^a Additional reagents present in the reaction mixture and in the final products are indicated.

For Group 4–6 metals, imido-deoxygenation with primary amines is inapplicable with rare exceptions, because of high oxophilicity of the metal. In this case, imidation requires additional promoting reagents, for example, a Me₃SiCl–Et₃N mixture, which chemically binds water (see Section II.1.c). Imido-deoxygenation of polymolybdates (Bu₄N)₂[Mo₆O₁₉] (**1a**) and (Bu₄N)₄[Mo₈O₂₆] (**1b**) with aromatic amines occurs efficiently in the presence of dicyclohexylcarbodiimide (DCC) (Scheme 2).^{107–109} The reaction of polymolybdate **1a** with *p*-phenylenediamine in the presence of triethylamine has been reported.¹¹⁰ Depending on the reactant ratio, this gave imido complexes with different compositions, in particular (Bu₄N)₂[H₂NC₆H₄N={Mo₆O₁₇}=NC₆H₄NH₂], (Bu₄N)₄·[{Mo₆O₁₈}=NC₆H₄N={Mo₆O₁₈}], etc.

For successful imidation of the oxo complex MoOCl₂·(S₂CNEt₂)₂ (**2**) with various amines, adjustment of the reaction conditions for each particular case is required. For example, when sterically unhindered *ortho*-substituted anilines, *o*-NH₂C₆H₄NH₂ and *o*-HSC₆H₄NH₂ are used, the reaction is carried out in the presence of triethylamine (Scheme 3, paths *a* and *b*).^{111,112} In the case of sterically hindered anilines, the reaction yields the target oxo–imido metathesis products only in the presence of the strong base BuⁿLi (Scheme 3, path *c*).¹¹³ Meanwhile, imido-deoxygenation of complex **2** under the action of various *p*-phenylenediamines, 1,5-bis(dimethylamino)naphthalene and *para*-substituted anilines can proceed without any auxiliary reagents (Scheme 3, paths *d–f*).¹¹⁴

The complex $\text{Tp}'\text{W}(=\text{NPh})(\text{CO})\text{I}$ [Tp' is tris(3,5-dimethylpyrazol-1-yl) borate] was prepared by imido-deoxygenation of $\text{Tp}'\text{W}(\text{O})(\text{CO})\text{I}$ with aniline in the absence of other reagents.¹¹⁵ No such reactions are known for metals of titanium and vanadium groups, which is due to higher oxophilicity of these elements.

The imido-dehalogenation (replacement of halogen atoms by the imido function) of transition metal halides with primary amines is widely used in the synthesis of imido complexes. The reaction of amines with homoleptic halides of Group 4–6 transition metals, for example, with TiCl_4 ,^{116–118} NbCl_5 ,^{77, 119–121} TaCl_5 ,^{77, 120} WX_6 ($\text{X} = \text{F}, \text{Cl}$),^{122, 123} usually afford dimeric imido complexes; however, the reaction carried out in the presence of n -donor compounds [py, 4- $\text{Bu}^t\text{C}_5\text{H}_4\text{N}$, MeCN, 1,2-dimethoxyethane (DME), *etc.*] results in mononuclear complexes.

$\text{M} = \text{Nb}, \text{Ta}$; $\text{R} = \text{Bu}^t, \text{Ph}, 2,6\text{-Me}_2\text{C}_6\text{H}_3, 2,6\text{-Pr}_2\text{C}_6\text{H}_3, \text{anthracen-2-yl}, \text{Ad}, 2\text{-naphthyl}, 4\text{-NCC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$.

Various heteroleptic transition metal chlorides are also successfully used for the preparative synthesis of imido complexes. Examples of imido complexes prepared by imido-dechlorination of heteroleptic metal chlorides with primary amines are summarised in Table 2. It is noteworthy that some of these can be prepared with equal success by imido-dehalogenation with trimethylsilylamines (see Section II.1.c, Table 5).

Table 2. Synthesis of Group 4–8 transition metal imido complexes by imido-dechlorination with primary amines.

A convenient preparative-scale method for the synthesis of arylimido complexes of Group 4–6 transition metals is transimidation with various anilines. The method is based on equilibrium replacement of some imido ligands by other imido ligands.

tert-Butylimido complexes are the best starting compounds, because in this case, the shift of the equilibrium toward the substitution product is easily attained by removing volatile *tert*-butylamine from the reaction mixture. This method has opened the way to various arylimido titanium complexes (Table 3).

Transimidation with amines is successfully used to prepare arylimido complexes of other metals. This method was first used to prepare vanadium phenylimido complexes **3**.^{143, 144}

R = SiMe₃ (53%), Et (22%), Bu^t (69%).

The method appeared to be especially convenient for the synthesis of asymmetric bisimido complexes. For example, treatment of the symmetric bisimido complex (Bu^tN=)₂MoCl₂(DME) with one equivalent of C₆F₅NH₂ or 2,6-Pr₂C₆H₃NH₂, gave the complexes (Bu^tN=)(RN=)MoCl₂(DME) (R = C₆F₅, 2,6-Pr₂C₆H₃) containing two different imido ligands in high yields (>90%).^{145, 146}

The reaction of (Bu^tN=)₂CrCl₂ with two equivalents of 2,6-diisopropylaniline gives bis(arylimido) complex **4**.¹⁴⁷

Other metal-containing compounds, for example dimethyl-amido, carbene and σ-alkyl complexes of transition metals, can also be used in the imidation with amines. The reaction of titanium diamide complex Ti(NMe₂)₂Cl₂ with amine **5** afforded imido chelate **6**.¹⁴⁸

Table 3. Synthesis of titanium imido complexes by transimidation with amines.

Starting compound	R in RNH ₂	Product	Yield (%)	Ref.

R = Me (58%), Prⁱ (64%).

A similar exchange of the NMe₂ ligands in titanium polyamide complex **7** yielded imido complex **8** containing simultaneously three types of metal–nitrogen bonds.¹⁴⁹

L is 4,4'-bis(*tert*-butyl)-2,2'-bipyridyl.

Imido-deamidation of homoleptic niobium and tantalum dimethylamide complexes M(NMe₂)₅ by amines is a convenient method for the synthesis of mixed imidoamide complexes of these metals (RN=M(NMe₂)₃ [R = Bu^t, 2,6-Prⁱ₂C₆H₃; M = Nb (79%), Ta (86%)].^{150, 151} By combining imido-deamidation and chloro-deamidation of the homoleptic complex V(NMe₂)₄ as a one-pot process, a series of d¹-vanadium complexes have been prepared.^{152, 153}

Ar = 2,6-Me₂C₆H₃ (79%), 2,6-Prⁱ₂C₆H₃ (88%), 2,6-Cl₂C₆H₃ (96%), Ph (80%), C₆F₅ (73%).

Examples of a methylene ligand displacement in carbene complexes by primary amines are known. In particular, this approach was used in the synthesis of tantalum imidohydride complex **9**.¹⁵⁴

[Complex **9** is produced in higher yield in the redox imidation of (η⁵-Cp*)₂TaCl (see Section II.2.f, Table 12).]

Tantalum imidoamide complex **10** containing sterically hindered aryl groups has been prepared by imido-dealkylation of the trimethyl complex TaMe₃Cl₂ on treatment with 2,6-disubstituted aniline.¹⁵⁵

b. Imidation with lithium derivatives of primary amines

Lithium amides are widely used to prepare transition metal imido complexes. Examples of imidation of various homo- and heteroleptic Group 4 and 5 metal halides with lithium amides are given in Table 4. Lithium amides are, however, used much more rarely to prepare derivatives of transition metals of Group 6–9. Only a few examples of imidation of complexes containing Os, Ru and Ir in low oxidation states with lithium derivatives of a number of sterically hindered amines have been reported. In particular, imido-dechlorination of osmium^{168, 169} and ruthenium^{170, 171} arene chlorides or iridium pentamethylcyclopentadienyl chlorides^{172, 173} led to unusual mononuclear d⁶-complexes **11**–**13**.

11: M = Os; R = Bu^t (60%), 2,6-Prⁱ₂C₆H₃ (36%), 2,6-Me₂C₆H₃ (96%);
12: M = Ru; R = 2,4,6-Bu₃C₆H₂ (40%).

R = Bu^t (91%), 2,6-Me₂C₆H₃ (33%), Bu^tMe₂Si (90%), 2,6-Prⁱ₂C₆H₃ (77%).

c. Imidation with trimethylsilylamines

The use of trimethylsilyl derivatives of primary amines is among the most common methods for intermolecular imidation. Two versions of this process are known: one uses pre-synthesised mono- or bis(trimethylsilyl)amines, while in the other, trimethylsilyl derivatives of amines are prepared *in situ* by introducing the

TaMe ₃ Cl ₂	2,6-Mes ₂ C ₆ H ₃ NHLi		71	155

RNH₂–Me₃SiCl–B ternary system in the reaction (B is a base). Either the initial amine or another amine (most often, triethylamine or pyridine) is used as the base, and homo- and heteroleptic halides of Group 4–6 metals and oxo complexes of Group 5 and 6 metals, in particular, sodium or ammonium metallates, are used as the metal-containing compounds. The formation of imido complexes is due to thermodynamically favourable replacement of oxygen or chlorine atoms in the starting compounds by imido groups. In the former variant, Me₃SiCl, (Me₃Si)₂O or HCl (a base is added for binding of HCl) are formed together with target complexes (Scheme 4).

Imido-dechlorination of transition metal chlorides with trimethylsilylamines proceeds smoothly and, most often, gives products in high yields. Examples of imido complexes obtained by this method are presented in Table 5. Note that the use of primary amines (see Section II.1.a) and lithium amides (Section II.1.b) in imido-dechlorination gives most often comparable results.

Another type of starting compounds frequently used for imidation with silylamines are oxohalides of Group 5 and 6 transition metals. The synthesis of imido complexes using these compounds is chronologically one of the earliest, because V, Cr, Mo and W oxohalides are easily available (either commercially or synthetically). Imidation can be accompanied by replacement of

either oxygen or chlorine atoms. The first vanadium imido complex MeN=VCl₃ was prepared by imido-deoxygenation of VOCl₃.¹⁸⁷ Later, the same method was used to prepare the phenylimide analogue, PhN=VCl₃.¹⁸⁸

R = Me (80%), Ph.

Conversely, the reaction of WOCl₄ with 4-MeC₆H₄NHSiMe₃ in the presence of 2,2'-bipyridyl involves replacement of chlorine atoms to give the oxo–imido complex 4-MeC₆H₄N=W(O)Cl₂·(bipy).¹⁸⁵ The introduction of chlorotrimethylsilane directs the reaction along the imido-deoxygenation route. For example, on treatment with trimethylsilylamines, the chlorine atoms in chromium and molybdenum dioxodichlorides are replaced by the imido group, giving rise to silyloxyimido complexes (RN=)₂M(OSiMe₃)₂ [M = Cr: R = Bu^t (54%),^{123, 150} Ad (26%);¹⁸⁹ M = Mo: R = Bu^t (93%), 1-norbornyl (80%),^{123, 150} Me₃Si (60%)¹⁹⁰], whereas treatment with amines or their mono-silyl derivatives in combination with chlorotrimethylsilane leads to imido-deoxygenation.^{191–193}

Ar = 2,6-Prⁱ₂C₆H₃, B = 2,6-Me₂C₅H₃N.

Ar	X	B	Yield (%)
2,6-Pr ⁱ ₂ C ₆ H ₃	H	2,6-Me ₂ C ₅ H ₃ N	70
	SiMe ₃	2,6-Me ₂ C ₅ H ₃ N	64
2,4,6-Me ₃ C ₆ H ₂	H	Et ₃ N	91

It is noteworthy that diimidomolybdenum dichlorides are prepared more conveniently directly from sodium or ammonium molybdate (see below).

Examples of the synthesis of imido complexes by treatment of transition metal oxides with silylamines are known. The complex (Bu^tN=)₂Cr(OSiMe₃)₂, which is the key compound in the chemistry of d⁰-chromium imido complexes, can be obtained by imido-deoxygenation of chromium(VI) oxide with Bu^tNHSiMe₃

(yield < 30%).¹⁵⁰ Silyloxyrhenium trioxide ReO₃(OSiMe₃) reacts with three equivalents of Bu^tNHSiMe₃ to give the trisimido complex (Bu^tN=)₃Re(OSiMe₃) (**14**) in 64% yield.¹⁹⁴ Complex **14** is also formed in the reaction of rhenium(VII) oxide with

tert-butylamine in the presence of chlorotrimethylsilane.¹⁹⁵ The introduction of aromatic amines, together with Me₃SiCl and pyridine, allows one to synthesise complexes **15** of a different composition.

(a) $\text{Bu}^t\text{NH}_2 - \text{Me}_3\text{SiCl}$; (b) $\text{ArNH}_2 - \text{Me}_3\text{SiCl} - \text{py}$;
 Ar = 2,6- $\text{Me}_2\text{C}_6\text{H}_3$ (83%), 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$ (76%).

The successive addition of *tert*-butylamine, chlorotrimethylsilane, 1,4,7-triazacyclononane and lithium perchlorate to rhenium(VII) oxide yielded cationic rhenium oxo–imido d⁰-complex **16**.¹⁹⁶

The reaction of osmium tetroxide with $\text{Bu}^t\text{NHSiMe}_3$ affords either osmium dioxo diimido ($\text{Bu}^t\text{N}=\text{OsO}_2$)¹⁹⁷ or osmium tetraimido ($\text{Bu}^t\text{N}=\text{Os}$) complexes depending on the amount of the amine.¹⁹⁸ It is worth noting that a similar reaction with trimethylsilylanilines proceeds as a redox process (see Section II.2.e).

For the synthesis of V, Mo and Re imido complexes, it is rather convenient to use their metallates, in particular, NH_4VO_3 , Na_2MoO_4 , $(\text{NH}_4)_2\text{Mo}_2\text{O}_7$ and NH_4ReO_4 . The use of these compounds opened up the route to a broad range of imido derivatives. Thus ammonium vanadate reacts with silylamines giving imido-trimethylsilyl oxide complexes.^{143, 199}

R = Pr^n , Bu^t (72%).

Schrock^{200, 201} developed a general method for the synthesis of molybdenum bisimido complexes **17** [L = DME: R = Bu^t ,

C_6F_5 , Ph, 2- $\text{Bu}^t\text{C}_6\text{H}_4$, 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$, 2,6- $\text{Me}_2\text{C}_6\text{H}_3$, 4-Br-2,6- $\text{Pr}_2\text{C}_6\text{H}_2$, 4-CN-2,6- $\text{Pr}_2\text{C}_6\text{H}_2$, 3,5- $\text{Me}_2\text{C}_6\text{H}_3$, 2- $\text{Pr}^i\text{C}_6\text{H}_4$, 2- $\text{CF}_3\text{C}_6\text{H}_4$, Ad, 2-($\text{CH}_2=\text{CHCMe}_2\text{CH}_2\text{CH}_2$) C_6H_4 (see Ref. 202); L = py: R = 2- PhC_6H_4] based on the one-pot reaction between ammonium molybdate and two equivalents of a primary amine, which takes place in the presence of chlorotrimethylsilane and triethylamine in a coordinating solvent L (usually in 1,2-dimethoxyethane).

L = DME, py.

Gibson and co-workers,²⁰³ without changing the synthetic strategy as a whole, proposed to use sodium molybdate instead of ammonium molybdate. A number of publications^{204–213} demonstrate broad synthetic potential of this approach. Starting from Na_2MoO_4 , oxo–imido complexes (**18**) [R = Ad,²⁰⁴ 2,4,6- $\text{Ph}_3\text{C}_6\text{H}_2$,²⁰⁵ C_6F_5 (Ref. 206)] (Scheme 5, path *a*) and bisimido complexes (**17**) [R = 2,6- $\text{Et}_2\text{C}_6\text{H}_3$,²⁰⁷ 4-Fc-2,6- $\text{Pr}_2\text{C}_6\text{H}_2$, 4-(Fc $\equiv$ C)-2,6- $\text{Pr}_2\text{C}_6\text{H}_2$,²⁰⁸ 2- $\text{Bu}^t\text{C}_6\text{H}_4$, 2-Me-6- $\text{Pr}^i\text{C}_6\text{H}_3$,²⁰⁹ 2-NCC C_6H_4 ,²¹⁰ 2,5- $\text{Cl}_2\text{C}_6\text{H}_3$, 2,6- $\text{Cl}_2\text{C}_6\text{H}_3$ and 2,4,6- $\text{Cl}_3\text{C}_6\text{H}_2$ (Ref. 206)] were prepared (Scheme 5, path *b*), respectively. The ease of imido-deoxygenation is noticeably affected by the steric factor and by the electronic effects of substituents in the starting anilines. Thus the reaction of Na_2MoO_4 with sterically hindered 2,4,6-triphenylaniline precludes incorporation of more than one imido group into the molybdenum coordination sphere.²⁰⁵ The reaction with weakly nucleophilic perfluoroaniline results in a bisimido and oxo–imido products mixture with a substantial predominance of the latter. In the series of polychloroanilines, the yield of the target bisimido complexes decreases with a decrease in the nucleophilicity of the initial aniline, and 2,4,6-tribromoaniline does not enter into the reaction.²⁰⁶ The introduction of two different amines into the reaction allows one to prepare asymmetric diimidomolybdenum dichlorides **19** [R = Bu^t ; R' = C_6F_5 ,¹⁴⁵ 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$,^{146, 204} R = Ad, R' = C_6F_5 ¹⁴⁵ (Scheme 5, path *c*). This procedure with Na_2MoO_4 was also used to prepare some molybdenum bisimido chelates **20** [R = *o*- C_6H_4 ; X = CH_2 , $(\text{CH}_2)_2$; R = CMe_2 , X = CH_2] (Scheme 5,

Scheme 5

 (d) $o\text{-H}_2\text{NC}_6\text{H}_4\text{XRNH}_2 - o\text{-Me}_3\text{SiCl} - \text{Et}_3\text{N}$; (e) $(4\text{-H}_2\text{N}-3,5\text{-Pr}_2\text{C}_6\text{H}_2)_2\text{CH}_2 - \text{Me}_3\text{SiCl} - \text{Et}_3\text{N}$;
 (f) TADDAMIN – $\text{Me}_3\text{SiCl} - \text{Et}_3\text{N}$; (g) $o\text{-H}_2\text{NC}_6\text{H}_4\text{XH} - \text{Me}_3\text{SiCl} - \text{Et}_3\text{N}$;
 R, R', X — see text.

path *d*)^{211,212} and **21** (Scheme 5, path *e*)²¹¹ and the first molybdenum complex based on chiral (4*S*,5*S*)-4,5-di(aminodiphenyl)-methyl-2,2-dimethyl-1,3-dioxolane (TADDAMIN) (complex **22**, Scheme 5, path *f*)²¹³. The reactions of sodium molybdate with anthranilic acid and aniline-2-sulfonic acid are more complicated under similar conditions to give monoanionic (**23a**) [R = C(O).OSiMe₃, X = C(O)O] and dianionic (**23b**) (R = SO₃[Et₃NH]⁺, X = SO₃) complexes (Scheme 5, path *g*); their structure was confirmed by X-ray diffraction.²¹⁰

Ammonium perrhenate can be used to prepare rhenium d⁰-complexes of various compositions. For example, the reaction of NH₄ReO₄ with 2,6-diisopropylaniline in the presence of chlorotrimethylsilane and triethylamine gives trisimido complex **24**.²¹⁴ The use of excess pyridine instead of triethylamine results in bisimido complex **15**.¹⁹⁵

Ar = 2,6-Prⁱ₂C₆H₃, Ar' = 2,6-Me₂C₆H₃.

d. Imidation with organic isocyanates

Metathesis imidation of transition metal complexes with alkyl and aryl isocyanates are widely used in synthetic practice. Isocyanates are mainly used for imidation of oxo complexes (for example, Group 5–7 transition metal oxohalides, Table 6); in some cases, imido complexes are used as the starting compounds. In the former case, metathesis imido-deoxygenation with carbon dioxide evolution takes place, while in the latter case, equilibrium transimidation occurs.

The reactions proceed *via* the formation of four-membered metallacycle intermediates, *viz.* *N,O*-carbamates and *N,N'*-ureates. *N,O*-Carbamates were not detected experimentally, while *N,N'*-ureates were in some cases isolated and characterised by spectral methods and X-ray diffraction.^{215–218} In both cases, to attain satisfactory yields of the products, long-term refluxing of the reactants in high-boiling solvents (xylene, toluene, octane,

etc.) is most often required; therefore, this method is inapplicable to thermally unstable complexes. Yet another drawback of the method is toxicity of organic isocyanates.

The imidation of polyoxo complexes by this method allows one to introduce varying numbers of imido groups in the complex. It was shown using polymolybdate **1a** as an example that by varying the amount of isocyanate used, one can incorporate one to five imido groups into the anion.^{233,234} The use of diisocyanates in the reaction with polymolybdate **1a** yields complexes **25** containing two polymolybdate moieties bridged by diimido ligands.²³⁵ Compounds of this type can also be prepared by imido-deoxygenation with amines, iminophosphoranes or by cross-coupling, the yields being comparable in all cases.

(a) R¹ = Buⁿ (56%), Cy (73%), Fc (19%);

(b) R² =  (80%),  (60%),  (60%);

(c) x = 1–5 (20%–86%).

By the use of three equivalents of 2,6-disubstituted aryl isocyanates in the reaction with silyloxytechnetium and -rhenium trioxides, all oxygen atoms were replaced by imido functions to give trisimido d⁰-complexes (RN=)₃M(OSiMe₃) [M = Tc: R = 2,6-Me₂C₆H₃ (61%), 2,6-Prⁱ₂C₆H₃ (60%);²³⁶ M = Re: R = 2,6-Me₂C₆H₃ (82%), 2,6-Prⁱ₂C₆H₃ (46%), 2,6-Cl₂C₆H₃ (79%)²³⁷].

Examples of successful use of isocyanates for the synthesis of imido derivatives of transition metal σ- and π-complexes are known. In particular, the reactions of binuclear cyclopentadienyl

R = H: R' = Ph (41%); R = Me: R' = Ph (26%), 4-MeC₆H₄ (10%); R = Prⁱ, R' = Ph (12%).

complexes $[(\eta^5\text{-RC}_5\text{H}_4)\text{MoO}(\mu\text{-O})_2]$ with aryl isocyanates were reported. This reaction is a rare example of imido-deoxygenation occurring with replacement of both terminal and bridging oxygen atoms in the initial compound.^{238–240}

The synthesis of tungsten bisimido complex **26** has also been reported.²¹⁷

Study of the reaction of methyltrioxorhenium MeReO_3 with aryl isocyanates has shown that by varying the reactant ratio, one can obtain products with different imido-deoxygenation degrees. Upon the addition of one, two or three equivalents of aryl isocyanate to MeReO_3 , mono-, bis- or tris-imido complexes, respectively, are formed,^{131,241} while the addition of 1.5 equiv. RNCO results in the binuclear complex **27** containing terminal and bridging imido ligands.

$\text{R} = 2,6\text{-Me}_2\text{C}_6\text{H}_3, 2,6\text{-Pr}_2\text{C}_6\text{H}_3; n = 1\text{--}3$.

It has been noted above that this method is mainly used to imidate thermally stable compounds. The imido-deoxygenation of, for example, the complex $\text{MoO}_2(\text{S}_2\text{CNET}_2)_2$ with aryl isocyanates is accompanied by thermally induced destruction of the diethyldithiocarbamate group. As a result, the target bisimido complexes $(\text{ArN}=\text{Mo}(\text{S}_2\text{CNET}_2)_2)$ (**28**) are formed in low yields comparable with the yields of side products, *i.e.*, imido disulfide (**29**) and various binuclear (**30**) complexes.^{242–246}

$\text{Ar} = 2,6\text{-Me}_2\text{C}_6\text{H}_3, 2,6\text{-Pr}_2\text{C}_6\text{H}_3, 2,6\text{-Cl}_2\text{C}_6\text{H}_3; \text{X}, \text{X}' = \text{NAr}, \text{O}, \text{S}$.

The destruction products become predominant if aryl isocyanates without *ortho*-substituents, for example, phenyl and *p*-tolyl isocyanates, are used.

Transition metal imido complexes can also undergo transimidation with isocyanates; however, this method is seldom used in practice, unlike transimidation with primary amines. This is due to the very low rate of the process and the need to use high-boiling solvents. Nevertheless, this approach is one of the few known methods for the synthesis of bis(arylimido)chromium d⁰-complexes **31**.²⁴⁷

$\text{Ar} = \text{Mes}$ (75%), $2,6\text{-Me}_2\text{C}_6\text{H}_3$ (80%).

During thermolysis of the binuclear complex $[(\eta^5\text{-C}_5\text{Me}_5)\text{Mo}(=\text{NPh})(\mu\text{-NPh})_2]$ with excess $4\text{-MeC}_6\text{H}_4\text{NCO}$, successive replacement of two phenylimido groups by *p*-tolylimido groups was observed; transimidation involved only the

terminal imido groups, while bridging ligands remained intact even after long-term heating (8 weeks) with an excess of the starting isocyanate.²⁴⁸

e. Imidation with *N*-sulfinylamines

The scope of using *N*-sulfinylamines for the synthesis of transition metal imido complexes has remained scarcely studied until recently. As regards the type of action, *N*-sulfinylamines are analogous to organic isocyanates, but they have advantages of being more readily available and more reactive toward imido-deoxygenation. It is essential that they are effective with both electron-donating and electron-withdrawing substituents. For example, sulfinyl derivatives of arylamines readily imidate the complex $\text{ReOCl}_3(\text{PPh}_3)_2$ (see Ref. 249).⁸

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$.

Molybdenum dioxodichloride easily undergoes imido-deoxygenation under the action of a number of halogen-substituted *N*-sulfinylanilines ArNSO to give corresponding bisimido complexes **17**.^{206,250} This approach was successfully used to prepare bisimido chelates **32**,^{250,251} the structure of which was confirmed by spectroscopic means.

$\text{Ar} = \text{C}_6\text{F}_5, 2,6\text{-Cl}_2\text{C}_6\text{H}_3, 2,4,6\text{-Cl}_3\text{C}_6\text{H}_2, 2,4,6\text{-Br}_3\text{C}_6\text{H}_2; \text{X} = \text{O}, \text{S}$.

Owing to the high reactivity, *N*-sulfinylamines can be efficiently used for imidation of some thermally labile complexes, for example, molybdenum dioxobis(dialkylthiocarbamates) (**33a,b**). On treatment of complexes **33** with one equivalent of *N*-sulfinylanilines, monosubstitution takes place to give products **34**,²⁵² while the action of two equivalents of *N*-sulfinylanilines or one equivalent of *N*-sulfinyl derivatives of some diamines allows the preparation of full substitution products (compounds **35** or **36**, respectively),^{251,253} whose structure was confirmed by spectroscopic means.

$\text{L} = \text{S}_2\text{CNET}_2$ (**33a**), S_2CNMe_2 (**33b**), *acac* (**33c**); $\text{Ar} = 4\text{-MeC}_6\text{H}_4$ (64%), $2,4,6\text{-Cl}_3\text{C}_6\text{H}_2$ (86%), $2,4,6\text{-Br}_3\text{C}_6\text{H}_2$ (73%).

N-Sulfinylamines are able to transimide transition metal imido complexes; however, this reaction is of low practical value due to the low rate. Only prolonged heating (≥ 40 h) of 2,6-

[§] For the imidation of $\text{ReOCl}_3(\text{PPh}_3)_2$, amines, isocyanates, iminophosphoranes and hydrazines can be used with equal success.

e. Imidation with iminophosphoranes

$$\{M\}=O + R'_3P=NR \longrightarrow \{M\}=NR + R'_3P=O.$$

An essential advantage of iminophosphoranes is that they allow imidation of metal oxides that possess pronounced oxidative properties without reduction of the metal. For example, iminophosphoranes $R'_2P=NR$ enter into metathesis with osmium tetroxide or osmium oxoimides to yield bis- and tris-imido complexes $(RN=)_2OsO_2$, $(RN=)_3OsO$ with retention of the d^0 configuration of the metal.²

$$R = \text{Bu}^t, \text{Ad}, \text{CMe}_2\text{Et}; R' = \text{Bu}^n, \text{Ph}.$$

Examples of formation of transition metal imido complexes upon the action of the Schiff bases on other imido or carbene complexes of this metal are documented. In the former case, reversible metathesis transimidation takes place, while in the latter case, irreversible alkylidene-imine methathesis occurs giving rise to imido complexes and alkenes.

A study of the reaction of stoichiometric amounts of the complex $\text{Bu}^i\text{N}=\text{TiCl}_2(\text{py})_3$ and the Schiff bases $\text{ArN}=\text{CHPh}$ (NMR detection and a preparative experiment) has shown that the equilibrium is completely shifted towards the formation of the arylimido complex **37**,²⁶⁴ the imido–imine methathesis being slower for sterically more hindered 2,6-dimethylphenylimine (the process is over only after 96 h) than for *p*-tolylimine (4 h).

Ar = 4-MeC₆H₄, 2,6-Me₂C₆H₃.

During the imido–imine exchange between molybdenum bisimido complexes **38** and various Schiff bases, the equilibrium (a 1 : 1 ratio of the initial complex **38** and product **39**) can be attained relatively fast (after ~20 h) only for the imido ligand with alkyl groups (example *a*), whereas for aryl substituents (example *b*) this ratio is attained only in 18 days.²⁹

(a) $R = Bu^t$, $R' = Pr$, $R'' = Ph$; (b) $R = 2,6-Pr_2C_6H_3$, $R' = Ph$, $R'' = Bu^t$.

Thus, imido–imine metathesis reactions are seldom useful for the synthesis of transition metal imido complexes, because they are too slow. The best outcome of transimidation is attained when primary amines are employed (see Section II.1.a). Nevertheless, the imido–imine exchange underlies catalytic metathesis of azomethines, for which some molybdenum^{27–30} and zirconium³¹ imido complexes have been proposed as catalysts.

Niobium and tantalum carbene complexes $\text{Bu}^t\text{CH}=\text{MCl}_3(\text{THF})_2$ ($\text{M} = \text{Nb, Ta}$) undergo alkylidene-

Table 7. Synthesis of Group 6–8 transition metal imido complexes by imido-deoxygenation with iminophosphoranes.

imine metathesis with some azomethines to give the corresponding imidochlorides and a *cis*- and *trans*-alkene mixture.^{266, 267}

M = Nb: R = Ph (40%); M = Ta: R = Ph, Me, Bu^t (80%–81%).

A study of the reactions of various molybdenum alkoxide imidocarbene complexes ($\text{ArN}=\text{C}(\text{Bu}^t\text{CH}=\text{CHPh})\text{Mo}(\text{OR})_2$ (**40**) with Schiff bases has demonstrated that the rate of alkylidene–imine metathesis depends substantially on the nature of the RO-ligands.²⁹

Ar = 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$; R = $\text{C}(\text{CF}_3)_2\text{Me}$, $\text{C}(\text{CF}_3)_2\text{Me}_2$.

For example, when complex **40** containing ligands $\text{Me}(\text{CF}_3)_2\text{CO}$ is treated with $\text{Pr}^n\text{N}=\text{CHPh}$, complete exchange is attained after 20 h, while the exchange depth in complex **40** with less fluorinated $\text{Me}_2(\text{CF}_3)\text{CO}$ ligands is only 10% over the same period of time. The complex with ligands Bu^tO does not enter into this reaction.

h. Imidation with hydrazine derivatives and azo compounds

Hydrazine derivatives and azo compounds are typical imidating oxidants (see Section II.2.b); however, there are some examples where a redox process involving these compounds does not result in a change in the formal oxidation state of the metal. This may be due to the presence of another reducing agent, and this role may be played, in particular, by hydrazine. For instance, treatment of the rhenium oxo complex $\text{ReOCl}_3(\text{PPh}_3)_2$ with a number of dialkylhydrazines in the presence of triphenylphosphine leads to imido-deoxygenation of the starting complex.²⁶⁸ This is obviously a redox reaction, nevertheless, rhenium retains its d²-configuration, because triphenylphosphine acts as a reducing agent.

R = Me, Et, Prⁿ, Cy.

Substituted benzohydrazides can also function as imidating agents. On treatment with phenylhydrazides, the oxo complex $\text{ReOCl}_3(\text{PPh}_3)_2$ is converted into the imido complex $\text{RN}=\text{ReCl}_3(\text{PPh}_3)_2$.²⁶⁹ The reaction of $\text{MoOCl}_2(\text{PMe}_2\text{Ph})_3$ with *N*-arylbenzohydrazides results in imido complex **41**,^{257, 269} the formation of the imido ligand being accompanied by autooxidation of benzohydrazide.

R = 4-XC₆H₄ (X = H, Cl, Me, MeO), 1-C₁₀H₇.

An example of insertion of benzo[*c*]cinnoline **42** into the Ti–C bond in the complex $\text{Et}_4\text{C}_4\text{Ti}(\text{OAr})_2$ to give complex **43**

containing 2,3-diazatitanacyclohepta-4,6-diene fragment is reported (the conclusion about the structure of complex **43** was based on spectroscopic characteristics). Treatment of complex **43** with the second equivalent of benzo[*c*]cinnoline induces an intramolecular bond redistribution in the complex, which is thus converted into imido complex **44**, the structure of which was confirmed by X-ray diffraction.²⁷⁰

Ar = 2,6- $\text{Ph}_2\text{C}_6\text{H}_3$.

i. Imidation with nitriles

Nitriles have also found application as imidating reagents, but processes involving these compounds differ from those for all reagents described previously. Whereas reactions with isocyanates, *N*-sulfonfylamines, imines, iminophosphoranes, *etc.*, occur as metathesis, nitriles are formally inserted into the metal–carbon bond as a result of an electrocyclic rearrangement.

Typical examples of synthesis of imido complexes by this method are presented in Table 8.

The insertion of acetonitrile into the metal–carbon multiple bond in uranium complex **45** has been described.²⁷⁵ This reaction yields imido complex **46**.

Examples of reactions involving two nitrile molecules are known. The high-spin vanadium d²-complex **47** reacts with two equivalents of pivalonitrile to give imido complex **48**,[¶] in which the imido ligand contains 1,3-di(*tert*-butyl)isoindol-1-yl as the organic group.²⁷⁶ It is believed that this compounds is formed upon two successive steps of nitrile insertion into the metal–carbon bonds with subsequent rearrangement of the intermediate into a more stable product.

¶ The structure of complex **48** was confirmed by X-ray diffraction data.

Table 8. Synthesis of transition metal imido complexes using nitriles.

Starting compound	R in RCN	Product	Yield (%)	Ref.
	Bu ^t , Cy		—	271
	Me		—	272
	Ph, Me		60–61	273
	Bu ^t		48	274

reaction of tetrahedral molybdenum bisimido complex (**49**) with tungsten imidocarbene (**50**) complex showed that the equilibrium is attained only after several days at 60 °C.²⁸⁰

In the reaction of alkylidene–imido metathesis between half-sandwich tantalum complexes **51** and **52**, the equilibrium can be reached over the same time under more drastic conditions (120 °C).

j. Imidation with transition metal imides

In some studies, the possibility has been demonstrated to prepare transition metal imido complexes by the equilibrium metathesis transfer of the imido ligand from one metal complex to another. This intercomplex exchange can occur for oxo, carbene and imido complexes of Group 5–8 metals (Scheme 6).

In the reactions shown in Scheme 6, the equilibrium is shifted toward the formation of thermodynamically more favourable products.

Upon the oxo–imido exchange, the imido group is bound preferably to the more electron-deficient metal. Examples of imido complexes prepared by intercomplex oxo–imido exchange are presented in Table 9.

The Schrock carbenes can undergo metathesis with the imido complexes; however, unlike the oxo–imido metathesis, this approach is of low utility for preparative purposes due to the low reaction rate and the difficulty of isolation of the desired product from the equilibrium mixture. Thus NMR monitoring of the

The possibility of equilibrium imido–imido exchange between Group 5 and 6 metal complexes was demonstrated; however, in this case, too, a low reaction rate was noted. Thus symmetric molybdenum bisimido complexes with *tert*-butyl- (**53**) and 2,6-diisopropylphenylimido (**49**) ligands slowly exchange the imido ligands only at elevated temperature ($K_{60\text{ }^\circ\text{C}} = 25$), apparently, for steric reasons.²⁸⁰

The rate of intercomplex imide exchange can be considerably affected by Brønsted acids. Thus the addition of $(\text{Et}_2\text{O})_2\text{HB}[\text{C}_6\text{H}_3(\text{CF}_3)_2-3,5]_4$ into a mixture of complexes **49** and **53** substantially accelerates the exchange reaction ($K_{25\text{ }^\circ\text{C}} = 95$, $k = 5.0 \times 10^{-6} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$).²⁸³

k. Imidation using miscellaneous nitrogen-containing compounds

Examples of the use of some other nitrogen-containing compounds as imidating reagents, in particular, formimidamides, isocyanides and iminoboranes have been documented.

Formimidamides imidate the oxo complex $\text{ReOCl}_3(\text{PPh}_3)_2$ to give the imido complexes $\text{RN}=\text{ReCl}_3(\text{PPh}_3)_2$.²⁸⁴ It is noteworthy that in this case, the yields of rhenium arylimido complexes are lower than those attained upon imidation with amines and hydrazines.

When Group 4–6 metal σ -alkyl complexes react with isocyanides, these are inserted into the metal–carbon bond to afford azavinyl intermediates, which undergo intramolecular rearrangement to yield imido products. (These reactions present no interest from the preparative standpoint, because they are not straightforward and their outcome is not always predictable.) The reaction may involve one to three isocyanide molecules. The homoleptic complex WMe_6 reacts with three equivalents of *tert*-butyl isocyanide to yield imido complex **54**, the structure of which was confirmed by X-ray diffraction. Presumably, this product is formed in a complicated sequence of insertion and rearrangement reactions (Scheme 7).^{285, 286}

An example of formal substitution of an arylimido group for the alkyl groups in guanidinate complexes **55** on treatment with one equivalent of aryl isocyanide has been reported.^{287, 288} The formation of imido complexes **56** is attributed to redistribution of bonds in the intermediate resulting from isocyanide insertion into the metal – carbon bond (Scheme 8).

On treatment of the complex $(\eta^5\text{-C}_5\text{Me}_5)\text{TaMe}_2\text{Cl}_2$ with 2,6-Me₂C₆H₃NC, isocyanide is also inserted into the metal–carbon bond, which is followed by migration of the other methyl group to the electrophilic acetimidoyl carbon atom to give aza(tantalum)-cyclopropane complex **57**, which was isolated and characterised by spectroscopic means.²⁸⁹ This complex easily reacts with a second isocyanide molecule to give thermally unstable azatantalacyclobutane intermediate **58**, which eliminates arylketeneimine to give imido complex **59**, which is formally the substitution product of an imido ligand for two methyl groups in the starting complex.

Trimethylsilyl azide is rarely used for imidation of transition metal chlorides. This is due to the fact that the trimethylsilylimido chlorides formed are as a rule labile and readily eliminate chlorotrimethylsilane to give nitrido complexes. Thus it was found that vanadium tetrachloride reacts with Me_3SiN_3 yielding the unstable complex $\text{Me}_3\text{SiN}=\text{VCl}_3$,²⁹⁹ which, as has been specially shown,²⁷⁷ readily eliminates Me_3SiCl to afford vanadium chloronitride.

By varying the ratio of molybdenum (or tungsten) dichloride and trimethylsilyl azide used in the reaction, one can obtain labile complexes **64** and **65**, respectively.³⁰⁰

M = Mo, L = PMe_3 ; M = W, L = PPh_2Me .

Organic azides are effective imidating agents for diverse metal complexes containing mono- and polydentate O-, S-, N- and P-ligands (Table 10). They are successfully used to prepare

imido derivatives of metallocenes and Group 4–9 transition metal carbene and σ -alkyl complexes (Table 11).

b. Imidation with azo compounds, hydrazines and their derivatives

Azo compounds are typical reagents imidation with which is accompanied by an increase in the formal oxidation state of the metal. They can be used in reactions with various mononuclear π -complexes and binuclear metal complexes. The mechanism of formation of imido derivatives from mononuclear complexes is not entirely clear; however, the process is considered to proceed *via* an η^2 -diazene or diazametallacyclopropane intermediate, in which activation of the $\text{N}=\text{N}$ bond and a decrease in its order take place and which is further converted into the mono- (path *a*) or bis-imido (path *b*) complex (Scheme 10).^{321, 325–327}

Scheme 10

However, examples are known where imidation follows a different mechanism. In a systematic study of the reaction of Cp_2TaMeL with azobenzene, the formation of diazametallacyclopropane product **66**, which is not converted into imido complex **67**, was confirmed by X-ray diffraction. Having studied

the process kinetics, the researchers suggested that adduct **68** is the true intermediate on the route to imido product **67**.³²⁸

It was found that mononuclear bisimido complexes are formed along path *b* only starting from d⁴-complexes, while monoimido products (path *a*) are obtained by treating d²-complexes with azo compounds. Thus on treatment with azobenzene, the d²-complex (η²-Bu^tN=CBn₂)Ti(OC₆H₃Prⁱ-2,6)₂L is converted into η²-azo complex **69**. The latter is thermally unstable and is transformed on heating into imido d⁰-complex **70**.³²⁵

Ar = 2,6-Prⁱ₂C₆H₃, L is 4-pyrrolidinopyridine.

The d²-complex (TTP)Ti(η²-EtC≡CEt) and azobenzene taken in 2 : 1 ratio react in a similar way. The first step is replacement of the diethyacetylene molecule by the azo ligand to give the complex (TTP)Ti(η²-PhN=NPh), which was isolated and characterised. In the second step, the azo complex reacts with another

(TTP)Ti(η²-EtC≡CEt) molecule, being converted into mono-imido d⁰-complex (TTP)Ti=NR.^{158, 326}

The oxidative addition of symmetric and non-symmetric (including cyclic) azo compounds to tungsten d⁴-complex **71** has been studied.^{329, 330} The structure of bisimido d⁰-complex formed (Scheme 11) was confirmed by X-ray diffraction.

The reaction of dimeric d³,d³-complex [CpCrCl₂]₂ with four equivalents of Me₃SiN=NSiMe₃ results in binuclear d¹,d¹-complex **72**, which contains, according to X-ray diffraction data, both terminal and bridging ligands.³³¹

Scheme 11

Ar = 2,3,5,6-Ph₄C₆H; L = PMe₃, PMePh₂; R, R' = Ph, 4-MeC₆H₄, Mes.

A two-stage method for the synthesis of symmetric and asymmetric bisimido uranium complexes **73** is based on the reaction of azo compounds with the complex $[(\eta^5\text{-C}_5\text{Me}_5)_2\text{UCl}_2 \cdot (\text{NaCl})]$, which is formed *in situ* upon the reduction of decamethyluranocene dichloride with sodium amalgam.³²¹

$\text{R} = \text{R}' = \text{Ph}$ (92%); $\text{R} = \text{Ph}$, $\text{R}' = \text{SiMe}_3$ (70%).

Complexes **73** can also be prepared by imidation of the complex $(\eta^5\text{-C}_5\text{Me}_5)_2\text{UCl}_2$ with azides or diphenylhydrazine.

Imidation of binuclear complexes containing multiply bonded metal atoms follows a different route as compared with the imidation of mononuclear complexes. The reaction of azobenzene with binuclear complexes $\text{M}_2\text{Cl}_6(\text{SMe}_2)_3$ proceeds as the metathesis of multiple bonds, $\text{M}=\text{M}$ and $\text{N}=\text{N}$, to give imido dimers **74**.^{332, 333}

$\text{M} = \text{Nb}$ (55%), Ta (58%).

The reaction of azobenzene with the binuclear complexes $\text{W}_2(\mu\text{-H})(\text{OPr}^i)_7$ and $\text{W}_2(\text{OPr}^i)_6(\text{py})_2$,³³⁴ which also contain metal-metal multiple bonds, follows a more complex pattern, as indicated by the formation of a mixture of products, including clusters.

Imidation with hydrazine derivatives is usually a redox process. In those cases where other reducing agents are present or hydrazines undergo autooxidation, the initial electronic configuration of the metal can be retained (see Section II.1.h); however, more often, is oxidation state increases. The oxidative imidation of transition metal complexes with hydrazine derivatives can be exemplified by a one-stage synthesis of diimido complex **75**.³¹⁹

The imidation of the binuclear complex $\text{W}_2(\text{OCH}_2\text{Bu}^t)_6$ on treatment with 1,2-diphenylhydrazine is accompanied by oxidative cleavage of the metal-metal triple bond to give imido complex **76**.³³⁴

Conversely, the reaction of ammonium pertechnetate with phenylhydrazide in the presence of phosphines and small amount of a hydrohalic acid is accompanied by the reduction of technetium giving rise to d^2 -complexes **77**.^{335, 336}

$\text{X} = \text{Cl}, \text{Br}$; $\text{L} = \text{PPh}_3$ (68%–75%), PMePh_2 (30%).

c. Imidation with organyl isocyanates

The imidation with isocyanates is usually a metathesis-type reaction occurring without a change in the formal oxidation state of the metal in the complex (see Section II.1.d). However, there are some examples where complexes of metals in low oxidation states are inserted into the $\text{N}=\text{C}$ bond of isocyanates to give azametallacyclopropane derivatives **78** (oxidative insertion, Scheme 12), which can subsequently be converted into imido complexes with elimination of carbon monoxide (path *a*) or form imido carbonyl complexes (path *b*).

The d^2 -complex $[(\eta^5\text{-Me}_3\text{SiC}_5\text{H}_4)_2\text{NbCl}]_2$ coordinates phenyl isocyanate PhNCO to give stable compound **79** (characterised by X-ray diffraction). Thermolysis of complex **79** occurs with elimination of carbon monoxide to give imido complex **80**.^{337–339}

Scheme 12

With diisocyanates [1,3- or 1,4-(OCN)₂C₆H₄], binuclear imido complexes **81** are formed.

Molybdenum and tungsten d⁴-complexes MCl₂L₄ also react with various isocyanates RNCO; however, in this case, the insertion of the complex into the C=N bond is not accompanied by carbon monoxide evolution, but rather results in the formation of d²-imido carbonyl complexes **82**.^{340–342} A series of binuclear tungsten complexes **83** have been obtained in this way using various diisocyanates OCN–Ar–NCO.^{343, 344}

M = Mo, W; R = Bu^t, SiMe₃, Ph, 4-MeC₆H₄; Ar = 1,4-C₆H₄, 1,4-(2-MeC₆H₃), 1,4-(2,3-Me₂C₆H₂), 1,4-(2,5-Me₂C₆H₂), 1,4-C₆Me₄, 1,3-(4-MeC₆H₃), 1,3-C₆H₄, 1,5-C₁₀H₆, (4-C₆H₄)CH₂(C₆H₄-4), 1,1'-(2,6-Me₂C₆H₂-4)₂, 1,1'-(2-MeOC₆H₃-4)₂.

A few examples are known where imidation with isocyanates results in reduction of metal compounds having pronounced oxidative properties. For example, osmium tetroxide is reduced by three equivalents of 2,6-Pr₂C₆H₃NCO to give the imido d²-complex (2,6-Pr₂C₆H₃N=)₃Os in 50% yield.³⁴⁵ It should be noted that a similar reaction pattern is observed when OsO₄ is treated with trimethylsilylanilines (see Section II.2.e), whereas trimethylsilyl derivatives of aliphatic amines and iminophosphoranes imidate osmium tetroxide with retention of the oxidation state.

The imido-deoxygenation of molybdenum oxotetrachloride with excess 2,6-Pr₂C₆H₃NCO in *p*-xylene is also accompanied by the reduction of molybdenum and results in imido d¹-complex **84**.³⁴⁶

d. Imidation with nitriles

Group 4 and 5 transition metal halides in intermediate oxidation states can undergo redox reactions with nitriles to give binuclear imido complexes, the diimido fragment of which is formed by coupling of coordinated nitrile molecules. The mechanism of this multistep process has not been studied in detail so far.

The reaction of the complex (TMEDA)₂TiCl₂ with acetonitrile is a typical example of this type of reactions. It was suggested that the formation of binuclear complex **85** is due to dimerisation of mononuclear carbene intermediates **86**;³⁴⁷ however, the possibility of stepwise (two-step) coupling to give, first, a single and then a double carbon–carbon bond cannot be ruled out either.

In the reduction of niobium or tantalum tetrachlorides with zinc in acetonitrile, a similar coupling of two nitrile molecules takes place to give binuclear diimido complexes **87**.³⁴⁸

Under the action of an equimolar amount of tributyltin hydride in 1,2-dimethoxyethane, niobium tetrachloride induces hydrodimerisation of benzonitrile. Presumably, this reaction involves successively the formation of the hydride Cl₃NbH, insertion of benzonitrile into the Nb–H bond and recombination of the Cl₃Nb=N–C[•](Ph)H radicals thus formed.³⁴⁹

The reaction of trisamido complex Mo(NBu^tAr)₃ with benzonitrile gives diiminato complex **88**, the nitrile coupling product. Thermolysis of complex **88** is accompanied by homolytic cleavage of the Bu^t–N bond of the amido ligand followed by bond redistribution in the molecule, resulting in binuclear imidoamide

complex **89**.³⁵⁰ The formation of *tert*-butyl radicals is confirmed by the presence of their recombination and disproportionation products.

e. Imidation with amines, lithium amides and *N*-trimethylsilylamines

The imidation with amines and their lithium and trimethylsilyl derivatives usually proceeds with no change in the formal oxidation state of the metal (see Sections II.1.a–c). However, some reactions are accompanied by an increase in the metal oxidation state. This may be due to the action of some extraneous oxidant, disproportionation processes or other reasons. Examples of oxidative imidation of transition metal complexes involving amines or lithium amides are given in Table 12.

A unique compound **90**, which is the key derivative in the chemistry of manganese imido d⁰-complexes, was prepared by the reaction of manganese(III) chloride with Bu^tNHSiMe₃ in acetonitrile.

Presumably, complex **90** is formed in a multistep disproportionation of intermediate manganese compounds.^{358, 359}

Table 12. Synthesis of transition metal imido complexes by oxidative imidation with amines and their lithium derivatives.

	1,2-(2-NH ₂ C ₆ H ₄) ₂ C ₂ H ₄		46	353
	2-NH ₂ C ₆ H ₄ PPh ₂		30	353
Na(THF)₃⁺	Bu ^t ₃ SiNHLi		50–60	354

Table 12 (continued).

Starting compound	Imidating reagent	Product	Yield (%)	Ref.
 (X = Me, Cl)	ArNH ₂ (Ar = Ph, 4-ClC ₆ H ₄)		70–75	355
ReCl ₄ (OPPh ₃) ₂	2-MeNHC ₆ H ₄ NH ₂	2-MeNHC ₆ H ₄ N=ReCl ₄ (OPPh ₃)	22	356
	2,6-Pr ⁱ ₂ C ₆ H ₃ NHLi–O ₂		16	357

For metal compounds with pronounced oxidative properties, the imidation reactions can be accompanied by reduction of the metal. For example, on treatment with excess *N*-trimethylsilylalkylanilines, osmium tetroxide undergoes reductive imidation to give tris(imido) d²-complex **91** as the only osmium-containing reaction product.¹⁹⁸

$$\text{Ar} = 2,6\text{-Me}_2\text{C}_6\text{H}_3 \text{ (46\%)}, 2,6\text{-Pr}_2\text{C}_6\text{H}_3 \text{ (62\%)}. \quad \text{---}$$

It is of note that imidation of osmium tetroxide with aliphatic silylamines is not accompanied by its reduction (see Section II.1.c).

Ammonium pertechnetate is also reduced by a mixture of 2,6-diisopropylaniline and chlorotrimethylsilane in the presence of pyridine to give monoimido d²-complex **92** (see Ref. 85, p. 268).

$$\text{Ar} = 2,6\text{-Pr}_2\text{C}_6\text{H}_3.$$

It should be noted that no reduction of rhenium takes place in the imidation of ammonium perrhenate under similar conditions (see Section II.1.c).

f. Imidation with miscellaneous nitrogen-containing compounds

The use of other nitrogen-containing organic compounds as sources of imido groups is a specific case. A few examples of oxidative imidation of complexes of metals in low oxidation states with carbodiimides, aldimines, ketimines, sulfodiimines, aziridines, 2*H*-azirines and nitroso compounds have been reported.

Thus reactions of N,N' -di(*tert*-butyl)carbodiimide^{341, 342, 360} and ketimine 4-MeC₆H₄N=CR₂ (see Ref. 361) with molybdenum and tungsten dichlorides MCl₂L₄ occur as oxidative addition to give imidoisocyanide (**93a.b**) and imidocarbene (**94**) complexes.

M = Mo (**a**), W (**b**); L = PPh₂Me; R₂ = Me₂, (CH₂)₄ (45%).

The reaction of tungsten dichloride with *N*-substituted aziridines is accompanied by ring opening and results in imidoethylene complexes **95**.³⁶²

R = Me, Ph.

2*H*-Azirines can also be cleaved by treatment with some binuclear complexes of Group 6 metals to give various imido complexes.³⁶³

Ar = Ph, 4-Bu^tC₆H₄.

The reaction of niobium tetrachloride with an equimolar amount of *N*-benzylidene-*N*-trimethylsilylamine results in the formation of binuclear d⁰,d⁰-complex **96** with a diimido bridging ligand.³⁴⁹

The formation of complex **96** is believed to be due to dimerisation of mononuclear radical intermediates.

The formation of imido complexes in the reactions with nitrosoarenes and sulfodiimines follows a complex route and is formally an oxidative addition of the metal to the nitrogen–heteroatom bond. For example, d⁴-complex **71** is oxidised with nitrosobenzene to give oxoimido d⁰-complex **97** and azoxybenzene.³³⁰

Ar = 2,3,5,6-Ph₄C₆H.

The reaction of two equivalents of nitrosobenzene with the d³,d³-complex W₂(OBu^t)₆, containing multiply bonded metal atoms, affords dimeric d⁰,d⁰-complex **98** with bridging *tert*-butoxide ligands and an oxygen atom.³⁶⁴ Thus, the outcome of the process is asymmetric oxidative addition of nitrosobenzene to metal sites accompanied by cleavage of the metal–metal bond.

Long-term refluxing of the binuclear complex [(η⁵-Cp)Mo(CO)₃]₂ with sulfodi(*tert*-butyl)imine in benzene induces oxidative imido-decarbonylation to give disulfido complex **99** in low yield.³⁶⁵

III. Intramolecular imidation methods

The other strategy of the synthesis of transition metal imido complexes is based on intramolecular formation of the imido group in the metal complex from nitrogen-containing ligands of a different type. Intramolecular imidation procedures are not so numerous as intermolecular imidation methods and are less often used in synthetic practice. The N-ligand precursors used to construct the imido group are nitrido, amido and some other ligands.

1. Transition metal nitrides

Complexes of transition metals of Group 6–8 with terminal nitrido ligands are convenient substrates for the synthesis of neutral and cationic imido complexes. The imido complexes are formed upon an electrophilic attack by alkylating reagents on the nitrogen atom of the nitride group of anionic or neutral transition metal complexes (Scheme 13). Trialkyloxonium tetrafluoroborate, methyl iodide, alkyl and trimethylsilyl triflates, tritylhexafluorophosphate, and so on are used as alkylating reagents.

Scheme 13

A kinetic study of the reaction of the nitrido complex (NBu₄⁺)[N≡Os(CH₂SiMe₃)₄] with methyl iodide has shown that the reaction is first order with respect to each reactant, which is indicative of the S_N2 mechanism.³⁶⁶ It is worth noting that only electron-enriched nitrido complexes, for example, osmium and ruthenium nitride s- and p-complexes and molybdenum, tungsten, rhenium and osmium complexes with S-, O- and N-ligands possess nucleophilicity sufficient for this electrophilic attack. Table 13 presents examples of the use of Group 6–8 transition metal nitrido complexes for the synthesis of the corresponding imido complexes.

Table 13. Synthesis of Group 6–8 transition metal imido complexes by alkylation of nitrides.

2. Transition metal amides

Intramolecular imidation methods based on the transformation of amido ligands have been reported. In this case, imido ligands are formed upon either 1,2-elimination of fragments of the initial amide groups or intramolecular interligand transfer of a hydrogen atom or trialkylsilyl groups.

a. Synthesis of imido complexes with elimination of an amido group fragment

An imido ligand may be formed from an amide ligand upon elimination of molecules such as trialkylsilyl halides, primary and secondary amines, alkanes, hydrogen halides, *etc.* Depending on the structure of the starting amido complex and the nature of the leaving molecule, these reactions may be induced thermally or chemically. In some cases, a combination of these variants is used.

Trimethylsilylamidometal chloride easily eliminate chlorotrimethylsilane in the presence of various n-donor compounds L. The formation of a stronger Si—Cl bond and steric crowding in the metal coordination environment arising upon the formation of adducts with n-donors are apparently the driving forces of the process.

On treatment of the complex $\text{TiCl}_3[\text{N}(\text{SiMe}_3)_2]$ with pyridine, a Me_3SiCl molecule is eliminated to give the imido complex

$\text{Me}_3\text{SiN}=\text{TiCl}_2(\text{py})_2$.³⁸¹ The same is observed for the tantalum diamido complex $\text{TaCl}_3[\text{N}(\text{SiMe}_3)_2]$ on treatment with tetrahydrofuran.³⁸²

Elimination of chlorotrimethylsilane can take place spontaneously in the synthesis of bis(trimethylsilyl)amido complexes or in parallel with other transformations. For instance, on treatment of $\text{TaCl}_3[\text{N}(\text{SiMe}_3)_2]$ with trimethylsilyl halides, elimination of trimethylsilyl chloride, resulting in dimeric imido complexes **100**, takes place in parallel with ligand exchange.^{163, 382}

X = Br (25%), I (75%).

Upon the reaction of equimolar amounts of the complex $(\eta^5\text{-C}_5\text{Me}_5)\text{TaCl}_4$ and dilithium derivative of 2,2'-bis(trimethylsilylamino)biphenyl, amido–imido complex **101** was isolated; the complex is obviously formed upon spontaneous elimination of chlorotrimethylsilane from the reaction intermediate.³⁸³

The reaction of the complexes $(\eta^5\text{-C}_5\text{Me}_5)\text{MCl}_4$ ($\text{M} = \text{Ta}, \text{Nb}$) with one³⁸⁴ or two¹⁶⁷ equivalents of lithium hexamethyldisylazide proceeds in a similar way

It is noteworthy that spontaneous elimination of chlorotrimethylsilane is apparently the key step in the formation of the imido complexes in the reaction of transition metal polyhalides with bis(trimethylsilyl)amines (see Section II.1.c).

Polyamido (more rarely, alkylamido) complexes eliminate amines (alkanes) on treatment with n -donor compounds or on heating, resulting in the formation of imido products.

$\text{X} = \text{NHR}, \text{Alk}.$

Examples of the use of this synthetic approach are listed in Table 14.

In some cases, thermolysis of polyamido complexes leading to imido products occurs in a more complicated way. Thus thermolysis of homoleptic sterically hindered complex $\text{Nb}(\text{NMeBu}^n)_5$ involves elimination of butylmethylamine and but-1-ene, which affords mixed amido-imido complex **102** in low yield.³⁹¹ Thermolysis of the complexes $\text{Ta}(\text{NR}_2)_5$ proceeds in a similar way.^{392, 393}

$\text{M} = \text{Nb}$: $\text{R} = \text{Bu}^n$, $\text{R}' = \text{Me}$;

$\text{Me} = \text{Ta}$: $\text{R} = \text{R}' = \text{Et}$ (35%–47%), Pr^n , Bu^n ; $\text{R} = \text{Bu}^n$, $\text{R}' = \text{Me}$.

Table 14. Synthesis of transition metal imido complexes from amides by elimination of amines and alkanes.

Neutral and cationic monoalkyl- and monoarylamido complexes can be deprotonated under the action of nitrogenous bases to give the corresponding imido products. The cationic complex **103** is deprotonated with diazabicyclo[5.4.0]undecene (DBU) to give neutral imido complex **104**.¹³²

The amidocarbene complex $\text{Bu}^t\text{C}\equiv\text{Re}(\text{NHC}_6\text{H}_3\text{Pr}_2^i-2,6)\cdot\text{Cl}_3(\text{py})$ is also deprotonated with DBU in the presence of pyridine to give imidocarbene complex **105**.³⁹⁴

$\text{Ar} = 2,6\text{-Pr}_2\text{C}_6\text{H}_3$.

Half-sandwich titanium imido complex **106** was prepared by deprotonation of *tert*-butylamido complex **107** with lithium hexamethyldisilazide.³⁹⁵

The only, to our knowledge, nickel complex **108** with a terminal imido group was synthesised in a similar way.³⁹⁶

$\text{Ar} = 2,6\text{-Pr}_2\text{C}_6\text{H}_3$.

Examples of transformations of monoamido complexes into imido complexes upon abstraction of a hydride ion are known. Thus amido carbonyl complexes **109** are converted into cationic imido products **110a–d** under the action of trityl cation.^{372, 397}

$\text{R} = \text{Bu}^n$ (a), Bu^t (b), Ph (c), CH_2Ph (d).

The complexes $\text{Tp}'\text{W}(\text{CO})_2(\text{NHR})$ (**109b,c**) and the related complex $\text{Tp}'\text{W}(\text{CO})(\text{PhC}\equiv\text{CMe})(\text{NHPh})$ (**111**) are oxidised to the corresponding imido derivatives **112** and **113** under the action of molecular iodine.³⁹⁸

$\text{R} = \text{Bu}^t$ (b), Ph (c).

$\text{Ar} = \text{C}_6\text{H}_3(\text{CF}_3)_{2-3,5}$.

b. Synthesis of imido complexes through intramolecular migration of an amido group fragment

In some cases, imido complexes of Group 5–7 transition metals are formed upon intramolecular rearrangement of amido, mainly oxotrimethylsilylamido, complexes. In the synthesis of these complexes, spontaneous 1,3-migration of the trimethylsilyl group from the nitrogen atom of the amido ligand to the oxo group often takes place.

Thus, the reaction of VOCl_3 with three equivalents of $\text{NaN}(\text{SiMe}_3)_2$ results in the imido complex $\text{Me}_3\text{SiN}=\text{V}(\text{OSiMe}_3)_3$. $[\text{N}(\text{SiMe}_3)_2]_2$.³⁹⁹ Presumably, the reaction involves intermediate formation of the unstable oxotriamido complex $\text{O}=\text{V}[\text{N}(\text{SiMe}_3)_2]_3$, which is spontaneously rearranged to the final product.

The reaction of the oxo complex $\text{O}=\text{V}(\text{OSiMe}_3)_2\text{Cl}$ with two equivalents of *tert*-butyl(trimethylsilyl)amine yielded the complex $\text{Bu}^t\text{N}=\text{V}(\text{OSiMe}_3)_3$. This product may have formed upon 1,3-migration of the trimethylsilyl group in the intermediate oxo-amido complex **114**.¹⁵⁰

The reaction of chromyl chloride with hexamethyldisilazane has been shown to furnish dioxoamido d⁰-complex **115a**. Treatment of the latter with excess pyridine results in its reduction accompanied by 1,3-migration of the trimethylsilyl group to give dimeric imido d¹-complex **116**, the structure of which was con-

$\text{M} = \text{Cr}$ (a), Mo (b).

firmed by X-ray diffraction.¹⁹⁰ The reaction of molybdenum dioxodichloride with hexamethyldisilazane yields diimido complex **117**. By analogy with the previous case, this outcome was attributed to the intramolecular rearrangement of dioxodiamido complex **115b**.

The formation of the rhenium imido complex $(\text{Me}_3\text{SiN}=\text{O})_2\text{Re}(\text{OSiMe}_3)_2[\text{N}(\text{SiMe}_3)_2]$ in the reaction of ReO_3X ($\text{X} = \text{Cl}, \text{OSiMe}_3$) with three equivalents of $\text{LiN}(\text{SiMe}_3)_2$ apparently also includes 1,3-migration of the SiMe_3 group.⁴⁰⁰

Yet another type of intramolecular rearrangement resulting in imido complexes is observed for monoarylamidocarbene complexes. In particular, it was shown that triethylamine induces interligand migration of the proton in amidocarbene complexes of molybdenum (**118a**)¹⁹¹ and tungsten (**118b**),^{193,401} resulting in imidocarbene complexes **119a,b**.

$\text{M} = \text{Mo}$ (**a**), W (**b**); $\text{Ar} = 2,6\text{-Pr}_2\text{C}_6\text{H}_3$.

Rhenium amidocarbene complexes behave in a similar way. On treatment of dimer **120** with six equivalents of potassium polyhalogenophenoxides, proton migration from the amido group to the carbene group to give imidocarbene complexes **121** takes place in addition to the replacement of chlorine atoms.⁴⁰²

$\text{Ar} = 2,6\text{-Pr}_2\text{C}_6\text{H}_3$; $\text{Ar}' = 2,6\text{-Cl}_2\text{C}_6\text{H}_3$ (67%), C_6F_5 (78%), C_6Cl_5 (48%).

3. Transition metal complexes with other types of nitrogen-containing ligands

Metal complexes with other types of nitrogen-containing ligands can also be used to synthesise imido complexes. In particular, examples of transformation of metal-coordinated primary amines, nitriles, nitrosoarene, nitrosyl and some other ligands into imido ligands have been reported.

Thus osmium porphyrin complexes containing coordinated *tert*-butylamine are oxidised under aerobic conditions to give imido derivatives **122**.⁴⁰³

$\text{Por} = \text{TTP}$ (68%), TPP (70%), 4-Cl-TPP (75%),
3,4,5-(MeO)₃- TPP (72%) ($\text{Ar} = 3,4,5\text{-(MeO)}_3\text{C}_6\text{H}_2$,
see notation in Table 10).

Rhenium nitrosoarene complex **123** is converted into imido complexes under the action of oxophilic tertiary phosphines or isocyanides.⁴⁰⁴

$\text{L} = \text{Ph}_3\text{P}, \text{PhEt}_2\text{P}$.

Examples of spontaneous rearrangements of dialkyl(aryl)-nitroso complexes of Group 6 metals involving nitrogen–oxygen bond cleavage and resulting in imido complexes have been

described. The reaction of nitrosyl complex **124** with diarylmagnesium leads to imido complex **125**⁴⁰⁵ with one σ -aryl ligand, which was characterised by X-ray diffraction. This product is believed to result from the rearrangement of unstable intermediate bis(σ -aryl) complex **126**.

$\text{Ar} = 2\text{-MeC}_6\text{H}_4$.

A similar transformation occurs on storage of dimethylnitrosyl complex **127** in solution. According to X-ray diffraction data, the rearrangement of complex **127** gives dimer **128** comprising fragments of the intramolecular rearrangement product and the starting complex moieties.⁴⁰⁶

Replacement of the counter-ion in the cationic complex *trans*- $[\text{CrCl}(\text{MeCN})(\text{dmpe})_2]^+(\text{BPh}_4)^-$ (dmpe is $\text{Me}_2\text{PCH}_2\text{CH}_2\text{PMe}_2$) on treatment with barium triflate in methanol involves a redox process resulting in the ethylimido d²-complex *trans*- $[\text{EtN}=\text{CrCl}(\text{dmpe})_2]^+(\text{OTf})^-$ in parallel with the protonation of the coordinated acetonitrile molecule.⁴⁰⁷ The formation of the ethylimido d²-complex was confirmed by both spectroscopy and X-ray diffraction.

Examples of modification of an imido ligand directly within the complex are documented. It was demonstrated that imido complex **129** can be used in the palladium-catalysed Sonogashira cross-coupling, which opens the way to various metal complexes containing conjugated systems of multiple bonds^{408–410} (Scheme 14).

Recently, the possibility of elongation of the carbon chain in the alkylimido group by one methylene unit as a result of consecutive deprotonation and alkylation of the cationic methyl-imido complex **130** was demonstrated. It was shown that the complex can be deprotonated to the ketimido derivative **131**, which, in turn, is readily alkylated with methyl iodide to give compound **132**, a homologue of the starting complex.³⁶⁹

$\text{Ar} = 3,5\text{-Me}_2\text{C}_6\text{H}_3$.

Scheme 14

(a) $\text{HC}\equiv\text{CAr}-\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$ ($\text{Ar} = 3,5\text{-Bu}_2\text{C}_6\text{H}_3$, $4\text{-MeC}_6\text{H}_4$), CuCl , Et_3N ; (b) $(\text{Bu}_4\text{N})_2[\{\text{Mo}_6\text{O}_{18}\}=\text{N}(4\text{-HC}\equiv\text{C}-2,6\text{-Me}_2\text{C}_6\text{H}_2)]-\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$, CuI , Et_3N , K_2CO_3 ; (c) $\text{HC}\equiv\text{CFc}-\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$, CuI , Et_3N ; (d) $3,6\text{-(HC}\equiv\text{C)}_2\text{-1,4-(Bu}^t\text{CH}_2\text{O)}_2\text{C}_6\text{H}_2-\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$, CuI , Et_3N , K_2CO_3 .

We would like to add that the possibility of converting metal ketimides into imido complexes was first demonstrated for complex **133**. In particular, this was found to be readily methylated with methyl fluorosulfate to give cationic complex **134**.⁴¹¹

For the synthesis of tungsten imido carbonyls **135**, zwitterionic complex **136** can be used. The latter is smoothly oxidised with iodine, bromine or phosphorus pentachloride with N–N bond cleavage to give binuclear complexes **135** with bridging halogen atoms.^{412–415}

$\text{X} = \text{I}$ (76%), Br (13%), Cl (63%).

IV. Conclusion

The chemistry of transition metal imido complexes has long aroused particular interest owing to the remarkable ability of imido ligands to stabilise transition metals in higher oxidation states. The introduction of imido ligands into the coordination environment allowed, for example, preparation and characterisation of organic derivatives of chromium(VI) and manga-

nese(VII), *i.e.*, the elements the oxides of which are classical oxidants used in organic chemistry.

Over the last 15 years, the focus has moved toward the application of transition metal imides, which has, in turn, stimulated the development of new methods for the synthesis of metal imido complexes of diverse structural types. Currently, the reactions of a broad range of nitrogen-containing reagents with transition metal compounds have been studied in sufficient detail, the features of these reactions were revealed and their synthetic potential was demonstrated.

A wide diversity of imido complexes was attained, first of all, owing to the use of intermolecular imidation methods. Currently, it can hardly be expected that the range of imidating reagents would be extended; further development of intermolecular imidation methods is possible, most of all, through the use of new transition metal-containing substrates and new types of imido ligands, in particular, heteroarylimido ligands. The progress in this field may also be connected with modern quantum-mechanical calculations of potential energy surface fragments. Such calculations are now virtually missing, and detailed structures of the transition states often remain obscure.

The methodology of intramolecular imidation has been developed less extensively than the intermolecular imidation strategy; therefore, there are grounds for expecting fruitful development of this line of research. In our opinion, the most interesting prospects are related to selective inner-sphere modification of the imido ligands, for example, functionalisation, elongation of the organic group, design of polymeric or dendrimeric molecules. Examples of such modifications are still few, but further development of this field would favour the synthesis of new promising compounds and material based on them.

IV. Naphthylmetals in cross-coupling reactions	732
V. Conclusion	733

Abstract. The review summarises procedures for the synthesis of organolithium and organomagnesium compounds of the naphthalene series, including binaphthyls, the properties of these compounds and their use in organic synthesis. The bibliography includes 283 references.

I. Introduction

Organometallic, primarily, lithium and magnesium, derivatives of naphthalene play an exceptionally important role in organic synthesis. In recent years, these compounds have been widely used in the synthesis of chiral binaphthyl catalysts and complex natural compounds. Of special note are various 1,8-disubstituted naphthalenes necessary for studying the *peri* effects. However, reviews of a vast literature on the synthesis of organometallic derivatives of naphthalene are lacking. Scarce data are available in monographs.^{1–6} The main aim of the present review is to close this gap as regards Li and Mg derivatives of naphthalene. The review summarises data published predominantly in the last two decades. An earlier literature is cited if the corresponding data remain to be important and are of principal significance.

II. General features

1. Synthesis

There are four main methods for the synthesis of organolithium and -magnesium compounds of the naphthalene series: (i) the reactions of the corresponding metal with naphthyl halides, (ii) the reactions of commercial organolithium or -magnesium compounds with naphthyl halides, (iii) direct deprotonation of aromatic C–H bonds and the formation of C–M bonds (CH-metallation) and (iv) transmetallation. Examples of the reactions are presented in Scheme 1.

The first of the above-mentioned procedures is most often used for the synthesis of organomagnesium compounds (Grignard reagents), for example, **1** → **2**.⁷ It was proposed to use chemical activation of magnesium with the aim of increasing the product

Scheme 1

yield.[†] Of various methods for magnesium activation, the method of auxiliary reagents is the most widely used procedure. This method is based on an increase in the reactivity of inert aryl halides by adding more active alkyl halide, which rapidly reacts with magnesium and activates its surface. 1,2-Dibromoethane has gained wide acceptance as an auxiliary reagent, in the presence of which even chloronaphthalenes are involved in the Grignard reaction.⁸ Rieke magnesium prepared by reduction of anhydrous MgBr_2 or MgCl_2 with sodium or potassium in THF is an efficient reagent.^{8,9}

The synthesis of 1- and 2-lithium-substituted naphthalenes by the reactions of metallic lithium with halonaphthalenes also gives good results, although this method is nowadays rarely used and only if the presence of another stronger base, for example, of butyllithium, in the mixture is undesirable.¹⁰

The second procedure presented in Scheme 1 (**3** → **4**) is used primarily for the synthesis of organolithium compounds. This method has gained wide acceptance due to the pioneering studies by Gilman.¹¹ Commercial lithium alkyls (*n*-, *sec*- or *tert*-butyl-

[†] Methods for magnesium activation were covered in detail in the review.⁸

lithium) are generally used as organometallic reagents. In this connection, it should be kept in mind that the synthesis of lithium-substituted naphthalenes from commercial reagents used after a long storage can be accompanied by side reactions.¹² Metal–halogen exchange reactions of aryl halides can be performed with the so-called *ate*-complexes R_3MgLi instead of lithium alkyls.¹³ In this case, the exchange of the bromine and iodine atoms occurs at 0 and -78°C , respectively. Mild conditions of the exchange reactions and their high rate allow one to perform these reactions with substrates containing functional groups active toward lithium alkyls (CN, CONR_2 , CO_2R , *etc.*). Most studies of metal–halogen exchange in aryl halides dealt with metallation of substituted phenyl halides. However, the results of the reactions with halides **3** and **9** giving rise to 1-allylnaphthalene (**10**) in high yield show that this method is also applicable to naphthyl halides.

Iodine atoms are most readily involved in exchange with metals; bromine atoms are the second in activity (see, the example with compounds **3** and **9**). Attempts to perform metal–halogen exchange reactions with 1-chloronaphthalene failed.¹¹ Fluorine is virtually not replaced with metal.[‡]

Metallation based on direct ionisation of C–H bonds gives good results in two cases: (i) if the naphthalene ring contains a strong electron-withdrawing substituent, for example, the cyano group (see the synthesis of 2-naphthyllithium **6** from cyanide **5**^{14,15}) and (ii) if the ring contains the so-called directing groups, which coordinate the organometallic reagent, thus lowering the activation energy of metallation (see numerous examples in Sections II.4 and III.3–III.11). Ionisation of C–H bonds is most often performed with the use of Bu^nLi ,¹⁶ Bu^sLi ^{17,18} or Bu^iLi ¹⁶ (selected references are given). Examples of the use of MeMgI ,¹⁸ MeLi ,^{16,18} $n\text{-C}_5\text{H}_{11}\text{Li}$,¹⁹ PhLi ^{17,20} and a Bu^nLi – Bu^iOK mixture (the superbasic reagent LICKOR)^{21–24} for this purpose were documented. Lithium amides, such as lithium tetramethylpiperidide (LTMP)^{14,25–27} or lithium diisopropylamide (LDA),¹⁸ are particularly useful when the strength of the base should be combined with its low nucleophilicity as in the transformation **5** → **6** (see Scheme 1). Compounds of the naphthyloxazoline series were subjected to metallation with ethoxyvinyl lithium (EVL)²⁸ (reactions with other bases afforded addition products to the aromatic system, see Section III.11).^{22,29,30}

Unsubstituted naphthalene is subjected to metallation with difficulty and non-selectively. For example, prolonged reflux of this compound with an excess of Bu^nLi in diethyl ether afforded 1- and 2-lithium-substituted naphthalenes in a ratio of 7 : 3 in a total yield of as low as 20%.³¹ The use of the LICKOR system (as a stronger base) led to an increase in the total yield;²¹ however, after

the addition of CO_2 , the reaction products contained considerable amounts of isomeric dicarboxylic acids along with small amounts of tricarboxylic acids. The reactions in high-boiling solvents, for example, in decalin (see Section II.5), lead to the addition of organometallic reagents to the naphthalene system.

Transmetallation is widely used for the introduction of heavy metals (see examples in Section III.1). In addition, this reaction is used for the transformations of organolithium compounds into their magnesium-containing analogue (**7** → **8**, Scheme 1).^{32,33} In particular, the oxidative synthesis of naphthols (for example, of **11**)³⁴ and Kumada cross-coupling involve this reaction (see Section IV.1).

On the whole, the mechanism of formation of metal naphthalenes is analogous to that for other lithium and magnesium arenes.⁵ It should be noted that the one-electron transfer plays a considerable role in metal–halogen exchange,³⁵ and the surface factors are of importance in the synthesis of Grignard reagents.³⁶

2. Influence of solvents and coordinating additives

Diethyl ether, THF (more rarely, 2-methyltetrahydrofuran³⁷), anisole, toluene, hexane, tertiary amines and their mixtures generally serve as solvents in the synthesis of organomagnesium³ and -lithium^{2,4,5} compounds of the naphthalene series.⁴ The choice of the solvent is mainly determined by the ability of the metallating agents to undergo aggregation. On the whole, a decrease in aggregation leads to smaller dispersion of the negative charge in the alkyl carbanion, which increases its activity in metallation reactions. It is also important that a decrease in aggregation leads to an increase in coordinative unsaturation of the lithium ion, whose typical coordination number, like that of the magnesium ion, is four. Due to this fact, metal can interact with the adjacent groups, including C–H σ -bonds (agostic interactions),³⁰ thus decreasing the activation barrier to the reaction and resulting in its higher selectivity.

For example, Bu^nLi exists in a hydrocarbon medium as a hexamer, whereas it forms tetramers in diethyl ether and THF.^{2,5,20,25,38} A further decrease in aggregation of Bu^nLi is achieved by the addition of the following coordinating additives to the reaction mixture: diazabicyclo[2.2.2]octane (DABCO),⁴ hexamethylphosphoramide (HMPA),^{28,39,40} N,N,N',N',N'' -pentamethyldiethylenetriamine (PMDTA)²⁰ or tetramethylethylenediamine (TMEDA),^{21,41,42} TMEDA being most widely used. The latter compound promotes the transformation of *n*-butyllithium into the dimeric form.^{20,41,43,44} Attempts to transform Bu^nLi into the monomeric form failed even in THF in the presence of 1 equiv. of PMDTA.²⁰ In this connection, it is clear why, for example, metallation of 1-methoxynaphthalene occurs slowly and in low yield in hydrocarbons, whereas this reactions readily proceeds in the presence of TMEDA⁴⁰ or with the use of Et_2O and THF.^{45,46}

3. Kinetic and thermodynamic control

The direction of metallation of naphthalenes can be influenced by the temperature. For example, the reaction of Bu^nLi with 1-methoxynaphthalene (**12**) in Et_2O , THF or a PhMe –TMEDA mixture at room temperature or lower temperatures produces predominantly 1-methoxy-2-naphthyllithium (**13**) (Scheme 2).^{41,45} Heating of compound **13** leads to its isomerisation into more stable 1-methoxy-8-naphthyllithium (**14**). Calorimetric measurements demonstrated that the energy difference between the 1,2- and 1,8-isomers is 1.9 kcal mol^{-1} (Ref. 47) (this difference estimated by PM3 calculations⁴¹ is twice larger, $3.95\text{ kcal mol}^{-1}$). Presumably, the $\text{Li}\cdots\text{O}$ distance in derivative

‡ Under particular conditions, chloro- and fluoronaphthalenes can react with phenyllithium and other strong bases to form dehydronaphthalenes (see Section III.14); the reactions of metallic lithium with chloro- and fluoronaphthalenes are accompanied by reductive processes giving rise to radical anions and dianions and elimination of halogen.²

14 is shorter than that in compound **13**, which provides its higher stability.

The direction of metallation of 1-methoxynaphthalene (1-MeONp) depends also on the nature of the metallating agent and the solvent. For example, the addition of BuⁿLi to 1-methoxynaphthalene in toluene-d₈ (Tol-d₈) at –65 °C (or at room temperature) does not lead to lithiation;⁴¹ instead, the reaction affords, apparently, complex **15**, in which the methoxy oxygen atom of substrate **12** is coordinated to the lithium ion (Scheme 3). This assumption is supported by downfield shifts of the protons of the MeO group ($\Delta\delta = 0.05$ ppm) and the H-2 proton of naphthalene ($\Delta\delta = 0.11$ ppm) in the ¹H NMR spectra. The addition of one equivalent of TMEDA to this complex causes reorganisation of the latter to form aggregates **16** or **17**. The latter serve as models of transition states for abstraction of the H-2 and H-8 protons, respectively. Quantum-mechanical calculations⁴¹ demonstrated that transition state **16** lies substantially lower than transition state **17**, metallation rather than complexation being the rate-determining step of the process. These conditions are referred to as the kinetic control.⁴¹

Metallation of 1-methoxynaphthalene with *tert*-butyllithium proceeds more slowly and affords exclusively 8-lithium derivative **14** (see Scheme 2). In this case, the NMR spectra did not reveal complexation. Nevertheless, it is hypothesised that the formation of *peri*-complex **17** does occur but very slowly, and this complex is present in solution at an insignificant equilibrium concentration. It is the formation of complex **17** that is the rate-determining step, whereas metallation of the C–H bond occurs rather rapidly. This assumption is evidenced by the fact that the kinetic isotope effect was not observed in the reaction of BuⁿLi with a mixture of 8-D- and 8-H-methoxynaphthalenes, whereas the isotope effect in 2-metallation of a mixture of 2-D- and 2-H-methoxynaphthalenes

Np is 1-naphthyl.

in the BuⁿLi–TMEDA system is as high as 15±3. These conditions were classified as the thermodynamic control conditions. In the reaction with 1-methoxynaphthalene, *sec*-butyllithium behaves as BuⁿLi.⁴¹

4. Influence of directing groups

As a rule, substituents in the naphthalene ring, particularly, those containing heteroatoms direct metallation to the *ortho* or *peri* position or, more commonly, simultaneously to both positions. These substituents are called directing groups. The methoxy group in compound **12** provides a classical example. Data on other directing groups are summarised in Table 1. The directing effect of the group is determined by the following two main factors: (i) the ease of coordination of this group to the organometallic reagent determining its orientation for deprotonation, and (ii) the electron-withdrawing properties of this group resulting in an increase in CH-acidity of the adjacent protons.

Only a few directing groups promote selective *peri*-lithiation. Among them are primarily dialkylamino and dialkylaminomethyl groups. This is not surprising taking into account the relatively low electronegativity of the nitrogen atom and a weak ‘acidifying’ ability of such groups (see also selective *peri*-lithiation of 1-naphthyllithium, Section II.8). To the contrary, due to a high electronegativity, substituents containing the carbonyl group (OCONR₂ or CONR₂) facilitate the replacement with metal primarily of the

ortho-protons. Changes in the reaction conditions can substantially influence the direction of metallation. For example, the reaction of BuⁿLi or Bu^tLi with 1-methoxynaphthalene in the presence of TMEDA affords predominantly the 2-Li derivative, whereas the reaction of compound **12** with Bu^tLi in a purely hydrocarbon medium (n-pentane–cyclohexane) produces a mixture of the 8-Li and 2-Li isomers in a ratio of 97:3, although the total yield of the products is at most 20% (see Table 1).

The hierarchy of the directing groups taking into account, in particular, their relative directing ability and stability to organometallic reagents was discussed in the review²⁵ for compounds of the benzene series.

5. Side reactions

The character of side reactions substantially depends on the procedure for the synthesis of organometallic compounds. For example, CH-metallation of naphthalenes containing electron-withdrawing substituents in the naphthalene moiety leads predominantly to the addition of the metallating agent to the aromatic system. Naphthyloxazolines provide a typical example.^{12,19,55} For instance, (1-naphthyl)oxazoline **18** reacts with lithium alkyls in THF at low temperature to form azaenolates **19**, which give oxazoline derivatives of 1,2-dihydronaphthalene **20** (generally, as the only diastereomer) in 60%–99% yields after the addition of iodomethane.¹² This reaction can be used for the stereospecific synthesis of optically active derivatives of hydrogenated naphthalenes, in particular, of aldehydes **21** and alcohols **22** (Scheme 4).

The procedure for the preparation of lithium alkyls is responsible for whether or not these transformations occur successfully. For example, the addition of commercial or long-stored RLi occurs slowly and ambiguously. The best results were obtained in the reactions with lithium alkyls prepared *in situ* by treatment of methylithium with the corresponding stannanes R₄Sn. Apparently, this is associated with the formation of the *ate*-complex R₄Sn·MeLi, in which the nucleophilicity of alkyl anions is substantially higher. In these transformations, lithium dialkylamides,^{56,57} lithiosilane (PhMe₂SiLi)⁵⁸ or vinylolithium⁵⁹ can be used instead of lithium alkyls.

(2-Naphthyl)oxazoline **23** behaves analogously to the 1-isomer, the attack of the nucleophile occurring exclusively on position 1 of the naphthalene ring. Methylation of intermediate azaenolate affords the oxazoline derivative of dihydronaphthalene **24**.^{12,55,56}

The CO₂H,⁶⁰ CO₂R,^{61–64} COR,^{61–64} CONR₂,^{12,16} CH=NR,^{65–67} NO₂,^{68–70} SO₂R⁷¹ and BR₂ groups⁷² also promote the addition of metallating agents to the naphthalene π-system. Selected examples of the addition of metallating agents to naphthalene derivatives **25**–**29** are shown in Scheme 5. In essence, the carboxamide group is the only electron-withdrawing

Scheme 5

Scheme 5 (continued)

substituent providing a rather high percentage of metallation (for more details, see Section III.10).^{16, 25, 73, 74}

At high temperature, alkyllithium reagents can add to unsubstituted naphthalene.^{75–77} For example, heating of a mixture of equimolar amounts of naphthalene and Bu^nLi , Bu^sLi or Bu^iLi (decalin, 20 h) at 165 °C afforded the corresponding monoalkylnaphthalenes in 15%, 20% or 30%–45% yields, respectively, the replacement occurring predominantly (> 90%) at the α position. The reaction with Bu^iLi additionally produces di(*tert*-butyl)naphthalene (30%–50%). Kinetic measurements led to the conclusion that alkylation is preceded by the rapid formation of the $(\text{RLi})_2\text{ArH}$ complex, which is slowly transformed into adducts **30a** and **30b**. At high temperature, the latter undergo fast aromatisation accompanied by elimination of lithium hydride to form 1- and 2-alkylnaphthalenes (Scheme 6).

