}$ ,  $\text{M} = \text{Ni}$ ,<sup>430</sup>  $\text{Cu}$ ,<sup>431</sup>  $\text{Pt}$ <sup>432</sup>).

Typically, complexes **230** have *trans*-planar structures; however, in the case of a Pt-complex it was possible to isolate and determine the structure of the *cis*-isomer **232**.<sup>432</sup>

The formation of six-membered chelate structures is also typical of nickel complexes with aminoazo-ligands of the pyrazole series **231** ( $X = \text{NR}^4$ ,  $\text{M} = \text{Ni}$ ).<sup>425, 433</sup>

According to the <sup>1</sup>H NMR data and measurements of the dipole and magnetic moments, nickel pyrazole complexes (**231**,

$X = \text{O}$ ,  $\text{R}^1, \text{R}^2, \text{R}^3 = \text{Alk}$ ,  $\text{Ar}$ ) adopt tetrahedral structures in solution and the crystalline state.<sup>434</sup> According to X-ray diffraction data, the copper complex **231** ( $\text{M} = \text{Cu}$ ,  $n = 2$ ,  $\text{R}^1 = \text{R}^2 = \text{Ph}$ ,  $\text{R}^3 = \text{Me}$ ) is characterised<sup>435</sup> by planar structure, whereas the corresponding zinc complex is pseudotetrahedral; octahedral structures are observed for cobalt and nickel complexes ( $[\text{CoL}_3] \cdot 3 \text{ MeOH}$ ,  $[\text{NiL}_2] \cdot 2 \text{ MeOH}$ ;  $\text{LH}$  is the ligand **220**). The octahedral structure is also realised in the chelate **233**.<sup>436</sup>

Complexes with ligand **227** ( $X = \text{S}$ ) can contain two five-membered metallacycles (compound **234**)<sup>437–441</sup> or a five- and a six-membered (compound **235**)<sup>411, 442</sup> metallacycle (intrachelate isomerism).

$\text{M} = \text{Ni}$ ,  $\text{Zn}$ .

Meanwhile, chelates based on 4-azo-derivatives of pyrazole-5-thione (**228**,  $X = \text{S}$ ) contain only six-membered metallacycles, as in complex **236**.<sup>443, 444</sup>

$\text{M} = \text{Zn}$ ,  $n = 2$  (**a**);  $\text{M} = \text{Ru}$ ;  $n = 3$  (**b**).

Chelates based on aromatic azo-compounds **227** with coordinatively active substituents ( $\text{R}^1$  is a derivative of a nitrogen heterocycle  $\text{Het}$ ) manifest intrachelate isomerism due to the possibility of the closure of metallacycles with different numbers of atoms. For instance, complexes **237a,b** synthesised based on aminoazo-ligands of the type **227** contain two five-membered metallacycles **187**,<sup>445, 446</sup> as evidenced by X-ray diffraction.

$\text{M} = \text{Pd}$ ,  $n = 1$ ,  $\text{R} = \text{OAc}$  (**a**);  $\text{M} = \text{Ni}$ ,  $n = 2$ , no  $\text{R}$  (**b**).

Pyrazole aza-ligands of the type **228** ( $X = \text{O}$ ,  $\text{S}$ ;  $\text{R} = 8\text{-quinolyl}$ ) form five- and six-membered metallacycles (compounds **238** and **239**)<sup>447</sup> upon coordination with metal atoms.

The structure of complex **239** was confirmed by X-ray diffraction.<sup>447</sup>

## VII. Conclusion

The ligand systems discussed in the present review are widely employed in the synthesis of typical metal chelate complexes. These complexes contain the ligands in the deprotonated ( $L^-$ ) form with delocalised intrachelate bonds. The involvement of the protonated ligand (LH) in coordination with a metal atom gives rise to molecular complexes containing the ligand in a non-standard tautomeric form. The experimental evidence summarised above implies that coordination with a metal represents an efficient means for stabilisation of non-standard tautomeric forms of these chelating ligand systems.<sup>27–30, 58</sup>

To intensify research in the field of coordination-dependent stabilisation of tautomers, it would be desirable to extend the range of prototropic ligand systems under study.<sup>34, 35, 448</sup> In addition to the chelating ligands mentioned in the present review, heterocyclic amino-, hydroxy- and thio-derivatives<sup>6, 28, 326, 327, 449–452</sup> as well as tosylamino-<sup>453</sup> and hydroxy-phenylazines<sup>454, 455</sup> can be considered. Taking into account that complex formation can stabilise not only prototropic but other tautomeric forms as well, the range of ligand systems can be extended to include those manifesting elementotropic (see Section III.4), photo- and thermochromic (see Section V), ring-chain (see Section V) and azido-tetrazole<sup>6</sup> tautomerism. Studies of such tautomeric systems are still in the maturation stage.

The competitive coordination (see Ref. 326) and stabilisation of non-classical organometallic structures are worth special attention.

The review was written with financial support from the Ministry for Education of the Russian Federation (Project NSH-945.2003.3), the programme 'Universities of Russia' (Project UR 05.01.028) and the Russian Foundation for Basic Research (Project Nos 03-03-32842 and 04-03-96805).

**Abstract.** Data on methods of synthesis, physicochemical characteristics, reactivity and biological activities of isomeric thienothiophenes and their analogues and some of their properties of practical importance are summarised and analysed. The present review covers the last 25 years. The bibliography includes 417 references.

## I. Introduction

In the last 25 years, annelated heterocyclic systems have attracted considerable attention both from a theoretical standpoint and in view of their various practical applications. This interest is evidenced by a sharply increasing number of publications devoted to various aspects of the chemistry of fused thiophenes. For example, about 300 papers have been published during 90 years since the discovery of thienothiophenes (in 1886)<sup>1</sup> up to the publication of the most recent reviews devoted to this field of chemistry,<sup>2–5</sup> whereas the number of such papers has considerably increased in the last 10–15 years. The character of publications has also changed. In recent years, procedures for the synthesis of annelated derivatives and the physicochemical properties, reactivity and potentially useful properties of isomeric thienothiophenes and their analogues have attracted growing interest. In particular, the percentage of studies on practical applications of such systems exceeded 30% of the total number of publications. To represent information on the chemistry of this class of fused heterocycles in more detail, it is worthwhile to discuss not only investigations performed in the last decade but also earlier studies, which have not been included in the latest review<sup>2</sup> on this problem or those reported more recently.

## II. Methods of synthesis

Data presented in this Section are classified according to the nature of the starting compounds involved in the synthesis of isomeric thienothiophenes.

V P Litvinov N D Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Leninsky prosp. 47, 119991 Moscow, Russian Federation. Fax (7-095) 135 53 28, tel. (7-095) 135 88 37, e-mail: vpl@ioc.ac.ru

Compounds characterised by three modes of fusion of the thiophene rings, *viz.*, [2,3-*b*] (structure **A**), [3,2-*b*] (**B**) and [3,4-*b*] (**C**), have attracted most attention. These isomers are referred to as conventional (or classical) thienothiophenes, because structures of the type **D** ([3,4-*c*]-fusion) are much less accessible.

For isomeric thienothiophenes, both general methods of synthesis and original procedures applicable only to the preparation of particular types of compounds have been developed. In recent years, along with conventional methods based on thiophene derivatives as substrates, other approaches using, in particular, cyclopropenethiones, dithiynes and dithiolium salts have been successfully designed. Special sections in the review deal with high-temperature synthesis of annelated thienothiophenes and procedures used for the preparation of particular representatives of this class of heterocycles.

### 1. Thiophene derivatives in the synthesis of thienothiophenes

Bromine derivatives of thiophene are most widely used for the preparation of isomeric thienothiophenes and related systems. A classical example of this approach is illustrated by the following transformation sequence: formylation of 3,4-dibromothiophene (**1**) through a lithium derivative, repeated metallation and treatment with elemental sulfur and methyl bromoacetate. The closure of the second heterocycle occurs in the presence of sodium alkoxide. Decarboxylation of the resulting 4-bromothiopheno[2,3-*b*]thiophene-2-carboxylic acid (**2a**) affords 3-bromothiopheno[2,3-*b*]thiophene (**3a**).<sup>6</sup> The reaction with the use of selenium instead of sulfur produced 4-bromoselenopheno[2,3-*b*]thiophene-2-carboxylic acid (**2b**) and 4-bromoselenopheno[2,3-*b*]thiophene (**3b**).

† Dedicated to Academician Yuriy Bubnov on the occasion of his 70th birthday.

Scheme 1

MPA is methylphenylformamide, Quin is quinoline.

Scheme 2

More recently, this approach was applied<sup>7</sup> to the synthesis of 3-bromothiopheno[3,2-*b*]thiophene (**4**). It should be noted that bromothiophenothiophenes have considerable synthetic potential for transformations into various functional derivatives and synthesis of polyannulated thiophenes. For example, treatment of bromide **4** with Bu<sup>n</sup>Li and then with di(3-thienyl) disulfide affords sulfide **5**. Oxidative cyclisation of the latter gives tetrathienocene **6**. Penta-thienocene **7** was prepared according to an analogous scheme (Scheme 1).

Three approaches to the synthesis of dithieno[2,3-*b*:3',2'-*d*]thiophene (**10**) and dithieno[3,4-*b*:3',4'-*d*]thiophene (**11**) starting from di(bromothieryl) sulfides **8** and **9** were developed.<sup>8,9</sup> One procedure (conditions *a*) involves cyclisation of sulfides **8** and **9** with hexamethyldistannane catalysed by a palladium complex. Two other procedures involve lithiation, the formation of organo-copper (conditions *b*, *c*, *e*) or organozinc (conditions *b*, *d*, *e*) derivatives and their oxidation by molecular oxygen (Scheme 2).

Bromine-substituted thiophenecarbaldehydes were used as the starting compounds in the synthesis of isomeric thienothiophenes.<sup>10</sup> The second sulfur-containing ring can be constructed using ethyl thioglycolate (**12**). The reactions of 3-bromine-substituted thiophene-2-carbaldehydes **13–15** with ester **12** are most often carried out in DMF in the presence of K<sub>2</sub>CO<sub>3</sub> as a base.<sup>10–15</sup> These reactions produce thieno[3,2-*b*]thiophene-5-carboxylates **16–18**, whose yields vary substantially depending on the structure of the starting aldehyde. The reaction of 3,4,5-tribromo derivative **15** with ethyl thioglycolate **12** was studied under different conditions. It should be noted that the reaction in boiling anhydrous ethanol in the presence of EtONa afforded ethyl 2,3-dibromothiopheno[3,2-*b*]thiophene-5-carboxylate (**18**), whereas the reaction in the presence of even traces of water *in situ* was accompanied by hydrolysis of ester **18** to the corresponding carboxylic acid. In

Analogously, thienothiophene systems **21** and **22** were derived from thiophene-3-carbaldehydes **19** and **20**, respectively<sup>10</sup> (cf. Ref. 16). Compounds **18**, **21** and **22** provide examples of isomeric thienothiophenes, which were prepared according to the same procedure but are characterised by different modes of fusion of the five-membered sulfur-containing heteroaromatic rings.

3-Bromothiophene-2-carbaldehyde **13a** served also as the starting compound in the synthesis of thieno[3,2-*b*]thiophene **23** containing the mercaptopropyl substituent.<sup>17</sup>

6-Bromo-5-methyl-3-trifluoromethylthieno[3,2-*b*]thiophene-2-carboxylic acid (**24**) was synthesised by the reaction of dibromo-substituted thienyl ketone **25** with ethyl thioglycolate **12** in an ethanolic solution of sodium alkoxide.

Under analogous conditions, the reaction with 2-mercapto-methylbenzothiazole afforded the corresponding 2-(benzothiazol-2-yl)thieno[3,2-*b*]thiophene derivative **26**.<sup>14, 15</sup>

Treatment of 3,3'-dibromo-5,5'-dimethyl-2,2'-bithiophene (**27**) with  $\text{Bu}^n\text{Li}$  and then with elemental sulfur produced 3-bromo-3'-mercapto-5,5'-dimethyl-2,2'-bithiophene (**28**). In the presence of  $\text{Cu}_2\text{O}$  and alkali, the latter undergoes cyclisation to 2,6-dimethyldithieno[3,2-*b*:2',3'-*d'*]thiophene (**29**).<sup>14, 18</sup> Compounds **26** and **29** were used to design new photochromic substances.<sup>14, 15, 18</sup>

(a)  $\text{Bu}^n\text{Li}$ ,  $\text{C}_6\text{H}_{14}$ ,  $-70^\circ\text{C}$ ; (b)  $\text{S}_8$ ,  $-35^\circ\text{C}$ ; (c)  $\text{Cu}_2\text{O}$ ,  $\text{KOH}$ ,  $\text{DMF}$ .

An analogous method was used<sup>19</sup> to introduce the thiol group into 3-bromothiophene **30** in the synthesis of 3-hydroxy-thieno[3,2-*b*]thiophene (**31**).

(a)  $\text{Bu}^n\text{Li}$ ,  $-70^\circ\text{C}$ ; (b)  $\text{S}_8$ ,  $-70^\circ\text{C}$ , 20%  $\text{NH}_4\text{Cl}$ ; (c)  $\text{ClCH}_2\text{CO}_2\text{H}$ ,  $40-45^\circ\text{C}$ ; (d)  $\text{H}_2\text{SO}_4$ ,  $95-100^\circ\text{C}$ .

Procedures were developed<sup>20-22</sup> for the preparation of isomeric thienothiophenes **32-34** by cyclisation of methyl  $\gamma$ -thienylthioacetates **35a,b** derived from substituted 3-bromothiophenes. Cyclisation occurs in chlorobenzene in the presence of polyphosphoric acid (PPA).

$\text{R}^1 = \text{Me}$ ,  $\text{Et}$ ;  $\text{R}^2 = \text{Me}$ ,  $\text{OMe}$ ;  $\text{R}^3 = \text{H}$ ,  $\text{Et}$ .

Acylation of thienothiophene derivatives **32** and **33** in an aliphatic acid anhydride–70% perchloric acid system was demonstrated to give the corresponding pyrylium salts **36** (for compounds **32**,  $\text{R}^2 = \text{Me}$ ).

$\text{R}^1 = \text{Me}$ ,  $\text{Et}$ .

The synthesis of isomeric thienothiophenes and benzothienothiophenes was successfully carried out starting from thiophene-carbaldehydes and their derivatives. Treatment of 2-mercapto-3-(3-thienyl)acrylic acid (**37**), which was prepared in quantitative yield from thiophene-3-carbaldehyde (**38**) and 2-thioxothiazolidin-4-one (**39**) through intermediate **40**, with two equivalents of iodine in dioxane afforded thieno[2,3-*b*]thiophene-2-carboxylic acid (**41**).<sup>23</sup>

Condensation of thiophene-3-carbaldehyde **38** with malonic acid (Doebner reaction) in a mixture of pyridine (Py) and piperidine (Pip) performed with heating affords (*E*)-3-(3-thienyl)acrylic acid (**42**), whose treatment with thionyl chloride in pyridine produces 3-chlorothiopheno[2,3-*b*]thiophene-2-carboxylic acid chloride (**43**).<sup>24,25</sup> Analogously, 3,5-dichlorothiopheno[3,2-*b*]thiophene-2-carboxylic acid chloride was prepared from thiophene-2-carbaldehyde.<sup>24–26</sup>

The same methodology was employed in the synthesis of a more complex heterocyclic system, *viz.*, 3-chloro-6-methoxycarbonylnaphtho[2',1':2,3-*b*]thieno[4,5-*d*]thiophene-2-carboxylic acid chloride (**44**). Annulated thiophenecarbaldehyde **45** reacts with malonic acid in boiling pyridine containing two drops of piperidine to give unsaturated acid **46**, which undergoes cyclisation to acid chloride **44** upon mixing with thionyl chloride in chlorobenzene with a small admixture of pyridine.<sup>27</sup>

3-Chloro-5-dichloromethylthieno[3,2-*b*]thiophene-2-carboxylic acid chloride (**47**) was synthesised by the reaction of thionyl chloride in pyridine with 5-formylthiophen-2-ylacrylic acid **48**.<sup>28</sup> 3-Chloro-5-dichloromethylthieno[2,3-*b*]thiophene-2-carboxylic acid chloride (**50**) was prepared analogously starting from isomer **49**.

X = CH=CHCO<sub>2</sub>H, Y = H (**48**); X = H, Y = CH=CHCO<sub>2</sub>H (**49**).

This method was applied to the synthesis of dithienothiophenes **51–53** from isomeric thiophenediacrylic acids (20%–40% yields).

The synthesis of thieno[3,2-*b*]thiophenes and their benzo- and naphthoannelated analogues was carried out starting from 4-chloro-5-formylthiophene-3-carboxylic esters. For example, the reaction of 2-substituted ethyl 4-chloro-5-formylthiophene-3-carboxylates **54a,b** with ethyl thioglycolate **12** afforded the corresponding thieno[3,2-*b*]thiophene derivatives **55a,b** in rather high yields.<sup>29,30</sup>

R = Me (**a**), PhNH (**b**).

An analogous approach was employed in the synthesis of benzo[*b*]thieno[3,2-*b*]thiophene-2-carboxylic acid (**56**) and naphtho[2,3-*b*]thieno[3,2-*b*]thiophene-2-carboxylic acid (**59**) from substituted benzo[*b*]thiophene-2-carbaldehyde **57**<sup>31</sup> (through thioglycolic acid derivative **58**) and naphtho[2,3-*b*]thiophene-2-carbaldehyde **60**, respectively.<sup>32</sup>

(a) HSCH<sub>2</sub>CO<sub>2</sub>H; (b) 30% KOH, 80–90 °C, 30 min.

Substituted thiophenecarbaldehydes were also used in the synthesis of thienothiophene-related systems. For example, cyclisation of thiophene-containing methyl selenylacetate **61** in the presence of EtONa in ethanol afforded selenopheno[3,2-*b*]thiophene-5-carboxylic acid (**62**).<sup>33,34</sup>

Furo-, pyrrolo-, selenopheno- and thieno[2,3-*b*]thiophene-2-carboxylic acids **64** were synthesised from various heterocyclic 2-chalcogenoacetic acids **63**.<sup>35</sup>

X = NMe, O, S; Y = S, Se.

Cyclisation of isomeric thiophenes **65** and **66** containing the aldehyde function and the SCH<sub>2</sub>CO<sub>2</sub>Me group at positions 2 and 3 by the reactions with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) affords methyl thieno[2,3-*b*]thiophene-2-carboxylates (**67**) and -[3,2-*b*]thiophene-2-carboxylates (**68**), respectively.<sup>36</sup>

X = SCH<sub>2</sub>CO<sub>2</sub>Me, Y = CHO (**65**);

X = CHO, Y = SCH<sub>2</sub>CO<sub>2</sub>Me (**66**).

Intramolecular condensation was used also in the synthesis of more complex substances, including thienothiophenes containing various functional groups. The ester and nitrile functions can serve as the 'carbonyl component'.<sup>37,38</sup> Among examples of the synthesis of the thienothiophene system, worthy of mention is the transformation of thiophene-4-carbonitrile **69** in the reaction with KOH giving rise to 3,4-diamino-2,5-di[amino(cyanoimine)methyl]thieno[2,3-*b*]thiophene (**70**), which is cyclised to symmetrical tetracycle **71**.<sup>39,40</sup>

Thiophene derivatives were also used in the synthesis of derivatives of the fourth, the so-called non-classical, isomer of thienothiophene, *viz.*, thieno[3,4-*c*]thiophene.<sup>41,42</sup> For example, the reaction of a sodium salt of dithenoylmethane (**72**) and bromodithenoylmethane (**73**) in acetone produced 1,1,2,2-tetra-2-thenylethane (**74**). Sulfonation of the latter with Lawesson's reagent (RL) in boiling xylene afforded a mixture of two stereoisomeric 1,3-dihydrothieno[3,4-*c*]thiophenes (**75**). This mixture was oxidised without purification and then chromatographed on silica gel (CCl<sub>4</sub> as the eluent) to isolate individual *cis*- and *trans*-sulfoxides **76**. Dehydration of an unseparated mixture of isomers **76** in boiling acetic anhydride under nitrogen produced 1,3,4,6-

tetra-2-thienylthieno[3,4-*c*]thiophene (**77**) in 84% yield, whereas the yield of the product in an analogous transformation of the *cis*-isomer of **76** decreased to 68%.<sup>41</sup>

Unsubstituted thieno[3,4-*c*]thiophene was synthesised for the first time by Pummerer dehydration of 1*H*,3*H*-thieno[3,4-*c*]thiophene 2-oxide (**78**).<sup>42</sup> This compound was characterised using chemical traps (for example, as adduct **79** with *N*-phenylmaleimide).<sup>43</sup>

The reaction of thienyldinitrile **80** with thionyl chloride in the presence of triethylamine gives thieno[3,4-*c*]thiophene **81** containing only electron-withdrawing substituents.<sup>44,45</sup> This compound is very stable in the solid state.

Multistep syntheses involving aldol condensation of thiophene-3-carbaldehyde **38** with malonic acid or the Heck reaction using 3-bromothiophene **30** or 4-bromothiophene-2-carboxylate produced thieno[3',2':4,5]thieno[2,3-*c*]quinolones **82**, which exhibit high antitumour activity.<sup>46</sup>

R<sup>1</sup> = H, MeO<sub>2</sub>C, Me<sub>2</sub>N(CH<sub>2</sub>)<sub>3</sub>NH, Me<sub>2</sub>N(CH<sub>2</sub>)<sub>3</sub>NPh;  
R<sup>2</sup> = H, Me<sub>2</sub>N(CH<sub>2</sub>)<sub>3</sub>.

Benzothiophenes **83** containing the tertiary alcoholic group undergo cyclisation in the presence of thionyl chloride.<sup>47</sup> The reaction affords benzo[*b*]thieno[3,2-*b*]thiophenes **84**.

R = Pr<sup>i</sup>, Bu<sup>t</sup>.

Isomeric thienothiophenes can also be synthesised from other thiophene derivatives. In the studies of the 3,3-sigmatropic rearrangement of allyl 2-thienyl sulfide (**85**), 2-methylthieno[2,3-*b*]thiophene (**86**) and 3-chloro-3,4-dihydro-2*H*-thieno[2,3-*b*]thiopyran (**87**) were isolated from the reaction mixture in a total yield of up to 60%.<sup>48–50</sup>

Refluxing of sulfur-containing tricyclic dinitrile **88** in xylene was found to give 3*a*,5-dimethyl-3*aH*-6,7,8,9-tetrahydrobenzo[*c*]thieno[3,2-*b*]thiophene (**89**).<sup>51</sup>

Analysis of the above methods for the synthesis of thienothiophenes and their analogues based on thiophene derivatives demonstrates that mono- and dibromo-substituted thiophenes are most often and successfully used as the starting compounds. It should be noted that intramolecular cyclisation of compounds derived from the above-mentioned thiophenes serves as the key step in this approach. In this step, vicinal carbonyl functions (generally, formyl or acyl) interact with fragments containing the activated methylene group.

## 2. Cyclopropenethiones in the synthesis of thienothiophenes

Cyclopropenethiones are transformed into thienothiophenes both under irradiation and on heating. However, this method has not received wide acceptance because the starting compounds are difficult to prepare and also because of low yields of the desired products.

Photodimerisation of 2,3-diphenylcyclopropenethione (**90**) in benzene<sup>52</sup> occurs regioselectively to give the expected 2,3,5,6-tetraphenylthieno[3,2-*b*]thiophene (**91**). This reaction in methanol

afforded methyl 1-methoxy-2-phenylthiocinnamate (**92**) as the major product; in addition, thienothiophene **91** and 3,4-diphenyl-2-methoxythiethane (**93**) were isolated as by-products.<sup>53, 54</sup>

Refluxing of cyclopropenethione **90** with 4,5-disubstituted 1,2-dithiol-3-thiones **94** in anhydrous benzene in the dark is accompanied by elimination of two sulfur atoms to form thieno[3,2-*b*]thiophenes **95**.<sup>55</sup>

R<sup>1</sup> = R<sup>2</sup> = Me, Ph; R<sup>1</sup>–R<sup>2</sup> = (CH<sub>2</sub>)<sub>4</sub>, (CH = CH)<sub>2</sub>.

Refluxing of 1,2-dithiole-3-thione **94** (R<sup>1</sup> = R<sup>2</sup> = Ph) with powdered copper in chlorobenzene (6.5 h) led to its cyclisation to thienothiophene **91** in 39% yield.<sup>56, 57</sup>

In the presence of triphenyl- or tributylphosphine, 2,3-di-(alkylthio)cyclopropenethiones **96** are dimerised (refluxing in benzene under nitrogen, 4 h) to 1,3,4,6-tetra(alkylthio)-thieno[3,4-*c*]thiophenes (**97**) in moderate yields.<sup>58, 59</sup> The authors of the cited study also demonstrated that thienothiophene **97** (R<sup>1</sup> = R<sup>2</sup> = Pr<sup>i</sup>) is involved in cycloaddition with dimethyl acetylenedicarboxylate (**98**) to form 5,6-dimethoxycarbonylbenzo[*c*]thiophene (**99**).

R<sup>1</sup> = Pr<sup>i</sup>, Bu<sup>t</sup>; R<sup>2</sup> = Me, Et, Pr<sup>i</sup>, Bu<sup>t</sup>.

More recently,<sup>60, 61</sup> 1,4-bis(*tert*-butylthio)-3,6-diarylthieno[3,4-*c*]thiophenes **101** were prepared by treatment of cyclopropenethiones **100** with triphenylphosphine (benzene, 50 °C, argon atmosphere).

Ar = Ph, thien-2-yl.

An analogous procedure involving the reaction of cyclopropenethiones with tributylphosphine was employed in the synthesis of substituted thieno[3,2-*b*]thiophenes.<sup>62</sup>

## 3. Dithiynes in the synthesis of thienothiophenes

The use of dithiynes for the preparation of thienothiophenes is exemplified by four types of reactions. For example, 3-methylthio-1,2-dithiolium ions **102** react with malonic acid derivatives **103** to give  $\gamma$ -dithiolydene nitriles **104** and 6-cyanothieno[3,2-*b*]thiopyranones **105**. Oxidation of the latter with H<sub>2</sub>O<sub>2</sub> in acetic acid or successive treatment of **104** and **105** with NaOH and BrCH<sub>2</sub>CN affords 2-cyanothieno[3,2-*b*]thiophenes **106**.<sup>63</sup> This method was

applied to the synthesis of a rather broad range of nitrile-containing thienothiophenes promising for further modifications.

$\text{R}^1 = \text{H, Bu, SMe, Ph, 4-MeOC}_6\text{H}_4$ ;  $\text{R}^2, \text{R}^3 = \text{Ph, 4-MeOC}_6\text{H}_4$ ;  
 $\text{X} = \text{CN, CO}_2\text{Et}$ ; (a)  $\text{H}_2\text{O}_2$ ,  $\text{AcOH}$ ; (b) 1)  $\text{NaOH}$ , 2)  $\text{BrCH}_2\text{CN}$ .

Heating of dithienoannulated 1,2-dithiynes **107a–c** with powdered copper (200 °C, 45 min) afforded dithieno[3,2-*b*:2',3'-*d*]thiophenes **108a–c**.<sup>64,65</sup> An analogous transformation of benzoannulated dithiyn **107d** [ $\text{R}-\text{R} = (\text{CH}=\text{CH})_2$ ] produced bis(benzo[4,5]thieno)[3,2-*b*:2',3'-*d*]thiophene (**108d**).<sup>66</sup>

$\text{R} = \text{H (a), Me (b), Ph (c)}$ .

Unsubstituted dithienothiophene **108a** has been synthesised earlier by treating 2,2'-dilithium 3,3'-dithienyl sulfide with copper dichloride in diethyl ether.<sup>67</sup> This method was also successfully applied to oxidative cyclisation of the corresponding dilithium dithienyl sulfide **109** giving rise to dithieno[2,3-*b*:3',4'-*d*]thiophene (**110**) (29% yield).<sup>68</sup> The above-described dithieno[2,3-*b*:3',2'-*d*]thiophene (**10**) (32%) and dithieno[3,4-*b*:3',4'-*d*]thiophene (**11**) (31%) were synthesised analogously (see Section II.1).<sup>68</sup>

Heating of a suspension of 4,5-ethylenedithio-1,2-dithiol-3-one (**111**) in trimethylphosphite under nitrogen (110 °C, 2 h) afforded 2,3:5,6-bis(ethylenedithio)thieno[3,2-*b*]thiophene (**112**).<sup>69</sup>

It should be noted that almost all the above-described reactions gave products in low yields. Hence, this approach is of theoretical rather than preparative interest.

#### 4. Carbon disulfide in the synthesis of thienothiophenes

Methods based on the reactions of carbon disulfide with compounds containing conjugated triple-bond systems or the active methylene group are rather successfully employed in the synthesis of thienothiophenes. Generally, these procedures involve many steps, which require a thorough preparation and purification of the reagents and solvents.

Unsubstituted thieno[2,3-*b*]thiophene was synthesised in satisfactory yield from trimethylsilylpenta-1,3-diyne (**113**) under very mild conditions. In this procedure, the reagents should be added in a reverse order: *n*-butyllithium is initially added to a suspension of  $\text{Bu}^t\text{OK}$  in dry THF at –100 °C followed by the addition of alkyne at –80 °C,  $\text{CS}_2$  at –100 °C and a solution of  $\text{Bu}^t\text{OH}$  in dry HMPA at –30 °C.<sup>70</sup>

In the studies,<sup>71–73</sup> a one-pot procedure was developed for the synthesis of thieno[2,3-*b*]thiophenes **114** using diynes **115** and  $\text{CS}_2$  as the building blocks (in 44%–48% yields). Allene derivative **116** was detected as an intermediate. If the trimethylsilyl group is present as a substituent at the triple bond, it is eliminated during the reaction (as in the above-considered reaction).

$\text{R}^1 = \text{Me}_3\text{Si}$  (H for **114**), Alk,  $\text{N(Alk)}_2$ , SAlk;  
 (a)  $\text{Bu}^n\text{Li}$ ,  $\text{Bu}^t\text{OK}$ , THF,  $\text{C}_6\text{H}_{14}$ ; (b)  $\text{CS}_2$ , –100 °C; (c)  $\text{Bu}^t\text{OH}$ , HMPT (HMPT is hexamethylphosphorous triamide).

A technologically convenient one-pot synthesis of 2,5-functionalised thieno[2,3-*b*]thiophenes **117** starting from 1,3-diketones was proposed. In this procedure, carbon disulfide and alkylating agents containing electron-withdrawing groups are used. The reaction proceeds either in dry DMF in the presence of anhydrous  $\text{KF}$  as a promoter for condensation (36%–67% yields)<sup>74</sup> or under phase-transfer catalysis conditions (78%–93% yields)<sup>75</sup> (see also Ref. 76).

$\text{R} = \text{Me, Ph, 4-MeC}_6\text{H}_4$  (*p*-Tol); Hal = Br, Cl; EWG = CN, Ac,  $\text{CO}_2\text{Et}$ , CONHPh, CONH-thiazol-2-yl;  
 (a)  $\text{KF}$ , DMF; (b)  $\text{K}_2\text{CO}_3$ ,  $\text{Bu}_4\text{NBr}$ , PhH,  $\text{H}_2\text{O}$ .

More recently,<sup>77</sup> this approach was extended to the synthesis of oxo- and amino-substituted thieno[2,3-*b*]thiophenes. Compounds containing the active methylene group (3-keto esters, malononitrile, ethyl cyanoacetate or 3-ketonitrile) were used as the starting reagents, and ethyl bromoacetate or bromoacetic acid

nitrile served as the alkylating agent. The yields of thienothiophenes were 61%–87%.

X = Ac, CN; Y = Me, NH<sub>2</sub>;

X = Piv, CN; Y = Bu<sup>t</sup>, NH<sub>2</sub>;

(a) CS<sub>2</sub>, K<sub>2</sub>CO<sub>3</sub>, DMF; (b) BrCH<sub>2</sub>CO<sub>2</sub>Et (2 equiv.); (c) BrCH<sub>2</sub>CN (2 equiv.); Piv = Bu<sup>t</sup>C(O).

The reactions of carbon disulfide with malononitrile in the presence of sodium methoxide in methanol followed by treatment of the resulting dicyanodithioacetate **118** with  $\gamma$ -bromocrotonic acid derivatives can also be assigned to this reaction type.<sup>78</sup> These reactions give diamino-substituted thienothiophenes **119** as the final products.

X = CN, CO<sub>2</sub>Me; (a) MeONa, MeOH.

Dinitrile **118** was also used in the synthesis of other thieno[2,3-*b*]thiophene derivatives.<sup>79</sup> Various tri- and tetrasubstituted thieno[2,3-*b*]thiophenes were prepared according to modifications of this procedure.<sup>80–83</sup>

The synthesis of *peri*-substituted 3,4-diarylthienothiophene **120** from (4-MeC<sub>6</sub>H<sub>4</sub>CH<sub>2</sub>)<sub>2</sub>CO through the corresponding ketene dithioacetal, Dieckmann cyclisation, hydrolysis and decarboxylation was described in the study.<sup>84</sup>

## 5. High-temperature synthesis

High-temperature synthesis of sulfur-containing heteroaromatic systems has attracted attention of researchers (predominantly, of Russian scientists) in the last 30 years. This method assumes the use of both a broad range of the starting substrates (aliphatic, aromatic, heteroaromatic compounds) and various sulfur donors (elemental sulfur, hydrogen sulfide, dialkyl sulfides).

Friedmann was the first to describe the formation of thienothiophenes under pyrolysis conditions in 1916.<sup>85–88</sup> The reaction of aliphatic or aromatic hydrocarbons with sulfur proceeds at 270–320 °C and high pressure. More recently, this method was applied to the synthesis of benzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophene (**121**) in yields of up to 50% starting from benzyl bromide

and its derivatives,<sup>89,90</sup> 1,2,3-trichloro-1,2-diphenylethane<sup>91</sup> or *o*-halotoluenes<sup>92</sup> at 200–280 °C. Compound **121** was also prepared in 36% yield by tandem radical cyclisation of 2-methylthiophenyl-substituted phosphorus ylide **122** under conditions of flash vacuum pyrolysis at 850 °C.<sup>93,94</sup>

In addition, thienothiophene **121** was synthesised by gas-phase pyrolysis of benzotrichloride at 400 °C in a hydrogen sulfide atmosphere (67% yield).<sup>95</sup>

1,2-Dichloroethylene reacts with hydrogen sulfide in the gas phase at 420–520 °C in a quartz tube. The reaction produced a complex mixture, in which thieno[2,3-*b*]thiophene and thieno[3,2-*b*]thiophene were detected (in a total yield of 4.5%).<sup>96,97</sup> Thieno[2,3-*b*]thiophene was prepared by the gas-phase reaction of 2-chlorothiophene with hydrogen sulfide and acetylene at 600 °C.<sup>98</sup> The reaction with the use of dimethyl selenide instead of acetylene afforded a mixture of dithienothiophene **108a** and dithieno[3,2-*b*;2,3-*d*]thiophene (**123**) (3% yield).<sup>99</sup> The formation of dithienothiophene **10** along with other products was observed upon thermolysis (500–600 °C) of 2,2'-dithienyl sulfide under an atmosphere of nitrogen and hydrogen sulfide,<sup>100</sup> whereas dithienothiophenes **10** and **108a** were generated in a hydrogen sulfide atmosphere.<sup>101</sup>

Thieno[2,3-*b*]thiophene was also prepared by the high-temperature reaction of 2-chlorothiophene with acetylene and hydrogen sulfide<sup>102,103</sup> or dimethyl sulfide<sup>103</sup> and by the reaction of thiophene-2-thiol with acetylene.<sup>104</sup> An analogous reaction of 2-chlorothiophene with a mixture of diethyl di- and trisulfides produces a mixture of thieno[2,3-*b*]thiophene and thieno[3,2-*b*]thiophene in 10%–32% yields.<sup>105</sup> This reaction in the presence of acetylene affords a mixture of thienothiophenes in somewhat higher yield (36%).<sup>106</sup>

A mixture of thiophene and isomeric thienothiophenes (in a total yield of 85%) was prepared by the gas-phase reaction of dimethyl sulfide, diethyl disulfide, diethyl trisulfide and diethyl tetrasulfide with acetylene.<sup>107</sup> It was also found that gaseous allyl 2-thienyl sulfide is transformed into a mixture of thiophene-2-thiol, bis(2-thienyl) sulfide and 2-methylthieno[2,3-*b*]thiophene at 350–410 °C; in the presence of acetylene, the reaction gives these products along with thieno[2,3-*b*]thiophene.<sup>108</sup> Thermolysis (at 540 °C) of a mixture of di(prop-1-enyl) sulfide and 2-chloro(or bromo)thiophene affords a mixture of thieno[2,3-*b*]thiophene and thieno[3,2-*b*]thiophene.<sup>109</sup>

Therefore, the advantage of this method is that the starting compounds are readily available. Among the drawbacks are the necessity of using special apparatus, the formation of a large number of by-products in almost all reactions and low yields of the desired compounds.

## 6. Other methods for the synthesis of thienothiophenes and their analogues

There are a few original procedures, which were used to prepare particular representatives of this class of heterocyclic compounds and their selenium and tellurium-containing analogues. The most interesting procedures are considered below.

Among other approaches to the synthesis of thienothiophenes, worthy of mention are the Pummerer rearrangement of disulfoxide **124** giving a mixture of 2-acetylthieno[3,2-*b*]thiophenes **125a,b**<sup>110</sup> and the reaction of 2,4,5,7-tetrabromo-2,7-dimethyl-3,6-octanedione (**126**) with sodium sulfide hydrate yielding 2,2,5,5-tetramethyl-2,3,5,6-tetrahydrothieno[3,2-*b*]thiophene-3,6-dione (**127**).<sup>111</sup>

Substituted tetrahydrothieno[3,4-*c*]thiophene (**128a**) and its selenium analogue (**128b**) were synthesised by the reactions of lithium methoxide with γ,γ-dimethylallenyl thio(or seleno)cyanates **129a,b**.<sup>112–114</sup> The multistep mechanism of this reaction involves the formation of bis(dimethylallenyl) chalcogenides **130a,b** as the key intermediates, which undergo successive [3,3]-sigmatropic rearrangement and double Michael addition of a chalcogen-containing group.

X = S (**a**), Se (**b**).

A new procedure was developed for the synthesis of benzoan-related thienothiophene based on reduction of stilbene-2,2'-disulfochloride (**131**) with concentrated hydroiodic acid in acetic acid.<sup>115–118</sup> This approach is applicable also to the synthesis of 2,7-disubstituted derivatives of thienothiophenes **121** starting from the corresponding 4,4'-disubstituted disulfochlorides.

Diethyl 2,2'-dinitro-(*E*)-stilbene-4,4'-dicarboxylate **132** proved to be a convenient starting compound in the synthesis of diethyl benzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophene-2,7-dicarboxylate (**133**) and its selenium analogue **134** (Scheme 3).<sup>119</sup>

Sulfur-, selenium- and tellurium-containing heteroaromatic systems **121**, **135** and **136** were prepared by successive treatment of 2,2'-dibromodiphenylacetylene (**137**) with *tert*-butyllithium and chalcogens in anhydrous tetrahydrofuran at –80 °C under argon.<sup>120</sup>

X = S (**121**, 49%), Se (**135**, 52%), Te (**136**, 55%);  
(a) Bu<sup>t</sup>Li, THF, –80 °C, Ar; (b) chalcogen (S, Se or Te).

A selenium modification of the Claisen rearrangement of propargylselenochalcogenophenes was employed in the synthesis of fused bicyclic systems, *viz.*, thieno[2,3-*b*]-2*H*-selenopyran, thieno[3,2-*b*]-2*H*-selenopyran, 5-methylselenopheno[2,3-*b*]telluraphene and 5-methylselenopheno[3,2-*b*]thiophene.<sup>121</sup>

The reactions of sulfur with dimethylformamide dimethylacetal<sup>122</sup> and 2,5-dimethylhex-3-yne-2,5-diol<sup>123</sup> give substituted thieno[3,2-*b*]thiophenes.

The reaction of sulfenamide **138** with two equivalents of aluminium chloride produces 3-chloro-2-methylthieno[3,2-*b*]thiophene (**139**) in satisfactory yield.<sup>124</sup>

Scheme 3

Methyl 3-hydroxythieno[2,3-*b*]thiophene-2-carboxylates were also synthesised by cyclisation of substituted methyl 3-hydroxythiophene-2-carboxylates.<sup>125</sup>

Therefore, the above data demonstrates the diversity of synthetic approaches to thienothiophene derivatives.