Scheme 6

Let us mention other side reactions, which will be considered below. For example, the activated MeO and Me_2N groups in naphthalene derivatives can be replaced with a metallating agent (see Sections III.8 and III.11).^{78, 79} In the presence of a halogen atom ($\text{Br}^{77, 80}$ or F^{81}) in the *ortho* position with respect to the metal atom, the corresponding aryne can be formed (see Section III.14). In addition, when preparing organometallic compounds, it should be remembered that these compounds can undergo protolysis under the action of the solvent or the reagent (for example, of acetone⁸²).

Metallation of alkylnaphthalenes can give also benzyl-type anions, many of which are of interest on their own. For example, organosilicon compound **31** was prepared from 2,2'-dimethyl-1,1'-binaphthyl (**32**) through the intermediate formation of dilithium derivative **33**.^{25, 83–85}

In the synthesis of lithium-substituted naphthalenes by metal–halogen exchange, the products can undergo alkylation with the resulting alkyl halide.^{86–88} For example, 1-naphthyllithium (**4**), which was prepared by treatment of 1-bromonaphthalene with butyllithium at low temperature, is transformed at room temperature into 1-butynaphthalene in good yield.⁸⁷

The Schlenk equilibrium is characteristic of the Grignard reagents:³

For example, the reaction of 1,8-dibromonaphthalene (**34**) with magnesium in THF produces 1,8-di(bromomagnesio)naphthalene (**35**), which is transformed into tetramer **36** upon cooling of the solution. The structure of the latter compound was established by ^1H and ^{13}C NMR spectroscopy and X-ray diffraction.³⁷ The reaction of compound **35** with D_2O produces 1,8- D_2 -naphthalene in a quantitative yield, and the reaction of this compound with an excess of Me_3SnCl gives mono- and 1,8-bis(trimethylstannyl)naphthalenes.^{37, 89}

Table 2. Selected geometric parameters of lithium-substituted naphthalenes and comparison with lithium-substituted benzenes (X-ray diffraction data).

^a *d* Are the C—Li bond lengths; ^b δ is the deviation of the lithium atom from the plane of the aromatic ring; ^c α is the angle between the plane of C₂Li₂ and the plane of the naphthalene (or benzene) ring.

Gilman and Brannen⁹⁰ found that treatment of 1-naphthyl-lithium or 1-naphthylmagnesium bromide with various electrophiles, for example, with SiCl₄ or CO₂, often affords 1,1'-binaphthyl and perylene as by-products in low yields (< 3%). Presumably, naphthalene–naphthalene coupling occurs according to the free-radical mechanism and is associated with one-electron oxidation of metal naphthalenes.

There are many other specific side transformations, which depend on the nature of the substrate, the metallating agent and the reaction conditions. These transformations are considered below as needed.

6. Crystal structures of organometallic compounds

The Cambridge Structural Database (CSD, February 2005 release) contains data on one organomagnesium derivative of naphthalene **36** (PEFXIH) and four lithium-naphthalenes

(Table 2, Fig. 1). Compound **36** is a tetranuclear cluster with the symmetry *S*₄. The magnesium atoms form a distorted tetrahedron.

Each naphthalene fragment is located above one of the tetrahedron faces and is bound to three Mg atoms by two *peri*-carbon atoms. One carbon atom forms a σ -bond with the Mg atom, and another carbon atom forms a three-centre two-electron bond with two other Mg atoms. Each Mg atom is additionally coordinated by one THF molecule (standard Grignard reagents are coordinated by two solvent molecules). The crystals are stabilised by a large number of disordered solvent molecules. In the absence of the latter (for example, upon evacuation), crystals are destroyed.

**Figure 1.** Schematic representation of dimeric lithium-substituted naphthalenes and benzenes.

In crystals, all lithium-substituted naphthalenes have a dimeric structure (see Fig. 1). Dimerisation occurs due to coordination of the Li atoms by two *ipso*-carbon atoms, resulting in the formation of the rhomboid quasi-ring C_2Li_2 . Both solvent molecules (THF, Et_2O or TMEDA) and the chelating groups present in the ring [NMe_2 (**7**), MeO (**14**) or $CONR_2$ (**37**)] can serve as two other ligands for Li. In the dimer $(4 \cdot TMEDA)_2$, whose naphthalene ring contains no chelating groups, the α angle is nearly equal to 90 degrees (83°). Intramolecular chelation leads to a substantial decrease in this angle (see the data for dimers **7**, **14** and **37**, Table 2) and a decrease in the deviation of the Li atoms from the plane of the aromatic rings. In each dimer, the naphthalene fragments are virtually coplanar. In all lithium-substituted naphthalenes, the C—Li bond length varies only slightly (2.2–2.3 Å). These tendencies are typical also of phenyllithium (**38**) and its derivatives **39** and **40**. However, it should be noted that calculations (MNDO)⁹⁶ performed for the nonsolvated dimer $(PhLi)_2$ in the gas phase demonstrated that ‘planar’ structure **38a** is more favourable than ‘perpendicular’ structure **38b**.⁹⁷

7. NMR spectra

One-dimensional ^1H , ^{13}C and ^6Li NMR spectra and two-dimensional ^1H - ^1H (COSY), ^{13}C - ^1H and ^6Li - ^1H (HOESY) spectra were measured for a number of lithium-substituted naphthalenes.^{20,41,98} All signals were unambiguously assigned based on the analysis of cross-peaks. As can be seen from Table 3, in the ^1H NMR spectra of complex **4**·TMEDA, the H-2 (8.57 ppm) and H-8 (8.47 ppm) protons are the most deshielded because of their close proximity to the electropositive substituent (the lithium atom). This tendency persists in the ^1H NMR spectra of 1-methoxy-2-naphthyllithium (**13**) and 1-methoxy-8-naphthyllithium (**14**), in which the H-3 (in **13**) and H-2 (in **14**) protons are the most deshielded. Analogous conclusions can be drawn based on ^{13}C NMR spectra (Table 4), the metallated carbon atom resonating at the lowest field. The ^1H and ^{13}C NMR spectroscopic data were used for the determination of the degree of aggregation of lithium-substituted naphthalenes in solution and for the elucidation of the mechanism of lithiation. For example, the ^{13}C NMR spectrum of 1-methoxy-8-naphthyllithium (**14**) in THF- d_8 at $-100^\circ C$ shows a signal for C-8 as a septet with the spin–spin coupling constant $^1J(^{13}C, ^7Li) = 19.3$ Hz. Taking into account the nuclear spin of the ^7Li isotope ($I = 3/2$), this is evidence that the dimeric structure $(14 \cdot THF)_2$ observed in the crystals is retained in solution.

Table 3. ^1H NMR spectra of selected lithium-substituted naphthalenes.

The NMR method was successfully used for the explanation of the direction of metallation of 1-methoxynaphthalene (**12**) and 1-naphthyllithium (**4**) giving rise to naphthylene-1,8-dilithium. The ^1H NMR spectrum of the complex **4**·MeLi is indicative of a stronger deshielding of the H-8 proton compared to H-2 (unlike the free 1-naphthyllithium molecule).⁹⁸

8. Quantum-mechanical calculations

Almost all quantum-mechanical calculations for Li and Mg derivatives of naphthalene were performed with the aim of explaining the regioselectivity of lithiation of naphthalenes.^{29,30,98–101} The optimal structures and the energies of isomeric lithium-substituted naphthalenes, primary substrate–metallating agent complexes and the corresponding transition states were calculated. Calculations were performed predominantly with the use of the semiempirical MNDO method.

Schleyer and co-workers⁹⁸ came up with one of the most fruitful ideas. They postulated the existence of agostic interactions between the coordinatively unsaturated lithium atom and σ electrons of the adjacent C—H bonds in the transition state of lithiation.³⁰ These interactions should lead to an elongation of the C—H bond and an increase in the positive charge on the hydrogen atom that is replaced. These parameters can easily be calculated and serve as an indication of the direction of metallation.

Let us consider lithiation of 1-naphthyllithium (**4**) giving rise exclusively to naphthylene-1,8-dilithium (**41**) as an example.⁹⁸

An analysis of the optimised structure of the complex $(4 \cdot EDA)_2$ (EDA is ethylenediamine) did not explain the pathway of this reaction and even, on the contrary, provided evidence that 2-metallation is preferable. Quantum-chemical calculations combined with experimental observations were used to resolve these contradictions. It was found that the addition of Bu^nLi to the dimer $(4 \cdot TMEDA)_2$ is accompanied by heat evolution but does not lead to the immediate formation of dilithium derivative **41**. For this purpose, it is necessary to perform subsequent prolonged heating of the reaction mixture. This suggests that repeated lithiation occurs inside the complex between 1-naphthyllithium

and the metallating agent (the role of such complexes in metallation reactions was discussed in the review¹⁰²). The structure of the complex with MeLi optimised by the MNDO method actually confirmed that the C-8—H-8 bond in this compound is activated toward metallation to a greater extent than the C-2—H-2 bond.

These calculations demonstrated that lithiation of 1-naphthol occurs predominantly at position 8; of 2-naphthol, predominantly at position 3; of 1,3-, 1,4- and 1,5-binaphthols and 1,4,5-trinaphthol, exclusively at the *peri* position adjacent to the OH group (for the reaction conditions, see Section III.3).^{29, 30} As mentioned above, 1-methoxynaphthalene (**12**) is lithiated predominantly at the C-2 atom under kinetically controlled conditions, whereas lithiation occurs at the C-8 atom under the thermodynamically controlled conditions. In the former case, this is due to the fact that the transition state corresponding to metallation at the C-2 atom is energetically more favourable (by ~ 6 kcal mol⁻¹). The latter case is attributed to higher stability of the 8-lithium derivative (by ~ 4 kcal mol⁻¹).⁴¹ The energies of the 2- and 8-lithium derivatives of 1-aminonaphthalene were estimated by the *ab initio* method.¹⁰¹ The relative stabilities of the structures of **42**·EDA₂ with the perpendicular and parallel orientation of the naphthalene moieties and the rotation barrier about the C-1—C-1' bond were evaluated by the MNDO method.^{99, 100}

III. Synthesis and reactions of naphthylmetals

Organomagnesium compounds of the naphthalene series have found use immediately after the historical discovery by Grignard. As early as 1903, Gattermann¹⁰³ synthesised 1-naphthaldehyde by the reaction of ethyl formate with α -naphthylmagnesium bromide. Beginning in 1930s, lithium-substituted naphthalenes came into use along with Grignard reagents. In the present review, a vast literature on these compounds is systematised according to the type of additional substituents in the ring. As a rule, these substituents have a strong effect not only on the synthesis of organometallic derivatives but also on their reactivity. All reactions of magnesium- and lithium-substituted naphthalenes can, in essence, be classified into four main types: (1) reactions with C-electrophiles, (2) reactions with heteroelectrophiles, (3) oxida-

tion reactions and (4) cross-coupling reactions. Since the latter reactions are of particular importance, they are considered in the special section (Section IV). As for the difference in the reactivity, there are no general rules, which allow one to decide whether lithium or magnesium naphthalenes are reagents of choice. In many cases, both these types of naphthylmetals give comparable results. However, there are also many examples when the reactions better proceed with either magnesium or lithium derivatives.

1. Naphthylmetals based on naphthalene and alkylnaphthalenes

General features of the procedures for the synthesis of Li and Mg derivatives of naphthalene were considered in Section II.1. The reactions of these derivatives with various alkylating and carbonyl-containing reagents are the most abundant. For example, the reaction of 8-methyl-1-naphthyllithium with dimethyl sulfate produces 1,8-dimethylnaphthalene in 90% yield.¹⁰⁴ Analogously, 1-naphthylmagnesium bromide (**43**) is smoothly alkylated with dialkyl sulfates and S_N1-active reagents to form compounds **44a–f**.

RX	Product 44	R	Yield (%)	Ref.

1-FcCH ₂ N ⁺ Me ₂ EtBr ⁻	e	1-FcCH ₂	51	107
1-AdBr	f	1-Ad	2	108

The reaction of 2-methyl-1-naphthyllithium with ethylene oxide produces 1-(2-hydroxyethyl)-2-methylnaphthalene (67%).¹⁰⁹ Trisnaphtho[3.3.3]propellane (**45**) was synthesised by the reaction of 1-naphthyllithium (**4**) with epoxide **46** (Scheme 7).¹¹⁰ This reaction proceeds through the intermediate formation of alcohol **47**. The reaction with 1-naphthylmagnesium bromide (**43**) instead of the Li derivative affords a mixture of products **45** and **48** in a ratio of 1 : 1.8.

The reactions of CO₂ with 1-MgBr-, 2-MgBr- or 1,5-(MgBr)₂-containing naphthalenes produce the corresponding naphthalene-carboxylic or -dicarboxylic acids in good yields.¹¹¹ The reactions with lithium-substituted naphthalenes instead of Mg derivatives give comparable results.^{11, 112}

Scheme 7

Considerable study was given to formylation of magnesium- and lithium-substituted naphthalenes (data were briefly summarised in the review¹¹³). 2-(*N*-Methyl-*N*-formyl)pyridine,¹¹⁴ *N*-methylformanilide,^{46, 115} *N*-formylpiperidine,¹¹⁶ *N*-formylmorpholine¹¹⁷ and DMF^{118–120} are generally employed as formylating agents. As a rule, the reactions proceed rapidly and under mild conditions. However, in the reactions performed with a deficiency of a formylating agent, the resulting aldehyde can react with the starting organometallic compound to give the corresponding dinaphthylmethanol. The latter fact was used in the synthesis of 1,1'- and 2,2'-dinaphthylmethanols by treatment of 1- and 2-naphthylmagnesium bromides with 0.4–1.0 equiv. of ethyl formate.^{106, 121, 122}

Secondary and tertiary alcohols were synthesised by the reactions of 1-naphthylmagnesium bromides with propionic aldehyde,¹⁰⁵ aromatic aldehydes,¹²³ acetone, diethyl ketone, ethyl methyl ketone, di(1,1'-naphthyl) ketone¹²⁴ and acenaphthenequinone.¹²⁵ Analogous reactions were documented also for 2-naphthylmagnesium bromide¹²⁶ and lithium-substituted naphthalenes.¹²³

Tris(1-naphthyl)methanol (**49**) was prepared by the slow addition of 1-naphthoyl chloride to an ethereal solution of 1-naphthyllithium (**4**) at -78°C .¹⁰

Tris(2-naphthyl)methanol was synthesised analogously from 2-naphthyllithium and 2-naphthoyl chloride in 56% yield.¹⁰ Evidently, both reactions proceed through the intermediate formation of binaphthyl ketone (for example, **50**), which rapidly reacts with the starting naphthyllithium. This hinders the use of this method for the synthesis of ketones of the naphthalene series. Earlier, Blicke¹²¹ has synthesised ketone **50** (in 40% yield) by the reaction of 1-naphthoyl chloride with 1-naphthylmagnesium bromide.⁸ However, in Blicke's opinion, a procedure of choice for the synthesis of ketones is based on the reactions of organometallic compounds with an appropriate nitrile. For example, the reaction of 1-naphthylmagnesium bromide with 1-naphthonitrile produces ketone **50** in 75% yield.

The synthesis of naphthonitriles by electrophilic cyanation of lithium-substituted naphthalenes with 1-cyanobenzotriazole was documented.¹²⁷

In recent years, the reactions of lithium and magnesium naphthalenes with heteroorganic compounds as electrophiles have acquired great importance. In particular, of special interest (due to the wide use of cross-coupling reactions) are naphthylboronic acids and trialkynaphthyl stannanes, which can be prepared by the reactions with lithium or magnesium naphthalenes. For example, 1- and 2-naphthylboronic acids are generated in good yields in the reactions of triisopropyl borate with 1- and 2-lithium-substituted naphthalenes, respectively.¹²⁸ Organomagnesium compounds can also be used, for example, in the synthesis of naphthalene-1,4- (**51**)¹²⁹ and naphthalene-1,5-diboronic acids¹³⁰ from the corresponding dibromonaphthalenes.

A convenient procedure was developed for the synthesis of tris(1-naphthyl)borane (**52**) by stirring a mixture of α -naphthyl bromide, magnesium and boron trifluoride etherate,¹³¹ which does not require the special preparation of α -C₁₀H₇MgBr. The reaction is completed within 24 h. The ultrasonic treatment of the reaction mixture leads to a decrease in the reaction time to 30 min.¹³¹

Noyori and co-workers¹³² used the Grignard reagent, which was prepared from 2,2'-dibromo-1,1'-binaphthyl, for the synthesis of the well-known BINAP ligand and its analogues (see Section III.15, Scheme 16).

Silylation,^{133, 134} selenenylation,^{7, 135, 136} stannylation^{37, 137} and chloromercuration¹³⁸ of lithio- and magnesionaphthalenes (Scheme 8) were documented. For example, the reaction of 1,1-dichloro-1,2-dimethyl-2,2-diphenyldisilane with 1-naphthyllithium derivatives **4** and **7** under an inert atmosphere followed by the treatment of the mixture with ethanol afforded naphthyl-ethoxydisilanes **53a,b**, from which stable naphthylsilylenes were generated.¹³³ The reactions of naphthylmagnesium bromides **2** and **43** with di(*p*-anisyl) diselenide produce 1-(*p*-anisyl)selenyl-naphthalenes **54a,b**.⁷ The reactions with a selenium powder and oxidising agents afford dinaphthyl diselenides **55**.^{7, 135} The reaction of 1,8-di(bromomagnesium)naphthalene (**35**) with an excess of trimethylchlorostannane produce a mixture of mono- (**56**) and

Scheme 8

§ Blicke failed to reproduce the earlier procedure proposed by Schmidlin and Massini¹⁰⁶ due, presumably, to the presence of an intolerable impurity of unconsumed magnesium.

1,8-bis(trimethylstannyl)naphthalenes (**57**) in 67% and 22% yields, respectively.³⁷

There is evidence for the possibility of electrophilic amination¹³⁹ and hydrazination¹⁴⁰ of lithium and magnesium naphthalenes. For example, 2-hydrazino-6-methoxynaphthalene (**58**) and its precursor **59** were prepared by the reaction of Grignard reagent **60** with di-*tert*-butyl azodicarboxylate.

Undoubtedly, naphthalene-1,8-dilithium (**41**) is the most important reagent. This compound is regularly used in the synthesis of various 1,8-disubstituted naphthalenes and *peri*-fused heterosystems. This compound was synthesised for the first time by Letsinger^{141, 142} in 1962 by the reaction of butyllithium with

1,8-dibromonaphthalene (**34**) in diethyl ether at room temperature. Katz^{143, 144} recommended to perform the synthesis of naphthalene-1,8-dilithium with the available reagent diiodonaphthalene. Metallation of 1-bromonaphthalene or unsubstituted naphthalene with an excess of butyllithium is also a convenient procedure for the synthesis of compound **41**.^{98, 145–147}

Main types of compounds prepared by the reactions of various electrophiles with naphthalene-1,8-dilithium are listed in Table 5. As can be seen from this table, all structures are symmetrical and are either 1,8-disubstituted naphthalenes or *peri*-cyclic systems. Asymmetrical compounds of this series can be synthesised by the stepwise replacement of the Li atoms in compound **41** (synthesis of unsymmetrical *peri*-cyclic compound **61**, Scheme 9),¹⁶³ stepwise lithiation–replacement of 1,8-dihalo-naphthalenes (synthesis of compounds **62** and **63**)¹⁶⁴ or cleavage of the anionic borate ring in *peri*-fused system **64** with dialkylboryl bromides. The last original approach to the synthesis of unsymmetrical 1,8-diborylnaphthalenes **65** was developed by Gabbaï and Hoefelmeyer.¹⁵⁶

Four-membered *peri*-metallacycles can be synthesised with the use of both naphthalene-1,8-dilithium and its magnesium analogue **35**. This approach was applied in the synthesis of the (1,8-Np)ML_n complexes (see Table 5).¹⁶² In this connection, it should be noted that 1,8-bis(trimethylstannyl)naphthalene (**57**) is

Table 5. Types of naphthalene derivatives prepared by the reactions of various electrophiles with naphthyl-1,8-dilithium (**41**).

more easily produced from naphthalene-1,8-dilithium (**41**)⁸⁹ than from 1,8-di(bromomagnesio)naphthalene (**35**),³⁷ whereas the yield of 1*H*-cyclobuta[*de*]naphthalene increases to 30% (*cf.* 18%–21%, Table 5) in the reaction starting from 1,8-di(iodo-magnesio)naphthalene with the use of methylene ditoluenesulfonate as the electrophile.¹⁶⁰ Additional data on the use of naphthalene-1,8-dilithium in the synthesis of heteroorganic *peri*-disubstituted naphthalenes were reported in the review.¹⁶⁵

2. Naphthylmetals containing alkenyl and alkynyl groups

Lithium and magnesium derivatives of naphthalene containing alkenyl or alkynyl substituents in the naphthalene ring are scarce. The intramolecular addition of the carbanionic centre to a multiple bond is very typical of compounds containing an

unsaturated group adjacent to the Li atom. The formation of benz[e]indane **66** in high yield from bromide **67** is a typical example.¹⁶⁶ The intramolecular addition in intermediate **68** occurs according to Markovnikov's rule.

The reaction of butyllithium with 1-bromo-8-phenylethynyl-naphthalene (**69**) produced 8-lithio-derivative **70**, which was isomerised to give lithium acenaphthylene **71** (Scheme 10). This reaction can be applied in the synthesis of various acenaphthylene derivatives, for example, of compounds **72** and **73**. Magnesium analogue **74** does not undergo the above isomerisation and gives compounds of the naphthalene series, for example, derivatives **75** and **76**, under the actions of electrophiles (see Scheme 10).¹⁶⁷

Direct CH-metallation of ethynylnaphthalenes was studied along with metal–halogen exchange. Metallation of unsubstituted 1-naphthylacetylene (**77**) with 2 equiv. of LICKOR in a THF–hexane mixture (1:1) occurs exclusively at position 2 (compound **78**), as evidenced by the formation of bis(trimethylsilyl) derivative **79** in high yield after the addition of Me_3SiCl to the reaction mixture.²³

Scheme 10

M = Li, K.

Under analogous conditions, 1-(3,3-dimethylbut-1-yn-1-yl)naphthalene (**80**) gives a mixture of metallation products, among which the 3-M derivative prevails (51%). Other isomers are distributed as follows: 4- and 5-M-substituted derivatives (in a total yield of 35%), 6- and 7-M-substituted derivatives (13%) and 2-metal derivative (1%). Interestingly, *peri*-lithiation products are absent in both cases, which is surprising in the light of the data on CH-metallation of other 1-R-naphthalenes.²³ The factors responsible for the difference in the behaviour of acetylenes **77** and **80** (as well as their benzene analogues) were studied in detail, including by theoretical methods. The *ortho*-directing effect of the metallated acetylenic group in the further metallation reaction was attributed to 'gliding' of the metallating agent along the triple bond toward the H-2 atom (A → B → C). It is assumed that the analogous motion toward the H-8 atom is sterically less favourable.

3. Naphthylmetals based on naphthols

Lithiation of naphthols with BuⁿLi or Bu^tLi occurs with different degrees of regioselectivity.^{29, 30, 48} Although the precise structures of metallated species are unknown, they have presumably the structures of complex lithium naphtholates **81**–**84**.

The highest selectivity is achieved in metallation of 2-naphthol, which gives only the corresponding 3-substituted derivative **85** in good yield after the subsequent treatment with *tert*-butyllithium in tetrahydropyran and an electrophile (Me₂NCHO, Me₂S₂ or MeI).^{29, 48}

E = CHO, MeS, Me.

Under the same conditions, 1-naphthol gives a mixture of *peri*- (**86**) and *ortho*-lithiation products (**87**), with the former generally predominating.⁴⁸

E	Yield (%)	
	86	87
CHO	40	20
MeS	50	19
Me	8	38

After metallation of 1-naphthol with a BuⁿLi–TMEDA system followed by the reaction with DMF, only 8-hydroxy-1-naphthaldehyde was found in 43% yield.³⁰ Metallation with a Bu^tLi–THP mixture followed by the addition of dimethylformamide afforded dialdehyde **88** (20%–43%), which is presumably generated from intermediate α-aminoalkoxide **89** as a result of lithiation.⁴⁸

It is worthy of note that 2-naphthol does not react with *n*-butyllithium in TMEDA,³⁰ whereas the corresponding reaction in diethyl ether produces (after the addition of CO₂) 3-hydroxy-2-naphthoic acid (7%) and the starting compound (62%).¹⁶⁸

The yields of substituted naphthols strongly depend on the reaction conditions. The best results were obtained in the case of the fast addition of a 2M Bu^tLi solution in pentane to the concentrated naphthol solution. The theoretical interpretation of the direction of metallation of 1- and 2-naphthols is considered in Section II.8.

Lithiation of 1,3-, 1,4-, 1,5- and 1,6-dihydroxynaphthalenes and 1,4,5-trihydroxynaphthalene with a BuⁿLi–TMEDA system occurs exclusively at the *peri* position with respect to the 1-OH group, which was confirmed by the synthesis of the corresponding monoaldehydes in high yields. When the reaction is initiated with ultrasonic irradiation (UI), 1,4- and 1,5-dinaphthols are subjected to dilithiation, as evidenced by isolation of compounds **90** and **91** after the treatment of the reaction mixture with trimethylchlorosilane.

Metal–halogen exchange is also used for the preparation of lithium naphthols. For example, bromine at position 3 in 1,3-dibromo-2-naphthol (**92**) is replaced with lithium under the action of Bu^nLi , as evidenced by isolation of acid **93** after the treatment of the reaction mixture with CO_2 .¹⁶⁹ In this case, the direction of metallation is identical to that for unsubstituted 2-naphthol. In 1-bromo-2-naphthol (**94**), metal–halogen exchange is also more preferable than metallation of the C–H bond at position 3. This allows one to prepare 1-lithium derivative **95**, which is difficult to synthesise according to other procedures (see also Ref. 170).

Analogous results were obtained by metallation of 4-bromo-1-naphthol and 4-, 6- and 8-bromo-2-naphthols.^{169, 171} Metallation of their derivatives containing the protected OH group provides additional possibilities for the synthesis of substituted naphthols (see Section III.4).

4. Metallation of alkoxy derivatives of naphthalene

The factors determining the direction of lithiation of 1-methoxynaphthalene (**12**) were discussed in Sections II.3 and II.8. In the general case, the reaction with Bu^nLi or a Bu^nLi – Bu^tOK mixture occurs predominantly at position 2, whereas the reaction with *tert*-butyllithium occurs at position 8. There are contradictory data on the degree of regioselectivity of the reaction and the total yield of metallation products. For example, Shirley and co-workers^{45, 49} prepared a mixture of 1-methoxy-2-naphthalene- and 1-methoxy-8-naphthalenecarboxylic acids by the reaction of 1-methoxynaphthalene with Bu^nLi – TMEDA – Et_2O – $n\text{-C}_6\text{H}_{14}$ and Bu^tLi – $n\text{-C}_5\text{H}_{12}$ – $n\text{-C}_6\text{H}_{14}$ systems followed by the treatment of the reaction mixture with CO_2 in total yields of 60% and 20% in a ratio of 99:1 and 1:9, respectively. However, more recent studies^{41, 170} demonstrated that the total yield of the acids in such reactions is substantially higher, whereas the regioselectivity is, on the contrary, somewhat lower. In addition to the synthesis of alkoxynaphthalenecarboxylic acids,^{16, 33, 41, 169} lithium derivatives of 1-alkoxynaphthalenes were involved in H/D exchange,^{41, 67} alkylation,¹⁶ acylation,³³ trimethylsilylation,^{50, 67} trimethylstannylation,⁶⁷ iodination¹⁷² and the reactions with aldehydes.^{173, 174} In some cases, when the reactions of lithium derivatives **13** and **14** with electrophiles give unsatisfactory results, good results can be obtained by transforming lithium derivatives into manganese- or

copper-containing compounds. For example, the synthesis of thiocarbamoyl derivatives **96** and **97** was documented.¹⁷⁵

RLi	Yield (%)	
	96	97
Bu^tLi	29	60
Bu^nLi	79	13

The reaction of Bu^tLi with 1,4-dimethoxynaphthalene afforded *peri*- and *ortho*-lithiation products in a ratio of 2:1 (products were detected by transforming them into the corresponding aldehydes).¹⁷⁶ Lithiation of 1,4,5,8-tetramethoxynaphthalene (**98**) produced the 2-lithium derivative, which gave alcohol **99** after the treatment with acetone.

Interestingly, 2-lithium derivatives **100**, which were derived from the corresponding bromides, undergo protolysis in the presence of acetone.⁸² Apparently, the protolysis rate in this case is substantially higher than the rate of formation of the corresponding alcohols due to steric effects.

R = PhCH_2 , $\text{PhCH}_2\text{OCH}_2$, $\text{Me}_3\text{SiCH}_2\text{CH}_2\text{OCH}_2$ (SEM).

Unlike 1-methoxynaphthalene, methoxymethyl ether of 1-naphthol (1-MOMO-Np) is lithiated exclusively at the *ortho* position.¹⁷³ The directing effect of the 1-MOMO group is stronger than the effect of the methoxy group, as exemplified by compound **101**^{67, 177} (see also Ref. 178). After completion of the reaction, the methoxymethyl group can be removed by the reaction with triethylsilane in an acidic medium.¹⁷⁷

In the presence of 2-(trimethylsilyl)ethoxymethoxy (OSEM) and carbamoyloxy groups at position 1, lithiation of the ring occurs exclusively at position 2.⁵⁰

2-Methoxy-^{169, 179} and 2-ethoxynaphthalenes¹⁶⁸ are metallated with high selectivity at position 3. By contrast, lithiation of 2-MOMO-Np affords a mixture of 1- and 3-lithium isomers in a ratio of 3:4.¹⁸⁰ A substituent can be introduced at position 3 of this compound and the corresponding product can be prepared in good yield after the protection of the more active position 1. This strategy was successfully applied in the synthesis of 3'-hydroxy-1,2'-binaphthyl (**103**) from bromide **104** (Scheme 11).³²

Metallation of 2-(trimethylsilyl)ethoxymethoxynaphthalene affords a mixture of 1- and 3-isomers in a ratio of 1:1 in a total yield of 80%.⁵⁰

In the reaction with BuⁿLi, 2,7-dimethoxynaphthalene, unlike 2-methoxynaphthalene, gives not only the 3-lithium-substituted derivative but also the 1-isomer (15%). In the presence of an excess of butyllithium, dilithiation can occur at positions 3 and 6.^{169, 181, 182}

Study of the reaction of 1,6-dimethoxynaphthalene (**105**) demonstrated that the 6-methoxy group exerts the stronger directing effect than the 1-methoxy group.

This conclusion is also true for 1,7-dimethoxynaphthalene (**106**), which undergo metallation at position 6 (the yield of the product was 98%).^{49, 181, 183}

Metal derivatives of alkoxy-naphthalenes, which cannot be prepared by direct metallation of the C–H bond in alkoxy-naphthalenes, are generated from the corresponding bromonaphthalenes. The synthesis of compound **107** from 2-bromo-6-methoxynaphthalene (**108**) through lithium derivative **109** is a typical example.¹⁸⁴

Additional data on metal–halogen exchange in halogen-substituted alkoxy-naphthalenes are given in Table 6.

1-Naphthyl-*N,N*-diethylcarbamate (**110**) is metallated at –78 °C to form 2-Li derivative **111**, whose treatment with electrophiles affords compounds **112** in high yield.²⁵

Since the nucleophilic site in the amide group is located on the carbonyl oxygen atom, such a high regioselectivity, apparently, indicates that carbamate **110** subjected to metallation has a conformation, in which the C=O bond is directed toward the C-2 rather than C-8 atom. At room temperature, naphthyllithium **111** is isomerised to give α-naphthol derivative **113**.

This rearrangement giving rise to β-naphthol **114** is typical also of the 3-lithium derivative of 2-naphthyl-*N,N*-diethylcarbamate. However, taking into account low yields of compounds **115**, metallation of derivative **116** is less regioselective.²⁵

Table 6. Reactions based on metal–halogen exchange in alkoxy-naphthalenes.

^a Substituents introduced instead of the halogen atom are given.

An analogous rearrangement was observed in the reaction of *tert*-butyllithium with 1-bromo-2-(1-phenyltetrazol-5-yloxy)-naphthalene (**117**).¹⁹⁵

The behaviour of organometallic derivatives of naphthyl triflates and naphthyl tosylates is considered in Section III.14.

5. Metallation of hydroxymethylnaphthalenes

Data on direct CH-metallation of hydroxymethylnaphthalenes are lacking. The corresponding lithium-substituted naphthalenes **118** and **119** were prepared from bromides **120** and **121** by metal–halogen exchange. Lithiated derivatives were used for the generation of partially hydrogenated naphthofurans **122–125**, which, in turn, were used for the preparation of *ortho*-quinonoid naphthofurans, for example, **126a,b**, the latter being highly active as dienes (Scheme 12).^{196–198}

6. Metallation of naphthaldehydes and their latent forms

The synthesis of organometallic derivatives of naphthaldehydes requires the pre-protection of the aldehyde group. Good results were obtained with the use of metal–halogen exchange, for example, in acetals. The successive treatment of bromide **127** with butyllithium and dimethylformamide affords aldehyde **128a** in almost quantitative yield. The reactions with benzaldehyde and 2-naphthaldehyde as electrophiles¹⁹⁶ produce alcohols **128b,c**, whereas the reactions with aryl isopropyl sulfenates, ArS(O)OPrⁱ, afford diaryl sulfoxides **128d**.¹⁹⁹

Scheme 12

CH-Metallation of naphthaldehyde acetals gives less satisfactory results. For example, the successive treatment of 1-dimethoxymethylnaphthalene (**129**) with *tert*-butyllithium and iodomethane followed by hydrolytic cleavage of the acetal afforded a mixture of aldehydes **130–132**.⁵⁴

It is worthy of note that *peri*-metallation dominates over *ortho*-metallation by a factor of more than two. The use of amins (for example, compounds **133**) instead of acetals leads to a decrease in the yield of compounds **130–132** to 6%, 12% and 15%, respectively.

Similar results were obtained by metallation of 2-substituted analogues of compounds **129** and **133**.⁵⁴

Metallation of Schiff bases (for example, of compound **28**, see Section II.5) leads primarily to the addition of the metallating agent rather than to metallation.⁵⁴

An original procedure for metallation of naphthaldehydes is based on the preliminary transformation of these compounds into the corresponding α -amino alkoxides by treatment with lithium (dimethylaminoethyl)methylamide (**134**).^{54, 200, 201} For example, metallation of amino alkoxide **135** derived from 1-naphthaldehyde (**132**) with an excess of butyllithium occurs predominantly at position 2 to form dilithium derivative **136**, whose methylation followed by hydrolysis affords a mixture of naphthaldehydes **130–132**, with compound **131** predominating (Scheme 13). The method is based on the fact that amino alkoxide **135** contains the 'built-in' chelating group, whose action is analogous to that of TMEDA. The transformation of lithium derivative **136** into boronic ester followed by oxidation with oxygen or hydrogen peroxide afforded 2-hydroxy-1-naphthaldehyde in 12%–17% yield.²⁰⁰

Metallation of 2-naphthaldehyde according to this procedure gave a mixture of the 3-Li and 1-Li derivatives in a ratio of $\sim 3:1$. The reaction of this mixture with iodomethane produces the corresponding methyl derivatives, whereas the treatment of this

mixture with sulfur affords 3-thio-2-naphthaldehyde in 94% yield.²⁰¹

The use of lithium diethylamide, pyrrolidide, piperidide or *N*-methylpiperazide instead of compound **134** gives worse results.⁵⁴

7. Metallation of naphthalenecarboxylic acids and their esters

Since the reactions of metallating agents with naphthalenecarboxylic acids or their esters afford addition products to the naphthalene ring (see Scheme 5), the corresponding metal derivatives are prepared by metal–halogen exchange at low temperature.²⁰²

8. Metallation of aminonaphthalenes

The most pronounced directing effect of the amino groups on metallation is observed for 1-dimethylaminonaphthalene. The treatment of this compound with Bu^nLi or Bu^tLi ^{16, 173} in diethyl ether affords exclusively 8-lithium derivative **7**,²⁰³ whose structure was established by X-ray diffraction. The reactions of compound **7** with different electrophiles, including CD_3OD , CO_2 , Ph_2CO , Ac_2O , DMF , BF_3 ,³⁴ Me_2AlCl ,²⁰⁴ MnCl_2 ,¹⁷⁵ MeNCS ,¹⁷⁵ Me_3SnCl , Me_3SiCl , R_2SnBr_2 ,²⁰³ $(p\text{-Tol})_2\text{SbBr}$,²⁰⁵ $\text{Pr}_2^i\text{NCOCl}$,¹⁶ $\text{Cl}_2\text{MeSiSiMePh}_2$ ¹³³ or $\text{F}_2\text{MeSi} - \text{SiMePh}_2$,²⁰⁶ produce the corresponding 1- NMe_2 -8-*E*-naphthalenes **137**. In the synthesis of 8-carbamoylnaphthalenes, it is necessary to add a suspension of compound **7** to carbamoyl chloride because the addition in the reverse order leads to the formation of binaphthyl derivative **138**.¹⁶

$E = \text{D}, \text{CO}_2\text{H}, \text{CHO}, \text{C}(\text{O})\text{Me}, \text{C}(\text{O})\text{NPr}_2^i, \text{Ph}_2\text{C}(\text{OH}), \text{BBu}_2^n, \text{C}(\text{S})\text{NHMe}, \text{SiMe}_3, \text{SnMe}_3, \text{etc.}$

The treatment of compound **7** with selenium followed by oxidation of the reaction mixture affords diselenide **139**.¹³⁶

The synthesis of other lithium derivatives of 1-dimethylaminonaphthalene (for example, **140**) is based on metal–halogen exchange. This procedure was applied in the synthesis of boronic acid **142** from 4-bromo-1-dimethylaminonaphthalene (**141**).²⁰⁷

2-Bromomagnesio-6-dimethylaminonaphthalene was prepared from 2-bromo-6-dimethylaminonaphthalene by metal–halogen exchange. Taking into account low activity of the latter, the Grignard reaction was carried out in the presence of the auxiliary reagent, dibromoethane.⁸

The reaction of 1,5-bis(dimethylamino)naphthalene (**143**) with *n*-butyllithium produces either 4-lithium (**144**) or 4,8-dilithium derivatives (**145**) depending on the amount of *n*-butyllithium. The reactions of compounds **144** and **145** with halosilanes [$\text{Si}(\text{OMe})_3\text{Cl}$, Ph_2SiHCl , Me_2SiHCl , *etc.*] were used for the synthesis of *peri*-substituted derivatives of naphthalenes **146** and **147** containing $\text{N} \rightarrow \text{Si}$ bonds.²⁰⁸

1,8-Bis(dimethylamino)naphthalene ('proton sponge') is not metallated by butyllithium.²⁰⁹ However, its 4-lithium,²¹⁰ 2-lithium and 2,7-dilithium derivatives^{88, 211} and their MgBr analogues can easily be prepared by metal–halogen exchange. Compounds **148a, b** are of particular importance. The reactions of the latter compounds with electrophiles produce 2,7-disubstituted proton sponges **149**, which are difficult to synthesise according to other procedures and which are of fundamental importance.^{88, 211}

Scheme 14

Metallation of naphthalenes containing a secondary or primary amino group as a substituent is complicated because of the initial formation of N-anions. Nevertheless, these compounds also generally undergo lithiation at the *peri* position.^{102,212} For example, the reaction of 1-allylaminonaphthalene **150** with an excess of BuⁿLi produces dianion **151**, whose treatment with *tert*-butyllithium affords trianion **152**, and the latter is transformed into compound **153** under the action of D₂O.²¹²

The reaction of 1-aminonaphthalene with BuⁿLi followed by the treatment with CO₂ gives rise to naphtholactam **154** in low yield.⁵²

According to *ab initio* calculations, *peri*-lithiated dianion **155** is 14.4 kcal mol^{−1} more stable than *ortho* isomer **156** and 27.3 kcal mol^{−1} more stable than dilithium naphthylamide (**157**).¹⁰¹

Katritzky *et al.*²¹³ developed a general one-pot procedure for *ortho*-lithiation of aminonaphthalenes (Scheme 14) providing great scope for their functionalisation. According to the proposed procedure, 1-methylaminonaphthalene is initially lithiated with *n*-butyllithium and then transformed into lithium carbamate **158** by the reaction with CO₂. Lithiation of the latter with *tert*-butyllithium occurs selectively at position 2 to form compound **159**, whose treatment with various electrophiles gives 2-substituted 1-naphthylamines **160** in a total yield of 48%–61%.

E = PhCH₂, Ph₂C(OH), PrⁱCH(OH), BuⁿNHCO.

Analogously, 2-methylaminonaphthalene can be transformed into 3-substituted derivatives but in lower yields.

The transformation of *peri*-diamine **161a** into urea derivative **162** by the successive treatment with butyllithium and 3-chloro-1-iodopropane is yet another example of *ortho*-lithiation.²¹⁴ Evidently, intermediate chloride **163** is generated by alkylation of the corresponding 2-lithium derivative. It is worthy of note that if both amino groups in *peri*-diamine contain the *tert*-butoxycarbonyl substituents (compound **161b**), cyclisation of diamine **161b** giving rise to 1-Boc-perimidone **164** occurs instead of metallation of the naphthalene moiety.

9. Nitronaphthalenes

Data on Li and Mg derivatives of nitronaphthalenes are lacking. As a rule, the reactions of organomagnesium reagents with nitronaphthalenes afford addition products to the naphthalene ring (see Scheme 5).^{68–70,215–217} The treatment of the latter with dichlorodicyanobenzoquinone (DDQ)⁶⁸ or KMnO₄⁷⁰ gives alkylnitronaphthalenes.

10. Dialkylaminomethyl- and dialkylaminocarbonylnaphthalenes

Metallation of 1-dimethylaminomethylnaphthalene (**165**) with butyllithium followed by the reaction of the resulting 8-lithium derivative with benzophenone afforded alcohol **166** in 58% yield. In addition, *ortho* isomer **167** was found in the reaction mixture, but attempts to isolate this isomer in pure form failed (presumably, the ratio of the *peri*- to *ortho*-lithiation products is 91 : 9).⁵³

The same alcohols were prepared in good yields from bromides through metal–halogen exchange.⁵³

Analogous experiments with 2-dimethylaminomethylnaphthalene demonstrated low selectivity of metallation (the ratio of the 3- to 1-substitution products was 55:45).

Clayden *et al.*¹⁶ used 1-dimethylaminomethyl-8-naphthyllithium in the synthesis of 8-carbamoyl-1-dimethylaminomethylnaphthalenes **168a,b**.[¶] The lithium derivative was prepared by the reaction of compound **165** with *tert*-butyllithium.¹⁶ The synthesis of compound **168c** was documented.²⁰⁵

R = C(O)NEt₂ (a), C(O)NPr₂ⁱ (b), (*p*-Tol)₂Sb (c).

As mentioned above (see Section II.4), the carboxamide group is one of few electron-withdrawing groups, which promote the efficient metallation of the naphthalene moiety. For example, the reactions of 1-naphthamides **169** with *sec*-butyllithium produce 2-lithium derivatives **170**; its treatment with electrophiles gives 2-substituted 1-naphthamides **171** generally in good yields (Table 7).

ortho-Lithiation is particularly favoured by low temperature (to $-100\text{ }^{\circ}\text{C}$) and the reverse order of mixing of the reactants (a solution of the substrate is added to the metallating agent).²²⁴

Based on the existence of atropisomerism in the series of *N,N*-dialkyl-2-*R*-1-naphthamides, Beak and co-workers²²³ studied asymmetric deprotonation of *N,N*-dihexyl-1-naphthamide under the action of Bu^sLi in the presence of chiral diamine, *viz.*, (–)-sparteine. Subsequent methylation and ethylation of the 2-lithium derivative obtained after lithiation afforded atropoisomers of *N,N*-dihexyl-2-alkyl-1-naphthamides with 50% and 55% *ee*, respectively.²²³

It is worthy of note that under the above-mentioned conditions, position 8 is not subjected to lithiation and no indication of the nucleophilic addition at the aromatic ring is observed. To achieve *peri*-metallation, various 2-substituted 1-naphthamides were tested as substrates. However, in none of the experiments,

Table 7. Reactions of 2-lithio-1-naphthamides **170** with electrophiles.

R	Electrophile	E	Yield of 171 (%)	Ref.
Et	1) TosN ₃ , 2) NaBH ₄	NH ₂	74	218, 219
Et	1) O ₂ , 2) H ₃ O ⁺	OH	34	220
Et	1) LiCu(CN)NMePh, 2) O ₂	NMePh	61	221
Et	Me ₃ SiCl	Me ₃ Si	80	25
Pr ⁱ	D ₂ O	D	93	16
Pr ⁱ	EtI	Et	82	85
Pr ⁱ	Pr ⁿ I	Pr ⁿ	78	85
Pr ⁱ	MeCHO	MeCH(OH)	92	74, 222
CH(Pr ⁿ)Bu ⁿ	MeCHO	MeCH(OH)	35	74
<i>n</i> -C ₆ H ₁₃	MeI	Me	30	223

did *peri*-metallation occur. Lithiation of 2-ethyl- and 2-propyl-1-carboxamides **172** afforded solely the corresponding benzyl anion; its treatment with electrophiles gave rise to a mixture of stereoisomers **173a** and **173b**, with one of them substantially predominating.⁸⁵ High stereoselectivity of metallation is attributed to the almost perpendicular orientation of the carboxamide fragment relative to the naphthalene moiety, resulting in stereochemical induction.

R = Me, Et; E = D, Alk, Me₃Si, Me₃Sn, *etc.*

Due to a high kinetic isotope effect in metallation reactions of naphthalene derivatives ($k_{\text{H}}/k_{\text{D}} > 80$ at $-78\text{ }^{\circ}\text{C}$), *N,N*-diisopropyl-2-D-1-carboxamide (**27**) would be expected to undergo *peri*-metallation. However, the reaction of this compound with BuⁿLi or Bu^sLi led only to the addition of the nucleophile at position 2 (see Scheme 5).^{16, 73} In the presence of the Buⁱ or Bn substituents at the nitrogen atom, the α -proton abstraction from the *N*-benzyl group was observed.^{73, 225}

Nowadays, the only procedure for the preparation of thermodynamically less stable 8-lithio-1-naphthamides is based on bromine–lithium exchange in 8-bromo-1-naphthamides.²²⁶ Recall also that the carboxamide group can be introduced at the *peri* position with respect to the already present substituent by the reaction of the corresponding carbamoyl chloride with 1-*R*-8-naphthyllithium.¹⁶

The 1-carboxamide group is superior to other groups,¹⁶ including the methoxy group,^{226, 227} in the directing ability.

X = CH₂NMe₂, NMe₂, OMe.

¶ According to the IUPAC nomenclature, these compounds are called *N,N*-dialkyl-8-(*N,N*-dimethylaminomethyl)-1-naphthamides.

The distinguishing feature of the carboxamide group is that it is stable to the action of organolithium compounds only at lowered temperature. At high temperature, the carboxamide group can be subjected to the nucleophilic attack. This fact was used in the synthesis of isomeric benzanthraquinones (for example, of compound **174**,²²⁸ dibenzanthracenes²²⁶ and cholanthrenes²²⁴) and a series of other polynuclear arenes²¹⁹ (see also the review²⁵).

Metallation of 2-naphthamides is very sensitive to the reaction conditions and steric factors. For example, compounds containing methyl groups at the amide nitrogen atom (compound **175a**) do not undergo metallation, and the reaction affords ketone **176** as virtually the only product regardless of the nature of the metallating agent (Bu^nLi or Bu^tLi). Metallation of compounds containing the *N*-isopropyl group (**175c**) gives only Li derivative **177c**, whereas diethylamide **175b** can form both ketone (in the reaction with Bu^nLi) and the Li derivative (in the reaction with Bu^tLi).²²⁹

$\text{R}^1 = \text{Me}$ (a), Et (b), Pr^i (c); $\text{R}^2 = \text{Bu}^n$ or Bu^t .

N,N-Diethyl-2-naphthamide containing the unsubstituted naphthalene ring reacts with Bu^tLi at -45°C to form a mixture of products, *viz.*, the product of the addition of the nucleophile to the naphthalene ring (50%), the 1-lithium derivative (30%) and *tert*-butyl 2-naphthyl ketone (10%).^{12, 25} Approximately the same ratio of metallation products was observed in the reaction with *N,N*-diisopropyl-2-naphthamide (**178**) with the only difference that the reaction occurs at positions 1 and 3.²³⁰

11. Naphthyloxazolines

As mentioned above, the oxazoline substituent promotes the addition of various metallating agents to the naphthalene ring (see Section II.5). In some cases, the oxazoline substituent activates the adjacent group (for example, the methoxy group) toward the nucleophilic substitution (Meyers's reaction).^{78, 231} In particular, this reaction was used for the preparation of 1,1'-binaphthyl-2-carbaldehyde (**179**) starting from (1-methoxy-2-naphthyl)oxazoline **180**.²³²

In the reactions with C- and N-nucleophiles, the methoxy group in (2-methoxy-1-naphthyl)oxazoline **181** is replaced to give compounds **182**.¹²

$\text{RM} = \text{MeLi}$, Bu^nLi , Bu^sLi , Bu^tLi (94%–98%),
syn- $\text{MeCH}=\text{CHLi}$ (60%), Me_2NLi , Pr_2NLi ,
 PhMgBr (98%–100%).

It is interesting that the reaction of compound **181** with allyllithium leads to the addition of the nucleophile at position 4 to give 3,4-dihydronaphthalenes **183a,b**. The latter can be subjected to aromatisation with DDQ.^{66, 78}

$\text{R} = \text{H}$ (a), SiMe_3 (b).

The replacement of the NMe_2 group in (2-dimethylamino-1-naphthyl)oxazolines with Bu^tLi was documented.^{78, 79}

The only example of successful metallation of naphthyloxazolines by the reaction of compound **184** with ethoxyvinyl lithium (EVL) in the presence of hexamethylphosphoramide was documented. Contrary to expectation, the reaction occurs at the *ortho* position with respect to the 6-methoxy group, and the addition of iodomethane to the reaction mixture affords 7-methyl derivative **185**.^{28, 233}

This anomalous situation remains to be explained. However, in the absence of HMPA and at higher temperature ($-10\text{ }^\circ\text{C}$), ethoxyvinyl lithium also adds to the naphthalene moiety of compound **186** at positions 1 and 2, and the treatment of the resulting compound with MeI and a hydrochloric acid solution yields 1,2-dihydronaphthalene **187**.²³⁴

12. Metallation of phosphorylated naphthalenes

Data on organometallic derivatives of phosphorylated naphthalenes are scarce. For example, the use of 1-lithium-substituted 8-phosphinonaphthalenes **188** in the synthesis of pentacoordinate phosphodisilanes **189** was documented,²⁰⁶ however experimental details were not reported.

13. Sulfur-containing naphthalenes

Metallation of naphthalene-2-thiol with *n*-butyllithium affords solely 3-lithium derivative **190**, which was detected as compound **191**.²³⁵

Metallation of 1- and 2-methylthionaphthalenes occurs at the methyl group, whereas the naphthalene ring remains intact, as evidenced by isolation of acids **192** and **193** after carbonisation of the reaction mixture. This is quite understandable because the sulfur atom better stabilises the adjacent carbanionic centre in compound **194** through the unoccupied 3d orbitals.

Nevertheless, 2-ethylthionaphthalene undergoes metallation at the ring, and carbonisation of the resulting compound affords 3-ethylthio-2-naphthoic acid.²³⁶

tert-Butyl 1-naphthyl sulfoxide (**195**) is metallated with *n*-butyllithium at the *ortho* position, which is confirmed by the isolation of alcohol **196** after the treatment of the mixture with paraformaldehyde.¹⁹⁹

At $-70\text{ }^\circ\text{C}$, *tert*-butyl 1-naphthyl sulfone (**197**) is metallated with Bu^nLi or MeLi to form the 2-lithium derivative, whose carbonisation affords carboxylic acid **198**.⁷¹ At high temperature, the reaction with MeLi proceeds analogously, whereas the reaction with Bu^nLi gives addition product **199**, which is transformed into either *trans*-1-*tert*-butylsulfonyl-2-butyl-1,2-dihydronaphthalene (**200**) or 2-butyl-1-naphthoic acid (**201**) depending on the subsequent treatment of the mixture (with H_2O or CO_2).

In the presence of the methyl group adjacent to the arylsulfonyl group, the initially formed benzyl-type anion **202** is rearranged into the corresponding benzylnaphthalenesulfinic acid **203**.²³⁷

In addition to sulfone **204**, the reaction was performed with 2-SO₂Ph-1-Me-, 2-SO₂Ph-3-Me and 1-SO₂Ph-8-Me-naphthalenes. Naphthalene-1-sulfamides undergo metallation at position 2.²³⁸

14. Halogen-containing naphthylmetals. Formation of dehydronaphthalenes

The following two types of halogen-containing naphthylmetals should be distinguished: compounds containing the metal and halogen atoms in the *ortho* positions with respect to each other and compounds in which these atoms are more distant from one another. In the former case, metallation giving rise to metal *o*-halonaphthalenes can be followed by elimination of metal halide to form 1,2- and 2,3-dehydronaphthalenes, which is facilitated by heating. Naphthyne can add a metallating agent at the triple bond. These compounds can also be trapped by special scavengers of the furan type. For example, the reaction of 2-fluoronaphthalene with phenyllithium produces a mixture of 1- (**205**) and 3-lithium derivatives (**206**), whose heating followed

by treatment with CO₂ affords a mixture of naphthalenecarboxylic acids **207** – **209**.²³⁹

Evidently, acids **207** and **208** are derived from 1,2-naphthyne (**210**), whereas their isomer **209** is generated from 2,3-naphthyne (**211**). Under these conditions 1-fluoronaphthalene, as well as 1- and 2-chloronaphthalenes, behave analogously (although the reaction time in the case of the chlorides is substantially longer).²³⁹ Lithium alkyls^{81, 239} and lithium amides^{27, 240} can be used as metallating agents instead of phenyllithium although the specific features of each reagent should be taken into account. For example, the reaction of 2,3-dibromonaphthalene (**212**) with lithium tetramethylpiperidide results in CH-metallation giving rise to 1-lithium derivative **213**. After elimination of the LiBr molecule, the latter compound is transformed into 3-bromo-1,2-naphthyne, which gives compound **215** after the addition of isobenzofuran **214**. By contrast, the treatment of dibromide **212** with butyllithium affords 2-lithium 3-bromonaphthalene (**216**) as a result of metal – halogen exchange. In the presence of isobenzofuran **214**, the latter compound is transformed into tetracene derivative **217** through 2,3-naphthyne (**211**) (Scheme 15).

An analogous approach was successfully applied in the synthesis of 5,6,11,12-tetraphenylnaphthacene (rubrene) and its analogues starting from 2,3-dibromo-1,4-diphenylnaphthalene.⁸⁰

The introduction of the lithium atom at the *ortho* position with respect to good leaving groups, such as OTf or OTs, also leads to the formation of naphthyne.^{241, 242} The synthesis of 1,2-dimethylphenanthrene (**218**) from *o*-bromotoluenesulfonate **219** is a typical example.

To generate naphthyne from naphthyl triflates through CH-metallation, it is necessary to use strong low-nucleophilic bases (such as LDA). For example, the reactions of 1- and 2-naphthyl triflates (**220**) with LDA in an excess of diisopropylamine produce exclusively 1,2-naphthyne (**210**), which adds diisopropylamine to form 1- and 2-diisopropylaminonaphthalenes **221a** and **221b** in a total yield of 86 % in a ratio of 8 : 92.

Scheme 15

This reaction gives naphthalene as a by-product (7%–8%).²⁴³

At rather low temperature (below -45°C), metal *o*-halonaphthalenes are quite stable and can be used in various standard transformations, for example, in the synthesis of 2-bromo-1-fluoronaphthalene from 1-fluoronaphthalene.⁸¹

Halogen-containing metal naphthalenes, in which the metal and halogen atoms are distant from each other (including *peri*-substituted compounds), have no specific features (see the reactions involving 1-MgBr-4-Br,¹¹¹ 1-MgBr-6-Br,¹ 1-MgBr-8-Br,^{7, 123} 1-MgBr-8-Cl¹²³ and 1-Li-4,5-F₂-naphthalenes²⁴⁴).

15. Metal derivatives of binaphthyls

Organolithium and -magnesium derivatives are widely used for the synthesis of binaphthyls (see Section IV) and their functionalisation. The synthesis of 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl (BINAP, **222a**) is a prominent example. This chiral ligand was used for the design of efficient metal complex catalysts for asymmetric hydrogenation.^{245, 246} Racemic or optically active dihalides **223** serve as the starting compounds in the synthesis of BINAP. These reagents are lithiated with BuⁿLi or BuⁿLi at low temperature,^{99, 247} and then the resulting dilithium derivative **42** is treated with diphenylchlorophosphine. The Grignard reagents can also be used. The latter are transformed into diarylphosphinyl derivatives **224**, which are reduced to the target compounds **222a–c** (Scheme 16).¹³² In the reactions of dihalides **223** with one equivalent of a metallating agent [BuⁿLi (see Ref. 247) or Mg (see Ref. 132)] followed by the treatment with an electrophile, only one-half of the molecule is subjected to functionalisation, which provides a route to unsymmetrically substituted 1,1'-binaphthyls.

Dinaphthoheterols **225** were synthesised by the reactions of dichlorosilanes, dichlorogermanes and other 1,1-bifunctional reagents with dilithium derivative **42**.²⁴⁸

X = SiMe₂, GeMe₂, PPh, AsPh, etc.

Other positions in 1,1'-binaphthyls are most often functionalised by metal–halogen exchange (for example, in the case of 6,6'-dihalides **226**^{249–253} or isomeric 4,4'-dihalides²⁵⁴).

X = Br, I; R = H, OMe, OEt, OC₁₂H_{25-n}, OMOM;

E = I, CHO, CF₃, Me₃Si, B(OH)₂, etc.

Lithiation of 2,2'-bis(triphenylsilyloxy)-3,3'-dibromobinaphthyl (**227**) is accompanied by the migration of the Ph₃Si groups to positions 3 and 3' to form compound **228**.²⁵⁵

Scheme 16

X = Br (**223a**), I (**223b**); Ar = Ph (**222a**), 4-MeC₆H₄ (**222b**), 4-BuⁿC₆H₄ (**222c**).

Direct CH-lithiation of 2,2'-dialkoxy-1,1'-binaphthyls **229** was documented. Metallation occurs at positions 3 and 3', and the addition of an electrophile to the resulting compound affords compounds **230** (sometimes, with an impurity of monosubstituted product **231**).^{250, 256–264}

R = Me, Et, n-C₁₂H₂₅, MOM, C(O)NEt₂;

E = Hal, CHO, CO₂H, C(OH)Ph₂, B(OH)₂, etc.

It is interesting that lithiation of 2'-methoxy-1,1'-binaphthyl-2-carboxylic acid with BuⁿLi occurs at the *ortho* position with respect to the carboxy group.²⁶⁵

Hayashi and co-workers²⁶⁶ developed a procedure for the synthesis of optically pure 2'-substituted 2-diphenylphosphino-1,1'-binaphthyls **232**. This method is based on the treatment of the phosphine borane complex **233** with an excess of BuⁿLi giving rise to monolithium derivative **234**, whose treatment with electrophiles affords binaphthyls **232** in good yields.

E = D, I, SiMe₃, SnMe₃, etc.

The use of compounds containing the PPh₂ or P(O)Ph₂ groups instead of PPh₂·BH₃ as the starting reagents give worse results.

IV. Naphthylmetals in cross-coupling reactions

In recent years, organolithium and -magnesium compounds of the naphthalene series have been widely used in cross-coupling reactions, primarily, for the synthesis of binaphthyls, polynaphthyls and arynaphthalenes. There are several general approaches to these reactions. These approaches are based on catalytic, non-catalytic and oxidative cross-coupling of metal naphthalenes. The main catalytic methods are based on (1) Kumada cross-coupling,²⁶⁷ in which aryl halides (including naphthylmagnesium halides) are used, (2) Negishi cross-coupling (recent publications were summarised in the study²⁶⁸), (3) Stille cross-coupling²⁶⁹ and (4) Suzuki cross-coupling.²⁷⁰ In the last three methods, organo-

series are used, respectively, as the starting compounds. Although only the Kumada method is within the scope of the present review, it should be remembered that the synthesis of Zn, Sn and B derivatives of naphthalene generally involve the use of lithium-substituted naphthalenes in earlier steps.

1. Catalytic reactions

The application of the Kumada reaction in the synthesis of binaphthyls was described above (see Scheme 11). In the presence of the chiral ferrocenylphosphine nickel catalyst, which was prepared *in situ* from nickel bromide and (*S*)-1-[(*R*)-2-(diphenylphosphino)ferrocenyl]ethyl methyl ether (L*), this reaction proceeds with high enantioselectivity (95%–98% *ee*) and produces chiral binaphthyls,^{271, 272} ternaphthalenes²⁷³ and arynaphthalenes.²⁷⁴ For example, the reaction of 2-methyl-1-naphthylmagnesium bromide with 1,5-dibromonaphthalene gives ternaphthalene **235** and its *meso* isomer **236** in a ratio of 84:16 in a total yield of 89%. (Similar results were obtained for 1,4-dibromonaphthalene.²⁷³)

2. Non-catalytic reactions

The synthesis of 1,1'-binaphthyls by Meyers's reaction (see Section III.1.1, the synthesis of compound **179**) is a typical example of non-catalytic transformations. The Japanese chemists successfully used 1-alkoxy-2-naphthalenecarboxylates **237** as the substrates.^{275–277} It was demonstrated that if the group R¹ in compound **237** is rather bulky (for example, Prⁱ), organometallic reagents **238** or **239** do not virtually attack the ester group; instead, 1,1'-binaphthyls **240** or **241** are generated in high yield.

R¹ = Alk, Ar; R² = H, OMe.

If the substituent R¹ is chiral (for example, menthyl), stereochemical induction takes place, and the reaction affords

binaphthyl with high optical purity. Other modifications of these reactions were described in the publications.^{278, 279}

3. Oxidative coupling

Several procedures were developed for oxidative cross-coupling of naphthalenes with the aim of preparing binaphthyls. One of these methods is based on the direct reaction of oxidising agents with naphthylmetals. The advantage of this method is high activity of the latter compounds, which allows one to perform the synthesis at low temperature, thus preventing racemisation and retaining labile substituents in the substrate. For example, naphthyllithium **242**, which was prepared from bromide **243**, was transformed into binaphthyl **244** under the action of FeCl₃, and compound **244** was used for the synthesis of the phytotoxic plant pigment phlei-chrome.²⁸⁰

In addition to FeCl₃, cobalt and copper chlorides were tested as oxidising agents but with less success. It should be noted that 2,2'-dilithio-1,1'-binaphthyl (**42**), which was prepared from dibromide (*R*)-(+)-**223a**, was oxidised with CuBr₂ to form cyclooctatetraene derivative (*R*)-(+)-**245** in 16% yield with 90% *ee*.²⁸¹

An efficient procedure for the synthesis of biaryls (including arynaphthalenes and binaphthyls) is based on the transformation of lithium-substituted naphthalenes into cuprates followed by their oxidation.^{282, 283}

For example, the reaction of 1-naphthyllithium (**4**) with monovalent copper cyanide produces cuprate **246** (lower order cuprate). The reaction of the latter with another lithium aryl affords higher order cuprate **247**, whose oxidation with oxygen at low temperature gives the target compounds **248** generally in good yield.

Ar = 2,6-Me₂C₆H₃ (72%), 3-F-4-MeC₆H₃ (76%),
1-C₁₀H₇ (82%), 2-MeO-1-C₁₀H₆ (80%).

A considerable advantage of this reaction is that it is insensitive to steric factors and can be used for the preparation of highly functionalised compounds. It is interesting that the best results were obtained with the use *tert*-butyllithium for the synthesis of 1-naphthyllithium from 1-bromonaphthalene.

V. Conclusion

The above discussion demonstrated that organolithium and organomagnesium compounds of the naphthalene series find increasing application in organic synthesis. This refers to both rather simple functionalisations and the synthesis of various compounds with very complex structures. In many cases, the synthetic methods based on the reactions of lithium and magnesium naphthalenes provide the only route to the target compounds as, for example, in the synthesis of naphthylboronic acids, substituted binaphthyls, numerous *peri*-disubstituted naphthalenes and, particularly, polyfused systems containing small *peri*-rings. It should be noted that a search for new directing groups with the aim of increasing the selectivity of CH-metallation of the naphthalene ring, the development of convenient procedures for metal-halogen exchange in chloronaphthalenes, investigation of the structures of organometallic compounds and, in particular, of the nature of the so-called 'agostic interactions' and the further development of cross-coupling reactions of these compounds are still of importance in this field of science.

Optically active supramolecular systems based on porphyrins

V V Borovkov, N Zh Mamardashvili, Y Inoue

Contents

I. Introduction	1
II. 'Host–guest' systems based on monomeric porphyrins	1
III. 'Host–guest' systems based on dimeric and oligomeric porphyrins	5

Abstract. The published data on supramolecular complexes of porphyrins with optically active organic molecules are systematised. The key principles, mechanisms and driving forces of complexation and factors responsible for effective control over formation of supramolecular systems are considered. The bibliography includes 105 references.

I. Introduction

Among the immense diversity of 'host–guest' interactions, complexation of tetrapyrrole chromophores with chiral organic molecules has recently received considerable attention.^{1–27} The interest in these processes is largely determined by the necessity of identification and separation of chiral biologically active substrates. Porphyrins with rigid macrocycles and predetermined arrangement of substituents that specifically interact with different types of 'guest' molecules are ideally suited for the solution of this problem.

Mutual arrangement of porphyrin fragments in a supramolecular system can be controlled by chemical modifications of the macrocycle or by change in the solvent polarity. The relative positions of tetrapyrrole chromophores change during host–guest complex formation, exciton interactions appear between their π -electronic systems, which is accompanied by the corresponding spectral changes. This allows the successful use of diverse spectral analytical methods for the study of intermolecular interactions.

The examples of porphyrin-based host–guest systems documented in the literature illustrate the broad potential of their practical applications. However, no adequate rationale for the electronic or structural factors that control the complexation is available so far.

This review is the first generalisation and analysis of the results of investigations into porphyrin-based optically active supramolecular systems published over the past decade. The main principles, mechanisms and driving forces involved in the for-

mation of supramolecular systems and factors that efficiently control this process are considered.

II. 'Host–guest' systems based on monomeric porphyrins

Optically active host–guest systems based on monomeric porphyrins are conventionally divided into two main types, *viz.*, systems with achiral or racemic porphyrins ('hosts') that interact with optically active guest molecules and systems based on chiral porphyrins. The formation of supramolecular systems can be detected by various spectral analytical methods.

Host–guest systems based on monomeric porphyrins possess interesting properties. Thus fully substituted porphyrins **1–3** with a saddle-shaped structure of the macrocycle as a result of steric repulsion between neighbouring substituents exist in the form of two enantiomers; their interconversions yield a racemic mixture. This equilibrium can be shifted towards the formation of a particular structure (*de* > 98%) upon interaction with mandelic acid enantiomers.^{28, 29} This interaction involves the formation of H-bonds between the carboxy groups of the acid and the nitrogen atoms in the pyrrole fragments of the porphyrin macrocycle. The supramolecular host–guest complexes formed (1:2) possess a strong induced circular dichroism (CD) signal in the region of the Soret band. The sign of the CD signal correlated with the absolute configuration of the chiral centre of the guest. An interesting property of porphyrins **1–3** is their ability to retain the induced optical activity upon substitution of achiral acetic acid for chiral mandelic acid.

1: $R^1 = 2,6-(\text{MeO})_2\text{C}_6\text{H}_3$, $R^2 = R^3 = R^4 = \text{Ph}$;

2: $R^1 = R^3 = 2,6-(\text{MeO})_2\text{C}_6\text{H}_3$, $R^2 = R^4 = \text{Ph}$;

3: $R^1 = R^2 = R^3 = 2,6-(\text{MeO})_2\text{C}_6\text{H}_3$, $R^4 = \text{Ph}$.

Among ten disaccharides tested, only lactulose is selectively bound to the porphyrin receptor **4**. The position of the hydroxy groups of the carbohydrate matches that of two boronic acid

4

9

Porphyrin receptors **10** were designed³⁵ for specific binding of amines and amino acid esters. They should be used as esters in non-polar organic solvents and as acids in aqueous media. In organic solvents, the complexation is achieved due to coordination of the amino group of the amino acid by Zn of the porphyrin macrocycle (the enthalpy factor). In aqueous media, competitive binding of solvent molecules to Zn weakens the coordination interactions between host and guest molecules. Under these conditions, dispersion interactions between the long methylene chains of the host and the hydrophobic side substituent of the guest favour the complexation (the enthalpy factor). Dehydration of the interacting surfaces of the host and guest molecules is the principal factor that governs complexation in aqueous media (the entropy factor).

acac is acetylacetonate.

The recognition of optically active zwitter-ionic amino acids was studied in a two-phase system 'organic solvent – water'.³⁶ The amino acids were extracted from the aqueous phase using porphyrins **11**, which formed (1 : 1) complexes with the amino acids. The CD spectra of the resulting complexes manifested two well-resolved signals corresponding to the split Soret band. The magnitude of the molar amplitude of CD (*A*) strongly depended on the nature of the solvent and the substituents in the porphyrin and amino acid molecules, while the sign of the induced CD signals was determined by the chirality of the amino acid. The porphyrin containing di-*tert*-butylphenyl groups manifested the highest sensitivity in aromatic solvents. This method was proposed for determination of absolute configurations of α -amino acids.

Later, the sensitivity of the method was increased through incorporation of a crown-ether fragment into the porphyrin receptor **12**.³⁷ Simultaneous coordination of the CO₂⁻ group of the amino acid in the lanthanide reaction centre of porphyrin, the interaction of the NH₃⁺ group with the crown-ether fragment and the adequate choice of the coordinating metal increase significantly the extraction potential of the receptor and, as a consequence, the magnitude of the molar amplitude *A*.

Solid-phase optical detection based on the registration of the hypsochromic shifts in the visible region of the absorption spectrum of porphyrin **13** immobilised as a monolayer on a cellulose film was used for the recognition of amino acids.³⁸ The magnitude of the hypsochromic shift depends on the structure of the amino acid, which makes it possible to quantitatively determine amino acids in solutions.

There is an ample body of data on supramolecular systems in which both hosts and guests possess optical activities. Chiral recognition in such systems is based on three-dimensional structural matching of both molecules according to the 'key–lock' principle and intermolecular binding usually involves three centres. Ideally, only one out of two enantiomeric forms of the guest is bound efficiently to the host molecule to form a stable complex, whereas binding of the other enantiomeric form is much weaker. The difference in the binding strength can be established by different spectral methods. For example, two diastereomeric complexes formed by chiral non-planar porphyrin **14** and (*S*)-2-pyrrolidinemethanol owing to coordination and hydrogen bonds could be identified by ¹H NMR spectroscopy.³⁹

A direct correlation was found⁴⁰ between the enantioselectivities of complexation and catalytic oxidation. The chirality of the metal complexes of the 'strapped' porphyrin derivatives **15a,b** studied was due to steric hindrance to rotation of two binaphthyl fragments around the C(1)–C(1') bonds. The aluminium complex **15a** bound chiral epoxides and alcohols. Distinct differences between the electronic absorption spectra of complexes upon binding of enantiomers enabled determination of the complexation constants by spectrophotometric titration. The corresponding iron complex **15b** catalysed, with high efficiency and enantioselectivity, the epoxidation of non-functionalised alkenes. A linear relationship between the changes in the free energies of complexation and catalytic epoxidation suggests that both processes follow similar stereoselective mechanisms.

Porphyrins **16–18** possessing optical activities due to the 1,1'-binaphthyl fragments react with various phosphorus-containing chiral and achiral ligands. The complexes formed were used as

supramolecular bidentate templates in the palladium-catalysed asymmetric allylic alkylation of racemic 1,3-diphenylpropen-2-yl acetate with dimethyl malonate as a nucleophile. It was found⁴¹ that the enantioselectivity of alkylation was determined not only by absolute configurations of porphyrin receptors and ligands, but also by structural features of the porphyrins, *e.g.*, bulkiness (the introduction of the SiMe₃ groups into porphyrin **18**) and arrangement of the binaphthyl substituent in the *ortho*- and *meta*-positions of porphyrins **16** and **17**.

5,10,15,20-Tetraphenylporphyrin derivatives **19** containing L-amino acids in the *ortho*-positions of the phenyl substituents formed (1 : 2) complexes with carbohydrates.⁴² The fact that these porphyrins did not exceed tetrakis(decyl)-substituted receptors (**19**, R = NHC₁₀H₂₁-n) in binding capacity suggests the predominant contribution of urea fragments to H-bonding with the OH groups of carbohydrates.

A chiral derivative of ruthenium tetraphenylporphyrin complex **20** with optically active groups on both sides with respect to the porphyrin plane (the $\alpha,\beta,\alpha,\beta$ -isomer) recognises enantiomers of amino acid esters. The binding of valine methyl ester by the ruthenium complex **20** occurred with the highest enantioselectivity and it was the L-enantiomer that was predominantly bound (*ee* 66%).^{43, 44}

19, 20

19: M = 2H, Zn; R = L-ValOMe, L-ThrOMe, L-TrpOMe, NHC₁₀H₂₁-n;
20: M = RuO₂, Zn; R = C(OMe)(CF₃)Ph.

The zinc complex of the $\alpha,\beta,\alpha,\beta$ -isomer of porphyrin **20** efficiently recognised the *S*-enantiomer of bulky 1-(1-naphthyl)ethylamine; the ratio of the binding constants was $K_S/K_R = 2.4$.⁴⁵

The stereoselectivity of the binding of D-valine methyl ester reached $K_D/K_L = 7.5$ when bridged chiral metalloporphyrin **21** was used. The preferential supramolecular complex was stabilised due to coordination and H-bonding of the carbonyl group of the guest with the amide group in the isophthalalyl fragment of the host.⁴⁶

21

Thermodynamic analysis of the complexation revealed that the conformational freedom of the guest was largely lost as early as in the coordination step. The enthalpy factor that takes into account the formation of hydrogen bonds was suggestive of stabilisation of the complex as a whole.⁴⁶

Both enantiomers of *C*₂-symmetric chiral water-soluble porphyrin **22** were used for enantioselective recognition of a series of amino acids and dipeptides in alkaline aqueous solutions. The stereoselectivity was effected by virtue of coordination of the NH₂ group by the Zn atom, Coulomb attraction between the carboxylate anion and the cationic ammonium group and steric interactions between the side group of the amino acid and the phenyl group of the *ortho*-substituent of porphyrin.⁴⁷

22

The most efficient recognition of amino acid esters by porphyrins modified by amino acids (complexes **23–25**) has been described.⁴⁸ Thus the enantioselectivity of binding of D-phenylalanine methyl ester reached the value of $K_D/K_L = 21.54$ and showed an exponential dependence on temperature. Diastereomeric complexes exhibited different CD spectra. Thus the CD spectrum of porphyrin **23** weakly bound to L-alanine methyl ester was similar to that of free porphyrin **23** and contained a single negative Cotton effect in the Soret band region. On the other hand, the strong complex with D-alanine methyl ester possessed a split signal owing to exciton interactions between porphyrin and the carbonyl group of the amino acid.

23–25

R = BocAla (**23**), BocPro (**24**), BzGln (**25**); Boc = Bu^tOC(O).

The crucial importance of the three-centre model in chiral recognition was corroborated by low (*ee* 15%) binding stereoselectivity of racemic isocyanides by the Ru porphyrin complex **26**. This receptor was able to coordinate ligands, but had no additional centres for H-bonding.⁴⁹

X-Ray diffraction analysis and ^1H NMR spectroscopy of chiral cobalt porphyrin complex **27a** revealed that the combination of one coordination interaction and two hydrogen bonds enabled efficient enantioselective recognition of amino alcohols and amino acid esters.^{50–54} Moreover, cobalt porphyrin complex **27a** can be used for determination of enantiomeric excess in primary amines and aziridines by ^1H NMR spectroscopy.⁵³ A dependence of the conformation of the macrocycle on the nature of the central metal ion was established for metalloporphyrins **27b**; the $\alpha,\alpha,\alpha,\alpha$ -conformation was changed to the $\alpha,\beta,\alpha,\beta$ -conformation upon substitution of Ni for Zn.⁵⁴

M = Zn, Ni.

Different chiral porphyrin derivatives are also used for binding of optically active compounds. Thus the lasalocid–sapphyrin conjugates **28–30** were used for the transfer of aromatic amino acids from one aqueous phase to another through an organic layer.⁵⁵ The mechanism of this reaction includes formation of a stable supramolecular ensemble of the host molecule with the zwitterionic form of the amino acid by virtue of electrostatic interaction of the carboxylate anion with protonated sapphyrin and formation of H-bonds between the NH_3^+ group of the amino acid and the ionophore fragment of lasalocid.

III. 'Host–guest' systems based on dimeric and oligomeric porphyrins

The above-cited examples of host–guest systems based on monomeric porphyrins demonstrate broad potential for their practical application. However, very often efficient functioning of monomeric porphyrin receptors is impossible without a synergetic support by one or several porphyrins. This stimulates the construction of novel chirogenic host–guest ensembles based on dimeric and oligomeric porphyrins. Such systems are classified according to the presence of a chiral fragment and the number of porphyrin macrocycles in the host molecule and the type of the covalent bridge.

First, let us consider the ensembles consisting of achiral or racemic bisporphyrin hosts and optically active guests. An achiral bisporphyrin molecule should possess at least two reaction sites and a flexible covalent bridge in order to adopt a stereospecific three-dimensional conformation upon interaction with chiral guest molecules. Then a supramolecular chiral ensemble is formed.

Double-decker bisporphyrins **31–38** linked 'centre-to-centre' were designed for binding of miscellaneous guest molecules.^{56–61}

31, 32

33–38

31: R = C₆H₄B(OH)₂-3; 32: R = C₆H₄B(OH)₂-4;

35: R¹ = 3,5-(MeO)₂C₆H₃, R² = R³ = 4-Py;

36: R¹ = 4-MeOC₆H₄, R² = R³ =

37: R¹ = R² = 4-MeOC₆H₄, R³ =

38: R¹ = 4-MeOC₆H₄, R² = R³ =

The association mechanism involves the interaction of a bidentate guest with two complex-forming groups of adjacent porphyrins, which brings about twist of the porphyrin macrocycles around the central axis to the left or to the right depending on the stereochemistry of the guest molecule. This asymmetric twist results in changes in the interporphyrin exciton interactions and induction of optical activity in the region of absorption of the porphyrin. The induced optical activity retained for 3 days at 0 °C and over one year at –37 °C. The host–guest complexation occurred with a high degree of cooperativity, manifesting a positive allosteric effect; the characteristics of the CD signals strongly depended on the structure of the guest molecule,^{56,57} the nature of the solvent⁶¹ and pH.⁶⁰

Bisporphyrin systems **31**, **32**, **36** and **37** containing boronic acid were successfully employed for the recognition of carbohydrates; the dimers containing pyridyl substituents (**33–35**) were used for the binding of chiral dicarboxylic acids, while cationic bisporphyrin **38** interacted with dianions. Bisporphyrin receptor **35** possessed an ability of memorising chirality. Interestingly, bisporphyrin **36** interacts with glucose oligomers as guests, and the sign of optical activity of the complex changes depending on the number of monosaccharide units.⁵⁹

‘Face-to-face’ bisporphyrins **39** and **40** linked by covalent cryptand-containing bridges between the opposite positions of the macrocycles efficiently bind trisaccharides in aqueous solutions, predominantly by encapsulation.⁶² Very weak induction of CD in the region of the Soret band is observed due to the inability of bisporphyrins to change their conformations depending on the stereochemistry of guest molecules because of structural rigidity of the cryptand-containing bridges.

39, 40

39: R¹ = R² = H, R³ = C₆H₄Me-4;

40: R¹ = Me, R² = Prⁿ, R³ = H;

Dimers **41** and **42** containing flexible covalent bridges manifested good structural matching to bidentate pyridyl-anchored chiral peptides of appropriate lengths. As a result, stable inclusion complexes (1:1) with association constants of the order of $2.3 \times 10^6 \text{ M}^{-1}$ are formed. It was found that the helical structure of the guest plays a key role in the transcription of chiral information by inducing strong exciton interactions in the Soret absorption band.⁶³

41–43

M = Zn, R¹ = H, R² = 2,4,6-Me₃C₆H₂;

X = CO(NHMeCO)₉NH (**41**),

M = 2H, R¹ = Me, R² = 2,6-(MeO)₂C₆H₃,

X = 4-OCH₂C₆H₄CH₂O-4 (**43**).

Bisporphyrin **43** with shorter *para*-xylylene bridges was used for the complexation with mandelic acid. This resulted in a significant (more than sevenfold) enhancement of a CD signal ($A = 260 \text{ cm}^{-1} \text{ M}^{-1}$) in comparison with the complex based on monomeric porphyrin. This effect is due to induction of helical chirality upon forced changes in mutual arrangement of both porphyrin rings in the course of formation of the supramolecular ensemble. Increasing concentrations of guest molecules triggered complex changes in the CD spectra manifested as multistep equilibrium. Such systems present interest as candidate chirality sensors for the study of stereochemistry of interacting guest molecules.⁶⁴

Yet another structural type of bisporphyrins is based on combination of two chromophores linked through a single bridge. In this case, the mutual arrangement of the porphyrin macrocycles is less predictable because of lesser rigidity of the system. The complexation with a bidentate guest molecule can favour approach of the porphyrin moieties to each other and their fixation in the 'face-to-face' mode.

Lanthanide-containing bisporphyrins **44** and **45** linked through ether bridges of various lengths provide examples of such systems. These dimers were obtained as potential host molecules for binding cystine polyions.⁶⁵ The selectivity of recognition is largely determined by the size of the optically active guest molecules. Thus ytterbium bisporphyrin complex **44** with a short bridge effectively extracted cystine from aqueous solutions into the organic phase, but not cystathionine, homocystine or methionine. In contrast, bisporphyrin **45** effected preferential extraction of more extended homocystine. The formation of 'tweezers'-like 1:1 complexes was accompanied by the appearance of a complex CD signal in the Soret band region; its intensity was notably increased in comparison with the signal of the monomeric complex.

M = Yb(acac), Gd(acac); $R^1 = R^2 = \text{H}$; $R^3 = \text{Ph}$:

High binding selectivity of chiral diamines by bisporphyrins **46** and **47** linked through rigid bridges was reported.⁶⁶ The matching of the distance between the zinc atoms of the porphyrin macrocycles to the length of the chain linking two NH_2 groups of the guest is a prerequisite for efficient complexation. The highest association constant ($K_a = 2.4 \times 10^6 \text{ M}^{-1}$) was found for the pair dimer **47**-cystine ethyl ester. The induced CD signal strongly depended on the bulkiness of the peripheral substituents in the porphyrin macrocycles and temperature. Thus the molar ampli-

tude A increased 1.5-fold with a decrease in temperature down to -45°C .

The feasibility of control over bisporphyrin conformation increased substantially upon introduction of a crown-ether-type linkage into the host molecule by virtue of specific binding of the crown-ether fragment to alkali metal ions.⁶⁷⁻⁶⁹ Thus the addition of Na^+ ions to the bisporphyrin **48**-*trans*-1,2-diaminocyclohexane system caused a nearly twofold increase in the association constant due to the change in the bisporphyrin geometry and a concomitant significant increase in the molar amplitude A of the induced CD signal.⁶⁷

A similar effect was observed in the interaction of bisporphyrin **49** with *N*-alkyl-1,2-diaminocyclohexane.⁶⁸ However, in this case the formation of a complex with a larger crown-ether cavity required larger K^+ ions. Bisporphyrin **49** recognised the chirality of potassium camphorates and mandelates.

The chirality of porphyrin **50** in a 'tweezers' conformation which is conferred on it by its interaction with an optically active diamine, is retained after replacement of the chiral ligand by an achiral one in the presence of Ba^{2+} ions. The intensity of the CD signal in this particular system decreased only slightly within 24 hours.⁶⁹

The 'tweezers'-like systems discussed above manifest high optical activities due to asymmetric spatial arrangement of two porphyrin chromophores. However, no detailed interpretation of electronic and structural factors responsible for this phenomenon has been given so far. In a series of studies,⁷⁰⁻⁸⁰ attempts were undertaken to solve this problem using flexible bisporphyrin **51** that adopts 'tweezers'-like conformation upon complexation with bidentate ligands.

Presumably,⁷⁰⁻⁸⁰ optical activity observed in the formation of supramolecular systems results from the stereospecific differentiation of the relative bulkiness of substituents at the chiral carbon atom of the guest owing to the ability of bisporphyrin to adopt the sterically least hindered conformation. The factors that influence the geometry of the ensemble, *e.g.*, H-bonding, the presence of

heteroatoms, the nature of the solvent, *etc.*, should also be taken into consideration. The sign of the induced CD signal upon exciton interactions of two chiral tetrapyrrole fragments of bisporphyrin **51** can be used for determination of absolute configurations of bidentate guest molecules. In the case of discrepancies between the predicted and experimental chirality, conformational analysis was carried out using the molecular mechanics method. Some dependences of induced CD signals on the nature of the guest molecule, the solvent and temperature were given.^{70–80}

The complexation of bisporphyrins **52** in which the tetrapyrrole fragments are linked through C₂-bridges was studied in order to get a deeper insight into the mechanism of induction of optical activities of supramolecular systems based on bisporphyrins.^{8, 81–95}

$M^1 = M^2 = \text{Zn, Mg}; M^1 = \text{Zn}, M^2 = 2\text{H}.$

In contrast with the bisporphyrin systems considered above, this host molecule recognises chiralities of both bidentate and monodentate guests due to a limited number of conformations adopted by bisporphyrin with a short covalent bridge. Absorption, CD and ¹H NMR spectra suggest that bisporphyrin **52** interacts with primary amines by a cooperative mechanism to yield stable host–guest complexes (1 : 2) where bisporphyrin is in the *anti*-conformation. The Gibbs free energy for this complexation varies from -6.7 to -8.4 kcal mol⁻¹. The specific mechanism of induction of the optical activity in bisporphyrin **52** upon complexation with chiral monodentate guests stems from the difference in the repulsion forces of two bulkiest substituents at the asymmetric centre of the ligand and the ethyl groups of the neighbouring porphyrin fragment. The mutual repulsion of these groups forces the tetrapyrrole macrocycles to move away from one another and to twist, which results in generation of an intensive CD signal in the Soret band region, which is characteristic of exciton interactions. The correlation between the sign of the signal and induced helicity of the system enables determination of absolute configurations of monodentate guest molecules.