### III. Reactivity and chemical transformations

Heteroatoms in the five-membered  $\pi$ -excessive heteroaromatic compounds are responsible for the chemical behaviour of the molecules as a whole. The heteroatoms not only give electrons to form an aromatic  $\pi$ -electron system but also determine the direction of the attack of electrophilic or nucleophilic agents. In fused  $\pi$ -excessive heterocycles containing two or more heteroatoms, the reactivity of compounds and their physical properties are substantially affected by both the mutual arrangement of the heteroatoms and the electronic effects associated with their nature.

#### 1. Reactivity

First studies of the reactivity of thienothiophenes and their analogues by quantum-chemical methods were carried out in the mid-1970s.<sup>2, 5, 126</sup> More recently,<sup>127, 128</sup> the reactivity of thiophene, selenophene, various isomeric thienothiophenes, selenophenothiophenes, selenophenoselenophenes and their various C-protonated forms ( $\sigma$  complexes) in electrophilic substitution reactions was estimated by the semiempirical LCAO SCF MO method for all valence electrons (CNDO/2). The charges on the carbon atoms  $Q_c$  (static index) and the localisation energy  $A^+$  (dynamic index; in the CNDO/2 approximation, this index is determined as  $A^+ = E_{\text{total}}M - E_{\text{total}}MH^+$ , where  $E_{\text{total}}M$  and  $E_{\text{total}}MH^+$  are the total energies of the aromatic molecule and its  $\sigma$  complex with a proton, respectively) were used as the reactivity indices. The method of reactivity indices supplemented by a 'pseudoatom' approach (pseudoatoms simulate an electrophilic agent) provides a correct interpretation of experimental data on electrophilic substitution in fused heteroaromatic systems containing various heteroatoms. In addition, the values of  $Q_c$  and  $A^+$  (relative to position 3 in thiophene) indicate that the direction of electrophilic attack depends on the nature and size of the attacking species. This effect is mainly responsible for the difference in the reactivity of substrates.

The results of calculations made it possible to arrange the relative reactivities of different positions in compounds **140–151** in electrophilic substitution reactions in the following theoretical series: C(4) (**150**) > C(4) (**148**) > C(4) (**151**) > C(4) (**149**) > C(6) (**150**) > C(6) (**148**) > C(6) (**151**) > C(6) (**149**) > C(2) (**146**) > C(2) (**145**) > C(5) (**146**) > C(2) (**147**) > C(2) (**143**) > C(2) (**149**) > C(2) (**142**) > C(2) (**148**) > C(2) (**144**) > C(2) (**151**) > C(5) (**143**) > C(2) (**150**) > C(2) (**140**) > C(2) (**141**) > C(3) (**149**) > C(3) (**143**) > C(3) (**148**) > C(3) (**144**) > C(3) (**151**) > C(3) (**142**) > C(3) (**150**) > C(4) (**143**) > C(3) (**146**) > C(3) (**145**) > C(3) (**147**) > C(6) (**146**) > C(3) (**147**) > C(3) (**140**).<sup>5</sup> This series was confirmed experimentally. For example, the following series of reactivities of different positions in these compounds was obtained in studies of acetylation, formylation and chlorination of thiophene (**140**), thieno[2,3-*b*]thiophene (**142**) and thieno[3,2-*b*]thiophene (**145**): C(2) (**145**) > C(2) (**142**) > C(2) (**140**) > C(3)

(**142**) > C(3) (**145**) > C(3) (**140**).<sup>129</sup> In formylation, position 4 in thieno[3,4-*b*]thiophene (**148**) was found<sup>130</sup> to be more readily subjected to the attack of an electrophilic species compared to position 6.

The detritiation rate was studied for thieno[2,3-*b*]thiophene (**142**), thieno[3,2-*b*]thiophene (**145**), dithieno[2,3-*b*:3',2'-*d*]thiophene (**10**), dithieno[3,2-*b*:2',3'-*d*]thiophene (**108a**) and dithieno[2,3-*d*:2',3'-*d*]thiophene (**123**), which are specially labelled with the <sup>3</sup>H isotope at each position, in trifluoroacetic acid or its mixture with acetic acid.<sup>131, 132</sup> All thiophene systems were demonstrated to be rather active in electrophilic substitution reactions. The reactivity of the corresponding  $\alpha$  and  $\beta$  positions slightly increases in going from thiophene to thienothiophenes and increases to an even larger extent in going from thienothiophenes to dithienothiophenes.

The comparative reactivities in electrophilic substitution of selenopheno[3,2-*b*]thiophene (**143**) and -selenophene (**144**) with respect to thieno[3,2-*b*]thiophene (**142**) were studied by the method of competitive reactions.<sup>133</sup> The reactivity was found to change in the following order: **144** > **143** > **142**. This series agrees well with a higher substitution rate in selenophene compared to thiophene in acetylation, formylation and chlorination reactions.

Competitive metallation of two-component systems, *viz.*, thieno[3,2-*b*]thiophene (**142**) and selenopheno[3,2-*b*]thiophene (**143**), selenophenothiophene **143** and thiophene (**140**), selenophenothiophene **143** and selenophene (**141**), thiophene (**140**) and selenophene (**141**), was investigated.<sup>34</sup> The reactions were carried out with a deficient amount of Bu<sup>n</sup>Li in anhydrous diethyl ether at 25 ± 1 °C followed by hydrolysis with heavy water. Mass-spectrometric analysis of the products demonstrated that the relative reactivities of the compounds increase in the following order: **143** > **142** > **141** > **140**.<sup>34</sup>

The reactivities of thieno[2,3-*b*]thiophene (**142**) and selenopheno[2,3-*b*]thiophene (**143**) were also compared using competitive acetylation of their mixture with thiophene (**140**) or selenophene (**141**) by acetyl chloride in the presence of tin chloride (CHCl<sub>3</sub>, 25 °C).<sup>35</sup> The selenophene rings were found to be more reactive than the thiophene ring.

The above examples demonstrate that the theoretical estimates of the reactivities of the compounds in electrophilic substitution reactions most typical of aromatic systems agree well with the experimental data.

#### 2. Chemical transformations

In the last 20 years, studies of chemical transformation of isomeric thienothiophenes have been aimed primarily at examining the possibilities of using these substrates in the synthesis of new polyannellated heteroaromatic systems and compounds possessing practically useful properties. These compounds can exhibit both electron-withdrawing and electron-donating properties and they were used in the synthesis of numerous charge-transfer complexes. Thienothiophene derivatives have found application as medicines, pesticides, conducting polymers, liquid and clathrate crystals, organic conductors or superconductors, photosensitive receptors, materials for optoelectronics (nonlinear optical chromophores), dyes, *etc.* The most typical reactions of this class of compounds (metallation, condensation and photochemical cyclisations) clearly illustrate their high synthetic potential.

##### a. Metallation

Lithiation (generally, with *n*-butyllithium) is most often and successfully used in the synthesis of various functionalised thienothiophenes. The lithium intermediates thus formed can react with various electrophiles.

For example, thieno[3,2-*b*]thiophene (**142**)<sup>134–141</sup> and its alkyl derivatives<sup>136, 137, 142, 143</sup> are readily metallated with *n*-butyllithium at the  $\alpha$  position, which can be used for the preparation of  $\alpha$ -substituted thienothiophenes. This method was employed to introduce such substituents as Br,<sup>139</sup> I,<sup>134</sup> MgBr,<sup>143</sup> ZnCl, SnBu<sub>3</sub>,

$\text{B}(\text{OH})_2$ ,<sup>135</sup>  $\text{SeMe}$ ,  $\text{TeMe}$ ,<sup>136</sup>  $\text{SR}$  ( $\text{R} = \text{Me}$ ,  $n\text{-C}_{18}\text{H}_{37}$ ),<sup>137</sup>  $\text{SMe}$ ,<sup>141</sup>  $\text{SEt}$ ,<sup>142</sup>  $\text{SO}_2\text{Me}$ ,  $\text{SO}_2\text{NH}_2$ ,<sup>137</sup>  $\text{CHO}$ <sup>140</sup> and  $\text{CO}_2\text{Me}$ .<sup>137</sup>

Lithium derivatives of thieno[3,2-*b*]thiophene (**145**) were used in the synthesis of 2-arylthieno[3,2-*b*]thiophenes **152** through various organometallic (or -boron) intermediates.<sup>135</sup>

$\text{R} = \text{H}$ ,  $\text{NO}_2$ ,  $\text{CN}$ ,  $\text{CO}_2\text{Me}$ ,  $\text{SO}_2\text{Me}$ ;  $\text{Hal} = \text{Br}$ ,  $\text{I}$ .

| Method X | Reaction conditions                                      |                                                              | Yields (%) |
|----------|----------------------------------------------------------|--------------------------------------------------------------|------------|
|          | Step 1                                                   | Step 2                                                       |            |
| a        | $\text{ZnCl}$ $\text{ZnCl}_2$ , THF                      | $\text{Pd}(\text{dba})_2$ , $\text{PPh}_3$ , DMF             | 10–85      |
| b        | $\text{B}(\text{OH})_2$ $\text{B}(\text{OBu}^n)_3$ , THF | $\text{Pd}(\text{PPh}_3)_4$ , $\text{Ba}(\text{OH})_2$ , DME | 40–55      |
| c        | $\text{SnBu}_3^a$ $\text{Bu}_3^a\text{SnCl}$ , THF       | $\text{Pd}(\text{PPh}_3)_4$ , dioxane                        | < 60       |

*dba* is dibenzylideneacetone, DME is 1,2-dimethoxyethane.

Metallation of thieno[3,2-*b*]thiophene **145** with two equivalents of  $\text{Bu}^n\text{Li}$  affords the 2,5-dilithium derivative, whose treatment with various reagents [ $\text{CO}_2$ , DMF,  $(\text{MeS})_2$ ,  $(\text{PhS})_2$ ,  $(\text{Me}_3\text{Si})_2$ ,  $(\text{Bu}^t\text{Me}_2\text{Si})_2$ ] gives the corresponding disubstituted thienothiophene.<sup>15, 138, 144</sup>

Exchange halogen–lithium reactions provide an approach to thienothiophene sulfides **142** and **145**, which were used in the synthesis of tetrathienocene **6** and pentathienocene **7** (see Section II.1).<sup>7, 145</sup>

Lithium intermediates served as the starting compounds in the synthesis of the corresponding 2( $\alpha$ )- or 3( $\beta$ )-substituted derivatives of thienyl sulfides **153** and **154**, thieno[2,3-*b*]thienyl sulfides **155** and **156** and thieno[2,3-*b*]thienylthieno[2,3-*b*]thiophenes **157** and **158**.<sup>146</sup>

$\text{X} = \text{Br}$ ,  $\text{I}$ .

Lithiation of thieno[3,2-*b*]thiophenes **145a,b** gives 2-lithium derivatives, whose treatment with chalcogens and iodomethane affords chalcogenides **159**.<sup>136</sup> Vilsmeier–Haack formylation of the latter produces aldehydes **160**, whereas the reaction with tetracyanoethylene in DMF affords 5-tricyanovinyl derivatives **161**.

$\text{R} = \text{H}$  (**a**),  $\text{Me}$  (**b**);  $\text{X} = \text{S}$ ,  $\text{Se}$ ,  $\text{Te}$ .

Organolithium derivatives served as intermediates in the synthesis of 5-amino-substituted thieno[2,3-*b*] and -[3,2-*b*]thiophene-2-sulfonamides possessing biological activities. These compounds are carbonic anhydrase inhibitors (CAIs)<sup>36, 147</sup> and non-peptide fibrinogen receptor antagonists.<sup>148</sup> For example, the introduction of the sulfamoyl group into the dioxolane derivative of thieno[2,3-*b*]thiophene **162** can be efficiently performed by metallation with butyllithium at position 5 followed by treatment of the reaction mixture with  $\text{SO}_2$ , *N*-chlorosuccinimide (NCS) and ammonia. The acetal protection in the resulting 5-[1,3]dioxolan-2-ylthieno[2,3-*b*]thiophene-2-sulfonamide **163** was removed<sup>36</sup> by transacetalation giving rise to aldehyde **164** in high yield. The latter reacts with various primary and secondary amines to form imines **165** or immonium salts **166**, respectively, whose reduction with sodium borohydride affords tertiary amines **167**. Transformations of the amines into hydrochlorides **168** produced water-soluble salts, which were tested for biological activities. The same synthetic approach was applied to the synthesis of the corresponding thieno[3,2-*b*]thiophene analogues.

$\text{R}^1, \text{R}^2 = \text{H}$ , Alk.

The reaction of thieno[2,3-*b*]thiophene (**142**) with Bu<sup>n</sup>Li affords a lithium intermediate, whose treatment with elemental sulfur and bromopentane produces sulfide **169**. Regioselective *N*-sulfonation of the latter was successfully carried out by the successive reactions with Bu<sup>n</sup>Li, SO<sub>2</sub> and hydroxylamino-*O*-sulfonic acid. Selective oxidation of sulfide **170** with potassium peroxymonosulfate afforded sulfone **171**.<sup>147</sup>

(a) 1) Bu<sup>n</sup>Li, 2) S<sub>8</sub>, n-C<sub>5</sub>H<sub>11</sub>Br; (b) 1) Bu<sup>n</sup>Li, 2) SO<sub>2</sub>, 3) hydroxylamino-*O*-sulfonic acid; (c) K<sub>2</sub>SO<sub>5</sub>.

An analogous approach was employed in the synthesis of sulfonamide **172**, which is a potential non-peptide fibrinogen receptor antagonist.<sup>148</sup>

Metallation was involved also as the first step in the synthesis of di-, tri- and tetramers of 3,6-disubstituted thieno[3,2-*b*]thiophene (**145**) and selenopheno[3,2-*b*]selenophene (**147**).<sup>143</sup> These compounds are of practical interest. Many thiophene oligomers exhibit biological activity, which is enhanced upon exposure to visible light.<sup>149</sup>

Metallation of thieno[2,3-*b*]thiophene (**142**) followed by the reactions of the resulting mono- and dilithium derivatives with dimethylformamide afforded aldehydes **173** and **174**, which served as the starting compounds in the synthesis of heterohelicenes **175a,b** and **176a,b**.<sup>150</sup>

The Wittig reaction of aldehyde **173** with phosphonium salts **177a,b** gives alkenes **178a,b**, and the double Wittig reaction of dialdehyde **174** with phosphonium salts **179a,b** affords alkenes **180a,b**. Irradiation of suspensions of alkenes **178a,b** and **180a,b** in benzene in the presence of iodine produces heterohelicenes **175a,b** and **176a,b**.

With the aim of synthesising new photochromic dihetaryl-ethenes, viz., 5-substituted 1,2-bis(thieno[3,2-*b*]thiophen-3-yl)perfluorocyclopentenes **181a-c**, 2-(benzothiazol-2-yl)-6-bromo-5-

R<sup>1</sup> = R<sup>4</sup> = BTh, R<sup>2</sup> = R<sup>3</sup> = Me (a); R<sup>1</sup> = R<sup>3</sup> = BTh, R<sup>2</sup> = R<sup>4</sup> = Me (b); R<sup>2</sup> = R<sup>3</sup> = BTh, R<sup>1</sup> = R<sup>4</sup> = Me (c); BTh is benzothiazol-2-yl.

methylthieno[3,2-*b*]thiophene (**182**) was subjected to metallation. A mixture of lithium derivatives produced by this reaction was treated with octafluorocyclopentene ( $C_5F_8$ ).<sup>14, 15</sup>

The thieno[2,3-*b*]thiophene analogue of compound **181**, viz., 1,2-bis{2-ethyl-5-(benzothiazol-2-yl)thieno[2,3-*b*]thiophen-3-yl}-hexafluorocyclopentene (**183**), was synthesised according to an analogous procedure starting from (5-benzothiazol-2-yl)-3-bromo-2-ethylthieno[2,3-*b*]thiophene (**184**).<sup>151</sup>

Dithieno[3,2-*b*:2',3-*d'*]thiophene (**108a**) served as a building block in the design of photochromic materials for optical memory. Photochromic compounds **185** and **186** (Scheme 4) were prepared in satisfactory yields by successive transformations involving initial metallation of dithienothiophene **108a** with  $Bu^iLi$  at  $-78\text{ }^\circ C$ .<sup>152</sup>

Photochromic 1,2-bis(2,6-dimethylthieno[3,2-*b*:2',3'-*d'*]thiophen-3-yl)hexafluorocyclopentene (**188**) was synthesised<sup>18</sup> starting from 3-bromo-2,6-dimethylthieno[3,2-*b*:2',3'-*d'*]thiophene (**187**) according to a procedure described in the studies.<sup>14, 15</sup>

An analogous methodology was employed in the synthesis of new quadrupole photophores **189** and **190**, which have high two-photon excited fluorescence. Conjugated dithienothiophene **108a** was used as the starting compound. The reactions of dialdehyde **191** (see Ref. 153) with phosphonium salt **192** (2.1 equiv.) or

phosphonate **193** (2.2 equiv.) in the presence of phase-transfer catalysts<sup>154</sup> afforded compounds **189** and **190**, respectively, in 80%–90% yields.<sup>155</sup> After crystallisation, these compounds were isolated as pure *E* isomers.

(a)  $Bu^iLi$ , THF,  $-78\text{ }^\circ C$ ; (b) DMF,  $-78\text{ }^\circ C$ ; (c)  $4-Bu_3NC_6H_4CH_2P^+Ph_3I^-$  (**192**),  $Bu^iOK$ ,  $CH_2Cl_2$ ,  $20\text{ }^\circ C$ , 5 h; (d)  $4-F_3CC_6H_4CH_2P(O)(OEt)_2$  (**193**), NaH, THF,  $20\text{ }^\circ C$ , 24 h.

Polyfunctional thiophenes and enediynes were synthesised through the cleavage of the heterocycle in 3-lithiated thieno[2,3-*b*] and -[3,2-*b*]thiophenes, 3,4-dilithiated thieno[2,3-*b*]thiophenes and 3,6-dilithiated thieno[3,2-*b*]thiophenes.<sup>15, 156, 157</sup> For example, tetrabromothieno[3,2-*b*]thiophene (**194**)<sup>158</sup> was successively treated with two equivalents of *n*-butyllithium (THF,  $20\text{ }^\circ C$ ) and two equivalents of  $Bu^iMe_2SiCl$  to prepare dibromide **195**, which was treated with one equivalent of *n*-butyllithium. The corresponding bromothiophene **196** was isolated by flash chromatography on silica gel. Treatment of **196** with  $Bu^iLi$  (1 equiv.) and excess iodomethane afforded enediyne **197**. Both steps of ring opening can be carried out without isolation of intermediates (the so-called tandem process).<sup>157</sup>

(a) 1)  $Bu^iLi$  (2 equiv.), THF,  $20\text{ }^\circ C$ , 2)  $Bu^iMe_2SiCl$  (2 equiv.); (b)  $Bu^iLi$  (1 equiv.),  $-78\text{ }^\circ C$ ; (c)  $Bu^iLi$  (1 equiv.),  $0\text{ }^\circ C$ , MeI.

Scheme 4

(a) 1)  $Bu^iLi$ , THF  $-78\text{ }^\circ C$ ; 2)  $B(OBu^i)_3$ ; (b) 4-bromopyridine,  $Pd(PPh_3)_4$ ,  $Na_2CO_3$ ,  $H_2O-THF$ ; (c) NBS,  $CHCl_3-AcOH$ ; (d) 1,2-bis[2-hexyl-5-(dihydroxyboryl)thiophen-3-yl]hexafluorocyclopentene,  $Pd(PPh_3)_4$ ,  $Na_2CO_3$ ,  $H_2O-THF$ ; (e)  $CF_3SO_3Me$ ,  $CH_2Cl_2$ ; R = *n*-hexyl; NBS is *N*-bromosuccinimide.

The above reactions exemplify the wide range of applications of metallation of thienothiophenes, which allows one to prepare new derivatives of this class of heterocycles, including those having practically useful properties.

### b. Photocyclisation

In the last decade, photocyclisation<sup>159</sup> of thienothiophenes and their derivatives (primarily, of amides) has attracted considerable attention as a convenient method for the synthesis of sulfur-containing polyannulated heterocyclic systems.<sup>25,27,160–166</sup> Two examples of the synthesis of such compounds are given below. The reaction of aniline with 3-chlorothieno[2,3-*b*]thiophene-2-carboxylic acid chloride **43** produced *N*-phenylthieno[2,3-*b*]thiophene-2-carboxamide **198**.<sup>24,25</sup> Photocyclisation of the latter in benzene containing a small amount of triethylamine gave thieno[3',2':4,5]-thieno[2,3-*c*]quinolin-2-one (**199**), whose chlorination with POCl<sub>3</sub> afforded 6-chlorothieno[3',2':4,5]thieno[2,3-*c*]quinoline (**200**). The reaction of compound **200** with sodium methoxide produced the corresponding methoxy derivative **201**. All steps of this transformation sequence gave products in good yields.

6,9-Dichlorothieno[2',3':4,5]thieno[2,3-*c*]quinoline (**203**) was synthesised from 3,5-dichlorothieno[3,2-*b*]thiophene-2-carboxylic acid chloride (**202**). Catalytic dechlorination of **203** afforded unsubstituted thieno[2',3':4,5]thieno[2,3-*c*]quinoline (**204**).<sup>25</sup>

This procedure was employed to prepare various polyannulated thienothiophene- and benzo[*b*]thiophene-containing systems starting from thieno[2,3-*b*] and -[3,2-*b*]thiophene-2-carboxylic acid chlorides. The structures of these compounds and references to their synthesis are given below.

Dithieno[3,2-*b*:2',3'-*d*]thienyl[2'',3''-*c*:2'',3''-*c'*]-5,10-*N,N'*-dimethylquinoline-6,9-dione (**205**) was synthesised by double photochemical dehydrohalogenation of the corresponding thieno[3,2-*b*:2',3'-*d*]thiophene-2,6-dicarboxanilide.<sup>167</sup>

Conjugated thiophene polymers are of interest because of their electrical and optical properties. In this connection, photochemical polymerisation of dithieno[3,2-*b*:2',3'-*d*]thiophene **108a** and dithieno[3,4-*b*:3',4'-*d*]thiophene **11** was studied. Irradiation of solutions containing dithienothiophene and an electron acceptor (for example, *p*-dinitrobenzene, CCl<sub>4</sub>) gives rise to polythienothiophenes with molecular mass of ~10<sup>4</sup>. The radical cation of the starting thienothiophene is efficiently generated by photoinduced electron transfer from the excited state of the monomer to an electron acceptor. The subsequent coupling reaction affords polymers.<sup>168,169</sup>

### c. Fused thienothiophenes and their reactions

To construct additional heterocycles fused to the thienothiophene system, a number of approaches other than the above-mentioned photocyclisations were used. For example, heating of 2-acetyl-amino-3-hydroxythieno[3,2-*b*]thiophene (**206**) in the presence of P<sub>2</sub>S<sub>5</sub> afforded 2-methylthieno[3,2-*b*]thieno[3,2-*d*]thiazole (**207**).<sup>19</sup> Isomeric 2-methylthieno[2,3-*b*]thieno[3,2-*d*]thiazole was prepared by oxidation of 2-thioacetylaminothieno[2,3-*b*]thiophene with K<sub>3</sub>Fe(CN)<sub>6</sub> in aqueous alkali.<sup>170</sup>

Acylation of 3-acetyl-5-alkylthieno[2,3-*b*]thiophenes **208** and 3-acetyl-5-methylthieno[3,2-*b*]thiophenes **209** in a mixture of aliphatic acid anhydride and perchloric acid (actually, acylium perchlorate) was demonstrated<sup>171</sup> to occur at the free  $\alpha$  position followed by cyclisation and formation of perchlorates of tricyclic pyrylium salts **210** and **211** (yields > 80%). The latter are transformed into thieno[2',3':5,4]- (**212**) and -[2',3':4,5]thieno[2,3-*c*]pyridines **213** in yields of higher than 90% by passing ammonia through their suspensions.

$R^1 = Me, Et; R^2 = Me, Et, Bu^n$ .

Functionalised thieno[2,3-*b*]thiophenes **214** were transformed according to conventional procedures into the following tri- and tetracyclic systems: thienopyrimidines, thieno-1,3-oxazines, bis-(thieno-1,2,3-triazines), dithieno-1,4-oxazepines<sup>38</sup> (presented in Scheme 5) and fused thieno[2,3-*b*]thiophenes containing pyridine, pyrimidine, thiazine, thiazole, oxadiazole, isoxazole, pyrazole,

pyridazine, piperazine, pyrrolpiperazine and other heterocyclic fragments.<sup>172–175</sup>

The reactions of thienothiophenes **215**, **216** and **217** containing the amino- and carboxamide groups in the adjacent positions with triethyl orthoformate in boiling acetic anhydride produce thieno[2',3':4,5]- (**218**), thieno[3',2':4,5]- (**219**) and thieno[3',4':4,5]thieno[3,2-*d*]pyrimidin-7(6*H*)-ones (**220**), respectively.<sup>10</sup> The reaction of thienopyrimidine **219** with  $POCl_3$  affords 7-chloro derivative **221**.

(a)  $CH(OEt)_3, Ac_2O, \Delta, 1.5\ h$ .

Treatment of diethyl 3,4-diaminothieno[2,3-*b*]thiophene-2,5-dicarboxylate (**222**) with acetic anhydride afforded symmetrical tetracyclic derivative **223**, whose reactions with ammonium acetate, hydrazine hydrate or aniline produced its nitrogen analogues **224**.<sup>172</sup>

Scheme 5

$R^1 = NH_2, OH; R^2 = NH_2, OMe, Ph; R^3 = NH_2, OMe, Ph$ .

R = H, NH<sub>2</sub>, Ph.

2,3,6,7-Tetrathienobenzene[1,3-*cd*:4,6-*c'd'*]dipentalene (**225**) and its derivatives **226** are new fused polynuclear heteroarenes iso-electronic with perylene. Dipentalene **225** was prepared for the first time by dimerisation of thieno[2,3-*b*]thiophene (**142**).<sup>172</sup> More recently, it was found that catalytic reduction of 3,4-dibromothieno[2,3-*b*]thiophene (**227**) with an excess of activated zinc in the presence of bis(triphenylphosphine)nickel(II) chloride and tetraethylammonium iodide afforded only 4,4'-dibromo-3,3-bis(thieno[2,3-*b*]thiophene) (**228**) (in a maximum yield of 28%).<sup>176</sup> However, the reaction in the presence of a larger amount of the nickel catalyst afforded also dipentalene **225**. Optimisation of the reaction conditions made it possible to increase the yield of the latter to only 14%. An alternative procedure was employed to transform thienothiophene **227** into trimethylstannyl derivative **229**. The reaction of thienothiophene **227** with organotin intermediate **229** in the presence of the palladium triphenylphosphine complex afforded dipentalene **225** (13% yield). Derivatives **226** were prepared by lithiation of dipentalene **225** followed by the reaction with the corresponding alkyl iodide or dialkyl disulfide.<sup>79</sup>

RX = MeI, EtI, (MeS)<sub>2</sub>, (EtS)<sub>2</sub>; R = Me, Et, SMe, SEt;  
 (a) (Ph<sub>3</sub>P)<sub>2</sub>NiCl<sub>2</sub>, Me<sub>4</sub>NI, Et<sub>4</sub>Ni, Zn (excess), PhH, Δ; (b) Bu<sup>n</sup>Li (2 equiv.), Me<sub>3</sub>SnCl (2 equiv.), Et<sub>2</sub>O-TMEDA, -80 °C; (c) (Ph<sub>3</sub>P)<sub>4</sub>Pd, PhMe, 70 °C; (d) LDA, THF, -10 °C; TMEDA is *N,N,N',N'*-tetramethylethylenediamine, LDA is lithium diisopropylamide.

The oxidation potential of heteroarene **225** is equal to that of perylene, and compound **225** forms an analogous complex with iodine having rather high conductivity (0.11 S cm<sup>-1</sup>). However, it appeared that complexes of all derivatives **226** with iodine have low conductivity. In addition, compounds **225** and **226** form charge-transfer complexes with strong electron acceptors, such as 7,7,8,8-tetracyanoquinodimethane (TCNQ), 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (TCNQF<sub>4</sub>), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) and 1,1,2,3,4,4-hexacyano-1,3-butadiene (HCB<sub>6</sub>).<sup>79, 176</sup> However, the majority of these π complexes are low-conducting powdered polymers, whereas complexes of tetrakis(methylthio) derivatives **226** (R = SMe) form crystalline radical-cation salts with a conductivity of about 10<sup>-3</sup> S cm<sup>-1</sup>.

Friedel–Crafts condensation of benzo[*b*]thieno[3,2-*b*]thiophene-2-carboxylic acid chloride with *m*- and *p*-xylene affords ketones, which undergo Elbs pyrolysis (420 °C, 15 min) to form pentacyclic derivative **230**.<sup>177</sup> Analogous products were prepared from benzo[*b*]thieno[3,2-*b*]thiophene and (di)methyl homologues of benzoyl chloride.

Cyclisation of benzo[*b*]thieno[3,2-*b*]thiophene-2-butyric acid in the presence of P<sub>2</sub>O<sub>5</sub> gives benzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophene (**121**) in 80% yield.<sup>178</sup>

#### d. Other transformations

This Section deals with the most interesting reactions of thienothiophenes giving rise to various sulfur-containing heterocyclic systems.

The reaction of diethyl 3,4-dimethylthieno[2,3-*b*]thiophene-2,5-dicarboxylate (**117**, R = Me, EWG = CO<sub>2</sub>Et) with hydrazine hydrate afforded dihydrazide **231**, which was subjected to various transformations (Scheme 6). For example, the reactions with acetylacetone, ethyl acetoacetate or malononitrile<sup>75</sup> are accom-

Scheme 6

| Compound   | Het | Reaction conditions                                         | Yield (%) |
|------------|-----|-------------------------------------------------------------|-----------|
| <b>232</b> |     | CH <sub>2</sub> Ac <sub>2</sub> , fusion                    | 88        |
| <b>233</b> |     | AcCH <sub>2</sub> CO <sub>2</sub> Et, EtOH, AcOH            | 79        |
| <b>234</b> |     | CH <sub>2</sub> (CN) <sub>2</sub> , EtOH, Pip               | 73        |
| <b>235</b> |     | 1) CS <sub>2</sub> , KOH, 2) HCl                            | 82        |
| <b>236</b> |     | 1) CS <sub>2</sub> , KOH, 2) H <sub>2</sub> SO <sub>4</sub> | 85        |

panied by the closure of the exocyclic pyrazole ring to form the corresponding derivatives **232**–**234**. The reaction of dihydrazide **231** with carbon disulfide in the presence of KOH followed by decomposition with dilute HCl or concentrated  $\text{H}_2\text{SO}_4$  produces di(oxadiazole) (**235**) or di(thiadiazole) derivative (**236**). Condensation of di(oxadiazolyl)thienothiophene **235** with hydrazine hydrate affords di(triazolyl)thienothiophene **237** (Scheme 6).

Dihydrazide **231** was also used in the synthesis of thienothiophenes containing triazole substituents. For example, the reaction with phenyl isothiocyanate in ethanol produces di(*N*-phenylthiocarbamoyl)carbohydrazide **238**, whose treatment with KOH followed by acidification affords compound **239**. Diazotisation of dihydrazide **231** with a 10% sodium nitrite solution in acetic acid gives diazide **240**. The reactions of the latter with compounds containing the active methylene group, *viz.*, ethyl cyanoacetate, malononitrile or diethyl malonate, in the presence of sodium ethoxide, yield the corresponding ditriazole derivatives **241**–**243** (Scheme 7).

In the presence of zero-valent palladium complexes as the catalyst, 2,4-di-*tert*-butoxypyrimidine-5-boronic acid (**244**) reacts with the bromine derivatives of thieno[2,3-*b*]thiophene (**142**) and thieno[3,2-*b*]thiophene (**145**).<sup>179, 180</sup> This reaction was used to introduce fragments of isomeric thienothiophenes at position 5 of 2,4-di-*tert*-butoxypyrimidine. The resulting compounds **245** were transformed into uracils **246** in quantitative yields.

After the reaction of thieno[3,2-*b*]thiophen-2(3*H*)-one (**247**) with diazoethane in diethyl ether, thieno[3,2-*b*]thiophene-2,3-dione 3-ethylhydrazone (**248**), 2-ethoxythieno[3,2-*b*]thiophene (**249**) and 3,3-diethylthieno[3,2-*b*]thiophen-2-one (**250**) were isolated from the reaction mixture.<sup>181</sup> The reaction of hydrazone **248** with diazoethane yielded 2-ethoxy-3-ethylazothieno[3,2-*b*]thiophene (**251**).

Dehydrogenation of dione **252**, which was prepared by treatment of 2,5-di(*tert*-butoxy)thieno[3,2-*b*]thiophene (**253**) with *p*-toluenesulfonic acid, with DDQ in dioxane gave 2,5-dioxothieno[3,2-*b*]thiophene (**254**).<sup>182</sup> 2,6-Dioxothieno[3,2-*b*]thieno[2',3'-*d*]thiophene (**255**) was prepared according to an analogous procedure.

(a) TsOH, PhH,  $\Delta$ , 2 h; (b) DDQ, dioxane,  $\Delta$ , 5 h.

Dicyanodiimide **256** and its various derivatives were synthesised starting from dione **254**. These compounds form high-conducting charge-transfer complexes.<sup>183</sup>

Fluorenylidene derivative **257** was synthesised from diol **258** according to three procedures: by heating without a solvent (35% yield) and by irradiation for 5–10 h in the solid state ( $\sim 10\%$ ) or in a solution in  $\text{CH}_2\text{Cl}_2$  (86%). Irradiation was carried out using a high-pressure mercury lamp through a Pyrex filter.<sup>184</sup>

(a)  $> 200^\circ\text{C}$ ; (b)  $h\nu$ ; (c)  $h\nu$ ,  $\text{CH}_2\text{Cl}_2$ .

Recently, the first example of Pd-catalysed coupling of bromothiophene **259** with the chromium tricarbonyl complex with phenylacetylene (**260**) giving rise to complex **261** has been published.<sup>185</sup>

(a)  $\text{PdCl}_2(\text{PPh}_3)_2$ , CuI,  $\text{Et}_3\text{N}$ , THF,  $\Delta$ .

Catalytic liquid-phase oxidation of 3-methylthieno[2,3-*b*] and -[3,2-*b*]thiophenes in the presence of cobalt acetate and NaBr in acetic acid ( $90\text{--}110^\circ\text{C}$ ) gave rise to thieno[2,3-*b*]thiophene-2-carboxylic acid (**41**) and the 3-formyl derivative, respectively.<sup>186</sup> The kinetic data provide evidence that electron transfer from the peroxy radical to  $\text{Co}^{2+}$  is the rate-determining step.

Ionic hydrogenation of 2-methyl-2,3-dihydrothieno[2,3-*b*]thiophene (**262**) affords *cis*-2,8-dithiabicyclo[3.3.0]octane (**263**).<sup>187</sup>

TFA is trifluoroacetic acid.

Desulfation of methyl 5,6-dibromo-3-chlorothieno[3,2-*b*]thiophene-2-carboxylate with a Ni–Al melt in a 10% NaOD– $\text{D}_2\text{O}$  solution produced methyl heptanoate containing 96% of deuterium.<sup>188</sup>

As mentioned above, thieno[3,4-*c*]thiophene is very difficult to synthesise compared to all other isomeric thienothiophenes. A few derivatives are known: tetraphenyl-,<sup>189–191</sup> tetrakis(alkylthio)-,<sup>58</sup> tetra(2-thienyl)-,<sup>42</sup> tetrabromo-, 1,3-dibromo-4,6-dicyano-, 1,3-dibromo-4,5-bis(methoxycarbonyl)-,<sup>192</sup> 1,4-bis(*tert*-butylthio)-3,6-diphenyl- and 3,6-di(2-thienyl)thieno[3,4-*c*]thiophenes.<sup>61</sup>

The synthesis of 1,3-dibromo-4,6-dicyanothieno[3,4-*c*]thiophene (**264**) by the reaction of tetrabromide **265** with NaI in acetone is the first example of the synthesis of a stable thieno[3,4-*c*]thiophene derivative.<sup>193</sup>

Mono- (**266**) and diformyl derivatives **267**, which were prepared by formylation of 1,3,4,6-tetrakis(isopropylthio)thieno[3,4-*c*]thiophene (**268**) with the Vilsmeier reagent, also proved to be rather stable.<sup>194</sup>

The reactions of thienothiophenes **101a,b** with trifluoroacetic acid are accompanied by protonation of the thienothiophene system, resulting in the  $\text{Bu}^t\text{--S}$  bond cleavage to form the corresponding thieno[3,4-*c*]thiophene-1(3*H*)-thione (**269a,b**).<sup>60, 61</sup> Treatment of thienothiophene **269a** with sodium hydride and isopropyl iodide leads to regeneration of the thieno[3,4-*c*]thiophene system to give 1-(*tert*-butylthio)-3,6-diphenyl-4-(isopropylthio)thieno[3,4-*c*]thiophene (**270a**). The reaction of thienothiophene **101a** with trifluoroacetic acid in the presence of 10 equivalents of water is accompanied by elimination of one sulfur-containing group to form 4-(*tert*-butylthio)-3,6-diphenylthieno[3,4-*c*]thiophene-1(3*H*)-one (**271**).

Cycloaddition of thienothiophenes **101a,b** to *N*-phenylmaleimide and dimethyl acetylenedicarboxylate was described in the study.<sup>61</sup>

1,3,4,6-Tetraphenylthieno[3,4-*c*]thiophene (**272**) was derived from a mixture of *cis*- and *trans*-sulfoxides **273** by dehydration with bases [Ba(OH)<sub>2</sub>, MeMgBr, EtMgBr, MeLi, LDA]. Product **272** was isolated either directly or as adduct **274** with tetracyanoethylene (TCNE).<sup>194</sup>

B is a base.

The reactions of thienothiophene derivatives in the absence of a solvent were also described in the literature. For example, the solid-state thermally induced rearrangement of 9,10-dihydroxy-9,10-bis(thieno[3,2-*b*]thiophen-2-yl)-9,10-dihydroanthracene (**275**) occurs at 240 °C and gives 10,10-bis(thieno[3,2-*b*]thiophen-2-yl)anthrone (**276**).<sup>195</sup>

(Thienothienyl)anthracenes **277** were subjected to analogous transformations to prepare the corresponding anthrones.

(Hydroxyfluorenyl)thieno[3,2-*b*]thiophenes **278a–c** and their diphenyl analogue **279** were subjected to methanolysis.<sup>196</sup> Substitution of the hydroxy function with the methoxy group requires specific reactions conditions for each substrate.

R = Me (**a**), Cl (**b**), 9-hydroxyfluoren-9-yl (**c**).

For example, 2-(9-methoxyfluoren-9-yl)thieno[3,2-*b*]thiophene (**280**) was prepared by careful grinding an equimolar mixture of 5-(9-hydroxyfluoren-9-yl)-2-methylthieno[3,2-*b*]thiophene (**278a**) with DDQ followed by storage of the resulting dark-green powder in methanol at a temperature below 5 °C for 6 h.

The reaction of 1-methyl- or 1,6-di-*tert*-butylazulenes (**281a,b**) with 2,5-diformylthieno[3,2-*b*]thiophene **282** in acetic acid afforded diazulenyldimethylthieno[3,2-*b*]thiophenes **283a,b** along with products **284a,b** resulting from the reaction at one aldehyde group.<sup>197</sup> The reaction of thienothiophenes **283a,b** with two equivalents of DDQ produced dicationic species, which were isolated as stable hexafluorophosphates **285a,b** by treating the reaction mixture with a 60% HPF<sub>6</sub> aqueous solution. Treatment of salts **285a,b** with zinc powder in acetonitrile afforded 2,5-bis[di(azulenyldimethylene)-2,5-dihydrothieno[3,2-*b*]thiophenes (**286a,b**).

Electrophilic substitution reactions were studied for thienothiophenes annelated with one or two benzene rings. For example, benzo[*b*]thieno[2,3-*b*] and -[3,2-*b*]thiophenes and their 3-methyl derivatives undergo bromination, Vilsmeier–Haack formylation and Friedel–Crafts acylation at position 2. These results agree well with the calculated electron densities.<sup>32, 198–200</sup> If these compounds contain the methyl group at position 2, bromination occurs at position 3, whereas the direction of acylation of 2-methylbenzo[*b*]thieno[2,3-*b*]thiophene depends on the reaction conditions and the reaction produces either a 3- or 6-acetyl

derivative. Bromination of 3-formyl-substituted benzo[*b*]thienothiophenes affords 2-bromo derivatives, whereas the reactions with 2-formyl-substituted derivatives are accompanied by a loss of the formyl group to give, respectively, 2,3-dibromobenzo[*b*]thieno[2,3-*b*]- or 2,6-dibromobenzo[*b*]thieno[3,2-*b*]thiophenes. Nitration of 2-formyl derivatives also leads to the replacement of the formyl group and the formation of 2-nitro derivatives as the major product.<sup>200</sup>

Nitration of benzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophene **121** containing two fused benzene rings was studied. The reaction of **121** with concentrated nitric acid ( $d = 1.51 \text{ g cm}^{-3}$ ) in acetic acid produced 2- (**287**) and 4-nitro derivatives (**288**), which were reduced to the corresponding amines.<sup>201</sup>

Earlier,<sup>202</sup> it has been reported that nitration of benzothienobenzo[*b*]thiophene **121** with a mixture of nitric and acetic acids led to substitution at the carbon atoms in both rings to give 2,7-dinitrodibenzo[*b*]thieno[3,2-*b*]thiophene **289** in low yield. The latter was transformed according to conventional synthetic procedures into derivatives **290** containing various electron-donating and electron-withdrawing substituents.<sup>116</sup>

$R^1 = R^2 = \text{NH}_2$ ;  $R^1 = \text{NH}_2$ ,  $R^2 = \text{NO}_2$ ;  $R^1 = R^2 = \text{Cl}$ ;  $R^1 = R^2 = \text{Br}$ ;  
 $R^1 = \text{OH}$ ,  $R^2 = \text{Cl}$ ;  $R^1 = \text{NH}_2$ ,  $R^2 = \text{Cl}$ ;  $R^1 = \text{NO}_2$ ,  $R^2 = \text{OH}$ ;  
 $R^1 = \text{OMe}$ ,  $R^2 = \text{NO}_2$ ,  $R^1 = \text{NH}_2$ ,  $R^2 = \text{OMe}$ ;  $R^1 = R^2 = \text{NHAc}$ ;  
 $R^1 = R^2 = \text{NHCOCF}_3$ ;  $R^1 = \text{NO}_2$ ,  $R^2 = \text{NHCOCF}_3$ ;  $R^1 = \text{NHAc}$ ,  
 $R^2 = \text{Cl}$ ;  $R^1 = \text{NHAc}$ ,  $R^2 = \text{OMe}$ .

Nitration of 2-benzoyl- and 4-acetylaminobenzo[*b*]thieno[3,2-*b*]thiophenes with nitric acid occurs predominantly at the *ortho*-position with respect to the substituent to give the nitro derivative, whose deacylation and reduction affords 1,2- and 3,4-diaminobenzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophenes in high yields.<sup>203</sup>

Thermal decomposition of azidoacrylates, which were prepared by condensation of ethyl azidoacetate with heteroaromatic aldehydes, produced a series of the previously unknown fused heteroaromatic analogues of isoellipticine **291**.<sup>204</sup>

X, Y = S, Se.

The above-considered transformation convincingly demonstrate a high synthetic potential of thienothiophene derivatives.

## IV. Molecular structures and physical properties

Theoretical aspects of the structures, reactivities and physico-chemical properties of isomeric thienothiophenes have attracted attention of a wide range of researchers. Earlier investigations of these problems have been covered in reviews<sup>2,205</sup> and other publications (see, for example, Refs 206–212).

### 1. Structures

In the last 25 years, X-ray diffraction analysis has been particularly widely used (along with other methods) to determine the structures of thienothiophenes. For example, the crystal structures of the following compounds were established by X-ray diffraction: 3,4-dibromothieno[2,3-*b*]thiophene,<sup>79</sup> 2,2,5,5-tetramethyl-2,3,5,6-tetrahydrothieno[3,2-*b*]thiophene-2,6-dione (**127**) [the main chromophoric system of the thioindigo-like dye having the *trans*-(*S*)-*trans*-(*S*)-*trans*-configuration],<sup>111,213</sup> (5-benzoyloxy-methyl)thieno[2,3-*b*]thiophene-5-sulfamide 6,6-dioxide,<sup>147</sup> nitronyl nitroxide and imino nitroxide free radicals bound to isomeric thieno[2,3-*b*]- and -[3,2-*b*]thiophenes,<sup>214</sup> 2,3,5,6-bis(ethylene-dithio)thieno[3,2-*b*]thiophene,<sup>69</sup> 1,2-bis[2-methyl-5-(2-benzothiazolyl)-6-trifluoromethylthieno[3,2-*b*]thiophen-3-yl]hexafluorocyclopentane,<sup>17</sup> 2,5-bis(dicyanomethylene)-2,5-dihydrothieno[3,2-*b*]thiophene<sup>159</sup> and the 3,6-dimethylselenopheno[3,2-*b*]thiophene dimer.<sup>143</sup>

Recently, it has been demonstrated that 2,5-bis(9-hydroxyfluoren-9-yl)thieno[2,3-*b*]- and -[3,2-*b*]thiophenes form crystalline inclusion guest–host complexes with EtOH, Pr<sup>n</sup>OH, Pr<sup>i</sup>OH, DMSO, Me<sub>2</sub>SO and benzene, and the structures of these clathrates were established by X-ray diffraction.<sup>215–223</sup>

The structures of 1,3,4,6-tetraphenylthieno[3,4-*c*]thiophene (**272**),<sup>224</sup> 1,4-bis(*tert*-butylthio)-3,6-diphenylthieno[3,4-*c*]thiophene, 4-(*tert*-butylthio)-3,6-diphenylthieno[3,4-*c*]thiophene-1(3*H*)-thione and 4-(*tert*-butylthio)-3,6-diphenylthieno[3,4-*c*]thiophen-1(3*H*)-one<sup>61</sup> were also characterised by X-ray diffraction.

Study of the crystal structure of sulfur-containing heterocyclic compound **292**, which was prepared by the reaction of diethyl dihydroxythieno[2,3-*b*]thiophene-2,5-dicarboxylate with Lawesson's reagent in the presence of sulfur, revealed the presence of a three-dimensional S–S interaction.<sup>225</sup>

The  $\pi$ -electron systems of thiophene, isomeric thienothiophenes and other fused sulfur-containing compounds (58 compounds, including those annelated with the benzene and naphthalene rings) were considered from the viewpoint of the degree of contribution of the sulfur atom to the ability of the probable resonance structures to include the hydrocarbon portion of the molecule.<sup>226</sup>

Bicyclic conjugated systems consisting only of five-membered heterocycles were studied theoretically. The authors used the topological resonance energy (TRE) as a new aromaticity index,<sup>227</sup> which correctly predicts the aromatic behaviour of all groups of isomeric heteroaromatic systems, including thienothio-

phenes. These isomers are referred to as positional isomers, because they formally differ only in the position of  $\sigma$ -bivalent heteroatoms and can be considered as a special group in accordance with the mode of their annelation. The calculated TREs agree well with the experimental values.<sup>227, 228</sup>

To study the effect of the nature of the heteroatom on the aromatic system, the photoelectron spectra of thieno[2,3-*b*]thiophene (**142**), thieno[3,2-*b*]thiophene (**145**),<sup>229</sup> thieno[2,3-*b*]selenophene (**143**), selenopheno[3,2-*b*]selenophene (**147**), thieno[2,3-*b*]pyrrole, selenopheno[2,3-*b*]pyrrole, pyrrolo[2,3-*b*]pyrrole and selenopheno[3,2-*b*]pyrrole<sup>230</sup> were measured and analysed. The replacement of the sulfur atom with selenium causes slight changes in all characteristics in accordance with the simple excitation theory. The replacement of the sulfur or selenium atom with the NH group influences the  $\pi$ -electron system. In this case, an increase in the resonance integral of the bonds including the heteroatom is compensated by a strong destabilising inductive effect due to N–H bond polarity. The efficient electronegativity of the NH group was found to differ only slightly from that of the sulfur atom.<sup>230</sup>

Thieno[3,2-*b*]thiophene (**145**), thieno[3,2-*b*]thieno[2',3'-*d*]thiophene (**108a**), thieno[2'',3'':4',5']thieno[2',3'-*d*]thieno[3,2-*b*]thiophene (**6**) and dithieno[2,3-*d*:2',3'-*d'*]thieno[3,2-*b*:4,5-*b'*]thiophene (**7**) were studied by gas-phase and solid-state photoelectron spectroscopy.<sup>145</sup> For tetrathienocene **6**, the ionisation energy for the gas phase (7.22 eV) differs substantially from that for the solid state (4.86 eV), resulting in an increase in the polarisation energy by 2.36 eV, which is larger than the calculated value (1.83 eV). This phenomenon was interpreted in terms of intramolecular orbital interactions for the solid state of polythienothiophene **6**. This interaction is not observed for lower homologues (thienothiophenes **145** and **108a**).

Recently, among isomeric thienothiophenes, thieno[3,4-*c*]thiophenes have attracted most attention from both the theoretical and spectroscopic points of view as  $10\pi$ -electron heterocycles having a non-classical structure.<sup>61, 224, 231–239</sup> Examination of the photoelectron and UV-Vis absorption spectra of 1,3,4,6-tetraphenylthieno[3,4-*c*]thiophene (**240**)<sup>236</sup> confirmed the singlet aromatic ground state of the molecule predicted by quantum-chemical calculations<sup>224</sup> (by the MINDO/3 method without allowance for d-orbital interactions).

In the  $\pi$ -electron approximation of the MO LCAO SCF method, a procedure was developed on the basis of the Longuet–Higgins model to account for the d orbitals of the sulfur atoms. The chemical shifts in the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra, the lowest singlet–singlet and singlet–triplet transitions and the dipole moments of a series of sulfur-containing heterocyclic systems, including thieno[2,3-*b*]thiophene (**142**), thieno[3,2-*b*]thiophene (**145**) and thieno[3,4-*c*]thiophene, were calculated.<sup>240</sup> These results are in agreement with experimental data.

The multiplicity of the ground state, p-stability ('aromaticity'), the order and energy of the electron-excited and ionic states of thieno[3,4-*c*]thiophene were studied.<sup>235</sup> In particular, this compound was demonstrated to have 'aromaticity' analogous to that of thiophene, but it is much less stable due to a specific structure of its highest occupied molecular orbital.

## 2. NMR spectra

NMR spectroscopy along with and combined with other physicochemical methods is rather widely used to study the chemical structures of thienothiophenes and their heteroanalogs. In the study,<sup>241</sup> CNDO/2 calculations were carried out for selenophene and [2,3-*b*]-, [3,2-*b*]- and [3,4-*b*]-annelated thienoselenophenes **143**, **144**, **146** and **149–151**. Correlations between the calculated electron density and experimental  $^{77}\text{Se}$  NMR chemical shifts in the spectra of these compounds were revealed. The chemical shifts were demonstrated to depend substantially on both the total and  $\pi$ -electron density on the selenium atom.

The  $^1\text{H}$ ,  $^{13}\text{C}$  and  $^{77}\text{Se}$  NMR spectra of selenopheno[2,3-*c*]thiophene (**149**),<sup>242</sup> selenopheno[2,3-*b*]selenophene (**144**),<sup>243</sup> selenopheno[3,2-*b*]selenophene (**146**),<sup>244</sup> selenopheno[3,4-*b*]selenophene (**151**)<sup>245</sup> and a series of 2-substituted selenopheno[2,3-*b*]selenophenes<sup>246</sup> and -[3,2-*b*]selenophenes<sup>247</sup> were measured and analysed.

The  $^1\text{H}$  NMR spectra of isomeric thienothiophenes, selenophenothiophenes and their derivatives<sup>130, 248, 249</sup> revealed long-range spin–spin coupling through five and six bonds located in a 'direct zigzag' system. This phenomenon is analogous to that observed in a series of other bicyclic systems including sulfur, nitrogen and oxygen atoms [see, for example, Ref. 250].

X = S, Se.

It was also concluded that the signals for the  $\alpha$ - and  $\beta$ -protons of isomeric thieno- and selenophenothiophenes are characteristic of different modes of fusion of heterocyclic rings.<sup>205</sup> The chemical shifts of annelated thiophenes with X = S are given below (the values for X = Se are given in parentheses).

X = S, Se.

The spectra of isomeric selenophenothiophenes are characterised also by spin–spin coupling between the  $^{77}\text{Se}$  atom (spin 1/2) and protons of the selenophene fragment<sup>249</sup> analogous to that observed in selenides of the thiophene series.<sup>251</sup>

Tautomerism of 2-hydroxythieno[2,3-*b*]- and -[3,2-*b*]thiophenes, 2,5-dihydroxythieno[3,2-*b*]thiophene and their alkyl- and aryl-substituted derivatives was also examined by NMR spectroscopy.<sup>252, 253</sup> These compounds were demonstrated to occur predominantly as thiolactones rather than in the hydroxy form. For the thieno[2,3-*b*]thiophene system, this equilibrium is completely shifted to thieno[2,3-*b*]thiophen-2(3*H*)-ones, whereas the forms **B** and **D** were found for [3,2-*b*]-fused systems. The effect of the nature and positions of the substituents on the tautomeric equilibrium was discussed.

Alkyl- and aryl-substituted 2,5-dihydroxythieno[3,2-*b*]thiophenes appeared to occur exclusively as dithiolactones. In no case was the hydroxy form of these compounds was detected.<sup>253</sup> The results of NMR spectroscopy demonstrated that 2,3-dihydrothieno[3,2-*b*]thiophene-2,5-dione (**E**) is a favourable structure. The tautomer **F** was detected only for the unsubstituted compound. However, this tautomer is readily transformed into the tautomer **E**. For 6-substituted compounds, two stereoisomers of the form **G** are observed; these stereoisomers have opposite configurations at the C(6) atom.

$R^1 = \text{H, Me, Bu}^t, \text{Ph}$ ;  $R^2 = \text{H, Me, Ph}$ .

The effects of the nature and positions of the substituents on stability of tautomeric forms were discussed.

### 3. ESR spectra

The reactions of the diphenylphosphoryl ( $\text{OP}^*\text{Ph}_2$ ) and diethoxyphosphoryl [ $\text{OP}^*(\text{OEt})_2$ ] radicals with 3,6-dimethylthieno[3,2-*b*]thiophene-2,5-dione (**293**) were studied by ESR spectroscopy.<sup>254</sup> Both reactions produce the oxygen-containing (**294**) and cyclic (**295**) adducts. The hyperfine coupling constants of the former adducts are close to those of analogous oxygen-containing adducts of Group IVB organometallic radicals.<sup>255</sup> The attack can occur on the carbon atoms at positions 3, 6 or 4, 5 of the ring. In the former case, the structure of the adduct is similar to that of the substituted allylic system, and the ESR spectra would be expected to show methyl splitting with the constant of  $\sim 10$  Hz. The reactions of dione **293** with the  $\text{SP}^*\text{Et}_2$  and  $\text{P}^*\text{Ph}_2$  radicals afforded predominantly derivatives **294**, although the ESR signals of cyclic adduct **295**, which was generated simultaneously with **294**, were recorded.

$\text{X} = \text{O}$ :  $\text{R} = \text{Ph, OEt}$ ;  $\text{X} = \text{S}$ ,  $\text{R} = \text{Et}$ ;  $\text{X}$  is absent,  $\text{R} = \text{Ph}$ .

The hyperfine coupling constants for paramagnetic adducts of the  $\text{M}^*\text{R}_3$  ( $\text{M} = \text{Si, Ge, Sn}$ ) radicals with dithienyl and bis(thieno[2,3-*b*]- and -[3,2-*b*]thienyl) ketones were measured and compared with those of the diarylhydroxymethyl radicals. These

results were confirmed by INDO calculations and indicate that the  $2p_z$  orbital is involved in the  $\text{O}-\text{M}$  bond in dithienyl derivatives.<sup>256</sup>

Complexation of dibenzo-18-crown-6 ether with 3,6-dimethylthieno[3,2-*b*]thiophene-2,5-dione **293**,<sup>257</sup> homolytic aromatic silylation of 2-cyanothieno[2,3-*b*]- and -[3,2-*b*]thiophenes,<sup>258</sup> addition of silyl radicals to 3,6-dimethylthieno[3,2-*b*]thiophene-2,5-dione and 5-benzylidene-3,6-dimethylthieno[3,2-*b*]thiophene-2-one<sup>259</sup> and the conformational behaviour of the dithieno[3,2-*b*:2',3'-*d*]thiophene-2,6-dicarbaldehyde radical anions<sup>260</sup> were studied by ESR spectroscopy.

Diradical species **296–299**, in which two nitronyl nitroxide ( $\text{ONC}=\text{NO}$ ) or imino nitroxide ( $\text{NCNO}$ ) radical centres are bound to the thieno[2,3-*b*]thiophene and thieno[2,3-*b*]thieno[3',2'-*d*]thiophene chromophores, were investigated. Their intramolecular exchange coupling in frozen solutions and the magnetic sensitivity at low temperatures were examined by ESR spectroscopy.<sup>261, 262</sup>

The ESR spectra of mononitronyl nitroxide and imino nitroxide free radicals bound to isomeric thieno[3,2-*b*]thiophenes (**145**) and -[2,3-*b*]thiophenes (**142**) were measured in toluene at room temperature.<sup>212</sup>

### 4. UV spectra

The nature and properties of the ground and first low-lying excited states of the thieno[3,2-*b*]thiophene (**145**) molecule were investigated in a series of spectroscopic studies.<sup>263–268</sup>

The first UV spectrum of thienothiophene **145** in the gas phase was recorded in 1956.<sup>263</sup> However, some details of the spectrum have remained uninterpreted because of the complicated spectral pattern. Only 20 years later, complete spectroscopic study, including IR and UV-Vis spectroscopy, of this compound was carried out both in the gas phase and in the crystalline state.<sup>269</sup> Two systems of intense absorption bands at  $36\,000\text{--}40\,000\text{ cm}^{-1}$  were assigned to two electron transitions in the excited state, whereas a very weak band observed in the spectrum of the crystal at  $34\,394\text{ cm}^{-1}$  was assigned to a singlet–triplet transition caused by spin–orbit coupling. Calculations by the LCAO method with the STO/3G basis set<sup>270</sup> confirmed the assignment of the electron transitions.

The possibility of using the liquid-crystal linear dichroism (LCLD) technique for the assignment of electron transitions was exemplified by two models of chromophores with high (phenylthiol) and low (thienothiophene **145**) symmetry.<sup>271</sup> The LCLD spectrum of the thienothiophene chromophore revealed a new band, which has not been observed earlier, and confirmed the theoretical results.<sup>270</sup>

The thieno[3,2-*b*]thiophene (**145**), selenopheno[3,2-*b*]thiophene (**146**) and selenopheno[3,2-*b*]selenophene (**151**) charge-transfer complexes based on tetracyanoethylene (TCNE) were studied by UV and IR spectroscopy. The absorption spectra recorded in  $\text{CCl}_4$  and  $\text{CH}_2\text{Cl}_2$  show numerous charge-transfer bands.<sup>272</sup> A comparison with photoelectron spectra of other donors demonstrated that these bands appear due to transitions from two different occupied orbitals of the donor to unoccupied orbitals of the acceptor. The calculated ionisation potentials of the donors are consistent with the photoelectron spectroscopic data.

The quinoid compounds **A**, **B** and **E** have similar UV spectra, although the absorption maximum is shifted to longer wave-

lengths by approximately 50 nm with increasing number of thiophene rings.<sup>182</sup> The observed absorption maxima agree with the values calculated by the Pariser–Parr–Pople (PPP) method with allowance for restricted configuration interactions. For the **B–C–D** series, the long-wavelength band is shifted to higher frequencies in going from the first to the last compound, in spite of an increase in  $\pi$ -conjugation in this series of compounds. This may be a consequence of steric interactions between the phenyl fragment and the quinoid thienothiophene system, resulting in a deviation of the seven-membered ring from the plane. The discrepancy between the observed and calculated electron transitions for the long-wavelength band in the compounds **C** and **D** also confirms a non-planar structure of the total  $\pi$ -system of these molecules.

The UV spectra of 3,6-dimethylthieno[3,2-*b*]thiophene, 3,6-dimethylselenopheno[3,2-*b*]selenophene, their dimers, trimers and tetramers,<sup>143</sup> 2,2,5,5-tetramethylthieno[3,2-*b*]thiophene-3,6-dione,<sup>111,211</sup> and derivatives of benzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophene **121**<sup>115</sup> and compounds **300–305**<sup>119</sup> were measured and analysed.

X = Y = NMe (**300**); X = Y = S (**301**); X = Y = Se (**302**); X = NMe, Y = S (**303**); X = NMe, Y = Se (**304**); X = S, Y = Se (**305**).

The strongest absorption maximum in the UV-Vis spectra of compounds **300–305** is observed between 331 nm (for **301**) and 354 nm (for **300**); the longest-wavelength absorption is most intense, and the maximum is observed between 367 nm (for **301**) and 426 nm (for **300**). All compounds, except for **302**, show fluorescence: compound **300** shows strong fluorescence, whereas compounds **301** and **305** exhibit relatively weak fluorescence due, apparently, to the effect of the heavy atom.

The UV spectra of a homologous thienocene series show a shift of the long-wavelength band to the red region characterised by a good linear correlation with the number of the thiophene rings. A comparison of the UV spectra of heterohelicenes **175a,b**

and **176a,b**<sup>273–275</sup> with the spectra of benzohelicenes<sup>274,275</sup> demonstrated that the longest-wavelength band ( $\alpha$  band) is shifted to higher frequencies (by approximately 30 nm), whereas the positions of the second and third bands ( $\rho$  and  $\beta$  bands, respectively) are only slightly different.

The twist angles of the phenyl ring relative to the plane of the bicyclic fragment in 2-phenylthieno(or selenopheno)[2,3-*b*]thiophenes, -furans and analogous *N*-methylpyrroles were determined from absorption spectra and data on molecular refraction.<sup>276</sup>

## V. Fields of application

Earlier, the practical use of thienothiophenes has been limited primarily to the preparation of polymethine dyes, transition metal complexes,<sup>2</sup> as well as the synthesis of *N*-(aminoalkyl)thieno[3,2-*b*]thiophene-2-carboxamide derivatives, which were proposed as antidepressants and antitumor agents,<sup>277</sup> and the synthesis of benzo[*b*]thienobenzo[*b*]thiophenes, which are used as pesticides.<sup>200,278</sup> In recent years, the field of applications of these compound has been substantially extended due to the synthesis of numerous derivatives of this class of compounds. The introduction of pharmacophoric substituents into thienothiophene molecules and the use of these compounds in the synthesis of annelated systems gave rise to new types of biological activities. The discovery of unusual optical, electrical and complexation properties made it possible to prepare new materials for modern technology.

### 1. Biological activity

Since many thiophene-containing compounds, including annelated compounds, exhibit biological activities,<sup>279–282</sup> the structure–activity relationships for this series of heterocycles have attracted considerable attention. Studies are aimed both at using thienothiophenes as building blocks and searching for new types of biological activity of fused systems containing various central fragments.<sup>38,81</sup>

For example, 5-substituted thieno[2,3-*b*]thiophene-2-sulfonamides **306–312** were synthesised and proposed as glaucoma medicines.<sup>36,147,283–289</sup> In the cited studies, the substituents at position 5 were varied to increase solubility in water and achieve  $pK_a$  minimising binding of the iris pigment. The best results were obtained in tests of compound **306** [ $R^1 = (CH_2)_2O(CH_2)_2OMe$ ,  $R^2 = (CH_2)_2OMe$ ].<sup>36</sup>

$R^1 =$  Me,  $(CH_2)_2OH$ ,  $(CH_2)_2CH(OH)CH_2OH$ ,  $(CH_2)_2NMe_2$ ,  $(CH_2)_2S(O)Me$ ,  $(CH_2)_2O(CH_2)_2OMe$ ,  $(CH_2)_2N(CH_2CH_2)_2O$ ,  $(CH_2)_2N(CH_2CH_2)_2S$ ;

$R^2 =$  H, Me  $(CH_2)_2OH$ ,  $(CH_2)_2OMe$ .

R =  $n$ -C<sub>5</sub>H<sub>11</sub>,  $(CH_2)_3OH$ ,  $(CH_2)_3N(CH_2CH_2)_2O$ .

The results of pharmacological studies of the potential non-peptide fibrinogen receptor antagonist, *viz.*, thieno[2,3-*b*]thiophene-based compound **172**, were reported.<sup>148,290</sup>

A series of thieno[2,3-*b*]thiophene-based HIV protease inhibitors were synthesised and tested.<sup>291,292</sup> At low concentrations, these inhibitors are efficient against HIV, and some of them provide a satisfactory plasma level in animals upon peroral administration. Among compounds of this series, compound **313**

proved to be the most promising ( $IC_{50} = 0.12$  nM and  $IC_{95} = 6-12$  nM).<sup>291</sup>

Pyrimidine nucleosides **314** containing the thieno[3,2-*b*]thiophene substituent hold promise against HIV and hepatitis B and were covered by a patent.<sup>293</sup>

$R^1 = OH, NH_2$ ;  $R^2 = H, F, OH, OMe$ ;  $R^3 = H, F, OH$ ;  
 $R^4 = OH, (CH_2)_nP(O)(OMe)_2$ ;  $R^5 = H, C_1-C_{10}-Alk$ ;  $n = 0, 1$ .

2-(Thienothiethylglycyl)cephalosporin<sup>294, 295</sup> and 2-(thienothiethylphenyl)carbapenam derivatives<sup>296</sup> possess antibacterial properties.

Patents covered procedures for the preparation of 4(5)-(3-indolyl)imidazoles **315**, which are useful for treatment of central nervous system function disorders, cerebrovascular dementia, senile dementia and memory or learning disorder,<sup>297</sup> the synthesis of thieno[2,3-*b*]thienyl-containing carboxylic acids **316** and their derivatives used as analgetics, inflammation and thrombosis inhibitors<sup>298, 299</sup> and the synthesis of thieno[3,2-*b*]thiophene-2-carboxamides used as cyclooxygenase and lipoxygenase inhibitors.<sup>300</sup>

Thieno[3,2-*b*]thiophene-2-carboxamides **317**, which were prepared as mixtures of diastereomers and separated by high-performance liquid chromatography, were covered by patents as cysteine protease inhibitors.<sup>301-305</sup>

$X = N, N^+ - O^-$ .

Amidines of the thieno[3,2-*b*]thiophene series **318** were covered by patents as urokinase inhibitors.<sup>306</sup>

$R^1 = H, NH_2, Hal$ ;  $R^2, R^3 = H, Hal, HO, NH_2, NO_2$ ;  
 $R^4, R^5 = H, C_1-C_6-Alk$ .

Thieno[2,3-*b*] and -[3,2-*b*]thiophene-2-carboxylic acids and their benzo[*b*]annelated analogues were synthesised and their lipid-reducing properties were investigated.<sup>307</sup> A number of hydrazides and sulfonamides of the thienothiophene series were covered by patents as pesticides.<sup>308, 309</sup>

It was found that the smells given off by heated food include those of compounds formed by the reaction of thienothiophene-containing 4-hydroxy-5-methyl-3(2*H*)-furanones with cysteine or  $H_2S$ .<sup>310</sup> Thieno[3,2-*b*]thiophene derivatives were used in combinatorial synthesis to compile chemical libraries with the aim of examining the biological action of these compounds.<sup>311</sup>

## 2. Other areas of practical applications

Sulfur-containing heteroaromatic compounds, particularly, fused compounds having an extensive conjugated system can be used as building blocks for preparing organic conductors,<sup>312-315</sup> magnetic<sup>316</sup> and photosensitive receptors,<sup>317</sup> materials for optoelectronics,<sup>318, 319</sup> *etc.* These compounds most often belong to charge-transfer complexes.<sup>320-322</sup> A rational combination of conducting polymers<sup>323</sup> and magnetic materials<sup>324, 325</sup> requires the presence of precursors containing functional groups, which can enhance  $\pi$ -conjugation in the system as a result of condensation.

### a. Complexation properties of isomeric thienothiophenes

Isomeric thienothiophenes and their derivatives are of considerable interest as electron donors or acceptors for the design of new types of charge-transfer complexes and as ligands coordinating metal ions. As mentioned above (see Section IV.4), charge-transfer complexes of some five-membered fused heteroaromatic systems with tetracyanoethylene were studied by UV and IR spectroscopy and their relative stabilities were discussed using the association constants and enthalpies of formation.<sup>272</sup>

Thieno[2,3-*b*]thiophene and -[3,2-*b*]thiophene containing two 9-hydroxyfluoren-9-yl groups as substituents form charge-transfer complexes with 1,2,4,5-tetracyanobenzene (TCNB), which show fluorescence in the solid state.<sup>222, 326</sup> Benzo[*b*]thieno[3,2-*b*]thiophene forms charge-transfer complexes with various organic acceptors.<sup>327</sup>

In recent years, dithienothiophenes have attracted considerable attention because these compounds have three various types of  $\pi$ -conjugation, which play a decisive role in the donor ability of these compounds.<sup>7-9, 157, 215, 218, 328-333</sup> Two higher homologues of fused polythiophenes, *viz.*, thienocenes **6** and **7**, which are isoelectronic with chrysene and picene, respectively, but contain many fewer peripheral hydrogen atoms, were also used as precursors of organic conductors.<sup>7, 145, 315</sup>

As mentioned above (see Section III.2.c, and Ref. 334), 2,3,6,7-tetrathiabenz[1,3-*cd*:4,6-*c'd'*]dipentalene (**225**) and its derivatives **226** form charge-transfer complexes with strong electron acceptors (TCNQ, TCNQF<sub>4</sub>, DDQ and HCBd), most of which have a low conductivity.

New fused thienothiophene, *viz.*, 2,3:5,6-bis(ethylenedithio)-thieno[3,2-*b*]thiophene (**112**), was used to prepare conducting organic salts.<sup>69</sup>

Examples of the use of 2,5-bis(dicyanomethylene)-2,5-dihydrothieno[3,2-*b*]thiophenes (**319**) and -2,6-dihydrothieno[3,2-*b*:2',3'-*d'*]thiophenes **320** as electron acceptors were reported, and the resulting charge-transfer complexes have a very high (up to metallic) conductivity.<sup>157</sup>

2,5-Bis(3,5-di-*tert*-butyl-4-oxocyclohexa-2,5-dien-2-ylidene)-2,5-dihydro-1,4-dithiapentalene (**321**) is also a promising electron acceptor for the formation of complexes.<sup>335</sup>

Dinuclear complexes of Group VIB (Cr, Mo, W)<sup>336, 337</sup> and Group VIII (Pt)<sup>338</sup> metal ions with 3,6-dimethylthieno[3,2-*b*]- and dithieno[3,2-*b*:2',3']thiophene as ligands were synthesised and studied.

#### b. Thienothiophenes as liquid and clathrate crystals

In the last 15 years, the liquid-crystalline properties of azomethines, azines, vinylenes and hexatrienes containing the thiophene or thieno[3,2-*b*]thiophene fragment were examined. Their thermal and optical properties were compared with those of analogous compounds of the benzene series.<sup>144, 339</sup> Taking into account particular characteristics, these compounds were proposed as materials for various purposes of modern technology.

Certain thieno[2,3-*b*]- and -[3,2-*b*]thiophene derivatives can be used in liquid-crystalline mixtures for electrooptical switches and evaluation devices.<sup>340–342</sup>

Benzo[*b*]thieno[3,2-*b*]benzo[*b*]thiophene-2,7-dicarboxylate derivatives exhibit properties of smectic liquid crystals, whose stability depends on the length and nature of terminal chains. Samples of these liquid crystals show pronounced photoconducting behaviour.<sup>343</sup>

Liquid-crystal linear dichroism of the thieno[3,2-*b*]thiophene molecule has been examined.<sup>271</sup>

Recently,<sup>7, 145, 182, 215–223, 344–347</sup> a series of new compounds possessing host-type complexation properties, for example, 2,5-bis(9-hydroxyfluoren-9-yl)thieno[3,2-*b*]thiophene (**278c**), were introduced into crystals of complexes. Such compounds are referred to as 'clathrate crystals'.<sup>348</sup>

#### c. Materials for nonlinear optics

The recently discovered physical and chemical properties of thieno- and dithienothiophenes make it possible to use these fused heteroaromatic compounds for the design of new nonlinear optical materials. For example, the following two conjugated chromophoric charge-transfer systems were synthesised:<sup>136</sup> thieno[3,2-*b*]thiophenes **322**, which contain simultaneously electron-donating and electron-withdrawing substituents, and trinitriles **323**, which are heteroaromatic chromophores due to formation of charge-transfer complexes. The first hyperpolarisability ( $\beta$ ) of these compounds was determined by electric-field-induced second-harmonic (EFISH) generation; the replacement of the oxygen atom with sulfur leads to a substantial increase in  $\beta$ , which remains unchanged in going to other chalcogens (Se or Te).

2-(1,3-Dithian-2-ylidenemethyl)-5-(tricyanovinyl)thieno[3,2-*b*]thiophene (**324**) was used to prepare nonlinear optical polymers.<sup>349</sup>

Substituted thioethers of thieno[3,2-*b*]thiophenes **325** possess analogous optical properties. The procedure for their preparation was covered by a patent.<sup>350</sup>

R<sup>1</sup> = C<sub>1</sub>–C<sub>22</sub>-Alk, CH = C(CN)<sub>2</sub>; R<sup>2</sup>, R<sup>3</sup>, R<sup>4</sup> = H, Me;  
R<sup>2</sup> = H, R<sup>3</sup> = NO<sub>2</sub>, R<sup>4</sup> = CN, NO<sub>2</sub>.

Thienothiophene-containing chromophores bearing the TCNQ group as an acceptor are as thermally stable as analogous chromophores containing the strong tricyanovinyl substituent but they are characterised by a substantially larger second-order optical nonlinearity.<sup>351</sup>

Many thieno[3,2-*b*]thiophene derivatives are important synthons for the design of new functional materials possessing chromophoric, conducting or nonlinear optical properties.<sup>134, 137, 182, 183, 350, 352, 353</sup>

Materials containing hexathiaoctahelicene derivatives **326**, which show high third-harmonic generation and are resistant to thermal and optical laser action, were constructed.<sup>354</sup>

R<sup>1</sup>, R<sup>2</sup> = H, C<sub>1</sub>–C<sub>6</sub>-Alk, C<sub>1</sub>–C<sub>6</sub>-OAlk, OH, NO<sub>2</sub>, CN, CHO, Hal.

Photochromic compounds **181** were synthesised on the basis of benzothiazole derivatives of thieno[3,2-*b*]thiophene (see Section III.2). Their open (colourless, **181a**) and cyclic (coloured, **181b**) forms have high thermal stability, which makes it possible to perform repeated direct and reverse photoinduced transitions **181a**  $\rightleftharpoons$  **181b** with retention of the structure.<sup>14, 15</sup>

Analogous cyclobutenedione derivatives of thieno[3,2-*b*]thiophene **327** were synthesised in continuing studies of the use of thienothiophenes for the design of new photochromic materials.<sup>355, 356</sup> Under UV irradiation ( $\lambda = 313$  nm), compound **327** forms thermally stable (in the dark) cyclic form **327b**, which is again transformed into open form **327a** under irradiation with visible light ( $\lambda = 578$  nm).

The photochromic characteristics of 1,2-bis(2,6-dimethyldithieno[3,2-*b*:2',3'-*d*]thiophen-3-yl)hexafluorocyclopent-1-ene (**188**) were studied in an acetonitrile solution.<sup>18</sup> The photocyclisation **188a**  $\rightarrow$  **188b** was carried out under UV irradiation at  $\lambda = 313$  nm, and the reverse reaction was performed under irradiation at  $\lambda = 578$  nm. The long-wavelength absorption maxima for open form **188a** and cyclic form **188b** are 290 and 612 nm, respectively, which are comparable with the corresponding characteristics of benzothiazole derivatives.<sup>14, 15</sup>

Compounds **328a, b**, which have an extensive conjugation between two fused dithienothiophene fragments, were synthesised in the study.<sup>152</sup> High thermal stability, fatigue strength, sensitivity to the diode laser wavelength, nearly quantitatively reversible interconversion and, particularly, ability to perform nondestructive data reading give a real possibility to use these compounds as photoswitching elements in practice.

R = *n*-C<sub>6</sub>H<sub>13</sub>; X = N or MeN<sup>+</sup>(CF<sub>3</sub>SO<sub>3</sub>)<sup>-</sup>.

New quadrupolar photophores **189** and **190**, which contain fragments exhibiting very high two-photon absorption and simultaneously have high quantum yield, were synthesised.<sup>155</sup> Other dithienothiophene-containing nonlinear-optical chromophores were also prepared and have found use as optical relays of a new type.<sup>153</sup>

Benzo[*b*]annulated thieno[3,2-*b*]thiophenes were covered by patents as organic photoconductors<sup>357</sup> and fluorescent bleaching agents.<sup>358</sup>

#### d. Conjugated polymers

In recent years, the number of publications on photochemical and electrochemical polymerisation of thienothiophenes and their polyannulated analogues has been increased sharply. These compounds form conjugated polymers possessing unique properties. Since this field of thienothiophene chemistry is beyond the scope of the present review, only the references to such studies are given.<sup>7, 143, 167, 169, 347, 359–381</sup>

Studies of copolymerisation of a new class of highly efficient optical chromophores with thieno- and dithienothiophenes as linking units led to the design of conducting polymers.<sup>169, 353, 382–391</sup> Poly(thieno[3,4-*b*]thiophenes), which are stable conducting polymers, have attracted particular attention. These compounds were prepared by electrochemical polymerisation of thieno[3,4-*b*]thiophene and its derivatives. These polymers hold promise, in particular, as new materials for electrochromic devices.<sup>392–405</sup>

A new class of silicon-containing copolymers were synthesised by the Heck reaction of distyrylsilane monomers with thiophene and thieno[3,2-*b*]thiophene derivatives, their luminescence properties were studied, and these polymers were demonstrated to be promising electroluminescent materials.<sup>406, 407</sup>

The electropolymerisation kinetics of 3,6-dimethylthieno[3,2-*b*]thiophene was studied by cyclic voltammetry, chronoamperometry and chronopotentiometry on glassy carbon in the presence of a 0.1 M LiClO<sub>4</sub> solution.<sup>408</sup>

#### 3. Dyes

A few publications were devoted to the use of thienothiophene derivatives for the design of new dyeing materials. For example, diazotisation of aminothiophene derivatives afforded disperse azo dyes for colouring synthetic or polyester fibres.<sup>409–411</sup> Thieno[3,2-*b*]thienylidenebis(benzoquinones) were covered by a patent as dyes for optical recording devices.<sup>412</sup>

New electro- and photoactive multifunctional dyes were designed on the basis of dithienothiophenes.<sup>413–415</sup> The pigment properties of 2,2,5,5-tetramethyl-2,3,5,6-tetrahydrothieno[3,2-*b*]thiophene (**127**) were compared with those of analogous compounds containing the thioindigoid fragment, and thienothiophene **127** was demonstrated to belong to indigoid dyes.<sup>113, 213</sup>

Compounds of the thieno[2,3-*b*]thiophene (**142**), thieno[3,2-*b*]thiophene (**145**), dithieno[3,2-*b*:2',3'-*d*]thiophene (**108a**) and thieno[2',3':4,5]thieno[2',3'-*d*]thieno[3,2-*b*]thiophene (**6**) series were also covered by a patent as components (in amounts of 0.01%–0.8%) for the preparation of nonaqueous electrolyte solutions.<sup>416</sup>

## VI. Conclusion

In the chemistry of heterocyclic compounds, the end of the 20th century was marked by a growing interest in fused systems, as evidenced, in particular, by a snowballing increase in the number of publications in this field of chemistry. Analysis of the data published in the literature in the last 25 years demonstrates that the theoretical, synthetic, physicochemical and, particularly, practical aspects of the chemistry of thienothiophenes and their analogues attract growing attention of researchers working in different fields.

The range of practical applications of isomeric thienothiophene derivatives and their O-, N-, S-, Se-, Te-containing and fused analogues is very wide, from real prospects for the design of new medicines (due to a wide spectrum of pharmacological activities) to the design of the previously unknown liquid and clathrate crystals, charge-transfer complexes (organic conductors, magnetic and photosensitive receptors), electroconducting polymers, new nonlinear optical materials necessary for informational technologies, dyes, *etc.*<sup>417</sup>

The further development of the chemistry of fused chalcogen-containing heterocycles will be, apparently, associated with the introduction of various pharmacophoric groups at different positions of the molecules with the aim of preparing new efficient medicines and also with the use of these heterocycles as building blocks for the design of new highly conjugated heterocyclic systems as promising technological materials of the 21st century.