The effects of various factors on induction of chirality have been studied in detail.^{81–95} It was found^{81, 82, 84} that the value of the molar amplitude, *A*, in the CD spectra was proportional to the size of the bulkiest substituent at the asymmetric centre in homologous ligands. The crucial role of the solvent as an active component of the supramolecular system was determined^{89, 90} based on the analysis of solvent–solute interactions in the boundary zones where the difference between the complexation involving competing chiral ligands was small and the guest could be replaced by the solvent molecule. Temperature is yet another factor that governs chirogenic processes. Thus a drop in temperature, which diminished the mobility of the system, was accompanied by a significant increase in the molar amplitude *A*.^{85–87} In this case, chirality could be induced as a result of binding of optically active alcohols despite their low affinities for zinc porphyrins. The ability of chiral alcohols to induce optical activity is significantly enhanced upon substitution of the Mg²⁺ ion for the central Zn²⁺ ion in the porphyrin macrocycle.⁸⁸ Phase transition is yet another important factor that controls optical activities of bisporphyrin complexes **52** with monodentate

amines.⁹⁵ Phase transition in a system caused a significant (1.6–9-fold) increase in the anisotropy factor together with solid-phase ‘switch’ of chirality due to formation of intermolecular aggregates of opposite helicity.

The interaction of bisporphyrin **52** with bidentate guests yielded extremely stable ‘tweezers’-like complexes (1 : 1) with binding constants reaching 10⁷ M⁻¹. In the majority of cases, further increase in the concentration of bidentate guests shifts the equilibrium towards the formation of supramolecular host–guest complexes (1 : 2) where bisporphyrin adopts the *anti*-conformation.^{91–94} An interesting effect, *viz.*, switchover of chirality, which was controlled exclusively by the stoichiometry of the supramolecular system as a result of opposite mutual spatial arrangement of its porphyrin components in 1 : 1 and 1 : 2 complexes, was characteristic of enantiopure 1,2-diphenylethylenediamine used as a guest.

A more detailed rationale for induced optical activity in supramolecular systems based on bisporphyrins was gained with chiral 1,2-diaminocyclohexane as a guest. Based on X-ray data on the structure of bisporphyrin **52**–(*R,R*)-1,2-diaminocyclohexane complex and the Kuhn–Kirkwood mechanism of coupled-oscillator interaction, the intense bisigned CD signal (*A* = -590 cm⁻¹ litre mol⁻¹) was rationalised as a combination of two B_{||}–B_{||} and B_⊥–B_⊥ counter-clockwise electronic homo-interactions, whereas the contribution of the corresponding B_{||}–B_⊥-heterointeractions was insignificant.⁹⁴ Thus, high sensitivity and the ability of bisporphyrin **52** to recognise optical activities of different guest molecules, together with a deep insight into complexation mechanisms, make it a worthy candidate for versatile chirality sensors.

Bisporphyrin **53** with rigidly linked macrocycles was recommended for selective binding of oligosaccharides by a cooperative mechanism.^{60, 96} The fixed distances between the porphyrin fragments correspond closely to the size of maltotetraose, which results in stable host–guest complexes (1 : 2). This is concomitant with the appearance, in the CD spectrum in the region of the Soret band, of a complex chiroptic response consisting of three non-equivalent and asymmetric Cotton effects probably due to superposition of two or more CD signals.

53: $R = \text{—} \langle \text{C}_6\text{H}_4 \rangle \text{—} \text{B} \begin{matrix} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{matrix} \text{—}, n = 0;$

54: $R = \text{—} \langle \text{C}_6\text{H}_2(\text{CO}_2\text{H})_2 \rangle \text{—} \text{OC}_{12}\text{H}_{25-n}, n = 0, 1, 2, 6.$

The increase in the number of porphyrin macrocycles in *meso,meso*-linked oligomers **54** brought about significant enhancement of the effect of induced chirality.⁹⁷ In the presence of tetrahydropyrimidinone, these oligomers formed helical structures due to H-bonding of the carboxy groups in the *meso*-aryl substituents of porphyrin and the urea nitrogen atoms. The direction of helix formation was controlled by complexation with chiral diamino-1,1'-binaphthyl derivatives resulting in the appearance of induced CD signals. The intensity of the latter increased with the increase in the number of porphyrin units from

2 to 8. An interesting chirality memory effect was observed for octaporphyrin **54** ($n = 6$): the addition, to a helix formed by octaporphyrin and an optically active guest, of an opposite enantiomer caused a decrease in the induced chirality value, but not its complete cancel or switching the sign.

Yet another type of multiporphyrin systems was investigated.^{98,99} In the presence of enantiomerically pure 1-(1-naphthyl)ethylamines, hexamers **55** manifested intense CD signals in the Soret band region; other chiral amines induced weak Cotton effects.

High stereoselectivity was observed for a series of dendritic porphyrins **56–59** in their complexation with bidentate chiral guests. The induced CD signal strongly depended on the number of porphyrin fragments; the maximum value of A ($2693\text{ cm}^{-1}\text{ M}^{-1}$) was found for dendritic complexes **57**. However, this effect has not been comprehensively investigated yet.

An attempt to develop a supramolecular system for chiral recognition and enantioselective catalysis based on heterometallic trimer **60** was undertaken.¹⁰⁰ In the first step, optically active carboxylic acids bind to tin-containing porphyrin fragments of the trimer **60** in a hexacoordination mode with formation of a host–guest ensemble (1 : 4) with a chiral cavity. However, further attempts to use this ensemble for separation of a racemic mixture of chiral substituted pyridines with subsequent catalytic asymmetric epoxidation were unsuccessful, apparently due to the loss of rigidity of the chiral cavity.

Host–guest systems in which both components possess optical activities can find wide application. Thus a series of chiral sapphyrin dimers **61–63** were used for the recognition of dicarboxylate anions by virtue of Coulomb attraction and formation of hydrogen bonds.¹⁰¹ Dimers **61** and **62** formed stable complexes with *N*-benzyloxycarbonylaspartic and *N*-benzyloxycarbonylglu-

tamic acids ($K_a \sim 10^4 - 10^5 \text{ M}^{-1}$), the binding of glutamic acid being more preferable.

Despite its low affinity for the guest molecules considered above, the cyclic dimer **63** also possesses the ability for chiral recognition. Presumably, this is due to high structural matching of the host and guest molecules as a result of rigid fixation of saphyrin fragments by two covalent bridges. The detailed recognition mechanism demands additional investigation.

63

Bisporphyrin **64** with spatially fixed macrocycles was used for enantioselective binding of histidine and lysine esters (*ee* 80%–86% and 48%, respectively). The complexation was achieved through two-site interaction between two nitrogen atoms of the guest and two zinc ions of the host; this yielded ‘tweezers’-like structures.¹⁰²

64

$R = 3,5\text{-Bu}_2\text{C}_6\text{H}_3$.

Bisporphyrin **65** rigidly bridged by a 1,1'-binaphthyl fragment was used for chiral recognition of various amino acid derivatives.⁶⁶ This host molecule manifested especially high affinity for lysine derivatives due to formation of ‘tweezers’-like complexes. The stereoselectivity of binding is determined by steric repulsion of two methoxy groups of the bridge and the amide group of the amino acid derivative in the less favourable diastereomeric complex.

Chiral dimeric porphyrin **66** was used for stereoselective separation (*ee* 80%) of bidentate ligands of various lengths. Guest molecules contained an optically active leucine unit and two terminal pyridine fragments enabling two-site binding.¹⁰³ The formation of the preferential ‘tweezers’-like complex was accompanied by a significant increase in the CD signal intensity in the Soret band region. The observed effect is due to stabilisation of the twisted conformation of the host molecule as a result of its binding to the helical guest molecule.

66

On the contrary, the intensity of a negative single signal in the CD spectrum of bisporphyrin **67** decreased dramatically in the presence of limonene.¹⁰⁴ This was accompanied by a hypsochromic shift the magnitude of which depended on the configuration of the enantiomer bound.

68

References

- 

67

68

A similar decrease in the signal intensity in the CD spectrum of chiral bischlorin **68** was observed upon its interaction with optically active ligands.

The effect observed is also due to conformational changes in the host molecule. The significant differences between the chiroptical responses of the complexes with enantiomers suggests possible application of bischlorin **68** for chiral recognition.¹⁰⁵

* * *

The published data considered in this review suggest that optically active supramolecular systems based on porphyrins and their derivatives present indubitable interest for both determination of absolute configurations of different organic molecules and in-depth studies of transcription of optical activity. Recent progress in this area is an important prerequisite to the development of advanced molecular technologies, such as chiral nanotechnology, design of 'smart' molecular tools to memorise chirality and optical activity sensors.

Abstract. The results of investigations into the conditions of synthesis, structure and magnetic properties of quasi-one-dimensional perovskite-like complex oxides of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family ($A = \text{Ca, Sr, Ba}$; $A' = \text{Cu, Ni, Co, Zn, Mg}$; B are platinum metals, Mn and other d and p elements) are generalised. It is shown that the low-dimensional structure of the compounds is determined by the presence of isolated chains consisting of octahedra occupied by the B cations and trigonal prisms with the A' -cations which alternate in various ratios. The reasons for the formation of incommensurate compounds and the methods for the refinement of their structures are considered. It is demonstrated that the presence of transition metals and the quasi-one-dimensional structure are responsible for the high anisotropy of the magnetic properties of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ oxides and, in particular, for the preservation of the intrachain exchange interactions to relatively high temperatures and the low temperatures of three-dimensional magnetic ordering. The bibliography includes 127 references.

I. Introduction

Over the recent years, compounds with low-dimensional crystal structures, in particular, two-dimensional layered and one-dimensional chain compounds manifesting strongly anisotropic physical properties have attracted much attention from specialists in inorganic and solid state chemistry and solid state physics. Among quasi-one-dimensional compounds with chain structures, complex platinum metal oxides, which effectively served as a basis for the emergence of this class of low-dimensional oxides, are of particular interest. Presently, a series of oxides with the general formula $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ based on such metals as Pt, Ir, Ru, Rh, *etc.* have been synthesised.^{1,2} According to structural attributes, the Sr_4PtO_6 oxide³ (that belongs to the K_4CdCl_6 structural type⁴), where both A and A' cationic sites are occupied by Sr can be regarded as the first representative of this family. The values of m and n for this compound are 0 and 1, respectively.

G V Bazuev Institute of Solid State Chemistry, Urals Branch of the Russian Academy of Sciences, ul. Pervomayskaya 91, 620219 Ekaterinburg, Russian Federation. Fax (7-343) 374 44 95, tel. (7-343) 374 49 43, e-mail: bazuev@ihim.uran.ru

Later in the 1990s, other oxides with the common formula $A_3A'BO_6$, where $A = \text{Ca, Sr, Ba}$; $A' = \text{Cu, Ni, Zn, etc.}$; B are platinum group elements, were synthesised.^{5–9} Noteworthy, it was complex oxide $\text{Sr}_3\text{CuPtO}_6$ that was the first reported compound from this series.^{5,6} This new phase characterised by a distorted Sr_4PtO_6 structure with the Cu atoms substituting the Sr atoms in the positions A' formed spontaneously upon an attempted growth of single crystals of strontium cuprate, a high-temperature superconductor, in a platinum crucible. More recently, oxides with formulas $A_4A'B_2O_9$ ($m = 1$ and $n = 3$), $A_6A'B_4O_{15}$ ($m = 1$ and $n = 1$) and $A_9A'_2B_5O_{21}$ ($m = 1$ and $n = 2$) and other compounds have been prepared.^{10–12} A brief analysis of the conditions of synthesis and description of the structures of compounds from this class synthesised prior to 2000 can be found elsewhere.¹³

In structural inorganic chemistry, the above oxides are typically considered as perovskite-related, since complex oxides with the common formula ABO_3 can formally be regarded as a particular case of the formula $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ (for $m = 1$ and $n = 0$). The perovskite structure is usually described in one of two ways. On the one hand, the perovskite structure can be represented as a spatial network of polyhedra, *viz.*, BO_6 octahedra, which can be picked out based on the mutual arrangement of the metal and oxygen atoms constituting the compound. This polyhedral representation is especially pictorial and convenient for the analysis of various structural distortions of perovskites related to the rotation or tilting of the octahedra. The ideal cubic perovskite structure in the polyhedral representation is depicted in Fig. 1a.

On the other hand, a description of the perovskite structure can be based on the concept of cubic and hexagonal close packings of the atoms A and O constituting an ABO_3 perovskite. Strictly speaking, only the cubic close packing refers to the perovskite structure. The hexagonal close packing is typical of crystal structures of some other compounds with the same stoichiometry (*e.g.*, BaNiO_3 ,¹⁴ see Fig. 1b) or with several structural modifications [including BaMnO_3 (Refs 15 and 16)]. For some of ABO_3 oxides (in particular, for BaTiO_3)¹⁷ both perovskite and hexagonal modifications are known. Taking these factors into account, the hexagonal perovskite structure can be represented as a stack of closely packed AO_3 layers along the c axis (Fig. 2) with the B atoms occupying the octahedral cavities formed by the oxygen anions. The A cations are close in size to the O^{2-} oxygen anions, whereas the B cations are characterised by a smaller radius. According to the stoichiometry, the number of the octahedra is equal to the number of the A atoms. Chains (columns) composed

Figure 1. The cubic (a) and hexagonal (b) structures of an ABO_3 perovskite.

of face-sharing octahedra are characteristic of the crystal structure of the 2H polytype of an ABO_3 perovskite (see. Fig. 1 b).

An analysis of the structure of complex oxides belonging to the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family taking into account the stacking sequence of closely packed AO_3 layers (see Fig. 2 a) reveals its close relation to the hexagonal perovskite structure. For this purpose, it is convenient to triple the perovskite formula unit to $A_3B_3O_9$ and represent the composition of a layer with the hexagonal close packing as A_3O_9 . Then the structure of a compound belonging to the family $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ can be considered as a stack of layers with stoichiometries A_3O_9 and $A_3A'O_6$ along the c axis. The $A_3A'O_6$ layers can formally be generated from the A_3O_9 layers by replacing three oxygen atoms with an A' atom. The ratio between the number of $A_3A'O_6$ and A_3O_9 layers is determined by the n/m ratio in the formula $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$. The presence of the $A_3A'O_6$ layers in the oxide structures gives rise to a new type of coordination, additional to the octahedral one, *viz.*, trigonal prismatic (Fig. 2 b). The unit cell parameter a for these compounds relates to the respective parameter of the hexagonal perovskite lattice as $a = \sqrt{3}a_p \approx 10 \text{ \AA}$, whereas the parameter c depends on m and n . A change in the composition of the oxides from ABO_3 to $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ gives rise to the emergence of chains composed of alternating octahedra and trigonal prisms going along the c axis. This structure is typical, for instance, of Sr_4PtO_6 , where one out of four Sr atoms occupies a trigonal prismatic site (Fig. 3). In the $A_3A'BO_6$ oxides, the octahedra are occupied by the B cations, whereas the trigonal prisms are occupied by the A' cations. Evidently, the ratio between the number of prisms and octahedra in the structure is determined by the ratio of stoichiometric coefficients of the A' and B atoms in the formula. For instance, an $A_4A'B_2O_9$ oxide includes one prism per two octahedra and thus contains chains composed of dimers of octahedra

Figure 2. Compositions of alternating layers in oxides of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family for two ultimate stoichiometries. (a) A_3O_9 ($n = 0, m = 1$), (b) $A_3A'O_6$ ($n = 1, m = 0$). The unit cells in the ab plane are shown.

Figure 3. The crystal structure of Sr_4PtO_6 .

The octahedra are occupied by the Pt atoms, the trigonal prisms are occupied by the Sr atoms; open circles denote the Sr atoms that separate the Sr – Pt-chains.

separated by a trigonal prism. In the structure of an $A_9A'_2B_5O_{21}$ oxide, the chains are formed by dimers and trimers of the BO_6 octahedra separated by an $A'O_6$ prism (Fig. 4).¹⁸ The octahedra are connected to each other and to the prisms through face-sharing, which gives rise to rather short metal – metal distances. In these structures, the chains are isolated from each other by the A cations (most frequently, alkaline-earth metals).

Figure 4. A schematic representation of the chain composition for some oxides of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family.¹⁸ (a) $A_3A'MnO_6$, (b) $A_6A'Mn_4O_{15}$, (c) $A_{14}A'_3Mn_8O_{11}$, (d) $A_9A'_2Mn_5O_{21}$. Shaded squares denote trigonal prisms, plain squares denote octahedra.

II. Commensurate and incommensurate oxides

Following the synthesis of some representatives of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family as polycrystalline powders, the frequent formation of incommensurate structures was discovered.^{10, 11, 19} The incommensurability of the oxides is caused by such factors as their quasi-one-dimensional structure, different composition of the $[A]_\infty$ and $[(A',B)O_3]_\infty$ chains and relatively easily occurring inversion of cations over the polyhedral sites in the chains. The crystal structure of a compound is regarded as incommensurately modulated along the c axis provided that the ratio between the translation periods of the two chains is irrational.

Crystal structures of these compounds can be considered as a composite of two interacting subsystems characterised by identical unit cell parameters a and b but different parameters c , *i.e.*, c_1 and c_2 . The first subsystem includes the $[(A',B)O_3]_\infty$ chains with the parameter $c_1 \approx c_{\text{hex.per.}}/2$, which defines the mean distance between the cations within the polyhedral chains. The second subsystem is composed of the $[A]_\infty$ chains with the parameter $c_2 = c_{\text{hex.per.}}$, which defines the mean distance between alternating

A_3O_9 and $A_3A'O_6$ planes. Therefore, the ratio of the translation parameters c_1 and c_2 corresponding to the two mean sublattices is directly related to the stoichiometry. If the c_1/c_2 ratio (the so called γ -component of the modulation vector) is rational, the structure is regarded as commensurate; but if the ratio is irrational, the translation vector along the c axis becomes formally infinite and thus the structure should be regarded as incommensurate.

Therefore, for a commensurate unit cell, $pc_1 = qc_2$, i.e., $c_1/c_2 = q/p$ (q and p are integers). A unit cell of an oxide of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family consists of $2p$ A_3O_9 and/or $A_3A'O_6$ layers and q polyhedra.¹² {Within this model, the c_1 parameter refers to the $[A]_\infty$ -subsystem and the c_2 parameter refers to the $[(A',B)O_3]_\infty$ subsystem.} Each A_3O_9 layer occupies one octahedral site within the chain. Upon the introduction of an $A_3A'O_9$ layer, a prismatic site is generated, which is twice as large as the octahedral site.

Let us consider two ultimate compositions of oxides from the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family, viz., ABO_3 ($n = 0, m = 1$) and $A_3A'BO_6$ ($n = 1, m = 0$). A unit cell of a 2H-perovskite ABO_3 contains two A_3O_9 layers and two transition metal cations, thus $p = 1, q = 2, c_1/c_2 = 2$. Meanwhile, the structure of an $A_3A'BO_6$ oxide includes 6 layers (3 A_3O_9 layers and 3 $A_3A'O_6$ layers) and 4 cations per unit cell, i.e., $p = 3, q = 4, c_1/c_2 = 4/3$. These two limiting cases demonstrate that $(4p/3) \leq q \leq 2p$. For commensurate oxides with the stoichiometry $A_4A'B_2O_9$, $p = 2, q = 3$ and $c_1/c_2 = 3/2$, whereas $p = 3, q = 5$ and $c_1/c_2 = 5/3$ for the $A_6A'B_4O_{15}$ oxides. As has been shown by Blake *et al.*,¹² an analysis of stacking sequences of the $A_3A'O_6$ and A_3O_9 layers based on the parameters p and q allows one to predict possible stoichiometries of compounds from the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ ($m = 1$) $\equiv$ ($A_3A'O_6$) $_n$ (A_3O_9) family and, furthermore, establish criteria for their commensurability.

One compound can have both commensurate and incommensurate modifications. (However it should be kept in mind that these modifications would correspond to different, although quite similar, compositions.) The literature data on the conditions of formation of commensurate and incommensurate phases are somewhat self-contradicting. For instance, $Sr_4CuIr_2O_9$ phases with commensurate and incommensurate structures were prepared by the calcination of reactants in air at the same temperature of 1120 °C for 5 h and 4 days, respectively.¹⁰ A complex oxide Sr_3ZnRhO_6 as a commensurate phase was synthesised from Sr carbonate, Zn oxide and Rh metal by the calcination in a Pt crucible in air first at 800 °C for 10 h and then at 1150 °C for 3 days.²⁰ Meanwhile, the thermal decomposition of the respective metal nitrates at 450 °C for 24 h followed by the calcination at 1150 °C for 3 days yielded the incommensurate phase. The authors speculated that it is a prolonged thermal treatment that is responsible for the formation of incommensurate phases. The transition from the commensurate to the incommensurate phase is realised in a narrow temperature range. As has been suggested,²¹ the transition is irreversible. Information on the chemical composition of the commensurate and incommensurate phases is also ambiguous. According to results by Battle *et al.*,¹⁰ compositions of the two phases of $Sr_4CuIr_2O_9$ are indistinguishable within the error limit, whereas the incommensurate phase of $Sr_3ZnRhO_{6+\delta}$ was found to be richer in oxygen than its commensurate modification. Layland and zur Loye reported²⁰ that the Sr_3MRhO_6 oxide is extremely sensitive to fine details of the synthesis conditions (such as changes in the oxygen partial pressure, heating rate, temperature, duration, etc.), as evidenced by the emergence of the incommensurate phase. It is of note that the c_1/c_2 ratio can vary continuously during the thermal treatment. Moore and Battle argued²² that the composition of the starting load for the synthesis of $Sr_4CuMn_2O_9$ in the commensurate modification should be changed from the stoichiometric 4 : 1 : 2 (Sr : Cu : Mn) to 4 : 1.04 : 1.92.

It may well be suggested that any compound (either with a commensurate or incommensurate structure) is characterised by unique composition and intrinsic structural peculiarities. The

formation of incommensurate structures can be due to the insertion of oxygen into trigonal prisms giving rise to two octahedra instead of a prism, generation of vacancies and changes in the chain length (i.e., the c_1 parameter).

In principle, usual three-dimensional space groups can be used for the interpretation of incommensurate structures, but this requires the postulation of superstructures characterised by extremely large unit cells, which complicates their analysis. In particular, a structural description of an incommensurate phase of the $Sr_{1.3244}Cu_{0.3244}Mn_{0.6756}O_3$ oxide would require a c parameter as large as 191.92 Å.²¹

In practice, it is much more convenient to describe such crystal structures within the so-called superspace formalism with space groups of a higher dimensionality.^{2,19} For this purpose, additional coordinates associated with a shift of the modulation wave with respect to the parent structure by a vector d are introduced. The dimensionality of this new space is given by $3 + d$, where d is the number of linearly independent modulation vectors q . In the reciprocal space, the modulation vector q is defined as:

$$q = \alpha a^* + \beta b^* + \gamma c^*,$$

where α, β and γ are components of the vector q ; a^*, b^* and c^* are the reciprocal unit cell parameters of the unmodified phase.

In the case of $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ oxides, the incommensurability can occur only in one direction, viz., along the c axis, thus $q = \gamma c^*$ and the structure is described in the space of dimensionality $(3 + 1)$.

Four basis vectors are required to index all diffraction lines of a modulated phase

$$H = ha_1^* + kb_1^* + lc_1^* + mc_2^*,$$

where H is the diffraction vector in the reciprocal space. The 'principal' reflections ($hkl0$) with $l \neq 0$ and ($hk0m$) with $m \neq 0$ can be interpreted neglecting the modulation as Bragg reflections corresponding to the $[(A',B)O_3]$ and $[A]$ subsystems, respectively. In such a case, the diffraction pattern manifests no satellite reflections ($hklm$) with $l \neq 0$ and $m \neq 0$. If the two subsystems are mutually ordered, the satellite reflections appear imposed on the main set of principal reflections.

Sometimes, differences in the chemical composition of commensurate and incommensurate phases are so small that they cannot be determined by analytical techniques. To overcome this problem, a model was elaborated within the superspace formalism, which makes it possible to accurately determine the stoichiometry of an $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ oxide based on its X-ray diffraction parameters. For this purpose, the formula of a compound should be rewritten as $A_{1+x}A'_xB_{1-x}O_3$ [$x = n/(3m + 2n)$], since x can be directly related to the γ -component of the modulation vector^{2,19}

$$\gamma = \frac{c_1}{c_2} = \frac{c_2^*}{c_1^*} = \frac{1+x}{2}.$$

The γ value can vary from 0.5 to 0.75, which corresponds to variations in x over a range of $0 \leq x \leq 0.5$. Within this model, x can change continuously, which corresponds to various combinations of octahedra and trigonal prisms in the chain and gives rise to the infinite number of possible unique structures and chemical compositions. Oxides with stoichiometries from ABO_3 to $A_3A'BO_6$ fall into this range. As has been mentioned above, the ratio between the number of prisms and octahedra in the chain is determined by the ratio between the number of atoms A' and B

$$\frac{N_{\text{prism}}}{N_{\text{oct}}} = \frac{x}{1-x}.$$

Therefore, if the c_1/c_2 ratio is known, the value of x can be determined from the above expression with a high accuracy, which is equivalent to the precise knowledge of stoichiometry for an $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ oxide. This implies that a compound

$A_{1+x}A'_xB_{1-x}O_3$ can be considered as incommensurate or commensurate provided that x is irrational or rational, respectively.

Atomic density modulation functions for compounds of this family can be described within the superspace formalism with sawtooth functions of occupancies and modulations of shifts along the c axis. The major advantage of the use of sawtooth shift modulation functions is the significant decrease in the number of independent variables describing the structure. By varying the parameters, compounds with any stoichiometries (or with any values of x), including ultimate ones, such as 2H-perovskite ABO_3 ($x = 0$) or $A_3A'BO_6$ ($x = 0.5$), can be represented.

In a structural study of an incommensurate phase of $Sr_{1+x}Cu_xMn_{1-x}O_3$ ($x = 1/3$),²¹ the Bragg peaks observed in the experimental diffraction pattern were initially indexed based on two sublattices: $[(Cu, Mn)O_3]$ in the space group $R\bar{3}m$ and $[Sr]$ in the space group $P3c1$ (Fig. 5) with similar a parameters and different c parameters, i.e., c_1 and c_2 . The c_1/c_2 ratio was found to be 0.6625, which clearly indicated the incommensurability of the phase (a ratio 0.666 and $x = 0.3250$ are expected for the respective commensurate oxide with a similar composition). The refinement in the superspace group $R\bar{3}m(00\gamma)0s$ yielded the precise stoichiometry ($x = 0.3244$) and unit cell parameters $a = 9.5933(7)$ Å, $c_1 = 2.5933(3)$ Å and $\gamma = 0.6622(1)$. The stoichiometry determined differ from $Sr_4CuMn_2O_9$ by an increased Mn/Cu ratio and a larger number of octahedral sites in the chains going along the c axis. The elementary unit of the chain includes 11 combinations (1 TP + 2 O) and one combination (1 TP + 3 O), where TP means trigonal prism and O means octahedron.

Figure 5. The Rietveld refinement of the powder pattern for a composite oxide, $Sr_{1.3244}Cu_{0.3244}Mn_{0.6756}O_3$: experimental data (dots), best-fit and difference.²¹

The positions of reflections indexed for two independent sublattices in 3D-space groups are marked with dashes; non-indexable reflections are marked with arrows.

The results reported by Abakumov *et al.*²³ and by Mironov *et al.*²⁴ can be cited as an illustrative example on the structure determination of a quasi-one-dimensional oxide, $Sr_{1.32}Mn_{0.83}Cu_{0.17}O_3$, using a combination of techniques, including electron diffraction, high-resolution electron microscopy and X-ray diffraction coupled with the crystal structure refinement in the $(3+1)D$ -space. The experimentally found value of γ for this compound was 0.6616(1), which corresponds to $x = 0.3232$ in $A_{1+x}A'_xB_{1-x}O_3$. This value is close to the ratio $p'/q' = 1/3$,

where p' is the number of prisms in the chain and the number of octahedra is $q' - p'$ (see †). Taking into account that $x = p'/q'$, this may be rewritten as

$$\frac{N_{\text{prism}}}{N_{\text{oct}}} = \frac{x}{1-x} = \frac{p'}{q'-p'}.$$

Based on this expression, the sequence of octahedra and prisms in the chain was determined. According to the Farey's rule,² a sequence with the most uniform distribution of trigonal prisms is realised in the chain of polyhedra. Therefore, the ratio p'/q' for $x = 0.3232$ should be 32/99. This implies that the chain of polyhedra going along the c axis contains 99 polyhedra representing dimers and trimers of octahedra separated by single trigonal prisms. The overall parameter c appears close to 515 Å, which makes a traditional description of the structure in the 3D-approximation impossible. In contrast to the $Sr_{1.3244}Mn_{0.6756}Cu_{0.3244}O_3$ phase discussed above,²¹ the trigonal prismatic sites in $Sr_{1.32}Mn_{0.83}Cu_{0.17}O_3$ are occupied by the Cu and Mn cations $[Sr_{1.323}(Cu_{0.174}Mn_{0.149})_{\text{prism}}(Mn_{0.677})_{\text{oct}}O_3]$ (Ref. 23).

The X-ray diffraction pattern of $Sr_3ZnRhO_{6.34}$ can be indexed²⁰ assuming two sublattices with $a = 9.6378(5)$ Å and $c = 2.7012(2)$ Å in the space group $R\bar{3}m$ and with $a = 5.5640(9)$ Å and $c = 3.9539(7)$ Å in the space group $P31c$. For this phase, the ratio $c_1/c_2 = 0.6832$ is significantly smaller than the ideal value 3/4 expected for the commensurate phase Sr_3ZnRhO_6 . On the other hand, this value is close to 2/3 typical of structures comprising two octahedra and one trigonal prism along the c axis. Such a structure corresponds to the composition $A_4A'B_2O_9$. The increased oxygen content in the incommensurate phase can indicate the transformation of trigonal prisms into octahedra upon the respective synthesis conditions. Stitzer *et al.*¹³ noted that it should be possible to detect such a transition using the thermogravimetric analysis, although no experimental evidence of the process has been reported so far. Presently, the conditions of synthesis favouring the formation of the above oxides with either commensurate or incommensurate structures remain unclear.

III. Low-dimensional platinum group metal oxides

1. $A_3A'BO_6$ oxides

Platinum metals form an extended series of quasi-one-dimensional oxides with the common stoichiometry $A_3A'BO_6$. Oxides with other compositions have also been reported. Selected examples of these compounds are listed in Table 1. A systematic analysis indicates that the platinum group metals in the quasi-one-dimensional $A_3A'BO_6$ oxides can be in the tri- (Rh), tetra- (Rh, Pt, Ir or Ru) and pentavalent (Ru, Ir or Rh) states. It is of note that complex Rh^{5+} oxides from this family (e.g., Sr_3NaRhO_6 and Sr_3LiRhO_6) were the first examples of rhodium oxides in the formal oxidation state 5+ (see Ref. 53). These compounds were synthesised at 600 °C by the crystallisation of a melt of RhO_2 , $Sr(OH)_2$ and alkali metal hydroxides at ambient pressure. These compounds manifest low stability in air. Upon their storage in a humid atmosphere, Rh^{5+} undergoes partial reduction to Rh^{4+} .

The A' sites can be occupied by alkali metals, 3d elements (most typically, bivalent), Cd, Mg and rare-earth elements. The vast majority of $A_3A'BO_3$ oxides ($B = Pt, Ir, Rh, Ru$) are isostructural to Sr_4PtO_6 . The Sr_4PtO_6 oxide is crystallised in the rhombohedral space group $R\bar{3}c$ with $a = 9.740(2)$ Å and $c = 11.900(2)$ Å (in the hexagonal setting). A similar structure is also typical of Ca_4PtO_6 (Refs 25 and 26) and Ba_4PtO_6 (Ref. 30). The unit cell parameters of these oxides are somewhat modified as compared to the aforementioned values of the Sr^{2+} compound according to the ionic radii of Ca^{2+} and Ba^{2+} .

† The parameters p' and q' relate to the aforementioned parameters p and q through the following expressions: $p' = 2p - q$, $q' = q$.

Table 1. Chemical compositions of oxides of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family (B is a platinum group metal).

5	9	A ₁₄ A'B ₈ O ₃₃	
7	9	A ₁₆ A'B ₁₀ O ₃₉	

Oxides containing divalent copper in the A' sites (in particular, Sr₃CuPtO₆, Sr₃CuIrO₆, Ca₃CuIrO₆ and Ca₃CuRhO₆) are characterised by slightly different structures due to the Jahn–Teller nature of the Cu²⁺ cation. The change is due to a shift of the Cu²⁺ cation from the centre of the trigonal prism towards one of its rectangular faces. As a result, the symmetry lowers from rhombohedral to monoclinic (space group *C2/c*). The crystal structure of a monoclinic modification of the Ca_{3.1}Cu_{0.9}RuO₆ oxide is shown in Fig. 6. Interestingly, the presence of calcium cations in the trigonal prismatic sites does not increase the symmetry of the phase and both the Ca²⁺ and Cu²⁺ ions in the prismatic sites are actually located in one of the faces adopting the planar square coordination.

The A sites in the A₃A'BO₆ oxides are preferably occupied by alkaline-earth metals. The only exception to this rule is represented by the (Na,La₂)NaPtO₆ oxide, where La and Na jointly occupy the A sites. A half of Na⁺ cations in this structure occupy the trigonal prismatic sites.

2. Oxides with other stoichiometries

A number of platinum group metal oxides corresponding to other *n* and *m* have been synthesised, which are characterised by a larger ratio of the number of octahedral sites to that of prismatic sites than in A₃A'BO₆ (see Table 1). Among them, Sr₄Ru₂O₉ is worth mentioning, since a quasi-one-dimensional structure with empty trigonal prisms is known for this compound.

An increase in the fraction of octahedra in the chain gives rise to an increase in *c*. For instance, *c* is 35.0564 Å for Ba₁₆Cu₃Ir₁₀O₃₉. Such oxides are characteristic of two metals, *viz.*, Ir and Rh, with one exception represented by Ba₄Pt_{1.7}Cu_{1.1}O_x. This phase was obtained in an attempted growth of single crystals of ErBa₂Cu₃O₇, a high-temperature superconductor, in a platinum crucible.⁵⁹ The structural studies of these objects are complicated by the necessity to refine a large number of positional parameters. Nevertheless, the structure of

**Figure 6.** The crystal structure of Ca_{3.1}Cu_{0.9}RuO₆.⁴⁸

The orientation of chains of polyhedra in the monoclinic unit cell (*a*), the arrangement of atoms within a chain (*b*) and the expanded view of a trigonal prismatic site (*c*) are shown.

Ba₁₆Cu₃Ir₁₀O₃₉ with 54 independent atoms in a unit cell[‡] was successfully refined based on the neutron diffraction data.¹²

As a rule, only small plate-, needle- or rod-like single crystals of A_{3n+3m}A'_nB_{3m+n}O_{9m+6n} oxides (A = Ca, Sr, Ba; A' = Cu, Ni, Co, Zn, Mg; B is a platinum group metal, Mn, *etc.*) can be grown. The vast majority of single crystals was grown from various fluxes composed of metal carbonates, hydroxides, halides or their eutectic mixtures. Alkaline-metal carbonates, metals, simple or pre-prepared complex oxides with a specific composition were used as reactants. The syntheses were conducted in aluminium, platinum, silver or nickel crucibles in air or in sealed ampoules (as in the case of Sr₃NaIrO₆, see Ref. 43). In particular, single crystals of Ba₈CoRh₆O₂₁ were grown⁵⁶ from a potassium carbonate flux in an alumina crucible starting from Rh, BaCO₃ and Co₃O₄ powders. The loaded crucible was heated in air from room temperature to the reaction temperature of 1050 °C at a rate of 600 °C h^{−1}, kept at this temperature for 12 h and cooled down to 875 °C at a rate of 12 °C h^{−1}. Then the furnace was switched off and the crucible with the reaction product was left inside the furnace to slowly cool down. The flux was removed by washing with water, and the crystals were withdrawn from the crucible. Single crystals of Sr₁₄Cu₃Mn₈O₃₃ were synthesised in a similar way (the annealing at 1200 °C for 48 h followed by cooling down to 880 °C at a rate of 6 °C h^{−1}).²¹

[‡] To our knowledge, this is the most complex structure among this class of oxides solved and refined from powder diffraction data.

Relatively large single crystals were obtained using the method of crystal growth from salt melts. This enabled high-precision structural elucidations and verification of the magnetic anisotropy of these compounds. Studies of single crystals of the $\text{Ba}_8\text{CoRh}_6\text{O}_{21}$ oxide have shown⁵⁶ that its structure is built up of six successive RhO_6 polyhedra and a distorted CoO_6 trigonal prism. The cobalt–oxygen (2.184–2.197 Å) and rhodium–oxygen (1.905–2.055 Å) distances lie in the typical range of distances formed by these cations in similar oxides. According to calculations of the valence force sums, the Rh and Co ions in the chain are in the tetra- and divalent states, respectively, although the combination $\text{Co}^{3+}-\text{Rh}^{3+}-5\text{Rh}^{4+}$ also cannot be ruled out. With this respect, it has to be noted that the valence state combination $(\text{A}')^{2+}-\text{Rh}^{4+}$ has been postulated for $\text{Ca}_3\text{A}'\text{RhO}_6$

(A = Co and Fe) based on analysis of the structural and magnetic data.⁴⁹

IV. Low-dimensional d and p element oxides

Quasi-one-dimensional complex oxides of the family $\text{A}_{3n+3m}\text{A}'_n\text{B}_{3m+n}\text{O}_{9m+6n}$ with 3d elements occupying the B sites include cobalt and nickel compounds with the common formulas $\text{Ca}_3\text{Co}_2\text{O}_6$ ($m=0, n=1$),⁶⁰ $\text{Sr}_4\text{Ni}_3\text{O}_9$ ($m=1, n=3$),^{61,62} $\text{Ba}_6\text{Ni}_5\text{O}_{15}$ (Ref. 63) and $\text{Sr}_6\text{Co}_5\text{O}_{16}$ ($m=1, n=1$);⁶⁴ manganese compounds with the formulas $\text{Ca}_3\text{A}'\text{MnO}_6$ and $\text{Ba}_6\text{A}'\text{Mn}_4\text{O}_{15}$ ($\text{A}' = \text{Zn, Co, Cu}$)^{65–72} and some other examples, are listed in Table 2.

Table 2. The chemical compositions of oxides of the $\text{A}_{3n+3m}\text{A}'_n\text{B}_{3m+n}\text{O}_{9m+6n}$ family (B = Co, Ni, Mn and other 3d or p elements).

The structures of Co and Ni complex oxides are similar to those of the platinum metal-based compounds discussed above. Typically, octahedra and trigonal prisms forming the chains going along the *c* axis contain the same d element in different oxidation states.

In contrast to the Co and Ni compounds, quasi-one-dimensional manganese oxides were obtained only in a combination with other elements occupying the trigonal prismatic sites. Such compounds can be synthesised under normal conditions in air. The manganese atoms occupy the octahedral sites, whereas the A' sites can be occupied by such metals as Zn, Co, Ni, Cu or Mg, as in the case of platinum metal complex oxides.

1. $A_3A'MnO_6$ oxides

Manganese-containing oxides belonging to the $A_3A'MnO_6$ family were synthesised only with calcium. Ni, Co, Zn and Cu can act as A'. Attempted syntheses of $Sr_3A'MnO_6$ ($A' = Co, Ni$) oxides afforded a $Sr_3NiMnO_{6.36}$ phase, which appeared similar in terms of both stoichiometry and structure to $A_4A'B_2O_9$ compounds ($n = 3, m = 1$). A transition from the initial composition of $Sr_3NiMnO_{6.36}$ to $A_4A'B_2O_9$ has resulted⁸⁴ in a modified formula, viz., $Sr_4(Sr_{0.20}Ni_{1.40}Mn_{1.40})O_{8.88}$.

The crystal structure of $Ca_3A'MnO_6$ with $A' = Ni, Co$ or Zn was refined in the space group $R\bar{3}c$ in the hexagonal setting (the Sr_4PtO_6 structural type). A similar structure was earlier confirmed for $Ca_3Co_2O_6$.⁶⁰ In this oxide, Co^{3+} cations in the octahedral and trigonal prismatic sites adopt the low-spin (LS) and high-spin (HS) states, respectively. An investigation of the formation of $Ca_3Co_{1-x}Mn_{1-x}O_6$ solid solutions gave rise to two new isostructural oxides, Ca_3CoMnO_6 and $Ca_3Co_{1.25}Mn_{0.75}O_6$.⁷¹ The unit cell parameters of both Ca_3CoMnO_6 and $Ca_3Co_{1.25}Mn_{0.75}O_6$ are significantly larger than those of $Ca_3Co_2O_6$ due to the larger ionic radius of manganese as compared to cobalt.

The presence of cationic combinations $(A')^{2+} - Mn^{4+}$ in the $Ca_3A'MnO_6$ oxides ($A' = Ni, Co$ or Zn) was suggested based on the analysis of interatomic distances and magnetic susceptibility measurements. The trigonal prismatic sites in these oxides are occupied by the Co, Ni or Zn ions. (In the case of Ca_3NiMnO_6 , 8% of the Mn atoms are substituted with Ni;^{69,70} this explains the presence of admixing nickel oxide NiO in the samples studied.)

The Co–O (2.140 Å) and Ni–O (2.137 Å) interatomic distances, as determined in structural studies of these phases, are close to typical values observed in other oxides with the respective metals in the divalent state. The A'–Mn interatomic distances in the chains are 2.645 Å, 2.650 Å and 2.658 Å for Co, Ni and Zn phases, respectively. So short A'–Mn distances are explained by the fact that the octahedra containing the Mn^{4+} cations are combined with the trigonal prisms with the $(A')^{2+}$ cations into the infinite chains by face-sharing. Despite the presence of short Mn–A' contacts, no direct metal–metal bonds are formed, and all these oxides are insulators, according to the measurements of their specific resistivity.

In contrast to the manganese-based $Ca_3A'MnO_6$ oxides with $A' = Ni, Co$ or Zn discussed above, the crystal structure of a Ca_3CuMnO_6 oxide was refined in the triclinic space group $P\bar{1}$. According to the combined structure refinement against neutron and X-ray diffraction data, this triclinic unit cell can be derived from a C-centred monoclinic cell of Sr_3CuPtO_6 (the $C2/c$ space group). Nevertheless, in contrast to the structure of Sr_3CuPtO_6 , there are two independent positions of both Cu and Mn atoms in the unit cell of Ca_3CuMnO_6 . According to the refinement of partial occupancies of these atomic positions, 90% of the Cu(1) sites are occupied by the copper atoms, whereas 10% of them are occupied by the manganese atoms. The Cu(2) sites are exclusively occupied by copper. Both types of copper atoms are in the trigonal prismatic cavities. However, detailed analysis of the copper–oxygen interatomic distances has revealed that the coordination numbers of both types of copper atoms are better described as (4+2). Assuming the planar square coordination environment (the coordination number of 4), the mean copper–oxygen dis-

tances are 2.122 Å and 2.026 Å for the Cu(1) and Cu(2) sites, respectively.

Such a coordination environment is a manifestation of the Jahn–Teller effect typical of the divalent copper cations. Due to the substitution of 10% of the copper atoms in the Cu(1) sites with Mn, the mean cation–anion distances increase (2.122 Å for the coordination number of 4) and the atoms shift towards the centre of the trigonal prism. Taking into account two more remote oxygen atoms (*i.e.*, for the coordination number of 4+2), the mean Cu(1)–O distance is 2.201 Å. Meanwhile, the Cu(2) atoms are located virtually in the centre of a lateral face of the trigonal prism. Two types of manganese atoms [*i.e.*, Mn(1) and Mn(2)] are located inside the octahedra and the mean manganese–oxygen distances are 1.929 Å and 1.904 Å, respectively. A unit cell of Ca_3CuMnO_6 contains six crystallographically independent types of the calcium atoms, which occupy distorted square antiprismatic sites (the coordination number of 8). The mean Ca–O distances lie in the range from 2.425 Å to 2.513 Å. The octahedra accommodating the Mn(1) and Mn(2) atoms are combined with the trigonal prisms with the Cu(1) and Cu(2) atoms through face-sharing (Fig. 7) to form isolated zigzag chains composed of alternating copper and manganese atoms in a sequence: ... Mn(1)Cu(1)–Mn(2)Cu(2)Mn(1) ..., *etc.* The chains are isolated from each other with columns of distorted square antiprisms of oxygen atoms accommodating the calcium ions.

Figure 7. A projection of the crystal structure of Ca_3CuMnO_6 to the (010) plane.

A unit cell and isolated chains of the MnO_6 octahedra (two types) and CuO_6 trigonal prisms (two types) are shown.

It is of note that a minor modification of the Ca_3CuMnO_6 oxide afforded another compound, $Ca_{3.1}Cu_{0.9}MnO_6$.¹⁰² Its crystal structure at 302 K was refined in the rhombohedral space group $R\bar{3}c$, as for other $Ca_3A'MnO_6$ ($A' = Co, Ni, Zn$) oxides. However a new triclinic phase appears in the sample in addition to the rhombohedral one upon cooling to 294 K, which further becomes the dominant phase at 288 K. Similar phase transitions occurring at different temperatures were also detected for other compounds containing the Jahn–Teller Cu^{2+} ions in the A' sites, such as $Sr_3Cu_{1-x}M_xIrO_6$ ($M = Ni, Zn; 0 \leq x \leq 0.5$) and $Ca_{3.1}Cu_{0.9}RuO_6$.¹⁰² In particular, a disordered rhombohedral structure of $Ca_{3.1}Cu_{0.9}RuO_6$ converts into an ordered monoclinic phase upon cooling to below 623 K.

2. Oxides with other stoichiometries

Some more complex oxides belonging to the family $A_{3n+3m}A'_nMn_{3m+n}O_{9m+6n}$ (with larger *n* and *m* and with a higher fraction of the octahedral sites in the chains) are also given in Table 2. Due to the similarity of ionic radii of manganese and other 3d elements, these phases possess specific structures and

manifest particular magnetic properties thus attracting a lot of attention from researchers. In particular, Melkorezova and Bazuev⁸⁷ demonstrated the existence of solid solutions with the common stoichiometry $\text{Sr}_4\text{Ni}_{3-x}\text{Mn}_x\text{O}_9$ in addition to the individual $\text{Sr}_4\text{NiMn}_2\text{O}_9$ oxide. These solid solutions were synthesised by the citrate method, which usually affords commensurate phases. However it was found that $\text{Sr}_4\text{Ni}_3\text{O}_9$ samples prepared in this way contained some amounts of NiO and SrO . The solid solutions $\text{Sr}_4\text{Ni}_{3-x}\text{Mn}_x\text{O}_9$ reveal a complex pattern of changes in the unit cell parameters (Fig. 8). The a parameter linearly increases with an increase in the Mn content, whereas c first decreases but then starts to increase passing a minimum at $x = 1.5$. The unit cell volume increases non-monotonically with an increase in x (*viz.*, with an inflexion at $x = 1.5$). Two oppositely directed factors affect the value of c as a function of the solid solution composition. The first factor is a gradual replacement of smaller Ni^{4+} cations with larger Mn^{4+} cations in the B sites. The second factor is a shortening of the Ni–Mn interatomic distances due to a shift of a part of the Ni^{2+} cations in the A' sites towards the faces of trigonal prisms. The experimental dependence of c on the composition indicates that the effects of the shift of Ni from the centres of prisms towards their faces prevail in the initial stages of the formation of the solid solutions (below $x = 1.5$), whereas the effects of manganese substitution for nickel starts to dominate in the late stages ($x > 1.5$).

Quarez *et al.*¹⁰³ reported the synthesis of a new representative of the $\text{A}_{3n+3m}\text{A}'_n\text{B}_{3m+n}\text{O}_{9m+6n}$ family, $\text{Ba}_4\text{NaMn}_2\text{O}_9$ ($n = 3$, $m = 1$), which is characterised by a quasi-one-dimensional structure with $a = 10.006(2)$ Å and $c = 8.210(3)$ Å (the $P321$ space group). This compound was prepared as single crystals electro-

chemically in NaOH melt. All attempts at the solid-state synthesis of this phase under various experimental conditions failed. In the $\text{Ba}_4\text{NaMn}_2\text{O}_9$ oxide, the sodium and manganese cations occupy the trigonal prismatic and octahedral sites, respectively. The authors argue that this compound represents the first example of manganese in the mean oxidation state of $4.5+$. It has to be noted, however, that the mixed-valence state of manganese in this compound was confirmed through neither magnetic nor spectroscopic measurements. No experimental evidence on an ordered arrangement of the Mn^{4+} and Mn^{5+} ions in the available crystallographic sites was given.

A similar hexagonal phase was also detected in the Sr-Li-Mn-O system. It was synthesised by the solid-state method from manganese oxide and lithium and strontium carbonates.¹⁰⁴ The X-ray diffraction pattern of this phase was satisfactory indexed in the $P321$ space group with $a = 9.42(1)$ Å and $c = 7.85(1)$ Å, similarly to the respective diffraction patterns of $\text{Sr}_4\text{Ni}_3\text{O}_9$ (Ref. 61) and $\text{Sr}_{12}\text{Ni}_{7.5}\text{O}_{27}$.¹⁰⁵ However this phase cannot exactly correspond to the composition of $\text{Sr}_4\text{LiMn}_2\text{O}_9$, since a $\text{Sr}_7\text{Mn}_4\text{O}_{15}$ impurity is always formed in addition to the hexagonal product when the exact stoichiometric load is taken for the solid-state synthesis.¹⁰⁶

A few strontium-based incommensurate oxides, *viz.*, $\text{Sr}_{14}\text{A}'_3\text{Mn}_8\text{O}_{33}$ [$A' = \text{Cu}$ (Ref. 21) or Co (Ref. 98)] and $\text{Sr}_9\text{A}'_2\text{Mn}_5\text{O}_{21}$ [$A' = \text{Ni}$ (Ref. 92) or Co (Refs 97 and 98)], have been synthesised, whereas no Ca- or Ba-containing analogues have been reported. The idealised crystal structures of $\text{Sr}_{14}\text{Co}_3\text{Mn}_8\text{O}_{33}$ and $\text{Sr}_9\text{Co}_2\text{Mn}_5\text{O}_{21}$ are shown in Fig. 9.

Apart from Mn, Co and Ni, some other 3d transition metals form quasi-one-dimensional oxides. In particular, syntheses of chromium-containing oxides with the composition Sr_3MCrO_6 ($M = \text{Sc}$, In , Lu-Ho , Y) in sealed quartz ampules at 1050°C were reported.⁷³ The Cr^{3+} cations in these compounds occupy the octahedral sites, whereas the trigonal prismatic sites are occupied by rare-earth elements. Probably, the $\text{Sr}_4\text{Cr}_3\text{O}_9$ oxide with a chain-like structure synthesised as single crystals (the $C_3^1-P_3$ space group, $z = 3$)⁷⁹ also belongs to this family. In this structure, the Cr^{3+} and Cr^{4+} cations occupy the octahedral and trigonal prismatic sites, respectively. A series of quasi-one-dimensional $\text{Sr}_3\text{LnNiO}_6$ oxides ($\text{Ln} = \text{Sc}$, In , Lu-Er) have been reported.⁷⁴ In these phases, the Ln^{3+} cations in the stable oxidation state stabilise nickel in the oxidation state $3+$. Colourless crystals of Ba_3NaBO_6 ($B = \text{Nb}$, Ta) with a trigonal structure have been synthesised by Wehrum and Hoppe.⁷⁶

Figure 8. The unit cell parameters a (a), c (b) and volume V (c) for $\text{Sr}_4\text{Ni}_{3-x}\text{Mn}_x\text{O}_9$ solid solutions as a function of composition (x).

Figure 9. A polyhedral representation of the idealised crystal structures of $\text{Sr}_{14}\text{Co}_3\text{Mn}_8\text{O}_{33}$ (a) and $\text{Sr}_9\text{Co}_2\text{Mn}_5\text{O}_{21}$ (b).⁹⁸

Some low-dimensional $A_3A'BO_6$ oxides containing p elements, in particular, Pb (Ref. 75), Sb (Ref. 77) and Bi (Ref. 78) were synthesised (see Table 2). In these oxides, antimony and bismuth have an oxidation state of +5 and occupy the octahedral B sites in the chains. In contrast, the Pb^{4+} ions occupy the trigonal prismatic sites in the Sr_3PbNiO_6 oxide.

V. Specific features of the formation of $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ oxides

Oxides with the stoichiometry $A_3A'BO_6$ constitute the most numerous group of compounds within the family. The A sites in the oxides of this group are occupied by divalent alkaline-earth metals, *i.e.*, Ca, Sr or Ba (among them, strontium compounds are most widespread). The cationic pairs $A'B$ can correspond to various combinations of the oxidation states, *i.e.*, $(A')^+ - B^{5+}$, $(A')^{2+} - B^{4+}$, $(A')^{3+} - B^{3+}$ and $(A')^{4+} - B^{2+}$ (see⁸). In an analysis of reasons governing the distribution of cations over the two available sites it should be taken into account that the trigonal prismatic A' sites are characterised by a significantly larger size than the octahedral B sites. The B cations tend to occupy the octahedral sites since they typically have a higher charge and, respectively, a smaller ionic radius in the $A'B$ pair. The Sr_3LiBiO_6 oxide represents an exception to this rule, since it is the Li^+ cations that occupy the octahedral sites in this compound.[†] The authors suggested⁷⁸ that the trigonal prismatic sites are too large to accommodate the Li^+ cations. It is of note that this oxide is crystallised in a triclinic lattice, unlike the vast majority of the $A_3A'BO_6$ compounds.

Sr_3PbNiO_6 is another exception to the above rule. In this oxide, the highly charged Pb^{4+} ions ($r = 0.775$ Å) occupy the trigonal prismatic sites, whereas the smaller Ni^{2+} cations ($r = 0.69$ Å) appear in the octahedral B sites. Smith *et al.*,⁷⁵ who synthesised the Sr_3PbNiO_6 phase for the first time, utilised the term 'inverse' to describe its structure by analogy with the normal and inverse spinels. The presence of the Ni^{2+} ions in the octahedral sites of the Sr_3PbNiO_6 oxides is very surprising since nickel occupies the trigonal prismatic sites in all other known $A_3A'BO_6$ oxides.

The presence of large Ba^{2+} cations ($r = 1.42$ Å for the coordination number of 8)¹⁰⁷ in the A sites of $A_3A'BO_6$ oxides conforms to the general trend that only large alkali metal cations occupy the A' sites in the $Ba_3A'BO_6$ oxides, where $A' = Li, Na$; $B = Ir, Ru, Sb, Bi, Nb, Ta$). It might be suggested that a Ba_3MnBO_6 oxide containing the Mn^{2+} ions with the largest ionic radius among divalent 3d elements should exist. However this can be realised only with large tetravalent cations as B. The existence of complex oxides with the common formula A_4PtO_6 ($A = Ca, Sr, Ba$) with the A^{2+} cations in the trigonal prismatic A' sites, which are characterised by similar structures, probably means that there is no limitation on the maximum radius of an A' cation for the cationic pair $(A')^{2+} - B^{4+}$.

It has to be noted that only Ca^{2+} ions ($r = 1.12$ Å), which have the smallest ionic radius in the series $Ca^{2+} - Sr^{2+} - Ba^{2+}$, are capable of forming $A_3A'MnO_6$ oxides with the small Mn^{4+} ions in the B sites.

The influence of the size factor on the stability of the oxides has been analysed in detail for the cationic pair $(A')^{3+} - B^{3+}$. In a series of compounds with the common formula Sr_3LnRhO_6 [$r(Rh^{3+}) = 0.665$ Å], only phases with $Ln = Sc, In, Yb - Sm$ appear stable.^{51,52} For the Sr_3LnCrO_6 series [$r(Cr^{3+}) = 0.615$ Å], stable compounds were obtained with $Ln = Sc, In, Lu - Ho$ and Y .⁷³ Among Sr_3LnNiO_6 oxides (the ionic radius of the Ni^{3+} cation in the low-spin state is 0.56 Å), the

phases with $Ln = Sc, In, Lu - Er$ and Y are stable.⁷⁴ It is evident that the size of the trigonal prismatic cavities is insufficient to accommodate rare-earth metal cations larger than Ho^{3+} and Y^{3+} in the latter case. The above example demonstrates that a contraction of the octahedral site due to the introduction of smaller ions instead of larger ones results in the respective contraction of the trigonal prismatic sites and *vice versa*. Exactly due to this reason, the trigonal prismatic cavity appears quite appropriate for the Li^+ cations in Sr_3LiSbO_6 but too loose in Sr_3LiBiO_6 . The ionic radii of the alkaline-earth metal cations in the A (see above) and A' sites produce analogous effects. In particular, the Mg^{2+} cation can be introduced in an A_3MgBO_6 oxide only provided that $A = Sr$ (with the exception of Ca_3MgIrO_6).⁴¹

Let us now consider the specific features of the formation of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ oxides and the influence exerted on this process by the size of cations. Manganese-containing oxides with the stoichiometry $A_3A'MnO_6$ exist only for $A = Ca$. Meanwhile, stable $A_4A'Mn_2O_9$ oxides are known only for Sr (with the single exception of $Ca_4CuMn_2O_9$). Barium forms groups of oxides belonging to the family starting from the composition $A_5A'Mn_3O_{12}$. As has been discussed above, the n/m ratio determines the ratio between the numbers of the $[A_3A'O_6]$ and $[A_3O_9]$ layers stacked along the c axis. In the $A_3A'MnO_6$ oxides ($n = 1, m = 0$), all the $[A_3O_9]$ layers are replaced with $[A_3A'O_6]$. In the $A_4A'Mn_2O_9$ oxides, three $[A_3A'O_6]$ layers occur per $[A_3O_9]$ layer. Therefore, the distance between neighbouring A_3O_9 layers should increase with an increase in the number of octahedra in the chains; this is achieved by an increase in the ionic radius of the A^{2+} cation upon the replacement of Ca with Sr and Ba. In other words, a higher fraction of octahedra in the chains requires a larger cation in the A site.

The cationic compositions of the $A_3A'BO_6$ oxides is similar to the compounds from the Ruddlesden–Popper family (*i.e.*, $A_3B_2O_7$ or $A_{n+1}B_nO_{3n+1}$ with $n = 2$). Taking into account that some of the Ruddlesden–Popper oxides contain two different cations in the B sites [*e.g.*, $Sr_3FeCoO_{7-\delta}$,¹⁰⁸ $Sr_3Fe_{2-x}Mn_xO_{7-\delta}$ (Ref. 109)] and the oxygen deficiency δ can be as large as 1, it might be expected that they undergo structural transitions into quasi-one-dimensional structures. Indeed, a transition from the Ruddlesden–Popper structure to a quasi-one-dimensional structure of the $A_3A'BO_6$ type was observed in $Sr_3ScCoO_{6+\delta}$.¹¹⁰ The former phase, $Sr_3ScCoO_{6.08}$, was synthesised at 1250 °C, whereas the latter, at 1100 °C. However the quasi-one-dimensional Sr_3ScCoO_6 complex oxide undergoes amorphisation and probably decomposition upon storage in air.

VI. Magnetic properties

The presence of transition metals and the quasi-one-dimensional character determines the specific magnetic properties of the oxides under consideration. The relation of magnetic properties to the structure is governed to a large extent by a high degree of mutual isolation of the $[A'B_nO]_\infty$ chains. According to magnetic studies of single crystals of these compounds, the low-dimensional character of their structures gives rise to a pronounced anisotropy of their magnetic properties. These systems typically undergo magnetic ordering at low temperatures. Notwithstanding, some compounds from the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family are characterised by relatively high temperatures of the magnetic ordering, despite their quasi-one-dimensional structures. In particular, $Ca_3A'RuO_6$ oxides ($A' = Li, Na$) manifest a collinear magnetic structure with the Néel temperature of $T_N \approx 100$ K.⁹ So high value of T_N implies a three-dimensional antiferromagnetic ordering. $Sr_3A'BO_6$ complex oxides manifest the whole spectrum of magnetic properties (Table 3): they reveal either 1D-antiferromagnetism or ferromagnetism. Furthermore, ferromagnetic interactions inside the chain and antiferromagnetic interchain interactions are typical of these phases. The disordered quantum spin chain paramagnetism has been discovered for the first time in a compound from this family,

§ It is of note that strontium forms compounds with all possible cationic pairs, whereas barium-containing oxides are known mainly for the $(A')^+ - B^{5+}$ cationic pairs.

† The Li^+ and Bi^{5+} cations are characterised by identical ionic radii (0.76 Å).¹⁰⁷

Table 3. The magnetic properties of $\text{Sr}_3\text{A}'\text{BO}_6$ oxides ($\text{A}' = \text{Ni, Cu, Zn, Co}$; $\text{B} = \text{Ir, Pt}$).

Compound	Properties
$\text{Sr}_3\text{NiIrO}_6$	antiferromagnetism
$\text{Sr}_3\text{CuIrO}_6$	ferromagnetism
$\text{Sr}_3\text{ZnIrO}_6$	antiferromagnetism
$\text{Sr}_3\text{NiPtO}_6$	"
$\text{Sr}_3\text{CuPtO}_6$	"
$\text{Sr}_3\text{CoPtO}_6$	disordered spin chain paramagnetism
$\text{Sr}_3\text{ZnPtO}_6$	diamagnetism
$\text{Sr}_3\text{CuIr}_{0.5}\text{Pt}_{0.5}\text{O}_6$	disordered spin chain paramagnetism

$\text{Sr}_3\text{CuPt}_{0.5}\text{Ir}_{0.5}\text{O}_6$ (see Ref. 8). The $\text{Ca}_3\text{Co}_2\text{O}_6$ oxide undergoes the ferrimagnetic ordering at $T < 25$ K (Ref. 111) due to the ferromagnetic and antiferromagnetic exchange interactions between the cobalt cations located within the same chain and in neighbouring chains, respectively.

For the analysis of magnetic properties it would be convenient to subdivide the $\text{A}_3\text{A}'\text{BO}_6$ compounds into two groups: in the first group, magnetic cations occupy exclusively the octahedral sites and in the second group, the magnetic cations occupy both the octahedral and trigonal prismatic sites. In the former case, the distance between magnetic cations located in different chains is only slightly larger than that within the same chain. Usually, changes in the magnetic susceptibility (χ) for such compounds are interpreted within the one-dimensional Ising model. The interactions between the magnetic cations typically give rise to the antiferromagnetic correlations with maxima in $\chi = f(T)$ curves. Normally, no long-range magnetic ordering is observed in these compounds.

On the other hand, $\text{A}_3\text{A}'\text{BO}_6$ compounds with magnetic ions occupying both the A' and B sites often manifest a complex magnetic behaviour due to an interplay between the intrachain and interchain magnetic interactions. In particular, a magnetic structure was revealed for $\text{Ca}_3\text{Co}_2\text{O}_6$ in a low-temperature neutron diffraction study. Meanwhile, no magnetic reflections were observed in other isostructural compounds (such as $\text{Sr}_3\text{NiIrO}_6$).⁷ Taking into account that the basal plane in the crystal structure of $\text{Sr}_3\text{NiIrO}_6$ is described by a 2D hexagonal lattice (*i.e.*, each chain is surrounded by six neighbouring chains), it might be assumed that the lack of the magnetic ordering is caused by either a disorder in the distribution of the transition metal atoms over the crystallographic sites or a specific geometric structure of the crystal (the geometric frustration).

The magnetic properties of $\text{A}_3\text{A}'\text{BO}_6$ oxides ($\text{B} = \text{Pt, Ir, Rh, Ru}$) are strongly dependent on the electronic configuration of metals occupying both the A' and B sites. Many of these compounds are similar in terms of their structures but their magnetic properties are manifold. In the $\text{Sr}_3\text{A}'\text{PtO}_6$ oxides ($\text{A}' = \text{Cu, Co, Ni, Zn}$), the platinum atoms occupying the octahedral sites are in the low-spin (diamagnetic) state. As a consequence, the $\text{Sr}_3\text{ZnPtO}_6$ oxide with the diamagnetic Zn^{2+} cation behaves as a diamagnetic. In contrast, according to the magnetic susceptibility measurements, the Ni^{2+} cations in the $\text{Sr}_3\text{NiPtO}_6$ oxide manifest a strong one-ion magnetic anisotropy, which induces the local antiferromagnetic ordering at $T < 25$ K.³² Furthermore, $\text{Sr}_3\text{CoPtO}_6$ reveals the disordered spin chain paramagnetism. According to the magnetic susceptibility and heat capacity measurements, the behaviour of $\text{Sr}_3\text{CuPtO}_6$ (Refs 32 and 112) is well described by theoretical models for classical spin chain compounds with $S = 1/2$. It is ferromagnetism that is typical of such compounds (see Table 3).

The iridium-based $\text{Sr}_3\text{A}'\text{IrO}_6$ oxides are characterised by a more complex pattern of magnetic behaviour due to the replacement of the diamagnetic Pt^{4+} cations in the octahedral sites with the low-spin $\text{Ir}^{4+}(\text{d}^5)$ cations having an unpaired electron. The magnetic susceptibility of $\text{Sr}_3\text{ZnIrO}_6$ above the antiferromagnetic

transition (25 K) is well described by the Heisenberg linear chain model. The magnetic properties of $\text{Sr}_3\text{NiIrO}_6$ evolve in a complicated manner as a function of temperature, which is due to an interplay between the ferromagnetic interchain and antiferromagnetic intrachain exchange interactions. The first preliminary conclusion⁷ on the ferromagnetic behaviour of $\text{Sr}_3\text{CuIrO}_6$ was corrected in more recent studies. Actually,¹¹³ below the magnetic transition temperature in the zero field, this compound behaves as a spin glass, but it converts into the ferromagnetic state already in a weak magnetic field (~ 200 Oe). Similarly, detailed investigations^{114,115} into the magnetic properties of $\text{Sr}_3\text{Cu}_{1-x}\text{Zn}_x\text{IrO}_6$ and $\text{Sr}_3\text{CuPt}_x\text{Ir}_{1-x}\text{O}_6$ solid solutions reveal a more complex character of the magnetic interactions both in the individual quasi-one-dimensional oxides and solid solutions than that reported initially.

The $\text{Ca}_3\text{CuIrO}_6$ and $\text{Ca}_3\text{CuRhO}_6$ oxides undergo the magnetic ordering¹¹⁶ at ~ 15 K, but the nature of these magnetic transitions is rather complex. As for Co-based oxides, $\text{Ca}_3\text{CoIrO}_6$ undergoes the frustrated magnetic ordering below 30 K.^{38,117} Meanwhile, the $\text{Ca}_3\text{CoRuO}_6$ oxide behaves as a normal antiferromagnetic with $T_N = 55$ K.³⁸

When polycrystalline samples are studied, no saturation magnetisation can be achieved even in very strong magnetic fields, which is a specific feature of the magnetic properties of quasi-one-dimensional oxides. Therefore, accurate values of the saturation magnetisation and, consequently, ferromagnetic moments can only be determined for single crystals by performing careful measurements along specific crystallographic directions. The ferromagnetic moment of $\text{Ca}_3\text{Co}_2\text{O}_6$ was measured for a polycrystalline sample mixed with epoxy resin magnetised in a field of 80 kOe.¹¹¹ As a result of this treatment, the sample had a strong preferred orientation along the c axis and manifested highly anisotropic magnetic properties (Fig. 10). The character of the observed dependence of magnetisation M on the applied magnetic field strength H indicates that the ferromagnetic chains ($T_{C1} = 26$ K) interact antiferromagnetically ($T_{C2} = 13$ K). In weak fields, this system occurs in the partially disordered antiferromagnetic (PDA) state at $10 \leq T \leq 25$ K but converts into the ferrimagnetic state at $T < 10$ K. In the PDA state, one third of the chains are magnetically disordered while two third of the chains are ferromagnetic and interact with each other antiferromagnetically.

Smith and co-workers⁵⁶ observed a strong anisotropy of the magnetic susceptibility χ of single-crystalline $\text{Ba}_8\text{CoRh}_6\text{O}_{21}$ ori-

**Figure 10.** The magnetisation curves of $\text{Ca}_3\text{Co}_2\text{O}_6$ measured in a magnetostatic field of a strength $0 \leq H \leq 9$ T at 12 K (open symbols) and 35 K (closed symbols).¹¹¹

$M_{||}$, $M_{\perp}$ are the magnetisation values measured for the sample oriented with its c axis parallel and perpendicular to the applied magnetic field, respectively; M_r is the magnetisation for an unoriented samples.

ented with the crystallographic c axis either parallel or perpendicular to the applied magnetic field. The anisotropy is preserved up to room temperature. The rhodium cations in the $A_3A'RhO_6$ oxides can be tri-, tetra- or pentavalent, depending on the oxidation state of an element in the A' sites. The magnetic properties of the Sr_3LnRhO_6 compounds were interpreted⁵² assuming expected values of the magnetic moments for the Ln^{3+} cations and the low-spin state for the Rh^{3+} cations ($t_{2g}^6e_g^0$, $S = 0$). The cobalt and iron cations in Ca_3CoRhO_6 and Ca_3FeRhO_6 are divalent, while rhodium is tetravalent, according to measurements of χ .⁴⁹ Presumably, the temperature dependence of the magnetic properties of Ca_3CoRhO_6 is similar to that of Sr_3NiIrO_6 and Ca_3CoIrO_6 . The magnetic susceptibility measured in the zero-field cooling (ZFC) mode drops down at 35 K, whereas it remains virtually constant upon cooling in a magnetic field (*i.e.*, in the FC mode). According to the results reported by Niitaka *et al.*,⁴⁹ this compound is characterised by the antiferromagnetic interchain exchange interactions coupled with the ferromagnetic intrachain interactions. Neutron diffraction studies¹¹⁸ showed that this compound occurs at $T < 90$ K in the partially disordered antiferromagnetic state (1/3 of the chains are magnetically disordered, while 2/3 of the chains are ordered ferromagnetically and interact with each other antiferromagnetically). According to recent results by Niitaka *et al.*¹¹⁸ (in contrast to earlier data⁴⁹ on the magnetic susceptibility), both transition metals in the Ca_3CoRhO_6 oxide are trivalent. This conclusion is supported by an analysis of the oxidation states of cations in $Ca_3Co_2O_6$ and Ca_3CoRhO_6 based on theoretical electron band structure calculations.¹¹⁹ Despite the pronounced similarity between these two compounds in terms of both their structures and magnetic properties, the antiferromagnetic interchain interactions therein are substantially different, as evidenced by measurements of the specific heat capacity.¹²⁰ Studies of related rhodium oxides with the Co atoms substituted with Fe and Zn revealed that the Ca_3FeRhO_6 oxide undergoes a three-dimensional antiferromagnetic transition at 12 K, while Sr_3ZnRhO_6 experiences an inhomogeneous magnetic ordering below ~ 15 K.¹²¹ The antiferromagnetic interactions at $T < 10$ K were also observed¹²² for Sr_4RhO_6 and Sr_3CaRhO_6 . Mwamuka *et al.*¹²³ elucidated the magnetic behaviour of $Sr_4Fe_{0.73}Rh_{2.27}O_9$. Unfortunately, the experimental data on χ obtained were insufficient to unambiguously establish the oxidation states of Fe and Rh in this compound. A maximum in the $\chi = f(T)$ curve at 8 K points to a probable antiferromagnetic ordering.

Manganese-based complex oxides also exhibit diverse magnetic properties. The antiferromagnetic ordering in Ca_3ZnMnO_6 and Ca_3NiMnO_6 was established by means of neutron diffraction.⁶⁷ It is of note that the Ca_3ZnMnO_6 oxide, where a half of cationic positions in the chains (*viz.*, trigonal prismatic sites) are occupied by the diamagnetic Zn^{2+} ions, is characterised by a significantly lower Néel temperature ($T_N = 25$ K) than $Ca_3A'RuO_6$ ($A' = Li, Na$). The Ca_3NiMnO_6 oxide containing magnetic cations in both the octahedral and trigonal prismatic sites is an antiferromagnetic with $T_N = 20$ K (according to Ref. 67) or 18 K (according to Ref. 69). The $\chi = f(T)$ curve for this oxide obeys the Curie–Weiss law only above 300 K, which is probably due to the preservation of the local magnetic ordering up to high temperatures. In contrast to the ferro(ferri)magnetic $Ca_3Co_2O_6$ compound, its Mn-analogue, Ca_3CoMnO_6 , reveals the long-range antiferromagnetic ordering ($T_N = 13$ K).^{71, 124} It has to be however noted that only short-range magnetic ordering was revealed in Ca_3CoMnO_6 at 4.2 K using neutron diffraction:⁷¹ only broad weak reflexes were observed in the diffraction pattern instead of distinct magnetic reflections. Furthermore, the heat capacity *vs.* temperature curve for this phase has a kink at 13 K, which is indicative of magnetic correlations extending to a part of the crystal rather than to the whole crystal.¹²⁴ Probably, this is a reason for the absence of magnetic reflections in the neutron powder diffraction pattern of this compound. The magnetic properties of $Ca_3Co_{1.25}Mn_{0.75}O_6$ are similar to those of

Ca_3CoMnO_6 except for a higher T_N (18 K). For these phases, both the ferromagnetic ordering and spin glass state can be decisively ruled out. These oxides undergo spin-reorientation transitions at $T \leq 5$ K, as evidenced by the hysteresis loops in their magnetisation curves.

According to the measurements of the magnetic susceptibility and heat capacity,^{71, 125} the triclinic Ca_3CuMnO_6 oxide undergoes the antiferromagnetic ordering at $T < 6$ K. This compound manifests strict long-range magnetic order and is not liable to the magnetic structure frustration, despite the positional disorder of the Cu^{2+} and Mn^{4+} cations and the presence of several types of these cations, which are characterised by different Cu–O and Mn–O bond lengths. The heat capacity *vs.* temperature curve reveals two distinct λ -peaks at 5.2 K and 3.6 K. The experimental data^{69–72} on the magnetic susceptibility of $Ca_3A'MnO_6$ are shown in Fig. 11.

Figure 11. The temperature dependences of magnetic susceptibility (a) and the Curie–Weiss plots (b) for a series of $Ca_3A'MnO_6$ oxides. $A' = \text{Co}$ (1), Cu (2), Zn (3), Ni (4).

The magnetic susceptibility of $Sr_4ZnMn_2O_9$ and $Sr_4MgMn_2O_9$ as a function of temperature is shown in Fig. 12.⁸⁹ It is clearly seen that the magnetic susceptibility of these oxides reveals a complex temperature dependence at $T < 250$ K and does not obey the Curie–Weiss law. The apparent magnetic moments approach the purely spin value of the Mn^{4+} ions at a high temperature. The $\chi(T)$ curves exhibit a broad maximum at 100–150 K, which is more pronounced in the case of $Sr_4ZnMn_2O_9$. These experimental data on $\chi(T)$ for $Sr_4ZnMn_2O_9$ and $Sr_4MgMn_2O_9$ were analysed within a model of the isotropic exchange interactions between the Mn^{4+} – Mn^{4+} dimers. The dramatic increase in the magnetic susceptibility at low temperature obeys the Curie–Weiss law, which indicates that not all the Mn^{4+} ions in $Sr_4ZnMn_2O_9$ and $Sr_4MgMn_2O_9$ are combined into dimers.

Similar conclusions were derived for $Sr_4NiMn_2O_9$ (Refs 84–86) and $Sr_4CuMn_2O_9$ (Refs 20, 22 and 81). Each

Figure 12. The temperature dependences of magnetic susceptibility for $\text{Sr}_4\text{MgMn}_2\text{O}_9$ (open circles) and $\text{Sr}_4\text{ZnMn}_2\text{O}_9$ (closed circles).⁸⁴ The curves 1 and 2 show the contributions of the dimeric and paramagnetic components. The Curie–Weiss plot for the compound showing the linearity in the temperature range of 300–950 K is given in the inset.

Mn^{4+} ion in the chains present in the crystal structures of the $\text{A}_4\text{A}'\text{Mn}_2\text{O}_9$ oxides is involved in the exchange interactions with a neighbouring Mn^{4+} cation and a divalent cation (Zn, Mg, Ni or Cu). It is the exchange interactions between the Mn^{4+} ions that dominate the magnetic susceptibility of these phases at $T < 250$ K, although nickel and copper have their own unpaired electrons in the d shells (in contrast to zinc and magnesium). The contribution from the exchange interactions between the Mn^{4+} and Ni^{2+} (Cu^{2+}) ions is negligibly small.

Among the $\text{A}_4\text{A}'\text{Mn}_2\text{O}_9$ oxides, $\text{Sr}_4\text{CoMn}_2\text{O}_9$ is worthy of a special note. The temperature dependence of inversed magnetic susceptibility for this compound at $T > 150$ K obeys the Curie–Weiss law⁸²

$$\chi = \frac{C}{T - \Theta}.$$

The paramagnetic moment experimentally measured in this temperature range ($6.61 \mu_B$) is close to the theoretical value calculated for the cationic combination $\text{Co}^{2+} - 2\text{Mn}^{4+}$ ($6.71 \mu_B$). The negative value of Θ (-120 K) indicates that the antiferromagnetic interactions dominate. This oxide exhibits a spontaneous magnetisation at $T < 12$ K. In order to analyse the origin of this low-temperature magnetism, real and imaginary parts of the dynamical magnetic susceptibility were measured in the frequency range from 0.1 Hz to 10 kHz. It was found that the $\text{Sr}_4\text{CoMn}_2\text{O}_9$ oxide is characterised by a partially disordered magnetic structure close to that typical of spin glasses and different from that of $\text{Sr}_4\text{NiMn}_2\text{O}_9$, where pairs of the Mn^{4+} ions interact antiferromagnetically along the chains. Similar magnetic properties were observed in $\text{Sr}_{14}\text{Co}_3\text{Mn}_8\text{O}_{33}$ (Ref. 98) and $\text{Sr}_9\text{Co}_2\text{Mn}_5\text{O}_{21}$ (Refs 97 and 98). The temperature dependence of the magnetic susceptibility plotted in the coordinates $1/\chi = f(T)$ for some of the $\text{A}_4\text{A}'\text{Mn}_2\text{O}_9$ oxides discussed above are shown in Fig. 13. A step observed for $\text{Ca}_4\text{CuMn}_2\text{O}_9$ at 123 K is attributed to the presence of the perovskite CaMnO_3 phase, manifesting a weak ferromagnetism at $T < 123$ K, in the sample studied.

Figure 13. The Curie–Weiss plots for $\text{Sr}_4\text{NiMn}_2\text{O}_9$ (1), $\text{Sr}_4\text{CuMn}_2\text{O}_9$ (2), $\text{Ca}_4\text{CuMn}_2\text{O}_9$ (3) and $\text{Sr}_4\text{CoMn}_2\text{O}_9$ (4).⁸²

In the case of $\text{Ba}_6\text{ZnMn}_4\text{O}_{15}$, the magnetic susceptibility as a function of temperature deviates from the Curie–Weiss law in a temperature range of 4.2–300 K,⁶⁶ which is manifested in a drastic increase in χ at $T < 16$ K and a broad local maximum in the $\chi = f(T)$ curve at 45 K. It was suggested that the short-range antiferromagnetic interactions between the Mn^{4+} cations giving rise to the one-dimensional alignment of magnetic moments in the face-sharing octahedra is preserved up to 300 K. The increase in χ at $T < 16$ K is due to the contribution of the Mn^{4+} cations with uncompensated (owing to the structural disorder) magnetic moments into the total magnetic susceptibility.

The temperature dependence of the magnetic susceptibility for $\text{Ba}_6\text{CuMn}_4\text{O}_{15}$ was interpreted⁶⁶ as a joint effect of the paramagnetism of the Cu^{2+} ions in the trigonal prismatic sites and the ordering of the Mn^{4+} cations (that gives rise to a broad maximum at 90 K). The neutron diffraction patterns of $\text{Ba}_6\text{CuMn}_4\text{O}_{15}$ and $\text{Ba}_6\text{ZnMn}_4\text{O}_{15}$ measured at 1.7 K revealed magnetic reflections attributable to the appearance of the long-range magnetic order of the ions in the octahedral sites. The magnetic behaviour of these oxides was simulated using an unusual magnetic structure, in which the antiferromagnetic superexchange interactions in a strongly frustrated crystal structure gives rise to a rotation of spins in neighbouring chains by 120° .

The magnetic properties of the $\text{Ba}_6\text{A}'\text{Mn}_4\text{O}_{15}$ oxides ($\text{A}' = \text{Mg}, \text{Ni}$)⁹⁴ differ significantly from those of their zinc and copper analogues.⁶⁶ In particular, the $\chi = f(T)$ curve for the $\text{Ba}_6\text{MgMn}_4\text{O}_{15}$ oxide reveals no broad maxima at intermediate temperatures. This compound follows the Curie–Weiss law at $T > 125$ K. Since the magnetic susceptibilities of $\text{Ba}_6\text{ZnMn}_4\text{O}_{15}$ and $\text{Ba}_6\text{MgMn}_4\text{O}_{15}$ are governed exclusively by the exchange interactions between the Mn^{4+} cations, the differences between these two phases should be attributed to different distributions of the Mn^{4+} cations over the octahedral and trigonal prismatic sites therein. The experimentally determined value of the Curie constant for $\text{Ba}_6\text{NiMn}_4\text{O}_{15}$ appeared smaller than the respective theoretical value calculated as a joint contribution from the nickel and manganese cations. This discrepancy can be explained assuming that a part of the Ni^{2+} cations adopt the planar square coordination. This fraction should amount to $\sim 28\%$ to reconcile the experimental and theoretical values of the Curie constant.

The experimental data on the magnetic susceptibility and magnetisation of $\text{Ba}_9\text{MgMn}_7\text{O}_{24}$ (Ref. 96) are close to the respective results for $\text{Ba}_5\text{PdMn}_3\text{O}_{12}$, $\text{Ba}_6\text{PdMn}_4\text{O}_{15}$ and $\text{Ba}_7\text{PdMn}_5\text{O}_{18}$.⁹¹ In particular, a deviation of the $1/\chi = f(T)$ curve from the Curie–Weiss law is observed at $T < 225$ K owing to the magnetic ordering of the Mn^{4+} cations in the quasi-one-dimensional chains $-\text{MgO}_6-(\text{MnO}_6)_7-\text{MgO}_6-(\text{MnO}_6)_7-$ composed of trigonal prisms accommodating the Mg^{2+} cations and octahedra occupied by Mn^{4+} . Additionally, a

specific character of the magnetic susceptibility as a function of the applied magnetic field strength at 2 K suggests a low ferromagnetic moment.

It would be interesting to compare the magnetic properties of oxides from the $A_{3n+3m}A'_nMn_{3m+n}O_{9m+6n}$ family with those of $BaMnO_3$, the ultimate representative of the family.¹⁶ The magnetic susceptibility of $BaMnO_3$ and many quasi-one-dimensional oxides of the family deviates from the Curie–Weiss law in a temperature range from 4.2 K to 300 K. Furthermore, at temperatures $T < 215$ K, the magnetic susceptibilities χ measured in a magnetic field and in the zero field are different; the reason for this discrepancy remains unclear. The transition from a paramagnetic into a magnetically ordered state occurs at 59 K. Probably, this transition for $BaMnO_3$ and other $A_{3n+3m}A'_nMn_{3m+n}O_{9m+6n}$ oxides differs from ordinary transitions from a paramagnetic into an antiferromagnetic state. It should rather be considered as a transition from a 1D-magnetically ordered state into a 3D-ordered one. Within the chains, the spins of neighbouring Mn^{4+} cations interact antiferromagnetically and lie in the plane perpendicular to [001]. The comparative analysis of the magnetic properties of $BaMnO_3$ and other known $A_{3n+3m}A'_nMn_{3m+n}O_{9m+6n}$ oxides with $A' = Zn^{2+}$, Mg^{2+} demonstrates their essential similarity. This implies that in the case of compounds with diamagnetic cations in the trigonal prismatic sites, the interchain magnetic exchange prevails over the intrachain interactions. But when a second magnetic cation is introduced into the $[A'Mn_nO]_\infty$ chains, the pattern of magnetic behaviour becomes more complex. Jordan *et al.*⁹⁸ pointed out that the magnetic properties of the quasi-one-dimensional phases, such as $Sr_3NiRhO_{6+\delta}$, $Sr_3CuRhO_{6+\delta}$, $Sr_4NiMn_2O_9$ and $Ca_3Co_{1+x}Mn_{1-x}O_6$, are extremely sensitive to the positional disorder within the chains and structural transitions.

Interesting results were obtained in a study of $Ca_3A'MnO_6$ ($A' = Zn, Cu, Ni, Co$), solid solutions $Ca_3Zn_{1-x}Cu_xMnO_6$ ($0 \leq x < 0.75$) isostructural to the hexagonal K_4CdCl_6 phase, $Ca_3Zn_{0.25}Cu_{0.75}MnO_6$ (with a triclinic lattice similar to that of Ca_3CuMnO_6) and $Ca_4A'Mn_2O_9$ by means of ESR.^{126,127} The ESR spectra of the $Ca_3A'MnO_6$ oxides ($A' = Zn, Cu$) revealed intense signals of the Mn^{4+} cations, although there were no features attributable to Cu^{2+} . Furthermore, the integral spectral intensity and g-factors were temperature dependent. The lack of ESR signal from the copper ions in the spectra of Ca_3CuMnO_6 and solid solutions $Ca_3Zn_{1-x}Cu_xMnO_6$ ($0 \leq x < 1$) can be due to the planar square coordination of the Cu ions in these compounds. A weak signal emerging in the spectrum of the quasi-one-dimensional Ca_3CuMnO_6 oxide following its annealing at 470 K can indicate¹⁰² a change in the coordination type of the Cu^{2+} ions. Therefore, it might be suggested that the compound undergoes a structural phase transition at $T > RT$.

The ESR spectra of $Ca_3A'MnO_6$ ($A' = Ni, Co$) revealed no signals of the Mn^{4+} ions. The intensities of the observed lines (which are 4 orders of magnitude smaller than in the case of the oxides with $A' = Zn, Cu$) with $g = 2.11$ and widths $\Delta H \sim 590$ G are virtually independent of temperature in the range of 77–490 K.

According to the analysis of the ESR features of the Mn^{4+} cations in the spectrum of Ca_3CuMnO_6 , a weak antiferromagnetic ordering exists already at 300 K. Taking into account the absence of ESR signals of Mn^{4+} in the spectra and the lack of the magnetic order in $Ca_3A'MnO_6$ with $A' = Ni$ or Co , it might be suggested that relatively strong exchange interactions are realised between the nickel (cobalt) and manganese cations, which give rise to a redistribution of the electron density and a change in the charge state of the A' cations from $2+$ to $3+$ and, respectively, of the manganese cations from $4+$ to $3+$, in contrast to structural data that are indicative of the cationic combinations $(A')^{2+} - Mn^{4+}$.

The ESR spectra of the $Sr_4A'Mn_2O_9$ oxides ($A' = Zn, Cu, Ni$) also reveal distinct signals of Mn^{4+} and no signals of Cu^{2+} and Ni^{2+} .