I hope that the present review will be not only helpful to researchers dealing with the chemistry of heterocyclic compounds but also will attract attention of researchers working in other fields of science, such as pharmacology, technology, optoelectronics, *etc.*

I thank Professor M M Krayushkin, who has successfully combined the development of methods for the synthesis of the previously unknown thienothiophene derivatives and the use of these compounds for the design of new photochromic materials in his recent studies (see, for example, Ref. 417), for the idea to write this review and help in analysing published data.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-32063).

**Abstract.** The published data on the structures and properties of porphyrins with distorted aromatic macrocycles are generalised and analysed. Data on the crystal structures, spectra and kinetics of formation and dissociation of their coordination derivatives are summarised. It is demonstrated that the distortion of the planar structure of the tetrapyrrole core is one of the most efficient means of controlling spectral, physicochemical and coordination properties of these compounds. The bibliography includes 95 references.

## I. Introduction

That the tetrapyrrole rings of porphyrins ( $H_2P$ ) are non-planar was demonstrated for the first time more than 30 years ago based on the data from X-ray diffraction analysis.<sup>1–4</sup> Generalisation of X-ray diffraction data has led Hoard<sup>5</sup> to conclude that the non-planarity of porphyrins and their metal derivatives (MP) is their common feature. Yet another important conclusion was that the size of the coordination centre of the porphyrin core is limited due to its cyclic structure. Radial distortion of the macrocycle is a minimum where the radius of the central cavity is  $\sim 200$  pm. Any change in the size of the coordination cavity brings about distortion of the planar structure of the porphyrin macrocycle. These pioneering studies have formed the basis of conformational description of porphyrins.

In 1971, Hambright<sup>6</sup> proposed a mechanism of coordination of porphyrins by metal cations; its key idea was high deformability of the porphyrin macrocycle. Presumably, the Hambright mechanism is inapplicable for non-aqueous solutions;<sup>7</sup> however, distortion of the porphyrin core is obviously one of the most efficient mechanisms of controlling physicochemical, coordination and catalytic properties of porphyrins.

Distortion of porphyrin molecules (here, we imply distortion of the planar structures of their tetrapyrrole cores) can be achieved in various ways, *e.g.*, by introducing a large number of peripheral

substituents or short spacers that form bridges between the *meso*- or  $\beta$ -positions or by protonation, *N*-alkylation or *N*-arylation of the coordination centre. Metalloporphyrins also contain distorted macrocycles; the role of complex-forming agents is played by bulky and some highly charged cations. The main emphasis in this review will be laid on the porphyrins distorted due to peripheral substitution.

In the 1990's, Smith *et al.*<sup>8</sup> synthesised and characterised a large series of porphyrins containing up to 12 peripheral substituents as well as *N*-alkyl derivatives and porphyrins containing bulky *meso*-substituents inducing deformation of the tetrapyrrole core. The methods for the synthesis of this type of compounds have been reviewed.<sup>9</sup>

Analysis of NMR spectra revealed that in the majority of cases the structural parameters of such porphyrins are not changed on going from the crystalline state to solution, *i.e.*, distortion of polysubstituted porphyrins is a result of steric strains in the porphyrin molecules due to intramolecular interactions rather than intermolecular forces in crystals. If direct methods, *e.g.*, X-ray diffraction analysis or NMR, cannot be used, the structure of porphyrins can be deduced from calculations by molecular mechanics methods (MM), which reflect adequately their molecular geometry provided that competent approaches are used.

## II. Structural characteristics

Conformational flexibility of porphyrins can be exemplified by structurally simple compounds, such as tetraphenylporphine (**1**), octaethylporphine (**2**) and their nickel complexes (NiP). These compounds were obtained in the crystalline state with both planar and non-planar structures of their cores.<sup>1,2,10–14</sup> The X-ray diffraction data summarised in Table 1 suggest that in the tetragonal modifications the mean deviation of the C and N atoms of the porphyrin skeleton from the mean-square plane passing through 24 atoms ( $\Delta_{24}$ ) is  $\sim 20$  pm. The *meso*-carbon atoms ( $C_{ms}$ ) are at the largest distance from this plane (50 pm).<sup>1,10</sup>

Coordination of porphyrins by the  $d^8$ -nickel cation, which has a small radius in the low-spin state, leads to further distortion of the core and formation of a non-planar ruffled conformation where the pyrrole rings are tilted about the axes  $C_\alpha - C_\alpha$  eventually resulting in a significant displacement of the  $C_{ms}$  atoms. Two crystalline forms, *viz.*, the planar triclinic<sup>11</sup> and the highly ruffled tetragonal<sup>10</sup> forms of NiP (**2**), were first detected. Yet another planar triclinic modification of NiP (**2**) was described later.<sup>14</sup> The deviations of the carbon and nitrogen atoms from the mean planes of the macrocycles of NiP (**1**) and NiP (**2**) are shown in Fig. 1.

<sup>a</sup> Hereinafter,  $R$  is the radius of the coordination plane of the porphyrin core.

Octasubstituted tetraphenylporphines containing alkyl, cycloalkyl groups and halogens in the β-positions are studied in most detail in comparison with other porphyrins distorted due to the presence of a large number of peripheral substituents. The structural characteristics of β-octaethyl-*meso*-tetraphenylpor-

**Figure 1.** Deviations of carbon and nitrogen atoms from the mean plane passing through 24 atoms of the tetrapyrrole macrocycle in nickel complexes of octaethylporphine and tetraphenylporphine. (a) NiP (**2**) triclinic,<sup>11</sup> (b) NiP (**2**) triclinic,<sup>14</sup> (c) NiP (**2**) tetragonal,<sup>10</sup> (d) NiP (**1**).<sup>13</sup>

phine (**3**) and its complexes obtained by X-ray diffraction analysis and MM are listed in Table 2.<sup>15–19</sup>

The macrocyclic core of β-octaethyl-*meso*-tetraphenylporphine and its coordination compound has a symmetric saddle shape. A characteristic feature of this conformation is that two opposite pyrrole cores are raised above the mean plane of the molecule, while the other two are depressed as a result of the van der Waals repulsions of the *meso*-phenyl and alkyl groups; such *meso*-carbon atoms are coplanar with the macrocycle. This type of deformation is also characteristic of octamethyl analogues, *e.g.*, CuP (**3**) (see Ref. 16) and zinc β-octamethyl-*meso*-tetraphenylporphine pyridinate Zn(Py)P (**4**)<sup>†</sup> (see Ref. 19). Both complexes possess substantially distorted macrocycles, the differences between the methyl and ethyl derivatives being insignificant (Fig. 2).

The deviation of C<sub>β</sub>-atoms owing to sequential up-and-down displacement of the pyrrole rings relative to the mean-square plane (the torsion angle is ~30°) reaches 109–115 pm. Compared to tetraphenylporphin, the *meso*-phenyl rings of its β-octaalkyl-substituted derivatives are rotated by a smaller angle relative to the mean plane of the macrocycle (43–46°); however, this does not result in any significant decrease in the lengths of the C<sub>ms</sub>–C<sub>Ph</sub> bonds. Such a structural type is characteristic of all tetraphenylporphine derivatives containing methyl, ethyl, propyl and cycloalkyl substituents in the β-positions. It is noteworthy

<sup>†</sup> Coordinated acido- and molecular ligands are indicated in parentheses after the metal cation; crystallisation molecules of the solvent stand after a dot. For example: Zn(Py)P (**1**) · 2 MeOH.

**Table 2.** Structural characteristics of  $\beta$ -octaethyl-*meso*-tetraphenylporphine (**3**) and its metallocomplexes.

<sup>a</sup> The radical cation form of the copper complex with perchlorate as a counterion.

**Figure 2.** Structures of the copper complex of  $\beta$ -octaethyl-*meso*-tetraphenylporphine (**a**)<sup>16</sup> and zinc  $\beta$ -octamethyl-*meso*-tetraphenylporphine pyridinate (**b**)<sup>19</sup>.

that the saddle conformation of the  $\beta$ -octamethyl-*meso*-tetraphenylporphine (**4**) macrocycle is slightly ruffled (Fig. 3).

The shapes of the tetrapyrrole macrocycles of distorted porphyrins are rather diverse (Fig. 4).<sup>20</sup> In addition to the aforementioned saddle and ruffled structures, two wavelike, dome-shaped and propeller conformations are also known. In the majority of cases, the shape of the tetrapyrrole core of a distorted porphyrin can be described by one of the above-mentioned types or their combination.

Dodecasubstituted porphyrins and their planar analogues differ in the angles between the same type of bonds (see Tables 1 and 2). The increase in the  $\text{C}_{\text{ms}}-\text{C}_{\alpha}-\text{C}_{\beta}$  angles and the decrease in the  $\text{N}-\text{C}_{\alpha}-\text{C}_{\text{ms}}$  and  $\text{M}-\text{N}-\text{C}_{\alpha}$  angles in the distorted porphyrins by 3–4° in comparison with planar porphyrins are the most significant. This peculiarity is characteristic of all metalloporphyrins **3** (see Tables 1 and 2). Using nickel complexes of highly substituted porphyrins as an example, it was shown<sup>4</sup> that these parameters correlate with the degree of the non-planarity of the macrocycle.

Studies of the structure of Zn(Py)P (**4**) revealed<sup>19</sup> that the conformation of the macrocycle depends on the axial ligands. The displacement of the  $\text{C}_{\beta}$  atoms of the pyrrole rings close to the axial ligand is less pronounced (90 pm) than that of the opposite  $\text{C}_{\beta}$  atoms of the pyrrole cores (120 pm).

In the case of dodecasubstituted porphyrin complexes with 3d-metals, the degree of non-planarity of the tetrapyrrole macro-

**Figure 3.** Deviations of carbon and nitrogen atoms in dodecasubstituted porphyrins and metalloporphyrins from the mean plane of the macrocycle.

(a)  $\text{H}_2\text{P}(3)$ , (b)  $\text{H}_2\text{P}(4)$ , (c)  $\text{ZnP}(4) \cdot \text{MeOH}$ , (d)  $\text{Fe}(\text{Cl})\text{P}(3)$ , (e)  $\text{NiP}(3)$ , (f)  $\text{CuP}(3)$  and its radical-cation form.<sup>15</sup>

**Figure 4.** Typical conformations of non-planar porphyrins.

cycle depends on the size of the complex-forming atom (see Table 2). Judging from the displacement of N,  $\text{C}_\alpha$  and  $\text{C}_\beta$  atoms relative to the mean plane of the macrocycle, the distortion of the macrocycle decreases with an increase in the size of the metal cation in the series from  $\text{Ni}^{2+}$  (69 pm) to  $\text{Zn}^{2+}$  (74 pm). In this case, the lengths of the  $\text{M}-\text{N}$  and  $\text{C}_\alpha-\text{C}_{ms}$  bonds increase, while those of the  $\text{N}-\text{C}_\alpha$  bonds decrease; the angles between the  $\text{M}-\text{N}-\text{C}_\alpha$  bonds decrease, while those between the  $\text{C}_\alpha-\text{N}-\text{C}_\alpha$  and  $\text{C}_\alpha-\text{C}_{ms}-\text{C}_\alpha$  bonds increase. The changes in other structural parameters of metalloporphyrins on going from the smallest to the largest metal atom are insignificant and do not exceed  $1^\circ$ . It is of note that complexes of spatially distorted porphyrins with cations the sizes of which differ substantially from those of 3d-metals have not been investigated yet.

Similarly, the geometry of the complexes of the non-strained planar porphyrins **1** and **2** with 3d-metal cations depends on the sizes of these cations. The sizes of the coordination cavities of porphyrins decrease with an increase in the degree of distortion of the tetrapyrrole core. In turn, coordination of porphyrins by small cations results in further distortion of the macrocycle (Fig. 5).<sup>16</sup> It should be kept in mind, however, that coordination of porphyrins by cations having very large sizes, e.g.,  $\text{Pt}(\text{II})$ ,<sup>21</sup>  $\text{In}(\text{III})$ ,<sup>22</sup> or  $\text{Tl}(\text{III})$ ,<sup>23</sup> also results in the distortion of the tetrapyrrole cores of metalloporphyrins. According to spectral measurements and calculations, distortions of polysubstituted porphyrins are retained on going from the crystalline state to solution.<sup>24–32</sup>

**Figure 5.** Relationship between the radius of the coordination cavity and the bond angle  $\text{C}_\alpha-\text{N}-\text{C}_\alpha$  of octaethylporphyrine (**1**) and  $\beta$ -octaethyl-*meso*-tetraphenylporphyrine (**2**) complexes.<sup>16</sup>

Porphyrins halogenated in the  $\beta$ -positions constitute a large group of spatially distorted dodecasubstituted compounds. The tetrapyrrole cores in copper<sup>33</sup> and nickel<sup>33,34</sup> complexes of  $\beta$ -octabromo-*meso*-tetrakis(pentafluorophenyl)porphine (**5**) and  $\beta$ -octabromo-*meso*-tetramesitylporphine (**6**) and its nickel complex have a saddle conformation. The average distances of the  $\text{C}_{ms}$ ,  $\text{C}_\beta$  and Br atoms from the plane formed by four nitrogen atoms for the copper and nickel complexes of porphyrin **5** are 16.3, 112 and 199 pm and 18.7, 118 and 205 pm, respectively.<sup>33</sup> Very short contacts  $\text{Br}-\text{Br}$  and  $\text{Br}-\text{C}(1)_{\text{Ph}}$  were observed; the sums of the van der Waals radii of these pairs of atoms exceed the real distances between them by  $\sim 45$  pm. However, the lengths of the  $\text{C}-\text{N}$  and  $\text{C}-\text{C}$  bonds in the  $\beta$ -halogenated complexes are virtually the same as those of metalloporphyrins devoid of steric strains. Some structural characteristics of copper and nickel complexes of the porphyrin **5** are listed in Table 3. In these complexes, one of the two bromine atoms in each pair occupying the  $\beta$ -position of the pyrrole ring is more remote from the mean plane of the macrocycle than the other atom. Bulky *ortho*-substituents in the benzene rings of porphyrins **5** and **6** and the neighbouring halogen  $\beta$ -atoms form cavities on both sides of the porphyrin core (Fig. 6).<sup>34</sup> This restricts spatial arrangements of the ligands additionally coordinated by metalloporphyrins<sup>26,28,29,35</sup> and can be directly related to high and specific catalytic activity of polyhalogenated porphyrin complexes with iron(III) in oxidation processes.<sup>36–43</sup>

Dodecaarylporphine derivatives pertain to the class of porphyrins with the most strongly distorted macrocycle. Dodecaphenylporphine (**7**) has a saddle conformation with two highly asymmetric pairs of pyrrole rings in crystals with rhombohedral

**Figure 6.** Deviations of atoms (pm) from the mean plane of the tetrapyrrole macrocycle in a nickel complex of  $\beta$ -octabromo-*meso*-tetraakis(pentafluorophenyl)porphine (*a*),  $\beta$ -octabromo-*meso*-tetramesitylporphine (*b*) and its nickel complex (*c*).<sup>34</sup>

modification (Figs. 7 and 8 *a*).<sup>44</sup> Analysis of intra- and intermolecular interactions revealed<sup>44</sup> that the distortion of the macrocycle in this modification is due to the intramolecular repulsion of the phenyl substituents rather than to the crystal packing effects. Later, two new crystalline forms of dodecaphenylporphine, *viz.*, the triclinic form<sup>45</sup> [ $\text{H}_2\text{P}$  (**7**)  $\cdot 2 \text{ EtOH} \cdot 2 \text{ CH}_2\text{Cl}_2$ ] with a configuration similar to that described above (Fig. 8 *b*) and a much more symmetric rhombohedral conformation [ $\text{H}_2\text{P}$  (**7**)  $\cdot 3 \text{ H}_2\text{O}$ ], were found.<sup>46</sup> The latter has a saddle shape; its  $\text{C}_\beta$  atoms are displaced

**Figure 7.** Structure of dodecaphenylporphine of rhombohedral crystals of  $\text{H}_2\text{P}$  (7)  $\cdot$  3  $\text{CH}_2\text{Cl}_2$  (the hydrogen atoms are not shown).<sup>44</sup>

**Figure 8.** Deviations of carbon and nitrogen atoms in different crystalline modifications of dodecaphenylporphine and its nickel complex from the mean plane passing through 24 atoms of the tetrapyrrole macrocycle.<sup>44–46</sup>

(a)  $\text{H}_2\text{P}(\mathbf{7}) \cdot 3 \text{CH}_2\text{Cl}_2$  rhombohedral, (b)  $\text{H}_2\text{P}(\mathbf{7}) \cdot 2 \text{CH}_2\text{Cl}_2 \cdot 2 \text{EtOH}$  triclinic, (c)  $\text{NiP}(\mathbf{7}) \cdot 5.8 \text{C}_6\text{H}_{12} \cdot 0.9 \text{CHCl}_3$  cubic, (d)  $\text{NiP}(\mathbf{7}) \cdot 3.5 \text{CHCl}_3$  rhombohedral and  $\text{NiP}(\mathbf{7}) \cdot 1.5 \text{H}_2\text{O}$ . (e)  $\text{NiP}(\mathbf{7})$  rhombohedral.

by 132 pm relative to the mean plane of the tetrapyrrole core,<sup>46</sup> which markedly exceeds the corresponding parameter for  $\beta$ -octaethyl-*meso*-tetraphenylporphine H<sub>2</sub>P (**3**) (117 pm).<sup>15</sup> Some structural characteristics of the porphyrin **7** and its complexes are listed in Table 4; it can be seen that the macrocycle of the dodecaphenyl-substituted porphyrin is more flexible than that of octaalkyltetraphenyl derivatives. For example, four crystalline forms of NiP (**7**) differing notably from one another have been established. The cubic form has a purely ruffled configuration; its *C<sub>ms</sub>* atoms are displaced relative to the mean plane of the macrocycle by 86 pm (Fig. 8 *c*).<sup>45</sup> The rhombohedral modification of a solvate containing 3.5 molecules of CHCl<sub>3</sub>, albeit also ruffled, has an entirely different shape (Fig. 8 *d*). In this case, two C <sub>$\beta$</sub>  atoms in each pyrrole ring are displaced asymmetrically by 70 and 10 pm, while the deviation of the *meso*-atoms projecting from the mean plane of the macrocycle is as large as before.<sup>46</sup> Yet another crystal solvate, *viz.*, NiP (**7**)·1.5H<sub>2</sub>O, described in<sup>46</sup> has a similar conformation. And, finally, the fourth crystal modification,

which corresponds to the non-solvated form of the tetrapyrrole macrocycle represents a combination of ruffled and saddle conformations with a shift of the *meso*-carbon atoms from the mean plane by 60 pm and a non-symmetric shift of the C<sub>β</sub> atoms by 76 and 133 pm (Fig. 8e).<sup>46</sup>

Tetraphenylporphine derivatives containing from two to six ethyl groups in the β-positions were synthesised and characterised by X-ray diffraction.<sup>47</sup> The structural characteristics of 2,3-diethyl- (8), 2,3,7,8-tetraethyl- (9), 2,3,12,13-tetraethyl- (10) and 2,3,7,8,12,13-hexaethyl-5,10,15,20-tetraphenylporphine (11) and their nickel(II), copper(II) and zinc(II) complexes are listed in Table 5. For the sake of comparison, the corresponding parameters for tetraphenylporphine (1) and octaethyltetraphenylporphine (3) are also given. As expected, the degree of distortion of the tetrapyrrole macrocycle increases with an increase in the number of peripheral substituents. Of two tetraethyltetraphenyl-

porphine derivatives, the non-symmetrical isomer 9 is distorted to a much greater degree than the symmetrical isomer 10. All porphyrins of this series have a saddle conformation of the macrocyclic core (Fig. 9).

The planar structure of the macrocycle extended along the axis C(5)–C(15) is retained in the molecules of symmetrical 2,3,5,7,8,12,13,15,17,18-decaalkylporphyrins and 5,15-diaryl-β-octaalkylporphyrins.<sup>48,49</sup> At the same time, copper and nickel complexes of these porphyrins are subject to extraplanar distortion: their tetrapyrrole macrocycles are folded along the axis C(5)–C(15) and have a gable roof conformation.<sup>49–52</sup> Non-symmetrical 5,10-di- and 5,10,15-trisubstituted porphyrins are highly distorted.<sup>49</sup> The conformations of their macrocycles represent a combination of ruffled and saddle-like distortions.

Macrocycles of porphyrins containing only four substituents can also be distorted. Zinc *meso*-tetra-*tert*-butylporphine pyridinate (12) has a strongly ruffled aromatic core (Fig. 10).<sup>53,54</sup> Nickel

*meso*-tetraisopropylporphine manifests saddle-like distortion of the macrocycle.<sup>53</sup>

It is noteworthy that introduction of substituents into *meso*-positions brings about stronger deformation of the tetrapyrrole core of porphyrins in comparison with  $\beta$ -substitution.

### III. Physicochemical properties

Distortion of the planar structure of the tetrapyrrole core strongly affects the spectral characteristics of porphyrins. The  $^1\text{H}$  NMR spectra of octamethylporphine (**13**) and its *meso*-phenyl derivatives, *viz.*, 5-phenyl- (**14**), 5,15-diphenyl- (**15**), 5,10-diphenyl- (**16**), 5,10,15-triphenyl- (**17**) and 5,10,15,20-tetraphenyl-2,3,7,8,12,13,17,18-octamethylporphine (**4**), have been analysed.<sup>55</sup> Symmetrical compounds of this series have extremely low solubility in neutral and basic solvents; therefore, their  $^1\text{H}$  NMR spectra were recorded for solutions in deuteriochloroform with 0.5% trifluoroacetic acid. In this medium, porphyrins are easily soluble and exist in the protonated form.

As expected, the  $^1\text{H}$  NMR spectrum of porphyrin **13** contained only three singlet peaks corresponding to the protons in the *meso*-positions, of the methyl and NH groups (Table 6). The  $^1\text{H}$  NMR spectrum becomes more complicated on going to the monophenyl derivative **14** as can be evidenced from the splitting of the signals corresponding to the  $\beta$ -methyl groups and the appearance of peaks at  $\delta \sim 8$  corresponding to protons of the phenyl substituents. The results of MM calculations of the porphyrin **14** structure (Fig. 11) suggest that the methyl groups in positions 3 and 7 lie in the region of the anisotropic shielding by the ring current of the phenyl nucleus. The signals for the protons of these methyl groups at  $\delta \sim 2.3$  resonate and thus are upfield shifted by  $\sim 1.4$  ppm in comparison with the corresponding signals in the  $^1\text{H}$  NMR spectrum of octamethylporphine (**13**). The upfield shift of the signals by  $\sim 0.5$  ppm was also observed for the neighbouring 2,8-groups and even for the 12,18-methyl groups. Obviously, these shifts cannot be only due to the anisotropic effect of the ring

current of the phenyl residue. More probably, in this case two effects operate, *viz.*, the negative inductive effect of the phenyl group and the effect of deformation of the porphyrin macrocycle. Introduction of the phenyl group decreases the strength of the ring current owing to the porphyrin macrocycle as can be judged from the upfield shift of the signals for the *meso*-protons and the downfield shift of the central NH group protons. Both signals are split into two components, the splitting being large for the NH groups (by 1.2 ppm) and small for the *meso*-protons (by 0.13 ppm). Judging from the integral intensity, the signal at  $\delta$  10.37 corresponds to the hydrogen atom in position 15, whereas the signal at  $\delta$  10.50 corresponds to the protons at the C(10) and C(20) atoms. This suggests that the splitting is due to the negative inductive effect of the phenyl substituent.

MM calculations of two diphenyloctamethylporphine derivatives have shown that the tetrapyrrole core of the symmetrical isomer **15** is distorted to a much lesser degree than that of its 5,10-substituted analogue **16** (Fig. 12). The  $^1\text{H}$  NMR spectrum of porphyrin **15** (Table 6, Fig. 13a) contains one singlet for the protons of the NH groups ( $\delta -3.07$ ), two singlets for the methyl groups ( $\delta$  2.27 and 3.26), a multiplet for the *meta*- and *para*-protons of the phenyl substituents ( $\delta$  7.94–7.97), a doublet for the *ortho*-protons ( $\delta$  8.23) and a singlet for the *meso*-protons ( $\delta$  10.34). A comparison of average values of the chemical shifts of the *meso*-protons of monophenyl- (**14**) and 5,15-diphenyloctamethylporphine derivatives (**15**) revealed that the strength of the ring current induced by the aromatic macrocycle of diphenylporphyrin is reduced. A similar conclusion can be derived from a comparison of positions of the protons of the NH groups in the  $^1\text{H}$  NMR spectra of these porphyrins. Thus, introduction of the second phenyl substituent confers additional strain on the structure of the porphyrin macrocycle.

The  $^1\text{H}$  NMR spectrum of the non-symmetrical porphyrin **16** is even more complicated (see Table 6 and Fig. 13b). The protons of the central NH groups appear as three peaks at  $\delta -3.84$  (24-H),  $-2.23$  (21, 23-H) and  $-1.31$  (22-H); their assignment was based on the measurements of their integral intensities. The assignment of the protons of the methyl groups, which give four signals with the same integral intensities, was carried out taking account of the deshielding effect of the phenyl substituents on the neighbouring methyl groups:  $\delta$  1.81 — 7, 8-Me,  $\delta$  2.22 — 3, 12-Me,  $\delta$  3.23 — 2, 13-Me and  $\delta$  3.51 — 17, 18-Me. The *meso*-protons of the non-symmetrical porphyrin **16** resonate as a singlet at  $\delta$  9.99 and are shifted upfield in comparison with the symmetrical isomer **15**. At the same time, the protons of the NH groups of the porphyrin **16** are shifted downfield in comparison with compound **15**. The  $^1\text{H}$  NMR spectrum of the neutral form of compound **16** recorded

**Figure 13.**  $^1\text{H}$  NMR spectra of 5,15-diphenyl-2,3,7,8,12,13,17,18-octamethylporphyrine (a) and 5,10-diphenyl-2,3,7,8,12,13,17,18-octamethylporphyrine (b) in  $\text{CDCl}_3$  with 0.5%  $\text{CF}_3\text{CO}_2\text{H}$ .<sup>55</sup> TMS is tetramethylsilane.

in deuteriochloroform at room temperature differs from that of the protonated porphyrin in the absence of the signals for the protons of the NH groups. Apparently, these peaks can be detected at lower temperatures. Other characteristics of the  $^1\text{H}$  NMR spectra of protonated and non-protonated porphyrins are similar.

The  $^1\text{H}$  NMR spectrum of the neutral form of porphyrin **17**, like that of compound **16**, does not contain signals corresponding to the protons of the NH groups; the latter appear upon protonation of the porphyrin at  $\delta -2.47$  and  $-1.26$  (see Table 6 and Fig. 14). In the region of positive values of the chemical shifts, the  $^1\text{H}$  NMR spectra of the neutral and protonated forms are virtually the same. Upon protonation, the signals of the protons of the methyl groups are shifted downfield by 0.04–0.13 ppm, while those of the *meso*-protons are shifted by 0.2 ppm.

**Figure 14.**  $^1\text{H}$  NMR spectrum of 5,10,15-triphenyl- $\beta$ -octamethylporphyrine in  $\text{CDCl}_3$  with 0.5%  $\text{CF}_3\text{CO}_2\text{H}$ .<sup>55</sup>

Steric repulsion of the phenyl and methyl substituents in the porphyrin **4** results in the saddle-shaped conformation of the macrocycle. In its  $^1\text{H}$  NMR spectrum, this is manifested as a downfield shift of the signals for the protons corresponding to the NH groups and the appearance of a singlet at  $\delta -1.14$ . In addition, the  $^1\text{H}$  NMR spectrum of the porphyrin **4** contains a singlet corresponding to the protons of the methyl groups at  $\delta 1.84$  and two multiplets corresponding to the *ortho*- ( $\delta 8.35$ ), *meta*- and *para*-protons ( $\delta 7.93$ ).

Analysis of the data listed in Table 6 suggests that the signals for the protons of the NH groups are gradually shifted downfield with an increase in the number of the phenyl substituents in the *meso*-positions of octamethylporphyrine. The signals for the *meso*-proton are shifted in the opposite direction in the same series. This suggests that the strength of the ring current decreases, while the degree of distortion of the porphyrin macrocycle increases in the following series of substituted octamethylporphyrines: unsubstituted < 5-phenyl- < 5,15-diphenyl- < 5,10-diphenyl- < 5,10,15-triphenyl- < tetraphenyl-octamethylporphyrine.

A series of *meso*-phenyloctaethylporphyrine derivatives, viz., 5-phenyl- (**18**), 5,15-diphenyl- (**19**), 5,10-diphenyl- (**20**), 5,10,15-triphenyl- (**21**) and 5,10,15,20-tetraphenyl-2,3,7,8,12,13,17,18-octaethylporphyrine (**3**), have been investigated.<sup>56</sup> The structures of these porphyrins were calculated using the semiempirical quantum-chemical method (PM3).

The results of optimisation of the structure of the monophenyl octaethylporphyrine derivative (**18**) by molecular mechanics methods (force field MM+) and PM3 (Fig. 15) are qualitatively similar, although the MM method predicts a somewhat larger deformation of the planar structure of the macrocycle. What is essential, is that the introduction of even one aryl substituent in the *meso*-position of a  $\beta$ -octaalkylporphyrine results in the distortion of its planar structure. The results of calculations of the structures of *meso*-phenyloctaethylporphyrine derivatives are shown in Fig. 16; the  $^1\text{H}$  NMR spectra of porphyrins **3** and **18–21** are presented in Table 7.

**Figure 15.** Structure of porphyrin **18** optimised using the MM (black coloured) and PM3 (grey coloured) methods.<sup>56</sup>

As expected, the simplest  $^1\text{H}$  NMR spectrum was observed for  $\beta$ -octaethylporphyrine (**2**). This contains four signals: a singlet for the *meso*-proton ( $\delta 10.10$ ), a quartet ( $\delta 4.11$ ) and a triplet ( $\delta 1.92$ ) corresponding to the protons of the methyl and methylene groups and a singlet ( $\delta -3.75$ ) corresponding to the protons of the NH groups.

Introduction of a phenyl group into the *meso*-position of the macrocycle results in the complication of the  $^1\text{H}$  NMR spectrum of the porphyrin **18** manifested in the appearance of additional signals for the protons of the phenyl substituent. Splitting of these signals is due to the anisotropic effect of the ring current of the macrocycle. The intensity of the magnetic field induced by this current diminishes the effect of an external magnetic field on the *ortho*-protons which are deshielded more strongly ( $\delta 8.21$ ) than the *meta*- and *para*-protons ( $\delta 7.66$  and  $7.79$ , respectively). The signals of the ethyl groups adjacent to the benzene ring form a separate group as a result of anisotropic shielding by the phenyl substituent and are shifted upfield ( $\delta 2.78$  and  $1.18$ ) in comparison with the more remote ethyl groups ( $\delta 4.12$  and  $1.89$ ). The signals

of the protons in the *meso*-positions and in the NH groups are split into two components, *viz.*,  $\delta$  10.18, 9.93 and −3.02, −3.15, respectively. The fact that the signals of peripheral *meso*- and intracyclic NH group protons come closer suggests a decrease in the strength of the ring current of the macrocycle upon introduction of a *meso*-phenyl substituent into the octaethylporphine molecule.

Diphenyl- $\beta$ -octaethylporphine derivatives have a strongly distorted macrocycle, the distortion of the 5,15-substituted isomer **19** is much less pronounced than that of its non-symmetrical analogue **20** (see Fig. 16). The <sup>1</sup>H NMR spectra of these compounds manifest a downfield shift of the signals for the protons of the NH groups to  $\delta$  −2.08 (for the symmetrical isomer **19**) and to  $\delta$  −2.72 (for the 5,10-substituted analogue **20**). Special mention should be made of a significant broadening of the signals for the protons of the NH groups in the <sup>1</sup>H NMR spectrum of the porphyrin **20**.

The signals for the *meso*-protons of the porphyrin **19** are present at  $\delta$  10.23 and are slightly shifted downfield in comparison with the corresponding signals in the <sup>1</sup>H NMR spectrum of compound **18**. At the same time, the signals for the *meso*-protons

in the <sup>1</sup>H NMR spectrum of the porphyrin **20** are shifted noticeably upfield ( $\delta$  9.63).

The signals for the *meta*- and *para*-protons of the *meso*-phenyl groups in the <sup>1</sup>H NMR spectra of compounds **19** and **20** do not change their positions relative to the corresponding signals in the <sup>1</sup>H NMR spectrum of the porphyrin **18**. A noticeable shift of the signals for the *ortho*-protons of the phenyl groups of the non-symmetrical isomer **20** can be attributed to the effect of steric factors. The phenyl rings of the more strongly distorted porphyrin **20** cannot any longer be perpendicular to the plane of the macrocycle and are rotated relative to the framework of the molecule. As a result, the *ortho*-protons of the phenyl substituents that are close to the macrocycle are exposed to the stronger deshielding effect of the ring current of the porphyrin as a result of which their signals are shifted downfield ( $\delta$  8.30).

An analogous trend for the signals of the protons of the NH groups and the protons in the *meso*-positions to come closer to each other can also be traced in the <sup>1</sup>H NMR spectrum of triphenyloctaethylporphine **21**: the degree of the distortion of the macrocycle increases with an increase in the number of peripheral substituents.

The results of quantum-chemical calculations and <sup>1</sup>H NMR spectroscopic data suggest that dodecaphenylporphyrine (**7**) is distorted to the greatest extent. The protons of the NH groups in its <sup>1</sup>H NMR spectrum resonate in the lowest field, at  $\delta$  −0.85. The protons in the *meta*- and *para*-positions of the *meso*- and  $\beta$ -phenyl substituents are not resolved and appear as a multiplet at  $\delta$  6.69. The signals for the *ortho*-protons of the phenyl groups in the  $\beta$ -positions are observed at  $\delta$  7.06, while those in the *meso*-positions are observed at  $\delta$  8.02.

Analysis of <sup>1</sup>H NMR spectroscopic data revealed that the introduction of the phenyl substituents in the *meso*-positions of  $\beta$ -octaethylporphine causes distortion of the aromatic tetrapyrrole core which increases in the following order: **2** < **18** < **19** < **20** < **21** < **3** < **7**.

Porphyrins containing from 8 to 12 phenyl substituents have been synthesised and their <sup>1</sup>H NMR spectra have been analysed.<sup>31</sup> The strength of the ring current of the macrocycle decreases with an increase in the number of peripheral substituents (Table 8). One of two decaphenyl porphine derivatives, *viz.*, the non-symmetrical *cis*-isomer, manifests a higher degree of distortion than the 5,15-substituted *trans*-analogue.

**Table 8.** <sup>1</sup>H NMR spectra of phenyl-substituted porphyrins in CDCl<sub>3</sub> (TMS as an internal standard).<sup>31</sup>

| Porphyrin                                   | $\delta$ |                |

The dynamics of conformational changes in spatially distorted porphyrins in solution was monitored by following the temperature dependence in the <sup>1</sup>H NMR spectra.<sup>24, 25, 27, 57, 58</sup> At 298 K, dodecaphenylporphine (**7**) gives three low-field signals corresponding to the protons of the phenyl groups (Fig. 17). Splitting of two multiplet signals at  $\delta$  6.5–7 into two triplets is observed at temperatures below 253 K; the doublet at  $\delta$  ~7.6 corresponding to the *ortho*-protons of the *meso*-phenyl rings undergoes splitting at temperatures below 243 K. At 193 K, the <sup>1</sup>H NMR spectrum contains six doublets and nine triplets with the integral intensities of unity each. Similar temperature-dependent changes are observed in the <sup>1</sup>H NMR spectrum of the dication H<sub>4</sub>P (**7**)<sup>2+</sup>. An unusually broad range of chemical shifts of the signals for the *ortho*-protons of the  $\beta$ -phenyl rings of dodecaphenylporphine is observed.

**Figure 17.** Temperature dependence of the  $^1\text{H}$  NMR spectrum of dodecaphenylporphyrine in  $\text{CD}_2\text{Cl}_2$ .<sup>25</sup>

nylporphyrine and its protonated form at low temperatures was attributed<sup>25</sup> to different positions of these protons relative to the macrocyclic core and, correspondingly, to different effects of the ring current on these protons. The *ortho*-protons of the  $\beta$ -phenyl group deviate from the mean plane of the porphyrin skeleton to a larger distance and are shielded to a lesser degree in comparison with aromatic ring protons less deviated from the plane.

Analysis of the temperature dependence of the  $^1\text{H}$  NMR spectrum of the porphyrin **7** revealed that its molecules take part in two dynamic processes. One of them is NH-tautomerism.<sup>58</sup> The value of the Gibbs activation energy,  $\Delta G^\ddagger$ , calculated for this reaction is  $54 \text{ kJ mol}^{-1}$  (see Ref. 25), *i.e.*, is commensurate with the corresponding values for planar tetraarylporphyrins.<sup>49</sup> The second dynamic process, which is more characteristic of distorted porphyrins,<sup>19,29</sup> entails inversion of the macrocycle. The  $\Delta G^\ddagger$  value of this process for the porphyrin **7** is  $\sim 46 \text{ kJ mol}^{-1}$  (see Ref. 25). Only one dynamic process, *viz.*, inversion of the macrocycle ( $\Delta G^\ddagger = 45.5 \text{ kJ mol}^{-1}$ ), is observed for the dication  $\text{H}_4\text{P}(\text{7})^{2+}$ . It is noteworthy, however, that no dynamic processes take place in the case of the nickel dodecaphenylporphyrine complex ( $\Delta G^\ddagger < 30 \text{ kJ mol}^{-1}$ ) despite the same degree of distortion of the molecule. Presumably, the barrier to inversion of the macrocycle

in the complex  $\text{NiP}(\text{7})$  is too low to be recorded. This is consistent with the data for nickel complexes of octamethyl-, octaethyl- and octapropyltetraphenylporphyrines where the barriers to inversion of the macrocycles are much lower than those in the corresponding free bases and their dications.<sup>24</sup>

Distortion of the porphyrin core also manifests itself in the Raman spectra.<sup>59–61</sup> The frequency range ( $1300–1700 \text{ cm}^{-1}$ ) of porphyrin complexes, which comprises a series of structure-sensitive ‘marker’ lines ( $\nu_2–\nu_4$ ) corresponding to the stretching of the  $\text{C}_\alpha–\text{N}$  ( $\nu_2$ ),  $\text{C}_\alpha–\text{C}_{ms}$  ( $\nu_3$ ) and  $\text{C}_\beta–\text{C}_\beta$  ( $\nu_4$ ) bonds, is the most interesting and informative one.<sup>61</sup> Analysis of a series of distorted nickel complexes of octaalkyltetraphenylporphyrines and planar complexes of octaalkylporphyrines has shown<sup>60</sup> that in the former case the ‘marker’ line frequencies in the Raman spectra increase with an increase in the size of the coordination cavity. Contrariwise, in the case of octaalkylporphyrine complexes an increase in the size of the coordination cavity results in a shift of the structure-sensitive lines  $\nu_2$ ,  $\nu_3$  and  $\nu_4$  towards the lower frequencies. Based on the data obtained, the lines  $\nu_2–\nu_4$  were termed as ‘core-size marker lines’. The Raman spectra of a series of distorted porphyrin **3** complexes with Ni, Co, Cu and Zn have been analysed.<sup>16</sup> A correlation between the size of the central cavity and the frequency of the bands  $\nu_2–\nu_4$  was opposite to the dependence established<sup>60</sup> for a series of nickel complexes of  $\beta$ -octaalkyl-*meso*-tetraphenylporphyrines. The size of the coordination cavity is determined by both the deviation of the porphyrin core from planarity as a result of introduction of peripheral substituents and the size of the metal cation; however, the contribution of each of these factors is different.

It was found<sup>16</sup> that the size of the central cavity is not a crucial factor in determining the position of the ‘marker’ lines. The angle  $\text{C}_\alpha–\text{N}–\text{C}_\alpha$  is yet another parameter that influences the frequency of these marker lines. The lines  $\nu_2$ ,  $\nu_3$  and  $\nu_4$  are always shifted towards the lower frequencies with an increase in the angle  $\text{C}_\alpha–\text{N}–\text{C}_\alpha$ . Apparently, the magnitude of this angle is closely related to the vibration frequencies of the bonds contributing to the ‘marker’ lines.

The frequencies of the ‘marker lines’ in solution and in the crystalline states differ insignificantly, which suggests the similarity of the conformations of the macrocycle both in solution and in the crystal (Table 9).