* * *

An analysis of the available information concerning quasi-one-dimensional oxides of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family indicates that the number of theoretically predicted compounds belonging to the family presently significantly exceeds the number of actually synthesised and characterised compounds. This is equally true for platinum metal- and manganese-based complex oxides. Most probably, the major reason for this is a similar chemical composition of possible phases, which impedes the purposeful search for conditions of their synthesis. For instance, Bazuev *et al.*⁸¹ studied the $Ca - Cu - Mn - O$ system and obtained two compounds, Ca_3CuMnO_6 and $Ca_4CuMn_2O_9$. The latter phase contained admixtures of CuO (according to powder X-ray diffraction data) and $CaMnO_3$ (according to magnetic measurements). This compound is incommensurate. The ratio $c_1/c_2 = 0.6891$ is significantly larger than the value 0.666 typical of phases with this stoichiometry but rather close to the value of 0.6923 expected for a commensurate phase with the composition $A_{18}A'_5Mn_8O_{39}$ ($m = 1, n = 5$). Hopefully, the experimental conditions required to stabilise both these phases, *i.e.*, $Ca_4CuMn_2O_9$ and $Ca_{18}Cu_5Mn_8O_{39}$ will be found in the future.

The vast majority of quasi-one-dimensional oxides known to date have been synthesised using solid-state reactions, therefore, more efforts should be put forth for the search for conditions of solid-state syntheses affording single crystals of desired size and quality.

Although magnetic parameters are reported in virtually any study dealing with the synthesis of new oxides of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family, the general trends in the magnetic behaviour of quasi-one-dimensional compounds have not been elucidated in sufficient details. This relates to complex correlations between the structure of these compounds (including such features as short metal–metal distances within the chains and a substantial separation of neighbouring chains), electronic configuration of the d elements in the A' and B sites and their properties. The nature of low-temperature magnetic phases has not been determined to date. The interrelations between changes in the chemical composition of the compounds at the course of their synthesis and their magnetic behaviour are yet to be established.

For the compounds containing several (most frequently, two) transition metal cations in the $[(A'B)O_3]_\infty$ chains, the determination of valency combinations $A' - B$ becomes a challenge. As follows from the above discussion, even accurate structural data are insufficient in some cases to rationalise the results of magnetic measurements. This problem is especially severe for cobalt-containing compounds. Presumably, the involvement of theoretical methods for the electron structure calculation will help to overcome this problem.

Abstract. Published data on the activation parameters of bimolecular nucleophilic reactions in solution are generalised and described systematically. The factors that influence the relation between the activation parameters in these reactions are discussed. The relationships between the mechanisms of bimolecular nucleophilic substitution and addition reactions and their activation parameters are considered, and the role of the enthalpy–entropy compensation effect is analysed. The bibliography includes 229 references.

I. Introduction

Bimolecular nucleophilic reactions (BNR) provide the basis for the synthesis of various classes of organic compounds. These include S_N2, S_NAr, S_NV and Ad_N reactions, reactions at the carbonyl carbon atom, reactions of carbocations with anions, *etc.*¹ There is a substantial body of data on the kinetics and mechanisms of these reactions (see, for examples, Refs 2–6). However, after the publication of the monograph by Leffler and Grunwald,⁶ no generalisations of the changes in the enthalpy of activation ($\Delta H^\ddagger$), the entropy of activation ($\Delta S^\ddagger$) and the activation free energy ($\Delta G^\ddagger$) for bimolecular nucleophilic reactions were made although the number of studies on kinetics and mechanisms of these reactions is being increased steadily. It was demonstrated⁶ that the enthalpy and entropy of activation depend much more substantially on the reaction mechanism than the activation free energy. Hence, analysis of the main factors responsible for the ratio between the enthalpy and entropy contributions to the energy barrier for the reaction is of great importance. The present review is devoted to systematisation and analysis of the data on the energetics of the main types of bimolecular nucleophilic reactions in solution. Particular atten-

tion is given to the relationship between the reaction mechanisms and the activation parameters. In some cases, a comparison with the data for gas-phase reactions is performed. Of special interest are bimolecular nucleophilic reactions, that proceed by similar mechanisms and at nearly the same rates but are substantially different in the activation parameters.

In the present review, the enthalpy–entropy compensation effect, which is widely discussed in the literature, is considered from the viewpoint of factors responsible for changes in the activation parameters of bimolecular nucleophilic reactions in solution. Based on the published data, the difference between the compensation and isokinetic effects or their equality are noted.

Emphasis is given to typical bimolecular reactions of organic chemistry. For bimolecular reactions of inorganic compounds, only selected data for ligand substitution reactions of complex compounds are considered.

II. S_N2 reactions

S_N2 reactions in solution are characterised by negative entropies of activation $\Delta S^\ddagger$ because the transition states (TS) are well organised.^{7–10} The values of $\Delta S^\ddagger$ depend on the nature of the substrate and nucleophile and the reaction conditions.^{8–12} For example, the entropy of activation of S_N2 reactions at the saturated carbon atom involving anionic nucleophiles in proton-donor and polar aprotic solvents vary in the range from –2.3 to –83.1 J mol^{–1} K^{–1} (Table 1).

Nu is a nucleophile and LG is a leaving group.

It should be noted that negative $\Delta S^\ddagger$ for both fast and slow reactions vary in a narrow range (for example, see entries 3, 6, 14, 25, 27 and 33 in Table 1). Apparently, the structural features of TS-1 play the decisive role in the determination of $\Delta S^\ddagger$. An increase in the entropy of activation (smaller negative $\Delta S^\ddagger$) corresponds to the less organised and earlier TS-1 on the S_N2 reaction coordinate characterised by a lower degree of formation

Note. Hereinafter, in the tables $\Delta H^\ddagger$ and $\Delta G^\ddagger$ are given in kJ mol⁻¹; $\Delta S^\ddagger$, in J mol⁻¹ K⁻¹.

^a Names are given according to IUPAC nomenclature; ^b 1 M MeOH; ^c 0.1 M MeOH; ^d Alk = n-C₈H₁₇, Ar = 4-NO₂C₆H₄.

and longer Nu – C bond (entries 3 and 4, 8 and 9, 16 and 17, 21 and 23, 31 and 32 in Table 1).^{3, 25}

Gas-phase ion-molecular S_N2 reactions are also characterised by low $\Delta S^\ddagger$ indicative of a high degree of organisation of the transition state.^{7, 10, 26, 27} For example, $\Delta S^\ddagger$ for the gas-phase reactions of alkyl bromides with chloride ions at high pressure varies in the range from – 83.6 to – 100.7 J mol⁻¹ K⁻¹ (Refs 26 and 27); $\Delta S^\ddagger$ for the reactions of substituted benzyl chlorides with phenolate and benzenethiolate anions, in the range from – 160 to – 170 J mol⁻¹ K⁻¹ (calculations by the PM3 method).⁷

The enthalpy of activation for ion-molecular S_N2 reactions varies in a broad range and is generally smaller for faster reactions (for example, entries 1 and 2, 3 and 4, 5 and 6, 13 and 14, 22 and 23, 24 and 25, 27 and 28, 30 and 31 in Table 1). The enthalpies for faster reactions slightly increase only in the case of a sharp increase in the entropy (entries 31 and 32 in Table 1). The rates of all these reactions are controlled by the enthalpy of activation because $\Delta H^\ddagger \gg T\Delta S^\ddagger$ in all cases (see Table 1).¹⁰ This type of reactions is characterised by the isokinetic relationship with the isokinetic temperature $\beta = 6103$ K,¹⁰ which is substantially higher than the experimental temperature range. However, the isokinetic relation-

ship with a lower isokinetic temperature ($\beta = 1130$ K) is observed for S_N2 reactions at the sp^3 -hybridised carbon atom involving the thiosulfate ion in aqueous organic media, which is evidence for another (apparently, catalytic) reaction pathway in these media.¹¹

The activation parameters for the reactions of ethyl iodide with anionic nucleophiles substantially depend also on the composition of the solvent (entries 20 and 21, 22 and 23, 24 and 25, 26 in Table 1).^{16–20} There is no linear correlation between the parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for the reaction of each nucleophile with EtI in MeCN–MeOH with variation of percentage of MeOH. It should be noted that linear relationships between $\Delta H^\ddagger$ and $\Delta S^\ddagger$ were obtained considering the thermodynamic parameters of the passage from one solvent to another as well as the number of alcohol molecules involved in hydrogen bonding with anionic species.^{16–20}

The enthalpy of activation for the reactions of MeI is always lower than that for the analogous reaction with EtI due to a decrease in the steric hindrance in the transition state, as exemplified by the reactions of MeI and EtI with structurally different anionic nucleophiles (entries 5–20 in Table 1); the correlations between $\Delta H^\ddagger(\text{MeI})$ and $\Delta H^\ddagger(\text{EtI})$ for series of related nucleophiles have been revealed.¹⁵ An analogous influence of the structure of the substrate was found for gas-phase S_N2 reactions.^{26,27} The corresponding calculations for the gas phase and solutions were carried out.²⁸

Based on a comparison of the changes in the entropy of activation for the reactions of MeI and EtI with nucleophiles containing one reaction centre (for example, entries 5 and 13, 10 and 18, 12 and 20 in Table 1) in MeCN, it was concluded that partial desolvation of the nucleophilic centre in the formation of the transition state is the major factor responsible for the relative reactivities of alkyl iodides.¹⁵

The values of $\Delta G^\ddagger$ for the ion-molecular S_N2 reactions are rather high (see Table 1) due primarily to a contribution of the desolvation energies of the nucleophile and TS-1.^{3,22,24} Quantum-chemical calculations, which were performed with consideration of the solvent effect on the activation free energies for S_N2 reactions, agree well with experimental values.^{28–31} For example, the calculated $\Delta G^\ddagger$ for the reactions of MeCl with Cl^- in DMSO, MeOH and H_2O are 133.7, 145.9 and 147.5 kJ mol^{-1} , respectively.²⁸ For the reaction of EtCl with CN^- in DMSO, the calculated $\Delta G^\ddagger$ is equal to 100.7 kJ mol^{-1} (Ref. 29), whereas the experimental $\Delta G^\ddagger$ is equal to 94.5 kJ mol^{-1} .³⁰

For the reactions of *trans*- γ -derivatives of allyl chlorides $\text{YCH}=\text{CHCH}_2\text{Cl}$ with Cl^- and LiCl, the calculated energy barriers correlate with the substituent constants σ_p to give the reaction constants $\rho = -8.3$ and $\rho = +18.8$, respectively.³¹ An analogous substituent effect in the $\rho\sigma$ correlations is observed for ion and ion-pair reactions in solution as well. It was demonstrated that the ionic structure of the transition state is stabilised by double-bond polarisation rather than by the conjugation effect. At the same time, a substantial charge delocalisation is observed for the ion-pair structure of the transition state.³¹

The calculated activation barriers for the gas-phase S_N2 reactions $\text{F}^- + \text{MeX}$ ($\text{X} = \text{F}, \text{Cl}, \text{CN}, \text{OH}, \text{SH}, \text{NH}_2$ and PH_2) give the following series of the nucleofugic ability of the substituent X (the activation barriers in kJ mol^{-1} are given in parentheses): $\text{Cl} (-51.0) > \text{F} (-3.3) > \text{SH} (11.7) > \text{CN} (56.8) > \text{OH} (67.3) > \text{PH}_2 (82.3) > \text{NH}_2 (137.1)$.³² It should also be noted that the experimental and calculated rate constants for the gas-phase reaction $\text{MeBr} + \text{Cl}^-$ agree well with each other in a broad temperature range.³³

The enthalpy-controlled S_N2 reactions of aromatic radical anions with alkyl bromides in DMF in the temperature range from -50 to 20°C are characterised by low enthalpies of activation (29.3 – 34.3 kJ mol^{-1}) and essentially negative entropies of activation (-79.8 to -54.3 $\text{J mol}^{-1} \text{K}^{-1}$).⁹ Interestingly, the increase in the temperature leads to a switch of the S_N2 -reaction mechanism to the single-electron transfer (SET) mechanism,

which is accompanied by an increase in $\Delta H^\ddagger$ and $\Delta S^\ddagger$ to 47.6 – 56.8 kJ mol^{-1} and 20.9 $\text{J mol}^{-1} \text{K}^{-1}$, respectively.⁹

ArH is anthracene, Bu = Bu^n , Bu^s , Bu^t .

The same features were observed for the reactions of alkyl chlorides with NO^- .³⁴

Generally, S_N2 reactions at the saturated carbon atom with neutral O-, S- and N-nucleophiles proceed slowly and are characterised by very low $\Delta H^\ddagger$ and $\Delta S^\ddagger$ (Table 2) compared to the parameters for analogous reactions with charged nucleophiles (see Table 1). A noticeable decrease in $\Delta H^\ddagger$ and $\Delta S^\ddagger$ is attributed to the structural features of the transition states. The frontal attack of the nucleophile on the substrate gives rise to the four-membered transition state TS-2 involving a hydrogen bond^{35,40–42} or the three-membered transition state TS-3 without the involvement of a hydrogen bond.⁸

Cyclic TS-2 and TS-3 are late states characterised by a higher degree of the bond formation and cleavage.^{8,42}

It should be noted that S_N2 reactions at the saturated carbon atom with neutral nucleophiles can be controlled by both the enthalpy and entropy (Table 2). For example, methanolysis of 1-phenylethyl 4-nitro-benzenesulfonate (Table 2, entries 1 and 2) in a mixture of protic and aprotic solvents is controlled by the enthalpy unlike the entropy-controlled reaction in a protic solvent. However, an analogous change in the nature of the solvent in the reactions of ethyl α -bromoacetate with HetSH (Table 2, entries 3 and 4) and aminolysis of allyl bromide (Table 2, entries 7–10) leads to the opposite change in the control. Evidently, higher stabilisation of TS-2 for faster reactions in both protic and aprotic media leads to a decrease in both $\Delta H^\ddagger$ and $\Delta S^\ddagger$, resulting in the entropy control of the reaction (Table 2, entries 1, 4–7 and 9).

In the reactions of ethyl α -bromoacetate with HetSH in various protic and aprotic solvents (Table 2, entries 3 and 4), the enthalpy–entropy compensation effect with the compensation temperature $\beta = 292$ K (below the limit of the experimental temperature range) is observed.³⁶ However, the change in the energetics of the reaction of ethyl α -bromoacetate with thiol in methanol under changes in the nature of the substituent in S-nucleophiles is described by the compensation relation with $\beta = 338$ K (above the limit of the experimental temperature range).³⁶ At the same time, aminolysis of allyl bromide in an aprotic solvent (Table 2, entries 7 and 9) is characterised by the compensation relation with $\beta = 220$ K (much lower than the limit of the experimental temperature range), whereas no linear relationship between $\Delta H^\ddagger$ and $\Delta S^\ddagger$ is observed for this reaction in methanol.³⁷

^a In entries 1 and 2, the pseudo-first-order rate constant k_1 /s⁻¹; in entries 3–10, the rate constant of the formation of the transition state TS-2 or TS-3 as the rate-determining step in the nucleophilic attack of the substrate; in entries 11–14, the rate constant of decomposition of ion pairs (see the reaction equation).

Studies of the quaternisation reactions of aliphatic amines with MeI in an aqueous solution revealed an isokinetic relationship with a negative isokinetic temperature. This fact provides evidence for a stepwise reaction mechanism involving the reversible formation of the ion pair in the first step followed by its dissociation to form free ions.¹²

The quaternisation reactions $Et_3N + EtI$ in solutions of alcohols (entries 11 and 12 in Table 2) correspond to the isokinetic relationship with the positive isokinetic temperature $\beta = 730$ K (higher than the experimental temperature range).^{38, 39} The use of Et_3P as a nucleophile in the latter reaction (entries 13 and 14 in Table 2) leads to a decrease in the isokinetic temperature to 347 K. Therefore, a substantially lower degree of desolvation of Et_3P compared to Et_3N is required, and the positive isokinetic temperatures for both reactions in alcoholic solutions confirm the concerted mechanism.³⁹

A comparison of the energetics of reactions at the saturated carbon atom with charged and neutral nucleophiles demonstrated that these reactions are characterised by very close activation free energies $\Delta G^\ddagger$ in spite of the difference in the structure of transition states (TS-1 and TS-2 or TS-3). Therefore, these differences are reflected primarily in the changes in the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$.⁶

The substitution reactions at the sulfur atom of the sulfo group with anionic and neutral nucleophiles that proceed by a concerted mechanism *via* the trigonal-bipyramidal transition states TS-4 and TS-5 have very low enthalpies ($\Delta H^\ddagger = 8-40$ kJ mol⁻¹) and entropies of activation ($\Delta S^\ddagger$ from -220 to -277 J mol⁻¹ K⁻¹) if the reactivity is entropy-controlled.^{43, 44}

Evidently, these transition states, which are formally similar to the trigonal-bipyramidal transition state TS-1 in S_N2 reactions, are much more organised. It should also be noted that the reaction of benzenesulfonyl chloride with phenols in the presence of Et_3N is characterised by the compensation relation with $\beta = 171$ K (calculated using the experimental data⁴³), which is substantially lower than the limit of the experimental temperature range.⁴³

III. S_NAr reactions

The energetics of bimolecular S_NAr reactions depends on the nature of the leaving group and the nucleophile.⁴⁵ The reactivity in these processes is generally controlled by the enthalpy.⁴⁶⁻⁵¹ Table 3 gives the rate constants for the rate-determining step of the formation of the transition state TS-6 or TS-7 and the activation parameters for S_NAr reactions of various substituted arenes ArLG with charged hard and soft nucleophiles in protic and aprotic solvents. As can be seen from these data, $\Delta S^\ddagger$ varies from -250 to 255 J mol⁻¹ K⁻¹ and $\Delta H^\ddagger$ varies from 3.8 to 232 kJ mol⁻¹. The very low enthalpies of activation correspond to very low (large negative) entropies of activation (entries 14, 39, 41 and 42 in Table 3). In these cases, the reactivity is entropy-controlled. However, other S_NAr reactions listed in Table 3 are

entropy-controlled regardless of the electrophilicity of the substrate and the nature of the nucleophile, the leaving group, and the solvent. Transition states in the reactions of 2,2'-dinitrodiphenyl ether (entry 14 in Table 3) and halogen-substituted pyridines (entries 39 and 41 in Table 3) with sodium phenolate derivatives are well organised due to desolvation of the nucleophile in the formation of the transition state and weak solvation of the delocalised transition state, for example, of TS-6, approaching the σ complex.^{21, 49, 51, 59} By contrast, the entropy control of the reaction of 4-pentafluorophenoxy-2,3,5,6-tetrafluoropyridine with KF (entry 42 in Table 3) is most likely associated with the change from the S_NAr reaction mechanism to the concerted mechanism *via* the transition state TS-7.^{58, 60, 61} The more ordered (compared to TS-6) transition state TS-7 is typical of bimolecular concerted reactions with very low $\Delta S^\ddagger$.⁶²

The switch from the entropy control of the reaction to the enthalpy control can be achieved by varying the nucleophile. An increase in the negative charge delocalisation in a nucleophile leads to a decrease in its desolvation energy. Examples are provided by the reactions of 2-chloro-5-nitropyridine with sodium 4-methoxy- and 4-nitrophenolate in methanol (entries 39 and 40 in Table 3). The use of nucleophiles with a more delocalised charge (electron-withdrawing NO₂ group) instead of nucleophiles with a less delocalised charge (electron-donating MeO group) allows one to change the character of control of the reaction.⁵¹

Analysis of the activation parameters for the S_NAr reactions given in Table 3 revealed a number of compensation relations and isokinetic relationships (Fig. 1).⁶³⁻⁶⁵ Straight line I in Fig. 1 relates primarily to fast reactions (entries 10, 12, 27-31 and 33-37 in Table 3) with rate constants $k_2 > 1 \times 10^{-4}$ litre mol⁻¹ s⁻¹ and only the reaction of 4-nitrobenzonitrile with CsF in DMSO (entry 15 in Table 3) is slow [$k_2(80^\circ C) = 1.58 \times 10^{-7}$ litre mol⁻¹ s⁻¹] due to a substantial increase in the entropy contribution as a result of the formation of the late transition state and, consequently, a slight change in the

^a 9-Phenylfluorenylpotassium; ^b 1,3-dimethylimidazolidin-2-one; ^c in this case, η⁶-coordinated PhCl serves as the substrate.

entropy of solvation. Line *II* in Fig. 1 includes rather slow reactions with $k_2 = 1 \times 10^{-6} - 1 \times 10^{-2}$ litre mol⁻¹ s⁻¹ (entries 1, 2, 4, 7, 8, 11 and 32 in Table 3) with the most typical activation parameters.⁴⁶ Line *III* contains points for both fast (entry 42 in Table 3) and rather slow reactions (entries 16, 22, 39 and 40 in Table 3). The characteristic feature of the latter plot is a very strong decrease in the entropy in entries 22, 39 and 42. This can be attributed to an increase in the desolvation energy of the localised nucleophile (*cf.* entries 39 and 40 in Table 3)⁵¹ or an increase in the desolvation energy of the nucleophile due to the formation of the early transition state with a more electrophilic substrate (*cf.* entries 16 and 22 in Table 3)⁵³ as well as to a switch from the S_NAr mechanism to the concerted mechanism (entry 42 in Table 3).⁵⁸ Line *IV* (Fig. 1) includes data for reactions (entries 9, 13, 14 and 41 in Table 3) with low $\Delta S^\ddagger$. Low $\Delta S^\ddagger$ for reactions 14 and 41 were discussed above. A decrease in $\Delta S^\ddagger$ for slow reactions 9 and 13 can be attributed to the formation of the early transition state.^{48, 53} The reactions of halogen-substituted arenes with sodium methoxide and azide are described by straight line *V* (entries 3, 5, 6 and 38 in Table 3). It should be noted that these reactions are very slow and characterised by high $\Delta H^\ddagger$ and $\Delta S^\ddagger$ due apparently to stabilisation of the ground state of the nucleophile and, as a consequence, the formation of the late transition state.^{48, 53}

Lines *VI* (entries 17–21 in Table 3) and *VII* (entries 23–26) in Fig. 1 characterise slow reactions with very high $\Delta H^\ddagger$ and $\Delta S^\ddagger$, both relationships being isokinetic.⁵⁷ The activation free energies (120–140 kJ mol⁻¹) for all reactions corresponding to lines *VI* and *VII* are close to the range of $\Delta G^\ddagger$ determining the kinetics of S_NAr reactions of weakly activated arenes with O-charged nucleophiles.⁴⁶ The enthalpy and entropy of activation for the reactions of *meta*-substituted arenes with complexes of phenols with K₂CO₃ (Scheme 1) vary in unusually broad ranges. High sensitivity of the parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ to the structure of the reagents is due to the possible changes in the geometry of complex **1**.^{66, 67} Apparently, it is this property of complex **1** that determines similarity of these reactions to heterogeneous and enzymatic catalysis characterised by unusually broad ranges of $\Delta H^\ddagger$ and $\Delta S^\ddagger$.^{68–70} Then the transformation of complex **1** can occur either synchronously *via* the transition state TS-8 or stepwise *via* complex **2** and the transition state TS-9. Both pathways afford σ complex **3**. The formation of the latter is the rate-determining step and is characterised by usual activation free energies $\Delta G^\ddagger$.⁴⁶

The chemical nature of the observed compensation relations is confirmed by the fact that the observed compensation temperatures are noticeably different from the experimental temperature

Figure 2. Plots of the enthalpies vs the activation free energies for the S_NAr reactions of substituted arenes ArLG with charged nucleophiles (the numbering of the points corresponds to the entries in Table 3).

(*I*) $r = 0.966$, $n = 13$, $s = 8.0$; (*II*) $r = 0.949$, $n = 7$, $s = 6.6$; (*III*) $r = 0.983$, $n = 5$, $s = 6.4$; (*IV*) $r = 0.971$, $n = 4$, $s = 7.4$; (*V*) $r = 0.950$, $n = 3$, $s = 3.6$; (*VI*) $r = 0.835$, $n = 5$, $s = 24.0$; (*VII*) $r = 0.951$, $n = 4$, $s = 12.5$.

range. In addition, the relationships between the enthalpies of activation and the activation free energies for these reactions were found (Fig. 2).^{71–73} The opposite slopes of the lines in Fig. 2 are associated with considerable positive values of $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for the reactions described by lines *VI* and *VII*. As a result, $\Delta H^\ddagger$ can be larger than $\Delta G^\ddagger$ (entries 17–21, 23, 25 and 26 in Table 3).

Due to the kinetic enthalpy–entropy compensation effect represented by lines *I*, *II*, *VI* and *VII* in Fig. 1 for different S_NAr reactions, it became possible to compare the substitution effect of the nitro group and the fluorine atom on the energetics of these reactions.⁷⁴ For example, a comparison of the activation parameters ($\Delta H^\ddagger$ and $\Delta S^\ddagger$) for the substitution of the nitro group and the fluorine atom in 1,4-dinitro- and 4-fluoronitrobenzene in the reactions with ¹⁸F-labelled fluoride ions in DMSO (entries 11 and 12 in Table 3) demonstrated that the selectivity of replacement of these groups ($k_{\text{NO}_2}/k_{\text{F}}$ ratio) is controlled by the entropy of activation.^{53, 54} Evidently, the replacement of the nitro group (entry 11) is characterised by the earlier transition state on the

Scheme 1

reaction coordinate compared to the replacement of the fluorine atom (entry 12).⁷⁴

Recently, it has been demonstrated^{57, 66, 75} that the selectivity of replacement of the nitro group and the fluorine atom in the reactions of *meta*-substituted nitrobenzenes with phenols and arenethiols in the presence of K₂CO₃ in DMF at 40–125 °C is entropy-controlled because in all cases $T\Delta\Delta S^\ddagger > \Delta\Delta H^\ddagger$, where $\Delta\Delta S^\ddagger = \Delta S^\ddagger_{\text{NO}_2} - \Delta S^\ddagger_{\text{F}}$ and $\Delta\Delta H^\ddagger = \Delta H^\ddagger_{\text{NO}_2} - \Delta H^\ddagger_{\text{F}}$. Changes in the entropy $\Delta\Delta S^\ddagger$ have positive values (*cf.* entries 18 and 19, 20 and 21, 23 and 24, 25 and 26 in Table 3, lines VI and VII in Fig. 1), and, consequently, the reactions of fluoroarenes **4** and **5** with the ArOH·K₂CO₃ complexes are more organised than analogous reactions of nitroarenes **6** and **7**.

X = F: R = H (**4**), CF₃ (**5**); X = NO₂: R = H (**6**), CF₃ (**7**).

Hence, the S_NAr substitution of the nitro group in compounds **6** and **7** is characterised by the earlier transition state on the reaction coordinate compared to the substitution of the fluorine atom in compounds **4** and **5**.^{57, 66, 75} It should be noted that the replacement of the nucleophile ArOH·K₂CO₃ by 2 ArOH·K₂CO₃ has no effect on the character of the control of the reactivity of compounds **5** and **7**. In this case, the selectivity of substitution is also entropy-controlled.⁷⁶

It was demonstrated^{77, 78} that changes in the nature of the medium can lead to a switch from the entropy control of regioselectivity in S_NAr reactions to the enthalpy control. For example, the *ortho* to *para* isomer ratio in S_NAr reactions resulting in the replacement of halogens in alcohols as the solvents is entropy-controlled.^{79, 80} A comparison of the substitution of the fluorine and chlorine atoms in halonitrobenzenes shows that the fluorine atoms in monohalonitrobenzenes are replaced primarily due to smaller steric requirements of the *ortho*-fluorine atom (Table 4). However, the reverse situation is observed for dihalonitrobenzenes because the entropy control of the reactions in MeOH favours the *ortho*-substitution due to steric hindrance for solvation in the transition state (see Table 4).⁸⁰ However, the entropy control of the reactions of fluoronitrobenzenes with alkoxides changes to the enthalpy control at low temperature in liquid NH₃, resulting in sharp enhancement of *ortho*-substitution (see Table 4).

Table 4. Rate constant ratios of the replacement of halogens in the *ortho* and *para* positions of halonitrobenzenes with sodium methoxide in methanol (25 °C) or liquid ammonia (–70 °C) and the differences between the activation parameters for these reactions.

^a Data for the reaction with PhONa at –55 °C (see ⁷⁸).

The regioselectivity of replacement of the halogen atom can be influenced also by the structure of the nucleophile. Table 5 gives data on the regioselectivity of replacement of the fluorine atom in 2,4-difluoronitrobenzene under the action of lithium phenolates 4-RC₆H₄OLi in liquid ammonia. From these data it follows that the replacement of the *ortho*-fluorine atom is more favourable from the point of view of the enthalpy than the replacement of the *para*-fluorine atom. For the substituents R in nucleophiles, this tendency decreases in the series 4-MeO > 4-Me > H ≈ F. However, the enthalpy favours the replacement of the *para*-fluorine atom in the case of R = Bu^t.⁸³ This fact is associated with a change in the structure of the transition state. The replacement of the *ortho*-fluorine atom under the action of lithium phenolates containing electron-donating substituents where the higher positive charge is localised on the *ortho*-carbon atom with respect to the nitro group gives the early transition state. A decrease in the nucleophilicity of 4-Bu^tC₆H₄OLi due to the greater polarisability of the Bu^t group shifts the transition state toward the intermediate σ complex, *i.e.*, favours the formation of the late transition state and the replacement of the *para*-fluorine atom.⁸³

Of neutral nucleophiles, only amines were studied in detail in aromatic nucleophilic substitution reactions.^{45, 74} Unlike the reactions of charged nucleophiles, S_NAr reactions of primary and secondary amines can be catalysed by bases. The second amine molecule can serve as such a base.

The apparent second-order rate constant k_A at a stationary concentration of σ complex **8** can be calculated from the commonly accepted mechanism of S_NAr reactions with amines:^{45, 74}

$$k_A = \frac{k_1(k_2 + k_3[B])}{k_{-1} + k_2 + k_3[B]}.$$

Table 6 lists the rate constants (k_A) and the activation parameters for S_NAr reactions of various arenes ArLG with primary and secondary amines in protic, aprotic polar and non-polar solvents. It should be noted that for most of the reactions listed in Table 6 (entries 1, 2, 4–15 and 18–23), $k_A = k_1$ because $k_2 + k_3[B] \gg k_{-1}$, and the formation of σ complex **8** is the rate-determining step of the reaction. However, the reactions in non-polar n-hexane (entries 3, 16 and 17, Table 6) are characterised by a more complex dependence of k_A on [B], which includes the equilibrium constant K_s of the formation of $n-\pi$ -electron-donating complex **9** prior to the formation of σ complex **8**, decomposition of the latter being the rate-determining step.⁸⁵

Table 6. Rate constants and activation parameters for the S_NAr reactions at the sp²-hybridised carbon atom in compounds ArLG with amines.

^a Molar ratio is 1 : 1; ^b in this case, η^6 -coordinated PhCl serves as the substrate.

As can be seen from Table 6, $\Delta S^\ddagger$ varies from -265 to -98 J mol⁻¹ K⁻¹ and $\Delta H^\ddagger$ varies from 15.7 to 82.0 kJ mol⁻¹. It should be noted that low $\Delta H^\ddagger$ correlate with very low $\Delta S^\ddagger$, which corresponds to the entropy control of the reactivity, i.e., $T\Delta S^\ddagger > \Delta H^\ddagger$ (entries 1, 3, 4, 6–9, 14–20 and 23, Table 6). However, in other cases, where both the entropy and enthalpy noticeably increase (entries 2, 5, 10–13, 21 and 22, Table 6), the reactivity is controlled by the enthalpy regardless of the structure of the amine and substrate.

The entropy control can be switched to the enthalpy control by changing the solvent. For example, the reactions in a binary solvent system including MeOH is entropy-controlled if 1,1,1-trichloroethane is used as the second component, whereas these reactions are enthalpy-controlled in the presence of toluene instead of 1,1,1-trichloroethane due to a change in the contribution of the hydrogen bond between piperidine and MeOH (entries 5 and 6, Table 6).⁸⁷

Analysis of the activation parameters for the S_NAr reactions with amines revealed a number of the enthalpy–entropy compensation relations (Fig. 3). Straight line *I* in Fig. 3 includes data for very slow reactions (entries 1, 7, 12, 13 and 22, Table 6) with the rate constants $k_A = 3.08 \times 10^{-9}$ – 2×10^{-4} litre mol⁻¹ s⁻¹ and

high $\Delta H^\ddagger$ and $\Delta S^\ddagger$. Line *II* (entries 2, 5, 6, 10, 11 and 14) relates to the data for rather slow S_NAr reactions with amines. Faster reactions are described by line *III* (entries 4, 8, 9, 15, 18 and 23); very fast reactions, by line *IV* (entries 19 and 20). The reactions described by the compensation plots *III* and *IV* are characterised by very low $\Delta H^\ddagger$ and $\Delta S^\ddagger$. Line *V* (entries 3, 16 and 17, Table 6) almost coincides with line *III*, but low $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for these reactions are associated with a change in the mechanism of S_NAr

**Figure 3.** Compensation plots for the S_NAr reactions of substituted arenes ArLG with amines (the numbering of the points corresponds to the entries in Table 6).

(*I*) $r = 0.940$, $n = 6$, $s = 6.0$; (*II*) $r = 0.975$, $n = 6$, $s = 1.74$; (*III*) $r = 0.73$, $n = 6$, $s = 2.8$; (*IV*) and (*V*) $r = 0.864$, $n = 3$, $s = 3.3$.

reactions in nonpolar *n*-hexane due to formation of complex **9** (see above).⁸⁵

Analysis of the relationships between the enthalpies of activation and the activation free energies for the same S_NAr reactions with amines (Fig. 4) confirms the chemical nature of the observed enthalpy–entropy compensations presented in Fig. 3,^{71–73} and reveals the following characteristic feature: slower reactions are described by line *I* with the opposite slope compared to lines *II–IV* for faster reactions (see Fig. 4). The latter fact reflects the highest sensitivity of changes in $\Delta H^\ddagger$ depending on $\Delta S^\ddagger$ for the same reactions (line *I* in Fig. 3 has the largest slope).

Figure 4. Plots of the enthalpies vs the activation free energies for the S_NAr reactions of substituted arenes $ArLG$ with amines (the numbering of the points corresponds to the entries in Table 6).

A comparison of the activation parameters for the substitution of the nitro group and the fluorine atom in a series of nitro- and fluoroarenes under the action of aniline (entries 8 and 9, 14 and 15, 19 and 20, Table 6) shows that the selectivity of replacement of these groups ($k_A^{NO_2}/k_A^F$ ratio) is controlled by the entropy of activation. Evidently, the replacement of the nitro group (entries 9, 15 and 20) is characterised by the earlier transition state on the reaction coordinate compared to the replacement of the fluorine atom (entries 8, 14 and 19).

To summarise the results of consideration of the activation parameters for S_NAr reactions, let us note the following characteristic features: $\Delta H^\ddagger$, $\Delta S^\ddagger$ and $\Delta G^\ddagger$ vary in very broad ranges and there is no common enthalpy–entropy compensations for the reactions with both charged and neutral nucleophiles even in terms of the same reaction mechanism involving the formation of a σ complex as the rate-determining step. It should be emphasised that complexation between the substrate and the nucleophile can contribute significantly to changes in the activation parameters.

IV. S_NV and Ad_N reactions

Nucleophilic vinylic substitution (S_NV) can proceed by different mechanisms.^{90–94} If the S_NV reaction proceeds according to the addition–elimination mechanism, it has much in common with the nucleophilic addition to electron-deficient alkenes **10** (Ad_N reaction) because both S_NV and Ad_N reactions involve the same addition step of the nucleophile to the double bond to form carbanion **11** (products **12** and **15**, respectively). As a rule, the nucleophilic attack is the rate-determining step (rate constant k_1), but this is not necessarily the case.^{91,95,96} For example, the apparent second-order rate constant for *E–Z* isomerisation of compound **10** under the action of various amines giving rise to product **14** is not the constant k_1 but reflects a more complex process where the internal rotation with the constant k_{rot} giving

rise to carbanion **13** can be the rate-determining step. This conclusion is supported by very low values of $\Delta H^\ddagger$ (8.8–18.4 kJ mol^{−1}) and $\Delta S^\ddagger$ (from −242.4 to −179.7 J mol^{−1} K^{−1}) for these reactions.⁹¹

X and Y are electron-withdrawing groups.

Very low values of $\Delta H^\ddagger$ are also typical of S_NV reactions with amines in which the nucleophilic attack with the rate constant k_1 is not the rate-determining step.^{90,96} For example, very low $\Delta H^\ddagger$ (3.3–8.4 kJ mol^{−1}) and $\Delta S^\ddagger$ (from −234.1 to −217.4 J mol^{−1} K^{−1}) for the S_NV reactions of tricyanovinyl chloride with *N,N*-dialkylanilines in chloroform are indicative of the complex character of the apparent rate constant, which is evidently close to the rate constant for elimination of the chloride ion from intermediate zwitterion **A**.^{90,91}

The activation parameters are also useful in proving the elimination–addition ($E–Ad_N$) mechanism of S_NV reactions.⁹² It appeared that positive values of $\Delta S^\ddagger$ provide reliable evidence that S_NV reactions proceed by this mechanism. Under the action of strong bases, a proton can be abstracted from compound **16** to give carbanion **17**, from which the LG group is eliminated to form acetylenic derivative **18**, and the latter is involved in the addition reaction producing alkene **19**.

X is an electron-withdrawing group.

For example, *Z* isomer **16** (the *trans* orientation of the H atom and the leaving group LG) reacts with both hard nucleophiles RO^- and soft nucleophiles RS^- to form acetylenic derivative **18** and substitution product **19**.^{92,97} The fact that the reactions of *Z* isomers **16** with alkoxides RO^- proceed according to the $E–Ad_N$ mechanism is evidenced by positive values of $\Delta S^\ddagger$ (entries 4 and 6, Table 7).^{97,98}

^a LG = Cl, except for entry 7, where LG = Br.

The S_NV reactions with charged nucleophiles resulting in the replacement of halogen in compounds **20**–**25** proceed at similar rates (see Table 7) and their activation parameters obey the enthalpy–entropy compensations (Fig. 5). Straight line *I* includes the reactions of compounds **20** and **21** with O- and S-anions characterised by very low Δ*H*[‡], whereas line *II* includes data for the reactions of compounds **22**–**25** with O- and S-anions characterised by high Δ*H*[‡]. It should be noted that changes in Δ*H*[‡] are little sensitive to changes in Δ*S*[‡] for the reactions of compounds **20** and **21** (line *I*) due apparently to the entropy control of these reactions. The linear relationship between Δ*H*[‡] and Δ*G*[‡] is observed only for these reactions, the sensitivity of Δ*H*[‡] to changes in Δ*G*[‡] is also very weak. By contrast, Δ*G*[‡] for the reactions of compounds **22**–**25** varies in a narrow range (74.4 ± 2.4 kJ mol^{−1}, see Table 7), resulting in the absence of the dependence of Δ*H*[‡] on Δ*G*[‡] and the enthalpy control of these reactions.

**Figure 5.** Compensation plots for the S_NV reactions resulting in the replacement of halogen in compounds **20**–**25** with charged nucleophiles (the numbering of the points corresponds to the entries in Table 7). (*I*) *r* = 0.947, *n* = 4, *s* = 1.6; (*II*) *r* = 0.988, *n* = 8, *s* = 3.48.

In the case of charged nucleophiles, the nucleophilic addition to activated alkenes **10** via intermediate carbanion **11** giving rise to Ad_N reaction product **15** occurs very rapidly in both water or 50% aqueous DMSO⁹³ and anhydrous DMSO.¹⁰¹ The rate constant *k*₁ (20 °C) varies in the range of 10⁴–10⁷ litre mol^{−1} s^{−1} depending on the nature of substrate **10** and the nucleophile, but the data on the activation parameters for these reactions are lacking.^{93, 101} The

Ad_N reactions of activated alkenes with neutral nucleophiles proceed much more slowly.^{93, 101} For some of these reactions, the activation parameters were determined.^{101–110}

The rate constant *k*₁ (20 °C) of the reaction of benzylidene-malononitrile (**26**) with morpholinobutene as a π-nucleophile in CH₂Cl₂ is 1.24 × 10^{−2} litre mol^{−1} s^{−1}, and the activation parameters Δ*H*[‡] = 19.8 kJ mol^{−1} and Δ*S*[‡] = −214 kJ mol^{−1} K^{−1}.¹⁰¹ The [2 + 2]-cycloaddition reactions proceeding (the entropy control) stepwise via a zwitterionic intermediate are characterised by very low Δ*S*[‡] (as in this reaction).^{101, 111}

The rate constants and the activation parameters for the Ad_N reactions of activated alkenes with amines in acetonitrile are given in Table 8. Depending on the electrophilicity of alkene and the nucleophilicity of the amine, the rate constants vary by five orders of magnitude, Δ*H*[‡] varies from 2 to 65 kJ mol^{−1}, and Δ*S*[‡] varies from −267 to −40 J mol^{−1} K^{−1}. These substantial changes in the activation parameters are associated with the difference in the mechanism of these reactions. It was demonstrated^{105–110} that activated alkenes **27**–**42** react with benzylamines in acetonitrile according to the concerted mechanism in one step via the cyclic four-membered transition state TS-10.

Hence, these reactions are characterised by low Δ*H*[‡] and Δ*S*[‡] and the entropy control of the reactivity (entries 1–8, 11–14,

^a The second-order rate constant (*k*₁) of the addition of benzylamine to substrate **31**.¹⁰² ^b The second-order rate constant (*k*) of the addition of the nucleophile to substrate **26** according to a non-catalytic mechanism: $k = k_1 k_2 / k_{-1}$.¹⁰⁴ ^c The second-order rate constant (*k*₁) of the addition of the nucleophile to substrate **26** to form a zwitter-ionic intermediate.¹⁰⁴

20–23 and 30–37, Table 8). The formation of the transition state TS-10 occurs due to a lag in the resonance delocalisation of the negative charge of the C_β atom to the activating groups Z and Z' and a higher degree of N–H bond cleavage, than would be expected in the case of synchronous resonance delocalisation.^{105–110} The compensation plots of Δ*H*[‡] vs Δ*S*[‡] for the Ad_N reactions of alkenes **26**–**42** with amines are shown in Fig. 6. Straight line *I* in this figure represents the reactions of β-nitrostyrenes **32** and **33** with benzylamines. These reactions are characterised by the late transition state TS-10 on the reaction coordinate and the lowest values of Δ*H*[‡] and Δ*S*[‡].¹⁰⁵ The reactions of β-nitrostilbenes **27** and **28**, β-cyano-4'-nitrostilbenes **29** and **30**, benzylidenemalonates **37** and **38** and ethyl α-acetyl-β-phenylacrylates **41** and **42** with benzylamines are characterised by enthalpy–entropy compensation plot *II* (see Fig. 6). The transition state TS-10 for these reactions is earlier because the degree of

the lag in the resonance delocalisation of the negative charge of the C_β atom to the activating groups Z and Z' decreases.^{106, 108, 110}

It should be noted that the activation parameters for the reactions of benzylideneindane-1,3-diones **39** and **40** and -malononitriles **35** and **36** with benzylamines form straight line *III* (Fig. 6) with the almost constant Δ*H*[‡] due to the difference in the structure of TS-10. The reactions of compounds **39** and **40** afford the more loose transition state TS-10.^{107, 109} For compounds **35** and **36** possessing substantially higher electrophilicity,¹¹² the C_α reaction centre becomes more positive in TS-10 compared to the starting compounds due to strong polarisation of the C_α–C_β bond by two CN groups.¹⁰⁷

The activation parameters for the reactions of β-nitrostyrene (**34**) with anilines (entries 15–19, Table 8) and the reactions of compound **26** with benzylamines (entries 25–29, Table 8) in MeCN are described by compensation plots *IV* and *V*, respec-

Figure 7. Plots of the enthalpies vs the activation free energies for the Ad_N reactions of activated alkenes with amines in MeCN (the numbering of the points corresponds to the entries in Table 8).

–300 to –120 J mol^{–1} K^{–1} (Table 9). Interestingly, there are Ad_N reactions of activated alkynes with nucleophiles for which the enthalpy of activation is equal to zero (entries 1–5 and 10, Table 9).^{113, 114, 116}

In the attack of arenethiols ArSH on the triple bond of 1,3-diphenylprop-1-yn-3-one (**43**) in the presence of the non-nucleophilic base Et₃N in toluene, the nucleophile is involved in the reaction as complex **44**.¹¹³

Hence, the effective rate constant of the process is $k_{\text{eff}} = (k_1/k_{-1})k_2$, and the enthalpy of formation of complex **44** is close to the activation energy of the rate-determining step of the reaction with the rate constant k_2 via the transition state TS-11. Very low negative values of $\Delta S^\ddagger$ and the isoenthalpy character of the reaction are consistent with the structure of TS-11, in which Et₃N is involved in the S–H bond cleavage (entries 1–4, Table 9).¹¹³ Complex **44** can also be formed in the analogous reaction in a more polar medium (in methanol), but at a low concentration of Et₃N. An increase in the concentration of Et₃N in methanol leads to the formation of the ion pairs {ArS–Et₃HN⁺} and a sharp increase in the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for their reactions with compound **43** (entries 5 and 6, Table 9).¹¹⁴ Consequently, the formation of H-complex **44** before the formation of the transition state TS-11 is responsible for the entropy control of the reaction of compound **43** with arenethiols in the presence of Et₃N.^{113, 114}

The rates of the Ad_N reactions of alkyne **43** with amines at low concentrations of the latter (0.03–0.2 mol litre⁻¹) are independent of the concentration of amines if the reactions proceed in ethanols or aprotic polar solvents (entries 7–23, Table 9).^{115–119} This is possible if $k_2 + k_3[\text{amine}] \gg k_1$. In the latter case, the rate of the overall process is controlled by the rate of the nucleophilic attack of amine (k_1). Based on the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for these reactions, it can be concluded that the reaction mechanism changes from stepwise (*via* zwitterion **45**) to concerted

The Ad_N reactions of activated alkynes with various nucleophiles proceeded rather rapidly, and the activation parameters vary in the ranges of $\Delta H^\ddagger$ from 0 to 54.3 kJ mol⁻¹ and of $\Delta S^\ddagger$ from

Table 9. Rate constants and activation parameters for the Ad_N reactions of 1,3-diphenylprop-1-yn-3-one (**43**) with arenethiols in the presence of Et₃N and with amines.

^a An excess of Et₃N with respect to arenethiol; [Et₃N] = 0.1 mol litre⁻¹; ^b the apparent second-order rate constant; ^c at [Et₃N] = 1.5 × 10⁻⁵ mol litre⁻¹; ^d at [Et₃N] = 1.5 × 10⁻² mol litre⁻¹.

(via the cyclic transition state TS-12) depending on the nature of amine and the solvent.

Aprotic polar solvents are more favourable for the concerted mechanism due to weak solvation of zwitterion **45**.

Figure 8 presents the enthalpy–entropy compensations for the Ad_N reactions of compound **43** with amines. Plot *I* characterises the reactions of alkyne **43** with secondary aliphatic amines, which have very low Δ*H*[‡] and Δ*S*[‡] and are entropy-controlled (entries 7–12 in Table 9). Correspondingly, the transition state TS-12 is late.

The activation parameters for the reactions of compound **43** with anilines are described by straight line *II* with almost constant Δ*H*[‡] (see Fig. 8). In spite of high Δ*H*[‡], these reactions are also characterised by low Δ*S*[‡] and, on the whole, the entropy control (entries 13–17, Table 9). Evidently, these reactions have the earlier transition state TS-12.

The reactions of alkyne **43** with primary aliphatic amines (line *III*, Fig. 8) are characterised by high Δ*H*[‡] and Δ*S*[‡] and the enthalpy control (entries 18–23 in Table 9). In this case, the reactions proceed stepwise via zwitterion **45**.¹¹⁶

**Figure 8.** Compensation plots for the Ad_N reactions of activated alkyne **43** with amines in various media (the numbering of the points corresponds to the entries in Table 9).

(*I*) $r = 0.997$, $n = 6$, $s = 1.54$; (*II*) $r = 0.947$, $n = 4$, $s = 2.53$ (point 13 is omitted); (*III*) $r = 0.998$, $n = 6$, $s = 0.62$.

A comparison of the relationships between the enthalpies and the activation free energies for the Ad_N reactions of compound **43** with amines (Fig. 9) shows that lines *I* and *III* have opposite slopes, which confirms the above conclusion about the difference in the character of the control of the reaction depending on the structure of primary or secondary amines. Line *II* in Fig. 9 demonstrates that Δ*H*[‡] is independent of changes in Δ*G*[‡] for the reactions of alkyne **43** with anilines (*cf.* line *II* in Fig. 8).

Both the S_NV and Ad_N reactions are characterised by Δ*H*[‡], Δ*S*[‡] and Δ*G*[‡] varying in very broad ranges and the absence of the common enthalpy–entropy compensation effect. It should also be noted that positive Δ*S*[‡] allow the reliable identification of the

Figure 9. Plots of the enthalpies vs the activation free energies for the Ad_N reactions of activated alkyne **43** with amines in various media (the numbering of the points corresponds to the entries in Table 9). (I) $r = 0.975$, $n = 5$, $s = 4.9$; (II) $r = 0.697$, $n = 5$, $s = 0.29$; (III) $r = 0.967$, $n = 6$, $s = 2.5$.

E-Ad_N mechanism in $\text{S}_\text{N}\text{V}$ reactions and that complexation of a nucleophile with a base and the use of aprotic polar solvents can substantially change the activation parameters for Ad_N reactions.

V. Reactions at the carbonyl carbon

The energetics of bimolecular nucleophilic reactions at the carbonyl carbon atom was extensively analysed.^{6, 71, 72, 120, 121} In the last 10–15 years, these reactions were also extensively studied, the main attention being given to elucidation of their detailed mechanism based on both the kinetic data at different temperatures and for different substrates, nucleophiles and solvents and the data on the kinetic isotope exchange.^{5, 41, 122–128}

Table 10 gives the rate constants and the activation parameters for bimolecular reactions of carboxylic acid halides with neutral nucleophiles (alcohols and amines) in various media. The rate constants of these reactions vary by 4–5 orders of magnitude; $\Delta H^\ddagger$, from 14.9 to 82.3 kJ mol^{−1}; $\Delta S^\ddagger$, from −238 to −53.8 J mol^{−1} K^{−1}. The fact that the activation parameters vary in broad ranges is attributed to the difference in the mechanisms of these reactions. Ethanolysis of haloformates **46–53** was demonstrated^{129, 130} to proceed as addition–elimina-

Table 10. Apparent rate constants and activation parameters for bimolecular reactions of carboxylic and thiocarboxylic acid halides with alcohols and amines in various media.

tion *via* a cyclic intermediate due to the involvement of the associated form of ethanol.

R = Alk, Ar; Hal = F, Cl; X = O, S.

Alcoholysis of acid chlorides **58** and **59** proceeds apparently through the initial formation of charge-transfer complex **60**, which is transformed into an activated complex and then into the reaction products.¹³⁵⁻¹³⁷

The rate constants of alcoholysis of compounds **58** and **59** depend on the nature of the solvent (entries 28–30 in Table 10),¹³⁶ the structure of alcohol (entries 28 and 31–34 in Table 10)¹³⁵ and the acid chloride to alcohol ratio (entries 35–37 in Table 10).¹³⁷

Figure 10 shows the compensation plots for alcoholysis of compounds **46–53**, **58** and **59**. Line *I* describes ethanolysis reactions characterised by high $\Delta H^\ddagger$ and $\Delta S^\ddagger$ and the enthalpy control in spite of the proposed structure of the cyclic six-membered transition state.¹²⁹

Figure 10. Compensation plots for the reactions of carboxylic and thio-carboxylic acid halides with alcohols and amines (the numbering of the points corresponds to the entries in Table 10).

(I) $r = 0.985$, $n = 8$, $s = 1.75$; (II) $r = 0.989$, $n = 5$, $s = 2.1$; (III) $r = 0.994$, $n = 7$, $s = 1.94$; (IV) $r = 0.988$, $n = 5$, $s = 4.1$; (V) $r = 0.943$, $n = 4$, $s = 0.4$; (VI) $r = 0.844$, $n = 8$.

The alcoholysis reactions of phenyl haloformates **51** and **52** together with the reactions of acid chlorides **58** and **59** form compensation line *III* (see Fig. 10) because of conjugation of the double bond with the C=O group in these compounds. Hence, these reactions proceed *via* complex **60** with both the enthalpy and entropy control.

The reactions of acid chloride **58** with primary alcohols in low polar solvents are described by compensation plot *II* (see Fig. 10) with the lowest $\Delta H^\ddagger$ and $\Delta S^\ddagger$, the reactivity being entropy-controlled. Apparently, the formation of complex **60** plays an essential role under these conditions.^{135, 137}

A comparison of the activation parameters for the reactions of ethyl (**47**) and aryl chloroformates **51**, **54** and **55** and their sulfur-containing analogues **56** and **57** with pyridines and anilines (see Table 10) shows that changes in the parameters depend on the nature of the nucleophile.¹³¹⁻¹³⁴ For example, $\Delta H^\ddagger$ and $\Delta S^\ddagger$ are low (entries 5–7, 14–17 and 20–27 in Table 10) and aminolysis reactions of these compounds are entropy-controlled. However, aminolysis of these compounds is characterised by different compensation plots (lines *IV–VI* in Fig. 10). For example, line *IV* relates to the activation parameters for the reactions of chloroformate **47** with *N*-alkylanilines (entries 5–9 in Table 10) and is indicative of a high degree of order of the transition state giving rise to intermediate **61** the decomposition of which affords reaction products.¹³¹

An increase in steric hindrance to the attack on *N*-isopropyl- and *N*-cyclohexylanilines (entries 8 and 9 in Table 10) leads to an increase in $\Delta H^\ddagger$ and $\Delta S^\ddagger$ and, consequently, to a looser transition state, the reactions being enthalpy-controlled.¹³¹

Compensation plot *VI* (see Fig. 10) combines the activation parameters for the reactions of anilines with phenyl chloroformate **51** and its sulfur-containing analogues **56** and **57**. These results do not contradict to the concerted mechanism of these reactions in MeCN *via* the transition state TS-13 for compound **51**^{132, 133} and TS-14 for compounds **56** and **57**.¹³⁴ However, these reactions in aqueous solution proceed stepwise to form intermediate **61**.¹³⁴

Aminolysis of aryl chloroformates **54** and **55** with pyridines in MeCN also proceeds stepwise and involves the formation of intermediate **61** as the rate-determining step *via* the transition state TS-15, which is generated as a result of conjugation of the O–C–O fragment in aryl chloroformate with the π system of the pyridine ring.¹³³

Compensation plot *V* (Fig. 10) is close to the isenthalpy relation and reflects the interaction between the substituent Y in

the aryl fragment and the pyridine fragment through the π -bond system in TS-15.¹³³

A comparison of the relationships between the enthalpies and the activation free energies for the above-described reactions (Fig. 11) confirms the chemical nature of the compensation plots presented in Fig. 10.^{71–73} Lines I, IV and II, III, V, VI in Fig. 11 have opposite slopes due to the difference in the character of the control of the reactivity depending on the structure of the nucleophile.

Figure 11. Plots of the enthalpies vs the activation free energies for the reactions of compounds **46**–**59** with alcohols and amines (the numbering of the points corresponds to the entries in Table 10).

Aryl chloroformates **51**, **54** and **55** are good models for calculations of the electrophilicity and prediction of the reaction mechanism with neutral and charged nucleophiles.¹³⁸ The electrophilicities of alkyl aryl and diaryl carbonates were also calculated.¹³⁸ Hence, it is of interest to compare the rate constants and the activation parameters for the reactions of carbonates with nucleophiles and the mechanisms of these reactions. Aminolysis of aryl ethyl carbonates **62** and **63** with benzylamines in MeCN is characterised by high $\Delta H^\ddagger$ and $\Delta S^\ddagger$ (entries 1 and 2 in Table 11) and proceeds stepwise *via* a zwitterionic intermediate, the transformation of which into the reaction products *via* TS-16 is the rate-determining step of the reaction.¹³⁹ Low rate constants of the reactions of carbonates **62** and **63** characterise their moderate electrophilicities.¹³⁸

Y = 3-NO₂ (**62**), 4-CN (**63**); X = 4-MeO, 3-Cl.

Aminolysis of dimethyl carbonate **64** in the presence of CO₂ involves two steps; it is a slower reaction and is characterised by the activation parameters varying in a very broad range depending on the structure of alkylamine (entries 3–7 in Table 11).¹⁴⁰ The nucleophilic attack of the ion pair of carbamate anion **65** on the carbonyl carbon atom in compound **64** giving intermediate **66** is the rate-determining step.

A steric interaction between the substituents R in ion pair **65** and the methyl groups in compound **64** results in changes in $\Delta H^\ddagger$ and $\Delta S^\ddagger$,¹⁴⁰ which are described by the compensation relation (line I, Fig. 12)

$$\Delta H^\ddagger = 118.1 + 0.34 \Delta S^\ddagger \quad (r = 0.996, s = 3.28, n = 5).$$

However, the same reactions on the $\Delta H^\ddagger$ – $\Delta G^\ddagger$ coordinates form two lines with opposite slopes, which reflects the enthalpy (entries 3, 6 and 7 in Table 11) and entropy (entries 4 and 5 in Table 11) control of the reactivity.

Figure 12. Compensation plots for the reactions of carbonyl compounds **64** and **81**, **82** with amines (the numbering of the points corresponds to the entries in Table 11).

Aminolysis reactions of esters **67**–**74** and thioesters **75**–**79** with benzylamines (entries 8–21, 24 and 25 in Table 11), piperidine, piperazine (entries 28–30 in Table 11) and anilines (entries 22, 23, 26 and 27 in Table 11) involve two steps, where elimination of the leaving group from tetrahedral intermediate **87** is the rate-determining step.^{141–147} The only exception is the reaction of thioester **80** with piperidine in water (entry 30 in Table 11) where the formation of an intermediate is the rate-determining step.¹⁴⁷ Decomposition of zwitterionic intermediate **87** occurs *via* the cyclic transition state TS-17.^{141–147}

The reactions of compounds **67**–**70** with benzylamines (entries 8–15 in Table 11) and the reactions of compounds **77** and **78** with benzylamines and anilines (entries 24–27 in Table 11) are characterised by high activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ due to which these reactions are enthalpy-controlled. On the contrary, the reactions of compounds **71**–**76** with benzylamines and

anilines (entries 16–23 in Table 11) and of compound **79** with piperidine (entry 28 in Table 11) are characterised by lower activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ and the entropy control. The activation parameters for aminolysis of compounds **67–79** fall within two ranges (with low and high $\Delta H^\ddagger$ and $\Delta S^\ddagger$), however no enthalpy–entropy compensation effect is observed. The more organised transition states of the TS-17 type for aminolysis of compounds **71–76** are attributed to hydrogen bonding with the $\text{ZC}_6\text{H}_4\text{X}^-$ leaving group.^{142, 143}

A decrease in the contribution of the latter to the structure of TS-17 due to an increase in the steric effect of the substituent R in the substrate (for example, R = Et)¹⁴⁵ or the solvent effect^{141, 147} results in a looser structure of the transition state TS-17 and an increase in the activation parameters.

A much stronger donor effect of the PhNH and EtNH groups in thiocarbamates **81** and **82** leads to a switch from the stepwise mechanism to the concerted mechanism in the reactions of these compounds with benzylamines (entries 31–34 in Table 11).^{148, 149} The transition state TS-18 for these reactions involves a four-

membered ring, which is more rigid in the presence of a strong electron-donating substituent ($R = \text{Et}$).¹⁴⁹

The activation parameters for these aminolysis reactions are characterised by the compensation relations between $\Delta H^\ddagger$ and $\Delta S^\ddagger$ (line II in Fig. 12) and between $\Delta H^\ddagger$ and $\Delta G^\ddagger$:

$$\Delta H^\ddagger = 60.0 + 0.17 \Delta S^\ddagger \quad (r = 0.999, s = 0.38, n = 4),$$

$$\Delta H^\ddagger = 138.1 - 1.31 \Delta G^\ddagger \quad (r = 0.997, s = 0.94, n = 4),$$

which confirms the chemical nature of the compensation effect.^{71–73}

It should be noted that the activation parameters for aminolysis of thiocarbonates **81** and **82** proceeding by the concerted mechanism and aminolysis of esters and thioesters proceeding by the stepwise mechanism vary in the same range. Recently, it has been demonstrated that the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for the aminolysis of carbonates **62** and **63**¹³⁹ are rather close to those of related thiocarbonates¹³⁸ although the reactions of carbonates proceed by the stepwise mechanism, whereas the reactions of thiocarbonates occur by the concerted mechanism.^{139, 148, 154} Evidently, to estimate unambiguously the reaction mechanism, it is necessary to use the activation parameters along with the correlation analysis and data on the kinetic isotope effect.^{5, 41, 122–128}

The reactions of ester **86** and thioesters **83** and **84** with pyridines proceed stepwise *via* tetrahedral intermediate **87a**.^{150, 151, 153}

The reaction of phenacyl bromide **85** also proceed *via* an analogous intermediate.¹⁵²

The formation of intermediates **87a,b** was demonstrated to be the rate-determining step of the reactions with more basic pyridines, whereas decomposition of these intermediates is the rate-determining step of the reactions with weakly basic pyridines in low polar MeCN (entries 35–40 in Table 11).^{150–152} However, the influence of the basicity of pyridines on the reaction mechanism in aqueous-alcoholic media is less significant due to an increase in the contribution of solvation of the transition state TS-19. As a result, decomposition of the corresponding intermediate was the rate-determining step for all the pyridines examined.¹⁵³ Aminolysis reactions with pyridine, in which decomposition of intermediates is the rate-determining step, are characterised by much lower entropies of activation (entries 36, 38, 40 and 41 in Table 11). The latter fact is associated with the more organised and more solvated transition states TS-19 and TS-20 for the transformations of intermediates **87a** and **87b**, respectively.^{150–152}

The less organised and less solvated transition states TS-21 and TS-22 are typical of the reactions of pyridine with compounds **83–86** involving the formation of the corresponding intermediates as the rate-determining step.

An increase in $\Delta S^\ddagger$ is either not accompanied by changes in $\Delta H^\ddagger$ (entries 35–38 in Table 11) or is accompanied by a decrease (entries 39 and 40 in Table 11) or even an increase in these parameters (entries 41 and 42 in Table 11). Therefore, no compensation effects were observed for the reactions of compounds **83–86** with pyridine, although almost all reactions are entropy-controlled (entries 35–41 in Table 11). The reaction of ester **86** with weakly basic pyridine in aqueous EtOH, which is enthalpy-controlled is the exception (entry 42 in Table 11).¹⁵³

Aminolysis of carbonyl compounds with pyridine is similar in the energetics and the reaction mechanism to analogous reactions of triaryl phosphates. For example, study of the kinetics of the reactions of aryl bis(4-methoxyphenyl) phosphates **88a–c** with pyridines in MeCN showed that the activation parameters vary in broad ranges depending on the basicity of pyridine and the nature of the substituent Z in the leaving group ($\Delta H^\ddagger$ from 5.4 to 39.3 kJ mol^{−1} and $\Delta S^\ddagger$ from −259.2 to −137.9 J mol^{−1} K^{−1}). The use of less basic pyridine ($X = 3\text{-Cl}$) and a better nucleofuge containing an electron-withdrawing substituent Z ($Z = \text{CN}$ or NO_2) leads to a sharp decrease in the activation parameters.¹⁵⁵

This is associated with the fact that the reaction proceeds by the concerted mechanism *via* the transition state TS-23 with the apical arrangement of the nucleophile and the leaving group.

The more basic pyridine ($X = 4\text{-Me}$) and the poorer leaving group in the substrate ($Z = \text{Cl}$) lead to an increase in $\Delta H^\ddagger$ and $\Delta S^\ddagger$,

which is associated with the fact that this reaction proceeds by the stepwise mechanism involving the formation of an intermediate as the rate-determining step.¹⁵⁵ The activation parameters are described by the common compensation relations

$$\Delta H^\ddagger = 77.83 + 0.279 \Delta S^\ddagger \quad (r = 1.0, s = 0.014, n = 3),$$

$$\Delta H^\ddagger = 524.11 - 5.74 \Delta G^\ddagger \quad (r = 0.999, s = 0.167, n = 3)$$

for the reactions proceeding by different mechanisms.¹⁵⁵

Alcoholysis of *N*-acetylimidazole with 2,2-dialkyl-3-(*N,N*-dimethylamino)propan-1-ols in MeCN at 25–65 °C occurs stepwise and involves, as the rate-determining step, the formation of a tetrahedral intermediate, which is then transformed into the reaction products.⁶²

These reactions are characterised by very low entropies of activation ($\Delta S^\ddagger$ from -210 to -171 J mol⁻¹ K⁻¹), moderate enthalpies of activation ($\Delta H^\ddagger = 27.4$ – 40.9 kJ mol⁻¹) and the entropy control.⁶² There is the enthalpy–entropy compensation

$$\Delta H^\ddagger = 91.2 + 0.30 \Delta S^\ddagger \quad (r = 0.935, s = 1.43, n = 8).$$

However, the isokinetic relationships between the activation parameters depend on the structures of the substituents *R* in the starting amino alcohol.⁶²

Non-catalysed hydrolysis of substituted *N*-benzoylimidazoles in 10% aqueous MeCN proceeds *via* the transition state TS-24 with pronounced charge separation. The substituent *Z* has a considerable effect on solvation and $\Delta S^\ddagger$.

For example, $\Delta S^\ddagger$ varies from -186.4 J mol⁻¹ K⁻¹ for *Z* = 4-Me to -136.7 J mol⁻¹ K⁻¹ for *Z* = 4-NO₂; $\Delta H^\ddagger$, from 43.5 to 50.6 kJ mol⁻¹ for *Z* = Me and NO₂, respectively. The entropy control of the reaction changes to the enthalpy control with increasing electron-withdrawing properties of the substituent *Z*.¹⁵⁶ Evidently, the energy parameters for alcoholysis of acylimidazoles are very close to those for hydrolysis of these compounds.

Hydrolysis of enamines in 50% aqueous dioxane in the presence of an acetate buffer occurs stepwise and involves the addition *via* the transition state TS-25 as the rate-determining step to form an intermediate and then the reaction products.¹⁵⁷

The activation parameters are close to those for hydrolysis of *N*-benzoylimidazoles in the case of the entropy control of the reaction.¹⁵⁷ The hydrolysis reactions of the above-mentioned enamines are characterised by the following relation

$$\Delta H^\ddagger = 107.4 + 0.31 \Delta S^\ddagger \quad (r = 0.990, s = 1.5, n = 8),$$

which indicates that the equilibrium constant of association of the substrate with the buffer component HA makes a contribution to the apparent rate constant.¹⁵⁷

Alkaline hydrolysis of esters occurs stepwise and involves the formation of a tetrahedral intermediate as the rate-determining step.¹²⁵ For example, hydrolysis of ester **89** in 10% aqueous MeCN proceeds *via* intermediate **90** and is characterised by very low activation parameters: $\Delta H^\ddagger = 13.5$ kJ mol⁻¹ and $\Delta S^\ddagger = -277.1$ J mol⁻¹ K⁻¹.

Hydrolysis is sharply accelerated in the presence of polymeric bases as catalysts. In this case, the activation parameters are substantially higher: $\Delta H^\ddagger = 55.6$ – 65.6 kJ mol⁻¹, $\Delta S^\ddagger$ from -62.7 to -12.6 J mol⁻¹ K⁻¹. The reaction is controlled by the enthalpy.¹⁵⁸ The isokinetic relationship with $\beta = 313$ K found for the catalytic process is due to the contribution of the equilibrium constant between substrate **89** and the catalyst to the apparent rate constant.¹⁵⁸

In 10% aqueous dioxane, alkaline hydrolysis of diaryl sulfates **91** and **92**, *viz.*, sulfur-containing analogues of diaryl carbonates, proceeds apparently by the concerted mechanism *via* the transition state TS-26 and is characterised by high activation parameters ($\Delta H^\ddagger = 88.0$ and 84.8 kJ mol^{-1} and $\Delta S^\ddagger = -37.0$ and $-50.2 \text{ J mol}^{-1} \text{ K}^{-1}$ for compounds **91** and **92**, respectively) and the enthalpy control of the reactivity.¹⁵⁹

Ar = 4-Cl-3-NO₂C₆H₃ (**91**), 4-NO₂C₆H₄ (**92**).

It should be noted that the reactions of diaryl carbonates with phenolate anions in aqueous solution also proceed by the concerted mechanism.¹⁶⁰

Transesterification can occur by different mechanisms.¹²⁵ For example, the reaction of 4-nitrophenyl acetate with 4-chlorophenolate in aqueous media proceeds through the one-step concerted mechanism¹²³ with the activation parameters $\Delta H^\ddagger = 51.4 \text{ kJ mol}^{-1}$, $\Delta S^\ddagger = -75.7 \text{ J mol}^{-1} \text{ K}^{-1}$ and $\Delta G^\ddagger = 74.0 \text{ kJ mol}^{-1}$. These parameters are only slightly smaller for the reaction in 90% aqueous DMSO or for the reaction with butane-2,3-dione monooximate as the nucleophile, the enthalpy control being retained.¹⁶¹

The activation parameters for transesterification of 4-nitrophenyl benzoates **93a–g** with the nucleophile 4-ClC₆H₄O[−]·K⁺ differ substantially from those for the reaction with the 4-ClC₆H₄OH·K₂CO₃ complex.^{67, 162}

R = 4-MeO (**a**), 4-Me (**b**), H (**c**), 4-Br (**d**), 4-CF₃ (**e**), 3-NO₂ (**f**), 4-NO₂ (**g**); Ar = 4-NO₂C₆H₄, Ar' = 4-ClC₆H₄.

An increase in the electron-withdrawing properties of the substituent R in benzoates **93a–g** leads to a substantial decrease in the relative values of the parameters $\Delta\Delta H^\ddagger$ and $\Delta\Delta S^\ddagger$ for transesterification reactions due apparently to the characteristic features of complexes **94a–g**. The transformation of the latter through the cyclic transition state TS-27 into intermediates **95a–g**

is the rate-determining step of the process.¹⁶² The reactions of benzoates **93a–g** are characterised by the compensation relations

$$\Delta\Delta H^\ddagger = 2.23 + 0.39 \Delta\Delta S^\ddagger \quad (r = 0.999, s = 1.67, n = 7),$$

$$\Delta\Delta H^\ddagger = -9.49 + 4.64 \Delta\Delta G^\ddagger \quad (r = 0.984, s = 6.35, n = 7)$$

the reactivity being enthalpy-controlled.¹⁶² It should be noted that the isokinetic relationship for transesterification reactions is observed only for benzoates **93c–g** (see Ref. 162) due to destabilisation of the ground state of these compounds.^{125, 163–165}

Bimolecular nucleophilic reactions at the carbonyl carbon atom, like the reactions considered in the previous sections, are characterised by very broad ranges of the activation parameters within one class of substrates. It should be noted that complexation between carbonyl compounds and nucleophiles plays a considerable role in the changes in the activation parameters.

VI. Reactions of carbocations with nucleophiles

The energetics of the reactions of stable carbocations with nucleophiles is of particular interest because, first, the formation of the bond between these species is the rate-determining step and, second, most of these reactions are described by either Ritchie's equation^{166, 167}

$$\log \frac{k}{k_0} = N_+,$$

where k and k_0 are the rate constants of the reaction of the substrate with this nucleophile and water, respectively, and N_+ is the nucleophilicity, or by the equation proposed by Mayr and co-workers,^{167–169}

$$\log k(20^\circ \text{C}) = s(N + E),$$

where s is the specific parameter of the nucleophile ($s = 1$ for 2-methylpent-1-ene), N is the nucleophilicity for the nucleophile and E is the electrophilicity for the electrophile.

The rate constants and the activation parameters for the reactions of benzhydryl and benzopyrylium cations with neutral π -nucleophiles (alkenes and dienes) vary within broad ranges. The rate constants vary by 7–8 orders of magnitude; $\Delta H^\ddagger$, from 0 to 53 kJ mol^{−1}; $\Delta S^\ddagger$, from −180 to −80 J mol^{−1} K^{−1}.^{168–175} These broad ranges are attributed to the fact that the structure of the transition state TS-28 and its position on the reaction coordinate substantially depend on the nature of the reagents.^{170, 171, 175}

Hence, there is no common enthalpy–entropy compensations for the above-mentioned reactions of cations with π -nucleophiles. However, the compensation relations are observed for the reactions of benzhydryl cations with the same nucleophile, for example, for the reactions of cations **96–100** with alkene PrⁿMeC=CH₂ (entries 1, 4, 6, 8 and 10, Table 12) or Me₂C=CHMe (entries 2, 5, 7, 9 and 11 in Table 12), the reactions of cations **101–104** with alkene CH₂=C(OPh)OSiMe₃ (entries 12, 15, 18 and 20 in Table 12) or with 1-(trimethylsilyloxy)cyclopentene (entries 14, 17 and 19 in Table 12) and the reactions of cations **96**, **101** and **102** with alkenes Me₂C=CMe₂ and Me₂C=C(OMe)OSiMe₃ (entries 3, 13 and 16 in Table 12).

In the reactions of the cations with π -nucleophiles characterised by the activation parameters $\Delta H^\ddagger < 30 \text{ kJ mol}^{-1}$ and $\Delta S^\ddagger < -100 \text{ J mol}^{-1} \text{ K}^{-1}$, the reactivity is entropy-controlled. If these parameters are larger than the above-mentioned values,

Table 12. Rate constants and activation parameters for bimolecular reactions of benzhydryl carbocations with alkenes in CH_2Cl_2 .^a

^a Reactions were carried out at -70 °C (entries 1–11) and 20 °C (entries 12–20); ^b pyr is pyrrolidino; ^c mor is morpholino.

the enthalpy makes a larger contribution to the activation free energy of these reactions.

The fast reactions of highly electrophilic benzhydryl cations **96**, **99** and **100** with alkenes Me₂C=CHMe and Me₂C=CMe₂ are characterised by very low $\Delta H^\ddagger$ and $\Delta S^\ddagger$ (entries 2, 3, 9, 11 in Table 12).^{168, 170, 175} Changes in the electrophilicity of the benzhydryl cations were demonstrated¹⁷⁵ to have a stronger effect on $\Delta H^\ddagger$ than on $\Delta S^\ddagger$ (Figures 13 and 14). Hence, negative $\Delta H^\ddagger$ for the reactions of highly electrophilic carbocations can be attributed to the shift of the transition state TS-28 to the earlier position on the reaction coordinate, which is accompanied by an increase in the entropy of activation (entries 3 and 11 in Figures 13 and 14).¹⁷⁵

The reactivity of carbocations of the triarylmethane series **105–119** in the reactions with cyanide ions in aqueous media described by Ritchie's equation is substantially lower than that of the benzhydryl cations, and $\Delta H^\ddagger$ and $\Delta S^\ddagger$ vary in the ranges from 31 to 52 kJ mol⁻¹ and from -187 to -40 J mol⁻¹ K⁻¹, respectively (Table 13).¹⁷⁶ There is no common compensation relations

**Figure 13.** Plots of the enthalpy of activation vs the electrophilicity for the reactions of benzhydryl cations with neutral π -nucleophiles (the numbering of the points corresponds to the entries in Table 12).**Figure 14.** Plots of the entropy ($T\Delta S^\ddagger$) vs the electrophilicity for the reactions of benzhydryl cations with neutral π -nucleophiles (the numbering of the points corresponds to the entries in Table 12).

for the latter reactions (as in the case of the reactions of benzhydryl cations). Only certain series of these cations are characterised by the compensation (isokinetic) relations between $\Delta H^\ddagger$ and $\Delta S^\ddagger$ (Fig. 15).¹⁷⁶

The structure of the transition state TS-29 for the reactions of cations **105–116** controlled by the enthalpy of activation is described by a solvent-separated ion pair, whereas the structure of TS-29 for the reactions of cations **117–119** controlled by the entropy of activation can be represented as a contact ion pair.¹⁷⁶

The reaction of the most reactive cation **106** with the CN^- ions is characterised by the highest value of $\Delta S^\ddagger$, whereas the analogous reaction of the least reactive cation **117** is characterised by very low $\Delta S^\ddagger$ (see Table 13). The earlier and less-organised transition state TS-29 and the later and well-organised transition state TS-29 for the reactions of cations **106** and **117**, respectively,

are not contradictory to the reaction mechanisms through solvent-separated and contact ion pairs.

Heterocarbocations **120**–**123** are very reactive in the reactions with the MeO^- anion in MeOH. Both series of the cations (with $\text{X} = \text{O}$ and $\text{X} = \text{S}$) are characterised by isokinetic relationships and the enthalpy control of the reaction.¹⁷⁷ An increase in the charge on the carbocationic centre leads not only to an increase in the rate constant but also to a decrease in the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$, which is more pronounced in the case of less stabilised oxygen-containing cations **120** and **121**.¹⁷⁷ Presumably, the transition state TS-30 as the solvent-separated ion pair (as in the reactions of cations **105**–**116** with the CN^- anion) provides the best explanation for the character of changes in the activation parameters for the above-mentioned reactions.

Compound	R	X	$k_2(25^\circ\text{C})$ /litre mol ⁻¹ s ⁻¹	$\Delta H^\ddagger$	$-\Delta S^\ddagger$
120	Me	O	8.71×10^4	30	49

122	Me	S	0.107×10^4	46	32
123	Ph	S	0.16×10^4	42	40

Therefore, the reactions of cationic substrates with neutral and charged nucleophiles are characterised by broad ranges of the rate constants and the activation parameters. Depending on the electrophilicity of the cation and the nature of the nucleophile, the reactions proceed by different mechanisms, which is reflected in the relationship between the activation parameters.

Table 14. Inversion temperatures and differences between the activation parameters for bimolecular addition reactions of BuⁿLi and EtMgBr with (2*S*)-lactaldehyde derivatives.

^a $\Delta\Delta H^\ddagger = \Delta H_{\text{anti}}^\ddagger - \Delta H_{\text{syn}}^\ddagger$, $\Delta\Delta S^\ddagger = \Delta S_{\text{anti}}^\ddagger - \Delta S_{\text{syn}}^\ddagger$.

VII. Miscellaneous reactions

This section deals with the energetics of bimolecular nucleophilic reactions and their stereoselectivities, touches on certain aspects of micellar catalysis and considers the reactions of halide anions with aryl radicals and the reactions of organometallic compounds with neutral and charged nucleophiles.

For kinetically controlled reactions giving rise to two stereoisomers, the selectivity *S* is expressed by the equation

$$S = \frac{k}{k'},$$

where *k* and *k'* are the overall reaction rate constants for the formation of two stereoisomers.¹⁷⁸ The linear dependence of the stereoselectivity on the reverse temperature is described by the modified Eyring equation:¹⁷⁸

$$\ln \frac{k}{k'} = -\frac{\Delta\Delta H^\ddagger}{RT} + \frac{\Delta\Delta S^\ddagger}{R}.$$

Therefore, the stereoselectivity is expressed in terms of the differences between the enthalpies ($\Delta\Delta H^\ddagger$) and entropies ($\Delta\Delta S^\ddagger$) of activation for two reaction pathways.^{178, 179} The entropy and enthalpy can play opposite roles in the formation of a particular stereoisomer, resulting in the selectivity inversion with changes in the reaction temperature and the appearance of the inversion temperature T_{inv} and two systems of the activation parameters: $\Delta\Delta H_2^\ddagger$ and $\Delta\Delta S_2^\ddagger$ at $T < T_{\text{inv}}$ and $\Delta\Delta H_1^\ddagger$ and $\Delta\Delta S_1^\ddagger$ at $T > T_{\text{inv}}$. In other words, T_{inv} is the temperature at which the domination of the enthalpy or entropy changes (the transition point in an Eyring plot).^{162, 163} The isoinversion temperature $T_i^\ddagger$ at which the maximum stereoselectivity is expected, is also an important characteristics of the stereochemical results of the reaction. For example, the asymmetric synthesis of esters by the addition of achiral alcohols to non-symmetric disubstituted ketenes catalysed by chiral tertiary amines is characterised by $T_i^\ddagger = 210$ K, whereas for the non-catalysed addition of racemic secondary alcohols to non-symmetrically disubstituted ketenes, $T_i^\ddagger = 259$ K (Ref. 178).

The result of the asymmetric synthesis of amides by the addition of chiral primary amines to non-symmetric disubstituted ketenes also substantially depends on the temperature.¹⁷⁸

The nucleophilic substitution in secondary alcohol **124** with gaseous HBr affords enantiomers of (*S*)- and (*R*)-1-(bromoethyl)-benzene (**125**) with the ratio depending on the temperature ($T_{\text{inv}} = 248$ K).

$\dagger T_i = \partial(\Delta\Delta H^\ddagger) / \partial(\Delta\Delta S^\ddagger)$, where $\Delta\Delta H^\ddagger = \Delta\Delta H_2^\ddagger - \Delta\Delta H_1^\ddagger$, $\Delta\Delta S^\ddagger = \Delta\Delta S_2^\ddagger - \Delta\Delta S_1^\ddagger$.

At $T > T_{\text{inv}}$, the activation parameters $\Delta\Delta H_1^\ddagger$ and $\Delta\Delta S_1^\ddagger$ are low (-38 kJ mol^{−1} and -161.4 J mol^{−1} K^{−1}, respectively) and the reaction affords predominantly enantiomer (*R*)-**125** with inversion of the initial configuration (*S*_N2 mechanism). However, at $T < T_{\text{inv}}$, $\Delta\Delta H_2^\ddagger$ and $\Delta\Delta S_2^\ddagger$ are high (11.1 kJ mol^{−1} and -36.6 J mol^{−1} K^{−1}, respectively), resulting in the formation of an intermediate adduct of alcohol with HBr, and the reaction proceeds by the *S*_Ni mechanism to give predominantly enantiomer (*S*)-**125** in which the initial configuration is retained.¹⁷⁸

The stereoselectivity of the reaction is controlled not only by the temperature but also by the nature of the solvent. The latter is well exemplified by the reactions of carbonyl compounds and their derivatives with various nucleophiles in various media.^{179–183} For example, the diastereoselectivity (the ratio of *anti* to *syn* isomers **128** and **129**) of the reactions of (2*S*)-lactaldehyde derivatives **126** and **127** with BuⁿLi and EtMgBr in various ethers and n-hexane was found to depend strongly on solvation of the starting substrate^{179, 183} and, to a lesser degree, on the nature of the nucleophile.¹⁸⁰

Z = NSiMe₃ (**126**), O (**127**); RM = BuⁿLi (for **126**), EtMgBr (for **127**); Y = NH₂, R = Buⁿ (**128**); Y = OH, R = Et (**129**).

Table 14 gives the inversion temperatures and the differences between the activation parameters for two straight regions in the Eyring plot at $T > T_{\text{inv}}$ and $T < T_{\text{inv}}$. As can be seen from Table 14, T_{inv} strongly depends on the nature of the solvent and, therefore, this is the temperature at which one solvation cluster is transformed into another cluster, resulting in changes in the difference between the activation parameters and the ratio of *anti* to *syn* diastereomers **128** and **129**.¹⁸³

Negative values of $\Delta\Delta H^\ddagger$ signify that $\Delta H_{\text{syn}}^\ddagger > \Delta H_{\text{anti}}^\ddagger$, i.e., the enthalpy of activation corresponds to the predominant formation of the *anti* isomer. Positive values of $\Delta\Delta H^\ddagger$ are favourable for the predominant formation of the *syn* isomer.

Since the addition reactions are accompanied by a decrease in the entropy, the transition state leading to the *anti* isomer is more ordered at negative $\Delta\Delta S^\ddagger$ than TS through which the *syn* isomer is formed, and the entropy is favourable for the formation of the *syn* isomer. Positive values $\Delta\Delta S^\ddagger$ are favourable for the formation of the *anti* isomer. The diastereoselectivity, particularly, for the reactions with low $\Delta\Delta H_1^\ddagger$ or $\Delta\Delta H_2^\ddagger$, is entropy-controlled.¹⁸³

The diastereoselectivity of the reaction of chiral nitron **130** with vinylmagnesium chloride in THF is also entropy-controlled. The ratio of diastereomers **131a**:**131b** = 93:7 was demonstrated¹⁸⁴ to remain unchanged in the temperature range from 20 to -80 °C and the diastereoselectivity is entropy-controlled ($\Delta\Delta H^\ddagger = 0$ kJ mol^{−1}, $\Delta\Delta S^\ddagger = 21.7$ J mol^{−1} K^{−1}), which is

indicative of the absence of steric interactions between the substituents in compound **130** and the Grignard reagent.

However, acceleration of the reaction in the presence of Et_2AlCl as the catalyst leads to the following two regions in the Eyring plot: in the range from 40 to 0 °C, the entropy control of the reactivity and the above-mentioned ratio of diastereomers are retained, whereas the stereoselectivity is almost completely lost in the range from 0 to –94 °C (**131a**:**131b** = 55:45 at –94 °C). In the latter case, substantial changes in the parameters $\Delta\Delta H^\ddagger$ and $\Delta\Delta S^\ddagger$ are observed, which apparently reflects changes in the reaction mechanism at low temperature with the result that the stereoselectivity of the process changes.¹⁸⁴

The most pronounced changes in stereoselectivity due to changes in the activation parameters for different reaction pathways are the most pronounced in biochemical processes.^{185–187} The enantioselectivity E' was found¹⁸⁵ to be changed depending on the temperature in hydrolysis of enantiomeric derivatives of α -amino acids catalysed by the enzyme α -chymotrypsin. For example, E' for the hydrolysis reactions of L- (**132a**) and D-tyrosine methyl esters (**132b**), as well as of *N*-Boc-L- (**132c**) and *N*-Boc-D-tyrosines (**132d**), which is determined by the equation

$$E' = \ln \frac{k_L}{k_D},$$

where k_L and k_D are the apparent second-order reaction rate constants for the L- and D-enantiomers, respectively, can be expressed in terms of the differences between the activation parameters $\Delta\Delta H$ and $\Delta\Delta S$ with the use of the modified Eyring equation.

Compound	$\Delta\Delta H$ /kJ mol ^{–1}	$\Delta\Delta S$ /J mol ^{–1} K ^{–1}	T_{inv} /°C
132a,b	–22	–31	436
132c,d	25	174	–129

Here, $\Delta\Delta H = \Delta\Delta H^\ddagger - \Delta\Delta H_b$ and $\Delta\Delta S = \Delta\Delta S^\ddagger - \Delta\Delta S_b$, and the subscript b indicates binding in a substrate–enzyme–nucleophile complex.

From the Eyring plot it follows that $\Delta\Delta H$ is dominant at $T < T_{\text{inv}}$ and the stereochemical purity of the hydrolysis product

(α -amino acid) decreases with increasing temperature, whereas $\Delta\Delta S$ prevails at $T > T_{\text{inv}}$ and the stereochemical purity increases with increasing temperature.¹⁸⁵

The kinetic resolution of racemic β -lactam **133** by enzymatic hydrolysis in aqueous acetone in the presence of penicillin G acylase leads to an enantiomeric excess of the (*S*) isomer of compound **134** and the non-consumed (*R*) isomer of **133**, the maximum enantioselectivity $E' = 130$ being achieved at 328 K, which is higher than $T_{\text{inv}} = 301$ K. This reaction also exemplifies the fact that the formation of clusters of the substrate and the solvent influences both the relative contributions of the activation parameters and the enantioselectivity.¹⁸⁶

The enantioselectivity of enzyme-catalysed transesterification of vinyl acetate with a pair of *R*- and *S*-enantiomeric secondary alcohols in Pr_2O in the presence of subtilysine was estimated.¹⁸⁷ The enantioselectivity $E' = \ln(k_R/k_S)$ was demonstrated to decrease with increasing temperature. In this case, the enthalpy–entropy compensation effect and the enthalpy control of the reactivity are observed.¹⁸⁷

The catalytic effect of supramolecular systems in nucleophilic substitution reactions, in particular, the influence of solubilisation of reagents in micelles of surfactants, was studied.^{188,189} Such nucleophilic reactions as $\text{S}_{\text{N}}2$,¹⁹⁰ $\text{S}_{\text{N}}\text{Ar}$ ¹⁹¹ and alkaline hydrolysis of phosphonates,¹⁹² proceed more rapidly in micellar solution compared to the same reactions in the absence of surfactants. A comparison of the activation parameters for alkaline hydrolysis of esters **135** and **136** shows that these parameters for the reactions in a micellar pseudophase are lower than those in the absence of surfactants (Table 15).

X = EtO (**135**), *n*-C₆H₁₃O (**136**), ClCH₂ (**137**).

In a more concentrated micellar solution, the loss of entropy is apparently associated with a decrease in the degree of mixing and mobility of the reagents.¹⁹³ The activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ are described by the compensation relation

$$\Delta H^\ddagger = 64.61 + 0.242 \Delta S^\ddagger \quad (r = 0.995, s = 0.84, n = 4)$$

Table 15. Rate constants of the formation of the transition state as the rate-determining step and activation parameters for hydrolysis of phosphonates **135** and **136** and solvolysis of ester **137** in ethylene glycol in the absence and presence of surfactants at 25 °C.

for the reactions of ester **135** with the enthalpy control of the reactivity and the reactions of ester **136** with the entropy control. In the latter case, it is the entropy term that is responsible for a decrease in the reactivity in a micellar pseudophase.¹⁹³

However, solvolysis of ester **137** in ethylene glycol in the presence of surfactants is characterised by higher activation parameters compared to those for the reaction in the absence of surfactants, the reactivity being enthalpy-controlled in both reactions (see Table 15). Apparently, an increase in the entropy term for the reaction in the presence of surfactants is attributed to an increase in the contribution of the S_N1 mechanism compared to the S_N2 mechanism, and the reaction rate increases.¹⁹⁴

The energetics of very fast bimolecular reactions of halide anions with 4-nitrophenyl radical (**138**) in DMF is of interest because such reactions are the key step in processes proceeding by the S_{RN}1 mechanism.¹⁹⁵

A substantial increase in $\Delta S^\ddagger$ for Br[−] and Cl[−] compared to that for I[−] is apparently due to desolvation of these ions on going from the initial state to the transition state TS-31, and the reactivity is controlled by the enthalpy of activation (Table 16).¹⁹⁵ These reactions are characterised by the compensation relation

$$\Delta H^\ddagger = -25.8 + 1.8 \Delta G^\ddagger \quad (r = 0.954, s = 4.8, n = 3).$$

Table 16. Rate constants and activation parameters for the reactions of radical **138** with halide anions in DMF.¹⁹⁵

The kinetics of the addition of various nucleophiles to coordinated π -hydrocarbons to form new organometallic derivatives of 1,3-dienes was studied in detail, and the energy parameters for these processes were estimated.^{168–171, 196, 197} These reactions are characterised by low activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$.^{196, 197} For example, the dissociative addition reactions of anilines to complexes **139–141** have high negative $\Delta S^\ddagger$

$n = 1$: R = H (**139**), 2-MeO (**140**); $n = 2$, R = H (**141**); R' = H, Cl.

Table 17. Rate constants and activation parameters for the addition reactions of anilines to complexes **139–141** in MeCN at 20 °C.¹⁹⁶

due to formation of the highly organised transition state TS-32 on the coordinate of these reactions (Table 17).¹⁹⁶

In the absence of steric hindrance in a nucleophile, the following compensation relation is observed:

$$\Delta H^\ddagger = 62.2 + 0.350 \Delta S^\ddagger \quad (r = 0.980, s = 2.40, n = 6)$$

the association process being controlled by either enthalpy (entries 4 and 5 in Table 17) or entropy (entries 1–3, 6 in Table 17).¹⁹⁶

The addition of pyridine derivatives to the coordinated dienyl ligand in complexes **139–141** occurs according to the equation

The rate constants k_1 and the activation parameters for the process strongly depend on the basicity of pyridine and steric hindrance in the substrate in the formation of the transition state (Table 18).¹⁹⁷ The reaction with more basic pyridine leads to localisation of an early transition state in which the associative bond formation plays an important role. This is confirmed by negative activation volumes $\Delta V_1^\ddagger$, the reactivity being entropy-controlled (entries 2 and 5–8 in Table 18). The late transition state for slow reactions with $\Delta V_1^\ddagger$ equal to zero is characteristic of weakly basic pyridines and substrate **141** with the enthalpy control of the reactivity (entries 1, 6 and 7 in Table 18).¹⁹⁷ The most basic 4-ethylpyridine always leads to negative $\Delta V_1^\ddagger$; the least basic 4-cyanopyridine, to the zero value. Since 4-formylpyridine is intermediate in basicity between the above-mentioned pyridines, the nature of the substrate plays an important role. For the fast reactions (entries 2 and 4), $\Delta V_1^\ddagger$ are negative; for the slow reaction (entry 7), the activation volume is equal to zero.

Very broad ranges of the activation parameters are observed for decarboxylation of the cobalt(III) carbonate complexes *cis*-

Table 18. Rate constants and activation parameters for the addition reactions of pyridines to complexes **139–141** in MeCN at 25 °C.¹⁹⁷

Substrate	Entry	Nucleophile	k_1 /litre mol ⁻¹ s ⁻¹ (see ^a)	$\Delta H^\ddagger$	$\Delta S^\ddagger$	$\Delta V^\ddagger$ /cm ³ mol ⁻¹
139	1	4-NCC ₅ H ₄ N	1.2×10^3	42	46	0
	2	4-CHOC ₅ H ₄ N	1.8×10^3	25	100	-2.9
	3	4-EtC ₅ H ₄ N	1.9×10^4	16.9	106	(see ^b)
140	4	4-CHOC ₅ H ₄ N	4.4×10^2	21	123	-9.8
	5	4-EtC ₅ H ₄ N	3.1×10^3	15.5	126	-7.8
141	6	4-NCC ₅ H ₄ N	30	38	89	0

	8	4-EtC ₅ H ₄ N	8.4×10^2	26	102	-6.4

^a Calculated from the equation $k_{\text{obs}} = k_1[\text{pyridine}] + k_{-1}$; ^b cannot be determined due to a high reaction rate.

[CoL(CO₃)]⁺ (**142a–f**) with water, which occurs according to the scheme

L = (NH₃)₄ (**a**), (en)₂ (**b**), (py)₄ (**c**), *cis*-(en)₂(H₂O)₂ (**d**), *trans*-5,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene (**e**), 1,4,8,12-tetraazacyclopentadecane (**f**).

Depending on the structure of the ligand L, $\Delta H^\ddagger$ and $\Delta S^\ddagger$ can be either low or very high (Table 19). The first step involving the carbonate ring opening is rate-determining, which is apparently responsible for high positive $\Delta S^\ddagger$ for the reactions of substrates **142c,d,f**. The reactivity of all complexes **142a–f** is enthalpy-controlled. The activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ are described by the compensation relation¹⁹⁸

$$\Delta H^\ddagger = 96.6 + 0.28 \Delta S^\ddagger \quad (r = 0.985, s = 9.2, n = 6).$$

Table 19. Rate constants and activation parameters for decarboxylation of Co(III) carbonate complexes with water at 25 °C.¹⁹⁸

Substrate	$10^4 k_0$ /s ⁻¹ (see ^a)	$\Delta H^\ddagger$	$\Delta S^\ddagger$	$\Delta G^\ddagger$
142a	1.3	50	-155	96.2
142b	1.2	75	-63	93.7
142c	1.3×10^{-2}	139	109	106.5
142d	710	169	300	79.6
142e	0.75	115	65	95.6
142f	1.2	162	211	99.1

^a Pseudo-first-order reaction.

The reactivity of guanosine (Guo) in the substitution reaction of the platinum(II) complex *cis*-(NH₃)₂Pt(Guo)₂Cl₂ with the cyanide ion in water is also enthalpy-controlled.¹⁹⁹ This reaction is rather slow ($k_2 = 2.5 \times 10^{-4}$ litre mol⁻¹ s⁻¹ at 30 °C) and has high enthalpy of activation ($\Delta H^\ddagger = 76.2$ kJ mol⁻¹) and moderate negative entropy of activation ($\Delta S^\ddagger = -75.2$ J mol⁻¹ K⁻¹), which is attributed to the associative mechanism.¹⁹⁹

Analogous activation parameters are also typical of other substitution reactions of platinum(II) complexes.¹⁹⁹

Associative substitution reactions of the ruthenium carbonyl clusters Ru₅C(CO)₁₄L (**143a,b**) involving phosphorus-containing n-nucleophiles L' are either enthalpy- or entropy-controlled depending on the structures of the substrate and the nucleophile (Table 20).²⁰⁰

L = P(OPh)₃ (**a**), P(cyclo-C₆H₁₁)₃ (**b**).

Unexpectedly, faster reactions of compound **143a** with certain P-nucleophiles have positive entropies of activation (entries 1–3 in Table 20). The latter fact can be attributed to weaker binding of the reagents in the transition state accompanied by cleavage of the cluster.²⁰⁰ Nevertheless, the activation parameters for the reactions of cluster **143a** with P-nucleophiles (entries 1–7 in Table 20) are described by the compensation relation

$$\Delta H^\ddagger = 70.06 + 0.254 \Delta S^\ddagger \quad (r = 0.996, s = 2.41, n = 7).$$

The reactions of cluster **143b** containing the bulky ligand L with P-nucleophiles are characterised by very low $\Delta S^\ddagger$, resulting in the compensation straight line with a smaller slope

$$\Delta H^\ddagger = 70.43 + 0.186 \Delta S^\ddagger \quad (r = 0.995, s = 1.13, n = 3),$$

which apparently indicates that the entropy makes a larger contribution to the reactivity of cluster **143b** than to that of cluster **143a**.²⁰⁰

Evidently, the kinetics of nucleophilic substitution reactions in complex compounds has a number of specific features. This problem was discussed in the corresponding sections of the reviews.^{201–206}

Table 20. Rate constants and activation parameters for the substitution reactions of clusters **143a,b** involving phosphorus-containing nucleophiles in n-heptane at 25 °C.²⁰⁰

VIII. The role of the enthalpy – entropy compensation effect

The role of the enthalpy–entropy compensation effect and the isokinetic relationship in the elucidation of reaction mechanisms and estimation of their thermodynamic parameters based on correlation series has been extensively discussed in the literature.^{6, 63–65, 68–73, 207–214} It should be emphasised that for the true (not erroneous) compensation effect to be manifested, the series of the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ must cover ranges substantially larger than the experimental errors.^{71, 213} Undoubtedly, the compensation effect for reactions in the condensed phase has a cooperative character and correlates with the motion of the reagent and solvent molecules during an elementary event.^{65, 68, 70, 208–210, 213, 214} Based on the data surveyed in the present review, conclusions about the role of the compensation effect in bimolecular nucleophilic reactions can be drawn.

For example, the compensation temperature for the S_NAr reactions of substituted arenes with amines was demonstrated to be substantially higher for slow reactions (see Fig. 3). An analogous effect is observed in the reactions of EtI with Et₃N and Et₃P (see Table 2)³⁹ and the reactions of clusters **143a,b** with P-nucleophiles (Table 20).²⁰⁰ Evidently, an increase in the compensation temperature for related reactions may be indicative of a decrease in the reaction rate.

For bimolecular nucleophilic reactions at the carbonyl carbon atom,^{62, 157, 162} with carbocations^{168, 170, 171, 176, 177} and with organometallic complexes,^{198, 200} the compensation effects are observed with changes in the nature of the substituent in the substrate^{157, 162, 168, 170, 171, 176, 177, 198} or the nucleophile,^{62, 200} the reaction mechanism remaining unchanged. The slopes of the compensation plots of $\Delta H^\ddagger$ vs $\Delta S^\ddagger$ vary in rather broad ranges (from 200 to 700 K).

The reliable determination of the isokinetic relationship for a reaction series suggests a unified mechanism of the processes.^{6, 63–65, 69} However, the compensation relations can include the activation parameters for related BNR proceeding by different mechanisms. For example, the compensation relations for the S_NV reactions resulting in the replacement of chlorine in compounds **20–25** include the activation parameters for reactions proceeding as both addition–elimination and elimination–addition (see Fig. 5).^{97–100} The compensation relations for the reactions of triaryl phosphates **88a–c** with pyridines also include the activation parameters that characterise different substitution mechanisms (stepwise and concerted).¹⁵⁵ The compensation relations for the Ad_N reactions of alkyne **43** with amines include the activation parameters corresponding to the reactions proceeding by the same mechanism (see Fig. 8).^{115, 116} The compensation relations for alcoholysis of compounds **51, 52, 58** and **59**^{129, 135–137} and aminolysis of compounds **47, 51** and **54–57** (see Fig. 10)^{131–134} also characterise the same mechanism.

The compensation plots of $\Delta H^\ddagger$ vs $\Delta G^\ddagger$ for the Ad_N reactions of alkyne **43** with amines have opposite slopes depending on the structure of the nucleophile. A positive slope is indicative of the enthalpy control of the reaction, whereas a negative slope confirms the entropy control (see Fig. 9).^{115, 116, 119} Analogous compensation plots of $\Delta H^\ddagger$ vs $\Delta G^\ddagger$ are observed for the reactions of carbonyl compounds **46–59** with alcohols and amines (see Fig. 11)^{129–137} and of dimethyl carbonate **64** with alkylamines.¹⁴⁰

However, this is not true for the S_NAr reactions (see Figs 3 and 4) because the compensation relations include the activation parameters with a higher contribution of either the enthalpy or entropy term.^{46–48, 52–58, 84–89} The inclusion of substantially different $\Delta H^\ddagger$ and $\Delta S^\ddagger$ in the same compensation relation is also observed for hydrolysis of esters **135** and **136**,¹⁹³ the addition of anilines to carbocationic complexes **139–141**¹⁹⁶ and substitution reactions of clusters **143a,b** with P-nucleophiles.²⁰⁰

It should be noted that no compensation effects are observed for certain BNR. For example, the absence of compensation relations for aminolysis of carbonyl compounds **67–79** (see

Table 11),^{141–147} the reactions of carbonyl compounds **83–86** with pyridine (see Table 11)^{150–153} and the reactions of carbocations **96–104** with neutral π -nucleophiles is apparently associated with the difference in the structure of transition states for each type of reactions.

IX. Relationship between the mechanisms of bimolecular nucleophilic reactions and activation parameters

For bimolecular reactions, $\Delta S^\ddagger$ varies from -41 to $-210 \text{ J mol}^{-1} \text{ K}^{-1}$, and $\Delta S^\ddagger$ for reactions with moderate-density transition states vary in narrower ranges, from -125 to $-167 \text{ J mol}^{-1} \text{ K}^{-1}$.²¹¹ The latter values are similar to the range of $\Delta S^\ddagger$ from -62 to $-125 \text{ J mol}^{-1} \text{ K}^{-1}$ for BNR. This criterion is not rigorous because not all factors that influence $\Delta S^\ddagger$ (for example, changes in solvation of the transition states compared to the initial state) were taken into account.²¹⁵

Table 21 gives the limiting values of the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for all types of reactions, which were discussed in Sections II–VII of the present review. As can be seen from this table, $\Delta H^\ddagger$ varies from 0 to 232 kJ mol^{-1} ; $\Delta S^\ddagger$, from $+300$ to $-300 \text{ J mol}^{-1} \text{ K}^{-1}$. These limiting values of $\Delta S^\ddagger$ noticeably extend the range of this parameter compared to that published earlier.²¹⁵ Although $\Delta S^\ddagger$ are calculated by extrapolation to an uncertain temperature,²¹⁶ a comparison of the numerical values of $\Delta S^\ddagger$ for various bimolecular reactions may be useful for elucidation of their mechanisms.²¹⁷

Table 21. Limiting activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for various BNR.

Reaction type	Type of nucleophile	$\Delta H^\ddagger$		$-\Delta S^\ddagger$	
		min	max	min	max
S_N2	charged	8.0	100.8	2.3	277
	neutral	19.2	78.6	87.8	220
S_NAr	charged	3.8	232	-255	250
	neutral	15.7	82.0	98.0	265
S_NV	charged	9.4	101	-102	127
	neutral	3.3	18.4	179	242
Ad_N	charged	0	39.0	83.0	288
	neutral	2.0	65.0	40.0	300
Reactions at carbonyl C	charged	13.5	88.0	12.6	277
	neutral	6.7	105	35.6	285
Reactions of carbocations	charged	19.0	52.0	32.0	187
	neutral	0	53.0	46.0	180
Substitution in metal complexes	neutral	17.8	169	-300	211

Of special interest are the limiting values of the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ for BNR (see Table 21). For example, very low $\Delta H^\ddagger$ ($0–8 \text{ kJ mol}^{-1}$) are typical of certain S_N2 , S_NAr and Ad_N reactions proceeding by the concerted mechanism.^{10, 58, 105} The structural features of the transition state can also lead to low $\Delta H^\ddagger$ in S_NV reactions,^{90, 91} Ad_N reactions^{113, 114, 116} and the reactions of carbonyl compounds and carbocations with neutral nucleophiles.^{152, 175} Evidently, low values of $\Delta H^\ddagger$ in these reactions are compensated by very low $\Delta S^\ddagger$.

It is worthy of note that certain S_NAr and S_NV reactions with charged nucleophiles^{56, 57, 92, 97, 98, 100} and the reactions of organometallic compounds with neutral nucleophiles^{198, 200} are characterised by positive $\Delta S^\ddagger$, which is rather unusual for BNR.¹⁵⁶ The positive values of $\Delta S^\ddagger$ can be attributed to either the influence of the intermediate complex of a substrate with a nucleophile that is formed in S_NAr reactions⁵⁷ or the intermediate formation of an acetylene derivative in S_NV reactions^{92, 97, 98} or, alternatively, to

the structural features of substrates resulting in an increase in the entropy for the transition state.^{198,200} Positive $\Delta S^\ddagger$ were also observed for catalysed hydrolysis of substituted *N*-benzoylimidazoles in 10% aqueous MeCN due to desolvation of the hydroxide ion.¹⁵⁶

In some cases, the activation parameters appeared to be useful for elucidation of the reaction mechanisms. For example, positive $\Delta S^\ddagger$ for S_NV reactions confirm the $E-Ad_N$ mechanism.^{92,97,98,100} In two-step substitution reactions of carbonyl compounds, the values of $\Delta S^\ddagger$ allow one to identify the rate-determining step.^{150–152} An increase in the activation parameters for the reactions of triaryl phosphates with pyridines made it possible to identify the two-step and concerted mechanisms.¹⁵⁵ An increase in these parameters for the reactions of triarylmethyl cations with cyanide ion allowed the researchers to refine the details of the ion-pair mechanism.¹⁷⁶ The activation parameters play an important role in the analysis of the stereochemical result of the reaction.^{178–187} It should also be noted that an increase in $\Delta S^\ddagger$ in solvolysis of phosphonate **137** is associated with the change in the reaction mechanism from S_N2 to S_N1 .¹⁹⁴ There are also examples of related BNR, which proceed by different mechanisms but are characterised by similar activation parameters.^{139,148,154} In these cases, it is necessary to use other methods for elucidation of the reaction mechanism.^{41,122–128,217,218}

Solvation can have a noticeable effect on $\Delta S^\ddagger$. The latter fact is particularly pronounced for solvation of transition states with a large charge development, resulting in a decrease in $\Delta S^\ddagger$ (Ref. 156) upon solvation of the starting substrate, and influences the diastereoselectivity of the reaction due to a strong change in entropy.^{179,183} Desolvation of a charged nucleophile before the formation of the transition state can lead to both a sharp increase in $\Delta S^\ddagger$ (Refs 156 and 195) and a decrease in this parameter.^{51,53} depending on the reaction type.

The formation of an intermediate complex between a neutral nucleophile and a base^{113,114,120} or between a substrate and a nucleophile^{57,66,67,121,135–137,162} has a substantial effect on the activation parameters and the reaction mechanism. Hence, the problem of the effect of complexation between the reagents on the energetics and mechanisms of BNR has attracted considerable interest.^{219–229}

* * *

In conclusion, there is nowadays a large body of data on the energetics of bimolecular nucleophilic reactions in solution. In the present review, an attempt was made to generalise the results of investigations in this field. The necessity of systematisation is dictated by a rapid increase in the number of studies aimed at refining the theoretical views of the energetics of nucleophilic reactions in organic chemistry and biochemistry.

This review has been written with the financial support of the Division of Chemistry and Materials Science of the Russian Academy of Sciences (Programme of Fundamental Research 'Theoretical and Experimental Studies of the Nature of Chemical Bonding and Mechanisms of Important Chemical Reactions and Processes', Project No. 4.1.11).

Oximes as reagents

A I Mikhaleva, A B Zaitsev, B A Trofimov

Contents

I. Introduction	797
II. Acidity of oximes	798
III. N- and O-nucleophilicity of the oxime function	801
IV. Nucleophilic attack on the C=N bond of oximes	808
V. Dehydration	816
VI. The Beckmann rearrangement	817
VII. Reaction of oximes involving substituents	818
VIII. Conclusion	819

Abstract. Data on the chemical properties of oximes and their derivatives widely used in the synthesis of different nitrogen-containing acyclic and heterocyclic compounds are systematised and analysed. The polyfunctional nature of oximes is emphasised and their uniqueness as the reagents for directed organic synthesis in the presence of bases is shown. The bibliography includes 332 references.

I. Introduction

Oximes have found their application in organic synthesis back in the 19th century¹ and as analytical reagents, in the beginning of the 20th century.^{2,3} At present, oximes surpass carbonyl compounds and alcohols in both the diversity of reactions and the extent of their application in synthetic chemistry. The oxime function can rather easily be introduced into an organic molecule. This may involve oximation of a carbonyl group with hydroxylamine, nitrosation of hydrocarbons, reduction of nitro compounds, oxidation of amines, oxidative ammonolysis, *etc.* At the same time, the oxime function is readily transformed into such important groups as carbonyl, amino, nitro and cyano groups and can also serve as a convenient protective group.

All compounds that contain the oxime fragment, which represents a pharmacophore group, exhibit diverse biological activities.^{4–11} For example, oximes of the furan and thiophene series and their ethers possess vasorelaxant, antispasmodic, seda-

tive, antidepressant, tranquillising, anticonvulsive, analgesic, anti-inflammatory, cytotoxic, anticancer, antiviral and bactericidal properties.⁴ These derivatives are also recommended as insecticides, fungicides, pesticides, herbicides, protozoacides and plant growth regulators.⁴ A wide spectrum of biological activity was revealed for oximes of the pyridine,⁵ indole,⁶ pyrrole⁷ and quinoline series.¹¹ Oximes of α,β -unsaturated ketones are known as insecticides,⁸ vasorelaxants⁹ and antimicrobial agents.¹⁰

A recently published series of comprehensive reviews^{4–7,11} devoted to the chemistry and biological activity of oximes of heterocyclic ketones generalises the latest achievements in this field. They provide information on the development of most typical, classical reactions of oximes and the discovery and elaboration of novel or specific transformations characteristic of certain classes of compounds. The present review does not discuss the papers cited in this series; however, it cannot be considered as an exhaustive supplement to this series. The purpose of our survey is to generalise (using typical examples) and systematise new information on the most typical chemical reactions of oximes, based on the structural peculiarities of the oxime group and its nearest environment. Attention is paid to the reactions that proceed in the presence of bases. In the analysis of the published material, this aspect seems to be important, because it focuses attention on the multifacet nature of reactivity of oximes and oximate anions. Traditionally, these compounds are considered as the objects of the Beckmann rearrangement that takes place in the presence of acids.

Oximes (**A**) and their tautomers, NH-nitrones (**B**) and the corresponding anions can exist in various tautomeric and resonance forms (Scheme 1), which allows one to call them 'chemical chameleons'. The following properties of oximes in the presence of bases can be mentioned: (1) OH- and CH-acidity; (2) O- and N-nucleophilicity; (3) the possibility of the nucleophilic attack on the C=N bond; (4) dehydration; (5) various transformations of substituents (including their migration).

To make systematisation and analysis of base-promoted reactions of oximes easier, it seemed reasonable to assign them to one of the types listed. However, such an assignment is not always unambiguous, because many reactions of oximes simultaneously manifest several sides of their multifacet reactivity.

Scheme 1

B is a base.

II. Acidity of oximes

On treatment with bases, oximes (**1**) undergo deprotonation to give oximate anions (**2**).

R¹, R² = H, Alk, Ar, Het.

Oximes that contain hydrogen atoms in the α -position relative to the oxime function exhibit sufficiently high CH-acidity together with OH-acidity. Moreover, coordination of a transition metal with an oxime group results in activation of the β -C–H bond.

1. OH-Acidity

Studies of acid–base properties of mono- and dioximes of diketones are associated with their wide use in analytical chemistry. OH-Acidity of oximes and its correlation with their configuration was the subject of several studies.^{12–27}

Table 1 shows the data on the acidity of certain oximes. The pK_a values depend on the effect of substituents at the oxime function.

The values of the acidity constants of dioximes of α -diketones are in the ranges of 10.4–10.8 (for the first hydroxyl group) and 11.9–12.4 (for the second hydroxyl group).^{16–21}

A substantial increase in the oxime acidity is observed for α -oxo aldioximes **3a–e**.²² For these compounds, pK_{a1} changes from 8.30 (for oxime **3a**) to 6.54 (for **3e**), the latter oxime being among the most acidic oximes known.

R = H (**a**), MeS (**b**), MeSO (**c**), MeSO₂ (**d**), Me₂S⁺ (**e**).

It should be noted that the acidity of poly(acrolein oximes) is independent of their molecular mass and the content of oxime units; moreover, the pK_a (9.8)²⁸ value is lower than that of the monomer, acrolein oxime (10.61).²⁹

Table 1. Acidity constants of certain oximes.

Oxime	pK _a	Ref.
	11.48	13
	9.38	13
	9.76	14
	9.05	12
	9.94, 11.49	26
	10.29, 11.91	27
	10.68, 11.92	26

2. CH-Acidity

a. α -CH-Acidity (reactions of oxime carbanions)

The above-mentioned α -oxo aldioximes **3** exhibit sufficiently high CH-acidity, namely, pK_{a2} = 12.23 (for compound **3c**), 11.10 (**3d**), 10.55 (**3e**).²² In the general case, the electron-acceptor nature of the C=N–OH function enhances the mobility of the α -hydrogen atoms, which makes it possible to synthesise the corresponding C-anions of oximes (or of their esters) under the action of organometallic compounds.^{30–32} This reaction is widely used in organic synthesis for the formation of new C–C bonds.

Generation of C-anions often faces a problem of low solubility of dimetallated oximes, which can be solved by different methods. Thus Ensley and Lohr³³ proposed to carry out aldol condensation with lithiated *O*-tetrahydropyranyloximes as carbanions, which can be prepared using only one equivalent of lithium diisopropylamide (LDA). Gawley *et al.*³⁴ employed cuprates of oxime ethers for 1,4-addition to cyclohexenone. These reagents are synthesised by treating the corresponding oxime ethers with potassium diisopropylamide followed by their reaction with the Cu₂Br₂·Me₂S complex. This approach allows one to enhance the efficiency of carbanion generation as compared with LDA.

Stereochemistry of oxime metallation was the subject of several studies.^{35–38} Thus, being treated with two equivalents of butyllithium, acetone oxime (**4**) exclusively forms *syn*-dianion **5**, methylation and deuteration of which leads to products **6a,b**, respectively.³⁵

$\text{R} = \text{Me}$ (**a**, 73%), D (**b**, 100%).

Being treated with NaOH , the *Z*-isomer of *O*-methyloxime of a decalone derivative with a tertiary hydroxyl group **7** undergoes dehydration more readily as compared with the *E*-isomer.³⁶ This is explained by the higher rate of anion formation from compound (*Z*)-**7** upon proton abstraction from position 1. In this case, the ratio of *syn*- and *anti*-anions in the deprotonation product is 95 : 5.

The assumption of the higher mobility of the *syn*-hydrogen atoms as compared with the *anti*-hydrogen atoms was confirmed also for deuteration (D_2O , -60°C) of a metallation product of *O*-methyl dibenzyl ketoxime with lithium isopropylcyclohexylamide in ether.³⁶

Ketoxime dianions with lithium cations can exist in the free state at 20°C for several hours; moreover, neither the equilibrium between *syn*- and *anti*-forms nor the isomerisation of dianions are observed even at elevated temperatures.³⁸ This is associated with the enhanced stability of *syn*-dianions due to the formation of chelate structures with an alkali metal. It is assumed that the formation of dilithio derivatives occurs stepwise, namely, the lithium salt is converted into a soluble dilithio derivative under the action of the second equivalent of butyllithium.

$\text{R} = \text{Bu}^n, \text{Bu}^s$.

However, systematic studies of metallated compounds that contain heteroatoms capable of forming complexes with lithium made it possible to assume a different mechanism of selective *syn*-lithiation.³⁹ An organolithium compound is preliminarily coordinated by the oxygen atom of the oxime function, which is followed by the transfer of lithium to the α -carbon atom. Thus, selective

syn-metallation is due to the combined effect of kinetic and thermodynamic factors.

Stabilisation of *syn*-anions is also explained³⁵ by their partly aromatic nature. It is assumed that in a system containing six π -electrons, attractive interaction arises between the α -carbanionic site and the oxygen atom, which selectively stabilises the *syn*-form.

LDA was used as a base for the generation of a *syn*-dianion of aldoloxime **8**.³⁹

$\text{R} = \text{Me}$ (**a**, 86%), D (**b**, 100%).

Z-Configuration of the starting oxime, which is not isomerised under mild conditions of lithiation, favours the formation of *syn*-dianion **9**. This is confirmed by high yields of methylation (**10a**) and deuteration (**10b**) products.³⁹

Propanal oxime carbanion (**11a**) was used as a methylene component in the condensation with cyclohexanone to yield aldol **12**. However, in the case of isobutyraldehyde oxime (**11b**), condensation together with dehydration of the oxime led to nitrile **13**.³⁹

$\text{R} = \text{H}$ (**a**), Me (**b**).

Oxime C-anions react with different electrophiles including carbonyl compounds. As the result of intramolecular dehydration of the adducts of these reactions, namely, alcohols, they are heterocyclised into isoxazole derivatives. Thus, when treated with α -chloroacetophenones under very mild conditions, dilithio derivatives of alkyl aryl ketoximes **14** form isoxazolines **15**.

$\text{R}^1 = \text{H}, \text{Alk}$; $\text{R}^2, \text{R}^3, \text{R}^4 = \text{H}, \text{Alk}, \text{Ar}$.

However, their reactions with α,β -unsaturated aldehydes and ketones lead to acyclic 1,2-adducts **16**. The latter are cyclised into 5-vinylisoxazolines **17** under the action of P_2O_5 .⁴⁰

Numerous of 5-alkyl-3-methylisoxazoles **18** were synthesised from the dilithio derivative of acetone oxime (**4**) and *N*-methoxy-*N*-methylamides of carboxylic acids (the Weinreb amides).⁴¹

R = Alk, cyclo-Alk, Ar.

Reactions of dilithiated acetylferrocene oxime with methyl benzoates afford (5-arylisoxazole-3-yl)ferrocenes **19**.⁴²

A Schiff base was used as the electrophile in reactions with oxime dianions. Thus starting from α -oxophosphonate derivatives **20** and benzylideneaniline, 2-alkoxy-3-hydroxyamino-2-oxo-1,5-diphenyl-1,2-azaphosphol-3-enes **21** were synthesised (yields 10%–30%).⁴³

R = Et, Prⁿ, Buⁿ.

Information on oxime 1,4-dianions and their cyclisation can also be found in Refs 44–46.

b. β -CH-Acidity (cyclopalladation)

Mono- and dioximes capable of chelation are good ligands for complexes with transition metal cations. This property forms the basis for the wide use of oximes as analytical reagents for different metals, namely, nickel, copper, cobalt, iron, palladium, platinum, manganese, rhodium, rhenium, molybdenum, *etc.*⁴⁷ In contrast to 'hard' lithium cations, transition metal cations coordinate preferentially to the nitrogen atom of the oxime group. Such an interaction is most likely a result of donating of electrons from the occupied d-orbitals of the metal to the lowest unoccupied molecular orbitals (LUMO) of the C=N bond, which leads to π -binding and additional stabilisation of the complex as a whole.

Coordination of a palladium atom to the oxime nitrogen atom favours the activation of the β -C–H bond. Thus cyclopalladation of oximes of aromatic ketones in the presence of bases results in the formation of bis(palladazole) system **22**, which is surprisingly stable in air and in aqueous medium.^{48–54} This process is usually carried out at room temperature by treating an oxime with lithium tetrachloropalladate (Li_2PdCl_4) in methanol in the presence of sodium acetate as the base.

Analogously, pinacolone and acetylferrocene oximes yielded palladium complexes **23** and **24**.⁵⁴

It should be mentioned that in the absence of a base in the reaction of 1,3-diacetylbenzene dioxime (**25**) with palladium(II) bis(benzonitrile) dichloride in acetonitrile cyclopalladation occurs, which involves only one oxime group to yield a dimeric complex **26**.⁵⁴

The CH-acidity of *syn*- α -methyl (or methylene) groups is not manifested in cyclopalladation, in contrast to lithiation reactions.

At present, complexes of the type **22** are actively studied as the catalysts of different cross-coupling processes⁵⁵ (including the Heck,^{56,57} Suzuki,^{58–60} Stille,⁵⁶ Ullmann,⁵⁸ Sonogashira^{61,62} and Glaser⁶² reactions). They are effective in both organic^{54,56,58,61,62} and aqueous^{57,59,60} media. Palladium and rhenium oxime complexes are also used as catalysts in the aza-Heck reaction.⁶³ In addition, terminal alkynes have recently been acylated with acid chlorides in the presence of such systems.⁶⁴

Controlled mono- and diarylation of α,β -unsaturated carbonyl compounds by aryl iodides was carried out using cyclopalladated 4-hydroxyacetophenone oxime (**27**) as the catalyst.⁵⁷ The yields of the reaction products were high (up to 98%).

$R^1 = \text{OH}, R^2 = \text{Me}$ (**27**); Z = CO_2Bu^t , C(O)NMe_2 , CN, C(O)Me ;
Ar = Ph, 4-ClC₆H₄, 4-FC₆H₄, 4-MeOC₆H₄.

Palladacycles **27** and **28** ($R^1 = \text{Cl}, R^2 = 4\text{-ClC}_6\text{H}_4$) proved to be efficient catalysts in the synthesis of methylated resveratrol (**29**) and its analogues,⁶⁵ which exhibit high antineoplastic activity.

Cross-coupling of the corresponding styrene with *p*-iodomethoxybenzene is carried out in the presence of methylcyclohexylamine and tetrabutylammonium bromide in aqueous dimethylamine (or in water) at 120 °C in air or under microwave irradiation. The reaction is highly regiospecific, *viz.*, stilbene **29** and its analogues are obtained in virtually quantitative yields.

Thus, under the action of strong bases, oximes acquire α -CH-acidity, while in the presence of palladium cations aryl ketoximes acquire β -CH-acidity of the aryl substituent. This allowed the development of a convenient method of synthesis of *ortho*-substituted aromatic compounds based on the catalytic version of cyclopalladation.

III. N- and O-nucleophilicity of the oxime function

Nucleophilicity of oximes is their most important chemical property that manifests itself most clearly in basic media. The oxime function contains three nucleophilic reaction sites, *viz.*, N, O and C atoms. The neutral molecule usually plays the role of an N-nucleophile, while an anion (oximate) plays the role of a strong O-nucleophile (due to the α -effect^{12, 13, 66–68}). Nucleophilicity of the carbon atom is determined by the contribution of a nitroso tautomer into the equilibrium.

1. Reactions with electrophiles in the presence of bases

The N–O-selectivity of reactions of oximes with electrophiles depends on their structural features, the reagent nature and the reaction conditions. As a rule, the implementation of one or another reaction pathway can be rationalised within the framework of the theory of hard and soft acids and bases. The material of this section is arranged according to the type of the electrophilic agent. Reactions of oximes with alkyl halides, oxirane, bifunctional electrophiles, acylating agents and organoelement halides, which occur under different conditions, are considered.

Substitution of oximate ions for a halogen atom was studied in sufficient detail for various classes of organic substances. Having no intention to comprehensively survey the literature on this issue, we merely show the most typical examples of such reactions.

O-Alkyl(aryl)oximes can be obtained from the corresponding oximes and organyl halides in alkaline medium.^{69, 70} Alkylation of oxime salts (oximates) with alkyl halides often involves not only the oxygen atom but also the nitrogen atom (the manifestation of N-nucleophilicity). The direction of the reaction depends on the structure of substituents in the reagents and the solvent polarity. The nature of the alkali metal cation and the halogen (*e.g.*, in benzyl halides^{69, 70}) affects little the ratio of the substitution products. The dependence of the direction of alkylation on the oxime configuration was the subject of several studies.^{71–74} It was shown⁷¹ that the reaction of (*E*)-benzaldoxime with alkyl halides preferentially yields the *O*-alkylation products, while *Z*-isomer gives the *N*-alkylation products (nitrones).

Regioselectivity of *O*-alkylation of oximes can be increased by carrying out the reaction in a two-phase system. Under conditions of phase-transfer catalysis in the presence of K₂CO₃, furyl and thienyl ketoximes **30** were alkylated at the oxygen atom; the yields of products **31** were 15%–83%.⁷⁵

O-Butyl-, *O*-allyl-, *O*-(2-chloroethyl)oximes and *O,O'*-methylene dioximes were prepared from the corresponding halides and oximes in a two-phase system (NaOH, Bu₄NBr).⁷⁶ The alkylation of *E,E*-dioximes of 1,2-diketones, such as dimethylglyoxime, with dichloromethane under the conditions of phase-transfer catalysis (K₂CO₃, 18-crown-6), results in methylene dioximes and 21-membered heteromacrocycles, the oxime fragments in which are sequentially linked by methylene bridges.^{77, 78}

Oximate anions generated in the KOH–DMSO system substitute readily a halogen atom in allyl and propargyl halides to form the corresponding *O*-allyl- (**32**) and *O*-propargylketoximes (**33**).⁷⁹

It should be noted that no expected shift of the multiple bond to the oxygen atom to form prop-1-enyl and allenyl ethers was observed (for acid–base rearrangements of *O*-propargylketoximes in *N*-alkenylacrylamides, see Section IV.1). The fundamental reasons for the inertness of *O*-allyloximes as regards prototropic isomerisation were analysed by quantum-chemical methods.⁸⁰

Earlier, *O*-allylketoximes were obtained⁸¹ in a reaction of ketoximes with allyl halides in the presence of alkali metal hydroxides in polar aprotic solvents (*N*-methylpyrrolidone, dimethylacetamide, DMF).

Condensation of sodium or potassium salts of acetone oxime (**4**) with epichlorohydrin in aqueous ethanol produced *O*-glycidyl-oxime **34**.⁸²

M = Na, K.

Cyclisation of γ -chloroximes^{83,84} and γ -sulfonyloximes⁸⁵ into 1,2-oxazines in the presence of bases proceeds as an intramolecular nucleophilic substitution with involvement of oximate anions as the *O*-centred nucleophiles.

As in the reactions with alkyl halides, the direction of oxime reactions with oxirane depends first of all on the oxime configuration. Thus alkylation of the *E*-isomer of benzaldehyde 35a with oxirane yields the *N*- (36a) and *O*-substitution (37a) products in a ratio of 1 : 5.^{72,73} *Z*-Isomers of oximes of benzaldehyde (35a) and furfural (35b) give preferentially nitrones 36a,b (36a : 37a = 6 : 5, 36b : 37b = 10 : 1).⁷⁴

R = Ph (a), 2-furyl (b).

Alkylation of acetone oxime (4) with oxirane leads to the *O*-alkylation product, namely, acetone *O*-(2-hydroxyethyl)oxime in quantitative yield,⁷² whereas *Z*-oxime of 2-acetylpyridine is not alkylated with this reagent even under drastic conditions.⁷⁴ *O*-(2-Hydroxyalkyl)oximes are also prepared under the action of oxiranes in the presence of secondary amines.^{86,87}

The one-pot synthesis of pyrroles 38 and 39 by the Trofimov reaction^{88–90} (see Section IV.2.b) from ketoximes and dihaloethanes (synthetic equivalents of acetylene) in superbasic media leads in certain cases to the substitution of oximate anions for a halogen atom. As a result of this process, side products, namely, ethylene glycol diethers of ketoximes 40 (*E,E*-, *E,Z*- and *Z,Z*-isomers) are formed; their content in the mixture can reach 47%.

R¹ = Me, Et, Prⁿ; R² = H, Me, Et, Prⁿ, Prⁱ; R¹–R² = (CH₂)₅;

X = Cl, Br; M = Li, Na, K.

A regiospecific reaction of dilithiated oximes 41 with epibromohydrin produces 6-hydroxymethyl-5,6-dihydro-4*H*-1,2-oxazines 42.⁹¹

Ar = Ph, 2-MeC₆H₄, 3-MeC₆H₄, 4-MeC₆H₄, 3-MeOC₆H₄, 4-MeOC₆H₄, 1-naphthyl, 2-naphthyl.

Under similar conditions, epibromohydrin reacts with dithio derivatives of cycloalkanone and tetralone oximes to afford the corresponding bicyclic 1,2-oxazines 43 and their condensed tricyclic analogues 44.⁹¹

43: R¹ = R² = H: *n* = 1 (38%), 2 (51%), 3 (49%), 7 (52%);

44: R¹–R² = benzo, *n* = 1 (48%).

It should be noted that the acyl group in *O*-acyloximes is easily replaced by an *O*-alkyl group upon treatment of the substrate in a phase-transfer system alkyl halide–KOH–18-crown-6–benzene.⁹²

Substitution of a fluorine atom in an aromatic ring under the action of sodium oximates is described.⁹³ *O*-Aryloximes 45 formed are converted into benzofurans 46 upon refluxing with HCl in anhydrous ethanol.

R¹, R² = Alk.

O-Aminomethyloximes 47 were synthesised⁹⁴ by the Mannich condensation.[†] The same products are formed upon alkylation of oximes with aminomethyl halides.

R = Alk.

Acylation of oximes can be effected under different conditions. For example, in benzene in the presence of solid K₂CO₃ and 18-crown-6, *O*-acylated derivatives 48 are formed from 2-furyl and 2-thienyl ketoximes 30; this involves no Beckmann rearrangement.⁹⁶

[†] The Mannich reaction with aldoximes is known⁹⁵ to involve the α -carbon atom.

X = O, S; R¹ = H, Br; R² = Me, Et, Prⁱ; R³ = Me, Et, Bu^t, Ph.

If the acylation agent represents a mixture of Ac₂O and AcCl, then ketoximes are converted into oxazoles **49** in the presence of pyridine. The reaction proceeds *via* β-acetoxy enamides **50**.⁹⁷

R¹ = Me, Bn, Ph; R² = Me, Ph; R¹–R² = (CH₂)₄, (CH₂)₂CHMeCH₂.

Recently, it has been shown⁹⁸ that the acylation of ketoximes with carboxylic acid chlorides in the presence of organic bases under conditions of microwave activation (150 W) also affords oxazoles **49**.

R¹ = Me, Et, Prⁱ, Ph, 4-BrC₆H₄; R² = Me, Ph; R¹–R² = (CH₂)₄;
R³ = Bu^t, Ph, 4-MeOC₆H₄, 4-CF₃C₆H₄, BnOCH₂, PhCH=CH;
DMAP is dimethylaminopyridine.

This process also occurs in the absence of microwave irradiation; however, the yields of oxazoles are substantially lower. For example, the yield of oxazole **49** (R¹ = Me, R² = Ph, R³ = 4-CF₃C₆H₄) is 43% *versus* 62% with microwave activation.⁹⁸

The cyclisation mechanism was not discussed in Ref. 98. However, since no intermediates of the type **50** were detected, the transient formation of *O*-acylketoximes **51** seems to be the most likely. The consecutive 1,3-prototropic shift and [3,3]-sigmatropic rearrangement are similar to the mechanism of pyrrole synthesis *via* *O*-vinyloximes by the Trofimov reaction (see Section III. 2.b).

R¹–R⁴ = Alk.

The reaction of aliphatic and aromatic ketoximes containing α-methylene groups with dimethyl carbonate in the presence of K₂CO₃ leads to 4,5-disubstituted 3-methyloxazolin-2-ones **52**.⁹⁹ Presumably, the reaction involves the [3,3]-sigmatropic rearrangement and the role of dimethyl carbonate is the initial N-methylation of oximes.

R¹ = Me, Et, Prⁿ, Ph; R² = Me, Et, Ph; R¹–R² = (CH₂)_n (n = 4, 5).

In the presence of tertiary amines, furfural oxime **35b** reacts with trialkylchlorosilanes to give *O*-silyl ethers **53**.¹⁰⁰ This is a typical example of nucleophilic substitution at the silicon atom where oximes play the role of O-centred nucleophiles.

R = Alk.

Recently,¹⁰¹ O,O'-centred dianions of vicinal dioximes **54** have been used for the synthesis of 7-membered silicon- (**55**) and tin-containing (**56**) heterocycles. The reaction occurs as the nucleophilic substitution of chlorine atoms in the corresponding dichlorides.

Ar = 4-XC₆H₄ (X = H, Me, Cl, MeO);

E = Si (**55**): R¹ = Me, Buⁿ, Ph; R² = Me, Buⁿ, Ph, Cl;

E = Sn (**56**): R¹ = R² = Me, Buⁿ, Ph.

In this Section, it is appropriate to mention the conversion of oximes into diazoalkanes **57** under the action of N-electrophiles, namely, chloroamine or hydroxylaminosulfonic acid (the Forster reaction).^{102, 103} In the first stage of this reaction, oximes act as N-nucleophiles.

R¹, R² = H, Alk, Ar; X = Cl, OSO₃H.

Various diazo compounds were synthesised by this method.^{103–108} Table 2 shows the most interesting of them (including diazomethane).

Thus, using the substitution reactions involving oximes as O- and N-nucleophiles, it is possible to synthesise various *O*-organoyloximes, nitrones and diazo compounds, which are valuable intermediates in organic synthesis. The selectivity of these reactions can be controlled by varying the substituents in oximes and electrophilic agents and changing the oxime configurations and experimental conditions.

Table 2. Oximes in the Forster reaction.¹⁰²

Oxime	Diazo compounds	Yield (%)
Formaldoxime	$\text{H}_2\text{C}=\text{N}_2$	75
3-Hydroxyiminocamphor		70
2-Hydroxyimino-1-tetralone		57
α -Hydroxyiminonopinone		85
2-Hydroxyimino-3,3-diphenyl-1-indanone		65

2. Nucleophilic addition of oximes to unsaturated systems

a. Reactions with alkenes

Bases catalyse the addition of oximes to electron-deficient alkenes. The catalysts are usually represented by alkali metal hydroxides^{109,110} and alkoxides,¹¹¹ quaternary ammonium salts.¹¹⁰ However, the reaction proceeds most smoothly in the presence of triphenylphosphine:¹¹² in some cases, adducts **58** were obtained in quantitative yield.

R ¹	R ²	X	Yield (%)
Bu ^t	H	SO ₂ Ph	89
Cy	H	SO ₂ Ph	88
Styryl	H	SO ₂ Ph	90
4-NO ₂ C ₆ H ₄	H	CO ₂ Et	85
3-NO ₂ C ₆ H ₄	H	CO ₂ Et	80
	H	CN	80
	H	SO ₂ Ph	95
3-HSC ₆ H ₄	H	SO ₂ Ph	92
3-Py	H	SO ₂ Ph	88
Et	Me	SO ₂ Ph	84
Ph	Me	SO ₂ Ph	87
4-MeSO ₃ C ₆ H ₄	H	SO ₂ Ph	96
	Me	CO ₂ Et	30
	Me	SO ₂ Ph	84

Under the action of bases, oximes add to trialkoxy(vinyl)silanes **59** to form the corresponding *O*-alkylated derivatives **58** [$\text{X} = \text{Si}(\text{OEt})_3$].¹¹³

$\text{R}^1 = \text{Alk}$; $\text{R}^2 = \text{H, Alk}$; $\text{B} = \text{AlkONa, AlkSNa, NaNH}_2$, etc.

Different nitrogen bases were used as the catalysts in the reactions of oximes with polyfluoroalkenes. Thus *O*-chlorofluoro-

ethyloximes **60** were synthesised in high yields from chlorotri-fluoroethylene in the presence of pyridine.¹¹⁴

$\text{R}^1, \text{R}^2 = \text{Alk, Ar}$.

Acetone oxime (**4**) reacts with perfluoropropylene to form acetone *O*-hexafluoropropyl oxime (**61**).¹¹⁵

However, the reaction of acetone oxime (**4**) with perfluoro-2-methylpent-2-ene (dimer of perfluoropropylene) in the presence of triethylamine proceeds in a more complicated fashion. In addition to adduct **62**, the reaction gives the product of formal replacement of one of fluorine atoms, namely, compound **63**, which is rearranged upon heating into 4-hydroxy-2-methyl-5,5-bis(tri-fluoromethyl)-4-pentafluoroethyl-1-pyrroline (**64**).¹¹⁵

It should be mentioned that this rearrangement exactly corresponds to a proved stage of the Trofimov reaction, *viz.*, the [3,3]-sigmatropic shift in *O*-vinylloximes, which leads to the formation of, first, hydroxypyrrolines and, then, pyrroles.

The addition of oximes to alkenes can also occur in the absence of bases upon heating of the reactants. Thus thermolysis of a mixture of perfluoro-2-methylpent-2-ene and cycloalkanone oximes produced pyrrolines **65** and the Beckmann–Chapman rearrangement products, namely, *N*-perfluoroalkenyllactams **66**.¹¹⁶

$n = 1$ (a), 2 (b).

1,3-Dipolar cycloaddition of formaldoxime with electron-deficient alkenes is shown¹¹⁷ to afford 5-substituted isoxazolidines **67**. This reaction pathway is attributed to the fact that it is the mesomeric form of formaldoxime, *i.e.*, betaine, with a positive charge on the oxygen atom and a negative charge on the carbon atom that is involved in cyclisation.

X = CN, CO₂Me.

This transformation is an unusual example of [2 + 3]-cycloaddition of nitrones with the change in polarity ('Umpolung').

It is known^{118–121} that oximes can be thermally isomerised into nitrones as a result of the 1,2-prototropic shift.

The fact that oximes react with alkenes in the form of NH-nitrones is also confirmed by the synthesis of isoxazolidines **67**. The mechanism of addition can be either intermolecular (as in the above example) or intramolecular.^{122–136}

Up to recently, information on the use of oximes in the NH-nitrone form in the intermolecular addition to dipolarophiles was limited to a few studies.^{117,120} Thus it was reported¹²⁰ that cycloadduct **68** is formed in the reaction of oxime **69** (or, more exactly, its NH-nitrone tautomer **70**) with *N*-phenylmaleimide.

R = OMe, OEt; R–R = CH₂CM₂CH₂.

The prospects of studying the isomerisation of oximes into NH-nitrones with the aim of generating NH-1,3-dipoles and their synthetic application are evident. Recently, it has been reported¹³⁷ on a successful addition of oximes of 4-oxo-4*H*-pyrido[1,2-*a*]pyrimidine-3-carbaldehydes **71** in their nitrone form **72** to the activated double bond of *N*-substituted maleimides. The yields of diastereomeric isoxazolidines **73** and **74** depend on the

X = pyrrolidin-1-yl, morpholin-1-yl, NBn₂, OEt;

R = Me, Ph; solvent is PhH, EtOH, MeCN.

structure of the reactants and the reaction conditions and amount to 66%–82%.

Thus, in the synthesis *O*-organyloximes, the nucleophilic addition of oximes to electron-deficient alkenes is an alternative to the nucleophilic substitution involving oximate anions. This reaction can follow a synchronous mechanism (like cycloaddition), which opens up an easy way to the synthesis of pyrrolines and isoxazolidines that contain reactive functional groups. These hydrogenated azoles are promising building blocks in organic synthesis. It should be stressed that, in the latter case, the reaction takes place in the absence of a base, *i.e.*, oximes play the role of non-ionised nucleophilic reagents.

b. Reactions with alkynes

Like other electrophilic reagents, alkynes can attack an oxime molecule at both oxygen and nitrogen atoms. However, the fate of intermediates differs in many aspects and depends on various factors. Reactions of nucleophilic addition of acetylene derivatives to oximes usually lead to *O*-vinyl ethers. However, examples of heretocyclisation of intermediates formed as a result of the alkyne attack on the N-nucleophilic site are also documented.

The reactions of oximes with ethoxyacetylene on moderate heating in the absence of catalyst result in regiospecific formation of bis-adducts **75**.¹³⁸

R = H, Me, Et, Ph.

75 (30%–63%)

Under similar conditions, aromatic aldoximes (both *syn*- and *anti*-isomers) sometimes give dehydration products, *viz.*, nitriles and ethyl acetate, together with the addition products.¹³⁸ For example, *syn*- and *anti*-benzaloximes form benzonitrile in the reaction with ethoxyacetylene. This reaction route was explained¹³⁸ by decomposition of intermediate monoadducts, which, however, could not be isolated.

Substituted benzonitriles were also prepared in the reaction of benzaloximes with 1-(*N,N*-diethylamino)propyne.¹³⁹

X = H, Cl, NO₂, OMe.

The yields of products depend on the configuration of the starting oxime. The low yield of benzonitrile (X = H, 21%) in the case of *Z*-benzaloxime is probably due to steric factors.

The reaction of acetophenone oxime with dimethyl acetylenedicarboxylate in the presence of sodium methoxide leads to *O*-adduct **76** in quantitative yield.¹⁴⁰

Compound **76** was obtained as a mixture of *cis*- and *trans*-isomers (1 : 2, according to the ^1H NMR data).

Cyanoacetylene adds to cyclohexanone oxime in a mixture of ethanol and *N*-methylmorpholine (5 : 2 by volume) at 0–20 °C to yield β -cyclohexylideneiminoxyacrylonitrile (**77**).¹⁴¹

B is *N*-methylmorpholine.

Mild acid hydrolysis of the synthesised compound **77** converts it into 3-aminoisoxazole **78** and regenerates the ketone.¹⁴¹ This suggests high susceptibility of such *O*-vinyl oximes to the electrophilic addition of water to the C=N bond to form intermediates **79**.

Oximes react with diacetylene in DMSO in the presence of catalytic amounts of KOH at temperature not exceeding 60 °C, which leads to the (*Z*)-*O*-ethynylvinyl derivatives **80**.^{142, 143}

$\text{R}^1, \text{R}^2 = \text{Alk.}$

Whereas oxime adducts to activated alkynes are formed even in the presence of weak bases (e.g., triphenylphosphine-catalysed reaction of oximes with ethyl propiolate¹⁴⁴), the vinylation of oximes with acetylene occurs only in superbasic media (e.g., in the KOH–DMSO system), which enhance the nucleophilicity of oximate anions. Under such conditions, oximes add to acetylene and its alkyl and aryl derivatives to form *O*-vinyl oximes **81** or **82**. This process represents the first stage of the Trofimov reaction,^{88, 145–156} which leads to pyrroles **83** and *N*-vinylpyrroles **39** (the latter are formed in the excess of acetylene).

$\text{R}^1, \text{R}^2 = \text{Alk, Ar, Het}$; $\text{R}^3 = \text{H, Alk, Ar}$;
B are alkali metal hydroxides or alkoxides.

The yields of pyrroles depend on the structure of starting ketones and usually amount to 50%–70%; in certain cases, they can be nearly quantitative. The prerequisite for this reaction is that a ketoxime had an α -methyl or methylene group relative to the oxime function. If an oxime has both groups, then the methylene group is involved, as a rule, in the pyrrole ring formation.^{88, 147, 149, 156–170}

In the absence of α -methylene groups in the oxime molecule [e.g., in methyl (het)aryl, methyl *iso(ter)*alkyl, diaryl, aryl hetaryl ketoximes], intermediate *O*-vinyl ketoximes can be isolated.^{88, 147, 149, 156–169, 171, 172} Isopropyl (het)aryl ketoximes were used for the synthesis of 3*H*-pyrroles, which are difficult to synthesise.¹⁷³

O-Vinyl oximes **81** and **82** easily rearrange into pyrroles upon heating in the KOH–DMSO system^{88, 147, 149, 167} or in pure DMSO.^{174, 175}

Recently, a similar reaction scheme was used for the synthesis of 4-oxo-4,5,6,7-tetrahydroindoles **84** from nitron **85**.¹⁷⁶

$\text{R}^1 = \text{H, Me}$; $\text{R}^2 = \text{H, CO}_2\text{Me}$.

It should be noted that *O*-vinylamidoximes synthesised by the addition of amidoximes to acetylene in superbasic media do not undergo the [3,3]-sigmatropic rearrangement that would lead to the formation of the desired imidazoles.¹⁷⁷

The reaction of ketoximes with the simplest homologue of acetylene, *i.e.*, propyne, its isomer allene and their mixture was studied¹⁷⁸ in the MOH–DMSO system. In all the cases (at ordinary and elevated pressures, at different temperatures and reaction times), 5- (**86**) and 4-methylpyrroles **87** are formed.

$\text{R}^1 = \text{Me}, \text{Pr}^i, \text{Bu}^i, \text{Ph}, 2\text{-furyl}, 2\text{-thienyl}; \text{R}^2 = \text{H}, \text{Me};$
 $\text{R}^1-\text{R}^2 = (\text{CH}_2)_4; \text{M} = \text{K}, \text{Cs}.$

Under these conditions, easy prototropic isomerisation of propyne to allene and *vice versa* occurs. The result of the reaction depends substantially on the ketoxime structure, being determined not only by electronic factors, but also by steric factors. Thus the more branched is the substituent at the oxime function, the larger the fraction of 4-substituted pyrrole **87**. This synthesis of pyrroles, which involves the use of a propyne–allene mixture, *i.e.*, a large-scale waste of pyrolysis of hydrocarbons into acetylene, extends significantly the scope of this reaction for the synthesis of 4- and 5-methylpyrroles with various substituents in positions 2 and 3 accessible.

The reaction of oximes of acetone and acetophenone with phenylacetylene carried out under conditions of the Trofimov reaction produced 2-phenylpyrroles **88a,b**.¹⁷⁹

$\text{R} = \text{Me}$ (**a**), Ph (**b**).

Thus, the reaction of ketoximes with acetylene allows one to easily obtain pyrroles with alkyl, aryl and hetaryl substituents as well as different systems annelated with the pyrrole ring. This reaction makes an almost unlimited series of *N*-vinylpyrroles available. These compounds, on the one hand, contain a convenient protective *N*-vinyl group which can easily be removed^{180,181} and, on the other hand, represent good building blocks for the synthesis of pyrrole derivatives and monomers with wide synthetic potentials.

As in the case of reactions with diacetylene (see above), no pyrroles are formed in the reaction of ketoximes with vinylacetylene in systems MOH–DMSO ($\text{M} = \text{K}$ or Li). This reaction produces only mixtures of *O*-butynyl and *O*-butadienyl ketoximes **89–91** (yield < 50%).¹⁸²

$\text{R}^1 = \text{Me}, \text{R}^2 = \text{H}, \text{R}^1-\text{R}^2 = (\text{CH}_2)_4.$

Recently, information on the nucleophilic addition of heterocyclic oxime **71** to dimethyl acetylenedicarboxylate, dibenzoylacetylene and methyl propiolate has appeared.¹³⁷ The reaction proceeds on refluxing the reactants in benzene for 2 h. In place of expected *O*- or *N*-adducts, enamines **92** and traces of nitriles **93** were isolated.

$\text{R}^1 = \text{R}^2 = \text{CO}_2\text{Me}, \text{C}(\text{O})\text{Ph}; \text{R}^1 = \text{H}, \text{R}^2 = \text{CO}_2\text{Me}.$

The formation of enamines **92** is explained by the *O*-nucleophilic attack of oxime **71** on the triple bond. *O*-Vinylloxime **94** formed undergoes decomposition along the Beckmann rearrangement path to give carbocation **95** and an enolate; these react to afford imine **96**. Rearrangement of the latter leads to enamine **92**, while nitrile **93** is formed as a result of elimination of the ketone from *O*-vinylloxime **94**.

Synthesis of the first spirocyclic bis(isoxazole) **97** as a racemate is described.¹⁸³ This cyclic bis(*O*-vinylloxime) represents a C_2 -symmetric chiral ligand used in enantioselective catalysis. Intramolecular cyclisation of diacetylenic dialdoxime occurs under the action of 5% aqueous NaOCl. According to the researchers cited, the reaction yields bis(nitrile oxide). However, another possible mechanism includes the primary *O*-nucleophilic attack of the oxime function on the triple bond followed by oxidation of intermediates. Resolution of this racemate into optical isomers was accomplished by column chromatography on a chiral stationary phase.

Summarising, we show several examples of reactions of oximes with acetylene derivatives that involve an electrophilic attack on the nitrogen atom.

Thus acetone oxime (**4**) adds to dimethyl acetylenedicarboxylate (DMAD) to form a cyclic product, namely, functionalised 4,5-isoxazoline **98**.^{184–186}

Presumably, the addition of oxime to the $C\equiv C$ bond produces a zwitterionic intermediate **99**, *i.e.*, the oxime plays the role of an uncharged nucleophile. Intramolecular transfer of a proton in the intermediate **99** results in the formation of nitrone **100**. The latter enters 1,3-dipolar addition with the second molecule of dimethyl acetylenedicarboxylate to yield isoxazoline **98**, which is the 1:2 adduct.

It should be noted that in some cases the data on the reactions of oximes with acetylenes conflict with one another. For instance, the results of a publication¹⁸⁷ describing synthesis of simplest *O*-vinylloximes by vinylation of oximes with calcium carbide in an

aqueous medium at 200–220 °C were checked in another study¹⁸⁸ and were not confirmed. Under these conditions, instead of *O*-vinylloximes, pyridines were obtained in low yields.^{88, 189}

In the presence of KOH, cyclohexanone oxime reacts with unsubstituted acetylene to form 6-methyl-1,2,3,4,7,8,9,10-octahydrophenanthridine (**101**) in a yield of up to 30%.⁸⁸ However, the conditions of this reaction were not optimised by the authors.

3,5-Diethoxycarbonylpyridine **102** was synthesised in a reaction of formaldoxime with ethyl propiolate.¹¹⁷ Here, the hydroxyl group of oxime remains inert with respect to the triple bond and the nitrogen atom plays the role of a nucleophilic centre. The reaction proceeds on refluxing the reactants in 50% aqueous methanol; no intermediate adduct was isolated.

Reactions of α -chlorooximes^{190, 191} and α -amido-oximes^{192, 193} with acetylenes are also documented. However, since these compounds may be considered as the derivatives of hydroxamic acids (acid chlorides and amides), their reactions are beyond the scope of our survey.

IV. Nucleophilic attack on the $C=N$ bond of oximes

Being treated with bases, oximes not only undergo deprotonation, which enhances their nucleophilicity, but are also subjected themselves (especially, oxime ethers) to a nucleophilic attack on the nitrogen atom. Thus, competition often exists between the roles that an oxime plays as the nucleophilic reagent and as the object of a nucleophilic attack.

The presence of an oxygen atom adjacent to the $C=N$ double bond that can exert both negative inductive and positive mesomeric effects reduces the basicity of the nitrogen atom as compared with imines and decreases the positive charge on the carbon atom, making the latter less susceptible to the nucleophilic attack. For instance, the higher resistance of oximes against hydrolysis as compared with imines is explained¹⁹⁴ by the participation of the oxygen atom in charge delocalisation.

On the other hand, the electronegative nature of the oxygen atom favours nucleophilic substitution at the nitrogen atom of the oxime function.

1. Intramolecular nucleophilic substitution at the nitrogen atom

a. Heterocyclisation of oxime derivatives into azoles

Oximes with a nucleophilic site in the side chain and the N–O bond activated by the introduction of an acceptor substituent at the oxygen atom undergo intramolecular nucleophilic substitution to afford 5-membered nitrogen-containing heterocycles.[‡]

Thus *O*-mesyloxime **103**, which has an activated methine group in the γ -position with respect to the oxime function, is converted quantitatively into pyrroline **104** upon its treatment with a strong organic base, namely, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).^{196, 197}

Heating of *O*-acetyloxime of γ,δ -unsaturated ketone **105** (the ratio of *Z*- and *E*-isomers is $\sim 1:1$) in an acidic medium in the presence of hydrogen donors (AcOH, cyclohexa-1,4-diene, dioxane) under reflux for 6 h leads to a mixture of 2-acetoxymethyl-3,4-dihydro-2*H*-pyrrole **106** and 2-methyl-3,4-dihydro-2*H*-pyrrole **107**, which are formed by different mechanisms.¹⁹⁸ The reaction was assumed to proceed *via* a cationic intermediate **108**.

However, since 2-methylpyrroline **107** could not be formed according to a nucleophilic substitution mechanism, it was assumed¹⁹⁸ that an additional pathway of radical cyclisation exists.[§]

[‡] During preparation of this review for publication, one more review¹⁹⁵ appeared, which is devoted to the use of intramolecular nucleophilic substitution at the oxime nitrogen atom for the synthesis of various nitrogen heterocycles and contains partially the material presented in this section.

[§] Although homolytic reactions of oximes are not considered in a special Section, it seemed reasonable to present the scheme of the radical mechanism. Studies of the synthesis of pyrrolines by photochemical cyclisation of *O*-acetyl- and *O*-methyloximes of γ,δ -unsaturated ketones were continued in a recent publication.¹⁹⁹

The possible mechanism was confirmed in experiments carried out in toluene-*d*₈ in the presence of free-radical traps such as hydroquinone and naphthalene-1,5-diol. The sequence of transformations that involve naphthalene-1,5-diol is as follows:¹⁹⁸

The transfer of an electron from naphthalene-1,5-diol to oxime **105** leads to the formation of radical **109**, which cyclises to form pyrroline radical **110**. The latter splits a hydrogen atom from cyclohexa-1,4-diene to form pyrroline **107**.

Under similar conditions (AcOH, hydroquinone, cyclohexa-1,4-diene, dioxane, reflux, 6–24 h), *O*-acetyloximes **111**, which contain alkyl substituents, cyclise to pyrroles **112**.¹⁹⁸

$R^1 = \text{Me, Ph, (CH}_2\text{)}_2\text{Ph}$; $R^2 = \text{H, Ph, CO}_2\text{Et}$.

The direction of heterocyclisation of phenols depends on the mutual arrangement of the hydroxyl group and the side-chain oxime fragment. Intramolecular nucleophilic substitution of the S_N2 type at the nitrogen atom is observed in the reaction of ketoxime **113** with tetrabutylammonium perhenate in the presence of trifluoromethanesulfonic acid (TfOH). Here, the phenolic substituent plays the role of a nucleophile.²⁰⁰

Examples of an intramolecular nucleophilic attack of a phenoxide ion on the nitrogen atom in an acetylated oxime function are known²⁰¹. Thus the treatment of *O*-acetyloximes **114** with potassium carbonate in benzene leads to benzoisoxazoles **115**.

$R^1, R^2, R^3 = \text{H, Alk.}$

Reduction of *O*-2,4-(dinitrophenyl)oximes of γ,δ -unsaturated ketones **116** in the presence of a radical trap (3,4-methylenedioxyphenol) leads to cyclisation to pyrrolines **117**.²⁰²

As a result of the aza-Heck intramolecular reaction, *O*-methylsulfonyloxime **118** is converted into pyrrole **119**, the yield of the expected Beckmann rearrangement products being 10% (see below, Section VI).²⁰³

(a) Pd(OAc)₂ (10 mol.%), P(*o*-Tol)₃ (30 mol.%), Et₃N, DMF, 80 °C, 0.5 h.

The use of *O*-acyloximes increases the regioselectivity of the process. Thus, irrespective of its configuration, *O*-pentafluorobenzoyloxime **120** undergoes Pd(0)-catalysed cyclisation to pyrrole **121**. The high yield of the product was explained by the absence of side Beckmann rearrangement.²⁰³

(a) (1) Pd(PPh₃)₄ (3 mol.%–10 mol.%), Et₃N, DMF, 80 °C, 1 h;
(2) Me₃SiCl, CH₂Cl₂, 20 °C, 0.5 h.

This version of the aza-Heck reaction is a simple approach to the synthesis of 2,5-disubstituted pyrroles provided oximes of the types **118** and **120** are available. Surveys^{195, 204} show several more examples of such cyclisation and also discuss relevant publications^{205–211} describing intramolecular nucleophilic substitution reactions at the oxime nitrogen atom that involve unsaturated substituents and proceed under the action of, *e.g.*, Ni(0)²¹⁰ and copper salts.^{211–217} Similar reactions that lead to quinoxalines and 2*H*-dihydropyrroles were considered.²¹⁸

b. The Neber rearrangement

The mechanisms of the Neber and the Hoch–Campbell reactions (see Section IV.1.c) assume the formation of intermediate azirines as the key stage. Intramolecular nucleophilic substitution of the groups at the oxime nitrogen atom is realised by a carbanion, which is generated as a result of the abstraction of an α -proton under the effect of bases. It thus seems reasonable to discuss these reactions in the Section devoted to the nucleophilic attack on the C=N bond.

The Neber rearrangement^{84, 219–229} represents a transformation of ketoxime sulfonates into α -amino ketones in the presence of bases. In certain cases, intermediate azirines **122** were isolated from the reaction mixtures.^{226–229}

Two possible mechanisms of the rearrangement were proposed,^{227, 230} namely, the nitrene mechanism (route *a*) and the anionic mechanism (route *b*).

The mechanism of the Neber rearrangement was also considered in other studies.^{231, 232} The use of chiral quaternary ammonium salts as the phase-transfer catalysts allowed preparation of optically active amino ketones (*ee* reaches 70%).²³² This suggests that the reaction follows the anionic route *b*, because the route *via* nitrenes should lead to the loss of stereochemical information transferred in the deprotonation of oxime upon the action of a chiral base.

The reaction of *O*-methyloximes of substituted α -chloro acetophenones **123** with LDA leads to *O*-methyloximes of 1,3-diarylpopyn-1-ones **124** and bis(*O*-methyloximes) of 1,4-diketones **125** (in certain cases, *e.g.*, for Ar = Ph, their yield reaches 38%).²³³

Ar = Ph, 4-MeOC₆H₄, 4-BrC₆H₄, 2-naphthyl.

Bisoximes **125** are formed in the reaction of the starting substrate with its lithiation product **126**, while alkynyloximes **124** are formed as a result of several rearrangements *via* chloroazirines **127**.

It was assumed²³³ that, first, aziridine **128** is formed from chloroazirine **127** and its lithium derivative **126**, which is followed by a two-step fragmentation of the intermediate 1-aza-2-chlorobicyclo[1.1.0]butane **129**. Its dehydrochlorination with ring-opening yields unstable azacyclobutadiene **130**, which decomposes into alkyloxime **124** and HCN. In certain experiments (e.g., for Ar = 4-ClC₆H₄), the addition of MgBr₂ to the reaction mixture substantially increases the yield of alkyloximes **124** (from 19% to 70%), which at best reaches 81%.

In reactions of two different α -chlorooximes one of which has a good leaving group (TsO, EtCO₂) at the nitrogen atom, cross-coupling occurs.²³³ As a result, alkyloximes **124** with different substituents are formed. If an oxime has no bulky groups (e.g., *tert*-butyl), the reaction proceeds stereoselectively.

R ¹	R ²	Yields of compounds 124 (%)	Ratio Z : E
Me	Ph	57	> 95 : 5
Bu ^t	Ph	63	62 : 38
cyclo-C ₅ H ₉	Ph	73	> 95 : 5
n-C ₈ H ₁₇	Ph	69	> 95 : 5
Ph	4-ClC ₆ H ₄	73	94 : 6
4-MeOC ₆ H ₄	Ph	68	> 95 : 5
4-ClC ₆ H ₄	Ph	65	> 95 : 5

The Neber rearrangement was used for the synthesis of compounds that can influence the cardiovascular system,^{234,235} exhibit antipsychotic activity²³⁶ and are potential histamine antagonists (H₂).²³⁷

c. The Hoch–Campbell reaction

Hoch²³⁸ and Campbell^{239–242} have independently discovered that, when treated with Grignard reagents, ketoximes afford aziridines in the yields varying from low to moderate. Later, this reaction was used in the synthesis of various compounds of this class.^{101, 108, 243–248} Upon hydrolysis, the aziridine ring opens to yield amino alcohols.²³⁹

Formally, the Hoch–Campbell reaction is similar to the Neber rearrangement, because it involves a nucleophilic attack of a carbanionic centre on the oxime nitrogen atom.²¹⁹

A mixture of aziridines **131** and **132** with α -phenylethylamine in the 64 : 1 : 35 ratio was isolated upon the reaction of acetophenone oxime with EtMgBr in the presence of LiAlH₄. The formation of aziridine **131** confirms the role of azirines as the intermediates in this reaction.²⁴⁹

By the example of benzyl methyl ketoxime, it was shown²⁴⁴ that the formation of an azirine ring is stereospecific in toluene. This reaction preferentially involves a substituent in the *syn*-position with respect to the hydroxyl group of the oxime function and produces aziridine **133**. However, in THF both possible isomers, *viz.*, compounds **133** and **134**, are formed.

It was assumed¹⁰¹ that the cationoid Mg atom favours the proton abstraction from the *syn*-methylene group due to the intramolecular stabilisation of the carbanionic centre formed.

B = AlkMgBr.

The preferential involvement of *syn*-methylene groups in the formation of aziridines was also observed in the reaction of *O*-alkylketoximes with the Grignard reagents.³⁶ The steric effect of substituents in the azirine ring determines the stereoselectivity of the addition of an organomagnesium compound to the intermediate azirine.²⁴⁴

Three types of compounds, namely, aziridine **135**, ketimine **136** and a product of the Hoch–Campbell reaction **137**, were

R¹, R² = Alk, Ar; R³ = Bu^t, Cy.

obtained in a reaction of a series of aliphatic and aromatic ketoximes with organomagnesium derivatives.²⁵⁰

The result of this reaction depends strongly on the nature of both the oxime and the Grignard reagent used. Thus cyclohexanone oxime is converted exclusively into the Hoch–Campbell reaction products **137** [$R^1 - R^2 = (CH_2)_4$], whereas benzophenone oxime and camphor oxime form only ketimines **136**. Among all organomagnesium compounds used, isobutylmagnesium bromide showed the best results in the reductive formation of aziridine, whereas in the case of phenethyl- and 2,2-diphenylethylmagnesium bromides the reaction did not follow this pathway.

Trifluoromethylaziridines **139** were synthesised in reactions of trifluoromethyl ketoxime **138** with Grignard reagents.^{251, 252}

$R = \text{Alk, All.}$

Substituted aziridines **140** are formed together with amines in reactions of oximes with lithium aluminium hydride.^{253, 254} It is evident that this kind of transformation can be considered as an analogue of the Hoch–Campbell reaction.

$R^1, R^2 = \text{H, Alk, Ar.}$

Reflux of a mixture of *syn*- and *anti*-isomers (1 : 4) of β -naphthylpropan-2-one oxime with 2 equivalents of LiAlH_4 in THF yields *cis*-3-methyl-2-(β -naphthyl)aziridine **141**, 2-(β -naphthylmethyl)aziridine **142** and a primary amine **143**.²⁵⁴

Naph = naphthyl.

Reduction of 1,1-diphenylpropan-2-one oxime with lithium aluminium hydride in boiling THF produces 3-methyl-2,2-diphenylaziridine **144** in 41% yield.²⁵³ Its structure was also confirmed by an independent synthesis according to the Campbell method from ethyl phenyl ketoxime and PhMgBr .²⁴¹

It was noted²⁵³ that the methyl group is involved in the formation of an aziridine ring upon the reduction of 1-alkyl-1-

phenylpropan-2-ones with LiAlH_4 . Thus the reactions of 1-methyl-1-phenyl- and 1-ethyl-1-phenylpropan-2-ones produced, in addition to primary amines, 2-(1-phenylethyl)- and 2-(1-phenylpropyl)aziridines in 38% and 31% yields, respectively. Under similar conditions, aldoximes also form aziridines in 38% yield, whereas the attempts to obtain aziridines from *O*-tosylaldoximes by the Neber reaction failed.²¹⁹

Reduction of di(*p*-methylbenzyl) ketone oxime and its acyl derivatives with LiAlH_4 in THF proceeds stereospecifically to give *cis*-aziridines (yields > 80%).²⁵⁵ Complex hydride $\text{NaAlH}_2(\text{OC}_2\text{H}_4\text{OMe})_2$ exhibits higher selectivity, it reduces ketoximes and their ethers into substituted aziridines in high yield with only trace amounts of amines.²⁵⁵

Thus, the conversion of oximes into aziridines under the action of LiAlH_4 and related hydrides resembles the reactions with organomagnesium compounds: in both cases aziridines are the intermediates which are formed in an intramolecular nucleophilic attack of the α -carbanionic centre on the oxime nitrogen atom.²⁵⁶

d. Miscellaneous reactions

In closing this Section, we consider two examples of the nucleophilic attack on the $\text{C}=\text{N}$ bond. Thus it is assumed that the intramolecular nucleophilic substitution at the oxime nitrogen atom is the key stage of the mechanism of strong-base-induced rearrangement of *O*-propargylketoximes **145** into *N*-1-alkenylacrylamides **146**.²⁵⁷

$R^1 = \text{Alk, Ar; } R^2 = \text{H, Alk; } R^1 - R^2 = (\text{CH}_2)_n; n = 3, 4.$

Carbon and nitrogen atoms in the $\text{C}=\text{N}$ bond manifest simultaneously their electrophilic properties in the reaction of acetone oxime esters **147** with butylamine to give diaziridine **148**.²⁵⁸

For similar acetaldoxime derivatives, the yield of diaziridine is only 16% due to the concomitant elimination of the acid AlkCO_2H .

2. Addition of organometallic compounds to the $\text{C}=\text{N}$ bond

The reaction of organometallic compounds with oximes or their ethers is of interest for the synthesis of hydroxylamines. Addition of alkyl- or phenyllithium to unprotected oximes requires a substantial excess of the organolithium compound.²⁵⁹ Moreover, the presence of active α -hydrogen atoms relative to the oxime function substantially reduces the yield of the adduct.

Lewis acids favour the reaction of organometallic compounds with the oxime group probably due to the coordination to nitrogen and oxygen atoms, which increases the positive charge on the carbon atom. Thus in the presence of 1 equivalent of $\text{BF}_3 \cdot \text{OEt}_2$,

(het)aryllithium compounds add to aldoxime ethers to form *O*-alkylhydroxylamines **149** (in yields up to 64%).²⁶⁰

R¹ = Me, Prⁱ; R² = Me, Buⁿ; R³ = Ar, Het.

In this case, the oxime group configuration has a strong effect on the yield of the reaction product, which is substantially higher for *Z*-isomers.²⁶⁰

The addition of organolithium and organomagnesium compounds to (*R*)-*O*-(1-phenylbutyl)cinnamaloxime **150** was used as the key stage in asymmetric synthesis of α -amino acids.²⁶¹ The highest yields of adducts **151** were achieved in reactions with alkyl(or aryl)lithium.

The reaction of organolithium compounds with oximes of α -oxo carboxylic acids, their esters and amides **152** produces derivatives of *N*-hydroxy amino acids **153**.²⁶²

R¹ = OH, OMe, OBu^t, NMePh; R² = Bn, PhCHMe; THP;

R³ = H, Me; R⁴ = Me, Buⁿ, Bu^s, Bu^t, Ph;

THP is tetrahydropyran-2-yl.

High yields of products of this reaction were explained by the activating effect of the acceptor substituent at the oxime function. However, organomagnesium and organozinc compounds do not react with oximes **152** under these conditions.²⁶²

A series of chiral ferrocenylalkylamines (*e.g.*, compound **154**) were synthesised by diastereoselective 1,2-addition of organometallic reagents to esters of ferrocenecarbaldehyde oxime **155** containing a chiral substituent, which was followed by reduction of hydroxylamines **156** formed.²⁶³

156: R = Prⁱ (85%), Buⁿ (81%), All (70%);

M = Li, MgHal; Cbz is benzyloxycarbonyl.

Recently, an asymmetric synthesis of α -amino acids, which is based on diastereoselective addition of organolithium compounds (2-furyllithium, phenyllithium, vinylolithium) to (*R*)- and (*S*)-*O*-(1-

phenylbutyl)oximes **157** was carried out.²⁶⁴ The corresponding hydroxylamines **158** were obtained with high diastereoselectivity (the configuration of the new chiral centre is given first).

R ¹	R ²	R ³	Yield (%)	de (%) (configuration)
Pr ⁱ	Me	2-furyl	31	52 (<i>R,S</i>)
4-BrC ₆ H ₄	Me	2-furyl	14	> 95 (<i>R,S</i>)
4-BrC ₆ H ₄ CH ₂	H	2-furyl	40	83 (<i>S,R</i>)
Pr ⁱ	H	Ph	38	95 (<i>R,S</i>)
Bu ^t	H	Ph	31	> 98 (<i>R,S</i>)
EtMe ₂ C	H	Ph	32	> 98 (<i>R,S</i>)
Pr ⁿ	H	H ₂ C=CH	87	84 (<i>R,S</i>)
Pr ⁱ	Me	H ₂ C=CH	54	> 95 (<i>S,R</i>)
H ₂ C=CH(CH ₂) ₂	H	H ₂ C=CH	77	94 (<i>R,S</i>)
Cy	H	H ₂ C=CH	74	92 (<i>S,S</i>)
Ph	H	H ₂ C=CH	46	98 (<i>S,S</i>)

Reductive cleavage of the N–O bond in hydroxylamines **158**, followed by a series of successive transformations produces *N*-substituted amino acids and their esters.²⁶⁴

O-Methyloximes add chlorotitanium enolate of *N*-propionylthiazolidine-2-thione **159** to form azetine **160**.²⁶⁵

R = Cy, Ph, styryl, 1-naphthyl, 2-thienyl.

3. Reduction of oximes

Depending on the reagent nature, the reduction of oximes may produce amines, hydroxylamines or alcohols. As a rule, alkali metals or complex metal hydrides are used as the reducing agents. The key stage of this reaction is the transfer of a hydride ion or an electron to the antibonding orbital of the C=N bond to form an N-anion or a radical anion. Below, different types of reagents used in the oxime reduction are considered.

Oximes are smoothly reduced with sodium in liquid ammonia to form amines.²⁶⁶ Optically pure menthylamine (**161a**), (–)-8-methylmenthylamine (**161b**) and (–)-8-phenylmenthylamine (**161c**) were prepared from the available menthone (**162**, R = H) and (+)-pulegone (**163**) by reduction of the corresponding oximes with the Na–ethanol system in refluxing toluene.²⁶⁷

R = H (**a**, 59%), Me (**b**, 67%), Ph (**c**, 93%).

Refluxing of ketoximes in THF in the presence of LiAlH_4 usually leads to aziridines in addition to amines (yields up to 47%).^{253,255} TiCl_4 or FeCl_3 additives to lithium aluminium hydride make the process more selective in the case of oximes of chroman-4-one, acetophenone and benzophenone. The corresponding amines were obtained in 60%–70% yields.²⁶⁸

A search for reagents for the reduction of camphenylone oxime **164** was carried out²⁶⁹ with the aim of preparing *endo*-2-camphenylamine **165**.

Systems LiAlH_4 –THF (product **165** is formed in 72% yield, the ratio *endo*:*exo* = 5 : 3), NaBH_4 – TiCl_4 –glyme (76%, 100 : 0) and Na – Pr^nOH (78%, 100 : 0) have proved to be effective.

In the presence of chiral additives, the asymmetric reduction of oximes is possible. Thus a complex of lithium aluminium hydride with 3-*O*-benzyl-1,2-*O*-cyclohexylidene- α -D-glucopyranose reduces different aliphatic and aromatic ketoximes and their methyl and tetrahydropyranyl ethers to chiral amines in low or moderate optical yields.²⁷⁰ The best enantioselectivity (56% *ee*) was achieved in the reduction of methyl cyclohexyl ketoxime.

Borane and its complexes are widely used for the reduction of various oximes. For example, the possibility of stereoselective reduction of cyclic α -hydroxy *O*-benzylketoxime **166** with borane to form 1,2-aminoalcohol **167** was demonstrated.²⁷¹ The yields were in the range 68%–86%, the mixture preferentially contained the *cis*-isomer (68%–92% *de*).

Pyridine–borane is a selective reductive system. Upon the action of this reagent, oximes are converted into substituted hydroxylamines in high yields; other functional groups (ester, nitrile, nitro groups) remaining unaffected.²⁷² Thus the pyridine–borane complex prepared by reaction of pyridine hydrochloride with sodium borohydride reduces oximes of aliphatic and aromatic ketones and of aromatic aldehydes to the corresponding hydroxylamines **168** in 74%–92% yields.²⁷³ This method can also be applied for the efficient reduction of *O*-acyl- and *O*-methyloximes.²⁷⁴

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Ph}$, 3- $\text{NO}_2\text{C}_6\text{H}_4$, 4- CNC_6H_4 , 4- ClC_6H_4 ; $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{PhCH}_2\text{CH}_2$; $\text{R}^1 = \text{Pr}^n$; $\text{R}^2 = \text{Pr}^n$, Ph .

Sodium borohydride is also an efficient reducing agent under various conditions. For example, silica gel-supported NaBH_4 reacts with oximes at room temperature in benzene to form borane complexes of hydroxylamines **169**.²⁷⁵

Refluxing of oximes with sodium borohydride in aqueous alkali affords alcohols formed upon reduction of the corresponding ketones.²⁷⁶

$\text{R}^1, \text{R}^2 = \text{Alk}$.

Oximes of α -oxo esters **170** are reduced with sodium borohydride in THF in the presence of I_2 , AcOH , TiCl_4 , ZrCl_4 , CoCl_2 , H_2SO_4 and Me_3SiCl to the corresponding amino alcohols **171**.²⁷⁷

R = Me, Et, Pr^i , Buⁿ, Ph.

The reduction of *O*-alkylketoximes with a system NaBH_4 – ZrCl_4 modified with chiral amino alcohols was studied.²⁷⁸ For example, reduction of acetophenone *O*-methyloxime **172** afforded (*S*)-1-phenylethylamine **173** in 89%–96% yield and optical purity of 42%–95% *ee*.

Cat* is (*S*)-valinol, 1,1-diphenyl-(*S*)-valinol, (*S*)-leucinol, (*S*)-isoleucinol.

Among amino alcohols studied, (*S*)-valinol and 1,1-diphenyl-(*S*)-valinol exhibit the highest enantioselectivity.