Distortion of the tetrapyrrole core is manifested specifically in the electronic absorption spectra. The electronic absorption spectra of some *meso*-phenyloctamethylporphyrine derivatives in acetic acid are shown in Fig. 18.<sup>55</sup> With an increase in the degree of distortion of the porphyrin macrocycle, all absorption bands manifest bathochromic shifts. These spectral changes are so characteristic that the red shift of all electronic absorption spectra bands can be reliably interpreted as the deformation of the tetrapyrrole macrocycle.<sup>8</sup>

The data from the electronic absorption spectra of octaethylporphyrine, its *meso*-phenyl derivatives and dodecaphenylporphyrine are listed in Table 10. As can be seen, the absorption maxima of the porphyrins are shifted regularly towards the red region with an increase in the degree of extraplanar distortion of the macrocycle irrespective of the solvent used. The reason for these spectral

changes is the deformation of the macrocycle, which reduces its aromaticity.

The ruffled and saddle conformations of zinc complexes of unsubstituted porphyrine (**22**) and *meso*-tetrakis(trifluoromethyl)porphyrine (**23**) were optimised using the density functional theory-

based analysis of configuration interaction calculations with single excitations (DFT/SCI).<sup>62,63</sup> An artificial distortion of the macrocycle of the zinc porphyrine complex was performed in order to prove the appearance of a bathochromic shift in the absorption spectra in the absence of electronic effects of substituents. The distorted skeleton of ZnP (**23**) with all the *meso*-CF<sub>3</sub> groups replaced by hydrogen atoms was used to derive a ruffled conformation of ZnP (**22**). A similar approach was used to derive a saddle conformation of ZnP (**22**) based on  $\beta$ -octamethyl-*meso*-tetraphenylporphyrine.

The results of DFT/SCI computations (Tables 11 and 12) provide an adequate description of excited states of different types of porphyrins.<sup>62,64,65</sup> As can be seen from Table 12, the *Q*-bands of the non-planar conformations of ZnP (**23**), *viz.*, the ruffled conformation at 582 nm and the saddle conformation at 576 nm, are shifted bathochromically relative to the *Q*-band of the planar conformation of ZnP (**22**) (by 24 and 18 nm, respectively), which is consistent with the experimental data.<sup>66,67</sup> The calculated data on simulated distortions of the ZnP (**22**) macrocycle also predicted a long-wavelength shift of the bands in the electronic adsorption spectra of the ruffled and saddle conformations (by 17 and 27 nm, respectively). The *B*-bands in all distorted porphyrins are shifted towards the red region, apparently as a result of destabilisation of their upper occupied orbitals.

Semiempirical quantum-chemical calculations of saddle, ruffled and dome-like conformations of a magnesium porphyrine complex<sup>68</sup> gave similar results, *viz.*, with an increase in the degree of distortion of the planar structure of the porphyrin core, all absorption bands manifested a bathochromic shift due to the advanced destabilisation of the HOMO.

The results of spectroelectrochemical<sup>69,70</sup> and electrochemical measurements<sup>70–75</sup> provide additional experimental evidence in favour of stronger destabilisation of the HOMO upon deformation of the macrocycle than the LUMO. The redox potentials of zinc complexes of tetrakis(pentafluorophenyl)porphyrine (**24**) and its octabromo- (**25**), octachloro- (**26**) and octamethyl- (**27**) derivatives are listed in Table 13. As can be seen, the octachloro and octabromo derivatives are reduced more easily (by 0.48 and 0.47 V, respectively) and are oxidised less easily (by 0.26 and 0.20 V, respectively) than the planar complex ZnP (**24**). Hence, the energy gap between the bonding and antibonding orbitals

**Table 10.** Electronic absorption spectra of octaethylporphyrine, its *meso*-phenyl derivatives and dodecaphenylporphyrine.<sup>56</sup>

**Note.** The potentials were measured using a reference chloride electrode in 1.0 M KCl;  $E_{Fc1+/0} = 0.48$  V; 0.1 M  $[NBu_4]^+ [PF_6]^- / CH_2Cl_2$ .

diminishes upon distortion of the porphyrin macrocycle. When analysing the data presented in Table 13, account must be taken of the fact that, unlike the phenyl groups, pentafluorophenyl substituents and halogen atoms possess electron-withdrawing properties and thus make a greater contribution to the stabilisation of the HOMO and LUMO of ZnP (25) and ZnP (26) complexes in comparison with ZnP (24).

Zinc complexes of 2,3,12,13-tetrasubstituted 5,10,15,20-tetra-phenylporphyrins, which contain trifluoromethyl (28) and methyl (29) substituents and bromine atoms (30), have been synthesised.<sup>75</sup> The structures of the complexes (as crystal solvates) of ZnP (28)·(EtOH)<sub>3</sub>, ZnP (29)·(THF)<sub>1.6</sub>·(CHCl<sub>3</sub>)<sub>0.4</sub> and ZnP (30)·MeOH·DMF have been established. Their macrocycles have a saddle, slightly ruffled conformation; the structure of the porphyrin containing trifluoromethyl groups is deformed to the greatest extent (Fig. 19). Presumably, this deformation is due to the square-pyramidal coordination of the zinc cation rather than to the steric repulsion of the peripheral substituents. These structural data can be correlated to spectral and electrochemical characteristics.

**Figure 19.** Deviations of the atoms in the macrocycles of zinc complexes of porphyrins 28 (a), 29 (b) and 30 (c) from the mean plane passing through four nitrogen atoms.<sup>75</sup> The positions of the substituents are coloured black.

All absorption bands in the electronic spectrum of ZnP (28) are shifted bathochromically in comparison with the electronic spectra of ZnP (29) and ZnP (30) (Fig. 20). Cyclic voltammetric studies of the redox properties of zinc complexes of porphyrins (28–30) revealed that their oxidation and reduction potentials increase with an enhancement of the electron-withdrawing properties of the substituents, these dependences being nearly linear for the oxidation and S-shaped for the reduction (Fig. 21). The

**Figure 20.** Electronic absorption spectra of zinc complexes of 2,3,12,13-tetrasubstituted derivatives of tetraphenylporphine ZnP (**28**) (**1**), ZnP (**29**) (**2**) and ZnP (**30**) (**3**) in  $\text{C}_2\text{H}_4\text{Cl}_2$ . The intensities of the bands in the visible region of the spectrum are increased 5-fold.<sup>75</sup>

**Figure 21.** Dependences of the first oxidation (**1**) and reduction (**2**) potentials of zinc complexes of tetrasubstituted tetraphenylporphine derivatives measured in  $\text{C}_2\text{H}_4\text{Cl}_2$  vs. a saturated calomel electrode on the values of the Hammett constants  $\sigma_p$  of substituents.<sup>75</sup>

difference between the oxidation and reduction potentials decreases with an enhancement of the electron-withdrawing properties of the substituents, the destabilisation of the HOMO being greater than that of the LUMO. The difference between the orbital energies for ZnP (**1**) is 2.2 V, whereas that for its trifluoromethyl derivative is as small as 1.5 V. Thus, the energies of the MO of porphyrins and their redox characteristics strongly depend on spatial distortion of their central core and the electronic nature of substituents.

#### IV. Coordination properties

The effect of the distortion of the planar structure of a macrocycle on the coordination properties of porphyrins was observed for *N*-substituted derivatives.<sup>76</sup> However, one can hardly distinguish structural changes in the coordination centre of the macrocycle due to substitution from the distortion of the macrocycle itself. The effect of distortion as such on the coordination properties was established in the analysis of the dimeric tetraphenylporphine derivatives **31a–d** where the monomeric fragments are linked through benzene nuclei by four bridges of the type  $\text{O}(\text{CH}_2)_n\text{O}$ ,  $n = 2–4$ .<sup>77–83</sup>

For steric reasons, all C–C bonds of the bridging groups of the cyclophane dimer **31a** cannot adopt *trans*-configurations. The energy required for transition from the transoid configuration of one of these bonds to the gauche configuration is less than 4 kJ mol<sup>−1</sup>. The overall change in the configuration of one bond

*m*-bridge,  $n = 4$  (**a**), *m*-bridge,  $n = 3$  (**b**), *m*-bridge,  $n = 2$  (**c**), *o*-bridge,  $n = 3$  (**d**).

in each of the four bridges suffices for the disturbance of the planar structure of the tetrapyrrole cores in the dimer **31a**.<sup>77</sup> Studies on the kinetics of formation and dissociation of complexes of the dimers **31a–d** containing bridging groups of various lengths have shown<sup>78–83</sup> that the reactivities of these porphyrins increase by a factor of tens of thousands as a result of spatial distortion of their macrocycles. Considering that the acid–base and coordination properties of porphyrins are closely interrelated,<sup>90</sup> it is not surprising that spatially distorted porphyrins significantly exceed their planar counterparts in basicities.<sup>84–89</sup> Stretching and polarisation of the N–H bonds in the transition state of a reacting system ‘a metal solvatocomplex–porphyrin’ make a significant contribution to the energy of complex formation. At the same time, strong interactions of metal cations with tertiary nitrogen atoms of porphyrin occur in the transition state, which decrease both the energy of the transition state and the activation energy of the reaction. Thus, an increase in the electron density on the nitrogen atoms not only provides easier access to them due to the deformation of the macrocycle, but also increases appreciably the rate of formation of metalloporphyrins. This is confirmed by kinetic data on coordination of octamethylporphine, octaethylporphine and their phenyl derivatives by copper and zinc ions in pyridine and DMF (Tables 14 and 15).

The equation of complexation can be presented as follows:

The kinetic order of this reaction with respect to porphyrin for all the porphyrins described in this review is equal to unity. With respect to metal salts, the situation is more complicated, *viz.*, the kinetic order of the reaction depends on the degree of ionisation of the solvatocomplex in solution.<sup>91</sup>

The data presented in Tables 14 and 15 suggest that the complexation rates of phenyl derivatives of octamethyl- and octaethylporphine in pyridine and DMF increase with an increase in the number of peripheral substituents, 5,10-diphenyl derivatives reacting at much faster rates than their 5,15-substituted analogues. The reaction rate increases 3–4 orders of magnitude, while the activation energy decreases 2–2.5-fold on going from planar octaalkylporphines to the most deformed tetraphenyl derivatives. Introduction of eight  $\beta$ -alkyl substituents on going from porphine to etioporphyrin and of four *meso*-phenyl groups on going from porphine to tetraphenylporphine causes only a 7-fold increase in the complexation rate. In other words, the drastic increase in the complexation rates resulting from the introduction of *meso*-aryl substituents into  $\beta$ -octaalkylporphines

**Table 14.** Rate ( $k$ ), energy of activation ( $E$ ) and changes in the entropy of activation ( $\Delta S^\ddagger$ ) of the coordination of octamethylporphine (**13**) and its phenyl derivatives by copper and zinc ions in pyridine.<sup>55</sup>

cannot be due to the electronic effects of the substituents alone and is caused primarily by the changes in the geometry of the porphyrin molecules. Additional evidence in favour of this idea comes from the changes [more than 100 J (mol K)<sup>-1</sup>] in the entropy of activation of the complexation for the porphyrins under study. These structural changes influence indirectly the electronic structure of the macrocycle by decreasing its aromaticity and increasing the electron density on the nitrogen atoms in the coordination centres of porphyrins.

The changes in the reactivities of phenyl-substituted  $\beta$ -octaalkylporphyrins in acetic acid are different in principle (Tables 16 and 17). With an increase in the number of phenyl substituents, the rate of complex formation decreases  $\sim 10^4$ -fold. In acetic acid, no dodecaphenylporphine complexes are formed at all. The activation energy of this reaction increases threefold on going from octaalkylporphyrins to their tetraphenyl derivatives, whereas the changes in the entropy of activation exceed 100 J (mol K)<sup>-1</sup>. This can be attributed to the fact that the basicities of porphyrins increase with the degree of distortion of the tetrapyrrole macrocycles as a result of which tertiary nitrogen atoms acquire an ability to form more stable hydrogen bonds with acetic acid molecules blocking the coordination centre. Thus, the dicationic

form generated by dodecaphenylporphine in acetic acid is inert with respect to coordination by transition metal ions.

The dissociation kinetics of copper(II), cobalt(II) and manganese(III) complexes with spatially distorted porphyrins in mixtures of acetic and trifluoroacetic acids has been studied (Table 18).<sup>56,92,93</sup> The kinetic order of this reaction with respect to metalloporphyrin and trifluoroacetic acid is equal to unity, which suggests a two-step dissociation mechanism<sup>94</sup> according to which the first M–N bond of the metalloporphyrin is cleaved under the action of a strong proton donor, *e.g.*, MeCO<sub>2</sub>H<sub>2</sub><sup>+</sup>, formed upon protonation of the oxygen atom of acetic acid, while the second bond is cleaved by a relatively weak acetic acid present in the system in a large excess. This activation barrier is overcome upon cleavage of the second M–N bond.

As can be seen from Table 18, the dissociation rates of copper and cobalt complexes of porphyrins increase, while the energies of activation decrease with an increase in the degree of distortion of the aromatic tetrapyrrole core. Introduction of the first two *meso*-phenyl substituents affects the kinetic parameters of this reaction to a far lesser degree than the introduction of the next two substituents. Dodecaphenylporphine complexes dissociate upon dissolution in acetic acid in the absence of sulfuric or trifluoro-

**Table 16.** Kinetic parameters of coordination of octamethylporphine and its phenyl derivatives by copper and zinc ions in acetic acid.<sup>55</sup>

acetic acid. Apparently, the greater the distortion of the starting porphyrin the stronger are the strains of the coordination bonds M–N and the higher is the effective negative charge on the nitrogen atoms exposed to the electrophilic attack by the solvated proton.

The entropies of activation of the dissociation of copper and cobalt porphyrin complexes decrease regularly with an increase in the number of phenyl substituents, which suggests an increase in the degree of ordering of the ‘metalloporphyrin – solvated proton’ system in the transition state. The energies and entropies of the activation in the dissociation of cobalt complexes are significantly lower in comparison with the copper analogues. This correlates with the properties of Cu(II) and Co(II) cations: the formation of square-planar complexes is more characteristic of the former, whereas the latter largely produce octahedral complexes. Obviously, in the transition state the cobalt cation leaving the coordination centre of the porphyrin is solvated more efficiently than the copper cation.

Porphyrin complexes with Mn(III) are more stable than those with Co(II) and Cu(II) and their dissociation rates are two orders of magnitude lower under comparable conditions (see Table 18). However, the character of changes in the dissociation rates depending on the degree of deformation of the porphyrin ligands is the same: on going from octaethylporphine to the tetraphenyl derivative, the dissociation rate constants of the manganese complex increase by three orders of magnitude in a mixture of acetic and trifluoroacetic acids and 60-fold in a mixture of acetic and sulfuric acids. In these media, the manganese complex of dodecaphenylporphine dissociates at immeasurably fast rates.

Studies of axial coordination of piperidine and 1-methylimidazole by zinc complexes of spatially distorted porphyrins (Table 19) have demonstrated that stabilities of these complexes decrease regularly with an increase in the number of peripheral substituents.<sup>95</sup> This supports again an assumption that the deformation of cores in polysubstituted porphyrins decreases the aromaticity of the macrocycle and increases the negative charge

**Table 19.** Stability constants of axial complexes of zinc porphyrinates with piperidine and 1-methylimidazole in benzene at 298 K.<sup>95</sup>

**Abstract.** The review concerns the state-of-the-art in the field of investigations of the shape memory effect in various polymeric materials, namely, homopolymers, copolymers, polymer blends, filled polymer composites and polymer gels. New theoretical approaches to the description and practical applications of the shape memory effect are discussed. The bibliography includes 205 references.

## I. Introduction

Many polymers are used as structural materials for the production of various items and equipment.<sup>1–3</sup> Such materials must exhibit certain mechanical properties and operating characteristics and their production must be simple and cost-efficient. Another group of materials comprises the so-called functional polymeric materials. The function and field of application of such materials are mainly determined by the specific and sometimes unique properties they possess. Typical representatives of this class of compounds are polymers and polymer composites that possess the ability to recover their shape.

The ‘shape memory effect’ (SME) is characteristic of not only polymers. Initially, the term ‘SME’ was mainly used for metal alloys. In the case of high-molecular-mass compounds, the term ‘thermal shrinkage’ was often used because most studies on the problem were concerned with shape recovery features of stretched samples.

In this review we consider the behaviour of polymers deformed in various manners by applying a tensile, compression or shear deformation; therefore, the use of the term ‘SME’ seems to be appropriate. This effect manifests itself in a complete or partial recovery of the initial size of samples of simple geometrical shape exposed to external action. However, in some cases (if, *e.g.*, the shape variation obeys a ‘rod–helix–rod’ pattern) it is more appropriate to place the emphasis on the shape.

Pioneering communications on the SME in metal alloys and polymers were reported nearly five decades ago. Recently, numerous monographs concerning the SME in metallic materials have been published.<sup>4–10</sup> At the same time there are quite a few monographs or reviews on the shape memory effect in polymers and the results reported are mainly concerned with the behaviour of oriented synthetic fibres.<sup>11–14</sup> A detailed review<sup>15</sup> published in 1992 was also incomprehensive because the authors restricted themselves to coverage of some fundamental problems of thermal shrinkage of oriented homopolymers. That review included no data on more complex polymer systems and contained little information on applied studies and almost no information on investigations carried out by Russian researchers.

Since then there has been a considerable amount of literature on the SME in polymers. The subjects were the development of theoretical concepts of the mechanisms of thermally stimulated strain recovery; new approaches to the description of the deformation and relaxation behaviour of polymers; new information on the shape recovery features of deformed samples; and results of investigations of synthetic polymeric materials possessing unusual properties. Because research in the field covers a wide variety of aspects of the title problem, here we first of all tried to highlight the key recent advances and provide information on modern investigation avenues and practical applications of the SME.

According to Irie,<sup>16</sup> the SME in polymeric materials can be realised in three ways. The first way involves the formation of a shaped sample from melt. If necessary, cross-links can be formed by adding cross-linking agents or by irradiating the sample. Then, the sample is deformed at a temperature similar to the glass transition temperature,  $T_g$ , or the melting point,  $T_m$ , and cooled in order to retain the deformed state. Shape recovery is attained by heating the sample above  $T_g$  or to  $T_m$ . The second way involves a photochemically or electrochemically induced reversible change in the shape of the polymer sample. The third way involves a shape change induced by chemical reactions. In the objects considered in this review the SME occurs following the first way, *i.e.*, on heating. The mechanism and specific features of this kind of SME are to a great extent determined by the nature (structure and morphology) of the polymer.

## II. Glassy polymers

Shape recovery of deformed polymers originates from the system’s ‘quest’ for thermodynamic equilibrium, which is determined by the minimum value of the corresponding thermodynamic potential (*i.e.*, the difference between the internal energy and the

entropy of the components of the macromolecules in the polymer system). Strain-induced orientation of polymer chains causes the entropy of the system to decrease. Therefore, shape stability of a strained polymer would depend on the change in the internal energy. If the internal energy decreases on deformation and compensates the decrease in entropy, a stable structure is formed. This situation can be realised in crystallisable polymers where bonding between polymer chains is strong enough. In glassy polymers, the strain-induced nonequilibrium state is retained only after cooling below  $T_g$ . Because these differences to a great extent determine the laws of manifestation of the SME in the materials mentioned above, they deserve a separate consideration.

Without dwelling on details of macroscopic manifestation of the SME in glassy polymers (most of them have been reviewed<sup>15</sup>), we will point out the most characteristic features. Oriented glassy polymer samples (at least those having a simple shape) completely recover their initial size after heating to the glass transition temperature. The process begins at  $T < T_g$  and its rate and degree of shape recovery increase as the temperature increases.

By fixing the ends of a deformed sample and measuring mechanical stress developed during the constrained recovery it is possible to study the early stages of recovery, characterised by small variation of the size. Typical temperature dependences of shrinkage stress for polycarbonate (PC) oriented by stretching at room temperature with heating at a constant rate are shown in Fig. 1. For an unannealed PC sample, the shrinkage stress  $\sigma_s$  begins to increase at a temperature that is slightly higher than the stretching temperature, reaches a maximum at  $T < T_g$  and decreases down to zero as the temperature approaches  $T_g$ . Heating of an annealed PC sample to a temperature below the annealing temperature causes the shrinkage to virtually disappear. The position of the maximum in the  $\sigma_s(T)$  plot is shifted towards higher temperatures and its height decreases. At the same time the zero  $\sigma_s$  value is achieved under the same conditions as in the case of the unannealed sample, i.e., near  $T_g$ .

**Figure 1.** Isometric heating curves for PC.<sup>17</sup> Unannealed sample (1) and samples annealed at 348 (2) and 398 K (3).

If a sample with fixed ends is kept at a temperature that is higher than the deformation temperature but much lower than  $T_g$ , an induction period is observed (Fig. 2).<sup>18</sup> Duration of the induction period depends on the test temperature and sample prehistory and can vary by one or even two orders of magnitude. It is believed<sup>18</sup> that the phenomenon can be explained by a high degree of localisation of thermally stimulated molecular shrinkage in certain regions of the amorphous polymer. Activated molecular segments 'try' to shorten the distances between their ends; however, ambient macromolecules preclude shrinkage. Shrinkage forces developed in activated segments are responsible for compression stress in the vicinity of these segments. Therefore, further thermal activation of macromolecules will most probably be followed by shrinkage in the compressed regions. The higher the

**Figure 2.** Shrinkage stress plotted vs. time for PC.<sup>18</sup> (a) Measured at 323 (1), 328 (2) and 333 K (3) 14 days after deformation; (b) measured at 328 K 2 (1), 5 (2) and 14 days (3) after deformation.

degree of thermal activation, the shorter the induction period. At the same time if the activation energy is insufficiently high, local stress can relax owing to chain slip and thus lead to a decrease in the local orientation without corresponding spatial changes.

Shape recovery of glassy polymers is usually described using simplified phenomenological models. Some of them were considered in detail in a review.<sup>15</sup> Such models are usually based on the concept of one or more energy barriers separating different states of the condensed system. The barriers are treated as hindrances to mobile fragments in the bulk of glassy polymer. In particular, a model involving two energy states of a polymer segment was proposed.<sup>19, 20</sup> It was assumed<sup>19, 20</sup> that any molecular chain in an oriented polymer comprises submolecules that can be in the compressed (a) or stretched (b) states separated by an energy barrier. Assuming a constant number of submolecules in the chain, the relative shrinkage of a model macromolecule induced by temperature variation can be related to the population of states. Transitions between the states are described by the following equation

$$\frac{dn}{dt} = (1 - n_b)k_b - n_b k_a, \quad (1)$$

where  $n_b$  is the population of the state  $b$  and  $k_a$  and  $k_b$  are the rates of transitions to the states  $a$  and  $b$ , respectively,

$$k_a = A \exp\left(-\frac{\Delta E + M}{RT}\right), \quad (2)$$

$$k_b = A \exp\left(-\frac{\Delta E + \varepsilon - M}{RT}\right). \quad (3)$$

Here  $A$  is a constant,  $\Delta E$  is the activation energy for shrinkage,  $M$  is the energy associated with possible application of external stress and  $\varepsilon$  is the energy difference between the states.

Using Eqn (1), it is possible to calculate the temporal or temperature dependences of the populations of states and thus establish the corresponding dependence of thermal shrinkage of the model sample. The results obtained using the two-state model are in qualitative agreement with experimental data.<sup>21</sup> However, the model also has significant drawbacks, e.g., it can not predict the onset of shrinkage forces at the ends of the sample in the isometric heating experiments, because no interaction between submolecules is assumed.

According to Trznadel and Kryszewski,<sup>15</sup> a comprehensive rheological model of thermal shrinkage of oriented glassy polymers must account for:

- the possibility of relaxation of molecular orientation by thermally activated transitions,
- the possibility of propagation of local changes throughout the sample owing to the presence of an elastic physical network and
- the possibility of relaxation of the local stress as a result of intermolecular slip.

The four-state<sup>17,22</sup> and multi-state<sup>23,24</sup> mechanical models are successfully used for calculating the temporal and temperature dependences and for providing an explanation for the appearance of the induction period. The local relaxation can be best predicted at low temperatures, *i.e.*, in the absence of large structural changes. At the same time these models are too simple to describe the shrinkage process over a wide temperature region.

Yang and Sun<sup>25</sup> proposed a model based on the theory of conformational elasticity of molecular chains,<sup>26–29</sup> which allows a chain conformation distribution to be obtained with realistic information on the molecules. The model was used to analyse the experimental results of the SME studies in amorphous poly(ethylene terephthalate) (PETP).<sup>26,27</sup> A relation was established between the local structure of PETP and the structure of the entire system. The ensemble-averaged fraction of a local conformation is given by<sup>25</sup>

$$\langle X_s(r) \rangle = [Z_s(r)]^{-1} \int_r^{R_{\max}} \int_{E_{\min}}^{E_{\max}} P(R, E) X e^{-E/kT} dR dE, \quad (4)$$

where  $X$  is the fraction of the *trans*-conformation of  $\text{OCH}_2-\text{CH}_2\text{O}$  (ethylene glycol residue);  $Z_s(r)$  is the partial distribution function of the system that is locally extended by the distance  $r$ ;  $P(R, E)$  is the chain conformation distribution function and  $R$  and  $E$  are respectively the chain conformation length and energy.

It was established that dependence (4) fits experimental data well. It was shown that the deformation (extension) and shape recovery of cold drawn glassy polymers are different. The extension process involves at least two stages, *viz.*, the yield and molecular coil extension. The third stage, slip, can occur if a certain critical point is reached (in the case under study, at elongations greater than a value of 2.3). The shape recovery process involves a stage characterising the dependence of size on the chain conformation. This fact is explained by differences between the strain and shape recovery rates that are responsible for bringing the molecular chain conformations either closer to or farther apart from the state of thermodynamic equilibrium.

The examples given above show that the thermally stimulated strain recovery mechanism underlying the SME in glassy polymers is rather complicated. It involves the relaxation of the segmental orientation and the molecular chain orientation. These processes were studied<sup>30</sup> in order to establish the differences between the relaxation mechanisms of the local and total molecular orientation taking PC stretched at  $T > T_g$  as an example. The degree of segmental orientation was estimated by IR dichroism using function

$$f = \frac{(R_0 + 2)(R - 1)}{(R_0 - 1)(R + 2)}, \quad (5)$$

where  $R_0$  is the dichroic ratio for the perfectly oriented polymer. The degree of the molecular chain extension was determined as follows

$$\lambda = \frac{L_d}{L_s}, \quad (6)$$

where  $L_d$  is the length of the undeformed sample and  $L_s$  is the length of the shrunken sample.

It should be noted that conditions necessary for attainment of high segmental orientation are in contrast to those which lead to a

high molecular chain extension. In the first case, rapid stretching at temperatures close to the glass transition temperature are needed. In the second case slow stretching and high temperatures are required. With allowance for this, samples deformed at different temperatures and loads were studied.

The relaxation dynamics of segmental orientation and molecular orientation as functions of the deformation temperature  $T_d$  and tensile load  $F$  can be followed using the data shown in Figs 3 and 4. The temperatures of deformation and subsequent heating

**Figure 3.** Relaxation of segmental orientation (a) and molecular orientation (b) in PC plotted vs. time at different deformation temperatures.<sup>30</sup>  $T_d/\text{K}$ : 426 (1), 433 (2) and 443 (3).

**Figure 4.** Relaxation of segmental orientation (a) and molecular orientation (b) in PC plotted vs. time at different loads.<sup>30</sup>  $F/\text{N}$ : 574 (1) and 846 (2).

were equal. As can be seen, the degree of segmental orientation and the average relaxation time of segmental orientation decrease as the temperature increases (see Fig. 3 *a*). Strain rate (dead load) affects the initial degree of segmental orientation; however, the relaxation time is independent of the strain rate (see Fig. 4 *a*). The character of the relaxation of molecular orientation differs from that described above, namely, an induction period is observed in all  $\lambda(\log t)$  plots obtained under the same pre-stretching conditions at all temperatures (see Fig. 3 *b*). The higher the temperature, the shorter the induction period. No effect of the strain rate was observed for the dead load interval studied in this work (see Fig. 4 *b*).

Comparison of the plots constructed in the coordinates  $f(\lambda)$  allowed the ratio of the contributions of the segmental orientation and molecular orientation at various heating temperatures and loads to be analysed. It was concluded<sup>30</sup> that in a certain temperature interval an almost total relaxation of segmental orientation can occur without any relaxation of molecular orientation. The samples deformed at a higher rate are characterised by a greater loss of segmental orientation during the time before the start of relaxation of molecular orientation.

The character of the relaxation processes investigated was established based on correlations between  $f$  and  $\lambda$ . If the molecular orientation remains unchanged while segmental orientation decreases, the relaxation mechanism is local in character. Its kinetics are independent of the location of the segments along the chain and the process corresponds to a Rouse relaxation between two entanglements.<sup>31</sup> The relaxation of molecular orientation requires large-scale motions which are hindered by surrounding chains. This relaxation corresponds to a contraction inside the tube and to reptation. The results obtained in the study<sup>30</sup> are in good agreement with the assumption<sup>32</sup> that the macromolecule can lose its dichroism owing to local restructuring. They are also consistent with the results obtained by Brown and Windel<sup>33</sup> who found that the molecular orientation is more sensitive to the recovery process than the total deformation.

As a rule, the SME in amorphous polymers occurs without considerable variation of the volume. But if the starting material is characterised by an optimum porosity, shape recovery accompanied by an increase in volume can occur under certain deformation conditions. This is the case in a study<sup>34</sup> where a porous structure was formed in poly(vinyl chloride) (PVC) by dehydrochlorination of PVC powder at 503 K. Compact cylindrical samples of the dehydrochlorinated and cross-linked (in HCl) polymer were then compression deformed in a cylindrical cell of the same diameter. Heating of the samples obtained to  $T \geq T_g$  was accompanied by uniaxial volume recovery due to elongation of the samples. The effect was most pronounced at a degree of dehydrochlorination,  $x$ , of 12.9%.

Structural relaxation was described<sup>34</sup> in the framework of the two-state model. A number of parameters, in particular, the activation energy, population in the equilibrium state and empirical constants, were obtained for various  $x$ . Unfortunately, the authors did not discuss microscopic aspects of the SME in the objects under study. Considerable attention was paid to this subject in studies<sup>35,36</sup> on the mechanism of plastic deformation of glassy polymers. Two stages of shape recovery in polymer glasses were established. These are the low-temperature recovery (LTR) below  $T_g$  and the high-temperature recovery (HTR) at  $T_g$ . The temperature dependences of the residual strain recovery rates  $\dot{\epsilon}_{\text{res}}$  of uniaxially compressed amorphous PETP samples at  $T < T_g$  are shown in Fig. 5. Both stages are clearly seen. Analogous dependences were also established for other amorphous polymers.<sup>37,38</sup> It was shown<sup>35</sup> that the LTR dominates in the early stage of deformation. At high degrees of deformation, the contribution of the HTR to the overall process is much larger than that of the LTR. The contribution of the LTR increases as the deformation temperature decreases; the LTR process always begins near the deformation temperature, whereas the HTR peak lies at  $T_g$ .

**Figure 5.** Temperature dependences of the residual strain recovery rates for PETP.<sup>35</sup>

$\epsilon_{\text{res}}$  (%): 1.5 (1), 4.5 (2), 7.5 (3) and 14.5 (4).

These and other physical processes accompanying deformation of polymer glasses are explained using the concept of shear defects (SD).<sup>35</sup> Each SD bears a local residual shear strain and corresponding local excess internal energy. Similarly to the total excess internal energy, the total macroscopic residual strain of a sample is the sum of all elementary local energies or strains. An elementary act of a deformation process involves initiation and development of an SD. Heating of a deformed sample to  $T < T_g$  is accompanied by removal of those SD that are associated with the low-temperature stage of recovery and has no effect on the processes responsible for the HTR. Redeformation of the sample causes no increase in the HTR peak until the fraction of the SD-induced deformation reaches again a certain critical value. In other words, the SD can exist in the absence of the processes that initiate the HTR, but not otherwise. The HTR peaks appear during the annealing (at  $T > T_g$ ) of new conformational structures that were formed in the development of SD. These peaks are always preceded by the appearance of the LTR peaks.

Based on the results of studies on the features of the deformation behaviour of glassy polymers, a concept was proposed,<sup>36</sup> according to which the total inelastic deformation and steady-state plastic flow occur in the polymer structure saturated with small-scale plastic shear transformations (PST) rather than the initial polymer structure. In the former case we deal with an excited and therefore metastable structure and corresponding relaxation processes are closely related to the initiation and loss of PST. The appearance of the LTR peak is due to accumulation of PST, which leads to the total residual strain recovery below  $T_g$ . In the plot of the temperature dependence of  $\dot{\epsilon}_{\text{res}}$  the area under the LTR peak is a measure of the concentration of the PST that 'survive' in the unloaded (after deformation) polymer at given  $\epsilon_{\text{res}}$ ,  $T_d$  and ageing time. An increase in  $\epsilon_{\text{res}}$  causes an increase in the area under the LTR peak but is not accompanied by any conformational changes in the macromolecular chains. When the PST concentration reaches a critical value, an HTR peak appears in the recovery curves and increases with an increase in degree of strain. The appearance of the HTR peak indicates conformational transformations within distorted chains. At high strain, the HTR peak dominates while the LTR peak is of low intensity; because of this, no LTR stage was detected in the early studies of the SME in amorphous polymers.

The approach of Perez *et al.*<sup>39–41</sup> to the description of deformation of polymer glasses is analogous to that used in the studies mentioned above.<sup>35,36</sup> According to the model proposed, the main mechanism of deformation in amorphous polymers involves nucleation of localised shear microdomains (SMD) that

carry inelastic strain. The reason for the appearance of plastic deformation is the interaction between two or more SMD, which causes molecular rearrangements and conformational changes in the polymer. Different natures of coupled molecular motions are responsible for different time scales of the recovery of two strain components, namely, inelastic strain and plastic strain (original terms are given) at temperatures  $T < (T_g - 20 \text{ K})$ .<sup>42,43</sup> The former is characterised by fast relaxation while a slow relaxation is a feature of the latter. Inelastic strain can be completely recovered on heating of the material to  $T_g - 20 \text{ K}$ , whereas complete recovery of plastic strain requires heating to at least  $T_g$ .<sup>42-44</sup>

The approach<sup>35,36</sup> treats the LTR as a nonequilibrium polychromatic relaxation. In studies<sup>45-49</sup> the low-temperature component of the relaxation of deformed glassy polymers was associated with conformational changes of macromolecular fragments within local structural regions. Taking poly(methyl methacrylate) (PMMA) as an example,<sup>45</sup> it was shown that the LTR of the samples compressed to different deformation values  $\varepsilon$  at  $T < T_g$  can be described by a generalised curve plotted in the coordinates  $(\varepsilon - \varepsilon_T) - T$  (Fig. 6a), where  $\varepsilon_T$  is the residual strain at a given temperature. Analysis of the plots shown in Fig. 6a showed that the sample contains regions characterised by various packing density and local glass transition temperatures. This confirms structural heterogeneity of organic glasses.<sup>50</sup> Loading of material is accompanied by successive involvement of such structural regions in the deformation process and, therefore, in the recovery process on subsequent thermal activation.

**Figure 6.** Temperature dependences of the differences  $\varepsilon - \varepsilon_T$  (a) and the dependence of the total strain recovery temperature on the deformation temperature (b) for PMMA samples.<sup>45,48</sup>  
(a):  $\varepsilon = 6$  (1), 8 (2), 11 (3), 14% (4); (b): uniaxially compressed (1) and hydrostatically pressed (2) samples.

Treatment of experimental data on thermally stimulated recovery of a large number of deformed polymer glasses allows common features of deformation and recovery of this class of polymers to be established.<sup>46</sup> In particular, the temperature dependences of the residual strain plotted in the coordinates  $(\varepsilon - \varepsilon_T)/\varepsilon_{f,e} - (T - T_g)/(T_g - T_d)$ , where  $\varepsilon_{f,e}$  is the strain corresponding to the forced elasticity limit, fall on the same generalised curve as for glassy polymers. This points to a common deformation and subsequent recovery mechanism of glassy polymers, which is due to similarity in their structural organisation. Recovery of deformed polymers is reduced to successive devitrification of the structural regions with different packing densities and local glass transition temperatures.

Taking into account a quasi-equilibrium character of thermally stimulated recovery of deformed glassy polymers at  $T < T_g$  (see Ref. 45) and the fact that it can be described by a common generalised curve,<sup>46</sup> it is possible to explain the results,<sup>48</sup> namely, an increase in the complete recovery temperature,  $T_r$ , with an increase in the deformation temperature. Indeed, at a specified degree of deformation an increase in  $T_d$  is accompanied by involvement of structural regions with higher packing density (within these regions the recovery occurs at higher temperatures) in the deformation process.

Figure 6b presents the complete recovery temperatures of uniaxially compressed (by 6%) and hydrostatically pressed (0.3 GPa) PMMA samples plotted vs. deformation temperature.<sup>48</sup> They fall on the same straight line whose extrapolation to  $T_r = 0 \text{ K}$  gives a deformation temperature of 100 K. The case  $T_r = 0$  means that a PMMA sample deformed at  $T_d \leq 100 \text{ K}$  undergoes elastic recovery at any temperature, on unloading. With allowance for this fact the temperature found (100 K) can be treated as the transition temperature from ideal elastic deformation to plastic deformation, i.e., the temperature of transition from the brittle failure to the ductile failure mechanism.

Glassy polymers are structurally inhomogeneous. The inhomogeneity size varies from a few to tens of Ångström,<sup>51,52</sup> inhomogeneities have a fluctuative character. This is responsible for severe experimental difficulties in the studies of structural rearrangements, because they can not be visualised by traditional structural methods. Using an original microscopic technique which allows structural rearrangements in deformed amorphous polymers to be visualised, previously unknown features of the LTR were revealed<sup>53,54</sup> and a new mechanism of thermally stimulated recovery of polymer glasses was proposed. The method involves investigation of the structural-mechanical characteristics of deformed polymer films with thin solid coatings.<sup>53-59</sup> A direct microscopic investigation of the structural evolution of the coating during film recovery showed that thermal shrinkage causes the appearance of a regular microrelief on the polymer surface. The character of the microrelief depends only slightly on both the coating material and the substrate material. The relief is characterised by three types of morphological features.<sup>58</sup> The most pronounced is the first type, namely, irregular closed cellular structures formed by rather high buckles of the coating. The second type is represented by specific wavy structures inside the cells with somewhat lower buckles and the third type are rectilinear folds crossing the whole sample. Studies of such a microrelief gave important information on the structural rearrangements accompanying deformation of the polymeric substrate. This information also allows fine details of the LTR to be established.

Characteristic temperature dependences of the size recovery of glassy polymer (PETP) samples deformed below and above  $T_g$  are shown in Fig. 7.<sup>54</sup> Planar orientation of the PETP films was performed according to Refs 53 and 60. As can be seen, the size recovery of a film oriented at 373 K mainly occurs near the glass transition temperature. PETP deformed at room temperature completely recovered its size at temperatures below  $T_g$ . The LTR during annealing of the PC and PMMA samples deformed

**Figure 7.** Temperature dependences of strain recovery for PETP.<sup>54</sup>  $T_d$ /K: 293 (1) and 373 (2).

by the classical crazing mechanism<sup>61,62</sup> or by stretching in air occurs analogously.

Deformation of a polymer sample below  $T_g$  causes the appearance of specific zones containing oriented polymer and separated by well-defined interfaces.<sup>54,62</sup> In the case of both crazing and the development of shear bands, these zones penetrate throughout the bulk of the polymer and impart to the polymer the properties characteristic of oriented highly disperse material. The key factor responsible for the LTR is a decrease in the glass transition temperature of the surface layers. On progressive devitrification of the oriented material, filling the zones of localised deformation induces the force responsible for the LTR. It should be emphasised that the low-temperature recovery occurs in the shear bands that appear during deformation below and near the yield point and retain their individual features even after transition of the whole polymer to the oriented state. That is why the low-temperature shrinkage begins within these zones. The HTR is associated with the relaxation of molecular orientation in the bulk of the polymer, acquired during deformation after the yield point was achieved.<sup>62</sup>

Compared to the number of studies on the SME in linear amorphous polymers, the number of studies on this effect in polymer networks is much smaller (see, *e.g.*, Refs 63–67). Most experiments were carried out using epoxide polymers (EP) and by and large revealed the same laws. Namely, recovery of the initial sizes of samples on heating in the free state begins below  $T_g$  and completes at  $T \approx T_g$ , long-term ageing at  $T_d$  leads to complete relaxation of  $\varepsilon_{res}$  and the recovery curves of the samples deformed above and below  $T_g$  differ appreciably. The last-mentioned fact indicates a change in the residual strain recovery rate on heating deformed EP (Fig. 8).<sup>36,63</sup> A sample deformed by compression below  $T_g$ , always recovers a part of its residual strain below the glass transition temperature (LTR). The sample deformed above  $T_g$  exhibits no LTR peak.