Sodium cyanoborohydride is often used as the reducing agent. Thus cyclisation of oxime ethers of 2-(3-hydroxyphenyl)ethyl ketones into the corresponding quinolines under the action of NaBH_3CN is accompanied by the formation of hydrogenated derivatives.²⁷³

Ketone oximes are smoothly reduced with sodium cyanoborohydride in weakly acidic media (pH ~4) to form the corresponding *N*-alkylhydroxylamines **168**.²⁷⁹

R ¹	R ²	Time /h	Yield (%)
Me	Et	3	73
Me	Ph	1	75
	(CH ₂) ₄	3	77
	(CH ₂) ₅	3	66

Under these conditions, aldoximes undergo reductive *N*-alkylation to form bisalkylated hydroxylamines **174**.²⁷² These products may have been formed as a result of the following sequence of reactions:

A decrease in the pH of the medium (down to ~3) allows one to substantially diminish the contribution of this process and synthesise monoalkyl derivatives **175**. The change in the reaction pathway is explained²⁷² by the acceleration of the oxime group reduction.

RCH=NOH		pH~4	$\text{(RCH}_2\text{)}_2\text{NOH}$
		pH~3	RCH_2NHOH
			175
Compound	R	Time /h	Yield (%)
174	n-C ₆ H ₁₃	3	57
	Ph	4	60
175	n-C ₆ H ₁₃	1	33
	Ph	1	79

Sodium cyanoborohydride in acetic acid reduces *O*-benzoyloximes of aliphatic ketones **176** to the corresponding *O*-benzoylhydroxylamines.²⁷⁴

R¹–R² = (CH₂)₄, (CH₂)₅, (CH₂)₂CH(Bu^t)(CH₂)₂, (CH₂)₁₁;
R¹ = Bn, R² = Me.

The reduction of ethers of oximes of aromatic aldehydes and ketones proceeds much more slowly than the decomposition of sodium cyanoborohydride under the action of acetic acid. For this reason, the reduction of the C=N bond in these compounds is ineffective under these conditions.

Triethylsilane in trifluoroacetic acid is a good alternative to sodium cyanoborohydride. This system makes it possible to reduce the above-mentioned benzoyloximes **176** (yields 73%–95%) and ethers of oximes of aromatic aldehydes to hydroxylamines.²⁷⁴

The hydrazine–Raney Ni system in aqueous or aqueous ethanolic solutions easily reduces ketoximes to the corresponding amines; under these conditions, aldoximes do not react.²⁸⁰

4. Deoximation

Deoximation is a method of conversion of oximes into carbonyl compounds. In the general case, this reaction assumes a primary attack of an O-centred nucleophile (H₂O or OH[–]) on the carbon atom of the C=N bond. Apparently, the rate of the process will increase with an increase in the electrophilicity of the carbon atom of the C=N bond or the nucleophilicity of the O-nucleophile. The formation of complexes with Lewis acids (or protonation) and the oxidation of the oxime group should enhance the former parameter, while the use of superbasic media (such as KOH–DMSO) should enhance the latter parameter. The examples shown below agree well with these assumptions.

The deoximation reaction is widely used in organic synthesis and analysis, for example, in purification and identification of carbonyl derivatives.²⁸¹ Deoximation of oximes synthesised by nitrosation of active methylene groups in different organic compounds and also by condensation of nitroalkenes with aldehydes,²⁸² is the key stage in the synthesis of certain carbonyl compounds.²⁸¹ The oxime group can play a protective role and also selectively activate α-methylene groups;²⁸³ hence, the studies aimed at the conversion of oxime groups into carbonyl ones are topical. Deoximation in basic media is a less common and less efficient reaction as compared with the acid-catalysed process. However, it is of interest, first of all, as a method for synthesising carbonyl compounds from oximes that contain groups unstable in the presence of acids.²⁸¹ Oxidation of alkali metal ketoximates with, e.g., fluorochlorate, is often used for regeneration of ketones.²⁸⁴

Deoximation of sodium aldoximates and ketoximates with CuCl₂·H₂O in acetonitrile proceeds much faster and, in certain cases, leads to higher yields of carbonyl compounds as compared with deoximation of neutral oximes.²⁸⁵ This is explained²⁸⁵ by the greater susceptibility of oximates to oxidation due to the higher energy of the highest occupied molecular orbital (HOMO) and larger negative charge of the oximate anion, which favour the interaction with the electrophilic centre of the oxidant.

Deoximation is sometimes a side process, e.g., in the synthesis of pyrroles from ketoximes and acetylenes in superbasic media by the Trofimov reaction.^{88, 145–156}

At present, deoximation methods are being actively studied.^{286–300} In the past two years, several new efficient methods were developed for the removal of the oxime protection under mild conditions.^{296, 301–305}

One of modern methods of deoximation is based on the use of potassium salt of cobalt-tungstic heteropolyacid K₃CoW₁₂O₄₀·3H₂O, which is an inexpensive and easily recoverable heterogeneous catalyst.²⁹⁶ The reaction proceeds in acetonitrile at room temperature, the products are formed in good yields. This method allowed the conversion of various aldoximes and ketoximes, e.g., compounds **177a–g**, into carbonyl compounds.

Compound	R ¹	R ²	Time /min	Yield (%)
177				
a		H	60	95
b		H	45	90
c		H	30	93

Compound 177	R ¹	R ²	Time /min	Yield (%)
d		H	45	86
e		Me	90	92
f			90	90
g			60	85

The fact that in this case the removal of the oxime protection is not accompanied by the oxidation of the liberated aldehyde function (in contrast to other reactions of oxidative hydrolysis) is an important advantage of the proposed method. Even sterically hindered camphor oxime **177g** is successfully converted under these conditions into camphor with high yield, while the oxime of α,β -unsaturated aldehyde **177c** undergoes chemoselective deoxygenation with the retention of the double bond and its configuration. It should be noted that deoxygenation of optically active oxazolidine **177d** containing an aldoxime function in the α -position with respect to the asymmetric carbon atom did not affect the chiral centre configuration.²⁹⁶

Among other recently developed deoxygenation methods, cleavage of oximes with antimony pentachloride (CH_2Cl_2 , 0 °C – room temperature, the carbonyl compound is formed in 75%–92% yields),³⁰¹ hydrolysis of oximes in the presence of iodobenzoic acid and β -cyclodextrin (room temperature, yields 82%–96%)³⁰² and oxidative hydrolytic cleavage of oximes with *N*-bromosaccharin under microwave irradiation (acetone, H_2O , 2–3 min, yields 88%–97%)³⁰³ deserve mention.

V. Dehydration

Dehydration of aldoximes, like deoxygenation, is usually carried out with acidic reagents.³⁰⁶ However, when aldoximes contain groups sensitive to acids, the conversion of aldehydes into nitriles by elimination of water from the oxime group can be accomplished in basic media, *i.e.*, via oximate anions.

An effective synthesis of nitriles **178** by dehydration of aldoximes on heating in a superbasic system (KOH – DMSO) is described.^{88, 307}

Elimination of water from aldoximes can occur under the action of such a base as LDA.³⁹

Most probably, the aforementioned elimination processes follow the E2 [reaction (1)] and/or E1cB [reaction (2)] mechanisms.

The following mechanism was proposed³⁰⁸ for the dehydration of aromatic aldoximes to nitriles with chlorosulfonyl isocyanate in triethylamine (yields 74%–87%):

In the presence of triethylamine, the elimination of water from aldoximes also occurs under the action of SCl_2 , S_2Cl_2 , Cl_3CSCl , PhSCl , PhSeCl , PhSe(O)Cl (in Et_2O or CHCl_3)³⁰⁹ or succinimide-sulfonium (in triethylamine).³¹⁰

The rate of elimination of water or alcohols (in the case of oxime ethers) depends on the configuration of the aldoxime function. Thus upon dehydration in the system $(\text{CF}_3\text{CO})_2\text{O}$ –pyridine (ratio 1 : 4, 3 h, room temperature), (*E*)-benzaloxime is transformed into benzonitrile in 38% yield, whereas for its *Z*-isomer the yield is 90%.³¹¹ For *E*-isomers, the yields increase in the presence of excess of pyridine or with triethylamine and with an increase in the reaction temperature. At high temperatures, the nitrile yield is independent of the configuration of the original oxime due to easier *E*–*Z*-isomerisation of the oxime.

Unstable (*Z*)-benzaloxime acetate **179** obtained on treatment of the corresponding oxime with acetic anhydride readily loses acetic acid even upon slight heating in a sodium carbonate solution. At the same time, under similar conditions, the *E*-form is converted into the original oxime rather than nitrile.³¹²

In the water–dioxane system (4 : 1, 25 °C), the base-catalysed elimination of alcohols (phenols) from substituted *O*-alkyl(aryl)-benzaloximes takes place to afford the corresponding substituted benzonitriles.³¹³ Under these conditions, the elimination rate is higher by a factor of several tens for *Z*-oximes as compared with *E*-isomers. In the case of *E*-isomers, the rate of *syn*-elimination increases when electron-withdrawing groups are present in the leaving group and/or in the aromatic substituent at the oxime function. The elimination of phenols from (*E*)-*O*-arylbenzaloximes [$\text{Ar} = \text{Ph}$, 4- $\text{NO}_2\text{C}_6\text{H}_4$, 2,4-(NO_2) $_2\text{C}_6\text{H}_3$] proceeds smoothly in 60% aqueous DMSO under the action of hydroxide anions. As a result, benzonitriles are formed in quantitative yields.³¹⁴ The examples shown above suggest that the reaction

proceeds predominantly by the E2 mechanism, which is characterised by easier *anti*-elimination.

Earlier, it was assumed^{88, 157} that the synthesis of pyrroles from ketoximes and acetylene by the Trofimov reaction includes the stage of azirine formation. In this case, either 1,3-dehydration of the ketoxime, which is followed by the reaction of azirine formed with acetylene [reaction (3)], or elimination of vinyl alcohol (as acetaldehyde) from the intermediate *O*-vinyloxime followed by the addition of acetaldehyde as the enolate anion to azirine [reaction (4)] are possible. Both pathways lead to the formation of the pyrrole ring.

Although another mechanism is currently accepted, namely, a [3,3]-sigmatropic rearrangement of *O*-vinyloximes,^{88, 145–156} it is possible that the above-mentioned pathways are also realised in certain cases (or in parallel). This is confirmed by the fact that, being treated with strong bases, ketoximes undergo 1,3-dehydration and cyclise to azirines (the Hoch–Campbell reaction, see Section IV.1.c).^{239, 315, 316}

B = RMgX, LiAlH₄; M = MgX, AlH₄.

VI. The Beckmann rearrangement

The Beckmann rearrangement, *viz.*, the conversion of oximes into the corresponding amides, is traditionally considered as an acid-catalysed process.¹⁰⁸ The examples where it occurs in the presence of bases are less common; however, this is of particular preparative value for oximes with functions unstable in acidic media.

For example, the Beckmann rearrangement of *E*- and *Z*-oximes of benzoquinolizidones **180** into isomeric diazepinoisoquinolines **181**, **182** under the action of *p*-toluenesulfonyl chloride (TsCl) in the presence of Na₂CO₃ occurs with no side skeleton rearrangements typical of reactions in acidic media (yields 45%–50%).³¹⁷

Ring expansion of the cyclohexanone oxime fragment fused to heterocycles in oximes **183a–d** under the action of diisobutyl aluminium hydride (DIBAH) results in tetrahydrofuro- (**184a**), -thieno- (**184b**) and -pyrrolo-[3,2-*b*]azepines (**184c,d**).³¹⁸ It is evident that the reaction proceeds through the reduction of an intermediate amine, namely, the Beckmann rearrangement product.

X = O (a), S (b), NH (c), NMe (d).

The reaction of acetophenone oxime with LiAlH₄ in ether produces, in addition to the expected α -phenethylamine, *N*-ethyl-aniline, a reduction product of the Beckmann rearrangement.³¹⁹

The action of organomagnesium compounds on methanesulphonates of cycloalkanone and acetophenone oximes results in the Beckmann rearrangement to give intermediate imines, which are reduced (with DIBAH) or converted (by the reaction with R³MgX) into amines **185** or **186**, respectively (yields up to 79%).³²⁰

R¹ = Alk, Ar; R² = Alk; R³ = Alk, HC≡C, CH₂=CHCH₂, HC≡CCH₂; X = Cl, Br, I.

The second order Beckmann rearrangement can also proceed in the presence of bases. For example, under the action of acylating agents, monooximes of α -diketones **187** form nitriles in aqueous solutions of strong bases with elimination of carboxylic acids,³²¹ whereas in the presence of alcohols, the latter can form the corresponding esters.³²²

$\text{R}^1 = \text{Ph, Bn, CH=CHPh}; \text{R}^2 = \text{H, Me, Ph}; \text{R}^3 = \text{H, Me, Et}.$

Treatment of steroidal α -acetoxyimino ketone **188** with primary amines at 25 °C brings about the Beckmann rearrangement to give the corresponding amidonitrile **189**.³²³

$\text{R} = \text{Pr}^n, \text{Bu}^n, \text{Bn}, (\text{CH}_2)_n\text{OH} (n = 2, 3).$

Treatment of cyclohexane-1,2,3-trione-1,3-dioxime with acetic anhydride in the NaOEt–EtOH system yields ethyl 2-hydroxyimino-5-cyanopentanoate (**190**).³²⁴

Being treated with organoaluminium compounds in the presence of ZnCl_2 , esters of oximes of 2-alkyl-2,3-isopropylidenedioxycyclohexanones **191** undergo the Beckmann fragmentation with simultaneous formation of a new carbon–carbon bond to form nitriles **192**. The latter exist as a mixture of geometrical isomers, the overall yield reaches 83%.³²⁵

$\text{X} = \text{Ac, 2,6-Cl}_2\text{C}_6\text{H}_3\text{C(O)}; \text{R}^1 = \text{H, Alk}; \text{R}^2 = \text{Alk, CH}\equiv\text{C}.$

In the presence of thiols and trimethylamine, oxime *p*-toluenesulfonate **193** is rearranged into imines **194a,b**. This transformation is similar to the Beckmann rearrangement.³²⁶

$\text{R} = \text{Et (a), Bn (b)}.$

VII. Reaction of oximes involving substituents

Many reactions of oximes in the presence of bases occur with simultaneous involvement of both the oxime function and the reaction centres of peripheral functional groups to give heterocyclic compounds. Below, we show several typical examples.

Oximes of α -halo ketones react with isocyanides in the presence of sodium carbonate to form 5-aminoisoxazoles **195**.³²⁷

$\text{R}^1, \text{R}^2 = \text{Alk, Ar}; \text{Hal} = \text{Cl, Br}.$

Nitrosoalkenes are the intermediates in this reaction, which are converted into 5,6-dihydro-4*H*-oxazines in the presence of alkenes according to a mechanism of [4 + 2]-cycloaddition.³²⁸ For example, α -halo ketoximes react with trimethylsilyloxy alkenes **196** in the presence of Na_2CO_3 to form oxazines **197** (as a mixture of *cis*- and *trans*-isomers).³²⁹

$\text{R}^1 = \text{Ph, CO}_2\text{Et}; \text{R}^2, \text{R}^3, \text{R}^4 = \text{H, Alk, OSiMe}_3.$

In a similar way, the reaction of oximes of substituted α -chloroacetophenones **198** with ketene silyl acetals **199** in the presence of K_2CO_3 in THF produces 6-alkoxy-3-aryl-6-trimethylsilyloxy-5,6-dihydro-4*H*-1,2-oxazines **200** in moderate yields.³³⁰

$\text{R}^1 = \text{H, Alk}; \text{R}^2 = \text{Alk, Ar}; \text{R}^3 = \text{Alk}; \text{X} = \text{H, Cl, Me, OMe}.$

Substituted nitrosoalkenes obtained *in situ* from α -bromooximes add to dihydro(iso)quinolines to form fused oxazines **201** and **202**.³³¹

R = Ph, 4-NO₂C₆H₄, CO₂Et.

The reaction of β -keto ester oxime **203** with epoxypyranoside **204** under the action of butyllithium in THF produces oxazines **205** enantiospecifically.³³²

VIII. Conclusion

As is seen from the material shown above, oximes and their derivatives are widely used for the synthesis of amines, hydroxylamines, nitriles, amides, ketones, diazo compounds and various heterocycles (isoxazoles, isoxazolidines, benzofurans, pyrroles, pyrrolines, imidazoles, pyridines, oxazines, azirines, aziridines, diaziridines, palladacycles). In the presence of bases and competitive nucleophiles, oximes behave as real 'chemical chameleons'. Depending on substituents, reagents used and reaction conditions, they can play the role of N-, O- and C-nucleophiles, 1,3-dipoles (in the NH-nitron form), electrophiles (the objects of the nucleophilic attack on the C=N bond), selective ligands for transition metal cations and also the components of highly efficient palladium catalysts. Oximes can undergo dehydration, the Beckmann and Neber rearrangements, Hoch–Campbell and Trofimov reactions, recover aldehydes and ketones, be reduced and add organometallic compounds, etc. Such an astonishing chemical plasticity of oximes in the presence of bases makes them versatile synthons in directed organic synthesis.

We believe that systematisation and analysis of chemical properties of oximes as multifunctional nucleophilic agents, which are presented in this review, will help further unravelling of their synthetic potential.

Enediyne antibiotics and their models: new potential of acetylene chemistry

I A Maretina, B A Trofimov

Contents

I. Introduction	825
II. Typical representatives of enediyne antibiotics	825
III. Cycloaromatisation of enediynes	829
IV. Synthesis of enediyne antibiotics and their analogues	836
V. Introduction of the enediyne fragment into other classes of organic compounds	840
VI. Conclusion	842

Abstract. Structures and chemical properties of enediynes, viz., compounds comprising a system of conjugated double and triple bonds, are surveyed. The presence of this system in the molecules of enediyne antitumour antibiotics ensures their high activity. The mechanism of biological action of enediynes is discussed based on cycloaromatisation of the enediyne chromophore resulting in highly active benzenoid 1,4-diradicals, which selectively cleave DNA. The key strategies of enediyne synthesis are analysed. The bibliography includes 291 references.

I. Introduction

The role of antibiotics in nature and in the human life can hardly be overestimated. Compounds with conjugated double and triple carbon–carbon bonds occupy a special place among them. Compounds with acetylene, vinylacetylene and acetylene–allene type systems of bonds were first found in the late 19 century in some plants and mushrooms. Since molecules containing these fragments are most often unstable, their presence in natural objects appeared unusual. However, as experimental facts have been accumulated, it turned out that compounds of this type are characteristic of the living nature, are widely represented and perform important functions, in particular, act as antibiotics, fungicides and insecticides. By the early 1970s, more than 600 natural acetylene derivatives have been isolated and studied. The studies published by that time were summarised in the fundamental monograph by Kucherov, Mavrov and Derzhinskii.¹

The first representatives of enediyne antibiotics, natural antitumour compounds, were discovered in the second half of the 20th century.^{2–6} This was preceded by a discovery by Bergman of the thermal cycloaromatisation of (Z)-3-ene-1,5-diyne systems (enediynes), which was later named after him.⁷

The diradical intermediates formed upon cyclisation of enediynes were found⁸ to attack selectively the DNA regions responsible for cell functioning.

By the end of the 20th century, the structure of the enediyne antitumour antibiotics has been studied in outline, but many important details, especially those concerning their synthesis, reactivity and the mechanism of physiological action remained unknown. Therefore, the attention of researchers to the development of new approaches to their synthesis and construction of functional models does not decline. The success in the design of enediyne systems gave a large number of synthetic analogues of known natural antibiotics of this class.

Study of the factors that influence cycloaromatisation of enediynes resulted in the development of a simple model of DNA cleavage induced by the benzenoid[†] diradicals formed (see, for example, Ref. 8). The second and third generations of enediyne antibiotics appeared, which are more active towards tumour cells than the natural products. The present review is devoted to the studies along this line carried out mainly over the last decade.

II. Typical representatives of enediyne antibiotics

1. Neocarzinostatin

Neocarzinostatin was isolated in 1965 from the culture *Streptomyces carzinostaticus* var. F-41.² This was the first natural enediyne antibiotic to be described. This is a 1 : 1 complex of an apoprotein (a 113 amino-acid peptide) with chromophore **1**. Later, it has been shown that the chromophore component (generally designated as NCS in the modern literature on this subject) has a bicyclic dienediyne core.^{2, 8–11}

Received 10 January 2006

Uspekhi Khimii 75 (9) 913–935 (2006); translated by Z P Bobkova

[†] The systematic name of the parent compound of this diradical series is 1,4-phenylene or 1,4-didehydrobenzene; however, for compliance with the term generally used in the literature, below they are referred to as benzenoid diradicals.

The biological activity of NCS is due to the Myers–Saito cycloaromatisation of the *Z*-enyne–allene system:⁹

The mechanism of DNA destruction by the neocarzinostatin chromophore^{2,8} is shown in Scheme 1. The cascade of reactions resulting in DNA cleavage is initiated by the specific nucleophilic attack on the C(12) carbon atom. The addition of a nucleophile (for example, a free sulfide group from the chromophore-surrounding proteins) induces bond rearrangement in the ring accompanied by oxirane opening giving rise to cumulene **2**. (In model syntheses, activation is due to an external nucleophile, for example, methyl thioglycolate.) The unstable intermediate **2** rapidly undergoes cycloaromatisation to give diradical **3**. The

Scheme 1

latter abstracts hydrogen from DNA, thus inducing its destruction and being converted into compound **4**. The cumulene intermediate **2** is detectable in the NMR spectra at low temperatures.^{2, 12, 13}

The reaction of the diradical with DNA starts with the elimination of the hydrogen atom from position C(5) of the deoxyribose fragment (the major reaction route).¹⁴ The subsequent stages result in cleavage of the DNA chain.

A unique analogue of neocarzinostatin, *i.e.*, the non-protein antibiotic N 1999 A2, which is a potent growth inhibitor for tumour cells and bacteria, was isolated from *Streptomyces* sp. AJ 9493.^{15–20} The cytotoxic properties of this analogue with respect to some types of tumours are superior to the action of neocarzinostatin. The molecule of N 1999 A2 (**5**) also contains a nine-membered enediyne ring, but, unlike neocarzinostatin, it has neither a concomitant peptide nor a sugar residue.¹⁸

2. Calicheamicins, namenamycin, shishijimicin

Calicheamicins are a family of antibiotics isolated from *Micromonospora echinospora* ssp. *calichensis*.^{2, 21} The structure of one of them, calicheamicin γ_1^1 (**6**), is shown below.

Representatives of this family of antibiotics are active with respect to Gram-positive and Gram-negative bacteria in concentrations below $1 \mu\text{g ml}^{-1}$ (Refs 2–6 and 22) and with respect to malignant tumours in concentrations of $0.15–5 \mu\text{g ml}^{-1}$. The biological activity of these compounds is manifested as selective cleavage of double-stranded DNA *in vivo*; moreover, the carbohydrate part of the molecule was found to be responsible for selective coordination to the DNA minor groove (preferably, it binds to pyrimidine-rich regions).^{3, 6, 23–29}

The calicheamicin aglycon has a rigid bicyclic core. The enediyne fragment incorporated in a ten-membered ring is able to undergo the Bergman cyclisation. The allylic trisulfide fragment activates the process (Scheme 2).^{8, 23} An attack by a nucleophile on the central sulfur atom of the trisulfide fragment gives a thiol group, which adds intramolecularly to the double bond (the Michael reaction) giving enediyne **7**, which is highly prone to cycloaromatisation to give highly reactive 1,4-benzenoid diradical **8**. This diradical abstracts a hydrogen atom from DNA, thus inducing its cleavage. The aromatic compound **9** formed upon the addition of hydrogen atoms was identified²¹ based on low-temperature NMR spectra.^{23, 30}

Namenamicin (**10**) is isolated from the marine ascidian *Polysyncraton lithostrotum* (Didemniidae, the Fiji Islands). From 1 kg of the frozen ascidian, one can obtain 1 mg of the antibiotic. Its structure and the cytotoxic properties are similar to those of calicheamicin and esperamicin.^{16, 31}

Namenamicin exhibits a cytotoxic activity *in vitro* with an average IC_{50} value of $\sim 3.5 \text{ ng ml}^{-1}$, an antitumour activity *in vivo* with respect to the model leukemia P388 in rats (a 40% increase in the life time at doses of 3 mg kg^{-1}) and an antimicrobial action (see below). Its lower activity with respect to DNA destruction and higher selectivity compared to that of calicheamicin are due to differences in the structure of the carbohydrate fragment.¹⁶

Organisms	Minimum inhibitory concentration / mg ml^{-1}		
	namenamicin	calicheamicin	penicillin G
<i>Bacillus subtilis</i>	0.03	0.00005	0.25
<i>Candida albicans</i>	0.25	0.03	> 128

Shishijimicin (**11**) can be isolated from a methanolic or ethanolic extract of ascidian.^{9, 32} Its carbohydrate moiety contains a 6-hydroxy- β -carboline fragment, while the aglycon is represented by 13-(2-methyltrisulfanylethylidene)bicyclo[7.3.1]trideca-4,9-diene-2,6-diyne-11-one derivative. This compound is much more cytotoxic than namenamicin, which is devoid of the β -carboline heterocycle.

3. Esperamicins

Esperamicin is an exceptionally active broad-spectrum natural antibiotic. It was isolated from *Actinomadura verrucospora* Pto *Esperanza* in 1985.⁹ Its structure is similar to that of calicheamicin. The esperamicin molecule contains a bicyclic enediyne core. The absolute configurations of esperamicin A₁ (**12**) and calicheamicins were determined simultaneously.³³ Esperamicins and calicheamicins are the strongest known antitumour drugs. They are active against several model tumours in concentrations of $\sim 0.1 \text{ } \mu\text{g ml}^{-1}$.

4. Dynemicins

Dynemicin A (**13**), the first discovered representative of this family of antibiotics, was isolated from *Micromonospora chersina*.^{9, 34–36} It exhibits high activity against many types of tumours and increases the life span of rats infected by leukemia P388 and melanoma B16. Its high activity is combined with low toxicity.³⁵ Yet another member of this family is deoxydynemicin (**14**) isolated from *Micromonospora globosa* MG331-hF6.²

A distinctive feature of dynemicins is the combination of a ten-membered bridging enediyne ring with an anthraquinone fragment. X-Ray diffraction analysis has shown that the anthraquinone moiety of the molecule is bevel with respect to the enediyne ring.^{36–40}

Scheme 3

The tentative mechanism of DNA cleavage under the action of dynemicin A involves initial reduction of quinone **13** (Scheme 3).^{8,9} This is followed by opening of the epoxide ring to give intermediate **15**. Under the action of a nucleophile (for example, the hydroxide anion), **15** is converted into diol **16** with an unstable polycyclic system of multiple bonds, which undergoes fast cycloaromatization to give 1,4-benzenoid diradical **17**, which cleaves DNA. The final product **18** is formed upon oxidation of polyol **19**.^{2, 41, 42}

5. Kedarcidin, C-1027, maduropeptin

Studies of neocarzinostatin and the mechanism of its action demonstrated that a whole group of enediyne antibiotics represent non-covalent complexes formed by unstable chromophores and proteins that stabilise them. This resulted in the discovery of the kedarcidin,^{2, 8, 9, 43–51} C-1027^{2, 8, 9, 52–55} and maduropeptin^{2, 56, 57} chromophores. The kedarcidin chromophore (**20**) was first described in 1991.² Antitumour preparations based on kedarcidin, like many other enediyne antibiotics, are also active with respect to Gram-positive bacteria.⁴³

The kedarcidin apoprotein exists in a number of forms.² The main form contains 114 amino acid residues with predominance of alanine and serine. Whereas for neocarzinostatin the apoprotein:chromophore molar ratio is 1:1, in the case of kedarcidin, this ratio is equal 18:1. Cleavage of DNA by kedarcidin resembles the action of neocarzinostatin.⁴³

An analogue of the kedarcidin chromophore **21** exists as an equilibrium mixture with the cycloaromatization product, 1,4-didehydrobenzene **22**. This system was studied by the spin trap method^{58, 59} using 2-methyl-2-nitrosopropane (MNP), which allowed identification of intermediate monoradicals **23** and **24** having different reactivities.

Spin adducts **25** and **26** formed in 2 : 1 ratio were characterised by EPR and mass spectrometry.⁵⁹

An exceptionally active antitumour antibiotic C-1027 containing a polypeptide and a dienediene chromophore **27** was isolated from the culture broth of *Streptomyces globisporus*.² To date, this is the most labile nine-membered enediyne chromophore.⁹ Chromophore **27** is stable only when bonded to the apoprotein. In the free state, it undergoes rapid cycloaromatisation even at room temperature.^{60–72} Unlike other representatives of this subfamily, compound **27** can be cycloaromatised without the thiol activation.⁹

A two-stage mechanism of hydrogen atom abstraction from DNA by diradical **28** was established. First, one hydrogen atom adds slowly to position 6 giving free monoradical and then the second H atom rapidly adds at position 3 to give the aromatic structure.⁷³ The radical intermediates formed upon DNA cleavage by the antibiotic C-1027 were captured by spin traps, and the spin adducts were identified by EPR spectroscopy and mass spectrometry.^{60, 73} These data provide an insight into the mechanism of antibiotic action in DNA cleavage processes.^{59, 73}

The antibiotic maduropeptin, which possesses bactericidal and antitumour activities, was isolated in 1990 from *Actinomadura madurae*.^{2, 9, 56, 57} It is a 1 : 1 complex of a water-soluble protein comprising 32 amino acids and enediyne chromophore **29**.

Maduropeptin is also capable of forming diradicals without activation.⁹

III. Cycloaromatisation of enediynes

Cycloaromatisation reactions of enediynes have attracted considerable attention due to their high synthetic potential and the possible use in pharmaceutical chemistry,[‡] as indicated by numerous publications: monographs,^{2, 6} reviews^{8, 9, 74, 75} and original papers (see, for example, Refs 76–79). Below we consider the results of experimental studies and quantum-chemical simulation

‡ It was proved that the antitumour activity of natural antibiotics is directly related to their susceptibility to cycloaromatisation.^{80–90}

of enediyne systems. Note that apart from the thermal Bergman reaction, other (homolytic and heterolytic) ways to initiate cycloaromatisation are also possible.

1. Susceptibility to cycloaromatisation

The first theory that relates the susceptibility of a enediyne system to cycloaromatisation to the distance between the acetylenic bonds belongs to Nicolaou, who studied cycloaromatisation of monocyclic enediynes **30a–h**.⁹¹

$n = 1$ (**a**), 2 (**b**), 3 (**c**), 4 (**d**), 5 (**e**), 6 (**f**), 7 (**g**), 8 (**h**).

Nine-membered cyclic enediyne **30a** ($n = 1$) has not been synthesised, but the products of its cycloaromatisation have been identified. Other compounds have been isolated in a free state. Of these, only the ten-membered enediyne **30b** undergoes cycloaromatisation at moderate temperatures, while compounds **30c–h** do not cyclise under these conditions.

Thus, it can be seen that the ease of cycloaromatisation of the enediyne macrocycle depends on the distance between the terminal acetylenic carbon atoms. The range of 3.2–3.3 Å is critical; in this case, the reaction proceeds at a noticeable rate at moderate temperature. The transition state energy for this reaction was estimated based on calculations and kinetic data.⁹¹

In diol **31**, the distance between the terminal acetylenic atoms is equal to 3.20 Å; this compound cyclises at 37 °C. Diol **31** readily cleaves DNA, while the final product **32** does not react with DNA under the same conditions.⁹¹

Tris = HOCH₂C(CH₂OH)(NH₂)CH₂OH.

Diols **33** and **34** prepared from dialdehyde **35** cleave DNA *in vitro* (Tris – acetate buffer, pH 8.5); the half-conversion time is 4 h at 50 °C.⁹²

The synthesis of enantiomerically pure ten-membered cyclic tetrahydroenediynes from L-tartrates has been reported.^{93, 94} The introduction of silyl protecting groups allows one to control the cycloaromatisation rate in compound **36** (deprotection accelerates the process). The half-conversion time for compound **36** into product **37** is 2 h at 50 °C and pH 8.5.⁹⁴

Determination of the distance between the acetylenic bonds is the easiest method for predicting the tendency of a enediyne system to aromatisation. A more fundamental approach is to estimate the heat of formation of the diradical. For enediynes **38**–**40**, which mimic the chromophores of the calicheamicin antibiotics, the distances between the terminal carbon atoms of the acetylenic fragments and the enthalpies of formation of the respective diradicals **41**–**43** were determined by semiempirical calculations (AM1)⁹⁵

Compound	Distance / Å	Diradical	ΔH_f / kcal mol ⁻¹
38	3.24	41	48.2
39	3.09	42	40.9
40	2.98	43	38.1

The calculations predict a decrease in the susceptibility to cycloaromatisation (**40** > **39** > **38**) from the *cis*-fused to *trans*-fused bicyclic structure, which is correlated with the variation of the distance between the acetylenic carbon atoms. Compound **38** is expected to be much less reactive than the simplest ten-membered monocyclic enediyne **44**, which is cycloaromatised very slowly at 25 °C (the calculated heat of formation of the corresponding diradical is 45.2 kcal mol⁻¹).²

2. The diradical pathway of enediyne cyclisation

The simplest example of the Bergman cyclisation is the transformation of hex-3-ene-1,5-diyne (**45**) into 1,4-didehydrobenzene (**46**) through transition state **47** accompanied by hydrogen atom abstraction from 1,4-cyclohexadiene (CHD) to give benzene (Scheme 4).

Scheme 4

Recently, it has been found⁹⁶ that cyclisation of enediyne **48** in an aqueous medium (in the presence of traces of oxygen) gives quinone **49**, its yield being proportional to the concentration of dissolved oxygen.

In this connection, one more radical pathway for cyclisation of enediyne **45** was proposed, involving oxidation with oxygen to give peroxide diradical **50** and then quinone **51**. The possible radical pathways of cyclisation of enediyne **45** (see Scheme 4) were studied theoretically (DFT calculations, 6-31 G* basis set).^{86,96–98} For triplet and singlet diradicals and neutral species formed during cyclisation of compounds **45** and **48**, geometry optimisation was carried out and the relative energies and reaction barriers were estimated. To take into account the solvent effects, some calculations were repeated using the polarised continuum model (PCM).

It was shown that diradical **52** cannot react with O₂ in the gas phase. The assumption of direct reaction of enediyne **48** with oxygen is also not confirmed.⁸⁶ To elucidate the nature of the intermediate diradical, gas-phase thermolysis of 1,6-cyclodecadiyne has been studied.^{99,100}

Molecular orbital calculations [CASSCF(8,8)/6-31 G*] have been carried out for the gas-phase transannular ring closure in ten-membered cyclic diynes **53a–c** to give bicyclo[4.4.0]deca-1,6-diene-2,7-diyls **54a–c**.⁹⁹

The geometries were optimised for the ground states **53a–c**, transition states **55a–c** and intermediates **54a–c**. The activation energy for the transition **53** → **54** was found to depend on the distance between the triple bonds. The transition along the route **53a** → **57** → **56** has higher activation energy than **53a** → **55a** → **54a**.⁹⁹

Aromatic enediynes **58** cyclise at 25 °C to give fused systems (Scheme 5).^{8,101}

Thermolysis of compounds **58** initiates the cycloaromatisation of acetylenic bonds along the pathway *a* and is accompanied by the tandem radical cyclisation along the pathway *b* to give σ,σ -dehydrobenzene diradicals **59**.¹⁰¹ Subsequently, thermal radical cyclisation of diradicals **59** (along pathway *c* or *d*) gives two types of diradicals, **60** and **61**, respectively.

In particular, product **62** was obtained by this method in 10% yield from tetrayne **58** ($R = \text{C}\equiv\text{CSiMe}_3$). Synthesis of compounds **62** is accompanied by the formation of large amounts of by-products. Thermolysis of the same tetraacetylene in methanol-d₄ gives **62-d**₂ containing deuterium only in positions 5 and 7 (see Scheme 5).¹⁰¹

Upon thermal cyclisation (320 °C, 3 h) of 1,2-bis(phenylethynyl)benzene (**63**), the expected 1,2-diphenylnaphthalene **64** was detected in trace amounts (0.84%).¹⁰² The isomeric naphtha-

R = H, SiMe₃, Ph, C≡CSiMe₃.

lenes **65** and **66** resulting from migration of the phenyl groups were the major cyclisation products.

Analysis of the thermodynamics of these transformations is carried out using quantum-chemical calculations (DFT). Cycloaromatisation of these enediynes in the presence of tellurium proceeds under mild conditions.¹⁰³

Cyclisation of allene enynes **67** and **68** into benzene (**69**) and naphthalene (**70**) compounds occurs at 50–100 °C through diradicals **71**.^{50, 104, 105}

R¹ = H, Alk, Ph; R₂² = H₂ (**67**, **69**), (CH)₄ (**68**, **70**).

To elucidate the reaction mechanism, quantum-chemical calculations were carried out, and the geometric parameters of radicals **71** and thermodynamic parameters of their formation reactions were determined.¹⁰⁴

As noted above, an important feature of natural enediynes is the fact that some chemical reactions convert them from a stable form (e.g., **72**) into a reactive form (**73**), which is rapidly converted into benzenoid diradical (**74**).^{106–109}

The synthesis of *cis*-enediynes **75** by acid-catalysed rearrangement of 1,2-dialkynylprop-2-en-1-ols in the presence or in the absence of nucleophilic reagents (alcohols or thiols) can serve as an example of chromophore activation through isomerisation of double bonds.¹¹⁰

X = H, Ar; Nu = OH, OMe, SMe; R¹ = CH₂SPh; R² = (CH₂)₄OMe.

The activation of the enediyne bond system in compound **76**, which mimics calicheamicin, through the rearrangement of multiple bonds, resulting in structure **77** more prone to cycloaromatisation, was studied experimentally and by quantum-chemical calculations.¹¹¹ The diradical formed in the cycloaromatisation of enediyne **77** is converted upon reduction into the corresponding ketodiols in a high yield.

Cycloaromatisation of the 10-membered highly strained enediyne **78**, prepared from thermally stable precursor **79**, has been carried out.^{112, 113}

Nu = OH, OEt; R = anthraquinone-2-carbonyl.

Acid-catalysed dehydration of alcohol **79** affords allylic intermediate, which is attacked by the nucleophile exclusively on the γ -carbon atom to give enediyne **78** prone to cycloaromatisation.^{114–116} The same allylic rearrangement presumably takes place on heating alcohol **79** in a weakly basic medium in the presence of DNA.¹¹⁷

The formation of reactive enediynes upon allylic rearrangement obviously underlies the mechanism of action of the maduropeptin^{118, 119} and kedarcidin⁵⁸ chromophores.

3. Electrophilic activation of the cyclisation

As an alternative to the C(1)–C(6) cyclisation of enediynes such as *o*-bis(2-phenylethynyl)benzene (**63**), which proceeds through diradical **80**, C(1)–C(5) cyclisation proceeds through diradical **81** to yield benzopentafulvenes (Scheme 6).¹²⁰

The energy barrier to the formation of naphthalene diradical **80** is rather high (40 kcal mol^{–1}, according to UBS-B3LYP/6-31G* calculations). It was found that, unlike the homolytic reaction resulting in naphthalene derivatives, the reaction of the

enediyne **63** with bromine results in fulvene **82**.¹²⁰ The cyclisation of compound **63** induced by bromine proceeds through cation **83**.

4. Cyclisation under the action of nucleophiles

Cyclisation of non-functionalised enediynes along the diradical pathway and through electrophilic addition gives benzene derivatives and functionalised fulvenes, respectively.¹²¹ Base-induced aromatisation of enediynes (the Bergman anionic cyclisation) can be used for functionalisation of the benzene nucleus by nucleophiles.^{122–124}

A general method for the preparation of functionalised aromatic compounds from enediynes has been developed; the key stage of the method is cycloaromatisation of the enediyne fragment induced by nucleophiles.¹²² Depending on the reaction conditions and the substrate structure, either benzo[*c*]phenanthridinone or biaryls are formed. If the methoxide anion attacks the nitrile function, cycloaromatisation resulting in phenanthridinones takes place. If the attack is directed on the acetylenic C(2) atom of the enediyne system, biaryls are formed.¹²²

The cyclisation of enediynes with a terminal acetylene group induced by neutral nucleophiles (water, alcohols, aniline, acetylacetone, pyrroles, dimethyl malonate) and catalysed by the ruthenium complex [TpRu(PPh₃)₂(MeCN)₂PF₆] [Tp is hydrotris(pyrazol-1-yl) borate] can serve as a general method for the synthesis of functionalised benzenes and naphthalenes.

R = H, Me; [Ru] = [TpRu(PPh₃)₂(MeCN)₂]PF₆.

In particular, this method was used to prepare 1-alkoxy-2-substituted naphthalenes **84** by treatment of enediynes **85** with water or an alcohol (*n*-butyl, isobutyl or *tert*-butyl alcohol).¹²¹

R¹ = H, Me, Et; R² = H, Buⁿ, Buⁱ, Bu^s, Bu^t.

In this case, the addition of nucleophiles to the substituted triple bond and spontaneous cyclisation of the enediyne system take place in the coordination sphere of ruthenium.^{121, 125–128}

Presumably, the reaction involves vinylruthenium and vinylideneruthenium intermediates.¹²¹

This type of enediyne cycloaromatisation is quite unusual, because electrophilic metal complexes can catalyse hydration of terminal alkynes **85** to ketones **86**.¹²⁹ It was shown that the latter are not intermediates of cycloaromatisation, because they do not form naphthols under the conditions studied.¹³⁰

5. Cycloaromatisation of heteroatomic enediynes

It is expedient to consider the cycloaromatisation of enediynes containing heteroatoms taking nitrogen-containing derivatives as examples, as they attract most interest.^{131–133}

a. Acyclic nitrogen-containing enediynes

The thermal cyclisation of enediynes **87–90** in the presence of CHD is affected by steric factors.^{131–133}

This is believed¹³¹ to be caused by hindered rotation of substituents about the acetylene groups of the enediyne fragment. Enediyne **88** cyclises only at 186 °C, whereas the cyclisation temperature for 3-hydroxypyridine derivative **90** is 149 °C, which is attributable to the easier rotation of substituents. The cycloaromatisation temperature of 1,6-bis(3-pyridyl)hex-3-ene-1,5-diyne in which the pyridine rings are directly bound to the acetylene groups increases to 195 °C.

b. C,N-Dialkynylimines (aza-enediynes)

The replacement of the sp² carbon atom of an enediyne by a nitrogen atom results in C,N-dialkynylimines **91**. These compounds are synthesised from acetylenic ketoximes **92**.¹³⁴

Deprotection of the acetylene fragment in compound **91** destabilises the molecule, and rearrangement takes place at –45 °C giving rise to β-phenylethynylacrylonitrile derivative **93** (yield 89%).¹³⁵

Thermolysis of protected aza-enediyne **91** (heating in chlorobenzene in the presence of 20 equiv. of CHD in a sealed tube at 150 °C for 3 days) resulted in 2,5-diphenyl-3-triisopropylsilyl-pent-2-en-4-ynenitrile (**94**) (yield 35%).¹³⁵

The reaction proceeds presumably *via* 2,5-didehydropyridine intermediate **95** (the aza-Bergman cyclisation), which undergoes fast ring opening (the retro-aza-Bergman cyclisation).¹³⁵ Di-radical intermediates have not been isolated, although GC/MS analysis detected the formation of pyridine type products upon the thermolysis of aza-enediynes in acidic media.¹³⁵

The synthesis and transformations of dialkynyldiazenes (diaz-enediynes) that possess antitumour action have been described.¹³⁶

c. Hetarenediynes

The Bergman-type thermal cyclisation of 1,2-dialkynylimidazoles **96** (heating in a sealed tube with CHD at 75–100 °C for 2–4 days) gives, in addition to 5*H*-cyclopentapyrazine (**97**), spirobicyclo[4.1.0]heptane-7,5-5*H*-cyclopentapyrazines **98a,b**.^{137, 138}

R = H, Alk, Ar.

Quantum-chemical calculations (B3LYP/6-31G*) of the relative energies of the possible intermediates of this process indicate that cyclopentapyrazinecarbene intermediates **99** are most favourable.¹³⁸

The photoinduced (irradiation with a 450 W lamp) cyclisation of a number of 1-methyl-2,3-diethynylimidazoles **100** and their macrocyclic analogue **101** to give benzimidazoles **102** and **103** has been studied.^{139, 140}

R = Me, Buⁿ, Ph.

The cycloaromatisation products **102** are formed in good yields. Bicyclic compound **101** cleaves plasmid DNA at low temperatures.¹⁴⁰

Although the distance between the terminal acetylene atoms is the major factor affecting the cyclisation of enedynes,^{141, 142} electronic effects also play a role.^{143–145}

The influence of the electronic factors and the medium on the cyclisation of hetarenediynes **104–106** has been studied.¹⁴³

It was shown that the presence of the electron-deficient hetarene fragment decreases the activation energy of the reaction.¹⁴⁶ Using cyclisation of 2,3-diethynylquinoxaline (**106**) as an example, it was shown that the reaction kinetics depends appreciably on the nature of the solvent (acetonitrile, methanol, benzene, dioxane, carbon tetrachloride, THF); the half-conversion time may vary from 361 to 16 min.¹⁴³ Cyclisation in each solvent was carried out both in the presence and in the absence of CHD (*i.e.*, either CHD or the solvent served as the hydrogen source). The removal of CHD from the reaction mixture did not exert pronounced influence on the structures and yields of the cyclisation products. Less polar solvents ensured higher yields of the cyclisation products. In most solvents, phenazine **108a** was formed as the major product, while in benzene and carbon tetrachloride, the products formed in the reaction of diradical **107** with the solvent (**108b–d**) predominated.¹⁴³

R¹ = R² = H (**a**), Ph (**b**), Cl (**c**); R¹ = , R² =  (**d**).

Solvent	Half-life /min	Cyclisation products	Yield (%)
Acetonitrile	361	108a	7
Methanol	312	108a	2
Benzene	96	108b	58
Dioxane	60	108a	15
CCl ₄	14	108c	81
THF	16	108a + 108d	36, 9

d. Enediyne sulfonamides

A study of the thermal cyclisation of *N*-benzyl-*N*-(2-ethynylphenyl)ethynyl-*p*-toluenesulfonamide (**109**) (141 °C, benzene: CHD = 2:1) to naphthalene derivative **110** has shown that the half-conversion time of this compound (44 min) is much shorter than that for the parent compound of the series, 1,2-diethynylbenzene.¹⁴⁷ This is indicative of the activating effect of the sulfonamido group on the cyclisation; simultaneously, this group decreases the hydrolysability of the ynamine fragment.¹⁴⁸

Ts = SO₂C₆H₄Me-4.

This example confirms once again the general trend, namely, that σ-withdrawing substituents at the terminal acetylenic carbon atom of an enediyne increases the susceptibility of the compound to cycloaromatisation.

The synthesis and reactivity of cyclic enediyne sulfonamides are considered in a number of publications.^{149–153}

Enediyne sulfonamides have certain advantages as regards cycloaromatisation over the carbon and sulfur analogues. In particular, the presence of a short C–N bond (1.47 Å), which is shorter than the C–C (1.54 Å) or C–S (1.81 Å) bonds in the corresponding analogues, results in a decrease in the distance between the terminal acetylenic carbon atoms. Indeed, in sulfonamide **111** this distance is only 3.24 Å,⁹¹ *i.e.*, corresponds to the critical distance that ensures easy cyclisation.

Heterocyclic compound **111** slowly undergoes cycloaromatisation even at 25 °C in CDCl₃ to give tetrahydroisoquinoline.¹⁵² In acetonitrile, its half-life at 23 °C is 72 h, which implies an activation energy of 18 kcal mol⁻¹.

Cycloaromatisation of sulfonamide **112** occurs at 62 °C with a half-life of 52 h. Its low reactivity compared to that of enediyne **111** was attributed to less pronounced resonance energy stabilisation of the transition state and to different degrees of pyramidalisation of the nitrogen atom.¹⁵²

N-Deprotection of the 12-membered enediyne **113a** results in a quite stable cyclic amino ketone **114a**. Meanwhile, its 13-membered homologue, amino ketone **114b**, proved to be unstable, being rapidly converted into cycloaromatisation product **115**.¹⁵³ In this case, the Bergman cyclisation is stimulated by the parallel transannular cyclisation involving the amine and carbonyl function.

R = SO₂C₆H₄NO₂-4; n = 1 (a), 2 (b).

e. Lactenediynes

This is the name for ten-membered enediynes fused to β -lactam.^{154–156} The presence of *trans*-fused rings in the molecules of compounds **116–118** makes them rather thermostable. Cycloaromatisation is initiated by β -lactam ring opening.¹⁵⁵ N-Protected compound **118** is unable to cleave DNA, however after deprotection, the enediyne becomes reactive.¹⁵⁵ The parent compound of the series of substituted lactenediynes, bicyclic compound **116**, easily undergoes cycloaromatisation (the half-conversion time is 36 h at 30 °C).¹⁵⁴

f. Cyclic enediynes with a diazocarbonyl fragment

Irradiation of 11-membered enediynes with a diazo- β -dicarbonyl fragment results (through the Wolf rearrangement) in reactive ten-membered structures. Indeed, photolysis of enediyne **119** induces its rearrangement into oxo ester **120**,¹⁵⁷ which is in equilibrium with enol **121**. The latter undergoes fast cycloaromatisation to give reactive diradical **122**, which is converted into dihydroanthracene **123** in the presence of hydrogen donors. These reactions served as the basis for the development of a new concept of activation of enediyne antibiotics based on photochemical transformations of functional groups adjacent to the enediyne chromophore.

It is impossible to cover all types of cycloaromatisation of heteroatomic enediynes in a brief review. Note only that along with nitrogen-containing enediyne compounds, compounds with other heteroatoms adjacent to the enediyne system, in particular a sulfur atom, are also under study.^{158–160}

6. Metal complex enediynes

The thermal cycloaromatisation of enediynes is affected by complexation. For instance, the formation of a complex of enediyne **124** with copper decreases the distance between the acetylenic carbon atoms; as a result, the cycloaromatisation temperature for complex **125** is 70° lower than that for the starting ligand **124**.¹⁶¹

Synthesis of a number of enediyne macrocyclic ligands and their complexes with copper and zinc salts and DSC estimation of their relative reactivities towards cycloaromatisation have been reported.¹⁶²

Deprotonation of diethynylferrocene (**126**) with butyllithium and treatment of the resulting dianion with diiodobutane (or diiodopentane) results in enediyne complexes **127a,b**.¹⁶³

Methyl derivative **128** was prepared in a similar way. One can observe a correlation between the ring strain in compounds **127a,b** (based on *ab initio* calculations) and their susceptibility to electrochemical oxidation:

A similar trend can be followed in the variation of their ionisation potentials in both the liquid and gas phases.¹⁶³

IV. Synthesis of enediyne antibiotics and their analogues

Total syntheses of enediyne antibiotics and their analogues cannot be described within the limits of this paper; therefore, we only briefly consider the general approaches.

The Sonogashira cross-coupling of vinyl or aryl dihalides with terminal acetylenes catalysed by Pd(0) or Cu(I) complexes is used most often to prepare enediynes.¹⁶⁴ Good results are obtained in the Pd(0)-catalysed reaction of (*Z*)-1,2-bis(trimethylstannyl)-ethenes with iodoalkynes (the Stille cross-coupling).^{165, 166} A large number of methods of *cis*-enediyne synthesis are based on the introduction of a double bond into 1,5-diyne systems. These are based on reductive elimination¹⁶⁷ and acid-catalysed¹⁶⁸ and base-catalysed¹⁶⁹ elimination of alcohols or diols,¹⁷⁰ the Diels–Alder reaction¹⁷¹ and rearrangements of allylic alcohols.^{116–118, 172} Numerous studies along this line are devoted to the synthesis of the neocarzinostatin chromophore^{2, 51, 173–176} and its analogues.^{177, 178}

Typical strategies for the construction of enediyne system are described in brief below.

1. Construction of the bicyclic dienediyne system

The functionalised bicyclic system of enediyne antibiotics can be constructed by aldol condensation.^{179, 180} In the synthesis of NCS chromophore- and kedarcidin-related systems, dihydroxylated cyclopentenone often serves as the starting structural block.^{181–184} Early approaches to the synthesis of the bicyclic nucleus of NCS have been described by Myers *et al.*^{185, 186} A recent paper by Hiram and co-workers¹⁸⁷ presents an advanced approach to the construction of the molecule of this chromophore based on the convergent synthetic scheme. In some syntheses, cobalt carbonyls have been used to protect triple bonds.^{42, 188–190}

A typical synthesis of a bicyclic enediyne system includes: (i) construction of the enediyne fragment from simple starting compounds; (ii) its conjugate addition to the enone to form a cyclopentene fragment; (iii) closure of the second ring by aldol reaction.¹⁸⁰ Bromoiodoethylene **129** obtained from ethyl propiolate is coupled with trimethylsilylacetylene, and the resulting enyne ester **130** is reduced to alcohol **131**. The protection of the hydroxy group by *tert*-butylchlorodipropylsilane (compound **132**) and deprotection of the acetylene function yield terminal alkyne **133**. Compound **133** is converted into acetal **134**. This is followed by cross-coupling with trimethylsilylacetylene in the presence of Pd(II) to give compound **135** and by removal of the TMS-protection, which results in enediyne **136**.¹⁸⁰

Conjugate addition of enediyne **136** to enone **137** is carried out via the alkynylaluminium derivative.¹⁸⁰ The yield of product **138** is 51%.

The elaboration of adduct **138** requires benzoate protection (conversion into compound **139**) and protection of one triple bond with cobalt carbonyl to give complex **140** (84%).¹⁹¹ Acetal **140** is transformed into aldehyde **141**; its cyclisation (on treatment with di-*n*-butylboryl triflate and triethylamine) yields enediyne **142** (yield 75%). This route ensures high stereoselectivity of enediyne synthesis.

Most of chromophores of the enediyne antibiotics contain a ten-membered ring.^{2, 4} Some studies dealing with the construction of the bicyclic core of enediyne antibiotics are directed at preparation of larger rings (as they are formed more easily) followed by their contraction. A classical example of this approach has been demonstrated by Mayer and Sondheimer,¹⁹² who were the first to use electrocyclicalisation to form diradicals.

The synthesis of the bicyclic core of enediyne **143** by reductive cyclisation of the 12-membered tetrayne precursor **144** has been described¹⁹³ (Scheme 7).

Diol **145** synthesised from L-tartrate is converted into bis(di-bromoalkene) by oxidation followed by methylenation. Treatment of this product with *n*-butyllithium (4 equiv.) affords diyne **146**. Deacetalation followed by *O*-triisopropylsilylation (**146** → **147**) and oxidative dimerisation in the presence of copper derivatives converts this diyne into symmetrical cyclic tetrayne **148**.¹⁹³

The key step of the synthesis is the reductive cyclisation of non-symmetric tetrayne **144** on treatment with NaAlH(OCH₂CH₂NMe₂)₃ and KHMDS, which yields bicyclic compound **143** and two isomeric products: *trans*-alkene **149** and cumulene **150**.¹⁹³

The interest in the neocarzinostatin chromophore stimulated the search for its stable analogues and development of numerous new synthetic procedures. In a number of papers, the McMurry reaction [coupling of carbonyl compounds under the action of

Scheme 7

titanium(0) complexes] was shown to be promising for dienediyne ring closure.^{194–200}

On the way to NCS models containing an epoxy group and a carbonate ring (compound **151**), researchers^{195–198} prepared dienediynic oxo aldehydes **152** and successfully carried out the McMurry ring closure to obtain trienediyne products **153**.

X = CH_2CH_2 , CMe_2 .

An alternative retro synthesis of this type of bicyclic systems implies scission of the diyne ring at its second double bond. This approach was implemented using cyclisation induced by titanium complexes.¹⁹⁹ In this case, oxo aldehydes **154a,b** were involved in the reaction. Olefination was possible only for unsubstituted compound **154a**.

In the case of bis-silylated oxo aldehyde **154b**, pinacol coupling (carried out with the same titanium reagent but at -20°C) proved to be efficient. Note that both pinacol couplings, **154a** $\rightarrow$ **156a** and **154b** $\rightarrow$ **156b**, are diastereoselective. The yields of diols **156a,b** (60% and 40%) are much higher than that of alkene **155**.¹⁹⁹

Analogues of natural antibiotics having a dienediyne fragment^{200–202} are also synthesised from α -bromocyclopentenone,^{203–205} bis(enol triflates)^{206–208} and xylitol.²⁰⁹

A stereocontrolled and flexible strategy for the synthesis of acyclic (*Z,E*)- and (*E,E*)-dienenediynes from readily available organotin compounds **157** and **158** has been proposed.²¹⁰

For example, the synthesis of (*Z,E*)-dienenediynes **159a–c** starts from dienyne **157**.²¹⁰ The use of *N*-iodosuccinimide allows stereoselective preparation of derivatives **160**, which yield dienediynes **159a–c** upon cross-coupling with terminal alkynes in the presence of a Pd/Cu-catalyst. The workup and concentration of the reaction mixtures on deactivated silica gel yields pure (*Z,E*)-dienenediynes **159a–c** (yields 49%–51%).²¹⁰

2. Calicheamicin and related molecules

Following the first publications dealing with the structure of calicheamicin, publications concerning the construction of its enediyne core appeared.^{21, 23, 30, 211–216} The total synthesis of calicheamicin-aglycone (calicheamicinone) and its analogues was carried out by Danishefsky and co-workers.²¹⁷ They also compared the behaviour of calicheamicin γ_1^1 and calicheamicinone in DNA cleavage and demonstrated the importance of the presence

of carbohydrate fragments in the natural product.²³ The total synthesis of calicheamicin γ_1^1 carried out by Nicolaou and co-workers²¹⁸ includes 28 stages (1.4% overall yield).

A number of synthetic routes to calicheamicinone (**161**) (see Refs 211–216 and 219) and dynemicin (**13**) having a similar bicyclic core have been reported.^{214–216}

An attempt²¹³ to carry out interconversion of calicheamicinone and dynemicin analogues prompted by the obvious structural similarity of these two molecules deserves mention. A possible way of this transformation is the replacement of the 12-hydroxy group in compound **162** by an aniline fragment with retention of the configuration followed by intramolecular arylation.

However, the intermediate bicyclic ketones **163** formed underwent dimerisation through [2 + 4]-cycloaddition. Deprotection of the oxo group gave dimers **164** with different stereochemistry of ring fusion.²¹³

Detailed synthesis of optically pure calicheamicinone has been reported.^{220–222} The synthesis starts with stereoselective Diels–Alder reaction of ketene acetal **165** with chiral R^* -3-nitroprope-

Scheme 8

noate containing a (–)-8-phenylmenthol residue (Scheme 8).²²² Thus, the desired stereochemistry of the skeleton is founded in the initial stage. Then adduct **166** is converted, along two pathways, into ketones **167** (pathway *a*) and **168** (pathway *b*). These ketones add lithium trimethylsilylacetylide to give *syn*- and *anti*-addition products, *viz.*, alcohols **169** and **170**, respectively.

During the transformation of alcohols **169** and **170** into (–)-calicheamicinone, the stereogenic centres, except for C*, are racemised, both diastereomers giving the same final product.²²²

The subsequent series of oxidation stages (for introduction of double bonds), protecting group manipulations, halogenation and hydrolysis give aldehyde ester **171**, which stereoselectively adds lithium trimethylsilylacetylide to give diyne **172**. Calicheamicinone ring closure was accomplished by the reaction of diiodide **173** with *cis*-bis(trimethylstannyl)ethene to give precursor **174**. Nine more stages it took to introduce the trisulfide substituent and attain (after removal of the protecting group) the required functionalisation.^{223, 224}

3. Dynemicin and its analogues

Structural features, the activation mechanism and total synthesis of the dynemicin chromophore are considered in the papers by Nicolaou and Smith,² Danishefsky *et al.*,²¹⁷ Myers *et al.*^{225, 226} and other researchers.^{35, 227, 228}

The synthesis of the enediyne fragment of dynemicin is shown in Scheme 9.⁴² *O*-Tetrahydropyranyl ether of hept-4-ene-2,6-diyne-1-ol reacted with protected 3-hydroxyquinolines **174a,b** to give adducts **175a,b**. The removal of the tetrahydropyranyl protection and the reaction with $\text{Co}_2(\text{CO})_8$ yield complexes **176a,b**, which cyclise to give bicyclic structures **177a,b**. Decomplexation of the latter affords products **178**. The structure of enediyne **178b** was proved by X-ray diffraction.²²⁹

The aromatisation rates of the synthesised enediynes were considerably different, although the distances between the acetylenic bonds in them are approximately the same. The determination of the cycloaromatisation rate of enediyne **178b** to give compound **179** in the temperature range from 65 to 114 °C allowed calculation of thermodynamic parameters of the reaction.⁴² The experimental data extrapolated to 37 °C show that **178b** is stable under physiological conditions.

Amine **178d** undergoes cycloaromatisation in THF on heating to 51–67 °C. The cycloaromatisation rate of amine **178d** increases with temperature faster than that of carbamate **178b**. At 37 °C, amine **178d** cyclises 1.6 times faster than carbamate **178b**, while at 65 °C these rates differ by a factor of 20. The cycloaromatisation of nitrile obtained from ketone **178b** results in compound **180**. At 37 °C, this reaction proceeds 500 times faster than cycloaromatisation of ketone **178b**, although the distances between the acetylenic bonds in these compounds are almost the same.⁴²

The synthesis of the naphtho[2,3-*b*]quinoline part of the dynemicin molecule has been reported.^{42, 230, 231}

The subsequent development of the dynemicin chemistry^{232–236} confirmed that its specific antitumour properties are related to the presence of the 10-membered enediyne ring.^{237–242} Therefore, investigation into the synthesis of second-generation dynemicin analogues becomes topical.

The total synthesis of two diastereomeric dynemicin analogues (**181a,b**) was carried out and their activities with respect to DNA cleavage was studied.^{243–246} The retro-synthetic analysis is presented below.

Chiral quinoline derivatives prepared^{247, 248} in an optically pure state by enantiomer resolution or by a microbiological procedure were used as the starting compounds. The stereoselective addition of protected acetylide to quinolines **182** and the subsequent modification of the alcohol function leads to aldehydes **183** (Scheme 10). To introduce the second triple bond, aldehydes **183** were converted into dibromoalkenes **184** and then into alkynes **185**.²⁴³ The macrocycle was closed by treatment with *cis*-bis(trimethylstannyl)ethene. For cross-coupling, diyne **185** was converted into diiodide **186**.

Epoxide ring opening (on treatment with *p*-toluenesulfonic acid) in the target enediynes **181a,b** was accompanied by their fast Bergman cyclisation.^{249, 250} After neutralisation of the acid with triethylamine and stirring for 24 h in the presence of CHD (as a

Scheme 10

hydrogen atom donor), diol **187** and mono-*p*-toluenesulfonate **188** were isolated.

187 ($R^1 = \text{Me}$, $R^2 = \text{X} = \text{H}$);
188 ($R^1 = \text{H}$, $R^2 = \text{Me}$, $\text{X} = \text{Ts}$)

Biological tests revealed high activity of enediynes **181a,b** with respect to the plasmid DNA.²⁵¹

The stereoselective synthesis of the simplest dynemicin analogue **189**, which is active against plasmid DNA, has been described.²⁵²

The susceptibility to cycloaromatisation and the biological activity of tricyclic enediyne **190** have been studied.²⁵³

4. Antibiotic C-1027

The high biological activity of the enediyne antibiotic C-1027 stimulated the studies aimed at the construction of its nine-membered ring^{254,255} and its total synthesis.^{60,256–265}

The retro-synthetic analysis⁶⁰ of the chromophore macrolide **27** is shown in Scheme 11.

The total synthesis of molecule **27** is completed by introducing of an amino sugar and benzoxazine into the core **191** with simultaneous formation of two double bonds. Since diyne **191** is unstable (this is confirmed by experiments on model compounds),

Scheme 11

MOM = MeOCH₂, TES = Et₃Si.

it is necessary to construct the macrolactone system prior to construction of the nine-membered ring. Diyne **191** is formed upon cyclisation of aldehyde **192** under the action of the LiN(SiMe₃)₂–CeCl₃ system. In turn, aldehyde **192** is prepared by the convergent coupling of three fragments, **193**, **194** and **195**.⁶⁰

V. Introduction of the enediyne fragment into other classes of organic compounds

Studies of enediynes have long been concentrated on their synthesis and reactivity. However, when it became clear that the biological activity of this class of compounds is correlated with the presence of (*Z*)-1,5-diyne-3-ene fragment,^{266–271} attempts were undertaken to introduce this structural unit into other classes of biologically active and natural compounds. A number of typical examples are given below.

1. Enediyne tripeptides

The synthesis of amino acid **196** and peptides **197a–c**, promising compounds *en route* to new enediyne antibiotics, has been reported.²⁷²

$R^1 = R^2 = \text{Me}$ (**a**), Bn (**b**); $R^1 = \text{Me}$, $R^2 = \text{CH}_2\text{OH}$ (**c**).

Cycloaromatisation of protected enediyne peptides **197a–c** yields polymers. A DSC study has shown²⁷² that the reaction has an isothermal peak typical of the Bergman cyclisation. Peptide **197b** cyclises more easily (135 °C) than peptide **197a** (180 °C), which is related to the presence of the hydrogen bond in the latter.

Analysis of changes in the NMR spectra of peptide **197a** depending on temperature suggests stabilisation of its conformations owing to hydrogen bonds (a similar situation is observed for free amino acid **196**).²⁷³

2. Enediyne estrogens

By introduction of substituents containing an enediyne system into the estradiol molecule, a family of steroid hormones **198–201** has been obtained.^{274, 275}

Enedinyln- and enyneallenylestrogens **198** and **199** were actually found to produce diradicals in the Bergman or Myers cycloaromatisation processes.^{276–281} The diradicals abstract hydrogen from DNA and proteins, which results in their degradation and agglomeration.

Compound **201** undergoes the Bergman photocycloaromatisation to give product **202**.^{274, 282–284} A series of estrogen–enediyne conjugates have been prepared and their affinity with respect to the hER α receptor has been determined.

Estradiol derivatives of the type **203**[§] eliminate methanesulfonic acid to be converted into enediyne steroids **204**, which cyclise to give benzenoid diradical **205** at 25 °C (half-conversion time is 108 min).²⁸⁷

$R = \text{H}, \text{SiMe}_3$; $\text{Ms} = \text{MeSO}_2$.

3. Porphyrin enediynes

The synthesis of porphyrin **206** containing an enediyne fragment has been reported.²⁸⁸ Heating (180 °C) of derivative **206** in the presence of CHD results in cycloaromatisation to give porphyrin **207**.

[§] The synthesis of derivatives **203** has been described.^{285–287}

Porphyrin enediyne **208** with disubstituted triple bonds cyclises in a peculiar way, namely, with participation of neighboring phenyl groups to give a polyaromatic fragment in the porphyrin system **209**.²⁸⁹

Photoreactive porphyrin enediynes, which undergo cycloaromatisation on exposure to radiation, have been described.^{290, 291}

VI. Conclusion

During the last decade, a substantial progress in the enediyne chemistry has been achieved and information flow concerning these peculiar acetylenic derivatives has grown. The structures of the natural and synthetic compounds described above, which actively destroy cancer cells and suppress bacteria and microbes, are characterised by great diversity, but the presence of the (*Z*)-3-ene-1,5-diyne fragment is a common feature of all these derivatives. Its key chemical property and the cause for the unique biological action is the ability to undergo cycloaromatisation involving two acetylenic bonds, resulting in 1,4-benzenoid diradicals. Currently, this reaction is the subject of active theoretical and experimental research not merely due to the fact that this contributes to the understanding of the chemistry of enediyne antibiotics, but also because this is a new, exceptionally powerful synthetic method of organic chemistry as a whole¹²¹ and, in particular, acetylene chemistry.

The search for new types of enediyne structures active with respect to DNA cleavage remains topical; nitrogen-containing enediynes (dialkynyldiazenes) appear to be especially promising.¹³⁶

Abstract. The problem of search for new materials for spectrally positioned laser sources, which is central for modern photonics, is discussed. The use of the stimulated Raman scattering effect in crystals offers a highly efficient way to the design of such sources. The recent results of investigations into this effect for a large number of various types of crystalline materials are presented. The most promising compounds, as regards the realisation of different laser operation modes, are considered, including calcium, strontium, barium and lead molybdates and tungstates. Several examples of functioning efficient lasers based on novel materials exhibiting the stimulated Raman light scattering effect are given. The bibliography includes 50 references.

I. Introduction.

Modern solid-state lasers

Photonics is one of the most rapidly emerging fields within modern high technologies. Generally, the term photonics refers to techniques for the generation and conversion of light or other types of electromagnetic radiation. Over the recent years, photonics has experienced an explosive growth. Partly, this is due to the fact that it determines to a large extent the progress in such fields as medical, environmental and scientific instrument production, advanced technologies of materials processing and armament industry. But the most important reason is that photonics ever deeper penetrates into the information technologies, *i.e.*, the techniques used for the information acquisition, storage, processing, transmission and retrieval. Furthermore, many experts believe that it is photonics that will determine the cutting edge of informatics in the future. This forecast is based on the unprecedented high performance, information capacity and noise immunity provided by photonic devices. The greatest contribution to the emergence of photonics was made in the middle of the 20th century by academicians A M Prokhorov and N G Basov and by an American scientist, professor Ch Townes, who laid the

foundations of quantum electronics and laser physics (these achievements were recognised with the Nobel prize in physics for 1964). These pioneering results gave rise to the development of various types of lasers exploiting substances in all possible aggregate states, *i.e.*, plasma, gas, vapour, crystal, glass and liquid, as working media. More recently, academician Zh I Alferov invented semiconducting heterostructures (the Nobel prize in physics for 2000 shared with H Kroemer and J S Kilby), which enabled the miniaturisation and functional integration of photonic devices.

It is dielectric and semiconducting crystals and structures derived from them that are the most typical materials used in photonics.¹ Crystals are superior to other types of materials due to the following factors:

- a high density of active particles (*e.g.*, atoms, ions, molecules, atomic clusters), which can be as high as 10^{23} cm^{-3} ; this provides the small size of photonic devices and a possibility of their further miniaturisation and functional integration;
- a regular periodic packing of atoms (ions, molecules), which gives rise to symmetric structures and degenerate energy levels and, consequently, to narrow resonances and large photon absorption and emission cross-sections and also to large nonlinear optical coefficients;
- a variety of possible compositions (in particular, a huge number of combinations of crystalline matrices and active dopants) and crystal structures.

Contemporary photonics is an extended research field with numerous subfields. It is next to impossible to comprehensively address the multitude of directions of photonics development in one paper. Therefore, in the present review, we limit ourselves to only one of the current directions, *viz.*, the design of spectrally positioned light sources and give emphasis to materials science-oriented aspects of this problem. A few examples given below will help to outline the current challenges associated with this direction.

Figure 1 depicts a typical IR transmission spectrum of the Earth's atmosphere together with absorption spectra of some molecular gases. It is apparent that the atmosphere has several so-called transmission windows, *i.e.*, spectral ranges of the optical transparency to the electromagnetic radiation. One of such windows is located in the visible region of the spectrum, which is actually a prerequisite to the existence of life on the Earth. A few of such windows also occur in the IR region of the spectrum, *e.g.*, at $2\text{--}2.5 \mu\text{m}$ ($5000\text{--}4000 \text{ cm}^{-1}$) and $4\text{--}5 \mu\text{m}$ ($2500\text{--}2000 \text{ cm}^{-1}$). The latter region is of particular interest since it encompasses vibrational features of many molecules, including

common atmospheric pollutants that are to be controlled, such as hydrogen halides or oxides of carbon, nitrogen and other elements. Remote measurements of the concentration of these molecules in the atmosphere can be accomplished by their excitation with a laser. This requires lasers radiating at strictly defined wavelengths corresponding to the absorption bands of the respective molecules, *i.e.*, spectrally positioned laser sources.

Table 1. Chemical elements possessing useful 'analytical' lines of electronic transitions in the wavelength range of 200–400 nm.¹

Element	λ_{ex} /nm	λ_{fluor} /nm	Element	λ_{ex} /nm	λ_{fluor} /nm
Ag	328.1	338.3	Ni	301.9	310.1
Al	308.2	308.2	Pb	283.3	405.8

Mg	285.2	285.2	Y	297.4	302.2
Mn	279.5	279.5	Zn	307.6	307.6
Mo	294.4	444.3	Zr	296.1	301.1
Nb	374.2	376.4			

Here is another example. The wavelengths of the most intense atomic absorption (λ_{ex}) and fluorescence (λ_{fluor}) lines for a series of common metals are summarised in Table 1. These are the so-called 'analytical' spectral lines suitable for the determination of trace concentrations of these metals using atomic absorption or atomic emission spectroscopy. The remote determination of trace concentrations of metals in the atmosphere, subterranean waters or soils, for instance, for environmental control, also requires spectrally positioned sources but rather in the near UV spectral range.

The list of tasks requiring spectrally positioned sources is rather long. In addition to the aforementioned environmental science, it includes ground-based equipment for the communication with aircrafts and spaceships, fibre-optical communication systems, medicine, *etc.*

Conceptually, the problem of the design of such sources is similar to the problem of the generation and reception of radio waves with a radio receiver strictly tuned to the wavelength emitted by a transmitter. However in the present case, it is the operational frequency of the receiver that is strictly defined and thus the transmitter frequency has to be adjusted accordingly. Besides, modern radio devices allow easy frequency adjustments of the radio signal over a broad range to achieve the resonance. On the other hand, the majority of lasers emit nearly monochromatic radiation at a fixed frequency. Data on the most efficient modern laser crystals are compiled in Table 2. Unfortunately, the 'as is' spectral properties of radiation generated by laser crystals is unsuitable for the design of spectrally positioned radiation sources (since the emission frequencies of these crystals are not resonant with the absorption frequencies of the most convenient receivers). It has to be stressed that spectral lines in the absorption spectra of atoms, ions and molecules are very narrow with typical widths of only 10^{-1} – 10^{-2} cm^{-1} . The emission spectra of the majority of lasers are similarly narrow (0.1 – 1 cm^{-1}). Therefore, a random exact coincidence of a laser emission frequency and an absorption line of an atom or molecule is of vanishingly low probability.

Table 2. Most popular crystals used in monochromatic lasers.

Crystal	Activator : sensitiser	Oscillation wavelength /μm
Y ₃ Al ₅ O ₁₂	Nd ³⁺	1.064 (0.94; 1.32; 1.444)
	Yb ³⁺	1.030

Gd ₃ Sc ₂ Ga ₃ O ₁₂	Nd ³⁺ : Cr ³⁺	1.061
YAlO ₃	Nd ³⁺	1.079
KGd(WO ₄) ₂	Nd ³⁺	1.067
YVO ₄	Nd ³⁺	1.064
LiYF ₄	Nd ³⁺	1.047 (1.053)

Two major ways to solve the problem of the design of laser sources with strictly spectrally positioned radiation for remote resonant excitation of atomic or molecular systems that are characterised by narrow spectral resonances can be envisaged:

(1) the application of tunable lasers generating light at a variable frequency according to the principle of a transmitter adjustment to resonant absorption frequencies of atoms or molecules;

(2) the conversion of radiation generated by existing lasers by a shift to shorter or longer wavelength ranges to make the spectrum of the transformed radiation match the required wavelength. The radiation of both monochromatic and tunable lasers can be a subject of conversion. A shift in the radiation wavelength

can be achieved with crystals manifesting prominent nonlinear optical properties based on such physical phenomena as harmonic conversion, parametric light generation or stimulated light scattering.

The most promising crystals applicable in tunable lasers and their respective tunability ranges are given in Table 3. It is evident that the frequency tuning can indeed fill up some gaps in the accessible range of laser frequencies, but only to a limited extent.

Table 3. Most popular crystals used in tunable lasers.

Crystal	Activator	Oscillation wavelength range / μm
Al_2O_3	Ti^{3+}	0.650–1.110
$\text{Y}_3\text{Al}_5\text{O}_{12}$	Cr^{4+}	1.340–1.570
Mg_2SiO_4	Cr^{4+}	1.130–1.367
LiSrAlF_6	Cr^{3+}	0.780–0.990
	Ce^{3+}	0.285–0.315

	F_2^+ (see ^a)	0.800–1.100

^a F colour centre.

A significant extension of the accessible range of frequencies has recently been achieved owing to the discovery of materials capable of changing the laser frequency through the stimulated Raman scattering.

II. The laser wavelength conversion using stimulated Raman light scattering

1. Theoretical fundamentals of the purposeful search for efficient materials

The phenomenon known nowadays as Raman light scattering was discovered in 1928. It was independently observed by Raman and Krishnan in liquids² and by Landsberg and Mandelshtam in crystals.³ Essentially, this phenomenon consists of the generation of a secondary radiation shifted to longer wavelengths by a value corresponding to the energy required to excite vibrations of atoms or molecules upon the propagation of an intense monochromatic light beam in a transparent medium. The Raman scattering event can be conveniently considered as a two-photon resonance achieved when the difference between the frequencies of incident (ν_I) and scattered (ν_S) light becomes equal to the frequency of an atomic or molecular vibration in the medium (ν_R)

$$\nu_I - \nu_S = \nu_R.$$

Due to the two-photon nature of the process, its cross-section (σ) is extremely small, *i.e.*, of the order of 10^{-30} cm^2 . That is the reason, why light sources with ultimately high radiation spectral densities are necessary for the observation of Raman scattering.

In 1962, Woodbury and Ng⁴ observed an intense IR component shifted by 1345 cm^{-1} with respect to the incident light in experiments on the ruby laser light modulation with a nitrobenzene-filled Kerr cell. Later on, this effect was interpreted as the stimulated Raman scattering (SRS).⁵

According to the quantum theory,^{5,6} the SRS intensity (associated with the Stokes scattering, *i.e.*, scattering accompanied by a shift to the IR spectral range) is proportional to the density of occupied states corresponding to three interacting fields, *viz.*, laser pumping photons (N_I), photons of the generated scattered wave (N_S) and ground-state phonons (or, equivalently, molecular vibrations) of the crystal (N)

$$\frac{dN_S}{dz} \sim N_I N_S N$$

(z is a coordinate).

In a steady-state mode where the duration of the incident laser pulse is longer than the vibrational phase relaxation time of the medium ($\tau_p \gg T_R$), the SRS intensity (I_S) generated in a layer of a scattering medium with a thickness l is given by

$$I_S(l) = I_S(0) \exp(g_{\text{st}} I_I l), \quad (1)$$

where I_I is the incident light intensity, g_{st} is the steady-state-mode gain coefficient

$$g_{\text{st}} = \frac{(d\sigma/d\Omega) \lambda_I \lambda_S^2 N}{\pi c \hbar n_S^2 \Delta\nu_R}.$$

Here, $d\sigma/d\Omega$ is the integral scattering cross-section, c is the speed of light, n_S is the refraction index of the medium at the scattered light wavelength, $\Delta\nu_R$ is the width of the respective line in the Raman spectrum.

Therefore, in a steady-state mode, the gain coefficient g_{st} is directly proportional to the integral Raman scattering cross-section and inversely proportional to the width of the respective Raman transition. The line width is, in turn, governed by the mechanism of the vibrational phase relaxation in the medium.⁷ The product $\Delta\nu_R^{-1} d\sigma/d\Omega$ quantifies the scattering amplitude in the spectral maximum. Hereinafter, this parameter is referred to as the peak Raman scattering cross-section and denoted as Σ_{peak} .

Wang considered⁸ the so-called transient Raman light scattering occurring when $\tau_p \leq T_R$ and the pumping spectral width is larger than $\Delta\nu_R$. Under these conditions in the case of a rectangular-shaped pumping pulse, the transient SRS gain coefficient g_{tr} relates to the above parameters through the following expression

$$g_{\text{tr}} l \approx 2(g_{\text{st}} l c \Delta\nu_R \tau_p)^{1/2}.$$

It is apparent from this expression that g_{tr} depends on the pumping pulse duration τ_p and $g_{\text{st}} \Delta\nu_R$ product, which represents the integral Raman scattering cross-section. Furthermore, Wang suggested⁸ a more straightforward relation of the gain coefficient to fundamental properties of the material. The SRS intensity in the analytical form is given by the following expression

$$I_S(l) \sim I_S(0) \exp \left[2 \left(\frac{I_I \tau_p l 8\pi^2 c^2 N}{\hbar \omega_S^3 n_S^2} \frac{d\sigma}{d\Omega} \right)^{1/2} \right].$$

As follows from this equation, the SRS gain coefficient is proportional to square root of the integral Raman scattering cross-section $d\sigma/d\Omega$. In this case, the SRS amplification can be estimated from the integral intensity of the respective line in the spectrum of spontaneous Raman scattering

$$\Sigma_{\text{int}} \sim \frac{d\sigma}{d\Omega}.$$

This implies that the performance of a material as regards the efficiency of the SRS conversion of the laser radiation can be evaluated based on an analysis of the respective spontaneous Raman scattering spectra. Importantly, such measurements can be performed not only for bulk optically homogeneous species but also for fine polycrystalline powders, which greatly simplifies their experimental realisation.

2. Performance of various inorganic crystals in SRS lasers as estimated by spontaneous Raman light scattering

According to theoretical calculations, the SRS threshold corresponding to $I_S \approx I_I$ is achieved at an exponent argument in the formula (1) of ~ 30 . Typical values of g_{st} for gaseous and liquid

media lie in the range of $1\text{--}3\text{ cm GW}^{-1}$ (e.g., $g_{\text{st}} = 1.5\text{ cm GW}^{-1}$ and 3 cm GW^{-1} for hydrogen and nitrobenzene, respectively). This implies that the realisation of the SRS mode in these systems requires either a thick scattering medium layer ($30\text{--}100\text{ cm}$) or a highly intense ($\sim 1\text{ GW cm}^{-2}$) pumping radiation.

Among potential media for the SRS conversion of the laser radiation, solid systems and crystals in particular exhibit the following clear advantages:

- a high concentration of Raman-active sites, $N = 10^{22}\text{--}10^{23}\text{ cm}^{-3}$;
- a high gain coefficient, $g = 1\text{--}50\text{ cm GW}^{-1}$;
- a small scattering length (thin layers of a scattering medium), $1\text{--}10\text{ cm}$;
- a variety of possible Raman shifts, from 10 cm^{-1} to 2000 cm^{-1} ;
- a broad optical transparency range, from $0.2\text{ }\mu\text{m}$ to $100\text{ }\mu\text{m}$;
- a high heat conductivity, $1\text{--}20\text{ W (cm K)}^{-1}$;
- a weak temperature dependence of the refraction index n , $dn/dT = 10^{-6}\text{--}10^{-5}\text{ deg}^{-1}$;
- a resistivity towards adverse ambient conditions;
- a high thermal stability.

The first observation of the SRS in solids dates back to 1963. Eckhardt *et al.*⁹ investigated this effect in crystals of diamond, calcite and α -sulfur. Naturally occurring calcite CaCO_3 is a very common SRS material, since it typically forms large single crystals characterised by a relatively high optical homogeneity. Calcite reveals an intense quasi-molecular SRS-active vibrational mode at 1086 cm^{-1} with a width of $\sim 1.2\text{ cm}^{-1}$. The SRS gain coefficient is 5.5 cm GW^{-1} at an incident wavelength of 532 nm . Diamond crystals are characterised by a record high gain coefficient and a large Raman shift (1332 cm^{-1}) but are of low practical importance due to their small sizes and high costs. In 1980, crystals of metal nitrates, i.e., NaNO_3 , $\text{Ba(NO}_3)_2$ and $\text{Pb(NO}_3)_2$, were proposed as promising candidates for observation of the SRS effect.¹⁰ These materials reveal intense vibrational modes at $\sim 1050\text{ cm}^{-1}$ due to the internal totally symmetric vibrations of the quasi-molecular NO_3 groups. The gain coefficient of $\text{Ba(NO}_3)_2$ is 47 cm GW^{-1} at an excitation wavelength of 532 nm .¹¹ With these crystals, the conversion efficiency of the incident laser radiation as high as 80% was achieved at a duration of the laser pulse of a few nanoseconds.^{7, 12, 13} Owing to this high efficiency, a number of commercial solid-state SRS lasers were designed based on the $\text{Ba(NO}_3)_2$ crystals, in particular, those operating in a spectral range of $\sim 1.5\text{ }\mu\text{m}$, which is safe for human eyes. However barium nitrate performs well only for the conversion of nanosecond laser pulses. Upon a transition to shorter, picosecond, pulses, the performance of $\text{Ba(NO}_3)_2$ is drastically decreased: the SRS threshold is increased by one order of magnitude due to slow relaxation of the vibrational excitations therein ($\sim 30\text{ ns}$).¹⁴ In addition, $\text{Ba(NO}_3)_2$ is characterised by a low moisture resistance, poor heat conductivity and moderate mechanical properties.

Andryunas *et al.*¹⁵ and Basiev *et al.*¹⁶ observed the SRS activity in $\text{KGd(WO}_4)_2$ (potassium gadolinium tungstate, hereinafter, referred to as KGW) crystals. The SRS gain coefficient of this tungstate at an incident wavelength of 1064 nm is twice lower than that of $\text{Ba(NO}_3)_2$ (6 cm GW^{-1}). Nevertheless, owing to a higher integral gain coefficient, KGW crystals are highly efficient in ps-pulsed SRS lasers.¹⁷ Furthermore, in contrast to nitrates, KGW is characterised by a substantially higher hardness and chemical stability and is relatively inexpensive and available as large single crystals.

Over the last decade, hundreds of crystalline compounds belonging to different classes have been evaluated and compared in the Laser Materials and Technologies Research Centre at the A M Prokhorov General Physics Institute of the Russian Academy of Sciences. The classes of compounds studied include metal and ammonium carbonates, nitrates, phosphates, borates, sili-

cates, niobates, chlorates, bromates, iodates, sulfates, molybdates and tungstates. As a basic method for the preliminary evaluation of crystals under study, spontaneous Raman light scattering was utilised.^{16, 17}

An Ar ion laser operated at a wavelength of 488 nm was used as a radiation source in Raman scattering experiments. The power of the laser beam at a sample surface was 1 W . The Raman scattering spectra were acquired with a Spex Ramalog-1403 double spectrometer in the backscattering geometry. The spectral resolution of the setup was $0.2\text{--}1.0\text{ cm}^{-1}$. Both single crystals and polycrystalline powders were investigated. For a correct comparison of the integral and peak scattering cross-sections among different samples, the measurements were performed on rectangular plates with thicknesses of 0.7 mm or 2 mm cut from the respective single crystals. A plate with a thickness of 0.7 mm cut from a diamond crystal was used as an intensity reference. The intensity of the laser radiation and slit settings of the spectrometer were kept constant throughout the measurements. In order to study the orientational effects, the measurements were performed at different crystallographic orientations of the samples relative to the polarisation plane ($\mathbf{E}$) of the incident laser radiation. The as-measured Raman spectra were processed with a specialised software code to retrieve line widths as well as peak and integral scattering cross-sections. The accuracy of the line width determination, which is determined by the spectral resolution of the setup, was $\sim 10\%$ for moderately broad ($\Delta\nu_R > 1\text{ cm}^{-1}$) lines. The peak scattering cross-sections Σ_{peak} were determined to within $\sim 10\%$ and $\sim 20\%$ for broad and narrow lines, respectively. The accuracy of the Σ_{int} determination is estimated as 10% and $20\%\text{--}40\%$ for narrow and broad lines, respectively.

Results of the measurements are compiled in Table 4. The values of Σ_{int} and Σ_{peak} for all materials are scaled to those of diamond, since diamond is characterised by one of the most intense Raman lines. As has been discussed above, the integral Raman scattering cross-section determines the SRS gain coefficient in a transient mode. According to the tabulated data, large Σ_{int} are observed, apart from diamond, for lithium niobate (166%) for a vibrational mode at 632 cm^{-1} , various molybdates and tungstates (from 46% to 65%) and lithium iodate (54%). Smaller integral Raman scattering cross-sections are typical of sodium and barium nitrates (23% and 21% , respectively), calcite (6%), calcium and strontium fluorapatites (3.4%) and quartz (2.2%). All molybdates and tungstates studied can be subdivided into two groups based on their crystal structures: compounds with the scheelite (CaWO_4) structure corresponding to the tetragonal space group C_{4h}^6 and monoclinic structures characterised by the space group C_{2h}^0 . For the first group of crystals, intense Raman scattering lines are attributed to totally symmetric vibrations of the WO_4 tetrahedra. For the second group of compounds, the two intense lines observed in the Raman spectra are attributed to vibrations of the W--O bonds in the WO_6 octahedra.¹⁸

Meanwhile, the SRS amplification in a steady-state mode is determined by the peak scattering cross-section Σ_{peak} . According to the experimental data in Table 4, a large gain is expected for diamond and sodium and barium nitrates. Because of very narrow Raman lines, crystals of $\text{Ba(NO}_3)_2$ and NaNO_3 manifest large values of Σ_{peak} , despite the fact that the integral cross-sections corresponding to their SRS-active vibrational modes are $2\text{--}3$ times smaller than those of tungstates. Accurate measurements^{19, 20} afforded the record small line width of $\sim 0.4\text{ cm}^{-1}$ for $\text{Ba(NO}_3)_2$, which is severalfold smaller than that for diamond. The peak cross-section Σ_{peak} of this Raman mode in $\text{Ba(NO}_3)_2$ amounts to 63% of the respective diamond value and is more than twice larger than that in KGW crystals. In the case of NaNO_3 , Σ_{peak} is only 44% due to the larger line width ($\sim 1\text{ cm}^{-1}$). Lithium iodate and monoclinic tungstates are characterised by moderately broad Raman lines ($5\text{--}8\text{ cm}^{-1}$) and relatively large peak cross-sections ranged from 10% to 35% . A Raman mode of lithium niobate at 632 cm^{-1} is significantly broader (27 cm^{-1}) but is characterised by a relatively large peak cross-section Σ_{peak} (18%)

owing to a very large integral cross-section of 166%. A comparable value of Σ_{peak} is observed for crystals of natural calcite (10.6%). CaWO₄ crystals demonstrate a large integral cross-section of 50% but relatively low peak cross-section of 18.6% due to a significant line broadening of 6.95 cm⁻¹. As for SrWO₄ and BaWO₄, owing to small line widths of 3 cm⁻¹ and 1.63 cm⁻¹, their peak cross-sections Σ_{peak} amount to 41% and 64%, respectively, which is larger than that in other tungstates and comparable to values typical of nitrates. The highest-frequency Raman lines of lanthanum and lithium niobates (at 805 cm⁻¹ and 872 cm⁻¹, respectively) are characterised by relatively low Σ_{peak} values of 7.1% and 5%, respectively. Calcium and strontium fluorapatites reveal even higher-frequency lines but smaller Σ_{peak} values of 3.8%. All these values are small but nevertheless close to the respective Σ_{peak} value of calcite, which is used for the SRS generation on a commercial basis both with ns- and ps-pulsed lasers.

Due to the large Raman shifts (800–960 cm⁻¹) and broad lines ($\Delta\nu_R = 3–20$ cm⁻¹), the crystals of aforementioned niobates and apatites can prove useful for SRS in the picosecond range.

Other materials listed in Table 4 exhibit small peak Raman scattering cross-sections. Notwithstanding, they still can be useful, since they provide different Raman shifts.

Therefore, the above comparative analysis of the SRS-active modes for various crystalline materials based on their spontaneous Raman scattering spectra indicates that calcite and sodium and barium nitrates should provide large SRS gain coefficient in a steady-state mode for nanosecond pulses. A shortening of pumping pulses to 20–30 ps switches the SRS mode to a transient one, which gives rise to a substantial increase in the SRS threshold for these crystals. A more efficient SRS generation at shorter pumping pulses can be achieved with tungstate crystals, which are characterised by relatively broad Raman lines. Due to the large integral cross-sections, these crystals are expected to perform well

in a transient SRS mode. Due to their outstanding spectroscopic properties, SrWO_4 and BaWO_4 crystals are capable of providing high SRS gain coefficients both for ns- and ps-pulsed lasers, which substantiates their great potential as versatile nonlinear optical media for the highly efficient SRS-based frequency converters. It is also of note that, in addition to tungstates, molybdates demonstrate very attractive SRS properties.

III. The preparation and characterisation of single crystals of calcium, strontium, barium and lead molybdates and tungstates for SRS lasers

Calcium, strontium, barium and lead molybdates and tungstates represent congruently melting compounds having no (except for BaMoO_4) phase transitions over the entire temperature range from room temperature to the melting point. Single crystals of these compounds can be grown by melt crystallisation. Their melting points lie below 1535°C and thus platinum crucibles can be used for crystal growth. Platinum is characterised by a melting point of 1770°C , and platinum crucibles can be used in air. Most typically, crystals of molybdates and tungstates are grown by the so-called Czochralski method based on a slow pulling of a crystal growing on a seed from the respective melt.²¹ Ivleva *et al.*²² reported on the growth of single crystals of some tungstates by the modified Stepanov method based on the use of a bulk shaper.

Below we consider in more details the growth of barium tungstate crystals by the Czochralski and Stepanov methods. Barium tungstate crystallises in the tetragonal scheelite structure and has a melting point of 1475°C . Single crystals of this compound were grown on a Kristall-3M crystal-growth furnace equipped with an inductively heated platinum crucible with a melt. Starting BaWO_4 was prepared by sintering of BaCO_3 and WO_3 of the purity grade 5N taken in a stoichiometric ratio. The seed was oriented along the $[100]$ direction. The crystalliser is schematically depicted in Fig. 2. A cylindrical platinum screen was placed above the crucible to prevent overheating of the crucible walls and reduce temperature gradients along the growing crystal. The axial temperature gradient was kept in a range from

Figure 2. A scheme of the crystalliser furnace used for crystal growth of calcium, strontium, barium and lead molybdates and tungstates using the Czochralski method.

(1) Platinum crucible, (2) platinum thermal shield, (3) heat-insulating elements made from corundum ceramics, (4) seed holder, (5) growing crystal, (6) RF heater.

50 to 100°C per cm, while the radial temperature gradient was fixed at $\sim 5^\circ\text{C}$ per cm. High optical-quality crystals were grown at a pulling rate of $2\text{--}6\text{ mm h}^{-1}$ upon a constant rotation at 30 rpm . An excess of WO_3 of $0.5\text{ mass \%}$ – $1.2\text{ mass \%}$ was added to the melt to suppress emergence of light-scattering inclusions in the crystals.

The crystalliser used for crystal growth by the modified Stepanov method is schematically depicted in Fig. 3. According to this method, a special platinum shaper is plunged into the melt. The melt from the crucible is supplied through the feeding capillaries of the shaper to a thin layer of the melt in the contact with the crystal growth front. The thickness of the contact melt layer is controlled by the temperature of the crucible and the position of the shaper relative to the crucible. Meanwhile, the shape of the crystallisation field and the cross-section of the growing crystal are determined by the shaper profile. A crystal is grown on a seed, typically, without rotation. The growth process can be optimised by varying the shaper design and temperature gradients. The growth of specifically shaped crystals has some distinctive features related to their structures. In particular, the anisotropy of growth rates of different crystallographic faces has to be taken into account. According to the Curie principle, in the case of BaWO_4 that crystallises in the tetragonal space group $C_{4h}^{6_2}$, the crystallographic a axis is the preferable growth direction and a rectangle is the preferable contact surface of the shaper.

Figure 3. A scheme of the crystalliser furnace used for crystal growth of calcium, strontium, barium and lead molybdates and tungstates using the modified Stepanov method.

Photographic images of the tungstate crystals grown by both methods are shown in Fig. 4.

Laser devices place extremely strong requirements on the quality (optical perfection) of materials to be used as working media.²³ Such crystals and glasses should contain no solid or gaseous inclusions, domain boundaries and cracks. Refraction index gradients of a medium should not exceed $10^{-4}\text{--}10^{-6}\text{ cm}^{-1}$. The presence of any of these defects in an optical medium gives rise to efficiency losses (due to light scattering on optical inhomogeneities) and radiation damage of the material. Consequently, such materials are unsuitable for the practical use. The above requirements are even stricter for

Figure 4. Photographic images of BaWO₄ crystals grown from melts using the Czochralski method at a pulling rate of 2–6 mm h⁻¹, a rotation rate of 30 rpm and a volume growth rate of < 1 cm³ h⁻¹ upon an excess of WO₃ in the melt of 1 mass %–1.5 mass % (a) and using the modified Stepanov method at a pulling rate of 5 mm h⁻¹ (no rotation) and a volume growth rate of 0.5 cm³ h⁻¹ upon an excess of WO₃ in the melt of 1 mass % (b).^{22, 23}

potential SRS crystals, which often operate at ultimately high laser radiation intensities of the order of 10⁸–10⁹ W cm⁻².

The crystal growth by the Czochralski method can produce the following specific defects intrinsic to the method:

Figure 6. Microscopic inclusions of a foreign phase in a BaWO₄ single crystal grown by the Czochralski method (observation in a laser beam).^{22, 23}

— ‘a core’, *i.e.*, a central part of the crystal in the form of a core defect going along the entire crystal from bottom to top; the emergence of this defect relates to the face growth from the cone vertex at the interface between solid and liquid phases (Fig. 5);

— growth striations;

— microscopic inclusions of foreign phases (Fig. 6);

— cracks along the cleavage planes of a crystal.

In order to prevent or suppress the formation of a ‘core’, the growth front has to be the least convex or ideally flat. This can be achieved by a decrease in both the vertical temperature gradient along the crystal and the radial temperature gradient across the crystallisation front.

Growth striations occur as a result of a periodically inhomogeneous distribution of the main crystal components or admixtures due to variations in the growth rate. Typically, elimination of possible factors responsible for these variations, such as instabilities of pulling of the crystal and rotation mechanisms or fluctuations in the temperature of the melt, minimises this defect.

Tungstate crystals grown from exactly stoichiometric melts often contain microinclusions of foreign solid phases, which cause opalescence of crystals. These defects are attributed to a violation of the melt stoichiometry in the course of crystal growth due to progressive evaporation of tungsten trioxide. The use of a small excess of WO₃ (up to 1.5 mass %) in the furnace charge makes it possible to avoid the emergence of such light-scattering inclusions. Alternatively, optically homogeneous tungstates can be grown by the addition of ~0.5 mass % rare-earth metal oxides (La₂O₃, Nd₂O₃, *etc.*) to the melt for the crystal growth.

The specific defects in BaWO₄ crystals grown by bulk shaping methods include cracks along certain crystallographic directions, in particular, parallel to [001] and light-scattering micro- and macroinclusions. The use of exactly stoichiometric melts and too high pulling rates increases the probability of the appearance of inclusions. In this method of crystal growth, the shape of the crystallisation front is strongly dependent on the design of the shaper. The flatness of the crystallisation front is violated in the case of shapers with excessively wide slits (Fig. 7). This gives rise to crystals with a prominent domain structure and, consequently, abundant cracks. Ivleva *et al.*²² utilised shapers with capillary slits of 1 mm and 0.1 mm. In the latter case, the crystallisation front was nearly flat, which afforded highly homogeneous crystals.

The use of smaller temperature gradients also improves the optical homogeneity of the resultant crystals. In the growth experiments, platinum crucibles with diameters from 40 mm to 80 mm were tested. It is known that an increase in the crucible size and, respectively, in the melt volume decreases the temperature gradients, which gives rise to larger and higher-quality crystals.

Figure 5. A typical central defect (a ‘core’) in a BaWO₄ single crystal grown by the Czochralski method.^{22, 23}
(a) A cross-section perpendicular to the growth axis, *a*; (b) a cross-section parallel to the growth axis, *a*.

Figure 7. The crystallisation surface of a BaWO₄ single crystal grown by the modified Stepanov method with a shaper having slits with a thickness of 1 mm.^{22, 23} The intergrowth of the crystal into the capillary slits can easily be seen.

The optimum conditions for the growth of tungstate crystals were found to be: the pulling rate of 1–5 mm h⁻¹ at a volume growth rate no faster than 0.5 cm³ h⁻¹, the capillary slit width (if a shaper is used) of 0.1–0.2 mm, the excess of WO₃ in the melt of 1 mass %, the axial temperature gradient of 50 °C per cm. Under these or similar conditions, optically homogeneous crystals of calcium, strontium, barium^{22, 24–26} and lead²⁷ molybdates and tungstates with sizes of 30 × 100 mm were successfully grown.

IV. Raman scattering spectra of calcium, strontium, barium and lead molybdates and tungstates

As has been discussed above, crystals of molybdates and tungstates are characterised by similar integral scattering cross-sections, whereas the widths of the respective spectral lines are substantially different. It is the line width that determines the peak scattering cross-section provided that the integral cross-sections are almost identical. Furthermore, the value of the Raman shift strongly varies in a series of molybdates and tungstates. It is necessary to correlate these parameters with the chemical composition and crystal structure in order to enable the prediction of Raman scattering and SRS effects and purposeful search for novel efficient SRS-based laser converters. These issues are considered in detail elsewhere.²⁶ The spectra of spontaneous Raman light scattering were measured for an extended series of molybdates MMoO₄ and tungstates MWO₄ (M = Ca, Sr, Ba, Pb, Zn). The vast majority of samples for measurements were prepared as bulky single crystals. Only ZnMoO₄ and ZnWO₄ were obtained as polycrystalline ceramic specimens by sintering of thoroughly mixed zinc carbonate with either MoO₃ or WO₃ at 1100–1200 °C. The sample plates were cut from the single crystals either parallel or perpendicular to the crystallographic *c* axis upon the determination of the orientation by X-ray diffraction.

Raman spectra were excited with Ar laser radiation with $\lambda = 488$ nm and registered using a Spex Ramalog-1403 spectrometer at 77 K and 300 K. High-temperature Raman spectra (up to 1920 K) were measured using an original method described elsewhere.²⁸ Excitation was achieved with a pulsed Cu vapour laser operated at a wavelength of 501.5 nm and a pulse repetition rate of 10 kHz. The spontaneous Raman scattering spectra were recorded using the time-resolved technique, which provides a high signal-to-thermal background ratio. High-temperature Raman spectroscopy is indispensable in studies of solid-state phase transitions; additionally, it yields important information on

positions and widths of Raman lines as a function of the temperature up to and above the melting point.

First measurements of room-temperature spontaneous Raman scattering spectra of calcium, strontium and lead molybdates and tungstates date back to the mid-1960s.²⁹ Meanwhile, barium molybdate and tungstate spectra remained unstudied. All the above molybdates and tungstates except for zinc compounds crystallise with the scheelite structure corresponding to the tetragonal space group C_{4h}^6 . A primitive unit cell contains two formula units. The Mo–O and W–O bonds in the quasi-molecular tetrahedral [MoO₄]²⁻ and [WO₄]²⁻ anions are essentially covalent, and the anions are only weakly bound to the M²⁺ cations. With this regard, features in the Raman spectra of these crystals can be subdivided into two groups, *viz.*, internal and external vibrational modes. The internal vibrations include totally symmetric vibrations of the oxygen atoms relative to the central Mo or W atom, *i.e.*, the so-called breathing modes. The external (or lattice) phonons correspond to vibrations of the M²⁺ ions relative to rather rigid quasi-molecular [MoO₄] and [WO₄] groups. Free MoO₄ and WO₄ tetrahedra are characterised²⁹ by the point symmetry T_d . According to the group theory, 15 degrees of freedom are possible in this symmetry group, which can be classified into four internal vibrational [$\nu_1(A_1)$, $\nu_2(E)$, $\nu_3(F_2)$ and $\nu_4(F_2)$], one rotational [$\nu_{tr}(F_1)$] and one translational (F_2) modes. When [MoO₄] or [WO₄] groups are placed into the scheelite lattice, the crystal-field symmetry is lowered to S_4 . This gives rise to splitting of all degenerate vibrations due to the crystal field effects.²⁹ Furthermore, the presence of two formula units in a unit cell gives rise to an additional, the so-called Davydov, splitting (DS) of the vibrational modes. For instance, the $\nu_1(A_1)$ and $\nu_3(F_2)$ vibrational modes of a free tetrahedral group are split in the scheelite crystal field in the following way:

$$\nu_1(A_1) \longrightarrow \nu_1(A) \longrightarrow \nu_1(A_g) + \nu_1(B_u),$$

$$\nu_3(F_2) \longrightarrow \nu_3(E) + \nu_3(B) \longrightarrow \nu_3(E_g) + \nu_3(E_u) + \nu_3(B_g) + \nu_3(A_u).$$

Calculations within the group theory gives 26 different vibrations

$$\Gamma = 3A_g + 5A_u + 5B_g + 3B_u + 5E_g + 5E_u \quad (2)$$

corresponding to the wavevector $\mathbf{K} = 0$. All gerade vibrations (*i.e.*, $3A_g$, $5B_g$ and $5E_g$) are Raman-active, whereas the ungerade modes (*i.e.*, $4A_u$ and $4E_u$) can only be observed in IR absorption spectra. Three B_u vibrations represent the so-called silent modes. Two acoustic vibrations, A_u and E_u , also occur in the expression (2).

The Raman spectra measured by Basiev *et al.*²⁶ agree well with the earlier reported data.^{29, 30} The spectra of BaMoO₄ and BaWO₄ crystals studied for the first time are shown in Fig. 8. The results of spectra processing are collected in Table 5. The BaWO₄ crystals retain the scheelite structure over the entire temperature range from room temperature to the melting point. Meanwhile, it was found that BaMoO₄ undergoes a phase transition at 1600 K from the tetragonal modification (β) into a cubic structure (α). The Raman spectra in Fig. 8a clearly demonstrate that two ν_3 vibrations coalesce and the ν_{ext} band strongly shifts above 1600 K. A comparison of the Raman spectra of BaMoO₄ measured at two ultimate temperatures indicates that the crystal-field symmetry experienced by a [MoO₄] group in a melt at 1800 K is nearly the same as that in the crystalline state at 1605 K.

Shifts in the Raman-active frequencies for calcium, strontium, barium and lead molybdates and tungstates as a function of the cation mass and the unit cell parameter *c* are depicted in Figs 9 and 10, respectively. It is evident that the trends are identical in both series. There are several factors affecting the observed Raman shifts. Kanamory *et al.*³¹ suggested that it is the cation mass that is mainly responsible for the frequency of the low-energy external vibration ($2B_g + 2E_g$). This suggestion is supported by a monotonic decrease in the external vibrational frequency ν_{ext} with an increase in the cation mass *M* (see Fig. 9). However experi-

Figure 8. Temperature-dependent non-polarised Raman scattering spectra of BaMoO₄ (a) and BaWO₄ (b) in the crystalline and molten states.²⁶ Here and in other figures, the notation VV (VH) denotes the experimental geometry with the polarisation plane of the scattered beam parallel (perpendicular) to the polarisation plane of the incident beam.

ments showed²⁶ that the frequencies of the internal vibrational modes of the [MoO₄] and [WO₄] groups [except for the $\nu_2(E)$ doublet] also depend on the cation nature.

One of possible reasons for this effect lies in the fact that an increase in the ionic radii in the Ca–Sr–Ba series gives rise to some dilatation of the unit cell and, subsequently, to a small change in the Mo–O and W–O bond lengths within the tetrahedra. This should also be accompanied by a change in the force constants corresponding to certain internal vibrational modes. Apparently, the unit cell parameters exert the strongest influence on the force constants corresponding to the $\nu_4(F_2)$ and $\nu_{fr}(F_1)$ modes (see Fig. 10). On the other hand, the unit cell parameters of PbMoO₄ and PbWO₄ are close to those of SrMoO₄ and SrWO₄ (Table 6) and it seems logical to expect

similar internal vibrational frequencies for them. In contrast to these expectations, frequencies of all internal vibrations of PbMoO₄ and PbWO₄ deviate from the monotonic dependences plotted in Fig. 10. The largest shifts are observed for the high-energy modes, *i.e.*, $\nu_1(A_g)$, $\nu_3(B_g)$ and $\nu_3(E_g)$. This deviation cannot be explained by effects of the unit cell parameters alone. It was suggested that another crystal-chemical factor gets involved, *viz.*, a partially covalent character of the chemical bonds formed by the M²⁺ cations with the oxygen atoms constituting the MoO₄ and WO₄ groups. This factor also affects³² the force constants of the internal vibrations. A higher electronegativity of an M²⁺ cation gives rise to larger force constants corresponding to centrosymmetric vibrations and, respectively, to higher frequencies of the vibrational modes (see Table 6). Additionally, the formation of

Figure 9. Changes in the Raman frequencies along the MMoO₄ and MWO₄ homologous series (M = Ca, Sr, Ba, Pb) as a function of the cation mass M²⁺ (see Ref. 26).

partly covalent M–O bonds changes the effective mass of vibrating atomic groups in a way that a reduced mass of the metal–oxygen pair should substitute the mass of a single oxygen atom in the frequency calculations. In this indirect way, the mass of an M²⁺ cation can affect the internal vibrational frequencies of the [MoO₄] and [WO₄] groups. The influence exerted by the nature of an M²⁺ cation on the internal vibrational frequencies is dominantly ascribed to the effects of force constants. However Lazarev *et al.*³² did not specifically address the case of a very heavy cation simultaneously characterised by a high electronegativity, such as Pb²⁺.

The ambiguity of the above interpretation concerning the dependence of the internal vibrational frequencies on the cation

Figure 10. Changes in the Raman frequencies along the homologous series of calcium, strontium, lead and barium molybdates and tungstates as a function of the unit cell parameter.²⁶

nature relates to the fact that this dependence in real crystals is masked by static crystal-field effects and dynamical coupling of different vibrational modes. The crystal lattice effects can be excluded by measuring Raman spectra in melts of the respective compounds. High-temperature Raman spectra of the melts were measured using the experimental setup described above. The experimental spectra of melts derived from the scheelite-type crystals are fully consistent with the presence of tetrahedral groups with the *T_d* point symmetry (Fig. 11). They reveal four vibrational modes, *viz.*, ν₁(A₁), ν₂(E), ν₃(F₂) and ν₄(F₂). The ν₁(A₁) mode is attributed to totally symmetric vibrations of the oxygen atoms relative to the central atom (Mo or W). In order to monitor the effects of the cation mass on the internal vibrational frequencies, the Raman spectra of ZnMoO₄ and ZnWO₄ melts were also included into the comparative analysis. Zinc is characterised by

Note. The following notations are adopted: *m*_{cat} is the atomic mass (a.u.); *r*_{cat} is the ionic radius; η_{cat} is the electronegativity; Δ*E* is the Davydov splitting. The electronegativities values used in this table and below were taken from the monograph by R T Sanderson *Chemical Bonds and Bond Energy* (New York: Academic Press, 1976).

Figure 11. Temperature-dependent non-polarised Raman spectra of CaWO_4 crystals and polarised Raman spectra of CaWO_4 melt.²⁶

nearly the same electronegativity as lead, whereas the atomic mass of lead is far larger than that of zinc and other cations under consideration. It is of note that the crystal structures of zinc molybdate and tungstate differ from that of scheelite. The molybdenum and tungsten atoms therein are octahedrally coordinated by the oxygen atoms.³³ However it was established that their coordination changes to the tetrahedral one upon melting (Fig. 12).

Therefore Raman studies of melts make it possible to separate the effects of the cation mass and electronegativity on the Raman frequencies. Frequencies of the $\nu_1(\text{A}_1)$, $\nu_2(\text{E})$, $\nu_3(\text{F}_2)$ and $\nu_4(\text{F}_2)$ vibrational modes as a function of the cation electronegativity for melts of metal molybdates and tungstates are shown in Fig. 13. Frequencies of all these vibrational modes increase with an increase in the electronegativity in the Ba–Sr–Ca–Zn series thus indicating that it is the cation electronegativity that mainly determines the force constants corresponding to the internal vibrations within the $[\text{MoO}_4]$ and $[\text{WO}_4]$ groups. In contrast, the reduced mass of the M–O pair only weakly influences the vibrational frequencies within these groups for any M^{2+} except for Pb^{2+} . The vibrational frequencies of the $[\text{MoO}_4]$ and $[\text{WO}_4]$ groups in the melts of PbMoO_4 and PbWO_4 are drastically diminished with respect to compounds of other cations. Taking this into account, it might be suggested that the influence of a high electronegativity of Pb^{2+} on the Raman frequencies of the $[\text{MoO}_4]$ and $[\text{WO}_4]$ groups is effectively compensated by a large reduced mass of the Pb–O pair.

The above results imply that the cation radius, mass and electronegativity jointly influence the internal vibrational frequencies of the tetrahedral groups not only in the crystalline but also in the molten state, where these quasi-molecular groups experience a spherically symmetric crystal field. This effect has not been considered so far (see, for instance, Ref. 30). Only the spectra of PbMoO_4 and PbWO_4 deviate from the common trend for both crystals and melts (see Figs 9, 10 and 13). This can be explained by the prevailing influence of a large mass of the lead atom on the vibrational frequencies of the $[\text{MoO}_4]$ and $[\text{WO}_4]$

Figure 12. Temperature-dependent non-polarised Raman spectra of ZnWO_4 crystals and polarised Raman spectra of ZnWO_4 melt.²⁶

groups. Meanwhile, no strong mass dependence is observed in the Ba–Sr–Ca series. A monotonic increase in the internal vibrational frequencies for the melts of Ba-, Sr- and Ca-derived scheelites is totally consistent with an increase in the electronegativity of these cations (see Fig. 13). It is of note that the highest-frequency totally symmetric mode, $\nu_1(\text{A}_g)$, demonstrates the reverse trend in the crystalline state (see Figs 9 and 10). This effect was referred³⁴ to as the ‘negative mass dependence’. This dependence can be rationalised neither by an elongation of the Mo–O and W–O bonds due to a lattice dilatation nor by a decrease in the cation electronegativity. Both these factors would give rise to a decrease in the $\nu_1(\text{A}_g)$ frequency in the series of Ca–Sr–Ba scheelites, which is in direct contradiction to the experimental observations. Such a behaviour of the Raman frequencies can be explained assuming that it is the Davydov

Figure 13. Changes in the Raman frequencies for melts of Ca, Sr, Ba, Zn and Pb molybdates and tungstates at 1920 K as a function of the cation electronegativity.²⁶

splitting that dominantly affects the $\nu_1(A_g)$ frequency. For the scheelite structures, the Davydov splitting gives rise to a splitting of the $\nu_1(A_g)$ mode into two components, A_g and B_u [see the expression (2)]. Provided that the ‘silent’ component $\nu_1(B_u)$ corresponds to a higher energy than $\nu_1(A_g)$, the frequency corresponding to the lower-lying $\nu_1(A_g)$ mode should increase with a decrease in the splitting gap $\Delta E = \nu_1(B_u) - \nu_1(A_g)$. According to the results by Scott,³⁴ the splitting gap ΔE depends on the Mo–Mo and W–W interatomic distances in the crystal structures. An increase in these distances coupled with a lattice dilatation gives rise to a decrease in ΔE and, respectively, to an increase in the $\nu_1(A_g)$ frequency. The problem is that ΔE cannot be directly determined from experimental data, since the $\nu_1(B_u)$ is inactive in both Raman and IR absorption spectra. Basiev *et al.*²⁶ utilised high-temperature Raman spectroscopy to estimate ΔE . Indeed, in the case of melts, the spontaneous Raman scattering spectra are not affected by the Davydov splitting and the vibrational modes of the MoO_4 and WO_4 groups appear unsplit. A frequency shift of the $\nu_1(A_g)$ mode upon melting can directly be determined from the temperature dependence of Raman spectra

$$\Delta = \nu_1(A_g)_{\text{cryst}} - \nu_1(A_g)_{\text{melt}}.$$

Assuming that the Davydov splitting of ν_1 is symmetric, the splitting gap ΔE can be estimated as 2Δ . The experimental temperature dependences of the $\nu_1(A_g)$ frequencies over a wide temperature range from 77 K to above the melting points for a series of molybdates and tungstates are plotted in Fig. 14. It is apparent that the $\nu_1(A_g)$ frequency demonstrates a jump-like increase upon melting for the majority of scheelites, whereas it changes rather smoothly for $BaMoO_4$ and $BaWO_4$. This strongly suggests that the $\nu_1(A_g)$ frequency in the scheelite crystals is smaller than the $\nu_1(B_u)$ frequency. The magnitudes of the Davydov splitting estimated under the assumption that $\Delta E = 2\Delta$ are listed in Table 6 (calculated based on the experimental data from

Figure 14. Changes in the Raman frequency of the $\nu_1(A_g)$ mode for homologous series of barium (1), strontium (2), calcium (3) and lead (4) molybdates (a) and tungstates (b) in the crystalline and molten states as a function of temperature.²⁶

Fig. 14). The data allow one to trace the character of changes in ΔE along the series of scheelites (both molybdates and tungstates). The splitting increases with a decrease in the Mo–Mo and W–W interatomic distances in the unit cell. It turns to zero in the case of large unit cells of $BaMoO_4$ and $BaWO_4$ and reaches the maximum of 52–58 cm^{-1} for the smallest unit cells of $CaMoO_4$ and $CaWO_4$ (see Table 6). Therefore it is the Davydov splitting that is responsible for a decrease in the $\nu_1(A_g)$ frequency in the series of Ba–Sr–Ca scheelites. The influence of this splitting on the $\nu_1(A_g)$ frequency prevails over all other factors involved.

The influence of various crystal-chemical factors on the spectral widths ($\Delta\nu_R$) of Raman lines has also been analysed in detail.²⁶ The values of $\Delta\nu_R$ corresponding to the $\nu_1(A_g)$ vibrational modes as a function of temperature for a series of molybdates and tungstates in both the crystalline and molten states are plotted in Fig. 15. In the scheelite crystals, $\Delta\nu_R$ is virtually linearly dependent on the temperature. Meanwhile, the spectral line widths of all scheelites increase drastically upon melting. This trend in $\Delta\nu_R$ was attributed²⁶ to a homogeneous broadening of Raman lines due to the dephasing and depopulation of the $\nu_1(A_g)$ vibrational modes. A substantial difference in the line widths between molybdates and tungstates, on the one hand, and nitrates, on the other hand, can be rationalised based on the different energy diagrams of the internal vibrons for the MoO_4 or WO_4 tetrahedra and the NO_3 triangles, which gives rise to different degeneracies of the phonon relaxation processes. In particular, the energy gap between the $\nu_1(A_g)$ mode and adjacent modes in $Ba(NO_3)_2$ is $\sim 300\text{ cm}^{-1}$. In such a case, a three-phonon relaxation is impossible and thus four-phonon relaxation processes characterised by low probabilities prevail. As a consequence, the experimental Raman spectra reveal

Figure 15. Changes in the widths of the Raman lines corresponding to the $\nu_1(A_g)$ mode for homologous series of barium (1), strontium (2), calcium (3) and lead (4) molybdates (a) and tungstates (b) as a function of temperature.²⁶

a small homogeneous broadening and an extremely narrow line corresponding to a large Σ_{peak} value. In the case of scheelites, the energy gap is $30\text{--}130\text{ cm}^{-1}$ and $70\text{--}150\text{ cm}^{-1}$ for molybdates and tungstates, respectively. At these energy gap values, the phonon relaxation is already dominated by three-phonon processes that are characterised by higher probabilities, which gives rise to a substantial homogeneous broadening of spectral lines corresponding to the internal vibrations.

A careful profile analysis of the $\nu_1(A_g)$ vibrational lines in the Raman spectra of a series of molybdates and tungstates measured under identical conditions revealed a continuous line narrowing in the Ca–Sr–Ba series (Fig. 16), which correlates with a decrease in the Davydov splitting and an increase in the cation mass. Lead molybdate and tungstate strongly deviate from the common trend showing an abnormal increase in $\Delta\nu_1(A_g)$, which can be explained by an increase in the Davydov splitting for the heavy but small lead cation as opposed to the heavy but large barium cation. Another prominent anomaly observed in the spectra of lead molybdate and tungstate by Basiev *et al.*³⁵ is related to their integral Raman scattering intensity. The experimental intensity of the $\nu_1(A_g)$ line was severalfold higher than that for other scheelites and the most intense scattering was observed in the orthogonal geometry, *i.e.*, with $E \perp C4$ (Table 7).

Based on the results of temperature-dependent spontaneous Raman scattering measurements performed over a wide temperature range, the following conclusions can be derived:

- parameters of vibrational spectra of crystals with the scheelite structure are dependent on the mass, size and electronegativity of the cation M;
- the cation mass factor prevails in the case of low-energy external vibrational modes;
- the internal vibrational frequencies of the MoO_4 and WO_4 groups are primarily dependent on the unit cell parameters and the degree of covalency of the M–O bonds;
- the Davydov splitting of totally symmetric $\nu_1(A_g)$ vibrational modes in the tetrahedral MoO_4 and WO_4 groups continuously increases in the Ba–Sr–Pb–Ca series.

Table 7. Abnormally high Raman scattering cross-sections Σ_{peak} and Σ_{int} for PbWO_4 and PbMoO_4 crystals.

Crystal	Polarisation of the pumping radiation	Σ_{peak} (%)	Σ_{int} (%)
BaWO_4	$E \parallel C4$	64	47
	$E \perp C4$	52	38
PbWO_4	$E \parallel C4$	65	120
	$E \perp C4$	97	171
PbMoO_4	$E \parallel C4$	64	203
	$E \perp C4$	146	397

The widths of Raman lines depend on specific features of the crystal lattice and the nature of an M^{2+} cation. A combination of ‘lightweight’ cations with short interionic distances gives rise to a substantial line broadening. The narrowest lines corresponding to the $\nu_1(A_g)$ modes are observed for the case of heavy cations with large ionic radii, *i.e.*, in BaMoO_4 and BaWO_4 (2.1 cm^{-1} and 1.6 cm^{-1} , respectively), which results in the record high SRS gain coefficients. The abnormal trends in the changes of vibrational modes for PbWO_4 and PbMoO_4 cannot be explained taking into account only atomic masses, ionic radii and structure type. A more careful in-depth analysis of effects related to the character of

Table 8. Integral Raman scattering cross-sections (relative to diamond) in crystals of different compounds and effective radii of the oxygen-containing anions.

the Pb—O chemical bonds is required. The integral line intensity represents the most difficult problem as regards the interpretation and prediction of Raman scattering and SRS parameters. This problem is additionally complicated by the fact that an incident radiation generates simultaneously several Raman components characterised by different intensities in the vast majority of crystalline media, which effectively gives rise to a distribution of the converted radiation energy over several vibrational modes (in contrast to, for instance, diamond, where all scattered energy is concentrated in a single line profile).

The integral intensities Σ_{int} corresponding to internal vibrational lines of quasi-molecular ions in different types of crystals are compiled in Table 8 together with their respective effective radii.³⁶ A correlation between Σ_{int} and the effective anion radius exists: Σ_{int} increases with an increase in the anion size. In particular, Σ_{int} in crystals of molybdates, tungstates, niobates and iodates significantly exceeds those in such compounds as borates, carbonates and nitrates.

V. SRS converters and lasers based on novel crystals

According to the data considered in previous sections, it can be concluded that an efficient SRS conversion of the laser radiation (that is the conversion with a high efficiency) can be realised in materials complying with the following requirements:

- large peak and integral Raman scattering cross-sections;
- low optical losses of both pumping radiation and SRS radiation; this implies that the crystals have to be optically homogeneous and defect-free and have a wide spectral window of transparency;
- crystals should be mechanically strong and chemically stable; in particular, they should provide a high radiation damage threshold and do not degrade in terms of optical homogeneity under atmospheric humidity, sun light, *etc.*

Below we give a few examples of successful application of novel crystals in SRS lasers.

1. Nanosecond SRS lasers with BaWO₄ and SrWO₄ crystals

Zverev *et al.*³⁷ reported on the results of comparative tests of novel BaWO₄ crystals and well-known Ba(NO₃)₂ and KGd(WO₄)₂ crystals. The crystal elements made from BaWO₄, Ba(NO₃)₂ and KGd(WO₄)₂ were placed into a Fabry–Perot resonator with a length of 9 cm. The input mirror had a reflection coefficient of 5% and 98% at the pumping radiation wavelength of 1.064 μm and in the range of the generated Stokes components, *i.e.*, $\lambda = 1.1$ –1.25 μm , respectively. The output mirror had a reflection coefficient $R_{1.0-1.2} = 55\%$. As a pumping source, a single-mode Nd-doped yttrium–aluminium garnet laser (YAG:Nd³⁺) with a passive LiF:F₂[−] Q-switch was used. The pulse duration of SRS radiation was 20 ns at a repetition rate of 10 s^{−1}. The efficiency of SRS radiation was 26% and 20.5% with Ba(NO₃)₂ and BaWO₄ crystals, respectively. In both cases, the slope efficiency exceeded 75% at nearly identical SRS thresholds. It is of note that the SRS properties of BaWO₄ are polarised; in particular, the efficiency was higher for $E \parallel C4$ and lower for $E \perp C4$. The KGd(WO₄)₂ crystals demonstrated a higher SRS threshold and a slope efficiency of only 45% under strictly identical experimental conditions.

The SRS-based frequency conversion of radiation produced by an Nd-doped gadolinium–gallium garnet laser was also elucidated.³⁸ A BaWO₄-based SRS converter shifted the incident laser wavelength from 1.0621 μm to 1.1779 μm . As a result of the conversion with a slope efficiency above 30%, pulses with an energy of 15 mJ at a power in the MW range and a repetition rate of 10 s^{−1} were produced.

The efficiency of an SrWO₄-based SRS laser was characterised under similar conditions.³⁹ Strontium tungstate crystals can be doped with a large amount of neodymium. In such a case, the same crystal can simultaneously serve for the generation of the laser radiation with $\lambda = 1.06 \mu\text{m}$ on Nd³⁺ sites and its SRS conversion to $\lambda = 1.18 \mu\text{m}$. This functional integration admits a significant decrease in the size of the laser device and strongly enhances the reliability of its operation.

2. Nanosecond SRS lasers in the mid-IR region with BaWO₄ crystals

BaWO₄ crystals are highly transparent in the intermediate IR spectral range, which can be exploited in the design of lasers generating radiation with a wavelength within 2–5 μm . As has been mentioned above, this spectral range is extremely important for practical applications but remains poorly developed. The major problem there is that the longest possible wavelengths of pumping radiation have to be used in a combination with the second (or even the third) Stokes components of the Raman spectrum, since a typical SRS frequency shift is on the order of $\sim 1000 \text{ cm}^{-1}$. Furthermore, the SRS gain coefficient rapidly decreases with an increase in the pumping wavelength. Basiev *et al.*⁴⁰ utilised crystal elements made from BaWO₄ with a length of 42 mm to convert the pumping radiation of 1.34 μm generated by a YAG:Nd³⁺ laser equipped with an acoustooptic Q-switch. The SRS-converted spectrum is shown in Fig. 17. The spectrum reveals the first (1.53 μm), second (1.78 μm) and third (2.13 μm) Stokes components. The slope efficiency for the conversion of the pumping energy (1.34 μm) into the first and the second Stokes components was higher than 22%.

Figure 17. The SRS generation spectra of BaWO₄ crystals pumped by a neodymium-doped yttrium–aluminium garnet laser operated at a wavelength of 1.34 μm .⁴⁰

Recently, a significant advancement towards the mid-IR region has been achieved.⁴¹ It relates to the SRS spectral conversion of nanosecond laser pulses at wavelengths of 1.56 μm and 1.91 μm with BaWO₄ crystals. It has been shown that the pumping radiation with $\lambda = 1.56 \mu\text{m}$ undergoes a multi-stage conversion into the first, second, third and fourth Stokes SRS components corresponding to wavelengths of 1.82, 2.19, 2.75 and 3.69 μm , respectively. The generated SRS components are shown in Fig. 18 in a comparison with the transmission spectrum of BaWO₄ crystals.

In the case of nanosecond pumping pulses with $\lambda = 1.91 \mu\text{m}$, the first Stokes SRS component with 2.32 μm was successfully generated. It is important that the BaWO₄ crystal utilised in the converter was only 27 mm long.

Figure 18. A transmission spectrum of BaWO₄ crystals (1) and the BaWO₄ Raman laser oscillation spectra in the mid-IR region (2).

3. The SRS conversion of picosecond laser pulses with BaWO₄ crystals

Černý *et al.*⁴² accomplished a comparative analysis of the performance of BaWO₄, KGd(WO₄)₂ and KY(WO₄)₂ crystals in the SRS conversion of picosecond pulses. The pumping radiation was characterised by wavelengths of 0.53 μm and 1.064 μm and pulse durations of 28 and 40 ns, respectively. In the case of the green pumping light (0.53 μm), the gain coefficients were 14.4 cm (GW)⁻¹, 11.5 cm (GW)⁻¹ and 18.7 cm (GW)⁻¹ with BaWO₄, KGd(WO₄)₂ and KY(WO₄)₂ crystals, respectively. While the gain coefficient provided by the BaWO₄ crystal was three times larger than that with KGd(WO₄)₂ in the steady-state SRS mode, its advantage was not as evident in the picosecond mode. This is explained by the narrower Raman line and shorter relaxation time in BaWO₄ as compared with the respective values in KGd(WO₄)₂. A different situation is observed when the BaWO₄ performance is compared with that of Ba(NO₃)₂. For nanosecond pumping pulses (in the steady-state mode), the gain coefficient provided by the BaWO₄ crystal was 20%–30% lower than that with Ba(NO₃)₂. Meanwhile, in the picosecond (transient) mode, BaWO₄ performs three times better than Ba(NO₃)₂. The gain coefficients for picosecond pumping pulses with λ = 1.064 μm were 3.8 cm (GW)⁻¹, 4.7 cm (GW)⁻¹ and 3 cm (GW)⁻¹ for BaWO₄, KY(WO₄)₂ and KGd(WO₄)₂, respectively. The maximum efficiency of a working element made from BaWO₄ with a length of 30 mm for picosecond pumping pulses with λ = 0.53 μm was 30% for the first Stokes component. The respective value for a KGd(WO₄)₂ crystal with a length of 40 mm was only 18%. According to the detailed measurements on the efficiency of the SRS generation,⁴³ the efficiency of the conversion of pulsed pumping radiation with a wavelength of 1.064 μm and a pulse duration of 50 ps into the first Stokes component of 1.180 μm increases from 25% to 35% on going from a one-pass to a two-pass optical scheme. When the BaWO₄ element was placed into a resonator with a length of 38 cm equipped with an output mirror with the optimised transmission spectrum, the absolute efficiency increased to 55%, whereas the slope efficiency (estimated by the slope) reached nearly 100%.⁴⁴

4. SRS frequency converters and lasers with PbWO₄, PbMoO₄ and PbMoO₄:Nd³⁺ crystals

Kaminskii *et al.*^{45,46} studied radiation of an SRS laser with PbWO₄ crystals pumped by a YAG:Nd³⁺ pulsed laser with λ = 1.064 μm and a pulse duration of 100 ps. The conversion efficiency of 20% was achieved at an energy of the pumping pulses of 5 mJ using a resonator with planar-convex mirrors having a length of 200 mm. The length of a working PbWO₄ element was 30 mm. The same authors reported on the SRS conversion of

pulsed green radiation with a wavelength of 0.53 μm and a pulse duration of 30 ps. The PbWO₄ crystal provided a gain coefficient of 8.4 cm (GW)⁻¹.

Another study⁴⁷ was devoted to the generation of SRS by one or two elements made from PbWO₄ with a length of 45 mm placed into a ring resonator. The pumping was achieved with the first harmonic of a pulsed YAG:Nd³⁺ laser with a pulse duration of 7 ns. With one element in the resonator, the energy of SRS radiation was 5.3 mJ at an energy of pumping pulses of 36 mJ (which is already close to the laser damage threshold of PbWO₄ crystals). The conversion efficiency of 20% was achieved with two elements in the resonator.

Atypically high values of Σ_{peak} and Σ_{int} observed for PbMoO₄ crystals make it a promising candidate for achieving unprecedentedly high efficiencies of the SRS conversion for both nanosecond and picosecond pulse duration regimes. Furthermore, the PbMoO₄ crystal lattice easily accommodates a large amount of doping rare-earth elements, which makes it possible to combine the laser light generation and its SRS conversion within one crystal. According to a series of recent publications,^{27,35,48} these predictions are well justified. The following experiments have been reported:

- the generation of SRS in PbMoO₄ crystals as a function of the sample orientation relative to the polarisation vector of the incident radiation;
- the laser light generation by the Nd³⁺ ions in PbMoO₄:Nd³⁺ in the free-running mode;
- the laser light generation by the Nd³⁺ ions in the Q-switched mode;
- the laser light generation by the Nd³⁺ ions with its simultaneous conversion to the first Stokes SRS component.

The pumping was achieved with a semiconductor laser diode emitting at a wavelength of 0.808 μm and a power of 1.5 W. The radiation of the laser diode was fully linearly polarised and pulsed with a pulse duration of 250 μs at a repetition rate of 5 s⁻¹. As laser elements, PbMoO₄:Nd³⁺ crystals with neodymium concentrations of 0.3 mass % and 2 mass % were employed. Rectangular plates with thicknesses of 1 mm were cut perpendicular to the crystallographic *a* axis. In the free-running oscillation mode, the radiation with a wavelength of 1.0556 μm was produced. The differential generation efficiency was 53% for the sample with 0.3 mass % of Nd. In the case of the sample with 2 mass % of Nd, an average oscillation power of 0.65 W was achieved.

Q-Switching was accomplished with a passive shutter based on lithium fluoride crystals with F₂⁻ colour centres. Under these conditions, a pulsed SRS oscillation mode was realised with a pulse repetition rate of (7.5–190) × 10³ s⁻¹ at a peak power of ~2 kW and an average power of ~0.36 W. The pulse duration was from 8.7 ns to 1.4 ns. These results prove that PbMoO₄:Nd³⁺ provides a high average power in the Q-switched operation mode (only 1.8 times lower than in the free-running oscillation mode).

In experiments on the self-conversion of the laser radiation generated by the neodymium ions in PbMoO₄:Nd³⁺ into the SRS, the thickness of working elements was 3 mm. With a LiF:F₂⁻ Q-switch, the first Stokes SRS component was observed at a wavelength of 1.163 μm. The output pulse energy was 6 μJ at a pulse duration of < 500 ps. This implies that the peak pulse power achieved was higher than 12 kW.

Potential application fields of the novel SRS crystals and lasers on their base are comprehensively considered elsewhere.^{49,50}

* * *

The recent experimental data on the SRS-based laser wavelength conversion considered above proves the significant predictive power of the approach to the search for novel SRS-active media described in the present review. The theoretical conclusions on the

frequencies and widths of SRS lines with their relation to the conversion efficiency of laser pulses with different durations are fully supported by experimental results.

The conclusions regarding the homologous series of alkali-earth metal molybdates and tungstates can be extended (with minor correction) to other homologous classes of inorganic compounds.

Therefore, the use of stimulated Raman scattering in crystals of inorganic compounds has a huge potential in solving the problem of the design of spectrally positioned laser sources.

The authors are grateful to L N Ershova and M N Basieva for help in the manuscript preparation.

IV. Triarylmethyl type di- and polyradicals	866
V. Conclusion	882

Abstract. The synthesis and properties of triarylmethyl di- and polyradicals including perchlorinated ones are considered. The achievements in the design of magnetic clusters and organic magnets based on the Gomberg radical are described. Data on mixed-valence compounds containing triarylmethyl type radicals and carbanions as electroactive groups are given. The bibliography includes 117 references.

I. Introduction

Magnetism as a universal natural phenomenon is intensively studied by fundamental science. Magnetic phenomena are widely used in engineering. The traditional magnetic materials (ferro-, ferri- and antiferromagnets) contain metal atoms or ions with partially occupied d and f shells and represent metals, metal alloys and ceramics. In both fundamental and applied aspects, the interest of researchers is aroused by creation of an organic magnet, *i.e.*, an ensemble of organic molecules or macromolecules containing only light (non-metal) elements (C, O, H, N, S, *etc.*) and possessing spin ordering, *i.e.*, ferro- or ferrimagnetism. Various approaches to the design of organic magnets and achievements along this line have been summarised in reviews.^{1–6}

This review considers the key methods for the synthesis and properties of di- and polyradicals and organic magnets based on the first experimentally detected (Gomberg, 1900) triphenylmethyl radical (TPMR). The chemical and spectroscopic properties of the Gomberg radical and other triarylmethyl type (TAMT) radicals have been described, for example, in a number of books.^{7,8} The research area related to the molecular magnetism has developed so vigorously in recent years that it is difficult to cover it within one review. Works devoted to particular types of radicals are therefore required. For example, of the 373 references present in the recent review by Blundell and Pratt⁶ dealing with organic and molecular magnets, only two references concern polymeric polyradicals. Somewhat more information on these species can be found in another publication.⁴ A number of reviews by Rajca,^{3,9–13} who is actively engaged in the synthesis of TAMT

polyradicals, have been published; the recent review¹³ deserves special mention.

The problem of the creation of organic magnets can be divided into the molecular and supramolecular aspects. In the molecular aspect, it is clear that organic paramagnetic compounds with unpaired electrons, stable radicals and carbenes should serve as the building blocks for organic magnets.

Currently, an enormous number of paramagnetic organic species are known, and ferromagnetic spin ordering in the crystal or in an amorphous solid, *i.e.*, the supramolecular aspect, remains the major problem. Indeed, according to Dougherty,² ‘...Nature favours antiferromagnetic coupling of two weakly interacting electrons’. However, several cases of ferro- and ferrimagnetism in the crystals of small radicals or organic charge transfer salts have recently been observed experimentally.^{1–6} Two McConnell mechanisms demonstrating the possibility of through-space intermolecular ferromagnetic ordering of organic paramagnetic molecules (radicals and carbenes) have been considered in detail in reviews^{1,4} which give references to original publications.

II. Exchange interactions in di- and polyradicals

Yet another approach to the design of organic magnets (alternative to the spatial ordering of small radicals) is the synthesis of polyradicals in which the intramolecular magnetic ordering of unpaired electrons occurs through chemical bonds. It is meant that pair exchange interactions between unpaired electrons are transferred through a system of conjugated π -bonds of a polymer. Since in some conjugated diradicals (including those stable under ambient conditions), very strong ferromagnetic coupling has been found,³ this approach offers hope for the preparation of organic magnets with the Curie temperature equal to, or higher than, room temperature.

The descriptions of di- and polyradicals widely use^{2,3} the notions ‘ferromagnetic coupling unit’ (FCU) and ‘antiferromagnetic coupling unit’ (ACU) (in some cases, they are referred to as the corresponding bridges). The simplest π -conjugated hydrocarbon diradical is trimethylenemethane (TMM) (CU-1 structure in Fig. 1). In this diradical, two methyl radicals are attached to one end of the ethylene molecule (1,1-coupling) and the p orbitals with unpaired electrons are conjugated with the π -system of ethylene. The electron coupling is ferromagnetic, and TMM exists in a triplet ground state (T) with the full spin $S = 1$. In this case, ethylene acts as an FCU. Conversely, for the CU-2 structure in Fig. 1 in which the radical centres are attached to different ends of the ethylene molecule (1,2-coupling), the ground state is singlet (S, $S = 0$) and in this case the double bond is an antiferromagnetic

Figure 1. Structure (topology) of conjugated diradicals and spin coupling in them (see the text).

coupling unit. The exchange interaction of the unpaired electrons through a benzene ring also depends on the arrangement of the radical centres. The 1,3-coupling (*meta*-coupling) usually results in a triplet ground state of the molecule and a ferromagnetic coupling of electrons (CU-3 structure in Fig. 1), whereas 1,4(*para*)- and 1,2(*ortho*)-coupling of the radical centres gives rise to a singlet ground state and, correspondingly, antiferromagnetic coupling of the unpaired electrons (CU-4 and CU-5 structures in Fig. 1).

It should be emphasised that the type of binding through phenylene units as well as the conjugation effect depend appreciably on the mutual arrangement of the orbitals bearing unpaired electrons and the plane of the benzene ring. Conformational distortions of the structure may result in a decrease in the exchange coupling and in the reversal of its sign, *i.e.*, a *meta*-phenylene unit may become an ACU, and a *para*-phenylene unit may be transformed into an FCU. Zang *et al.*¹⁴ calculated the dependence of the singlet–triplet splitting energy and, hence, the exchange integral on the rotation angle of the p orbitals with unpaired electrons with respect to the plane of the benzene ring for the CU-3–CU-5 units and gave references to the experimentally proven cases of sign reversal in the exchange coupling caused by steric distortion of the structure of the unit. Some examples of this sort are considered below.

A ‘magnetic’ polymer should, in a general case, be a macromolecule with a large number (10^3 – 10^4 or more) radicals that interact through coupling units, *i.e.*, a polyradical. Two differing in principle approaches for radical coupling within a conjugated polymer have been developed: in class I polyradicals, the radicals alternate with the coupling units, while in class II polyradicals, the radicals are attached to the conjugated polymer backbone (Fig. 2). The idea of using the conjugated polymer backbone as the common ferromagnetic coupling unit was first proposed by Ovchinnikov and co-workers¹⁵ and subsequently developed by Nishide *et al.*¹⁶

The progress in the design of magnetic polymers may be evaluated using the average full spin S in the ground state of the macromolecule (for n ferromagnetically coupled spins equal to $1/2$, $S = n/2$).

III. Mesoscopic and monomolecular magnets. Spin clusters

On the one hand, researchers try to obtain magnetic molecules as large as possible (ideally, macroscopic, for example, as networks). On the other hand, it should be borne in mind that for the

Figure 2. Two classes of polyradicals. R is a stable radical.

condensed phase, three main sorts of magnetic ordering (ferro-, antiferro- and ferrimagnetism) may be supplemented still by at least nine types (metamagnetism, ‘seed’ ferromagnetism, superparamagnetism, speromagnetism, asperomagnetism, helimagnetism, spin glass, mictomagnetism, sperimagnetism).¹⁷ These sorts of magnetic order can apparently be also manifested in organic magnets, and one should, first, be ready to encounter them, and, second, to deliberately prepare compounds with these sorts of ordering. In particular, a new line of research closely connected with the superparamagnetism, called magnetic mesoscopies, has been actively developed in recent years;^{18,19} this deals with small magnetic particles with a size of ~ 1 – 100 nm containing ~ 10 – $10\,000$ atoms. These mesoscopic magnets (or nanomagnets) are of obvious fundamental interest as regards transition from the magnetism of separate atoms to the collective magnetism (ferro, ferri, *etc.*) of amorphous and crystalline macrobodies. From the technology standpoint, the use of mesoscopic magnets is promising for increasing the density of magnetic data recording.

Now we consider briefly the magnetic properties of mesoscopic magnets, which are rather small single-domain particles and often behave as superparamagnets.^{3,18,19} In small single-domain particles, magnetisation along the easy magnetisation axis is blocked: an energy barrier (E_A) to the rotation of the magnetisation vector appears due to the anisotropy energy. There are many types of magnetic anisotropy;²⁰ the most frequently encountered types are the crystallographic anisotropy caused mainly by the spin–orbit coupling and the shape anisotropy the microscopic cause of which is the long-range dipole–dipole coupling between the elementary magnetic moment carriers.²⁰

Figure 3 shows the dependence of the energy (E) of a single-domain particle on the angle (θ) between the magnetisation vector (M) and the easy magnetisation axis in the absence of a magnetic field and on its switching on. The field is oriented oppositely to the z axis, which is directed upward. The transition of a magnetic particle from the metastable state (the left minimum in Fig. 1b, $\theta = 0$) to the equilibrium state ($\theta = \pi$) requires overcoming an energy barrier the height of which decreases with an increase in the field and becomes equal to zero at the critical value $H_c = 2E_A/M$. At this instant, the particle is remagnetised, namely, the magnetisation vector is oriented along the external field. This process is called switching and the H_c is the switching

Figure 3. Energy barrier to remagnetisation of a single-domain particle of an oblong shape: (a) without an external magnetic field; (b) in an external magnetic field H .

field. This bistability of small magnetic particles can be used for data recording. The transition over the barrier is facilitated by thermal fluctuations of magnetisation, which are, in particular, interfering factors for data recording. Owing to the thermal fluctuations, magnetisation of a material consisting of small magnetic particles decreases with time, the relaxation rate decreasing with a decrease in temperature according to the Arrhenius law

$$\tau^{-1} = f_0 \exp\left(-\frac{E_A}{k_B T}\right),$$

where τ is the characteristic relaxation time, f_0 is the pre-exponential factor equal to $\sim 10^{-9} - 10^{-10} \text{ s}^{-1}$ for typical magnetic particles, k_B is the Boltzmann constant, T is temperature.

It is noteworthy that the magnetisation vector may tunnel from one minimum to another upon quantum fluctuation, as shown by a dashed arrow in Fig. 3. These tunnelling transitions were actually detected experimentally; they are most clear-cut for a number of high-spin magnetic clusters that are considered below. This quantum effect is called macroscopic quantum tunnelling or magnetisation quantum tunnelling (MQT), its discovery being ranked among most prominent achievements of physics in the late 20th century. The violation of the Arrhenius

law at low temperatures ($T \rightarrow 0$), in particular, reaching a constant relaxation rate, is a consequence of the MQT.

In 1993, Rajca realised the possibility and importance of investigation of the magnetism of high-spin organic molecules on a mesoscopic scale.⁹ He noted that the spin-orbit coupling in carbon-centred radicals and carbenes is negligibly low, as follows from the small deviation of g -factors of these species from the g -factor of a free electron. Therefore, shape anisotropy is expected to be important for these species, and organic synthesis opens up extended opportunities for controlling this factor. For a particle with volume V , magnetisation I_s and the shape factor N , which is related to the demagnetisation factor ($0 \leq N \leq 2\pi$, $N = 0$ for a sphere, $N = 2\pi$ for an infinite rod), the energy barrier (in Kelvins) in the case of coherent rotation of the magnetisation is described by the formula

$$E_A = \frac{0.5 N I_s^2 V}{k_B}. \quad (1)$$

A calculation by this formula for triarylmethyl polyradicals with a moderately oblong shape (for example, an oblong ellipsoid of revolution with $a:b \approx 2$, $N \approx 3$) shows that about 200 ferromagnetically coupled spins (correspondingly, $S \approx 100$) are required to ensure a barrier of about 2 K.^{21, 22}

Nanomagnets can, in principle, be approached in two ways: 'top-down', *i.e.*, by grinding magnetic macrobodies, and 'bottom-up', *i.e.*, by synthesising large magnetic clusters. A magnetic, exchange or spin cluster is a set of several (two or more) spin centres connected by chemical or exchange interactions. Clusters in which magnetic transition metal ions (Fe, Mn, Cr, *etc.*) act as the spin centres are best known and best studied. The paramagnetic clusters are fairly convenient model systems in which all main physical interactions that form the properties of magnetic materials, including exchange interactions, are manifested for a limited number of atoms (ions) and, hence, they can be analysed more easily. Magnetic clusters, being adjacent to mesoscopic magnets, also represent a connecting unit between the microscopic and macroscopic magnetism. Extensive literature is devoted to various aspects of the physics and chemistry of inorganic exchange clusters; all relevant references can be found in books.^{23–25} The traditional theoretical base for the description of magnetic and spectroscopic properties of exchange clusters comes from the Heisenberg–Dirac–Van Vleck model, which is often called for short the Heisenberg model. In this model, exchange interactions for polynuclear clusters are described by the Hamiltonian

$$\hat{H} = - \sum_{ij} J_{ij} \hat{S}_i \hat{S}_j,$$

where J_{ij} is the exchange parameter, which is positive in the case of a ferromagnetic spin coupling and negative in the case of antiferromagnetic coupling; $\hat{S}_i$ and $\hat{S}_j$ are operators of the coupled spins.

For example, for a trinuclear cluster of the spins S_1 , S_2 and S_3 , the Heisenberg Hamiltonian in the general case has the form

$$\hat{H} = -2 J_{12} \hat{S}_1 \hat{S}_2 - 2 J_{23} \hat{S}_2 \hat{S}_3 - 2 J_{13} \hat{S}_1 \hat{S}_3.$$

With known structure or symmetry of the polynuclear cluster, the number of independent exchange parameters in the Hamiltonian can be reduced, which substantially facilitates its solution. The corresponding Hamiltonian can be composed based on simple considerations almost for any system of exchange-coupled spins (paramagnetic ions, radicals, *etc.*).²³ The next stage, namely, the calculation of the spin level energies and derivation of the

theoretical equation for the magnetic susceptibility for rather simple clusters, is not faced with serious difficulties either. The limitations inherent in the Heisenberg model have been considered in detail in books.^{23,24}

The research dealing with exchange clusters resulted in the development of single-molecular ensembles of paramagnetic ions, 'single-molecule magnets' (SMM). In 1980, Lis²⁶ reported the synthesis, structure and some magnetic properties of the nano-sized molecule $[\text{Mn}_{12}\text{O}_{12}(\text{OAc})_{16}(\text{H}_2\text{O})_4]$, which is usually designated as Mn_{12} . Each molecule contains a group of 12 manganese ions: four Mn^{4+} ions with the spins $S_1 = 3/2$ forming an internal tetrahedron and eight Mn^{3+} ions with the spins $S_2 = 2$ located outside the tetrahedron. The antiferromagnetic interactions of manganese ions with different oxidation states through oxygen ions give rise to a ferrimagnetic structure with the full spin of the molecule $S = 10$ ($8 \times 4/2 - 4 \times 3/2 = 10$). In 1993, it was found²⁷ that Mn_{12} has a substantial barrier of the magnetic anisotropy ($E_A = 60$ K) to the reversal of the magnetisation vector; this was manifested as a magnetic hysteresis loop at temperatures below 4 K. Since this type of hysteresis behaviour of these molecules is similar to the behaviour of small single-domain magnetic particles, the name 'single-molecule magnets' was proposed for them (as has been noted,²⁸ this name is not completely correct). This and similar molecular clusters demonstrate most clearly macroscopic quantum tunnelling mentioned above, as their chemical synthesis ensures the creation of ensembles comprising fully identical and equally oriented SMM.^{6,28}

The progress achieved in the preparation of mesoscopic magnets, magnetic clusters and SMM based on transition metal ions prompt the idea of preparing similar objects from organic radicals, the more so, that the synthesis of polyradicals having nanometre sizes is quite a realistic task.

IV. Triarylmethyl type di- and polyradicals

1. Diradicals

It is reasonable to consider first the diradicals obtained from the Gomberg radical in which the magnetic interactions of the unpaired electrons are manifested most clearly. The achievements in the synthesis of triarylmethyl diradicals and their properties have been discussed in a number of reviews and monographs (see, for example, the publications^{3,29,30}). Table 1 presents the properties of hydrocarbon diradicals of the triarylmethyl type **1–18** including both the diradicals synthesised recently and those known long ago with known magnetic properties. Let us briefly discuss some of the diradicals. It is believed that for structures **5** (Thiele's hydrocarbon), **13** (Chichibabin's hydrocarbon, ChH) and **16** (Muller's hydrocarbon, MH), the singlet states exist as

$\text{R}^1 = \text{R}^2 = \text{H}$ (**1**); $\text{R}^1 = \text{Bu}^t$; $\text{R}^2 = \text{H}$ (**2**), Me (**3**), Pr^i (**4**).

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**6**),
 $\text{R}^1 = \text{CF}_3$, $\text{R}^2 = \text{H}$ (**7**).

the corresponding quinonoid structures, which are in equilibrium with the triplet (diradical) states; for Thiele's hydrocarbon, the equilibrium is entirely shifted to the right due to the great energy difference between the singlet and triplet states and only the singlet state has always been observed.

$n = 1$ (**5**), 2 (**13**), 3 (**16**).

Table 1. Some properties of hydrocarbon diradicals of the triarylmethyl type.

^a D and E are zero-field splitting parameters; ^b in parentheses, the energy differences between the singlet and the triplet states $|\Delta E_{ST}|$ (kcal mol^{−1}) are given.

Analysis of the published data on the ChH casts some doubt in their interpretation. The solution of the famous diradical paradox formulated by McConnell⁴⁴ by no means completed the study of the ChH.^{35,45,46} Sugimoto *et al.*⁴⁵ concluded that the data obtained by Brauer *et al.*⁴⁰ refer, most likely, to radical pairs rather than to the triplet state of the ChH molecules. In their opinion, zero-field splitting (ZFS) parameters for the triplet state of the ChH should be much lower than those measured by Brauer *et al.*;⁴⁰ hence, its signal should be difficult to observe against the background of a monoradical impurity. According to Sugimoto *et al.*,⁴⁵ this is the reason why no triplet EPR signals were detected for the ChH single crystals studied earlier.³⁵ Indeed, it can be seen in Table 1 that the zero-field splitting parameters for Chichibabin's hydrocarbon are markedly distinguished from the general trend. It is beyond doubt that this fact requires additional reasoning and new experiments dealing with the triplet state of the ChH.

Muller's hydrocarbon also call for additional investigation, as a number of reasons have been proposed attesting to its triplet ground state.⁴⁷ Determination of the ground state of the Schlenk–Brauns diradical (10) is also doubtful.¹³

Using diradical 6 as an example, one can see that structural distortions may transform even an obvious FCU (with *meta*-phenylene connection) into an ACU, and this should be taken into account in the synthesis of magnetic polymers. An assumption³⁴ that diradical 6 has a conformer with $\Delta E_{ST} \approx -0.02$ kcal mol^{−1} also deserves attention. This brings about the question of how the singlet state is realised for this and other diradicals in which the formation of a quinonoid structure is impossible and what is the electronic spectrum of these diradicals in the singlet state.

An approximately twice higher singlet–triplet splitting of the cyclophane diradical 12 compared to diradical 11 is probably due to the presence of two parallel 3,3'-biphenyl exchange routes in the former case, while in diradical 11, only one route is present.³⁹

Diradical 17 is an analogue of the simplest and, hence, one of the best studied both theoretically and experimentally, π -conjugated organic diradical, trimethylenemethane (CU-1). This diradical is stable at room temperature and has a triplet ground state

with a relatively strong ferromagnetic interaction, which makes it, in the opinion of Rajca *et al.*,⁴² a promising structural block for organic magnetic polymers stable at room temperature.

A successful attempt⁴³ of the synthesis of combined diradical 18 comprising a triarylmethyl and a galvinoxyl radicals opens up the prospects for using other combinations of stable radicals, which may substantially extend the area of search for organic magnets.

Modes of interactions of unpaired electrons in TAMT tri- and tetradicals have been considered in reviews^{3,13} and experimental data for these radicals are presented below.

2. Theoretical background for the development of magnets based on triarylmethyl type radicals

Judging by the number of references, an important role in drawing the attention of researchers to the design of organic ferromagnets belongs to the theoretical publication by Mataga.⁴⁸ He was the first to propose planar high-spin two-dimensional hydrocarbon structures constructed from triphenylmethyl radicals (19) or from triplet diphenylcarbenes (20 and 21) as potential precursors of organic magnets. It can be seen that coupling of the unpaired electrons in structures 19, 20 and 21 occurs through the *meta*-position of the phenyl rings, as in the Schlenk diradical (1). The Leo triradical (22), which can be considered as a repeating unit for system 19, should have $S = 3/2$, according to the known Ovchinnikov rule.⁴⁹ For structure 19, the possibility of magnetic ordering at finite temperatures was demonstrated⁵⁰ in the framework of the Ising model; for an exchange integral of ~ 0.05 eV, the critical temperature should be ~ 1000 K. In an ensemble of one-dimensional chains of methyl radicals, the magnetic order can arise theoretically at a finite temperature only in the case where interchain exchange interactions are taken into account.⁵⁰ In a publication,⁵¹ a critical review of the theoretical studies on linear organic ferromagnets is given and the possibility of stabilisation of the ferromagnetic ordering in linear chains of methyl radicals bound through the *meta*-positions of the phenyl rings is demonstrated using the density of states method. In the polymers where the methyl radicals are bound by *para*-phenylene bridges, the density of states method predicts pairing of the neighbouring spins to give quinonoid structures. For the polymer with quinonoid and benzenoid types of conjugation resulting from the pairing of spins, a high electrical conductivity upon doping has been predicted.⁵¹

3. The Leo triradical and its analogues

The first attempt to synthesise triradical **22** (without the purpose to design organic magnets) dates back to 1937. Subsequently, it was found that the Leo radical (**22**) exists in solution mainly as diamagnetic tetramers, monomeric species in the quartet state ($S = 3/2$) being present only in minor amounts.⁵² Analogues of the Leo radical, compounds **23** and **24**, were prepared and shown, by EPR spectroscopy, to have the quartet ground state.^{53, 54}

4. Triarylmethyl type radicals in polymers

The first successful experiments on the synthesis of polyradicals based on TPMR in polymers were reported by Braun *et al.*^{55–58} and partially surveyed in a review⁵⁹ and a book.⁶⁰ Polymerisation of 4-vinyltriphenylmethanol (**25**) gave poly(*p*-vinyltriphenylmethanol) (**26**), which reacted with acetyl chloride in chlorobenzene to give poly(*p*-vinyltrityl chloride) (**27**). In order to obtain the expected poly(*p*-vinyltriphenylmethyl) radical (**28**), compound **27** was reduced with a zinc–potassium alloy.

Polymer **26** and, correspondingly, polyradical **28** had a degree of polymerisation of 300–350. The highest yield (~ 10 radicals per molecule) was attained when the K/Na alloy was used. Polyradical **28** gave an EPR signal with poorly resolved hyperfine structure (HFS). Poor resolution of the spectrum was attributed to the interaction of radicals at their relatively high local concen-

tration in macromolecular coils in combination with low splitting values for triphenylmethyl type radicals.

The same method was used to prepare poly(4-vinyl-4'-phenyltriphenylmethyl) radical (**29**) and poly(4-vinyl-4',4''-diphenyltriphenylmethyl) radical (**30**). These polyradicals had degrees of polymerisation of 325 and 350 and were formed in yields of 40 and 100 radicals per molecule, respectively (in the reduction of polymers with the K/Na alloy at room temperature in benzene or THF).

In the presence of oxygen, hydrocarbon radicals **28**, **29** and **30** form unstable peroxide radicals such as **31**; these readily react with the initial hydrocarbon radicals to give cross-linked polymeric radicals. For radicals **31**, a narrow smooth singlet was detected in the EPR spectrum (g -factor was not measured).

The use of the K/Na alloy results in high yields of radicals but leads to further reduction of the polymers to give carbanions; when the molecule contains biphenyl fragments, radical anions are formed, which can be detected by EPR and produce well-resolved spectra. The monomeric unit of polyradical **29** forms a doubly-charged radical anion, which can be represented as structure **32**. Unfortunately, Braun *et al.* did not report the electronic spectra of the polymeric radicals, carbanions or radicals but described only the changes in the solution colour during the reduction.

According to the views existing at that time, Braun believed in his early works that the radical centres of the polyradicals dimerise (both inside the coil and between the macromolecules) to give hexaphenylethane structures and that the dimers (non-radical species) and monomers (radicals) occur in equilibrium, which shifts, for example, toward the radicals as the temperature increases. This dimerisation equilibrium giving quinonoid structures can be depicted in the following way:⁶¹

Dimerisation, resulting in a lower concentration of the radicals and giving rise to cross-linked polymers can be diminished by introducing bulky substituent into the *ortho*-position with respect to the unpaired electron. Polyradicals **33**–**37** were prepared⁶² by a route similar to that described above, but chloro derivatives were reduced using mercury in order to stop the reaction after the formation of radicals. The least concentration of spins was found for polyradical **33**, because steric shielding by the methoxy groups

slightly influences dimerisation of the radical centres. This polyradical showed a resolved HFS in the EPR spectrum; this was attributed⁶² to insignificant interaction of the radical centres due to their low concentration. The highest concentration of spins and the highest stability (the radical centres survived for at least several months) were found for polyradical **36**, which had a violet colour in benzene solution. The other hydrocarbon polyradicals obtained by Braun's research group were yellow or reddish. The high stability of polyradical **36** is due to pronounced delocalisation of the unpaired electron over the cyclopentadienyl ring and to steric shielding of the radical centre by five phenyl groups, which cannot fit in the plane of the pentadienyl ring due to the mutual repulsion of hydrogen atoms. The EPR signal for polyradical **36** is a smooth singlet only ~ 4 G wide, whereas for other polyradicals, the signal widths are ~ 10 G. Polyradical **37** was found to be 100% dissociated, fully non-cross linked and fairly stable.⁶²

The polyradicals described above have unpaired electrons in the side chains of polymers. More interesting consequences of the interaction of radical centres in polyradicals should be expected for the case where they are located in the polymer backbone. Braun and Lehmann synthesised^{63,64} a number of polyradicals with triphenylmethyl type radical centers in the backbone. Bis(4-iodophenyl)phenylmethane (**38**) and bis(4-iodo-2,5-dimethylphenyl)phenylmethane (**39**) were prepared⁶³ and used as the starting compounds for the synthesis of polyradicals in which TPMPR are linked by *p*-phenylene bridges. Compounds **38** and **39** were condensed according to Ullmann to give the corresponding polymeric hydrocarbons, which were then brominated with *N*-bromosuccinimide at the tertiary carbon atom. This was

followed by generation of the triphenylmethyl type radicals. The bromo derivative obtained from compound **39** was reduced with mercury to the corresponding polyradical **40**.

Analogous chemical transformations in the case of compound **38** resulted, as expected, in macromolecules **41** containing some triarylmethyl type radical centres apart from the quinonoid structures of the Chichibabin hydrocarbon type. A benzene solution of polymer **40** is yellow, the colour being due to the radicals, while a benzene solution of polymer **41** is deep-blue in thick layer and blue-green in thin layer. This colour was attributed⁶³ to quinonoid structures.

The EPR spectrum of a benzene solution of compound **40** is nearly a singlet (four HFS components can be distinguished) with a total width of 27.5 G; the EPR spectrum of a benzene solution of polymer **41** shows fairly well resolved 16 components with a splitting of ~ 1.5 G, the total width of the EPR signal being 29 G. For the polymers, precursors of polyradicals **40** and **41**, the number-average molecular masses (M) and the average degrees of polycondensation (P) were determined by osmometry: for compound **40**, $M = 2300$, $P = 7$; for compound **41**, $M = 3970$, $P = 15$. Polycondensation of compound **39** was accompanied by an undesirable side reaction, *viz*, cross-linking of fragments through the methyl groups.

In order to avoid side reactions and annihilation of neighbouring radicals in the polymer, Braun and Lehmann synthesised,⁶⁴ by a similar route, polyradicals **42–44** in which the radicals are bound through the *meta*-positions of the phenyl groups.

This gives a polymer with paramagnetic structures such as the Schlenk–Brauns hydrocarbon (**10**) in which, in the Braun's opinion, no formation of a quinonoid structure is possible.

The polymeric precursors of polyradicals **42–44** had average degrees of polymerisation of 5–8 and average molecular masses of 1640–1940. The EPR signal of polyradical **42** in a benzene solution has an overall width of ~ 31 G and splits into (at least) 19 lines; the colour of the solution is dark yellow. The EPR signal of the solution of polyradical **43** in benzene has an overall width of ~ 30 G and a poorly resolved hyperfine structure; the solution is violet. The EPR spectrum of a benzene solution of polyradical **44** has a total width of ~ 31 G and a poorly resolved hyperfine structure, and the solution is red-brown. In the absence of air, benzene solutions of polyradicals are stable for more than a month even in the light. On contact with oxygen, the solutions are rapidly decolourised and no longer give EPR signals. Braun and

Lehmann⁶⁴ were unable to detect spin coupling in the polyradicals, which would produce broadening of the EPR spectra.⁶⁵

Thus, Braun's research group synthesised at least 13 polyradicals of the triarylmethyl type. Among compounds with radical centres in the side groups usually characterised by higher degrees of polymerisation (up to 350) than polyradicals with backbone radical centres, the highest concentration of radicals (nearly 100%) was found for compounds **36** and **37**. In the case of polyradicals with radical centres in the backbone, the degree of polymerisation was, most often, 5–8 and only in the case of compound **41**, it reached 15, *i.e.*, actually the obtained compounds were oligomers, and the yield of radicals in them was not estimated. Usually, the colour was indicated for polyradicals, but, unfortunately, in none of the cases, was the electronic spectrum reported. For all the obtained polyradicals, EPR spectra were recorded. No clear-cut manifestation of coupling (exchange, dipole–dipole, *etc.*) between neighbouring spins was noted for the polyradicals, except for some broadening of the spectral components, resulting in the loss of resolution. Usually, the EPR spectra of the polyradicals resembled the spectra of low-molecular-mass models, differing only in a poorer resolution. However, the loss of resolution in the EPR spectra may also be due to an increase in the viscosity of polymer solutions.

Film-forming cardo polymers, poly(arylenesulfophthalides) (PASP), are quite attractive for the generation of TAMT polyradicals and quinonoid structures; the synthesis and properties of these polymers have been reported.⁶⁶

Poly(biphenylenesulfophthalide) (**45**), poly(fluorenylenesulfophthalide) (**46**) and poly(terphenylenesulfophthalide) (**47**) have been studied; alkaline hydrolysis of compound **45** gives polymer **48**.⁶⁷

We have shown that the action of various physical and chemical factors on these polymers results in generation of the TAMT radicals and the quinonoid structures derived from them. First, the formation of TAMT radicals upon the thermolysis of polymers **45** and **48** was established.^{68, 69} The highest concentrations of the radicals ($\sim 10^{20}$ spin g^{-1}) were achieved for compound **48** at 280 °C and for compound **45** at 320 °C. At this concentration, one unpaired electron per ~ 20 polymer units is present. Upon thermolysis of polymer **48**, coupling of neighbouring TAMT radicals was observed as the formation of blue colour centres with an absorption band at 595 nm, which is attributable to the quinonoid structures like the Chichibabin hydrocarbon.

Quantum chemical PM3 calculations for the model diphenylsulfophthalide (DPSP) molecule show the presence of low-energy vacant orbitals and relatively large positive adiabatic electron affinity (1.76 eV), which should be favourable for the capture of electrons by the sulfophthalide ring. Indeed, DPSP is easily

reduced by hydroxide ions on alkaline hydrolysis in DMSO to give triphenylmethyl radicals, as was detected⁷⁰ by EPR and electronic spectroscopy. The TAMT radicals and the derived quinonoid structures are also formed on the alkaline hydrolysis of PASP,⁷¹ and in the complex system, PASP–aniline–cyclohexanone,⁷² in which the mechanism of their formation is still unknown.

As expected, the reduction of these polymers with alkali metals proved to be an appropriate method for radical generation. The reduction of both dilute ($\sim 10^{-3}$ mol litre⁻¹) solutions of polymers **45**–**47**^{73, 74} and concentrated (~ 0.1 mol litre⁻¹) solutions of polymer **45**⁷⁵ in DMSO with metallic lithium at room temperature has been studied by spectroscopic methods. The results (for compound **45** as an example) can be summarised as follows.

1. The transfer of an electron from the lithium atom to the sulfophthalide ring having high electron affinity results in its dissociation to give a triarylmethyl radical and a salt group (distonic radical anion). The weak absorption band at 410 nm and a singlet in the EPR spectrum with $g = 2.0028$ and $\Delta H = 10$ G were assigned to the TAMT monoradicals. The neighbouring TAMT radicals give rise to the ChH type quinonoid structures responsible for the strong absorption bands at 568 and 350 nm.

2. The reduction of the quinonoid structures and triarylmethyl radicals gives rise to carbanions responsible for an absorption band at 640 nm.

3. This is followed by protonation of the carbanions to give the major final reduction product.

The reduction process of compound **45** comprises a sequence of electron and proton transfer reactions, resulting in a mixture of the intermediate and final products listed above. The ratio of the formation rates of these products ensures a high yield of the ChH type quinonoid structures. The predominant formation of one final reduction product (protonated salt form) attests to a single major reaction route.

The reduction of polymer **46** also gives TAMT radicals and ChH type quinonoid structures. The reduction of compound **47** with lithium does not give quinonoid structures but results in a high content of TAMT radicals ($\sim 100\%$) in the polymer backbone. This fact confirms good prospects of PASP for the synthesis and study of high-spin polyradicals. In the case of polymer **47**, the absorption bands at 430 nm (allowed transition) and 638 nm

(forbidden transition) in the electronic spectrum and a singlet with $g = 2.0028$ and $\Delta H \approx 10$ G in the EPR spectrum were assigned to the TAMT radicals.

The possibility of reduction of films of polymer **45** and three poly(arylene phthalides) in the liquid ammonia–sodium system has been demonstrated.⁷⁶ Polyarylene phthalides are PASP-related polymers in which the labile sulfophthalide rings were replaced by more stable phthalide rings. The sulfophthalide and phthalide rings in these polymers are cleaved by solvated electrons to give TAMT radicals and quinonoid structures of the ChH type, which is confirmed by EPR and electronic spectroscopy. Poly(arylenephthalides) react with the $\text{NH}_3 + \text{Na}$ system more slowly and the radical products of this reaction are less stable than in the case of compound **45**. Apart from TAMT radicals, the reduction of poly(diphenylenesulfophthalide) affords paramagnetic species that produce a singlet EPR signal with $g \approx 2.0028$ and $\Delta H \approx 4\text{--}5$ G , while the reduction of poly(diphenylenephthalide) yields paramagnetic species responsible for a singlet EPR signal with $g \approx 2.0047$ and $\Delta H \approx 4$ G .

Low-temperature (77 K) γ -radiolysis of films of polymers **45–47** also gave rise to EPR singlets with $g = 2.0028$ and $\Delta H \approx 10$ G and electronic absorption bands at $\sim 410\text{--}430$ nm; it is beyond doubt that they refer to the TAMT radicals. In view of the radiolysis mechanism and the properties of PASP, it can be assumed with a high degree of probability that the TAMT radicals are formed upon dissociative capture of secondary electrons by the sulfophthalide ring. Whereas the reduction of compounds **45** and **46** yields mainly quinonoid structures derived from TAMT radicals, radiolysis of these polymers gives rise to single TAMT radicals, which is apparently due to the deficiency of secondary electrons under radiolysis conditions, *i.e.*, the probability that two secondary electrons occur in neighbouring sulfophthalide rings of the macromolecule is low.

It would hardly be possible to obtain practically valuable magnets from the linear polymers [poly(arylenesulfophthalides) and poly(arylenephthalides)] we consider. Nevertheless, the synthesis of relatively stable di- and polyradicals in these polymers is quite realistic. Good solubility in polar solvents and the possibility of their synthesis directly in the polymer films are promising properties of the polyradicals in PASP. Study of the properties of these radicals would evidently contribute to the views on the coupling of unpaired electrons in high-spin systems.

5. The latest achievements in the synthesis of triarylmethyl type polyradicals

a. Carbanionic method of synthesis

Apart from the diradicals mentioned above, Rajca's group (University of Nebraska, Lincoln) prepared a large number of polyradicals based on the Gomberg radical in which record values of the total spin were repeatedly attained. A 'carbanionic' method for the synthesis of triarylmethyl type polyradicals was developed.^{32, 77} According to this method, an appropriate polyether is prepared and reduced with an alkali metal in an ether type solvent (most often, THF) to the polyanion, which is then oxidised with iodine to the polyradical.

The synthesis and the properties of polyanions **49–51** were reported,⁷⁷ and the preparation and some properties of tetraradical **52** and diradical **53** were described.³² Subsequently, Rajca used this method relying on Mataga's ideas on polyradical polymers to synthesise the first plastic magnet in the world.

b. Star-shaped and dendritic polyradicals. The role of defects

Star-shaped homologues of tetraradical **52**, namely, heptaradical **54** and decaradical **55**, having the highest spin states ($7/2$ and 5 , respectively) among the radicals known at that time, have been synthesised.⁷⁸ EPR studies (at 100 K) and magnetic susceptibility measurements by NMR (at 150 K) showed that the heptaradical with $S = 7/2$ and the decaradical with $S = 5$ were the predominant species. The magnetic susceptibility measurements on a SQUID magnetometer gave lower values, $7/2 > S > 5/2$ [radical **54** in 2-methyltetrahydrofuran (MTHF) at $T \geq 5$ K] and $S = 4$ (radical **55** in THF at $T = 10$ K). Presumably, the lack of a noticeable amount of other paramagnetic species (thermal population of low-spin excited states) implies that both polyradicals have high-spin ground states with a strong intramolecular ferromagnetic coupling. Low-temperature magnetic susceptibility measurements for these polyradicals show weak intermolecular antiferromagnetic coupling at $T \leq 5$ K for heptaradical **54** and at $T \leq 20$ K for decaradical **55**. In the study cited, the decrease in the spin has not yet been attributed to the inevitable presence of defects in polyradicals.

Owing to lower sensitivity to defects, dendritic molecules should surpass the usual linear macromolecules as regards the spin order. Nevertheless, dendritic heptaradical **56**, pentadecaradical **57** and polyradical **58** with 31 radical centres synthesised by Rajca and co-workers had average total spins of only 3 , $7/2$ and $5/2$, respectively, instead of the expected $7/2$, $15/2$ and $31/2$.^{21, 22}

Among other reasons, the lower spins may be due to either chemical defects (an atom or a chemical group instead of the unpaired electron) or topological defects (interruption of the ferromagnetic coupling caused by unfavourable spatial arrangement of orbitals with neighbouring unpaired electrons). Generally, the common spin coupling is highly sensitive to both types of defects, as they break the exchange interaction paths. For example, an internal defect present in pentadecaradical **57** divides it into three non-interacting parts with lower total spins, which markedly

Figure 4. Effect of the defects on the total spin S of dendritic pentadecaradical **57**.

Light circles are defects; dark circles are unpaired electrons; lines are ferromagnetic coupling units.

decreases the effective total spin of the whole polyradical (Fig. 4). The peripheral defects have a less pronounced effect on the total spin.

c. Macrocyclic polyradicals

Rajca decided to avoid the problem of defects by designing polyradicals of the macrocyclic calixarene type, which should have low sensitivity to spin defects owing to multiple paths of spin coupling. The calix[3]arene triradical **59** and calix[4]arene tetradical **60** were synthesised.⁷⁹ It is clear that in the presence of one defect in the ring, exchange interaction between the spins is retained. It was found that triradical **59** readily dimerises, probably, due to insufficient steric shielding. The steric shielding in calix[4]arene **60** was sufficient for its stabilisation, and out-of-plane distortions were slight, which allowed the ferromagnetic spin coupling to be retained. It was concluded⁷⁹ that these macrocycles may be suitable as building blocks for polyradicals with low sensitivity to defects.