The temperatures at which the  $\varepsilon_{res}$  recovery begins are related to  $T_d$  only but not to the relaxation transition temperatures in the glass ( $T_\beta$ ,  $T_\gamma$ , *etc.*).<sup>36</sup> At the same time the onset of shape recovery correlates with  $T_g$ .<sup>64,65</sup> An analogous correlation was also established for the maximum stress developed on heating oriented samples with fixed ends.<sup>64,65</sup> Polymer networks (in contrast to linear amorphous polymers) have a narrower temperature interval of shape recovery. The maximum stress developed in this case increases with an increase in the degree of deformation and in the effective node density of the network.<sup>65,67</sup>

Shape-memory glassy polymers have found wide practical applications. For instance, they are used for the production of thermally shrinkable films utilised as packing material, thermally shrinkable insulating sleeves, details and profiles in the compressed state (convenient for transportation), rivets and fittings for all-in-one-type adhesive couplings for pipes.<sup>68–76</sup> In particu-

**Figure 8.** Temperature dependences of residual strain recovery rate for EP.<sup>36</sup>

$T_d$ /K: 423 (1), 293 (2) and 173 (3).

lar, such fittings made of EP (first of all couplings) allow fabrication of strong and pressure-tight constructions made of various (including different-type) materials that withstand high internal pressures of gas and liquids.<sup>74,77–80</sup> This is achieved by using a specific epoxy adhesive along with the thermally shrinkable coupling made of a material which possesses a good adhesion towards various substrates. The temperature–time regimes of coupling shrinkage and adhesive hardening are chosen in such a way that shrinkage be followed by hardening; this precludes formation of adhesive-free spots, thus forming a very thin adhesive layer which provides a joint of maximum strength.

Physical ageing processes in polymers are closely related to the SME.<sup>15</sup> The ageing is considerably enhanced with oriented polymers.<sup>81</sup> Therefore, to solve the ageing problem, it is necessary to know specific features of manifestation and the mechanism of the SME in such polymers. Often, solving particular engineering problems requires suppression of the SME.<sup>82,83</sup>

### III. Crystallisable polymers

#### 1. Amorphous-crystalline homopolymers

In contrast to the amorphous polymers mentioned above, the molecular orientations of both phases in amorphous-crystalline homopolymers can be locked at temperatures above the  $T_g$  of the amorphous phase because the stability of the orientation is determined by the network of crystalline domains. These homopolymers exhibit a more complex relation between the degree of molecular orientation and stability of oriented materials. Enhancement of molecular orientation can lead to formation of a structure with a high degree of continuity, which improves the stability in spite of high internal stress.<sup>14</sup> The SME occurring with an increase in temperature is due to (i) structural rearrangement of the amorphous phase with possible crystallisation of this phase; (ii) destruction and recrystallisation of crystallites with imperfect shape, (iii) thickening of crystalline blocks and (iv) melting of the crystalline phase.

The SME mechanisms considered in the study,<sup>15</sup> taking thermal shrinkage as an example, are based on such molecular ordering models as transformation of the paracrystalline phase into the crystalline phase; transformation of crystallites with extended chains into crystallites with packed chains; melting of crystallites; disorientation of amorphous regions followed by crystallisation and some other mechanisms. The authors<sup>15</sup> give no preference to a particular thermal shrinkage mechanism but seem to highlight the mechanisms based on the fibrillar structure models,<sup>84,85</sup> which allow quantitative description of the process.

In spite of the numerous publications concerned with the SME in amorphous-crystalline homopolymers (including recent communications<sup>16,86–101</sup>), investigations of this phenomenon are far

**Figure 9.** Degree of shrinkage ( $I-3$ ) and shrinkage stress ( $I'-3'$ ) of LDPE plotted vs. temperature.<sup>89</sup>  $T_d$ /K: 293 ( $I, I'$ ), 313 ( $2, 2'$ ) and 333 ( $3, 3'$ );  $\lambda = 4$ .

from being completed. At the same time a number of undoubted facts and laws were established, which are common to these materials. As a rule, they concern thermal shrinkage of film or block samples, mainly polyolefins. A typical example is shown in Fig. 9 where the degree of shrinkage,  $S$ , of low density polyethylene (LDPE) samples oriented by hydrostatic extrusion is plotted vs. temperature<sup>89</sup>

$$S = \frac{l_0 - \Delta l}{l_0},$$

where  $l_0$  is the initial length of extrudate and  $\Delta l$  is the shrinkage due to annealing. The shrinkage increases with an increase in the annealing temperature and with a decrease in  $T_d$ . Similar results were obtained for polyethylene and polypropylene (PP) films.<sup>88, 102</sup> As in the case of glassy polymers, the shrinkage onset temperature of oriented crystallisable polymers decreases as the degree of deformation increases.<sup>86, 90-92</sup>

Heating of LDPE samples with fixed ends to 350–355 K is accompanied by an increase in  $\sigma_s$ . Then,  $\sigma_s$  somewhat decreases and dramatically decreases after transition of the material to the molten state (see Fig. 9). The maximum values of shrinkage stress  $\sigma_s^m$  increase with an increase in the degree of extension,  $\lambda$ , and with a decrease in  $T_d$  (Fig. 10). Shrinkage stress disappears if samples are aged at  $T \geq 388$  K, which approximately corresponds to the melting completion temperature of crystallites in oriented LDPE [according to differential scanning calorimetry (DSC) data].

**Figure 10.** Maximum shrinkage stress of LDPE plotted vs. temperature of deformation ( $I$ ) and degree of molecular chain extension ( $2$ ).<sup>89</sup>  $\lambda = 4$  ( $I$ ) and  $T_d = 313$  K ( $2$ ).

A study<sup>89</sup> of LDPE extrudate morphology showed that deformation is accompanied by formation of layered structures (crystalline lamellae arranged normal to the extension direction). As  $T_d$  increases, the lamellae become thicker. Macromolecular fragments in the bulk of the crystallites that form layered structures acquire now a preferred orientation along the deformation direction. Shrinkage forces (entropic in character), which are developed in thus formed strained throughout-going chains or their clusters, are compensated by elastic forces in the layered crystalline cage. Heating of oriented LDPE samples is accompanied by shrinkage of extended macromolecules or their fragments under the action of entropic factors by transformation of the crystalline cage; this is the reason for such a molecular shrinkage.

Maxima of  $\sigma_s$  are observed in the temperature interval 358–363 K (see Fig. 9) corresponding to completion of the  $\alpha$ -transition in LDPE.<sup>103, 104</sup> On further heating the forces that hold the shrinking throughout-going chains within the block become weaker than the forces necessary for block displacement. As a result, chain slip through lamellae begins, resulting in a decrease in  $\sigma_s$ . The higher the temperature, the easier the slip of macromolecular fragments. Therefore, the number of strained throughout-going chains decreases with an increase in  $T_d$ , thus leading to a decrease in both  $\sigma_s$  and the degree of shrinkage. The latter is first of all due to the disappearance of the strained throughout-going chains in defect crystallites whose breakdown requires the lowest activation energy. Owing to the absence of low-temperature relaxators, the beginning of the shrinkage process is shifted towards higher temperatures (see Fig. 9). At the same time DSC data show that the shift of the  $\sigma_s$  maximum towards higher temperatures with an increase in  $T_d$  is due to the formation of the layers comprised of crystallites with increased cross sections (breakdown of these particles requires a higher activation energy).

Yet another factor responsible for structural rearrangement on heating of oriented LDPE samples, is thickening of lamellae during annealing. In this case certain segments can be drawn into the lamellae, thus leading to disordering of crystalline blocks and development of internal stress. This mechanism can also contribute to an increase in  $\sigma_s$  for the samples oriented at low temperatures. Namely, as  $T_d$  increases, partial annealing does occur, as indicated by the thickening of lamellae.<sup>89</sup>

Of particular interest is the investigation of the SME in microporous crystallisable polymers, which are widely used for, e.g., filtration, separation of liquid media, deaeration, etc. Shrinkage of microporous high-density polyethylene (HDPE) films prepared by melt extrusion, subsequent annealing at fixed size, uniaxial extension during pore formation stage and thermal fixation of porous structure was studied.<sup>94, 95</sup> Correlations between the shrinkage and the draw ratio, temperature of thermal fixation and the degree of extension ( $\epsilon$ ) were established.

The dependence of shrinkage on the degree of extension passes through an extremum (maximum) at  $\epsilon = 150\%$  whose position is independent of shrinkage temperature.<sup>94</sup> The results obtained were explained by competition between (i) orientational processes (pulling apart and bending of lamellae) and deformation of chains connecting lamellae and (ii) breakdown of the throughout-going chains. At low degrees of extension, the throughout-going chains are not stretched and lamellae are slightly bent. Temperature variation causes strained lamellae held by the throughout-going chains to return to the initial state; however, lamellae (both weakly strained or non-connected by the throughout-going chains) show low deformability; therefore, a small shrinkage is observed at small  $\epsilon$ . At  $\epsilon \approx 150\%$ , most throughout-going chains appear to be bent and strained, the degree of pulling apart a lamellae becomes high and the connecting chains still withstand the stress. This is the case for maximum shrinkage. At  $\epsilon > 150\%$ , a fraction of the throughout-going chains are broken and do not contribute to subsequent relaxation of the sample on heating.

The shape memory effect in microporous films is used in chemical cells. Such films act as membrane separators that are permeable to electrolyte and separate the anode and cathode

compartments.<sup>94, 95, 105</sup> For instance, to avoid ignition of lithium cells, the power source must be prevented from overheating. This is achieved by shrinkage of the separator, which results in closure of through pores and termination of cell operation.

Formation of a network of chemical cross-link points in crystallisable polymers offers additional possibilities of control of thermal-shrinkage characteristics. Such a network can be formed using radiation-induced, chemical or photochemical cross-linking. A hot-drawn polyethylene film prepared by radiation-induced cross-linking exhibits improved ultimate strength, shrinkage stress and a more stable shrinkage factor as compared to non-irradiated film oriented under the same conditions.<sup>106–108</sup> Similarly to the non-irradiated film, shrinkage increases with both an increase in the degree of deformation and a decrease in  $T_d$ . A distinctive feature of this material is a characteristic dependence of  $\sigma_s$ , which exhibits a plateau near  $T_m$ . For instance, the parameter  $\sigma_s$  of LDPE shows a dramatic increase at  $T = 353–383$  K, a constant value to 413–433 K and subsequent gradual decrease.<sup>108</sup>

Photochemically cross-linked and radiation-modified polyolefin samples exhibit a similar shrinkage behaviour.<sup>88</sup> They mainly differ in absolute values of the effects observed. However, this holds for those polymers that were oriented after cross-linking. The situation changes if orientation precedes cross-linking. Exposure to ionising radiation causes a considerable decrease in  $\sigma_s$ , while photochemical cross-linking has little effect on thermal shrinkage. The results of photochemical cross-linking also depend on the nature of initiators employed.<sup>88</sup>

If an amorphous-crystalline polymer contains a network of chemical cross-link points, orientation leads to an increase in the number of throughout-going chains. This is the reason for improved stress-strain properties<sup>88</sup> and increased  $\sigma_s$ . The shrinkage stress determined by the elastic properties of a uniaxially extended network of chemical cross-link points manifests itself in full measure only at  $T > T_m$ . In the case of radiation-induced cross-linking a large proportion of chemical cross-link points is formed as a result of recombination of radicals that were generated in crystallites and experience a diffusion motion towards relatively ordered transient layers on folded lamellae surfaces.<sup>109, 110</sup> These cross-links can control the degree of 'untwisting' of certain macromolecules and act as additional fixators of crystalline blocks with respect to transfibillar throughout-going chains, thus precluding chain slip at high temperatures.<sup>88</sup> The density of transient layers, in which efficient radiation-induced cross-linking can occur, is close to the density of crystallites;<sup>111</sup> therefore, they are inaccessible to photoinitiator molecules localised only in amorphous inter-lamellae regions.<sup>112</sup> This is the reason for their different influence on the formation of microfibrillar structure during deformation of cross-linked polyethylene (PE).<sup>88</sup> Lower efficiency of fixation of crystalline blocks on the throughout-going chains, due to inaccessibility of lamellae surfaces to cross-linking in the photoinitiated process, is the reason for insignificant differences between the  $\sigma_s$  regions for the samples cross-linked before and after orientation.

Improvement of the stress-strain and thermal-shrinkage characteristics, achieved as a result of cross-linking of polymers, favours a wide use of polymers in the production of thermally shrinkable items for electronics, the aviation industry, spacecraft industry, automotive industry and the shipbuilding industry.<sup>113</sup> Not only one-layer thermally shrinkable insulating sleeves but also two-layer coatings made of polymeric materials with different properties and different functions have come into use.

## 2. Copolymers

The synthesis of copolymers is an efficient method of modification of polymer structures and expansion of their functional possibilities. Among recent publications concerned with the SME in copolymers, we will first of all point out the studies of thermoplastic polyurethanes (PU).<sup>114–136</sup> Increased interest in these materials is due to relatively low cost, good processability, high stability to the surrounding atmosphere, convenient (for practical

applications) shape-memory temperature intervals and the high degree of shape recovery of PU.

Segmented PU having an SME-appropriate structure were first synthesised by researchers at Mitsubishi Heavy Industries (Japan)<sup>115, 116</sup> from 4,4'-diphenylmethane diisocyanate and polyol using 1,4-butanediol as a chain extender. The structures of these materials consist of soft and hard segments (reversible and 'frozen' phase, respectively). The reversible phase has an amorphous structure while the 'frozen', or fixed, phase has a crystalline structure. In the temperature range between the glass transition temperature and the melting temperature of the crystalline phase, the polymers are in the rubbery state. Deformation at  $T_g < T < T_m$  followed by cooling under load to  $T < T_g$  causes fixation of the shape acquired. If the material is then again heated to a temperature in the range  $T_g < T < T_m$ , the initial shape is recovered.

These materials exhibit not only shape memory but also a considerable change in the elastic modulus near the glass transition temperature. This is suggesting of elasticity memory,<sup>116</sup> which is widely used in temperature sensors, drives, low-power engine chokes, *etc.*;<sup>115, 116</sup> therefore, it is of great importance to know the behaviour of such materials in cyclic tests.

Figure 11 presents the residual and recoverable ( $\epsilon_r$ ) strain plotted vs. number of load/unload cycles ( $N$ ). The data were obtained in the extension of oligoester polyol PU samples characterised by a high elastic modulus at elevated temperatures.<sup>115</sup> Each cycle in the experiment included loading at a constant rate until maximum deformation,  $\epsilon_m$ , at 338 K ( $T_g = 318$  K) followed by cooling to 298 K under load and subsequent unloading. Initially, the  $\epsilon_{res}$  and  $\epsilon_r$  values differ appreciably (see Fig.11). As  $N$  increases,  $\epsilon_{res}$  also increases and  $\epsilon_r$  decreases; the greatest changes are observed at  $N < 5$ . At  $N > 20$ , the differences between  $\epsilon_{res}$  and  $\epsilon_r$  become small and the parameters remain practically unchanged on further cycling. Therefore, attainment of constant  $\epsilon_{res}$  and  $\epsilon_r$  values for this material requires cyclic preloading (5–20 cycles).

Figure 11. Residual (1) and recoverable (2) strain plotted vs. number of load cycles for PU.<sup>115</sup>

The parameter  $\epsilon_r$  of the PU in question can be as high as hundreds per cent; however, most shape-memory elements operate in the recoverable strain region ( $< 20\%$ ).<sup>116, 129</sup> This is due to the fact that the SME is often imparted by bending deformation. Even at  $\epsilon > 3\%$ , a nonlinear deformation can begin, which must be taken into account in the design of shape-memory elements.<sup>128</sup> A reference thermomechanical model proposed<sup>128</sup> with allowance for this fact includes nonlinear stress terms in the elastic and viscous components of the linear model.<sup>130</sup>

Plastic deformation recovery in the unloaded state is described by the following equations<sup>130</sup>

$$\dot{\epsilon} = \frac{\dot{\sigma}}{E} + \frac{\sigma}{\mu} - \frac{\dot{\epsilon} - \epsilon_{ur}}{\lambda} + \alpha \dot{T}, \quad (7)$$

$$\varepsilon_{ur} = S\varepsilon_{res}, \quad (8)$$

where  $E$ ,  $\mu$ ,  $\lambda$ , and  $\alpha$  are respectively the elastic modulus, viscosity, delay time and thermal expansion factor,  $\varepsilon_{ur}$  is the unrecoverable strain, and  $S$  is the coefficient of proportionality. With inclusion of nonlinear terms one has

$$\dot{\varepsilon} = \frac{\dot{\varepsilon}}{E} + m \left( \frac{\sigma - \sigma_y}{k} \right)^{m-1} \frac{\sigma}{k} + \frac{\sigma}{\mu} + \frac{1}{b} \left( \frac{\sigma}{\sigma_c} - 1 \right)^m - \quad (9)$$

$$- \frac{\varepsilon - \varepsilon_{ur}}{\lambda} + \alpha \dot{T},$$

$$\varepsilon_{ur} = S(\varepsilon_c + \varepsilon_p), \quad (10)$$

where  $\sigma_y$  is the yield stress;  $\sigma_c$  is the stress corresponding to  $\varepsilon_c$ ;  $\varepsilon_c$  is the unloading deformation of the sample; and  $\varepsilon_p$  is the time-independent plastic deformation. The results of calculations<sup>128</sup> show that the model gives a correct description of the  $\sigma$ - $\varepsilon$ ,  $\sigma$ - $T$ ,  $\varepsilon_r$ - $T$  and other dependences.

Figure 12 presents the temperature dependences of  $\varepsilon_r$  calculated for different heating rates of unloaded oriented PU samples.<sup>128</sup> Deformation recovery slows down with an increase in temperature, but the  $\varepsilon_{ur}$  rapidly increases at  $\dot{T} > 0.1 \text{ K s}^{-1}$  (Fig. 13). This feature must be taken into account in the design of bulk shape-memory elements for operation under rapid heating conditions because heating of surfaces to a preset temperature does not ensure the SME in the bulk of the material.

Kim *et al.*<sup>126</sup> reported polyurethanes with crystalline hard segments from the reaction of 4,4'-diphenylmethane diisocyanate

and 1,6-hexanediol and amorphous soft segments from the reaction of hexamethylene diisocyanate and 1,2-butanediol and studied their thermal, stress-strain and physico-mechanical properties and the SME in this type of PU. First, the materials show sharp glass-transition temperatures that could be used as shape-recovery temperatures. Second, as the block lengths decrease, phase mixing increases and hysteresis in the shape-memory behaviour decreases. Third, too low a content of hard segments (shape-'memorising' phase) increases the hysteresis in the shape-memory behaviour.

New information on the behaviour of segmented PU with a reversible amorphous phase was reported by Chun and co-workers.<sup>127</sup> who studied a material with diphenylmethane diisocyanate hard segments and poly(tetramethylene glycol) soft segments. The shape retention of PU samples with 30 mass %, 35 mass %, 40 mass % and 45 mass % of hard segment content was estimated after they were deformed by 50% at  $T = T_g + 20 \text{ K}$ , cooled under load at  $T = T_g - 20 \text{ K}$  and then unloaded. All the tested samples showed more than 90% shape retention. Shape recovery measured after the samples were kept at  $T = T_g + 20 \text{ K}$  with load removed varied from 80% to 95%. However, shape recovery was not observed at 20 mass %, 25 mass % and 50 mass % of hard segment content. This behaviour was associated with the character of intermolecular interactions between PU segments. The high degree of shape recovery at  $T > T_g$  is due to PU stabilisation by dipole-dipole interactions, hydrogen bonds and induction interactions between the hard segments. The PU samples with 20 mass % and 25 mass % of hard segment content cannot have strong intermolecular interactions and physical cross-links due to the low proportion of hard segments, which results in the loss of shape memory effect. At a hard segment content of 50 mass %, intermolecular interactions between them are strong enough to form a rigid structure, which is inappropriate for SME to occur.

Polyurethanes with the glass transition temperature of the soft segments close to room temperature have found wide application. They are characterised by a stepwise change of many parameters near  $T_g$ . The shape-memory function underlies the operation of studs, catheters, fittings, re-writable compact disks, implants for cardiology, *etc.*<sup>136-138</sup>

Crystallisable soft segments can also play the role of the reversible phase in segmented PU. A schematic illustration of the SME in segmented PU with both crystallisable phases and corresponding evolution of the polymer structure is shown in Fig. 14.<sup>117</sup> Crystalline regions formed by hard segments play the role of physical cross-links while soft segments can 'freeze' rubber-like elastic deformation. Initial samples can show microphase separation and both types of segments can crystallise separately with random distribution of crystallites over the sample without any macroscopic anisotropy. In this case at temperatures above the melting temperature,  $T_{ms}$ , of soft-segment crystallites but below the melting temperature,  $T_{mh}$ , of hard-segment crystallites, the sample is in the rubbery state. Samples can recover their initial sizes even at a high degree of extension. However, isometric cooling of extended samples down to low temperatures makes it possible to 'freeze' and retain the rubbery elastic deformation owing to crystallisation of soft segments. Reheating of such samples leads to melting of soft-segment crystallites and the elastic energy stored causes recovery of the initial geometric sizes.

According to the concept of existence of soft-segment and hard-segment crystalline regions, the crystal perfection, crystalline phase morphology and, hence, crystallisation conditions must significantly influence the shape memory of polyurethane samples. For instance, taking PU prepared from 4,4'-diphenylmethane diisocyanate and toluene diisocyanate and containing caprolactone soft fragments as an example, it was established<sup>117</sup> that some weak cross-links in the samples are broken after the first cycle of deformation, which results in the formation of a dynamically perfect elastic network capable of nearly complete shape recovery. Samples with short soft segments and low hard segment content exhibit small recoverable strain. Long soft segments and

**Figure 12.** Temperature dependences of recoverable strain for PU.<sup>128</sup>  $\dot{T}/\text{K s}^{-1}$ : 0.0167 (1), 0.0833 (2), 0.167 (3), 0.833 (4) and 1.67 (5).

**Figure 13.** Dependence of unrecoverable strain on the heating rate for PU.<sup>128</sup>  $T = T_h$  (see Fig. 12).

Graft copolymers are considered as promising shape-memory materials along with the segmented copolymers. Studies<sup>143</sup> of the PE–nylon-6 system with nylon content of 5 mass %–20 mass % showed that the role of physical cross-links is played by the nylon domains of size at most 0.3  $\mu\text{m}$ , dispersed in the polyethylene matrix. All the samples studied showed good shape recovery (the degree of shape recovery exceeded 95%). The recovery rate was comparable with that of irradiated polyethylene with a high density of chemical cross-links. However, it should be noted that these graft copolymers contain a certain proportion of chemical cross-links because of the use of initiator (dicumyl peroxide) in the course of sample preparation. Since the density of cross-link points is low, it is the nylon domains that are responsible for excellent shape-memory behaviour of the material. The authors proved this statement by the results of their study,<sup>144</sup> according to which, at a low density of chemical cross-links in PE, this component shows no necessary shape-memory characteristics. In particular, the strain mainly remains irreversible.

As in the case of homopolymers, radiation-induced cross-linking improves the properties of shape-memory copolymers. For instance, taking modified PE obtained by copolymerisation of ethylene with octene as an example, it was shown<sup>145</sup> that exposure to  $\gamma$ -radiation (at relatively low absorbed dose) leads to the formation of a material suitable for the production of thermally shrinkable items with a long working life. This material can remain in a stressed state more than 10 years after the origination of shrinkage stresses in it. At the same time the initial shrinkage stress of this radiation-modified copolymer is 1.3 and 1.9 times higher compared to HDPE and LDPE, respectively.

#### IV. Polymer blends and filled polymer composites

Polymer mixing techniques allows a gradual variation of their physico-mechanical properties including the SME parameters (recovery temperature and rate; shape fixity; stress developed during shape recovery, *etc.*).<sup>146</sup> Nevertheless, only a few studies on the SME in polymer blends are available. Among the reports published in the last decade, mention may be made of the studies<sup>147–154</sup> concerned with various methods for preparation of this class of materials with desired characteristics.

The authors of the studies<sup>147, 148</sup> (see <sup>†</sup>) used blends of thermoplastic PU having soft polycaprolactone segments, with PVC and phenoxy resin. It was established<sup>147</sup> that the structure of PU–PVC blends comprises amorphous domains of the mixed PVC–polycaprolactone phase and crystalline domains formed by the hard segments of PU. Partial mixing of the soft and hard segments increases as the polycaprolactone segments are shortened. The glass transition temperature of the mixed phase gradually varies as the blend composition changes. Although these variations are small, the initial shape recovery temperature of this polymer system is lower than that of PVC. Cyclic tensile tests of the PU–PVC samples (2 : 8 molar ratio) showed a smaller hysteresis compared to PVC. At the same time the samples with a 4 : 6 molar ratio of the components exhibited an increase in the residual deformation compared to PVC. This behaviour is associated with a change in the elastic modulus in the glassy and rubbery states caused by the variation of the blend composition.

The glass transition temperature of the system PU–phenoxy resin<sup>148</sup> (here, the amorphous mixed domain is formed by the polycaprolactone segments) also gradually changes depending on the component ratio, similarly to the PU–PVC system. Hysteresis in the shape recovery decreases with an increase in the hard segment content and with shortening of these segments, because a highly dispersed distribution of the hard segments constituting the ‘frozen’ phase favours better ‘memorising’ of the initial shape.

Polymers based on interpenetrating polymer networks (IPN) whose components strongly differ in hardness exhibit a specific deformation and shape recovery (shrinkage) behaviour. The results of studies<sup>64, 65</sup> carried out using a polyurethane–polyesteracrylate (PU–PEA) system suggest that orientational hardening affects mainly the elastic component, PU. Hardening is due to the fact that the hard network (PEA) precludes relaxation of the stressed PU chains by forming macromolecular entanglements each acting as a kind of stopper. At low PEA content, the deformation hardening is insignificant because the density of entanglements is low and the elastic component can relax with ease. As the PEA content increases, the degree of the orientation hardening also increases, but at a PEA content of nearly 30 mass % mechanical degradation processes begin, involving both the elastic and hard chains.

The temperature interval corresponding to the characteristic change in  $\sigma_s$  of the IPN studied (Fig. 15) indicates the dominant role of the elastic component. The decrease in the half-width of the  $\sigma_s(T)$  maximum with an increase in  $\varepsilon$  points to a simultaneously increasing contribution of destructive processes (materials with imperfect structure break down faster in the course of  $\sigma_s$  measurements). As  $\varepsilon$  increases, the height of the  $\sigma_s(T)$  peak varies non-monotonically (not shown in Fig. 15) and passes through a maximum. This behaviour of  $\sigma_s$  is associated to the network loosening and partial stress relaxation in the samples tested and kinks in the right branch of the bell-shaped  $\sigma_s(T)$  curve are related to the contribution of the hard component.

**Figure 15.** Temperature dependences of shrinkage stress for PU–PEA (70 : 30) blend.<sup>65</sup>  
 $\varepsilon$  (%): 25 (1) and 40 (2);  $T_d = 358$  K.

PE–PP blends are the most widely studied polymeric systems. In spite of the thermodynamic incompatibility of these polymers the stress-strain properties of their blends at small deformations (small extension) change in additive fashion depending on the blend composition.<sup>155–157</sup> At large deformations, deviations from the additive behaviour of the parameters are observed (decrease in ductility is particularly pronounced<sup>156</sup>). This is due to a weak interphase interaction between the components.<sup>152, 155</sup> To avoid undesired results, various methods are used, *e.g.*, photochemical cross-linking.<sup>52</sup> Figure 16 presents the temperature dependences of  $\sigma_s$  obtained for photochemically cross-linked LDPE films and for LDPE–PP (50 : 50) blend films deformed at room temperature. To reveal peculiarities of the behaviour of blends with different component ratios the temperatures were specified, corresponding to the onset of shrinkage ( $T_1$ ), maximum shrinkage stress ( $T_2$ ) and kinks associated with the melting temperature ( $T_3$ ). The  $\sigma_s$  peak is observed in the pre-melting region of the polymer blend. The parameter  $\sigma_s$  decreases due to slip of certain stressed chains between crystalline blocks (‘holders’). In contrast to non-cross-linked samples, the cross-linked ones retain a certain level of  $\sigma_s$  at temperatures above  $T_m$  owing to the elastic properties of the network. As the PP content in the blend increases to 50 mass %, the

<sup>†</sup> These studies are in essence a continuation of earlier studies<sup>123–126</sup> on shape memory effect in segmented PU.

**Figure 16.** Temperature dependences of shrinkage stress for LDPE (1) and LDPE–PP (50 : 50) blend (2).<sup>152</sup>

the  $\sigma_s^m$  and  $\sigma_{3s}$  values and the characteristic temperatures ( $T_1$ ,  $T_2$ ,  $T_3$ ) increase (Table 1) and the samples exhibit shape-memory behaviour at  $T > T_3$  ( $T_3$  much exceeds the melting temperature of LDPE). Thus, introduction of PP into LDPE followed by cross-linking of the blend favours retardation of relaxation processes in the oriented samples.

**Table 1.** Thermal shrinkage characteristics of photochemically cross-linked oriented LDPE–PP blends.

| $\frac{[\text{LDPE}]}{[\text{LDPE}] + [\text{PP}]}$ | $T_1/\text{K}$ | $\sigma_s^{\text{max}}/\text{MPa}$ | $T_2/\text{K}$ | $\sigma_{3s}/\text{MPa}$ | $T_3/\text{K}$ |
|-----------------------------------------------------|----------------|------------------------------------|----------------|--------------------------|----------------|
| 1.0                                                 | 47             | 4.4                                | 86             | 0.97                     | 122            |
| 0.9                                                 | 48             | 4.45                               | 87             | 1.56                     | 124            |
| 0.8                                                 | 48             | 4.52                               | 87             | 2.04                     | 125            |
| 0.7                                                 | 52             | 5.13                               | 91             | 2.89                     | 127            |
| 0.5                                                 | 54             | 5.30                               | 96             | 3.35                     | 129            |

To attain rather high degrees of extension in creating orientation order in LDPE–PP blends, hydrostatic extrusion was employed.<sup>151</sup> The technique permits nondestructive deformation of brittle materials. Similarly to cross-linked film samples,<sup>152</sup> LDPE–PP extrudates lose the shape at higher temperatures compared to LDPE samples (the higher the PP content, the better the shape fixity). The degree of shape recovery was estimated<sup>151</sup> from the change in the extrudate cross sections on heating

$$\Psi = \frac{d_h^2 - d^2}{d_h^2},$$

where  $d$  and  $d_h$  are the extrudate diameter before and after heating. It was established that the dependences of  $\Psi$  on the degree of extension  $\lambda$  in the whole temperature interval studied are non-monotonic and pass through a maximum near  $\lambda = 3-4$ . Both the  $\lambda$  value corresponding to the extremum and the respective  $\Psi$  value decrease as the PP content in the blend increases from 0 mass % to 60 mass %. The residual deformation increases as  $\lambda$  increases. This unusual (at first glance) pattern of the  $\Psi(\lambda)$  dependence is due to simultaneous action of two factors that cause swelling of an extrudate, namely, relaxation of viscoelastic deformations in the extrudate at the die outlet and an increase in the cross section of the extrudate on heating owing to the SME. A decrease in the maximum  $\Psi$  values and their shift towards smaller  $\lambda$  with an increase in the PP content are due to the lower shape recovery ability of the LDPE–PP blends compared to LDPE and to differences between the die swelling and  $\lambda$  for the materials under comparison.

A study<sup>151</sup> of thermal shrinkage characteristics of samples with fixed ends showed that the characteristic temperatures of thermal shrinkage processes (see Fig. 16) depend only slightly on  $\lambda$

and on the PP content and obey laws identical to those established for the film samples oriented by uniaxial stretching (see Table 1). The  $\sigma_s^m$  values increase with an increase in  $\lambda$  and PP content in the blend. Similarly to the case of cross-linked samples,<sup>152</sup> the process of stress relaxation is not completed at the melting temperature of the polyethylene phase; rather, it extends to a wider temperature range. The shrinkage stress corresponding to this temperature interval ( $\sigma_{3s}$ ) increases as  $\lambda$  and PP content increase.

In the preceding paragraph we described the behaviour of monolithic samples of LDPE–PP blends prepared using a Banbury-mill type mixer and orientationally stretched under high hydrostatic pressure. Using the method of plunger extrusion of polymeric powder billet,<sup>158</sup> which combines monolithisation and orientation stretching, the authors<sup>149</sup> prepared and studied samples of PP blends with LDPE and ultra-high-molecular-mass PE (UHMPE) as well as PVC–UHMPE blends. For comparison, the behaviour of UHMPE extrudates prepared by the same technique was studied. It was found that the UHMPE extrudates behave similarly to homopolymers on heating. Namely, the samples studied showed an increase in diameter accompanied by a decrease in length [i.e., the initial shape (dimension) recovery] at temperatures  $T$  such that  $T$  exceeds a value of 373 K, being close to the temperature of UHMPE melting (extrusion) (403 K). The volumes of the extrudates did not change. Relaxation processes in the polymer blends began at lower temperatures compared to the extrusion temperatures of the materials (433 K). For all the systems under study raising the heating temperature was accompanied by monotonic increase in the sample diameters and an unusual change in the degree of shrinkage. An increase in the length of the sample at the beginning was followed by its sharp decrease as a temperature close to the melting temperature of one of the components was achieved. According to calculations, these changes in the size of the sample cause an increase in volume (Fig. 17). The maximum value of the relative change in volume,  $(V - V_h)/V$ , where  $V$  and  $V_h$  are the extrudate volumes in the initial state and after heating to a preset temperature, lies in the concentration range corresponding to equal mass fractions and nearly equal volume fractions of the

**Figure 17.** Relative change in volume of polymer blends plotted vs. temperature (a) and concentration (b).<sup>149</sup>  
(a): PP–UHMPE (60 : 40) (1), PP–UHMPE (70 : 30) (2) and PP–PVC (40 : 60) (3); (b): PP–UHMPE blend,  $\lambda = 2$ ;  $T_h$ , K: 383 (1) and 393 (2).

components. The maximum increase in volume is attained at  $\lambda = 2$ .

The observed increase in volume is related to stress relaxation during the shape recovery process, accompanied by the appearance of discontinuities at interfaces. The anomalous increase in the extrudate length on heating was explained in terms of a model for extrusion of a two-phase composite, which is based on the self-consistent field approach.<sup>159</sup> The model assumes that the two-phase composite has a matrix–inclusion structure. The total deformation of a composite is given by<sup>149</sup>

$$\varepsilon_1 = \delta(1 - \delta) \left( \varepsilon_1^m - \varepsilon_1^i \right)^2, \quad (11)$$

where  $\delta$  is the relative volume fraction of the inclusions;  $\varepsilon_1^m$ ,  $\varepsilon_1^i$  are respectively the plastic deformation of the matrix and the plastic deformation of the inclusion. From expression (11) it follows that  $\varepsilon_1 > 0$  and the maximum  $\varepsilon_1$  value is attained at  $\delta = 0.5$ , i.e., the maximum stretching must be observed at a volume fraction of inclusions of 50%, which is consistent with experimental data (see Fig. 17).

A DF-10 composite based on polyarylate and copolyethersulfone also exhibits unusual behaviour during the heating of samples prepared by plunger extrusion of polymeric powder billet.<sup>160</sup> The shrinkage,  $S$ , defined as the relative change in the extrudate length after keeping at a preset temperature, decreases with an increase in  $\lambda$  and changes its sign near  $\lambda = 4$ . In other words, the length of the sample increases rather than decreases at a high degree of extension. A scheme illustrating deformation of macromolecular coils in the case of solid-phase extrusion was proposed.<sup>160</sup> According to this scheme, shrinkage is due to return of macromolecular coils to the initial state. The degree of return can be estimated as follows

$$\Psi_m = \frac{C_{\infty}^{\perp} - C_{\infty}^{\parallel}}{C_{\infty}^{\perp}}, \quad (12)$$

where  $C_{\infty}^{\perp}$  and  $C_{\infty}^{\parallel}$  are the characteristic ratios,  $C_{\infty}$ , calculated along the normal and parallel to the extrusion axis, respectively. The parameter  $C_{\infty}$  serves as a measure of the relative flexibility of the macromolecule and of the degree of compactness of the macromolecular coil.<sup>161, 162</sup>

Thermal shrinkage occurs until the macromolecular coil adopts a symmetrical shape, which corresponds to  $C_{\infty}^{\perp} = C_{\infty}^{\parallel}$ . Comparison of the parameters  $S$  and  $\Psi_m$  revealed their similarity in absolute value and an identical type of dependence on  $\lambda$ . Moreover, the  $C_{\infty}^{\perp}$  and  $C_{\infty}^{\parallel}$  values calculated from the equation derived<sup>160</sup> invoking the mechanism of plastic deformation of amorphous polymers (see Ref. 163), show inversion of absolute values at  $\lambda > 4$ .

Recently, considerable attention has been paid to blends of engineering polymers with liquid-crystalline polymers (LCP).<sup>164–169</sup> The addition of LCP improves not only the mechanical properties of thermoplastics but also the corresponding processing conditions. Therefore, interest in these systems in the framework of SME studies is not occasional. Peculiarities of the shape memory behaviour of a HDPE–LCP blend were studied.<sup>153</sup> The LCP was a liquid-crystalline copolyester of 40% PETP with 60% of 4-hydroxybenzoic acid. Stretching of samples was preceded by radiation-induced formation of a network structure in them. The shape memory effect was studied under conditions of isometric heating and cooling; to this end, thermorelaxation stress  $\sigma_{tr}$  (on heating) and thermal shrinkage  $\sigma_s$  (on cooling) were measured.

The samples of HDPE and HDPE–LCP blends containing 5 mass % and 10 mass % of LCP exhibit quite different temperature dependences of  $\sigma_{tr}$  and  $\sigma_s$ . Indeed, HDPE shows a dramatic increase in  $\sigma_{tr}$  in a narrow temperature interval near  $T_m$ , whereas the blends are characterised by a gradual increase in  $\sigma_{tr}$  over a wide temperature range (from 323 to 423 K for the HDPE–LCP blend containing 10 mass % of the LCP). This behaviour is due to the  $\alpha$ -

and  $\alpha'$ -transitions in the PETP phase of the LCP. At temperatures above 423 K, the  $\sigma_{tr}$  value remains virtually unchanged up to 533 K. The  $\sigma_s(T)$  dependence obtained for the blends also differs from the corresponding dependence for HDPE (kinks between 333 and 373 K in the former vs. nonmonotonic change in  $\sigma_s$  in the latter case). It is important that the  $\sigma_s$  value of the HDPE–LCP blend containing 10 mass % of LCP is 1.5 times higher than the  $\sigma_s$  value for pure HDPE. As the absorbed radiation dose increases from 50 to 150 kGy, the  $\sigma_{tr}$  and  $\sigma_s$  values increase but then decrease due to accumulation of radiation-induced defects in the material.

Physical modification of polyolefins by cross-linking them with various elastomers is one of the most efficient methods of preparation of thermosetting plastics possessing the properties of both elastomer and plastic, namely, flexibility, high impact toughness at low temperatures, etc. This modification technique is also of interest for obtaining shape-memory materials exhibiting the properties mentioned above. In particular, the behaviour of LDPE–ethylene/propylene/diene copolymer (EPDC) blends prepared by chemical (series A) and radiation-induced (series B) cross-linking and then orientationally stretched at 403 K and cooled to room temperature under isometric conditions was studied.<sup>170</sup> Series-A samples showed low  $\sigma_{tr}$  and  $\sigma_s$  values, the former increasing with an increase in the content of the cross-linked elastomer. Maxima in the  $\sigma_s$  plot were observed at minimum EPDC content in the blend, because their magnitudes are determined by the crystalline phase of LDPE. Series-B samples also exhibited a similar behaviour of  $\sigma_{tr}$  and  $\sigma_s$ , except for much higher absolute values of  $\sigma_s$  (compared to series-A samples) at the same LDPE/EPDC ratios. This is due to the fact that irradiation of samples causes cross-linking in both phases rather than in one phase. As a result, according to scanning electron microscopy data, fibrillation of the molecular structure occurs.

A study<sup>154</sup> of HDPE–ethylene-propylene rubber terpolymer (SKEPT)–LCP composite was carried out in a continuation of earlier investigations.<sup>153, 170</sup> Here, rubber is mainly introduced in order to improve the elasticity of the material and its adhesive interaction with steel; this is necessary for the improvement of the technical characteristics of the items produced. The effect of SKEPT and LCP on the maximum  $\sigma_{tr}$  and  $\sigma_s$  values can be followed using the plots shown in Fig. 18. With the SKEPT content below 40 mass % the LCP additive allows thermorelaxation and, of particular importance, shrinkage stress to be enhanced.

Long-term serviceability of items made of thermally shrinkable materials depends on the stability of size when stored; being mounted, they must provide sufficient compression stress during their service life. Hence, the reverse deformation effects (in unloaded state) and stress relaxation (when loaded) must be

**Figure 18.** Thermal shrinkage at 293 K (a) and thermorelaxation stress at 433 K (b) plotted vs. SKEPT content in HDPE–SKEPT–10 mass % LCP (1) and HDPE–SKEPT (2) blends.<sup>154</sup>

small. In radiation-modified PE, the crystalline phase hampers the return deformation. As to HDPE–SKEPT blends, an increase in the SKEPT content causes the proportion of the crystalline phase of PE to decrease, which can lead to shortening of service life. This assumption was tested<sup>153</sup> by measuring the return deformation (with load removed) of radiation-modified (absorbed dose 150 kGy) HDPE–SKEPT and HDPE–SKEPT–LCP samples heated to 423 K and stretched by 100% during cooling to room temperature in the loaded state (with fixed ends).

As samples are released from the clamps, a conditionally instantaneous shrinkage occurs. Subsequent reverse deformation is damping in character. A decrease in the preset extension depends on the material's composition. In particular, the decrease for the HDPE–SKEPT (20:80) blend was 33% [cf. 8% for the HDPE–SKEPT–LCP (25:65:10) blend] after 1000 h; *i.e.*, the addition of LCP improved the size stability of the oriented articles. Clearly, the reverse deformation is hampered by not only the crystalline phase of HDPE but also the liquid-crystalline polyester, which acts as a reinforcing agent when oriented.

Few studies on the SME in filled polymer composites are available. This may be due to the fact that the addition of fillers usually deteriorates the operating parameters of SME. Publications<sup>90, 92, 93, 171</sup> are concerned with the shape memory behaviour of polymerisation-filled, UHMPE-based composites extruded using a process proposed in Ref. 158. The fillers used were aluminum and bauxite. It was established that composites and UHMPE exhibit qualitatively similar dependences of the degree of shape recovery  $\Psi$ , estimated from the change in the cross section of extrudates, on  $\lambda$ . In both cases a nearly linear increase in  $\Psi$  is observed as  $\lambda$  increases from 1 to 9. However,  $\Psi$  decreases in absolute value in the order UHMPE–UHMPE-bauxite–UHMPE–Al. It was shown that shape recovery is due to rearrangement of the crystalline phase, as indicated by correlations between, *e.g.*,  $\Psi(T)$  and the temperature dependences of the degree of crystallinity and between  $\Psi$  and an increase in the degree of crystallinity due to orientational stretching.

Thermal shrinkage and molecular orientation of polymerisation-filled composites can be correctly described in the framework of the rubbery elasticity theory, namely, by the Mooney–Rivlin phenomenological equation<sup>171</sup>

$$\lambda_c^m = (\lambda^2 - \lambda^{-1}) \left( \frac{2C_1 + 2C_2}{\lambda} \right), \quad (13)$$

where  $\lambda_c^m$  is the degree of molecular orientation corrected for the presence of filler<sup>2</sup> and  $C_1$  and  $C_2$  are constants. In the case of molecular orientation,  $C_2 = 0.615$  for UHMPE–Al (70 mass %) and 0.53 for UHMPE–bauxite (45 mass %), the corresponding values for thermal shrinkage are 0.015 and 0.030; the  $C_1$  constants are zero in both cases.<sup>171</sup> Since the constant  $C_1$  is associated with the entropy contribution, it was concluded that entropy does not contribute to molecular orientation and thermal shrinkage and that the driving force of these processes is rearrangement of the crystalline phase during solid-phase extrusion. Comparison of the  $C_2$  constants for molecular orientation and thermal shrinkage showed that in the former case the proportion of structural regions involved in the rearrangement is much higher. While molecular orientation occurs involving the whole crystalline phase, thermal shrinkage involves only defect crystallites formed in the course of orientation crystallisation. This also follows from the fractal model for shrinkage.<sup>93</sup>

Conventionally, shape memory effect in polymeric materials is not accompanied by considerable changes in volume. However, as mentioned above, if a porous structure was created in the initial homopolymer billet<sup>34</sup> or discontinuities appeared as a result of internal stress relaxation on heating of oriented polymer blend samples,<sup>149</sup> shape memory effect is accompanied by an increase in volume. This effect can also be achieved by introducing a porous filler, in particular, thermoexpanded graphite (TEG) into the polymer matrix.<sup>172–176</sup> TEG has good compactibility, which

allows large deformations to be obtained when fabricating a compact billet. Subsequent heating of the billet will not be accompanied by recovery of the initial dimensions. At the same time, at particular TEG content in the EP–TEG system, it is possible to prepare a composite, which is well-deformable and possesses the ability to complete shape recovery, which occurs on heating to a temperature above the glass transition temperature.

Figure 19 presents the results of a study<sup>175</sup> of cylindrical rods deformed by compression in a mould. Heating of such samples in the unloaded state causes an increase in their length but their diameters remain unchanged. The largest  $\Delta l/l$  or  $\Delta V/V$  values can reach 45% at a TEG content of 6 mass %–8 mass %. As the degree of deformation decreases, this interval extends towards higher TEG content.

**Figure 19.** Relative change in length (volume) plotted vs. TEG concentration in an EP–TEG system.<sup>175</sup>  
 $\varepsilon$  (%): 10 (1), 30 (2), 40 (3), and 45 (4);  $T_h = 358$  K.

Taking into account the results considered above, thermal shrinkage studies of sleeve-shape samples were carried out. It was found that at a TEG content of 6 mass % in the composite, a piped sample can be deformed by up to 60%. On subsequent heating of the sample in the unloaded state the internal diameter decreases to the initial value while the outer diameter and length remain unchanged.

Rod-like articles capable of increasing their diameter with retention of length on heating were prepared using hydrostatic compression of cylindrical billets with fixed ends at 50–100 MPa. Such rods can be used for fabrication of disks with radial increase in volume.

By and large, TEG-filled composites based on UHMPE and PP behave similarly to EP–TEG composites.<sup>175</sup> At the same time, in contrast to the thermosetting composite, the degree of shape recovery for these materials is less than 100% up to the melting temperature of the crystalline phase of the polymer.

A physical model proposed to describe the kinematics of deformation of the porous composite is available.<sup>173, 175, 176</sup> The model was employed to construct the limiting surface of the material in the strain space. The limiting surface restricts the region where the material deforms without failure and represents the surface of a pyramid (Fig. 20). The basal plane,  $S_0$ , of the pyramid corresponds to the situation where the material deforms with no change in volume; the plane  $S_1$  corresponds to the limiting compaction of the composite; and the  $A$ -point corresponds to failure of the composite under cubic strain only. The compact material can be deformed only within the  $S_0$  triangle, on the boundaries of which the polymer fails. The porous polymer can be deformed within the truncated pyramid with the bases  $S_0$  and  $S_1$ . On the lateral surface of the truncated pyramid, the polymer matrix fails while the upper base corresponds to complete closure of pores.

At a sufficiently high porosity, the  $S_1$  plane will move beyond the  $A$ -point. In this case the reversible strain of the porous composite will be restricted by the pyramid of the limiting surface.

**Figure 20.** Limiting surface of porous composite in the strain space.<sup>175</sup>

Attempts at further compacting of the material in the stage of initial straining will lead to destruction of the polymer matrix and the recovery of the sample on heating will be incomplete.

Theoretical analysis showed that by prestraining the porous polymer or composite it is possible to form structures which, when recovering their shapes, imitate materials with different (including negative) Poisson ratios (coefficients of proportionality between the longitudinal and lateral strain developed during shape recovery of the sample).

The limiting relative change in the volume of the composite is given by<sup>175</sup>

$$\varepsilon_{\text{lim}} = \frac{\delta_V(1 - \theta)}{1 + \delta_V}. \quad (14)$$

Here  $\delta_V$  is the volume fraction of the filler prior to deformation ( $\delta_V = V/V_p$ , where  $V$  and  $V_p$  are the volumes of the porous filler and the polymer matrix, respectively),  $\theta$  is the relative bulk density of the filler in pores of the composite prior to deformation ( $\theta = V_1/V$ , where  $V$  and  $V_1$  are the volumes of the filler prior to and after deformation, respectively). This relationship shows that the lower the bulk density of the filler, the larger the absolute value of  $\varepsilon_{\text{lim}}$  and, therefore, the farther the  $S_1$  plane from the origin. This conclusion is in agreement with experimental results.

From relation (14) it follows that, at a high TEG volume fractions in the composite, the absolute value of  $\varepsilon_{\text{lim}}$  can become so large that the  $S_1$  plane will shift beyond the vertex  $A$  of the limiting surface. This means that there is a maximum permissible concentration of the carbon material in the composite.

Thermally expanded graphite is a conducting filler; therefore, shape-memory studies of the TEG-filled composites are of particular interest because the carbon material affects peculiar features of the shape memory effect<sup>173–177</sup> while the effect in question in turn affects the conductivity of the composites. Particular attention should be paid to the polymer composites with the nearly threshold filler content, at which the insulator–conductor transition occurs.<sup>178, 179</sup> In particular, being heated, these materials exhibit the effect of self-regulation of the heating temperature, which consists in a dramatic increase in the resistance in a certain critical temperature interval and is due to the thermal expansion of the polymer matrix.<sup>178</sup> However, the range of threshold concentrations is characterised by a very large scatter of resistance values owing to nonuniform distribution of the filler particles over the volume of the matrix, which hampers the attainment of the result mentioned above.<sup>180</sup> This problem can be solved by using those materials which recover their shape with simultaneous increase in volume on heating. Shape-memory behaviour is characterised by a much greater increase in the distances between contacting filler particles that are involved in the conduction process compared to thermal expansion of the polymer matrix. From here one has a wider interval of filler concentrations in which the resistance increases jumpwise.

We studied the resistance of the EP–TEG composite based on diglycidyl phthalate and a block oligomer of aliphatic epoxy resin with acid oligoether cured with isomethyltetrahydrophthalic anhydride. It was established that, at the TEG concentration of nearly 6 mass %, heating of the billets deformed by mould compression causes a sharp increase in the resistance near  $T_g$ . The bulk resistivity ratio corresponding to the deformed ( $\rho_d$ ) and recovered ( $\rho_r$ ) states can be as high as three orders of magnitude (Table 2).

**Table 2.** Characteristics of carbon-containing epoxy composites.

| Composite               | $\varepsilon$ (%) | $\rho_d$<br>/ $\Omega$ m | $\rho_r \times 10^{-3}$<br>/ $\Omega$ m | $\rho_r/\rho_d$ |
|-------------------------|-------------------|--------------------------|-----------------------------------------|-----------------|
| EP + 3% TEG             | 20                | 64 000                   | 502                                     | 11              |
| EP + 6% TEG             | 20                | 138                      | 60                                      | 435             |
|                         | 20                | 109                      | 60                                      | 550             |
|                         | 30                | 91                       | 60                                      | 659             |

Introduction of a binary filler including kaolin powder led to significant changes in the electrical properties of the composite (see Table 2). At the same (with the EP–TEG composite)  $\varepsilon$  values, the absolute values of  $\rho_d$  and  $\rho_r$  decrease in the presence of kaolin. The minimum  $\rho_d$  value and simultaneously maximum  $\rho_r/\rho_d$  ratio were established for the EP–TEG–kaolin (100 : 6 : 3) composite.

Analysis of the strain kinematics and subsequent strain relaxation showed the following. Low bulk density and good compactibility of TEG favour the decrease in the volume of the TEG-filled cavities in the initial cured billet upon deformation due to compression of the filler and filling of the voids thus formed with the polymer. The concentrations of TEG in the composites under study is high enough to ensure the conducting state of the materials, *i.e.*, the presence of a continuous infinite cluster of the filler particles. An increase in the TEG concentration or the degree of deformation of the material causes an increase in the contact area between the TEG particles and thus a decrease in the  $\rho_d$  value (see Table 2). When heated to temperatures close to  $T_g$ , at which the mobility of the chain fragments between cross-link points of the polymer network unfreezes, the deformed samples recover their shape (their volumes increase) through sample elongation. The polymer leaves pores and TEG remains in the compacted state. Breakage of bonds between the particles of the conducting cluster causes a decrease in the contact area and, as a consequence, an increase in resistance. The process goes to completion when the glass transition temperature is achieved and the shape recovery induced change in the length of the sample ceases.

Microstructural studies showed that the TEG distribution over the bulk of the polymer matrix in the presence of kaolin is more uniform, which favours an increase in the conductivity of the system. The results obtained are consistent with the published data (introduction of kaolin into epoxy polymer filled with graphite also led to a decrease in the system's resistivity).<sup>181</sup> This effect can be used in short-circuit thermal protection, namely, current limiters can be made of a shape-memory material.

## V. Polymer gels

Considerable interest<sup>16, 182–196</sup> of researchers in polymer gels as shape-memory materials is due to the fact that their volume can change by three orders of magnitude under the action of external factors (*e.g.*, temperature, solvents, electromagnetic field, *etc.*). Particular attention should be paid to polymer hydrogels in which water molecules fill the intermolecular space of the polymer

network. These materials are soft and ‘wet’, which improves their compatibility with biological tissues.<sup>186, 187</sup> The shape memory effect underlies the design of temperature-sensitive diaphragms, thermally activating clamps, ‘soft’ machines and other medical instruments.<sup>186</sup>

The mechanical properties of many water-swollen gels strongly depend on temperature. For instance, a gel prepared by copolymerisation of acrylic acid with *n*-stearyl acrylate<sup>188</sup> behaves as a hard plastic below 298 K. But at temperatures above 323 K it becomes very soft and can be stretched by 50% relative to its initial length. The elastic moduli of this material decrease by three orders of magnitude on heating, which can be due to reversible order–disorder transition associated with interactions between the alkyl side chains of the stearyl acrylate units. At  $T < 323$  K, long alkyl chains form the crystalline structure which reinforces the material. Above this temperature, the material has an amorphous structure, being soft and flexible. It is believed<sup>186</sup> that this mechanism (formation of crystalline aggregates between the side chains) causes the SME in the material.

The gel ‘remembers’ the shape in which it was initially formed. To show the shape memory, the gel is heated above the transition temperature (323 K), deformed (*e.g.*, stretched or coiled) and then cooled in the deformed state. If the unloaded, deformed gel is again heated, at  $T > 323$  K it recovers its initial shape and size in ten seconds.<sup>186</sup> It should be noted that the shape recovery rate and the degree of swelling can strongly depend on the temperature at which the gel was prepared. For instance, at  $T_p = 293$  K the degree of swelling of *N*-isopropylacrylamide gel is low ( $d/d_0 = 1.2$ , where  $d$  and  $d_0$  are the diameters of the swollen and freshly prepared gel, respectively). However, as  $T_p$  approaches the phase separation temperature (305 K) the  $d/d_0$  ratio considerably increases and then again decreases to 1.46 at  $T_p > 305$  K, which correlates with spatial inhomogeneity in the gel.<sup>197</sup> In turn, the shrinking time decreases from 500 min at  $T_p \leq 293$  K to 2 min at  $T_p \geq 299$  K.

Spatially modulated polymer gels prepared by restricting interpenetration of gel networks are widely used for fabrication of articles for biomedical applications.<sup>185, 195</sup> These are, *e.g.*, a bigel plate, which can bend and eventually form a ring with an increase in temperature or solution concentration; a gel, which changes its shape from a straight line to a pentagon and then to tetragon depending on temperature; a gel ‘hand’ which can clench or unclench various material things on temperature variation. The operation of these ‘devices’ is based on the ability of gels to change their volume depending on the environmental conditions.<sup>198–200</sup> Examples of spatially modulated gels are provided by the systems based on *N*-isopropylacrylamide (IPA) and acrylamide (AAM) gels.<sup>185</sup>

It is known<sup>201</sup> that the volume of ionic IPA gel rapidly decreases at  $T > 310$  K, whereas such is not the case for the AAM gel. In turn, it is the AAM rather than IPA gel that shows a large shrinkage in water-acetone mixtures. At room temperature, a completely swollen bigel plate is bent towards the AAM gel. If  $T > 310$  K, the plate is gradually bent due to shrinkage of the IPA gel and eventually forms a ring. Being immersed in a water-acetone mixture at room temperature, the plate hoops in the opposite direction but the ring can also be formed. Transition from the linear to a bent shape is reversible and the change in the degree of bending depends only slightly on the number of straightening–bending–straightening cycles, being at most 3% after 9 cycles.

Bending deformation can be estimated from the angle  $\theta$  between two tangent lines drawn to the ends of the gel arch,

$$\varepsilon = \frac{\theta d}{L},$$

where  $d$  and  $L$  are the diameter and the length of the gel sample, respectively. The maximum deformation of bigel is 49%.<sup>185</sup> This greatly exceeds the deformation developed in the polyvinyl alcohol–poly(sodium acrylate) system on application of an

electric field ( $\varepsilon = 20\%$ ).<sup>202, 203</sup> The kinetics of the shape memory effect in the bigel plate mentioned above can be followed using the plots shown in Fig. 21. Deformation of gel immersed in a high-temperature bath (311 K) increases with time; on cooling to 295 K the bigel gradually recovers its initial shape and size.

Figure 21. Bending deformation cycles plotted vs. time for bigel.<sup>185</sup>

The bigel bending mechanism<sup>185</sup> differs from the mechanisms of shape memory effects induced by electric field<sup>187, 192, 202, 203</sup> or by heating with an IR laser.<sup>184</sup> In the last two cases trigger-type bending of macroscopically homogeneous gels requires the presence of an electric or temperature field gradient. Clearly, these methods are inappropriate to achieve a high degree of deformation ( $\theta > 180^\circ$ ) owing to difficulties in the creation of high field gradients. The thermal expansion coefficients of two gels can differ much more than the corresponding parameters of two metals (*cf.* more than 0.5 per degree for the IPA–AAM bigel vs.  $\sim 7 \times 10^{-6}$  per degree for a typical brass–steel bimetallic plate; the difference is nearly five orders of magnitude). Therefore, bigels are much more sensitive to temperature changes in the environment compared to bimetals.

Compared to the bigels considered above, gels with a more complex modulated structure allow a variety of reversible transitions to occur. In addition to the ‘straight line–pentagon–tetragon’ transition (see above), they also include transitions to a sinusoid and helix, a transition from a planar sheet to a tube, *etc.* Such a diversity of transitions at different temperatures is achieved by appropriate modulation of particular regions of the polymeric systems. In this Section we restricted ourselves to illustration of those possibilities of polymer gels that are related to the thermally induced SME. A great body of information on the subject, including modern practical applications and promising projects, was summarised and analysed in a review.<sup>191</sup>

## VI. Conclusion

In the last decade, the shape memory effect in polymers has been the subject of intensive research. This provides diverse information on the structure of oriented polymers and mechanisms of their deformation and favours better understanding of the kinetic laws of thermally stimulated relaxation. New studies begin, aimed at the design of polymeric materials offering new possibilities for the shape memory effect to occur; this is important for the extension of the spectrum of practical applications of these materials. Interest in the SME studies is in line with rapid development of research on the so-called ‘smart’ or ‘intellectual’ materials including shape-memory polymers. Compared to shape-memory metal alloys, shape-memory polymers offer a number of advantages (low density, high strain-recovery ability, ready processability and dyeability and relatively low cost). It is also important that the SME in polymeric materials occurs at temperatures close to room temperature and in some cases these

materials can be controlled with ease by varying the chemical composition of the polymers.

Among recent achievements, there are considerable advances in studies of the properties (in particular, the LTR mechanism) of glassy polymers;<sup>46–48, 62</sup> preparation of unusual shape-memory polymeric materials (polymer composites with compactible filler,<sup>173, 175</sup> spatially modulated polymer gels<sup>185, 195</sup>); and fabrication of various articles for technological and biomedical applications from shape-memory functional materials.<sup>94, 95, 116, 127, 142</sup> There are also a number of problems that are still to be solved and require further investigations. In particular, the mechanism of SME in amorphous-crystalline polymers is still to be clarified and the mechanism of shape recovery and its relation to the state of the structure of such promising materials as oriented biodegradable polymers<sup>204, 205</sup> and the polymer blends and composites modified by various additives remain poorly studied. Search for new fields of application of shape-memory polymeric materials also remains an important investigation avenue.

Solving problems mentioned above requires further investigations of various aspects of SME in polymeric materials, aimed at gaining a deeper insight into the mechanisms of the shape memory effect, generalisation of experimental data and formulation of practical recommendations for potential users.

**Abstract.** Methodical approaches to the modification of the catalytic properties of enzymes by various means of directed evolution are summarised. A number of particular examples of the design of enzymes with new and enhanced properties, including higher thermal stability, solubility, substrate specificity, stereoselectivity, *etc.*, are considered. The prospects for further development of the directed evolution strategy for enzymes and proteins with other functions are discussed. The bibliography includes 67 references.

## I. Introduction

Enzymes are used more and more often in industrial engineering processes. The well-known advantages of enzymes over conventional catalysts include reduced energy consumption due to much higher efficiency, lower material consumption due to high specificity, simpler process design due to a smaller number of product isolation and purification stages, and so on. However, in some cases, these advantages turn into drawbacks. Enzymes, like other proteins, are subject to irreversible denaturation with temperature rise, treatment of organic solvents, or at higher or lower pH values. The too high specificity often does not allow the use of enzymes for reactions of the same type with a broad range of substrates belonging to the same class of compounds but having somewhat different structures. This brings about the task of modifying the properties of enzymes in order to extend the scope of their applicability.

The state-of-the-art knowledge of the principles of organisation of protein molecules does not allow one to predict what properties would arise upon targeted replacement of particular amino acid residues, although methods for such replacement have been developed rather thoroughly at the level of modifications of the corresponding genes. In recent years, methods for enzyme

modification by introducing random changes into the structure of the protein macromolecule have been proposed. This gives rise to a broad range of structures which may include the optimal ones for the solution of the particular problem. Then molecules with preferred properties are selected. These manipulations are repeated in several consecutive stages to finally obtain a variant that complies with the task. This approach is called 'directed evolution.' This review presents consideration of various types of this method and evaluation of the results, relying on the data published in 1993–2003.

## II. Key ways of directed evolution of enzymes

The modification of enzymes has been known for long time. Over several decades, this has been done mainly using specific chemical methods and has aimed at elucidating the role of particular amino acid residues in the mechanism of the catalytic action of enzymes.

The accumulation of data on the structures of enzyme-encoding genes and the development of the experimental procedures for work with genetic material provided the possibility of modifying the enzyme molecules by directed mutagenesis. This allowed more detailed investigation of the structure-functional organisation of enzymes. Simultaneously, attempts to modify enzymes in order to improve their operation properties for use in industry have been undertaken. This gave rise to a new line of research in molecular biology, 'protein engineering.'

However, currently it is impossible to predict the influence of one or other amino acid replacement on protein function. This is despite the numerous data on the 3D structures of enzymes obtained by X-ray diffraction and development of computer modelling (for example, molecular dynamics calculations). This is why methods of modification of enzyme properties along a specified direction based on the introduction of random replacements at the gene level followed by selection of the mutant variants according to a specified criterion have experienced vigorous development. In the numerous publications in this direction, one can distinguish several major approaches.

### 1. Incremental truncation for the creation of hybrid enzymes

Benkovic and co-workers<sup>1</sup> proposed a combinatorial approach in genetic engineering called incremental truncation. For this purpose, the gene encoding this enzyme is split into unequal parts in

S N Zagrebelny Novosibirsk State University, ul. Pirogova 2, 630090 Novosibirsk, Russian Federation. Fax (7-3832) 39 71 01, tel. (7-3832) 30 06 56, e-mail: snz@post.nsu.ru

two different ways using different restriction endonucleases so that in one fragment pair, the fragment encoding the N-terminal part of the protein is longer, while in the other pair, the longer fragment is that encoding the C-terminal part. The longer fragments are cloned in different plasmids. This gives the overlapping fragments of a gene, which can be modified independently. Then each fragment is truncated 'from the inside' by treatment with exonuclease. This results in generation of variants with deletions in the gene fragments that encode the N- and C-parts of the protein. The plasmids thus obtained are introduced simultaneously into the same cells devoid of the enzyme under study. The combined expression of gene fragments restores the ability of cells to grow on a minimum medium until the catalytic site of the enzyme is damaged due to shortening of the gene fragments. Using this method, the points at which some of the inner sections of the polypeptide chain can be removed without substantial damage of the catalytic properties of the enzyme were identified, and the monomeric enzyme (glycinamide ribonucleotide formyltransferase from *E. coli*, PurN) was converted into its functional heterodimer.

It is evident that the proposed method allows one to study the structure-functional organisation of the enzyme. Subsequently, chimeric enzymes were produced, irrespective of the degree of DNA homology, using the Incremental Truncation for Creation of Hybrid Enzymes (ITCHY) technique. Figure 1 shows a diagram showing the use of this method to create libraries of modified genes.

The possibility of this non-homologous recombination giving rise to interspecies functional hybrids was demonstrated<sup>2</sup> in relation to PurN and its analogues, the human GART enzyme (hGART), which have only a 50% homology at the DNA. ITCHY libraries between the amino end of PurN and the carboxy end of GART were obtained by successive truncation of the encoding sequences with exonuclease III and ligation of products. The most active PurN-GART hybrid was about 500 times less active than the wild-type PurN.

**Figure 1.** Block diagram for the creation of the library of modified genes by stepwise truncation of enzyme genes with non-homologous recombination.

Subsequently,<sup>3</sup> more general approaches to the compilation of libraries of shortened gene fragments have been proposed based on the possibility of assembling enzyme molecules from large numbers of molecular building units. To this end, when conducting the polymerase chain reaction (PCR),  $\alpha$ -thionucleoside triphosphates are added to the reaction mixture in order to insert  $\alpha$ -thiophosphate units into the chain being formed. During the subsequent cutting of gene fragments, exonuclease 'stops' at these units. The positions in which the thiophosphate residues occur are generated randomly, thus giving a set of fragments that compose the library. Its components can further undergo recombination *in vitro* in any combinations. Using *E. coli* PurN and its analogue, hGART, functional hybrids with recombination points in the regions with minimum homology were obtained.

The advantages of molecular evolution with non-homologous recombination *in vitro* require further investigation.

## 2. Evolution of enzymes by DNA family shuffling

The term 'DNA shuffling' has been proposed by Stemmer.<sup>4,5</sup> Figure 2 shows the pattern of creation of gene libraries by this method. The key idea of the approach is to generate short fragments of the nucleotide sequence of the gene, to multiply fragments using error-prone PCR (as a method for introducing random mutations), to assemble full-size gene sequences by means of PCR and finally to select the variants that meet the conditions imposed by the task set. The fragmentation is accomplished by hydrolysis of a large gene (the researcher cited used a ~1 kb long gene) with DNase I up to a pool of random fragments with a size of 10–50 bp. These fragments can further be assembled into a full-size gene by repeated hybridisation cycles in the presence of a DNA polymerase. The fragments themselves serve as primers due to the presence of homology, recombination taking place when

**Figure 2.** Block diagram for the creation of the library of modified genes by DNA family shuffling.

fragments from one copy of the gene initiate the synthesis on the other copy (which results in template switching). At the end of this round of procedures, selection is performed the pattern of which is chosen in conformity with the project goal. The selected best variant (or several promising variants) is subjected to one more set of the same procedures with the subsequent selection. Several DNA shuffling and selection cycles result in a satisfactory variant, which is subsequently cloned in vectors ensuring a high expression level. Stemmer demonstrated the potential of this approach in relation to *E. coli*  $\beta$ -lactamase and  $\beta$ -galactosidase and to interleukin 1. Shuffling can be performed for one gene to obtain its multiple variants or for families of homologous genes from different sources including those encoding enzymes that catalyse transformations of substrates with related structures. In the latter case, the probability of obtaining improved variants is higher; however, if the number of variants is too great, the selection process would be hampered.

It should be noted that each DNA shuffling gives rise to point mutations. This is undesirable when working with large genes, because the number of variants, among which selection is to be performed substantially increases. A new DNA shuffling protocol increases the accuracy of the procedure at the stages of fragmentation of the modified gene by DNase I, PCR and the assembly of the full-size gene.<sup>6</sup> This protocol includes, in particular, the replacement of  $Mg^{2+}$  ions by  $Mn^{2+}$  ions, the limited use of PCR (whenever possible) and the application of more accurate DNA polymerases. The frequency of mutations also decreases when a mixture of *Taq* and *Pfu* (or *Pwo*) in a 1 : 1 ratio is used. Finally, the mutation frequency was decreased to 0.05% and even below; in the case of large genes, this provides the possibility of obtaining a sufficient number of active variants. Further improvement of the protocol can be directed at decreasing the number of PCR cycles and using only *Pfu* polymerase, characterised by higher accuracy than *Taq* polymerase, in the last cycle.

The DNA family shuffling or evolution by recombination *in vitro* of natural homologous genes has been used to improve some properties of enzymes. The thymidine kinase of the herpes simplex virus (HSV TK) is used to obtain thymidine analogues suitable as antiviral agents. The homologous human enzyme has a high specificity towards thymidine, and its use for the synthesis of virus replication inhibitors is of low utility. In a study,<sup>7</sup> shuffling was performed for the two most closely related thymidine kinase genes from different strains of this virus (78% of DNA homology) in order to select chimeras with an enhanced ability to phosphorylate zidovudine (3'-azidothymidine, AzT). Four shuffling cycles resulted in two clones, which increased the sensitivity of the *E. coli* TK to AzT by a factor of 500 relative to the more active HSV-1 enzyme and by a factor of 4000 relative to HSV-2. The shuffling involving HSV-2 increased the yield of sensitive clones, although this enzyme is more stable with respect to AzT.

Under real conditions, an improvement of combinations of enzyme properties is as important as the enhancement of particular features. The shuffling of 26 subtilisin genes from various sources (56%–99% of DNA identity) has been reported.<sup>8</sup> Subtilisins are proteinases of the bacterial origin, which are used in food industry (to upgrade tough meat), in leather industry (to remove hair from the skin of animals), in medical industry (to prepare protein hydrolysates for parenteral feeding), *etc.*, are of substantial practical interest. Genes from various bacteria were used to generate chimeric libraries, which were evaluated using four parameters: activity at 23 °C, thermal stability, resistance against organic solvents and the pH dependence of the activity. Chimeras possessing all combinations of properties of the individual parent enzymes were identified, and structures with markedly improved particular properties have been found.

Controlled evolution methods have been used<sup>9</sup> to study the relationships between the stability and the activity of the mesophilic esterase. Previous studies of these properties in homologous enzymes have shown that the rise of the inactivation temperature under thermal treatment is incompatible with retention of a high

catalytic activity at low temperatures. One reason is the different conformation states (in particular, flexibility) responsible for stability and activity. Six generations of statistical mutagenesis, recombination and selection have substantially stabilised the *Bacillus subtilis* *p*-nitrobenzyl esterase (the inactivation temperature increased by more than 14 °C) without deterioration of the catalytic activity at lower temperatures. Analysis of the stability and the activity for a large number of random mutants has shown that these properties are not inversely correlated; nevertheless, mutations that increase the thermal stability while maintaining the low-temperature activity are very rare. Thus, evolution of one feature through accumulation of single amino acid replacements usually takes place at the expense of another feature, irrespective of whether these features obey an inverse correlation or do not correlate at all.

Directed evolution<sup>10</sup> has been proposed for modification of properties of diversified enzymes. This enables fast optimisation of enzymes as regards one or several properties even when data on the structure or the mechanism of action are missing. Directed evolution experiments make use of a simple Darwinian optimisation algorithm with successive approximations. The molecular diversity is brought about by random mutagenesis and/or recombination of the target gene or a family of connected genes. The modified variants are identified by selection, which allows one to choose the required variants. The genes encoding these improved enzymes are used as the initial ones for the subsequent evolution round.

During shuffling of DNA families, the DNA fragmentation by means of restriction endonucleases (instead of DNase I) increases the yield of recombinants<sup>11</sup> due to an increase in the chimerisation frequency. For example, an increase in the chimerisation frequency from 1% to 100% has been observed between two catechol-2,3-dioxygenase genes (*xylE* and *nahH*) from different sources having a 84% identity in the DNA sequence. Hydrolysis of each of the parent genes by several sets of restriction endonucleases resulted in the formation of more diverse chimeric structures, and the hybrid variants thus obtained were 8–13 times more stable at 50 °C than the parent enzymes.

A DNA shuffling protocol called degenerate oligonucleotide gene shuffling (DOGS) with an enhanced yield of target products in the molecular evolution of the gene has been described.<sup>12</sup> The advent of this new procedure was due to the fact that the proportion of parent (unshuffled) gene variants in the case of DNA fragmentation by DNase I was too high. This stipulated the necessity of labour-consuming screening for the selection of the chimeric genes, especially in the case of shuffling of loosely related DNA sequences. The new approach was tested using a family of xylanase genes from various sources. These enzymes are of interest as regards the development of advanced processes for the treatment of wastes from the wood processing industry: for destroying hemicelluloses and subsequent use of the hydrolysis products (*e.g.*, in the industrial production of ethanol). On the basis of homology of amino acid sequences, fragments were identified in the gene structures and degenerate primers used subsequently for amplification of these gene fragments were constructed. The amplification products were mixed and subjected to joint amplification to obtain full sequences of these genes. This gave a library of chimeric variants. The degree of mosaicism could be varied by specifying the ratio of the initial amplified fragments. The extensive library thus obtained contained variants that differed appreciably in the optimal temperature. Analysis of the nucleotide sequences of these variants identified the origin of the fragments contributing to new properties of enzymes. However, no variants with a changed optimal pH were encountered in this case. This was attributed to the fact that the enzyme active site incorporates two glutamic acid residues, which act as a nucleophile and an acid catalyst, respectively. The replacement of any of them results in the loss of a catalytic activity. This situation is apparently insurmountable in enzyme modification by this method.

A convenient supplement to DNA shuffling is heteroduplex recombination.<sup>13</sup> This method allows one to create libraries of chimeric DNA sequences derived from two homologous parent sequences. First, heteroduplexes are obtained *in vitro* from the parent sequences and then they are used to transform cells of an appropriate host. During the intracellular reparation, chimeric gene libraries are formed. No physical exchange by fragments of the parent genes takes place. The heteroduplex recombination generates numerous chiasmata and can be especially useful for recombination of large genes or whole operons. The method, however, has limitations: the more remote the mutation sites from each other, the higher the recombination frequency. The minimum distance between the mutated units that still allows recombination is 24 bp.

### 3. Staggered extension process (StEP)

The StEP procedure has been proposed by Zhao *et al.*<sup>14</sup> (Fig. 3). A polymerase chain reaction on a target enzyme gene is initiated by one pair of primers with a short-term stage of chain growth. The PCR products are then subjected to denaturation followed by annealing (heat-induced denaturation–renaturation) during which the synthesised fragments are switched to other chains of the template as all fragments possess a sufficient degree of homology. The process continues until a full-size gene is formed. Owing to switching of the growing chains from one template to the

**Figure 3.** Block diagram for the creation of a library of modified genes by the staggered extension technique; v are the positions of random mutations.

other, gene libraries for recombination containing information from different parent genes are formed. This approach has been used to obtain a thermally hyperstable variant of subtilisin E. The wild-type enzyme from the mesophilic strain *B. subtilis* has a half-inactivation time of ~5 min at 65 °C. The mutagenesis using the error-prone PCR and the subsequent selection gave rise to five variants with a 3–8-fold increase in the half-inactivation time. Equal amounts of genes of these five variants were subjected to StEP recombination. About 8000 clones expressing the resulting variants were tested for stability at 75 °C and three variants with half-inactivation times (at 65 °C) 25–50 times longer than those of the wild type were selected.

The efficiency of StEP recombination is close to that of other *in vitro* recombination methods; however, StEP can be used in one pot, as it does not require separation of the parent sequences and recombination products.

### 4. Random priming recombination (RPR)

An even simpler method for the compilation of mutant gene libraries has been proposed<sup>15</sup> (Fig. 4). For this purpose, a copy of the gene subject to modification (obtained by PCR amplification) is used as a template in the PCR, while a random set of oligonucleotides containing six nucleotide residues (dpN<sub>6</sub>) serve as primers. This PCR using an error-prone DNA polymerase generates a large number of short DNA fragments, which prove to be complementary to different sections of the matrix sequence. These fragments contain point mutations due to both the erroneous incorporations of nucleotides by the polymerase and imperfect hybridisation of primers with the template chain. In these complexes, short DNA fragments can act as primers for one another and are assembled into the full sequence by multiple repetition of these rounds with subsequent screening and selection. This method has a number of advantages compared to the DNA shuffling.

**Figure 4.** Block diagram for the creation of a library of modified genes by random priming recombination; v are the mutation points induced by the error-prone polymerase reaction.

1. For RPR recombination, both single- and double-stranded DNA can be used as the template without intermediate synthesis of the full-size second strand; potential mutations arise both at the level of single-stranded DNA using error-prone DNA polymerases and at the RNA level using RNA-dependent DNA polymerases.

2. DNA shuffling requires DNA fragmentation with the DNase I, which must be thoroughly removed prior to the assembly of a full-size mutant gene variant.

3. The random synthetic primers have equal lengths and do not induce predominant synthesis of any gene fragments. The heterogeneity of the sequence of primers allows them to form hybrids with template chains in many positions, so that each nucleotide of the template can be either copied or mutated, with the same frequency, during the chain growth. The random distributions of short fragments of the growing DNA chain along the template (or templates) and point mutations in the DNA fragment ensure the random character of distribution of the chiasmata and mutations in the progeny full-size genes.

4. The synthesis of DNA with random primers does not depend on the template length. Even on short DNA fragments (200 nucleotides long), the synthesis can be initiated equally efficiently as on large molecules (for example, on the linearised DNA of the  $\lambda$  phage). This provides unique opportunities for the engineering of short peptides.

5. Since the parent DNA chain is used only as the template for the synthesis of growing single strands, the whole cycle requires a 10–20 times smaller amount of the initial DNA than the DNA shuffling technique.

### III. Evolution of thermal stability

The enhancement of thermal stability is the widely used approach in the modification of enzyme properties. The modern concepts in changing thermal stability are discussed in reviews,<sup>16,17</sup> which report the structural features of thermally stable enzymes providing grounds for the development of rational approaches to their design and application in industry. Note the high level of similarity of primary structures of thermophilic<sup>†</sup> and mesophilic enzymes, which demonstrates once again imperfection in the state-of-the-art views on structural organisation of protein molecules and the limited nature of the prognostic conclusions.

The modification of a psychrophilic protease, subtilisin S41, has been reported.<sup>18</sup> Previously, this enzyme was subjected to three rounds of mutagenesis/recombination followed by screening. This gave a product with a half-inactivation time (60 °C) 500 times as great as that of the wild-type enzyme. Five more rounds of laboratory evolution gave a product 1200 times as stable as the wild-type enzyme and 20 times as stable as the homologous mesophilic subtilisins SSII and BPNP. About a half of 13 amino acid replacements in the resulting enzyme variants are mutations at serine residues, which occur in thermophilic enzymes less frequently than in mesophilic ones. The variant obtained after the eighth (the last) round of directed evolution contained the Asp216Glu replacement, which is not encountered in either mesophilic or thermophilic enzymes. A nearly neutral replacement resulted, nevertheless, in one more twofold increase in the subtilisin thermal stability with respect to the preceding variant.

Enzymes of thermophilic organisms are often not active enough at low temperatures. An attempt has been made<sup>19</sup> to increase the catalytic activity of the hyperthermophilic indole glycerophosphate synthetase, an enzyme involved in tryptophan biosynthesis, from *Sulfolobus solfataricus*, at moderate temperatures. Using DNA shuffling, *Sulfolobus solfataricus* mutated gene

variants able to restore the growth of the *E. coli* culture deficient in the proper enzyme were obtained. It was found that the low activity of the thermophilic enzyme at low temperatures was due to the slow dissociation of the reaction product. In modified enzyme variants, this stage is substantially accelerated, which results in a higher catalytic activity with only a minor decrease in the thermal stability. Thus, in some cases, molecular evolution methods also allow one to elucidate the structural factors responsible for the modified properties of enzymes.

The thermophilic xylose isomerase enzyme from *Thermus thermophilus* has been adapted to normal temperatures in a similar way.<sup>20</sup>

The molecular evolution of the fructosylamino acid oxidase from *Corynebacterium* sp. (strain 2-4-1) has been studied.<sup>21</sup> This enzyme is considered as a potential analytical reagent for determination of non-enzymic 'glycation' of proteins in clinical biochemical analysis.<sup>‡</sup> The researchers used mutagenesis *in vivo* by transforming the *E. coli* XL1-Red strain with the plasmid containing the fructosylamino acid oxidase gene.<sup>§</sup>

After selection of the clones with the modified enzyme, four rounds of mutagenesis and selection were carried out; finally, this gave an enzyme-expressing clone, which retained 94% activity at 47 °C (incubation for 10 min) against 1% for the wild-type enzyme. The mutagenesis *in vivo* used has a number of advantages over the error-prone PCR; however, this approach does not cover all the possibilities provided by the creation and use of mutant gene libraries.

An increase in thermal stability with the simultaneous increase in catalytic activity has been described<sup>22</sup> for the D-amino acid amidase from the soil bacterium *Ochrobactrum anthropi* SV3, which facilitates the preparation of optically pure amino acids during the synthesis of pharmaceuticals, agrochemicals and food additives. Unlike the analogues from other sources, this enzyme catalyses the transformations of a broad range of substrates (amides of amino acids), including those with a bulky side chain. The enzyme gene was subjected to molecular evolution, two rounds of PCR mutagenesis and selection gave a variant with a 5 °C higher denaturation temperature and with a higher catalytic efficiency.

### IV. Evolution of protein solubility and expression

The use of enzymes in organic synthesis brings about the problem related to their denaturation in organic solvents. Similar difficulties are faced by the development of cleansing agents that contain proteases and lipases susceptible to denaturation in the presence of detergents. Therefore, attempts have been made to develop enzymes stable against organic solvents. In particular, subtilisin has been modified by molecular evolution methods.<sup>23</sup> This was done using random mutagenesis with a polymerase chain reaction used as the generator of mutations. The selected variant of the PC3 enzyme was 130 times more active than the wild-type enzyme (subtilisin E) in a medium containing 40% DMF. The activity was also retained in a medium with 85% DMF. A study of the primary structure of the selected variant has shown that all 10 amino acid replacements were located near the active and substrate-binding sites of the enzyme. Seven of these can be found in other variants of subtilisin from different strains of the producer. Subsequently, researchers were able to enhance the subtilisin resistance against the organic environment and the thermal stability to an even greater extent.<sup>24,25</sup> Strains producing enzymes with the optimal

<sup>†</sup> The terms 'thermophilic,' 'mesophilic,' and 'psychrophilic' mean that higher, normal and lower temperatures, respectively, are preferred for enzyme functions; the normal temperature is about 37 °C.

<sup>‡</sup> The term 'glycation' is introduced to mean the non-enzymic modification of proteins (unlike glycosylation). This phenomenon takes place in the case of diabetic processes in the body and has a great diagnostic value for evaluation of the patient's condition during the therapy.

<sup>§</sup> *E. coli* XL1-Red is a mutant strain devoid of *mutS*, *mutD* and *mutT* genes, which participate in the DNA repair. The rate of mutations in this strain is 5000 times as high as that of the wild-type strain (see the STRATAGENE catalogue).

pH more convenient for technological purposes and simultaneously with a high stability in the presence of solvents (DMF) have been found<sup>8</sup> in the same library of subtilisin clones.

Attempt have been made<sup>26</sup> to improve the performance properties of the *Bacillus licheniformis* glucose dehydrogenase, which serves as an alternative reagent for glucose determination and ensures regeneration of the cofactor (NAD<sup>+</sup>) in the systems of enzymic synthesis using NAD<sup>+</sup>-dependent dehydrogenases. Using DNA family shuffling, a glucose dehydrogenase variant free from the proneness to dissociation at high pH values has been obtained. Study of the primary structure of the variant showed that it contained only one amino acid replacement with respect to that prepared previously, which, in turn, also differed from the wild-type enzyme by a single replacement. The thermal stability of the enzyme has also markedly increased.

The creation of superproducers of protein products is faced with problems related to the formation of insoluble grains of these proteins inside the producer cells, so-called 'inclusion bodies'. Their formation is usually due to an improper spatial folding of the protein molecules when present in the cell at high concentration. This results in procedural difficulties in the isolation of the target products and in the subsequent 're-folding' to give the native or a functionally active structure.

The molecular evolution technique can be used to solve this problem. When selecting protein variants able to be folded 'properly', the selection procedure is the most complicated. Two promising approaches to the selection according to solubility and protein expression have been developed. In one of these, the target protein is expressed as a recombinant product with the full sequence of chloramphenicol acetyltransferase (CAT) at the N-end.<sup>27</sup> It was shown that the addition of CAT to insoluble proteins induces a much more pronounced decrease in the stability against chloramphenicol than in the case of addition to soluble proteins. This feature provides the possibility to pick the variants with higher solubility. The soluble HIV integrase mutant was selected in this way from the pool of insoluble wild-type constructs.

Yet another method involves the addition of the target protein to the N-end of the GFP protein<sup>¶</sup> (see Ref. 28). The fluorescence of GFP as a part of these recombinants is related to the proper folding of the attached protein. The utility of GFP as a reporter protein has been confirmed by directed evolution of the folding and demonstrated using different examples. After several rounds of shuffling of DNA with a wild-type sequence, readily soluble proteins were selected [H-subunit of the bullfrog ferritin and the mutant form (Cys33Thr) of V protein of F1 bacteriophage], which usually aggregate during expression in *E. coli* due to improper folding. An important advantage of these approaches over mutagenesis with screening of functional activity is elimination of the necessity of the labour-consuming screening. However, testing of the variants selected in this way for functional activity is still necessary, because the solubility of chimeric protein or a proper folding of the reporter protein does not ensure the retention of activity in the target protein.

The molecular evolution with screening based on GFP has been used<sup>29</sup> for expression of the *Mycobacterium tuberculosis* Rv2002 antigen in the soluble form (usually, this protein is expressed in *E. coli* as 'inclusion bodies'). It was possible to obtain the soluble material in amounts required for detailed structural studies.

The same approach has been used<sup>30</sup> to develop a high-performance producer of gene fragments of HIV1 shell protein. The N-terminal recombinants of a fragment of the gp120 protein of HIV1 containing important immunodominant determinants of the virus with GFP were constructed and subjected to DNA shuffling in combination with PCR. Out of the 300 000 cell colonies, those with continuous fluorescence were selected. Only

one such colony was found (the fluorescence protein was distributed over the whole cell volume). The subsequent analysis has shown that under these conditions, the level of synthesis of the target product amounts to ~15% of the total cell protein. This approach led to the desired outcome, despite the lack of a functional test for the target product.

The scope of problems that can be solved by methods of the molecular evolution of enzymes is rather diversified. A study<sup>31</sup> reports an attempt to increase the stability of wild-type  $\beta$ -glucuronidase (GUS) to glutaraldehyde for its use as a reporter in a study of gene expression in the cells of transgene plants. The  $\beta$ -galactosidase system used most often for these purposes is inapplicable, as these cells synthesise their own enzyme. The *E. coli*  $\beta$ -glucuronidase is also not very convenient due to the sensitivity to glutaraldehyde and formaldehyde used to retain the tissue to be studied in order to preserve its structure. These and some other restrictions hampered the use of  $\beta$ -glucuronidase in eukaryotic systems as the reporter enzyme. Using molecular evolution of the enzyme, the sensitivity of  $\beta$ -glucuronidase to aldehydes was reduced. As soon as after one error-prone PCR round and two rounds of DNA shuffling, a mutant variant of GUS stable to higher (~80 times) concentrations of glutaraldehyde was isolated. Although glutaraldehyde is known to modify proteins through the formation of lateral cross-links at lysine residues; only one of the eight replacements involves this amino acid, while the other seven replacements are mapped on the protein surface near the lysine residue. Apparently, the surface amino acid residues affect appreciably the possibility of modification with glutaraldehyde.

An increase in the expression level of the *Myceliophthora thermophila* laccase in the *Saccharomyces cerevisiae* yeast has been attained by the same method.<sup>32</sup> Laccases present substantial commercial interest as ligninolytic enzymes used to degrade aromatic compounds. This problem often arises in developing industrial processes for bioremediation of areas contaminated by petroleum products. The attempts at elaboration of strains convenient for the industrial cultivation with a high level of laccase production does not always result in the desired outcome. However, using directed evolution, it was possible to increase the activity level of the enzyme in yeast 170-fold (due to increase in the enzyme production and taking into account the 8-fold increase in its catalytic activity). The formation of a site recognised by the Kex2 protease in the C-terminal section of the protein processing was found to be the most efficient (resulting in a 10-fold increase in the overall activity). This is the way the expressed protein accommodates itself to processing in the heterologous host.

## V. Modification of substrate specificity

During the design of biocatalysts for industrial use, the problem of adjustment of enzymes to substrates which they do not encounter in nature arises more and more often.

The efficiency of molecular evolution methods in modification of substrate specificity has been convincingly demonstrated<sup>33</sup> using the enhancement of the fucosidase activity of  $\beta$ -galactosidase as an example. The fucose (6-deoxygalactose) glycosides are weakly split by  $\beta$ -galactosidase. The  $\beta$ -galactosidase to  $\beta$ -fucosidase activity ratio of the enzyme attained over eight rounds of DNA shuffling was 1000.

In order to improve the operation characteristics, modification has been performed for xylose isomerase from the thermophilic bacterium *Thermotoga neapolitana*,<sup>34</sup> which also exhibits glucose isomerase activity and, therefore, it is used in the production of glucose-fructose syrups, which is among the largest-scale processes of industrial biotechnology. This enzyme catalyses the glucose to fructose isomerisation much less efficiently than the xylose to xylulose isomerisation. For this reason, attempts at modifying the enzyme for increasing its catalytic activity towards glucose have been undertaken. An increase in the activity of the thermophilic variants of the enzyme at moderate temperatures

¶ GFP — Green Fluorescent Protein — is widely used as a reporter protein in the design of recombinant microbe strains.

and displacement of the optimal pH towards lower values are also improvements of the operating properties of the enzymes. The latter is needed to simplify the process, because the preceding stage, starch conversion, is carried out using glucoamylase operating in a weakly acidic medium. The variant prepared previously was subjected to directed evolution; two rounds of PCR mutagenesis and activity selection (at moderate temperatures and required pH values) gave two new variants, which were much more active at any temperature and pH, the optimal pH being shifted by 0.5 units in the desired direction.

Studies on modification of the substrate specificity of aspartate aminotransferase have been carried out.<sup>35</sup> A combination of DNA shuffling and selection in an auxotrophic *E. coli* strain was used;<sup>†</sup> this markedly increased the enzyme specificity towards amino and keto acids with chain branching in the  $\beta$ -position. After five rounds of selection, one mutant had a  $k_{\text{cat}}/K_M$  ratio for unnatural substrates  $10^5$  times as high as the wild-type enzyme, the catalytic efficiency towards the main substrate being decreased 30-fold. This mutant variant contained 13 replacements of amino acid residues, six of these being responsible for 80%–90% of the effect. Five of these six replacements were stable, being retained in five mutants that exhibited the highest efficiency with respect to  $\beta$ -branched substrates; one of the six residues was located at a distance from the direct contact with the substrate. Thus, long-range interactions in the protein molecule can contribute significantly to functional properties, which hampers the use of a rational approach to the targeted modification of enzymes.

The mutant variants of cephalosporin acylase obtained from the glutaryl acylase *Pseudomonas* SY-77<sup>36,37</sup> make it possible to obtain, in one enzymatic stage, 7-aminocephalosporanic (7-ACA) or 7-aminodeacetoxycephalosporanic (7-ADCA) acids used to modify cephalosporin antibiotics. The solution of this problem markedly improves the economy and environmental characteristics of the industrial production of cephalosporins. These acids are prepared by deacylation of cephalosporin C and adipinyl-7-ADCA, respectively (Fig. 5). The removal of the side-chain acyl residue in the antibiotic is catalysed by glutaryl acylase, which, however, exhibits a low activity with respect to adipinic acid residues. A mutant variant of the enzyme with 10-fold increased activity ratio towards the adipinic-to-glutaric acid residues has been obtained; this markedly extends the scope of enzyme application in the modification of penicillin and cephalosporin antibiotics.

The modification of the specificity of the *Rhodobacter sphaeroides* phytoene desaturase has been described.<sup>38</sup> This enzyme catalyses the successive dehydrogenisation of phytoene in the biochemical pathway to isoprenoids, as shown in Fig. 6. In many bacteria, the process stops after the formation of neurosporene; this is also true for *Rhodobacter sphaeroides*. The product of the next dehydrogenisation stage, lycopene, is more valuable, as it has more pronounced antioxidant properties and, hence, it is used as a component of food additives. By using directed evolution technique, the researchers prepared a variant of the *Rhodobacter sphaeroides* enzyme able to synthesise lycopene.

This task was accomplished by two rounds of random mutagenesis with subsequent selection; modification was carried out for an enzyme belonging to the family of neurosporene producers, whereas most of phytoene desaturases (90% of the known enzymes) belong to another family of proteins. The homology in the primary structure between these two families is relatively low (less than 60%). Nevertheless, specificity modification is attained relatively easily: even a single replacement gave a variant with 39% production of lycopene. The final variant (after two more rounds) produced 90% of lycopene. Enzyme variants able to

**Figure 5.** Preparation of deacylated cephalosporins by means of glutaryl acylase (a) and adipinyl acylase (b).

catalyse the synthesis of  $C_{35}$  and  $C_{40}$  isoprenoids have also been obtained;<sup>39,40</sup> This opens up the way to the synthesis of new analogues of natural carotene derivatives.<sup>39,40</sup>

In recent years, substantial progress has been attained in the decoding of biochemical routes of microbial degradation of

**Figure 6.** Successive stages of phytoene dehydrogenisation during the formation of lycopene induced by phytoene desaturase.

<sup>†</sup> In this case, a strain with a damaged operon of isoleucine biosynthesis was specially designed. This damage could be counterbalanced by providing aspartate aminotransferase with the ability to catalyse transamination of amino acids with a branched side chain.

various aromatic compounds that are frequently encountered pollutants. The attention is focused on the creation of microbe strains able to degrade efficiently these compounds under natural conditions, which can be used for bioremediation of contaminated areas. To this end, attempts have been made<sup>41</sup> to extend the range of substrates for biphenyl dioxygenase by random priming recombination. Two rounds of manipulations with the *bphA1* *Pseudomonas pseudoalcaligenes* KF707 gene gave enzyme variants with new properties, in particular, those able to oxidise not only polychlorobiphenyls but also dibenzofuran, dibenzo-*p*-dioxin, dibenzothiophene, fluorene, *i.e.*, compounds hardly utilised by the initial strain.

The obtained<sup>42</sup> 2-hydroxybiphenyl monooxygenase variant from *Pseudomonas azelaica* HBPI catalyses hydroxylation of indole and its hydroxy and bromo derivatives (wild-type enzymes do not catalyse this reaction). The new variant of the enzyme was found to contain two amino acid replacements separated from each other by 146 residues. The enzymes that oxidise indole and its derivatives can also be used in biotechnological processes to produce indigoid dyes and other products of organic synthesis.

Studies into the development of microorganisms able to biodegrade halogenated organic compounds formed as wastes in the chemical industry or contained in many pesticides, which are degraded with difficulty by the natural populations of microbes in soil and water, are in progress. The activity of the key enzyme for 1,2,3-trichloropropane degradation, haloalkane dehalogenase from *Rhodococcus sp.* (m15-3), has been markedly increased by DNA shuffling.<sup>43</sup> 1,2,3-Trichloropropane is highly toxic and does not occur in nature, but is encountered as a man-made pollutant. The modified gene was introduced into bacteria (*Agrobacterium radiobacter* AD1) that utilise the product made by this enzyme, namely, 2,3-dichloropropan-1-ol. The resulting strain proved to grow on trichloropropane as the only carbon and energy source; thus, it can be used as a bioremediation agent.

## VI. Stereoselectivity and enantioselectivity

The production of enantiopure compounds becomes more and more important for chemical and pharmaceutical industries. In 2000, the world sales volume of optically active drugs was above \$100 billion. The demand in these products is due to the fact that the molecules of efficient drugs should comply with the asymmetry of the receptors. For example, the US Food and Drug Agency demands strict determination of whether it is possible to produce a drug as an optically pure isomer.

One way to solve this problem is to use enzymes in stereospecific reactions. However, the enantioselectivity of enzymes is often too low, but it can be increased using molecular evolution techniques. The results of such studies have been analysed in detail in a review.<sup>44</sup>

An approach to the development of enantioselective catalysts based on directed evolution *in vitro* has been proposed.<sup>45</sup> Hydrolysis of racemic *p*-nitrophenyl 2-methyldecanoate (**1**) was chosen as the test reaction. Free *S*-acid **2** [the product of hydrolysis of *S*-enantiomer of ester **1**] belongs to a class of compounds in which one finds pharmaceuticals, plant protection compounds and intermediates of organic synthesis. The *Pseudomonas aeruginosa* PAO1 lipase composed of 285 amino acids was used as the catalyst.

The wild-type enzyme exhibits only a 2% enantioselectivity in favour of the *S*-configuration. Using the error-prone PCR, the lipase gene comprising 933 bp was subjected to statistical mutagenesis. The frequency of mutations was varied in such a way as to introduce an average of one or two replacements into each copy of the lipase gene. This was attained by appropriate selection of the

PCR conditions (for example, by the change in the concentration of  $\text{Mg}^{2+}$  ions). The mutated genes were inserted into the expression vector, amplified in *E. coli* and introduced in *P. aeruginosa*. After four selection rounds, the enantioselectivity increased from 2% to 81%.

By inverting the enantioselectivity of D-hydantoinase, which is the key enzyme of the multienzyme route for methionine synthesis, the production of L-methionine in *E. coli* was improved.<sup>46</sup> The production of L-amino acids by means of hydantoinases (Fig. 7) is widely used in industry. For methionine, this reaction proceeds preferentially with the D-isomer of hydantoin, resulting in extremely slow transformation of D-*N*-carbamoylmethionine into the target product (D-selective hydantoinase induces accumulation of D-*N*-carbamoylamino acid, which is converted very slowly into the desired amino acid).

**Figure 7.** Enzymic synthesis of amino acids from racemic 5-substituted hydantoin.

Using successive PCR mutagenesis and screening procedures, the enantioselectivity of D-hydantoinase was inverted [from *ee*(D) 40% to *ee*(L) 20%], the overall activity being increased fivefold. The introduction of the modified L-hydantoinase gene into the recombinant bacterial strain with intact cells as the catalyst increased the productivity with respect to L-Met and decreased the accumulation of undesirable intermediates as compared with wild-type cells. This effect was attained by replacement of only one amino acid. Variants with high D-selectivity [*ee*(D) 90%], which also had a single amino acid replacement, were found. However, due to the lack of efficient screening methods, studies dealing with directed evolution of enantioselective catalysts are few in number.

In recent years, considerable progress has been achieved in the understanding of the role of carbohydrate components in glycosylated proteins; this enhanced the interest in the synthesis of glycoside derivatives of proteins. The chemical synthetic methods in the carbohydrate series are fairly complicated; therefore, enzymic methods become more and more attractive. Commercially justified glycosidases, which exhibit not only hydrolase but also glycosyl transferase activity, are the enzymes of choice. However, the regioselectivity of these enzymes is often inadequate. An attempt to modify the regioselectivity of the *B. stearothermophilus*  $\alpha$ -galactosidase has been undertaken.<sup>47</sup> The wild-type enzyme is specific towards 1,6-glycosidic bonds and, to a lesser extent, to 1,3-bonds. Using statistical mutagenesis and the StEP technique for the molecular evolution, enzyme variants that mainly cleaved the 1,3-glycosidic bonds were

obtained. For the majority of enzyme variants obtained, the activity towards 1,6-bonds decreased appreciably as regards both hydrolysis and transglycosylation. Enzyme variants with an (1,3):(1,6) regiospecificity ratio of 6.9 against 0.3 for the wild-type enzyme have been obtained. However, the transglycosylase activity was markedly lower compared to that of the wild-type enzyme. The researchers believe that they have demonstrated the feasibility of solving this problem; however, further studies are required.

An important application of the stereoselectivity of enzymes is separation of sterically hindered alcohols.<sup>48</sup> Enzymes have already been used for analogous purposes; however, in the case of sterically hindered alcohols, the attempts have often failed. The use of the *Pseudomonas fluorescens* lipase and molecular evolution using the *E. coli* XL1-Red strain with a high frequency of spontaneous mutations resulted in an enzyme variant with an enhanced stereoselectivity towards sterically hindered esters. However, the desired result has not been exactly attained, because mutations are introduced in one variant of the gene. A greater diversity of mutants can be obtained using DNA shuffling.

The esterase from *Pseudomonas fluorescens* KCTC 1767 is used for the preparation of optically pure ketoprofen (**3**) from a racemic mixture of ethyl esters.

The modification of the working properties of the enzyme in order to increase the thermal stability, shift the pH optimum towards higher pH and increase the stability against the action of some organic solvents, non-ionic detergents or high substrate concentrations has been carried out<sup>49</sup> with three cycles of molecular evolution. This example illustrates the possibility of simultaneous 'improvement' of several parameters using molecular evolution.

The modification of enzyme stereospecificity is related most often to changing their substrate specificity with respect to a particular enantiomer. Using a tagatose-1,6-diphosphate aldolase-catalysed reaction as an example, a new, in principle, approach has been proposed.<sup>50</sup> The approach implies the change in the reaction stereochemistry in such a way that the enzyme would catalyse the formation of a different product from the same substrates. After six DNA shuffling rounds, the aldolase subjected to the evolution has demonstrated a 80-fold increase in the  $k_{cat}/K_M$  ratio in the reaction with an unnatural substrate, fructose 1,6-diphosphate, because the enzyme has switched to the preferred (75%) formation of fructose diphosphate from glyceraldehyde 3-phosphate and dioxyacetone phosphate instead of the predominant (99%) formation of tagatose diphosphate. It is noteworthy that the direct reaction catalysed by this enzyme is cleavage of hexose diphosphates to triose phosphate; therefore, the results obtained could be attributed to the usual modification of the substrate specificity. Nevertheless, the use of this enzyme in the synthesis is of obvious interest.

## VII. Selection of the modified gene variants

It has already been noted that the selection procedure is a key stage in directed evolution, which is specific for each particular case. There exist, however, some common techniques that could underlie a selection strategy.

One method is the use of a phage display. This approach implies expression of the target protein as a recombinant with a bacteriophage surface protein, which is exposed on a phage particle and presents the target protein on the surface. The protein is thus brought in contact with the solution and can exhibit the enzymatic activity or present the antigenic determinants of the target protein to antibodies.

An example of using this approach is an attempt to transform the DNA polymerase (the Stoffel fragment of the *Thermus aquaticus* DNA polymerase I) into an RNA polymerase.<sup>51</sup> This was done by mutagenesis of the functional fragments (binding sites of metal ions, polynucleotide duplex, the substrate, and interaction with the matrix) performed separately, which was followed by the assembly of a full-size gene by means of polymerase (two PCR rounds) and by selection using the phage display method. This gave an effective RNA polymerase, which retained the DNA polymerase activity and had a sufficient processivity.

## VIII. Other methods of DNA recombination

The methods of directed molecular evolution of enzymes developed during the last decades has proved to be fairly efficient. Meanwhile, accumulation of the data on structural organisation of enzyme molecules is in progress; this allows also the use of rational approaches to modification of the protein structure in the design and perfection of biocatalysts. In some cases, it is useful to combine both approaches.

The possibility of increasing the thermal stability of glow-worm luciferase has been demonstrated.<sup>52</sup> The enzyme is used as an analytical reagent in medicine and in the quality control of foodstuffs (in particular, to detect some microorganisms). It can be conjugated to antibodies (specific to particular antigens), and the resulting fluorescence induction or suppression is used to judge the presence or absence of a structure containing this antigen. The insufficient thermal stability of the wild-type enzyme restricts its use; that is why attempts have been made to increase the thermal stability.

Molecular evolution has been used<sup>53</sup> to enhance the thermal stability of phytase, the enzyme that splits phytic acid (inositol hexaphosphate), which is the main form of phosphorus storage in plants. This enzyme, common in microorganisms and in herbivorous animal stock, is missing from the gastrointestinal tract of pigs and birds. The addition of inorganic phosphate to the fodder is uneconomic. To enhance the uptake of the green fodder, phytase tablets are added to the fodder, which requires increasing the natural thermal stability of phytase. The enzyme gene was subjected to site-directed and cassette mutagenesis in order to replace the  $\alpha$ -helical fragment of the enzyme from *Aspergillus terreus* by a similar fragment of the *Aspergillus niger* enzyme,<sup>53</sup> which ensured a higher thermal stability of the hybrid.

## IX. Rational approaches to enzyme modification

Rational approaches to increasing the thermal stability of enzymes involve either comparison of the amino acid sequences of the target protein and a thermally more stable related protein or detailed analysis of the 3D structure of the target protein in order to predict promising replacements of amino acid residues on the basis of both structural data and the accepted concepts of thermal stability design; the predictions are to be verified by introducing single mutations in the wild-type protein sequence.

The modern thermostabilisation concepts include, among other issues, the introduction of additional disulfide bridges, improvement of the packing of the hydrophobic core, creation of a network of surface salt bridges or dipole interactions in the  $\alpha$ -helix, change in the proneness to form the  $\alpha$ -helix and entropy changes (e.g., the X  $\rightarrow$  Pro or Gly  $\rightarrow$  Ala replacements). All rational approaches of this type have been used previously; however, the predictions are not always successful. The reason is that the replacement of the amino acid residue cannot only entail a local effect, but also induces unexpected conformational changes in various (including remote) parts of the molecule. Nevertheless, there are examples where rational methods led to the desired outcome. Thus using site-directed mutagenesis, the contributions of all 17 amino acid residues that were different for barnase and binase (bacterial nucleases with a 85% amino acid homology) to the protein thermal stability have been studied.<sup>54</sup> The effect of one

amino acid replacement on the activation energy of denaturation varied from +1.1 to  $-1.1 \text{ kcal mol}^{-1}$ . The multiple mutant that included six amino acid domains demonstrated an increase in the stability by  $3.3 \text{ kcal mol}^{-1}$  compared to the wild type. Thus, comparison of related proteins provides useful information regarding the increase in their thermal stability.

The data obtained by various researchers on the molecular evolution of proteases have been described systematically in a review.<sup>55</sup> The site-directed mutagenesis has been used to construct variants of subtilisin with enhanced storage stability and resistance against oxidation. The replacement of Met222 susceptible to oxidation with oxidation-resistant alanine, serine or glutamine residues in *B. amyloliquefaciens* BPN2 subtilisin resulted in prevention of enzyme inactivation by oxygen. Six individual replacements of amino acids (Asn218Ser, Gly169Ala, Tyr217Lys, Met50Phe, Gln206Cys and Asn76Asp) in different positions of the tertiary structure of subtilisin resulted in an increase in the enzyme stability at elevated temperature ( $65^\circ\text{C}$ ) and in alkaline media (pH 12). Under these denaturing conditions, the inactivation rate of this variant was 300 times lower than that for the wild-type enzyme. Other replacements of amino acids, resulting in a higher enzyme stability, have also been reported.

The rational approach in enzyme reconstruction has been applied<sup>56</sup> to D-amino acid oxidase from the *Rhodotorula gracilis* yeast, which is used to remove the side chain of cephalosporin in the synthesis of antibiotics of this series. Using X-ray diffraction data for the crystalline enzyme, a mutant variant of Met213Arg, capable of catalysing the oxidative deamination of aspartic acid has been obtained (the wild-type enzyme does not use the aspartic or glutamic acids as substrates). This results in a lower activity with respect to alanine; however, the substrate specificity is extended). It is worth noting that D-amino acid oxidase from *Rhodotorula gracilis* is the most promising enzyme for industrial use owing to the high catalytic activity and strong binding of the cofactor (FAD).

The specificity of *Bacillus megaterium* cytochrome P450 BM-3 has been modified<sup>57</sup> in order to make it catalyse hydroxylation of the hydrocarbon radical of short-chain (less than  $\text{C}_{12}$ ) fatty acids at the pre-terminal units. The rational approach was based on X-ray data for the enzyme. However, the choice of the replacement was determined by inclusion into the sequence of PCR primers of triplets of a random sequence into positions planned for the replacement. Finally, the resulting variants catalysed the oxidation of caproic acid, which cannot be hydroxylated by the wild-type enzyme.

Subsequently, modification of cytochrome has been carried out.<sup>58</sup> Thus it became capable of oxidising polycyclic aromatic hydrocarbons (naphthalene, fluorene, acenaphthene and other). To impart these properties to the enzyme, it was sufficient to modify the same amino acid residues as in the case of oxidation of

aliphatic fatty acids, although the replacements were different. The goal was attained in a triple mutant in which the Leu188Gln replacement proved to be the optimal, instead of Leu188Lys.

A concept of increasing the thermal stability of enzymes has been proposed;<sup>16</sup> the concept is based on not only a comparison of amino acid sequences of homologous enzymes from various sources but also on the construction of a consensus sequence from the amino acids found most often. This amino acid sequence is transposed into a nucleotide sequence with allowance for the frequency of codon use (using the library of the amino acid sequences of phytases as an example). Then the gene corresponding to the consensus sequence is synthesised by polymerase assembling, cloned and expressed. The very first variant was much more stable than any of the parent proteins. Several rounds with inclusion of additional genes from new sources into the comparison of sequences have resulted in an enzyme variant with a denaturation temperature of  $88.5^\circ\text{C}$ , which is higher by  $8^\circ\text{C}$  than that for the initial *Aspergillus fumigatus* enzyme. The activity of the consensus enzyme was higher than that of the parent enzymes over the whole pH range. The contribution of each amino acid replacement was evaluated. Later, the denaturation temperature of the consensus phytase was raised additionally by  $2^\circ\text{C}$ .

Most bacterial phytases have the pH optimum in the neutral region, whereas the medium in the gastrointestinal tract of animals is weakly acidic. Therefore, enzyme variants with the pH optimum shifted toward lower pH have been obtained<sup>59,60</sup> by site-directed mutagenesis based on the consensus phytase with replacement of amino acid residues affecting the pH optimum of the enzyme.

Modification of formate dehydrogenases by point replacements of amino acid residues has been reported.<sup>61,62</sup> Formate dehydrogenase is an effective component of systems for regeneration of the  $\text{NAD}^+$  cofactor; it is used in the enzymic synthesis of many pharmaceuticals. An increase in the thermal stability of the enzyme due to enhancement of the hydrophobic character of  $\alpha$ -helical fragments was induced by the replacement of serine residues in positions 131, 160, 184 and 228 by alanine residues by means of site-directed mutagenesis.<sup>61</sup> Interestingly, the effect of multiple replacements is additive, although these residues are rather remote in the protein chain. An enzyme variant capable of regenerating  $\text{NADP}^+$  has been prepared<sup>62</sup> on the basis of computer analysis of the structure by replacement of two neighbouring amino acid residues in formate dehydrogenase from bakers' yeast: Asp196Ala and Tyr197Arg. The ratio of the catalytic efficiencies ( $k_{\text{cat}}/K_M$ ) for NADP and NAD has increased by almost 10 orders of magnitude. This replacement of the cofactor increases the commercial value of the enzyme, because NADP serves as the cofactor for many dehydrogenases used in the synthesis and biotransformations of valuable chiral biologically active compounds. This result should be regarded as significant, despite the fact that the replacement has led to a substantial increase in  $K_M$  of the enzyme with respect to formate compared with the initial enzyme. This fact confirms once again the inadequacy of X-ray diffraction data on the structure of an enzyme globule for an exact prediction of the role of amino acid residues in its functions.

## X. Conclusion

In recent years, the directed evolution of enzymes has become the key technique for the creation of enzymes with new improved properties which are especially important for industrial use. This approach has provided the procedural basis for the design of enzymes with new properties without exact knowledge of the structure and the mechanism of catalytic action.

When choosing the way of solving a particular task, it should be borne in mind, however, that, as versatile as they are, different methods of directed evolution differ in results. In particular, the technique of stepwise truncation of enzyme genes with non-homologous recombination allows the modification of inner

areas of the enzyme, whereas the staggered extension technique results in the formation of hybrids with more homologies in the N-terminal fragment of the gene. The random priming recombination yields an almost uniform distribution of random replacements over the whole enzyme molecule.

The number of variants for the selection of enzymes with 'improved' properties is great with any methods of molecular evolution. Therefore, different ways for optimisation of compilation of gene libraries including computer methods are proposed. Recently, an approach of this type based on accounting of the thermodynamic and kinetic parameters of the DNA shuffling have been proposed and the predictions have been compared with the results.<sup>63</sup>

In some cases, it is necessary to protect an amino acid critical for the protein functions from participation in the mutation events. For this purpose, a procedure has been reported<sup>64</sup> based on introduction into the codon of this amino acid of an oligonucleotide fragment containing the splitting site of some restriction endonuclease. After DNA shuffling, this oligonucleotide is restricted by the restriction endonuclease and ligation is carried out. If mutation events have taken place in the codon, the complementarity of the extending ends of the restriction site is violated, no ligation occurs and these clones are excluded from the subsequent selection.

The molecular evolution techniques can be used not only to 'improve' the properties of particular enzymes but also to solve larger-scale problems, for example, to construct genetic regulatory systems.<sup>65,66</sup> This permits fine tuning of the biochemical parameters of a metabolic circuit done experimentally *in vivo*. By applying the directed evolution to genes that constitute the simple genetic circuit, researchers have demonstrated that a circuit that does not function due to an improper selection of components is rapidly evolved into a functional circuit. A library of genetic tools with different behaviours suitable for the construction of more complicated circuits has been composed.

The methods of directed molecular evolution can also be used successfully in the design of 'nucleozymes,' *i.e.*, catalytically active nucleic acids. A self-phosphorylated DNA has been designed and isolated from a pool of random mutant DNA sequences as a variant able to phosphorylate its own 5'-end.<sup>67</sup> Six selection rounds gave a nucleozyme, which efficiently phosphorylated both RNA and DNA.

The major difficulties faced by directed evolution are related to the development of an efficient strategy for the selection of variants that have enhanced properties compared with the initial material. The solution of this problem mainly rests on researcher's skill. Nevertheless, the information presented in the review demonstrates the exceptionally high potential of molecular evolution in the design of biocatalysts.

This review was prepared with financial support from the Russian Foundation for Basic Research (Project Nos 01-05-64615 and 04-05-64188).

**Abstract.** Published data on the theoretical conformational analysis of acyclic tri- and tetracoordinate phosphorus compounds by quantum-chemical methods are generalised and systematised. Theoretical results are compared with experimental data for a wide range of such compounds. The main characteristics and fine conformational details of their structures are considered. The bibliography includes 221 references.

## I. Introduction

The development of conformational analysis is associated primarily with the need to explain and predict the reactivity of molecules from their three-dimensional structures. Pioneering studies by Barton, published in 1950, marked the beginning of extensive progress in this field, which now covers virtually all areas of organic chemistry. Barton is the person to whom Eliel, Allinger, Angyal and Morrison dedicated their monograph 'Conformational Analysis',<sup>1</sup> and it remains a 'textbook' for researchers dealing with molecular structures. The well-known phrase of these authors states that a chemist who does not understand conformational analysis, does not understand organic chemistry.<sup>1</sup> Physical methods of investigating molecular structures and quantum-chemical calculations play an important role in this field of science.

However, theoretical conformational analysis of organoelement compounds remains poorly developed in spite of advances in quantum chemistry. In the cited monograph of Eliel *et al.*, the conformations of organoelement compounds were not even mentioned. For organophosphorus compounds (OPCs) in which the phosphorus atom has a coordination number of 3 or 4, the main geometric parameters of such molecules (bond angles, bond lengths, *etc.*) and the most important fundamental characteristics of their bonds with phosphorus (for example, polarity and polarisability) have not been determined at that time. This hinders the

use of conventional methods of organic chemistry in studies of OPC structures in solution.

Pure conformational control of a particular reaction is rare. For organoelement, in particular, organophosphorus, compounds, such examples are especially lacking. The reactivities of geometric isomers which model a particular conformational situation have received much more attention. This is associated primarily with the synthesis of compounds in which an anchor group (often the *tert*-butyl group or a heterocyclic substituent) stabilises only one conformer. Most of these studies have been carried out on substituted cyclohexanes and their heteroanalogues. For organophosphorus compounds, with rare exceptions, theoretical investigations of the fine details of their three-dimensional and electronic structures were not carried out until the 1980s.

The conformational analysis of organophosphorus compounds has attracted attention because they are widely used and, as a consequence, there is a need to synthesise compounds possessing desired properties. A knowledge of the structures and fine conformational features of these compounds is also of importance in studies of their reaction mechanisms and the reactivities. In the 1970s and 1980s, theoretical analysis of the general and specific features of the OPCs' spatial and electronic structures and comparisons of the results with the general concepts of organic chemistry became of importance.

The development of a methodology for the conformational analysis of complex organic and organoelement compounds, including OPCs, was a considerable step forward. This methodology was described in a review by Vereshchagin and Vulsfon<sup>2</sup> and proved to be very efficient in studies of the structures of a wide range of various compounds in solution, where most chemical reactions occur.

Numerous studies on the experimental conformational analysis of OPCs were performed in Kazan by researchers belonging to the schools founded by Academician B A Arbuzov and the Corresponding Member of the Russian Academy of Sciences A N Pudovik. These studies were carried out using various complementary physical methods (vibrational and photoelectron spectroscopy, NMR spectroscopy, X-ray diffraction analysis, the dipole moment method, Kerr effect measurements, Rayleigh scattering). The results of these studies were covered in several reviews.<sup>3–8</sup>

Attempts to provide a theoretical support for the abundant available experimental data on the conformations of organophosphorus compounds are scarce, although this problem has

<sup>a</sup> V V Zverev, unpublished data.

attracted increased attention in recent years. It should be emphasised that we are referring to high-level *ab initio* calculations here, because semiempirical quantum-chemical methods have been used for several decades. In spite of the fact that each method is of limited application and should be used with caution,<sup>9</sup> in some cases the implementation of these methods is justified.<sup>‡</sup> This is demonstrated with particular examples below.

It has been mentioned many times that *ab initio* calculations using the economical 3-21G\* basis set are sufficient for theoretical studies of the various properties of organophosphorus compounds. However, the calculated energies of the *cis*, *trans* and *gauche* conformers of the  $\text{H}_2\text{P}–\text{OH}$  and  $\text{H}_2\text{P}(\text{O})\text{OH}$  molecules (Tables 1 and 2) show that this model is of limited application. In the case of a small energy difference between the conformers, successive extension of the basis set up to 6-311 + + G(2d,2p) is not accompanied by a monotonic change in the calculated properties (analogously to that observed for the total energy), and the inclusion of electron correlation data results in a substantial change in the relative stability of the conformers. Apparently, it follows that the conformational energies of OPCs, estimated by quantum-chemical calculations without analysis of the role of correlation effects, can differ substantially from experimental data. In our opinion, with their large number of approximations used to analyse intramolecular interactions, simplified orbital models deserve attention. In some cases, these models, derived by factorisation of the electron shells, were confirmed by photoelectron spectroscopy.<sup>11–13</sup>

The present review is the first to summarise data on the internal rotation about single bonds of phosphorus obtained by calculation, and these data are compared with experimental results. The review covers organophosphorus compounds con-

<sup>‡</sup> In particular, the results of conformational analysis of a wide range of cyclic systems by *ab initio* (HF/3-21G) and semiempirical (AM1) quantum-chemical calculations and the molecular mechanics method (MM2) were compared in the study,<sup>10</sup> and it was concluded that calculations by different methods gave similar results. However, calculations by the AM1 method, though adequately predicting the molecular conformation, gave erroneous estimates of the relative stabilities of the conformers.

**Table 2.** The total energy ( $E_{\text{min}}$ ) of the *gauche* conformer of  $\text{H}_2\text{P}(\text{X})\text{OH}$  ( $\text{X} = \text{O}, \text{S}$ ), the XPOH torsion angle ( $\varphi_{\text{min}}$ ) and the rotation barrier  $\Delta E = E(\text{cis}) - E_{\text{min}}$ .<sup>a</sup>