Highly annulated polymacrocyclic systems are rather difficult to synthesise; however, Rajca's group have obtained, for example, trimacrocyclic tetradecaradical **61** and demonstrated that both π -conjugation and ferromagnetic spin coupling are retained in this

species even in the presence of defects.⁸⁰ A study of this polyradical in the THF- d_8 -MTHF system by SQUID magnetometry gave $S = 6.2$, which is lower than the theoretical value of 7 expected for a strong ferromagnetic coupling of 14 unpaired electrons.

An analysis of the products obtained by quenching of the polycarbanion corresponding to polyradical 61 with methanol showed that the insertion of approximately one deuterium atom per polyradical from the solvent (THF- d_8) is one of the reasons for the appearance of defects and the decrease in the spin. A study of the temperature dependence of the magnetisation showed that the ferromagnetic coupling between the spins is relatively weak, probably, due to the out-of-plane distortion of the π -system. It is

noteworthy that structure 61 can also be represented in a different way (see Section IV.5.d); the picture given here better represents the strain of the system, while the other representation is more economic and reveals more clearly the three rings. In another publication,⁸⁰ where Rajca summarised all his experimental results, he concluded that successful design of 2D and 3D ferromagnets requires that three factors be taken into account: π -conjugation; binding that complies with ferromagnetic coupling; and steric shielding for radical stabilisation. The strategy of organic synthesis should meet these conditions.

d. Spin clusters based on triarylmethyl type radicals

In principle, any polyradical can be considered as a spin cluster, as was actually done by Rajca in his early works where he analysed the spin states of the synthesised TAMT di- and polyradicals using the Heisenberg Hamiltonian. Subsequently, it has been proposed^{81,82} to design high-spin organic polyradicals as simple spin clusters consisting of high-spin modules with strong intra-module ferromagnetic coupling J' connected to each other by relatively weak inter-module ferromagnetic coupling J , the J value being comparable in magnitude with the thermal energy, *i.e.*, $J' \gg J \approx kT$. This splitting into modules and the introduction of a hierarchy of exchange interactions markedly simplified the problem of determination of the energy spectrum of the cluster (polyradical) and, hence, analysis of its magnetic characteristics (magnetisation, susceptibility, *etc.*). To construct high-spin clusters from the macrocyclic and dendritic blocks proposed previously in which 1,3-phenylene or benzene-1,3,5-triyl units were used as 'strong' FCU, Rajca chose biphenyl-3,4'-diyl bridges 62 as an alternative to *meta*-phenylene bridges. In a study of the properties of diradical 9, it was found that units 62 are ferromagnetic with weak coupling capable of additional stabilisation of radicals.³⁷ The properties of diradical 11 imply that the biphenyl-3,3'-diyl bridge 63 is an antiferromagnetic coupling unit, which, however, can also be used to construct ferrimagnetic high-spin clusters.

Using the Suzuki cross-coupling,⁸³ Rajca and co-workers synthesised⁸² spin clusters **64**–**67**, in which the intra-module ferromagnetic coupling through 1,3-phenylene units was much stronger than the inter-module coupling through biphenyl-3,4'-diyl (or biphenyl-3,5,4'-triyl) units. An estimate based on the hyperfine coupling in the triphenylmethyl and (biphenyl-4-yl)diphenylmethyl monoradical gives $J:J' \approx 1:6$. In addition, Rajca carried out energy scaling for the inter-module ferromagnetic coupling J'' in each cluster, according to the approach described earlier.⁸⁴ This scaling takes into account the number of coupling paths (1 path for biphenyl-3,4'-diyl and 2 paths for biphenyl-3,5,4'-triyl units) and the fraction of directly interacting spins from neighbouring modules. Polyradicals **64**–**66** have only one site where a single defect can interrupt the spin coupling, whereas polyradical **67** has two such sites. This can potentially be a hexadecaradical with $S = 8$; according to magnetic measurements, the spin value was high, $S = 7.2$, *i.e.*, the yield of generation of unpaired electrons for this polyradical reached 98%. Subsequently, using the Negishi cross-coupling reaction,⁸⁵ polyradical **68** with the total spin $S = 10$ was synthesised.⁸⁶

Four dendritic branches and the macrocyclic core of this polyradical form a ferromagnetically coupled pentamer, four terminal modules of which have $S = 5/2$, while the central fragment has $S = 2$. Theoretically, the total spin of polyradical **68** should be equal to 12. The dependence of magnetisation M on the H/T value (H is the magnetic field strength, T is temperature) gives $S \approx 10$ at 5 K. At that time (1998), this was the record-breaking value of the total spin.

More recently, spin clusters **61**, **69**–**74** based on TAMT radicals were synthesised and the properties of these clusters and the corresponding polyether precursors were studied.^{87–89}

The polyether precursors of the polyradicals were obtained by a multistep block-synthesis in which the key step was the Negishi cross-coupling of four monofunctional dendritic blocks with modules and a tetrafunctional calix[4]aryl-containing macrocyclic core for (compounds **68** and **72**), of difunctional calix[4]arene-containing macrocycles (for annulated structures **61**, **69** and **70**) and of mono-, di- and tetrafunctional calix[4]arene-containing macrocycles with (aryl)bis(4-halophenyl)methoxymethyl linking units (for polyradicals **71**, **73** and **74**). The target polyethers were isolated from the reaction mixtures by chromatography. The corresponding polycarbanions were then synthesised and oxidised to polyradicals in THF-*d*₈. The polyradicals thus formed were classified as spin clusters, their structures are given near the formulas. Some properties of these clusters and the starting polyethers are summarised in Table 2. The saturation magnetisation and the magnetic susceptibility values for all polyradicals reported in the studies cited^{87–89} indicate that $\sim 40\%$ – 60% of unpaired electrons are present at low temperatures ($T = 1.8$ – 5 K) and confirm the presence of high-spin ground states. Analysis of the S values and the mole fractions of the unpaired electrons (M_{sat}) suggests that ferromagnetic coupling predominates in these polyradicals. Nevertheless, significant antiferromagnetic coupling is also present and, together with chemical defects, it decreases the S and M_{sat} values with respect to the theoretical ones. It is believed that detailed interpretation of magnetic measurements becomes more complicated due to the possible presence of conformations with different exchange (ferro or antiferro) interactions, different methods of averaging for the measured values (S , M_{sat} and χT) and the possibility of incomplete transfer of the sample mass during experiments. In some cases (for polyradicals **68** and **72**), the magnetic data are described satisfactorily by the Heisenberg model for magnetic interactions in the cluster. For polyradical **70**, the magnetic characteristics

varying with temperature also comply with the model based on the Heisenberg Hamiltonian; however, this model is no longer applicable to the description of low-temperature data varying with

the magnetic field. In relation to spin trimer **73** and pentamer **71**, a two-parameter percolation model of organic spin clusters with a chaotic distribution of chemical defects and alternation of ferro-

^a $[M-\text{OMe}]^+$ is the mass of the positive ion formed upon abstraction of one ether group in the fast atom bombardment mass spectrum of the polyether;

^b R_g is the rotation radius of the polyether molecule determined in small angle neutron scattering (SANS) experiments; ^c S_{exp} is the average total spin of the polyradical determined mainly from representation of the SQUID magnetometry data by a linear combination of the Brillouin functions; ^d S_{theor} is the maximum possible total spin of the polyradical under ferromagnetic coupling of unpaired electrons, the values in parentheses represent the numbers of possible triarylmethyl fragments in the polyradical, i.e., the greatest number of unpaired electrons; ^e M_{sat} is the saturation magnetisation (a 1 μ_B value corresponds to one unpaired electron per triarylmethyl fragment); ^f χT_{max} is the maximum value of the product of the magnetic susceptibility into temperature in the χT vs. temperature curve; ^g M_w is the weight average mass of the polyether determined by gel permeation chromatography with large angle light scattering; ^h J/k is the spin–spin coupling constant corresponding to pair interaction of spin cluster components in the Heisenberg model; for polyradical **70**, the possibilities of both fully ferromagnetic and fully antiferromagnetic coupling (data in parentheses) were considered; ⁱ for information about this compound, see Section IV.5.e.

magnetic and antiferromagnetic coupling has been developed.⁸⁷ This model ensures a quantitative agreement between the experiment and the theory both for the clusters in question and for other spin clusters studied previously.^{87–89}

The value $S = 13$ achieved for nonamer **74** is now the record value for organic molecules.

For polyradical **68** (with the average spin $S = 10$), the size and the shape were estimated by the SANS method (see Table 2); the barrier to magnetisation reversal [Eqn (1)] determined by the shape anisotropy is rather low (about 0.001 K). It has been assumed⁸⁷ that macromolecular polyradicals with S values of about 10^3 – 10^4 similar to polyradical **68** as regards the shape and spin density distribution would behave as SMM at easily attainable temperatures $T > 2$ K.

e. Polymeric polyradicals of the triarylmethyl type

It is clear from the preceding sections that Rajca's group achieved great progress in the synthesis of diradicals and clusters; however, the synthesis of macromolecular polyradicals like the Mataga polymer **19** still remained the main goal of researchers. In 1993, high-spin linear polymer **75** was obtained.⁹⁰

Polyradical **75** was generated by the carbanionic method from polyarylmethane polymer **76** containing ~ 30 triarylmethane centres per macromolecule. The EPR spectrum of compound **75** recorded in MTHF or THF at 4 K in the region of $\Delta m_s = 1$ is a singlet; a weak signal is observed at $\Delta m_s = 2$, which implies the presence of high-spin species with $S \geq 1$. Magnetisation measurements for solutions of polyradical **75** at 10 K give $S = 2$, which indicates ferromagnetic interaction of at least four unpaired electrons, although some length distribution of exchange-coupled segments exists most likely in the polymer chain. The interruption of spin interactions in the chain is due to defects, which may be caused by partial protonation of polycarbanion **77**, its oxidation, intra- or intermolecular cross-linking of polyradical **75**, etc. This case clearly demonstrates the sensitivity of linear chains to chemical defects; it is this fact that stimulated Rajca to turn subsequently to dendritic and macrocyclic polyradicals. It was also found that at 5 and 2 K, $S < 2$. The decrease in the 'effective' spin of the polymer at low temperatures was attributed to the antiferromagnetic coupling between polymer chains. The same coupling results in a negative deviation of the plot for the product of magnetic susceptibility and temperature vs. temperature from a straight line at $T < 10$ K. This was the only attempt of Rajca's group to synthesise a linear one-dimensional triarylmethyl type polyradical.

A ferromagnetic–ferrimagnetic coupling scheme based on the non-equivalence of spin modules in the clusters has been used⁸⁹ to prepare two high-spin polymers **78** and **79** containing calix[4]arene macrocycles.

Polymer **78** in which macrocycles with $S = 3$ are linked by bridges with $S = 1/2$ can be regarded as a 'quasi-linear' chain of inequivalent spins with $S = 3$ and $S = 1/2$. It was found that polyradical **78** obtained from polyether with $M = 30\,000$ is characterised by an average S 18 at low temperatures. This value differs substantially from S of about 50–60, which would be expected if all the unpaired electrons were involved in ferromagnetic coupling and if no chemical defects were present. However, $S \approx 18$ is still higher than the best value $S \approx 5$ attained for other high-spin organic polymers. Some characteristics of polymer **78** are also presented in Table 2.

f. The first plastic magnet

Similarly to polymer **78**, the cross-linked polymer **79** can be considered as a network of non-equivalent spins, in particular, macrocyclic modules with $S = 2$ and linking modules with $S = 1/2$. The polyradical **79** synthesised⁹¹ from the soluble fraction of the polyether with $M = 300\,000$ – $500\,000$ has on average $S \geq 40$. The S value for polymer **79** obtained from insoluble polyether fractions which form a gel with THF- d_8 depends on the polymerisation time after gelation. If polymerisation stops near the gelation point (10–30 min), polymer **79** has $S = 600$ – 1500 ; for longer polymerisation times (5 h), the values $S = 3000$ – 7000 were attained.⁹² It was found that at low temperatures, $\sim 50\%$ of unpaired electrons are present. This fact is consistent with the views on inevitable presence of chemical defects and with the scheme of combination of ferro- and ferrimagnetic coupling. It should be borne in mind that structure **79** is rather arbitrary, as macrocyclic modules may form diverse structures during condensation and detailed analysis of the final insoluble polymer is almost impossible. In particular, polyradicals **61**, **69**–**74** have been considered^{87–89} as possible fragments of a plastic magnet **79**.

Conjugated organic polymer **79** was the first to exhibit magnetic properties other than merely paramagnetism. The magnetic ordering in this polyradical is switched on at ~ 10 K; for a typical sample with $S = 5000$, a sharp increase in the magnetisation (by two orders of magnitude) is observed. Below 10 K, magnetisation increases very rapidly with strengthening of the applied magnetic field and almost reaches saturation at relatively low fields. The saturation magnetisation for polymer **79** is ~ 10 emu g^{-1} , which is close to the paramagnetic saturation magnetisation for the poly(arylmethyl) polyradicals prepared previously. At a zero and low magnetic fields (about the Earth magnetic field), magnetic blocking was found, i.e., a substantial barrier to the magnetisation reversal was observed. Magnetic susceptibility studies in alternating fields gave a barrier of ~ 15 K and showed that very high magnetic moments ($S \approx 5000$) are frozen at low (≤ 10 K) temperatures with some degree of ordering (cooperativity). Generally, the magnetic properties of polymer **79** can be classified as being intermediate between the properties of non-conducting spin glasses and blocked superparamagnets but they are closer to spin glasses.⁹² As regards the magnetic behaviour, polymer **79** resembles known organic low-molecular-mass magnets, although the temperature of ordering in the polymer is higher.

6. Perchlorinated triarylmethyl type di- and polyradicals

Ballester^{93,94} has shown that perchlorinated di- and triphenylmethyl radicals synthesised by his group are fully monomeric both in solution and in the solid state and have high thermal stability and unique chemical stability, due to the essential localisation of the unpaired electron on the central carbon atom and considerable steric shielding of this atom. The first perchlorinated diradicals **80**⁹⁴ and **81**,⁹⁵ which are as chemically inert as the monoradicals, were also obtained.

The electronic spectrum and the EPR spectrum of compound **80** do not virtually differ from the corresponding spectra of the perchlorinated TPMR; in particular, the EPR spectrum of this diradical does not manifest the magnetic dipole–dipole coupling. Thus, the radical centres in diradical **80** do not interact with each other, despite their relative geometric proximity. This fact can be attributed⁹⁶ to the perpendicular arrangement of the benzene rings in the biphenyl bridge and, correspondingly, complete elimination of the conjugation between the unpaired electrons. Apparently, the localisation of unpaired electrons highly pronounced for perchlorinated radicals also plays a role, because partially chlorinated diradical **82** in which the benzene rings in the bridge are also nearly perpendicular has a singlet ground state (Table 3) and its EPR spectrum does exhibit⁹⁷ magnetic dipole–

Table 3. Some properties of perchlorinated and mixed di- and triradicals of the triarylmethyl type.

dipole interaction for thermally excited molecules in the triplet state.

The interaction between the ‘halves’ of diradical **82** is also manifested in a bathochromic shift of the absorption bands in its electronic spectrum with respect to the spectrum of the model monoradical. In the vinylene perchlorinated diradical **81**, the steric restrictions are less pronounced (the benzene rings in the bridge are not perpendicular) and in this case, spin–spin exchange can be observed as a twofold decrease in the coupling constant of the unpaired electrons with the ¹³C nuclei.

Naturally, Ballester’s followers (Veciana’s group) proposed^{98, 100, 103} a strategy for the synthesis of linear and dendritic perchlorinated polyradicals of types **83–85** as a possible base of organic magnets.

Radicals **86–90** have been synthesised and studied by spectroscopic and magnetic methods (see Table 3). Mixed diradicals **86** and **87** in which perchlorinated triphenylmethyl radical centres are connected by hydrocarbon bridges retained the thermal and chemical stability typical of perchlorinated radicals but the intramolecular magnetic dipole and exchange interactions of the unpaired electrons in them proved to be fairly weak.^{98, 99} The nature of the ground state for diradical **87** has not been elucidated;⁹⁸ for diradical **86**, the ground state is singlet, however, according to another publication,⁹⁹ the nature of the ground state cannot be regarded as definitely established for both diradicals. The greater *D* value and the greater bathochromic shifts of the absorption bands in the electronic spectrum of diradical **86** compared to diradical **87** are believed⁹⁸ to be due to more pronounced delocalisation of unpaired electrons with *para*-bridg-

ing. The weak spin coupling in these diradicals is obviously due to the large length of the bridges, which actually comprise three benzene rings and two double and four single bonds. In the AM1-optimised structures of the diradicals, the through-space and through-bond distances between the radical centres are 18.8 and 24.1 Å, respectively for diradical **86** and ~16 and 22.7 Å, respectively, for diradical **87**. It is worth noting that the distance between the spins determined from the parameter D in the point dipole approximation is 19 Å for diradical **86** and 22 Å for diradical **87**, *i.e.*, electron delocalisation in the *para*-coupled divinylphenylene bridge reduces the effective separation of spins in **86**.⁹⁹ Subsequently, diradicals **88**, **89** and triradical **90** in which the unpaired electrons were located much more closely to each other than in **86** and **87** have been prepared.^{100, 101} Radicals **88–90** were prepared by oxidation with chloranil of the corresponding carbanions, which were generated by treatment of hydrogen-containing precursors with $\text{Bu}_4\text{N}^+\text{OH}^-$. The presence of bulky *ortho*-chlorine atoms in the di- and triradicals thus formed brings about great steric restrictions to the rotation of pentachlorophenyl groups, which results in coexistence of various stereoisomers separated by high energy barriers (~24 kcal mol⁻¹). Full stereochemical analysis of compounds **88–90** was carried out; signals of separate conformers were identified in the experimental EPR spectra. Interpretation of the spectra was possible by virtue of isolation of the conformers by chromatography or recrystallisation. EPR spectroscopy and magnetic susceptibility and magnetisation measurements have shown that all conformers of these radicals have high-spin ground states, which are separated from the low-spin excited states by energy barriers substantially exceeding 200 cm⁻¹. For example, diradical **89** has a triplet ground state and is stable in air up to 250 °C. Thus, intramolecular exchange interactions in these radicals are ferromagnetic, *i.e.*, in this case, the perturbation by electronegative heteroatoms, the loss of planarity and symmetry changes have only a slight influence on the exchange interaction. It was concluded^{100, 101} that the topological model developed for planar and unsubstituted alternant hydrocarbons may be applicable to highly distorted and substituted systems. However, as we have demonstrated above for the hydrocarbon diradical **6**, this is not always the case. Later, the limitations of this conclusion have been manifested in an attempt to synthesise a perchlorinated tetradiradical (see below).

Veciana's group has synthesised and studied¹⁰² diradical **91** consisting of two perchlorinated triphenylmethyl radicals linked by a ferrocene-1,1'-diyldivinyl bridge. A study of the temperature dependence of the intensity of the EPR signal of this diradical showed that it has a triplet ground state; the triplet–singlet splitting was determined using the Bleaney–Bowers equation.¹⁰⁴ Rather unexpectedly, weak antiferromagnetic coupling was manifested even in diradical **92** (Ref. 105) in which the distance between the radical centres reaches ~4 nm.

Attempts to synthesise perchlorinated polyradicals with $S > 3/2$ have faced so far inextricable difficulties due to steric overcrowding of polychlorinated compounds. The precursor of the dendritic perchlorinated TAMT tetradiradical **93** was synthesised with great difficulty;¹⁰³ however, the attempts to obtain appreciable amounts of the tetradiradical from this precursor have failed due to the formation of numerous chemical defects.

Subsequently, these results were critically re-evaluated¹⁰⁶ and it was concluded that a tetradiradical in the chemical sense, *i.e.*, as a species containing four unpaired electrons, was actually synthesised in a high yield, but its quintet state with $S = 2$ was not

manifested due to the magnetostructural (topological) defects, *i.e.*, transformation of a large portion of *meta*-phenylene FCU into ACU, which took place due to steric crowding of molecules **93**. This is why magnetic measurements for these compounds reveal mainly (96%) triplet species with $S = 1$ (Ref. 106).

Unfortunately, the works on the synthesis of perchlorinated polyradicals have not been further developed as yet. Instead, another line of the use of polychlorinated stable radicals in the design of new magnetic materials is being actively developed. According to one more approach existing in the design of molecular magnets,¹⁰⁷ paramagnetic metal ions are combined with purely organic radicals, most often, iminoxyl radicals, as ligands. Four copper(II) complexes containing perchlorotriphenylmethyl radicals with carboxyl substituents as ligands have been prepared.¹⁰⁸ Magnetic susceptibility and magnetisation measurements for all complexes have shown the presence of fairly strong antiferromagnetic coupling between Cu(II) ions and two coordinated radicals. For example, for complex **94**, presentation of the magnetic data in the three-spin linear model gave $J/k_B = -24.9$ K.

Moreover, perchlorotriphenylmethyl radicals with three carboxyl groups as substituents were used to create¹⁰⁹ a polymeric magnetic nanoporous material $[\text{Cu}_3\text{L}_2(\text{py})_6(\text{EtOH})_2(\text{H}_2\text{O})]_n$ in which the presence of large pores with linear dimensions of ~3 nm was combined with ferrimagnetic ordering at low temperatures (the structure of ligand **L** is shown below).

7. Mixed-valence compounds based on triarylmethyl type radicals

As shown above, almost all methods for the preparation of TAMT di- and polyradicals are related to the reduction of molecular precursors and oxidation of the resulting carbanions. These reactions often yield mixed-valence organic compounds in

which intramolecular electron transfer (IET) is possible. The problem of intramolecular electron transfer in mixed-valence compounds and examples of this transfer in coordination and purely organic compounds have been discussed in a review.¹¹⁰

The transition from the diradical to doubly charged anion (and back) upon consecutive addition (abstraction) of electrons can be represented as follows:

In the case of carbon-centred radicals in compound II on the left (anion), carbon is tetravalent while on the right (radical) it is trivalent, *i.e.*, this is a mixed-valence compound.

Ballester *et al.*^{96,111} prepared the reduced (**95**) and oxidised (**96**) forms of diradical **80**, which retained the thermal and chemical stability.

The twofold decrease in the ¹³C coupling constants in the EPR spectra of compounds **95** and **96** with respect to the spectra of mono- and diradical shows the spin and charge delocalisation on an EPR time scale, *i.e.*, in these mixed-valence compounds, the perpendicular arrangement of the benzene rings in the biphenyl bridge does not prevent electron delocalisation.

A study of the HFS of the EPR signals of radical anions **97a** and **98** in the temperature range of 100–300 K indicates¹¹² that the unpaired electron spin density in the 1,3-coupled radical anion is localised on one triarylmethyl fragment, while in the 1,4-coupled radical anion it is delocalised over two triarylmethyl fragments. It was concluded that the arylmethyl fragments are strongly coupled through 1,4-phenylene and weakly coupled through 1,3-phenylene. The problem of the nature of the absorption bands in the electronic spectra of compounds **97a,b** at 740 and 770 nm, respectively, remains open, although it cannot be ruled out that they refer to electron transfer bands. Some properties of radical anions **97** and **98** are presented in Table 4.

R = H (a), Prⁱ (b).

A question has been raised¹¹³ of how an electron added to a chain of exchange-coupled (ferro- or antiferromagnetically) spins affects the interaction of the remaining unpaired electrons. This type of anionic defects can evidently occur in 'incompletely

Table 4. Properties of radical ions based on triarylmethyl type diradicals.¹¹²

oxidised' polyradicals obtained from polyanions. To answer this question, oligomeric radical anions **99–102** were specially prepared and studied (Table 5).

R = H (a), Me (b), Prⁱ (c).

R = H (a), Me (b), Prⁱ (c).

First, it was found that in all these compounds, the charge and the spin are localised on particular triarylmethyl fragments, as in compound **97a**. Second, it was demonstrated that if the charge (electron pair) is localised on a terminal fragment (compounds **100**, **101**), ferromagnetic coupling of the remaining unpaired

Table 5. Model oligomeric radical anions of the triarylmethyl type.¹¹³

^a The $|\Delta E_{\text{ST}}|$ value (kcal mol^{-1}) is given in parentheses.

electrons is retained. However, if the charge is concentrated on the central fragment (compound **102**), the remaining unpaired electrons are involved in antiferromagnetic coupling. Thus, spin coupling can be controlled by controlling charge localisation. Having summarised his own results and Ballester's data on radical ions **95** and **96**, Rajca put forward a hypothesis³ that ferromagnetic or antiferromagnetic coupling in the starting polyradicals leads to electron localisation or delocalisation, respectively, in the obtained radical ions.

In view of the electron localisation in the 1,3-coupled compounds, Rajca proposed¹¹² the following mechanism for their reduction with metallic lithium:

Presumably, intramolecular electron transfer processes would play an important role in the reduction of 1,4-coupled compounds.

X is an electron-withdrawing leaving group.

This scheme does not show the formation of the quinonoid structure from the diradical. For the radical anion, the IET results in spin and charge delocalisation over two positions. Note that this scheme does not contradict the putative mechanism of the electroreduction of dihalo-*p*-xylenes.¹¹⁴ In particular, the IET should apparently be taken into account when investigating the reduction of poly(arylenesulfophthalides) and poly(arylenephthalides) containing biphenyl-4,4'-diyl and fluorenediyl bridges.

The IET processes were found for compounds **103–105** (Table 6) in which the perchlorinated triphenylmethyl carbanion acts as the electron donor, while the perchlorinated triphenylmethyl radical is the electron acceptor.

Table 6. Properties of the radical anion systems based on perchlorinated triarylmethyl type radicals.

Com-pound	Ground state	a_{H} and a (^{13}C)/G	λ_{max} /nm	λ_{ET} /nm	V_{ab} /cm $^{-1}$	Ref.
103	T	—	368 508	~2900	320	115
104	D	—	368 508	~2900	390	115
105	D	1.9 (1H)	—	1400	121	99
106	D	1.8 (2H) 0.6 (2H)	—	none	—	99
107	D	—	—	none	—	116
108	D	1.6 (1H) 29.3 (C_α)	—	none	—	103, 116

In the near-IR region, broad intensive electron transfer bands typical of mixed-valence compounds were observed.¹¹⁰ With known peak position (λ_{ET}) and the extinction coefficient at the peak, one can find the electron coupling parameter V_{ab} using the Hush formula. Compound **103** is the first example of a purely organic mixed-valence compound in which intramolecular electron transfer was found in addition to the high-spin ground state. In the case of compound **105**, a thermally activated IET was also observed⁹⁹ by EPR in the temperature range of 200–300 K, the activation barrier being 0.117 eV. For radical anions **106–108**, no intramolecular electron transfer was found.

It can be seen from a comparison of compounds **105** and **106** that a *p*-phenylene fragment present in the bridge facilitates the electron transfer, while a *m*-phenylene fragment hampers the electron transfer, which is consistent, to some extent, with Rajca's data presented above. It is noteworthy that the problem of intramolecular electron transfer is tightly connected with the search for appropriate molecular wires for the various molecular devices;^{110, 116} meanwhile, the bridges in compounds **103–105** can be regarded as molecular wires.

V. Conclusion

Polymeric polyradical **79** can apparently be considered to be the world first polymeric organic magnet. It took almost a hundred years to create such a magnet based on the first discovered stable hydrocarbon radical (the Gomberg radical). Generally, the

achievements of Rajca's research group represent an example of deliberate consecutive work and the use of the whole power of the advanced methods of organic chemistry and physical techniques for substance investigation; however, these would be impossible without the preceding research into the TAMT mono-, di- and polyradicals.

Of course, Rajca's plastic magnet has only feebly pronounced magnetic properties and is far from being suitable for practical purposes. However, the ordering temperature of ~10 K is relatively high for organic magnets and confirms the great potential of the macromolecular approach to their design. The unavoidable presence of chemical and topological defects in the TAMT polyradicals also precludes the formation of ensembles of identical single-molecule magnets from these polyradicals. It is clear that the design of practically useful magnets requires the use of more stable radicals and the existence of magnetic ordering at room (or higher) temperature. A consistent application of Rajca's strategy to the synthesis of inert perchlorinated TAMT polyradicals may give organic magnets stable at room temperature; however, no data concerning any studies along this line are available to date.

As we have seen, the unsolved problems remain also in the studies of TAMT diradicals, even the best known ones such as the Chichibabin, Muller and Schlenk–Brauns hydrocarbons.

As regards the problem of organic magnets as a whole, it is quite possible that practically valuable organic magnets will be obtained in a quite unexpected way, for example, in the way the magnetic order was found at room temperature for the tetracyanoethylene complex with polyaniline.¹¹⁷ However, it must be remembered that the magnetic properties of organic compounds are often due to ferromagnetic impurities (known examples can be found in a review¹).

The author is sincerely grateful to Academician A L Buchachenko for attentive reading and useful discussion of the review.

Formazans and their metal complexes

G I Sigeikin, G N Lipunova, I G Pervova

Contents

I. Introduction	885
II. Structure of formazans	885
III. Synthesis and properties of formazan derivatives	889
IV. Formazan complexes with metals: structures and applications	893
V. Formazan-containing polymers	897

Abstract. The current data on the structure of formazans in crystals and in solutions are considered and some problems of tautomeric and conformational equilibria are discussed. Some novel classes of formazans synthesised over the past decade are presented. The results of structural studies of formazan complexes with various types of metal coordination are generalised. Examples of synthesis of formazan-containing polymers are given. Special emphasis is placed on analytical and practical applications of formazan derivatives. The bibliography includes 155 references.

I. Introduction

Studies into tautomerism and complexation of heterocyclic compounds are among the main lines of research at the Urals school of organic chemists founded by I Ya Postovsky. The main results and achievements in the chemistry of formazans have been surveyed.^{1,2}

Formazans were first synthesised over a century ago, but still attract attention of chemists, biologists, technologists and other specialists. The presence in formazans of a mobile π -system, the ease of redox reactions typical of these compounds, their ability for isomerisation and tautomeric transformations and enhanced acidity and basicity have determined the main areas of their practical applications. Formazan derivatives are widely used as dyes for different purposes, charge-generating compounds, biochemical markers for redox processes, analytical reagents, photo- and thermochromic materials and synthons for the synthesis of heterocyclic compounds. The data on the structures, properties

and applications of the known formazans and methods for their synthesis published before 1992 are generalised in a monograph.² However, the results of recent studies allow the consideration of problems of tautomerism and isomerism of this class of compounds at a higher level. Despite the large number of novel formazan derivatives synthesised over the last years, the number of publications devoted to the examination of chemical properties of these compounds is very limited. The interest of investigators was mainly focused on the description of different modes of coordination of formazans with metals and their novel applications. Therefore, the aim of the present review is to elucidate the state-of-the-art in theoretical and applied aspects of the chemistry of formazans.

II. Structure of formazans

Formazans represent compounds with an azohydrazone system of bonds:

This review is confined exclusively to the consideration of formazan derivatives with $R^4 = H$ among which 1,3,5-trisubstituted formazans have been studied in especially great detail. Traditionally, substituents at the N(1) and N(5) atoms are designated as R^1 and R^5 , and those at C(3) (which is also referred to as the *meso* position), as R^3 . Substituents in the formazan fragment are enumerated in the ascending order of the atom numbers in the azohydrazone chain; if the position of the substituents at the N(1) and N(5) atoms is not exactly known, they are additionally designated by numbers in parentheses. These rules will be followed in this review.

The molecules of all currently known formazans manifest extremely high conformational and tautomeric mobilities, the types of their isomerism being dependent on the nature of the substituents, first of all, those at the N(1) and N(5) atoms. Thus *N,N'*-diarylformazans **1** are characterised by prototropic tautomerism of the type R^5NH (compound **1a**) $\rightleftharpoons$ R^1NH (**1b**).

Received 15 May 2006

Uspekhi Khimii 75 (10) 980–997 (2006); translated by R L Birnova

$R^1, R^5 = \text{Ar}$.

If an α -azaheterocyclic substituent is linked to one of the nitrogen atoms of a formazan (compound **2**), an additional amine–imine tautomerism is observed, which involves the nitrogen atom of the heterocycle (**2a** $\rightleftharpoons$ **2b** $\rightleftharpoons$ **2c**).

Some types of formazans, *e.g.*, the well-known analytical reagent dithizone (1,5-diphenyl-3-mercaptoformazan), are subject to autoprotonation. *N*(5)-Acylformazans are also characterised by the presence of rotamers due to hindered rotation around the $N(5)–C=O$ amide bond. Besides, the system of double and single nitrogen–nitrogen and carbon–carbon bonds is responsible for different spatial arrangement of the fragments relative to one another, which determines the existence of geometric isomers.

Thus, structural studies of formazans consist in elucidating the prototropic equilibrium between possible tautomeric forms and analysing configurational isomerism.

1. Spatial structure of formazans

The presence in the formazan chain of two multiple bonds and the $N(5)$ atom with a lone electron pair brings about the formation of an overall conjugated system. This leads to an increase in the order of the $N(2)–C(3)$ and $N(4)–N(5)$ bonds and in the height of the rotation barrier around them. Therefore, the configurations of all the bonds in the formazan fragment are designated in terms of the *Z,E* nomenclature.²

X-Ray diffraction studies of a large series of formazans revealed³ three configurational combinations in the azohydrazone chains in the crystals, *viz.*, *EZZ*, *EEZ* and *EEE* [hereinafter, this refers to the bond sequences $N(1)–N(2)$, $N(2)–C(3)$ and $C(3)–N(4)$, respectively] (Scheme 1).

The configuration of formazans is largely determined by the steric effect of the substituent at the *meso*-carbon atom. Thus *EZZ* isomers (structure **A**) are characteristic of formazans with a bulky substituent R^3 (Ph, Bu^t, NO₂, *etc.*).^{3,4} For example, the chain of 1-phenyl-3-(4-bromophenyl)-5-(2-pyridyl)formazan (**3**) in crystals has an *EZZ* configuration.⁵

If the *meso*-carbon atom of formazan contains an alkyl substituent, the crystals can adopt both the *EEE* (structure **C** in Scheme 1) and *EEZ* (structure **B**) configurations. This can be attributed to the fact that the steric demands of these substituents and the phenylazo group are comparable. X-Ray diffraction data

for formazans³ suggest that these compounds exist in crystals exclusively as individual geometric isomers. However, co-crystallisation of 1-(*o*-tolyl)-3-methyl-5-(benzimidazol-2-yl)-formazan **Z** (**4a**) and *E* isomers (**4b**) relative to the $C=N$ bond (Fig. 1) has been observed.⁶

In the crystal lattices, both isomers form dimers, where the molecules are linked by an intermolecular H-bond between the hydrogen atom at the $N(5)$ atom and the nitrogen atom of the heterocycle; in addition, the molecule of compound **4a** contains an intramolecular H-bond with a length of 2.234 Å (see Fig. 1).

It is of note that formazans devoid of substituents at the $C(3)$ atom exist in crystals exclusively in the form of *EEE* isomers.²

The configuration of the azohydrazone chain in crystals of formazans is determined not only by the bulk of the substituent at the carbon atom, but, to a large extent, by the possibility of hydrogen bonding which stabilises their geometric structures.

Figure 1. Molecular structure of compound **4**.

Thus the *EZZ* configuration of formazans is stabilised by the intramolecular N(1)⋯HN(5) hydrogen bond in the six-membered ring (see structure **A** in Scheme 1), the *EEZ* isomer is stabilised by the N(2)⋯HN(5) bond in the five-membered ring (see structure **B**), while the *EEE* form is stabilised by intermolecular H-bonds. In *N*-azaheterocyclic formazans, which crystallise in the imino tautomeric form, the intramolecular N(4)⋯HN(heterocycle) H-bond provides additional stabilisation.⁷

A prominent role in stabilisation of one or another configuration of the formazan molecule is played by H-bonds with atomic groups in peripheral substituents. These include not only NH, OH or SH groups, but also CH groups. π -Interactions of aromatic rings with the heteroatom are also possible. For example, a significant role in stabilisation of the *EZZ* form of 3-arylformazans is played by two CH⋯N hydrogen bonds between the *ortho*-protons of the aryl fragment and the nitrogen atoms of the formazan chain (structure **5**). The replacement of the naphthalene rings ($R^1 = R^5 = 1$ -naphthyl) at positions 1 and 5 of compound **5** ($R^1 = R^5 = \text{Ph}$) with benzene rings did not influence the configuration of the molecule (the *EZZ* form), while the passage from 3-phenyl- to 3-naphthylformazans resulted in a shift of the tautomeric equilibrium towards the formation of an open form.² At the same time, the introduction of a hydroxy group into the *ortho* position of the *meso*-phenyl substituent (compound **6**) provided additional stabilisation of the *EZZ* isomer due to formation of an intramolecular H-bond.⁸

It is noteworthy that no compounds with the *EZE* configuration of the formazan chain are known so far. Apparently, such isomers would be energetically unfavourable due to repulsion between the lone electron pairs at the N(1) and N(4) atoms, whereas this configuration is rather common in metal complexes of formazans.²

Recently, theoretical data on the structures of unsubstituted and 3-nitro-substituted formazans, which are unstable under ordinary conditions and could not be prepared experimentally, have been obtained.⁹ The results of *ab initio* quantum-chemical calculations of all possible conformations of these compounds suggest that the *EZZ* configuration is the most stable (at least, in the gas phase). To a large extent, this structure is stabilised by a bridging N—H⋯N hydrogen bond in the six-membered chelate ring where proton transfer is possible. However, according to X-ray diffraction data, 3-unsubstituted 1,5-diphenylformazan (**7**) has the *EEE* configuration in crystals.³ Evidently, the formation of the crystal lattice is controlled by other factors the effects of which have not been taken into account in the quantum-chemical calculations.

The knowledge of spatial structures of arylformazans in solutions had long been confined to recognition of the ability of these compounds to exist in two forms which can conventionally be designated as 'red' (chelated) and 'yellow' (open) forms. It is the transitions from one form to another that underlie the well-established red–yellow photochromism of 1,3,5-triarylformazans. However, until very recently their structures have been a debated topic.²

Structural analysis of the 'red' form proved unequivocally this to be the *EZZ* isomer. The majority of formazans with this structure are characterised by the lack of absorption bands (ν_{NH}) in their IR spectra at 3100–3500 cm^{-1} , but manifest the presence of a low-field signal of NH in the ^1H NMR spectra and an intense absorption band around 480–500 nm in the electronic spectra

irrespective of the nature of the solvent. The chemical shift of the *meso*-carbon atom in ^{13}C NMR spectra of these compounds is at δ 148–151.¹⁰

In the absence of irradiation, 'yellow' forms of 1,3,5-triarylformazans are unstable, the long-wavelength band at 410–420 nm in the electronic spectra being their only spectral characteristics. Other spectral features of 1,3,5-triarylformazans do not allow their unambiguous structural identification.

Conformations of arylformazans were calculated using different quantum-chemical methods including DFT (density functional theory).¹¹ The effects of substituents on the spectral characteristics of 1,5-diphenylformazans **8** with a substituted phenyl group at position 3 have been described.¹²

X = 2-NO₂, 3-NO₂, 4-NO₂, 2-CO₂H, 3-CO₂H, 4-CO₂H.

A good correlation was found between the absorption maxima in the electronic spectra and the Hammett constants of the substituents in the benzene ring; however, this correlation was not related to the spatial structures of the formazans under study.

The 'chelate' structure of the *EZZ* isomer is also typical of 1,3-diaryl-5-hetarylformazans. However, the chelate ring with the intramolecular N(1)⋯HN(5) hydrogen bond appeared to be less stable in solution in comparison with 1,3,5-triarylformazans. The ring is easily opened in proton-acceptor solvents, which resulted in an equilibrium between the *EZZ* and *EEZ* forms; their ratio depends on the nature of the heterocycle and the solvent.¹³ This was manifested in the dependence of the position of the δ_{NH} signal in the ^1H NMR spectrum on the solvent polarity as well as in the presence of weak and moderate ν_{NH} bands at 3300–3340 cm^{-1} in the IR spectra.

1,5-Diarylformazans devoid of aryl substituents at the C(3) atom are often unable to preserve the configuration of the azohydrazone chain upon dissolution. The transition between their isomeric forms occurs spontaneously and is catalysed by Brønsted acids or by irradiation of solutions with visible light. Such a conformational lability of 1,5-diarylformazans hampers the elucidation of their structures in solutions and identification of spectral 'diagnostic' markers.²

The electronic spectra of substituted diarylformazans in organic solvents of different polarity and the effects of solvents on the position of the intramolecular charge-transfer band have been studied.¹⁴ The results of calculations of molecular orbitals (MO) by the MPDP/PM3 method point to the *EEZ* configuration of the formazan chain as the most preferable geometry of the diarylformazan molecule.

The problem of establishing spatial structures of 1-aryl-3-alkyl-5-(benzothiazol-2-yl)formazans in solutions was successfully solved¹⁵ using *N*-alkylated 3-methylformazans **9–11** as the

model compounds. The fixed configurations of the double bonds in these formazans rule out the formation of intra- and intermolecular H-bonds and their tautomerism.

In-depth studies of these compounds using a combination of modern physicochemical methods (X-ray diffraction, ^1H and ^{13}C NMR, electronic spectroscopy, dipole moment measurements) with consideration of the published spectral data for 1,5-diaryl-3-alkylformazans enabled establishing 'diagnostic' markers for determination of the configuration of the azohydrazone chain:

(1) The *EEZ* Isomers absorb visible light in a longer-wavelength region than compounds with the *EEE* configuration. The bathochromic shift of the absorption maxima (λ_{max}) of formazans containing an alkyl substituent at the *meso*-carbon atom on going from polar to nonpolar solvents (the so-called negative solvatochromism) is due to an increased content of *Z* isomers as regards substituents at the $\text{C}(3)=\text{N}(4)$ bond ($Z^{3,4}$). The *EEE* isomer with the absorption maximum around 400 nm is predominant in polar solvents.

(2) The chemical shift ($\delta^{13}\text{C}$) of the *meso*-carbon atom in the ^{13}C NMR spectra of *EEE* isomers is observed at lower field ($\delta^{13}\text{C} = 155.0\text{--}162.9$) in comparison with the *EEZ* isomers ($\delta^{13}\text{C} = 150.3\text{--}156.0$). The carbon atoms of alkyl substituents at the $\text{C}(3)$ atom (R^3) of the *EEE* isomers resonated at higher field in comparison with the *EEZ* isomer, the difference between them being equal to 5.4–9.5 ppm.^{16,17} The dependence of the chemical shift on the concentration of the solute is characteristic of only the carbon atoms that are directly linked to the $\text{C}(3)$ atom.

Analysis of the spectral data for 1-aryl-3-alkyl-5-(benzothiazol-2-yl)formazans with consideration of the observed regularities made it possible to calculate the ratio of the *EEE* to *EEZ* isomers in solution. An increase in the length of the alkyl substituent at the $\text{C}(3)$ atom results in the predominance of the $Z^{3,4}$ -isomer in solution, while an increase in its bulk (e.g., for $\text{R}^3 = \text{Pr}^i$) stabilises the *EEZ* configuration with a five-membered chelate ring (structure **B** in Scheme 1) irrespective of the nature of the solvent. The ratio of the $E^{3,4}$ to $Z^{3,4}$ isomers of compounds studied in solution depends on both the nature of the solvent (polar protic solvents stabilise the *Z* form, while non-polar solvents stabilise the *E* form) and on conditions of isolation and purification of formazans.¹⁶

The configurations and electronic structures of several novel 3-furyl-, 3-thienyl- and 3-pyrrolylformazans have been studied.¹⁸ The electron density distribution in these molecules was studied by the PPDP/2 method and related to the electronic structures of the substituents and the nature of the heteroatom in the heterocycle.

2. Tautomerism of formazans

It is believed that the tautomerism of triarylformazans containing identical substituents at the $\text{N}(1)$ and $\text{N}(5)$ atoms ($\text{R}^1 = \text{R}^5$) is an intramolecular process occurring between two degenerate forms. In 1,3,5-triphenylformazan with the *EZZ* configuration (structure **A** in Scheme 1), the proton forms covalent bonds alternately with the $\text{N}(1)$ and $\text{N}(5)$ atoms in the course of intrachelate proton transfer with the lifetime of the tautomers of about 10^{-3} s. The position of the hydrogen atom in the azohydrazone chain is important for formazans with different substituents R^1 and R^5 .

The tautomeric ratio in solution of a formazan is determined by the electronic characteristics of the substituents at the $\text{N}(1)$ and $\text{N}(5)$ atoms. The introduction of a strong electron-withdrawing (e.g., acyl, nitro or dinitrophenyl) or an electron-donating group may lead to only one tautomer. The levelling of the electronic characteristics of the terminal substituents (e.g., if R^1 and R^5 are different aromatic groups) results in a tautomeric equilibrium $\text{R}^1\text{NH} \rightleftharpoons \text{R}^5\text{NH}$; the position of the latter is judged upon by a number of features established from the analysis of ^1H and ^{13}C NMR spectra (see Refs 2 and 3).

The changes in the chemical shifts of the signals for the carbon atoms of the aryl substituent linked to the $\text{N}(1)$ or $\text{N}(5)$ atom in the ^{13}C NMR spectrum relative to the signal for the carbon atom of benzene or its derivative ($\Delta\delta^{13}\text{C}$) are the most informative. A method for the quantitative evaluation of the tautomeric equilibrium of formazans^{3,19} allowed determination of the percentage of one of the tautomers [e.g., that containing a proton at the $\text{N}(5)$ atom] according to the formula:

$$P_{\text{R}^5\text{NH}} = \left(\frac{\Delta\delta_{\text{R}^5} - \Delta\delta_{\text{R}^5\text{N}=\text{N}}}{\Delta\delta_{\text{R}^5\text{NH}} - \Delta\delta_{\text{R}^5\text{N}=\text{N}}} \right) \times 100\%,$$

where $\Delta\delta_{\text{R}^5}$ is the experimental change of the chemical shift ($\delta^{13}\text{C}$) of the carbon atoms of substituent R^5 relative to that in substituent R^5H ; $\Delta\delta_{\text{R}^5\text{NH}}$ is the change of the $\delta^{13}\text{C}$ of the carbon atoms of substituent R^5 relative to that in R^5H calculated for the R^5NH tautomer and $\Delta\delta_{\text{R}^5\text{N}=\text{N}}$ is the difference calculated for the R^1NH tautomer.

The nitrophenylhydrazone group of 1,3-diphenyl-5-(*p*-nitrophenyl)formazan (**12**) was used as a model of the R^5NH tautomer, while its azophenyl fragment, as a model of the R^1NH tautomer. It is considered¹⁹ that compound **12** exists in solution in the form of nitrophenylhydrazone.

The most characteristic changes in $\delta^{13}\text{C}$ induced by the azo or the hydrazone fragment were observed for the carbon atoms in the *ipso*, *ortho* and *para* positions. The calculations took into account the changes in the chemical shifts of these atoms.

At present, this method is considered to be the most convenient and reliable procedure for determining the percentage of tautomeric forms of different types of formazans. For example, a comparison of $\delta^{13}\text{C}$ in R^1NH and R^5NH tautomers of 1,3-diphenyl-5-(benzothiazol-2-yl)formazan (**13**) suggests that this compound exists almost exclusively in the form of a $\text{PhN}(1)$ tautomer irrespective of the solvent polarity.³

The enhancement of the electron-withdrawing properties of the aryl substituent at the $\text{N}(5)$ atom (introduction of the *p*-nitrophenyl group, formazan **14**), leads to co-existence of azoaryl tautomer **14a** with a considerable amount of the arylhydrazone tautomer **14b**.

Quantitative evaluation of the tautomeric equilibrium in solutions of formazan revealed that, unlike the gas phase, the effect of the electronic characteristics of substituents R^1 and R^5 on the position of the tautomeric equilibrium is very pronounced. In 1,3,5-triarylformazan solutions, the equilibrium is fully shifted towards the form where the proton is localised at the nitrogen atom linked to the substituent with the strongest electron-withdrawing properties.^{2,3}

Similar conclusions were made in studies on the tautomerism of 3-furyl(thienyl, pyrrolyl)formazans by mass spectrometry.^{18,20}

In addition to the aforementioned prototropic equilibrium ($R^1NH \rightleftharpoons R^5NH$), the amino–imino (formazan–formazene) tautomerism, which involves the nitrogen atom of the azaheterocyclic substituents, is observed for 1-aryl-5-hetarylformazans.² Quantitation of the isomer ratio in the gas phase of hetarylformazans by mass spectrometry presents a problem due to identical masses of the fragment ions of the imino (**15a**) and amino (**15b**) tautomers of the heterocycles.

However, the predominant localisation of the proton at the endocyclic nitrogen atom (the imine form of the type **15a**) of 1,3-diphenyl-5-(benzothiazol-2-yl)formazan (**13**) could be established on the basis of electron impact and chemical ionisation mass spectrometry and using semiempirical calculations.²¹

The position of the ν_{NH} band in the IR spectra of *N*-hetarylformazans has long remained the only spectral criterion of the amino–imino tautomerism in solutions. The imino form manifests a characteristic band around $3420\text{--}3460\text{ cm}^{-1}$, while the band around $3330\text{--}3360\text{ cm}^{-1}$ is more typical of the amino form.

^{13}C NMR spectroscopy is the most informative method for studying the amino–imino tautomerism in solutions. These conversions strongly affect the chemical shifts of the carbon atoms in azaheterocycles. The use of fixed models of different isomeric forms of 1-phenyl-3-methyl-5-(benzothiazol-2-yl)formazans **9–11** as examples revealed¹⁵ that the differences in the chemical shifts ($\delta^{13}\text{C}$) of individual atoms in the benzene rings of the heterocycle range from 7 to 11 ppm. A comparison of the $\delta^{13}\text{C}$ values in the ^{13}C NMR spectra of model compounds and the corresponding formazans enabled quantitative determination of the ratios of amino to imino tautomers in solutions of trisubstituted 1(5)-aryl-5(1)-(benzothiazol-2-yl)formazans.^{13,16} It was found that the concentration of the imino tautomer in a non-polar solvent decreases with an increase in the bulk of the substituent at the C(3) atom and the ability of formazans to exist in a ‘folded’ state stabilised by intramolecular H-bonds. Thus in CDCl_3 the contribution of the imino tautomer of formazans **13** (the *EZZ* isomer) and **4b** (the *EEZ* isomer) could not be reliably established because its percentage did not exceed 5%, whereas that of the imino tautomer of *EEE* formazan **4a** was 20%–25% [calculated from signals for the C(4), C(8) and C(9) atoms of the heterocycle]. In proton-acceptor solvents, the percentage of the imino tautomer increases (in some cases, up to 44%–76%).

A comparison of the tautomeric compositions of solutions of 1-aryl-3-phenyl-5-hetarylformazans differing in the substituents

at the N(5) atom demonstrated that the contribution of the imine structure increases with an increase in the basicity and a decrease in the aromaticity of the heterocycle. Thus in formazans containing thiazole, benzothiazole and benzoxazole rings the position of the tautomeric equilibrium in non-polar solvents was close to that for triarylformazans, *i.e.*, both classes of compounds exist predominantly in the amine form. In contrast, their benzimidazole analogues exist exclusively as imino tautomers with the *EEE* configuration.³

The preferable tautomeric forms of *N*-pyrazolyl-*C,N*-diarylformazans were established on the basis of a comparative analysis of quantum-chemical calculations and spectroscopic data.²²

III. Synthesis and properties of formazan derivatives

The majority of recent studies aimed at the synthesis of novel formazans are directed at the design of substances with valuable properties. Most often, the known approach to the synthesis of formazans is used, which is based on reactions of aryl(hetaryl)hydrazones with diazo compounds, non-traditional compounds being used as amine, hydrazine or aldehyde components in recent years. Thus the introduction, into the azohydrazone chain, of new heterocycles that play the role of additional addends for complexation and such metal-coordinating groups as podands, crown ethers, *etc.*, allows preparation of metal chelates with improved characteristics.

Allyl-substituted macrocyclic crown-formazans as non-traditional intermediates for the design of polymeric macrocycles have been synthesised.¹⁷ Thus bisphenol **16** was prepared by a reaction of diazotised 6-allyl-2-aminophenol with cyanoacetic acid. Diazotisation of diamine **17** and its subsequent azo coupling with compounds containing a reactive CH group have led to a vast variety of the corresponding macrocyclic formazans **18**.

(a) $\text{NCCH}_2\text{CO}_2\text{H}$, Py, Cu(II) (for $R = \text{CN}$);

(b) $\text{PhCH}_2\text{C}(\text{O})\text{CO}_2\text{H}$, NaOH, H_2O (for $R = \text{Ph}$).

The synthesis of 14- and 15-membered crown-formazans and estimation of the prospects of their use for spectrophotometric determination of lithium have been described.²³ These compounds were shown to be highly selective chelating agents for this ion. Some of these formazans were assayed as selective neutral conductors for caesium ion-selective electrodes.²⁴ Thus formazan containing a 4-pyridine *N*-oxide residue at the C(3) atom manifested the highest selectivity with respect to caesium ions with low selectivity for potassium and ammonium ions.

Crown formazans **19a–c** as well as 28- and 30-membered bisformazans **20a–c** have been synthesised in low yields.²⁵

19a–c

20a–c

X = CH₂C(=CH₂)CH₂ (**a**), (CH₂)₃ (**b**), (CH₂)₄ (**c**).

Mixtures of formazans **19** and **20** were separated into individual components by TLC.

Ozonolysis of compound **19a** at low temperature yielded ketone **19d**; reduction of the latter with sodium borohydride gave alcohol **19e**. The condensation of ketone **19d** with 1,3-diaminopropane yielded bisformazan **21** (Scheme 2).

A highly stereoselective synthesis of 15-membered macrocyclic crown formazans **22** with *Z* configuration of the C=C bond (the *Z*:*E* ratio varied from 90:10 to 97:3) has been carried out.²⁶

22 (60%–95%)

R = CN, Ph, 4-ClC₆H₄, 4-MeC₆H₄, 4-MeOC₆H₄, 4-C₅H₅N⁺O[−], PhSO₂; X = CO₂H or C(O)CO₂H; Cy = cyclo-C₆H₁₁.

The introduction of podands containing oligooxyethylene bridges of various lengths between two formazan fragments afforded new classes of bisverdazyls (**23**) and bisverdazylum salts (**24**) (Scheme 3).²⁷

Bisverdazyls **23** represent a novel class of stable biradicals: solid samples decompose at room temperature only after several days, while their solutions in organic solvents do not change optical densities over a course of several weeks. The calculated distances between the spin centres agree well with experimental values.²⁸ These compounds are good models for the study of 'host–guest' interactions.

Podands can be used as amine (like the aforementioned compounds **18–22**) or aldehyde components in the synthesis of formazans (in the latter case, the role of the azo component is played by diazonium salts). The synthesis of benzothiazolylfor-

Scheme 2

Scheme 3

mazans **25** containing oxyethylene groups ($n = 1–3$) has been described.²⁹ Cross-linked salicylaldehyde benzothiazol-2-ylhydrazones and diazonium salts prepared from aniline or *o*-anisidine served as the starting compounds in the synthesis of podands **25**.

The complexation ability of nickel(II), cadmium(II), zinc(II) and lead(II) ions toward compounds **25** has been investigated. Formazans **25** formed mono- and binuclear complexes with these metals. The introduction of an oxyethylene bridge not only expanded the range of the coordinated metals, but also conferred novel properties on the formazan complexes. Thus the binuclear lead(II)–formazan **25** complex (R = OMe, $n = 2$) shows photochromic properties.²⁹ After sunlight irradiation, the blue colour of a solution of the complex in ethanol changed into orange; the original colouring was restored in the dark. Such interconversions occur repeatedly with no change in the absorption intensity in the electronic spectra. The reaction of formazan **25** (R = H, $n = 3$) with solid metal salts yielded coloured complexes only with zinc(II) and cadmium(II) ions, which can be used for the extraction of these metals from mixtures. Some specific features of the

behaviour of zinc and cadmium formazanates with respect to sunlight were established.

A recently published review³⁰ devoted to macrocyclic formazans describes methods for the synthesis and properties of crown formazans, discusses elucidation of their structures by NMR, IR and UV spectroscopy and mass spectrometry and presents data on their reactivities and applications.

The synthesis of 1,5-diphenylformazans carrying a substituted benzene ring at the C(3) atom has been described.³¹ The structures of formazans were studied by IR, ¹H and ¹³C NMR spectroscopy. A good correlation was found between the absorption maxima in the electronic spectra and the Hammett constants of the substituents in the benzene ring. Tetrazolyl-substituted formazans were prepared from (tetrazol-1-yl)acetohydrazide and *p*-chloro- or *m*-nitrobenzaldehyde.³² The condensation was induced by microwave irradiation. The hydrazone formed was then treated with a diazonium salt to give a high yield of 1,3-diaryl-5-[(tetrazol-1-yl)acetyl]formazan.

The condensation of 1,5-diaryl-3-carboxyformazan with *o*-phenylenediamine yielded 1,5-diaryl-3-(benzimidazol-2-yl)formazans **26**.³³

Reductive cleavage of these compounds yielded benzimidazole-2-carboxamide arylhydrazones.

The ability of formazans to form complexes with metal ions is among their most salient properties. Thus 1,5-bis(2-carboxyphenyl)-3-(2-furyl)formazans gave complexes with zinc(II), cadmium(II), mercury(II) and lead(II) ions and mixed-ligand complexes of these formazans and 2,2'-bipyridyl with cadmium(II), mercury(II) and lead(II).³⁴ The structures and properties of the synthesised compounds were studied by IR, electronic and ¹H NMR spectroscopy; their thermal analyses were carried out.

The synthesis and spectroscopic analysis of 1-aryl-3-(*n*-heptyl)-5-benzothiazolylformazans and their complexes with metal

ions have been carried out.³⁵ It was found that these formazans form 1 : 1 complexes with silver(I) ions and 1 : 2 complexes with nickel ions. The ligands of some compounds of this series formed stable complexes with lead and rare-earth ions. In aprotic solvents (*e.g.*, acetonitrile), formazans manifested specific, *e.g.*, complexing, properties. For example, the *m*-nitro group in an aryl substituent at the N(1) atom is involved in the coordination to the metal.

The dependence of complexation of formazans with metals on the nature of the solvent has been studied.³⁶ A comparison of complexing properties of aryl- and hetarylformazans in acetonitrile revealed that the efficiency of the complexation depends on the ionic strength of the solutions and the donor-acceptor properties of the substituents in the ligand molecule.

Some recently published papers were devoted to practical applications of formazans as analytical reagents for the determination of microquantities of metals in various objects. Thus 1,5-bis(2-carboxyphenyl)-3-phenylformazan was used for spectrophotometric determination of copper ions in the presence of other metal ions.³⁷ The highly sensitive colour reaction of 1-(2-hydroxy-5-sulfophenyl)-3-(2-hydroxyphenyl)-5-(3,5-dibromo-2-pyridyl)formazan with copper ions for the determination of the copper content in ores has been studied.³⁸ Simple, rapid and accurate methods for the spectrophotometric determination of divalent cobalt, copper and palladium ions based on the formation of coloured complexes of these metals with 1-(2-arsenophenyl)- (Ref. 39) and 1-(2-carboxyphenyl)-3-benzoyl-5-phenylformazan (**27**) have been developed and employed for the quantitation of copper ions in alloys.⁴⁰ Carboxyphenylformazan **27** was recommended as an indicator in spectrophotometric titration of cobalt, copper and palladium by ethylenediaminetetraacetic acid (EDTA). In the series of hetarylformazans, 1-(2-hydroxy-5-nitrophenyl)-3-isopropyl-5-(benzoxazol-2-yl)formazan was found as a new extractant for preconcentration and determination of scandium(III) ions.⁴¹ This compound was highly selective with respect to Sc(III) in the presence of different metals. Its lower homologue, *viz.*, 1-(2-hydroxy-5-nitrophenyl)-3-ethyl-5-(benzoxazol-2-yl)formazan, proved to be a selective reagent for the photometric determination and preconcentration of lead.⁴²

Formazans are used more and more often in flow injection analysis (FIA). This method in combination with spectrophotometric detection of multicomponent mixtures can be used for simultaneous determination of cobalt, copper and zinc ions (in the concentration range 0.2–1.9 $\mu\text{g ml}^{-1}$) with 1-(2-carboxyphenyl)-3-phenyl-5-(2-hydroxy-5-sulfophenyl)formazan as the chromogenic reagent.⁴³ This procedure was employed for the determination of copper and zinc in blood sera, veterinary preparations⁴³ and plants.⁴⁴ Formazans were also proposed as sorbents for flow sorption–atomic absorption determination of metals in solutions.⁴⁵

A spectrophotometric procedure for the determination of copper ions in water using 1,5-bis(2-hydroxy-5-sulfophenyl)-3-cyanoformazan has been developed.⁴⁶ A rapid spectrophotometric method was described⁴⁷ for the determination of zinc in biological materials and pharmaceutical preparations using 3-acetyl-1,5-diarylformazans as ligands in the presence of cetylpyridinium chloride.

The ability of formazans to form complexes with metals is also used in some electrochemical analytical techniques. Thus the electrochemical behaviour of seven hetarylformazans used as components of carbon-containing inks of thick-film screen-printed electrodes was studied.^{48, 49} The compositions of complex compounds formed on the electrode surface and their stability constants were determined. It was shown, for example, that 1-(2-chlorophenyl)-3-phenyl-5-(6-methyl-4-oxo-3,4-dihydropyrimidin-2-yl)formazan (**28**) provides high sensitivity of graphite-containing modified electrodes, low detection limits with respect to Cu(II), Pb(II), Cd(II) and Zn(II) ions and high reproducibility of the results of analysis.

A mercury-free thick-film graphite-containing electrode modified with 1-(*o*-tolyl)-3-methyl-5-(1-benzylbenzimidazol-2-yl)formazan (**29**) was proposed for the determination of Mn(II) ions by the cathodic inverse voltammetric method.⁵⁰ The determination limit of manganese(II) with this electrode was 0.04 $\mu\text{g litre}^{-1}$; the preconcentration time was 60 s. The dependence of the analytical signal of Mn(II) on its concentration in solution was linear in the range from 0.1 to 30 $\mu\text{g litre}^{-1}$. This procedure was used for the analysis of natural and drinking waters for the detection of manganese(II) ions.

Gas-phase oxidation and reduction of 1-(benzothiazol-2-yl)-3,5-diphenylformazans as well as complex formation with transition metals under laser ionisation were studied.⁵¹ The data obtained suggest that formazan molecules are photoionised to molecular radical ions, which are further involved in ion-molecular reactions. Formazans give singly charged metal formazanates with the composition 1 : 2. Anionic metal complexes of formazans were also studied by capillary electrophoresis–mass-spectrometry.⁵²

Photochromic properties of formazans have been known since long ago and were repeatedly discussed in the literature. However, detailed mechanisms of their photochromic conversions still remain obscure. Therefore, the number of publications on this subject is steadily increasing. For instance, the dependence of spectral-kinetic characteristics of photochromic arylformazans on their structures was investigated.⁵³ It was found that enhancement of the electron-donor properties of substituents was accompanied by a bathochromic shift of the absorption bands of the original chelate structure, the positions of the absorption maxima of the photoinduced form being determined by the properties of the tautomeric structures. As for the kinetic characteristics, they depend exclusively on the thermal relaxation of the photoinduced form into the original state, the rate of this process being related to the nature of the substituents.

The photothermochromic conversions of 1-aryl-3-phenyl-5-(benzothiazol-2-yl)formazans **13**, **14** and **30–33** were studied under conditions of steady-state photolysis.⁵⁴

R = H (**13**), NO₂ (**14**), Cl (**30**), Br (**31**), NMe₂ (**32**), CO₂Me (**33**).

Irradiation of solutions of these compounds in toluene at $\lambda = 578 \text{ nm}$ resulted in changes of the colour of the solution from red and blue (for R = NO₂ and CO₂Me) to yellow. The relaxation of the photoinduced form into the original state takes place both as a result of either thermal dark reaction or irradiation

($\lambda = 436$ nm). In this case, the *E,Z* isomerisation of the C=N bond becomes the major photochemical reaction. The reverse reaction proceeds at a higher rate in comparison with triphenylformazan due to the presence of a weaker intramolecular hydrogen bond in the original forms of formazans **13**, **14** and **30–33**. Kinetic studies of photo conversions and thermal conversions of compounds **14** and **33** revealed the presence of an isosbestic point in their absorption spectra. This suggests that the lifetimes of their intermediate forms were significantly shorter than those of the starting compounds and the final products. The photothermal conversions of formazans **13**, **30–32** were accompanied by the formation of long-lived intermediate species.

Variation of substituents in the formazan molecule was aimed at a search for biologically active substances. Thus a series of 1-aryl-3-(3,4,5-trimethoxyphenyl)-5-(3-nitrobenzoyl)formazans were synthesised and assayed for antibacterial, antituberculosis and antifungal activities.⁵⁵ It was found that formazans comprising 2-chlorophenothiazine could be employed as antiinflammatory agents.⁵⁶

The synthesis of formazans **34** containing the piperazine fragment was described and their biological activities were investigated.⁵⁷ Compounds **34** were prepared by a reaction of *N*-amino-4-methylpiperazine with salicylaldehyde or vanillin with subsequent condensation of the hydrazones with aryldiazonium halides.

R¹ = 2-OH, 3-OMe-4-OH; R² = 2-OMe, 3-OH, 4-OH, 4-OMe.

Some formazans **34** manifest bactericidal activity against *Staphylococcus aureus* and *Mycobacterium* H₃₇R_v.

The synthesis of formazans containing the 1,8-naphthyridinyl fragment was described and the antibacterial effects of these compounds against Gram-positive and Gram-negative bacteria were investigated.⁵⁸

Several quinolinyl-diarylformazans **35** were assayed for tuberculostatic (*Mycobacterium* H₃₇R_v) and antibacterial (*E. coli*, *B. subtilis*, *S. paratyphi* B) activities.⁵⁹

R¹ = 4-OMe, 2-Cl; R² = 2-OMe, 4-OMe, 4-OEt, 4-OH, 3-OH.

Some of recently synthesised formazans containing a *p*-toluenesulfamide fragment possess high fungicidal activity.⁶⁰

A series of 1-[2-aryl-4-oxo-(3*H*)-quinazolin-3-yl]-5-phenylformazans **36** have been synthesised.⁶¹ *N*-Aminoquinazolinones **37** prepared by condensation of the corresponding benzoxazinone with hydrazine hydrate served as the starting compounds in the synthesis of formazans **36**. Diazotisation of compounds **37** and condensation of the diazonium salts with aldehyde phenylhydrazones gave quinazolinylformazans **36**. The latter manifest moderate activity against *Vaccinia* virus.

R = Ph, PhCH=CH.

Antiviral, antibacterial and fungicidal effects of formazan derivatives and the respective tetrazolium salts[†] have been studied.^{62–64}

In some cases, directed synthesis of formazans designed for biological studies was achieved through introduction of various pharmacophore groups into formazan molecules. 1-Phenyl-3-[2-methoxy-4-*N,N*-bis(2-cyanoethyl)aminophenyl]-5-arylformazans were assayed for anticancer and anti-HIV activities.⁶⁵ In a more recent study,⁶⁶ a series of 3-[2-methyl-4-*N,N*-bis(2-cyanoethyl)aminophenyl]-containing formazans were assayed for the same activities. Formazans containing *p*-tolylhydrazine residues were also synthesised,^{67,68} but they were found to be inactive.

A series of formazans containing benzenesulfamido groups were synthesised⁶⁹ and their properties including the fungicidal activity were investigated.

It was found⁷⁰ that hetarylformazans containing the indole fragment at position 3 possess contraceptive properties. Reactions of 6-substituted indole-3-carbaldehydes with (1-naphthyl)aceto-hydrazide and their subsequent coupling with aryldiazonium salts yielded indol-3-ylformazans⁷¹ possessing weak antiviral activity.

The above-mentioned examples unequivocally demonstrate that formazans hold little promise as basic materials for medicinal drugs. Unfortunately, the papers cited did not provide any information about the relationship between the results obtained and the nature of the substituents in the formazan fragment.

IV. Formazan complexes with metals: structures and applications

Complex compounds based on formazans constitute a well-known class of tetraaza-coordinated metal chelates.^{2,72} These ligands attract attention by virtue of stable intense colour of their metal complexes. Variation of substituents at positions 1, 3 and 5 of the formazan fragment enables the introduction of additional complexing groups which increases the denticity of the formazan ligands.

Reactions of 1,5-diarylformazans with metals yield three types of bicyclic compounds. Those containing two six-membered metallacycles (structure **37**) belong to the first type, two five-membered rings (structure **38**), to the second and one six-membered and one five-membered rings (structure **39**), to the third type.

[†] Tetrazolium salts are formed upon oxidation of 1,5-di- and 1,3,5-trisubstituted formazans.²

The calculation of relative stabilities of systems **37–39** by the molecular mechanics method using the PCMODEL software revealed⁷³ that their strain energies are very close, *viz.*, –915, –859 and –976 kJ mol^{–1}, respectively. It is noteworthy that six-membered metallacycles implemented in crystals are far from being energetically favourable. The loss of strain energy of these rings is compensated by intermolecular interactions. If metallacycles contain the same number of fragments, the type of the coordination polyhedron of the complex is determined by the structure of the substituent at the C(3) atom and the nature of the metal complexing agent.

Five- and six-membered rings in diamagnetic formazan complexes with transition metals can be identified by ¹³C NMR spectroscopy.⁷² The transition from the ligand to the metal complex (structure **40**) is accompanied by shielding of the C(1) atom of the phenyl ring at position 3 with a concomitant change in the chemical shift $\Delta\delta = 2.4–5.5$ ppm and deshielding of the C(2) and C(6) atoms ($\Delta\delta = 2.9–4.0$ ppm). Contrariwise, deshielding of the C(1) atom ($\Delta\delta = 1.6–3.0$ ppm) and virtually unchanged chemical shifts of the atoms in the *ortho* position of the benzene ring are more characteristic of structure **41**.

In the majority of metal formazanates, the ligand exists as an anion. Only in the Cu(I)–1,5-diphenylformazan complex (compound **7**) is the copper atom coordinated by a neutral molecule (X-ray diffraction data).⁷² This complex presents interest as a new example of a molecular adduct based on a chelating formazan ligand.

The introduction of additional complexing groups into the formazan molecules not only expands the range of metals able to form complexes with formazans, but also results in formation of new coordination sites. Thus the coordination units of the majority of metal chelates of 1,5-diaryl-3-mercaptoformazans (**42**) contain both nitrogen and sulfur atoms.^{2,72}

Metal complexes **42** are characterised by intrachelate bond isomerism, which underlies their photochromism. The changes in the colour of a substance from orange (or red) to blue (violet) upon irradiation are due to proton transfer and subsequent rearrangement of the π -electron system. It is structure **42b** that corresponds to the photocoloured form. Novel photochromic materials were designed based on such metal complexes.

Boron chelates with 1,5-diarylformazans that contain amide groups at position 3 able to bind to the boron atom have been described.^{74,75} For example, in compounds **43** the formazan molecule is involved in the formation of two six-membered heterocycles.

The ability of formazans containing hydroxy, carboxy, *etc.*, groups in the *ortho* position of the aryl substituents at the N(1) and N(5) atoms to coordinate metals, which is accompanied by the formation of five- or six-membered metallacycles, is especially pronounced. Such formazans play the role of tri- or tetradentate ligands.⁷²

The introduction of an α -azaheterocycle into the formazan molecule is equivalent to the presence of an aryl substituent with an additional coordinating group; as a result, the ligands acquire a tridentate character. The structures of hetarylformazan complexes were established by ¹³C, ¹⁵N, ¹⁹⁹Hg and ^{113,111}Cd NMR spectroscopy and X-ray diffraction.^{76–78} These studies demonstrated that Zn-, Cd- and Hg-containing benzazolyformazanates have pseudo-octahedral structures in solutions. The ligand in such complexes is coordinated through the N(1) and N(4) atoms of the formazan fragment and the nitrogen atom of the heterocycle. The changes in the chemical shifts of the heterocyclic substituent (similar to those observed for the transition from the amino to the imino tautomer) and the values of the spin-spin coupling constants of the carbon atoms in the benzene ring fused to the heterocycle [C(8) and C(9) atoms in structure **44**] were used as characteristic criteria for the identification of this coordination mode.⁷⁶

X = S, O; M = Ni, Co, Zn, Cd, Hg, Fe, Mn.
R¹ = H, OMe, Buⁿ; R² = Prⁱ, Buⁿ, Ph.

The chemical shifts in the ¹⁹⁹Hg and ^{113,111}Cd NMR spectra and the spin–spin coupling constants of these nuclei with the ¹³C nuclei of the ligand were measured.⁷⁸ For the first time, ¹⁴N NMR spectroscopy was used⁷⁷ in structural studies of zinc and cadmium complexes **44**, in the first place, with regard to the ¹⁴N nuclei in the coordination units.

It should be noted that independently of the isomeric form of the starting formazan, the complexes formed contained only an imino tautomer in the *EZZ* configuration. The results of X-ray diffraction studies of complexes **44** [M = Ni, X = S, R¹ = 4-Buⁿ, R² = 4-Buⁿ; M = Co, X = S, R¹ = 4-Buⁿ, R² = Ph; M = Fe(II), X = O, R¹ = H, R² = Prⁱ; M = Fe(II), Mn(II): X = S, R¹ = H, R² = Ph]^{79–82} suggest unequivocally the involvement of the nitrogen atom of the benzazole system in the formation of the metallacycle. The configuration of the metal bonds in these

complexes represents a distorted octahedron with an MN_4 coordination unit.

Complexes similar to compounds **44** were also prepared on the basis of formazans containing azine fragments.^{2, 72}

The geometry of metal hetarylformazanates is represented by only one type of a polyhedron, *viz.*, a distorted octahedron; the degree of distortion and the coplanarity of the metallacycles depend on the nature of the metal and the structure of the ligand. In contrast to their aromatic analogues, hetarylformazan complexes contained predominantly five-membered metallacycles.⁸³

It was found⁸² that reactions of 1,3-diphenyl-5-(benzothiazol-2-yl)formazan (**13**) with Fe(III) and Mn(III) ions result in the reduction of metal ions to the oxidation state 2+ and, as a consequence, in the oxidation of the formazan to the tetrazolium salt. The complex compounds formed had a composition L_2M ; the iron complex was diamagnetic. The structures of the formazanates were confirmed by X-ray diffraction data. At the same time, Fe(III) and Mn(III) ions retained a high oxidation state in reactions with 1-(2-carboxyphenyl)-3-alkyl-5-(benzothiazol-2-yl)formazan; the corresponding iron complex was paramagnetic. In the authors' opinion, in the latter case this was due to the involvement of the carboxy group in the complexation with the metals.

Indeed, 1-hetaryl-5-arylformazans with a hydroxy or a carboxy group in the *ortho* position of the aryl substituent at the N(1) atom can be regarded as tetradentate ligands that form complexes **45** with metals.^{72, 84}

X = NH, NAlk, S; Y = O, OC(O); M = Ni, Zn; R = Alk, Ar.

It is noteworthy that depending on the position of the nitro group in the *N*-aryl fragment in complexes **45** (M = Zn) with 1-[2-hydroxy-4(5)-nitrophenyl]-5-(benzazol-2-yl)formazan the ligand is coordinated to the zinc atom either in the hydroxyazo (similar to nickel complexes) or in the quinone–hydrazone form.⁸⁴ In contrast to nickel formazanates, zinc complexes readily undergo ligand exchange reactions with amines. Owing to this property, such complexes have been used for the design of thermochromic systems with positive and negative thermoinduction effect.

The compositions and structures of coordination units in Cu(II)–benzothiazolylformazan complexes were studied by EPR spectroscopy.⁸⁵ It was found that depending on the nature of the substituents at the N(1) atom, the copper atom acquires a square-planar or a pseudo-tetrahedral configuration. For L_2Cu complexes prepared in an excess of a ligand, the coordination unit CuN_4 formed contained the N(1) and N(5) atoms of formazan (see structure **37**). 1-(2-Hydroxyphenyl)-5-(benzothiazol-2-yl)formazan gave copper complex **46** (LCu) the copper atom in which is

coordinated to the nitrogen atoms of the heterocycle, to the N(1) and N(4) atoms of the formazan chain and to the oxygen atom of the hydroxy group (the coordination CuN_3O unit).

Mono- and binuclear metal formazanates present interest as catalysts for diverse chemical reactions. Thus benzazolylformazan–nickel complexes manifest high catalytic activity in the dimerisation of ethylene.⁸⁶ The synthesis of novel homo- and heterobimetallic catalysts based on 1,5-diaryl-3-ferrocenylformazan complexes has been described.⁸⁷

The structures and properties of thorium(IV), uranium(VI) and REE 3-acetyl- and 3-cyano-1,5-diarylformazanates have been studied.^{88–91} It was found that the stabilities of REE 1,3,5-triphenylformazanates correlated with the basicity of the ligand as well as with the ionisation potential, electronegativity and the ionic radius of the metal.

Ligands containing two formazan fragments were used in the synthesis of polymetallic complexes.⁹² Tetranuclear complexes with cobalt, nickel, copper, manganese, zinc, cadmium and mercury ions were prepared from bis[1-phenyl-3-(2-hydroxyphenyl)formazan]phenyl ether. The results of spectroscopic and magnetic studies suggest that Co(II)-, Cu(II)- and Mn(II)-containing complexes have an octahedral or a distorted octahedral structure; Ni(II) derivatives have a planar structure, while Zn(II), Cd(II) and Hg compounds have a tetrahedral structure. Palladium complexes with formazans containing a heterocyclic fragment (pyrrole and 1-methylpyrrole) were synthesised⁹³ and their properties were investigated.

Potentiometry, conductometry, IR spectroscopy, thermogravimetry and measurements of electroconductivity and magnetic susceptibility were used for the study of complexation of praseodymium, neodymium, samarium, gadolinium, holmium, erbium, thulium and ytterbium ions with symmetric 1,5-diphenyl-3-cyanoformazan.⁹⁴ In a study⁹⁵ of complexation of benzazolylformazans with uranyl ions and some REE, it was demonstrated that uranyl complexes have mainly the composition $L(UO_2)$ in solution and in the crystalline state, while benzazolylformazan–REE coordination complexes have the composition L_2M .

The same authors⁹⁶ studied the complexing properties of 1-(2-hydroxyphenyl)-5-benzazolylformazans with respect to scandium(III) ions in the pH range 3–10. The composition of scandium formazanates (L_2Sc) was confirmed by IR and electronic spectroscopy and the ligand exchange method, while the structure of the coordination unit depends on the nature of the heterocycle.

The fluorescence properties of formazan–REE complexes were studied in solutions and in monolayers.⁹⁷ For the first time, fluorescence in the IR spectral region of complexes of 1-aryl-3-alkyl-5-benzothiazolylformazans devoid of additional complexing groups was detected. It was found that the efficiency of fluorescence depends on the structure of formazans, nature of the metals and state of the surface of Langmuir–Blodgett films as supports.

Many properties of formazan–metal complexes (in the first place, their catalytic, photochemical and thermochromic properties) are connected with conversions that involve the metal chelate unit. However, only functional groups of the ligand can be involved in reactions of metal formazanates without affecting the nearest environment of the metal centre. These reactions include acylation of peripheral groups by acid derivatives (including those of the heterocyclic series), alkylation, reactions with azines (most commonly, introduction of pyrimidine and *sym*-triazine), *etc.*² These reactions are usually employed for the preparation of active metal-containing formazan dyes, which have long been used for the dyeing of miscellaneous materials. The main advantages of such dyes include high water and light resistance, good colour characteristics, *etc.* The methods for their preparation and dyeing technologies are usually covered by patents.⁹⁸ For example, a vast variety of copper complexes based on polydentate triarylformazans (structure **47**) are used as dye-stuffs for cellulose materials.⁹⁹

$R^1 = \text{H}, \text{SO}_3\text{H}, \text{OH}, \text{Cl}, \text{OMe}, \text{C}(\text{O})\text{Alk}$; $R^2, R^3 = \text{H}, \text{SO}_3\text{H}$;

$X = \text{N} \begin{array}{c} \diagup \diagdown \\ \text{O} \end{array}, \text{NHCH}_2\text{CH}_2\text{OH}, \text{N}(\text{CH}_2\text{CH}_2\text{OH})_2$;

$Y = \text{HN} \begin{array}{c} \text{---} \text{C}_6\text{H}_4 \text{---} \text{C}_6\text{H}_4 \text{---} \text{NH} \end{array}, \text{HN} \begin{array}{c} \text{---} \text{C}_6\text{H}_3(\text{OMe}) \text{---} \text{C}_6\text{H}_3(\text{OMe}) \text{---} \text{NH} \end{array}$.

The synthesis of metal complexes with aryl- and hetarylformazans containing a vast variety of substituents in different positions as promising pigments for cellulose tissues, cotton and synthetic fibres was patented.^{100–103} All these dyes contain sulfo groups and triazine fragments able to bind to fibres, whereas copper, nickel or cobalt ions usually play the role of metal centres, which made it possible to attain various shades of blue or green colour.

The use of formazan complexes **48**, which represent active dyes with good colour properties, as dyestuff for natural and synthetic cotton and hemp has been patented.¹⁰⁴

The use of a mixture of nickel – 1,3-diaryl-5-(2-pyridyl)formazan complexes **49** as a dye has been studied.¹⁰⁵ By varying aryl substituents, one can obtain dyes with different colour gamut.

$M = \text{Cu}, \text{Ni}$; $X, Z = \text{F}, \text{Cl}, \text{Br}$; $Y = \text{NH}(\text{CH}_2)_m\text{NH}$, etc.

Dyeing entails the use of mixtures of various classes of dyes. For example, formazan–cyanine copolymer dyes for the preparation of optical self-recording layers and sensors contain up to 70%–100% of molecular fragments of the general formula:

where F is the fragment of the formazan dye; G is the fragment of the cyanine dye; W is the (cyclo)alkylene, arylene, etc., bridging group and Z is the residue of a carbonic acid derivative, urea, an ester or an amide.¹⁰⁶

The use of composites containing formazans, azo dyes and benzoxazines carrying different substituents in each fragment, has been patented.¹⁰⁷ Such mixtures are distinguished for high colourability and high stability and are used as dyestuff for cellulose fibres. Mixtures of azo and formazan dyes, or pure formazan dyes manifest a synergistic effect in the formation of the colour gamut.^{108, 109}

A mixture based on cellulose triacetate, a formazan derivative and an organic solvent was proposed for the manufacture of light- and thermally inhibited films.¹¹⁰ Here, the nickel complex of 1-(1-methylbenzimidazol-2-yl)-3-methyl-5-(*p*-sulfamidophenyl)-formazan was used as the dyestuff.

The use of formazans, e.g., Zincon [1-(2-hydroxy-5-sulfo-phenyl)-3-phenyl-5-(2-carboxyphenyl)formazan], for staining proteins in polyacrylamide gels¹¹¹ demonstrated their advantages over traditional staining reagents, e.g., Brilliant Green.

An increasing attention in the past decade was given to the development and application of environmentally safe dyes. Formazan complexes with metals were synthesised where chromium, cobalt and copper ions were replaced by, e.g., iron ions.^{112, 113} Iron complexes based on 1,5-diaryl-3-cyanoformazans with the composition $\text{Fe} : \text{L} = 1 : 2$ were also synthesised.¹¹⁴ The structures of these compounds and their colour characteristics were studied by ¹H NMR, FAB (Fast Atom Bombardment Mass Spectrometry) and electronic spectroscopy. The complexes were used as acid dyestuffs for wool and polyamide fibres. A recently published review¹¹⁵ is devoted to the chemistry of this type of dyes.

Yet another trend in the practical application of metal complexes based on formazans is their use as materials for registration, recording and storage of information.^{116–118} The structures and properties of metal formazanates as optical recording media are described in a series of Japanese patents.^{119–122} It is of note¹¹⁹ that the recording layer contains a dye with the absorption maximum at 700–750 nm, is characterised by high photo and storage stability and is used for recording information on CD carriers.

Metal complexes **50**, which contain two formazan fragments with residues of nitrogen heterocycles, are described in a patent.¹²³ They were synthesised from formazans directly linked through methylene or sulfonyl bridges.

A, B is arylene; X = CH₂, SO₂; M is a divalent metal.

The material based on complexes **50** manifests high light resistance and good storage stability and is used for recording DVD.

There is an increasing number of patents devoted to the use of metal formazanates as optical elements (see, e.g., Refs 124–130). The use of a mixture consisting of cyanine or phthalocyanine and formazan derivatives for the manufacture of materials with high photo and storage stability has been described.^{124, 130} Such elements are usually employed in the commercial production of CD.

Yet another area of application of formazan-based metal chelates is worth noting, viz., a method for the manufacture of thermosensitive materials for lithographic boards based on complexation of formazans.¹³¹

V. Formazan-containing polymers

The advent and development of modern technologies brought forth the necessity of a search for novel materials endowed with desired properties. To such materials one can relate, in particular, formazan-containing polymers including high-molecular-mass metal complexes that have already found wide practical application. Several approaches to the synthesis of such polymers have been developed.

The simplest method includes introduction, into the formazan molecule, of polymerisable fragments. The preparation and properties of polymeric materials containing formazan units are described in a review.¹³² Formazans containing a styrene residue at positions 1 and 3 were subjected to anionic (or radical) polymerisation.¹³² The polyformazans thus prepared were used for the preparation of polymeric metal complexes, polyverdazyl radicals and polytetrazolium salts. The main advantage of this approach to the synthesis of polyformazans and their complexes is that the composition of the polymer formed and the structure of the metal chelate unit correspond to those of the original monomer. However, its practical application is limited due to possible complications during polymerisation.

The synthesis of polyformazans by polymer-analogous transformations was more successful. Thus numerous formazans containing polymeric fragments at position 1 were obtained from poly(*m*-aminostyrene). Polyacrolein and poly(*p*-formylstyrene) were used for the synthesis of formazans containing polymeric fragments at position 3. Such polymeric formazans were used for the synthesis of chelates with the coordination unit MN_4 .¹³² Some poly(acroleinphenylformazans) are efficient selective ion-exchangers for extraction of heavy metals: under certain conditions they bind Cu(II) and $UO_2(II)$ ions and do not react with Ni(II) and Co(II) ions. Analogously, poly(styrene-divinylbenzene) with an aldehyde group was transformed to hetarylformazan employed for the preparation of novel adsorbents.¹³³ The sorption properties of such polymers with respect to heavy metals and the possibility of selective extraction of copper ions were investigated.

Modification of cellulose by hetarylformazans is described in a monograph by V. M. Ostrovskaya *et al.*¹³⁴ This work deals with the description of different methods for immobilisation of formazan-containing reagents and provides examples of their practical applications. Many cellulose derivatives of hetarylformazans **51** were prepared by a reaction of aldehyde-cellulose with hetarylhydrazones and subsequent coupling with aromatic diazo compounds.

51

(P) is cellulose; R = H, OMe, SO_3H , CO_2H , Cl;

 2,6- and 4,6-disubstituted pyrimidines, thiazole, pyrazole, benzazoles, *etc.*

It was found¹³⁵ that the cellulose backbone exerts the same effect on the chromaticity of formazans as the alkyl substituent at position 3. The bathochromic colour reactions of formazans attached to modified α -cellulose at position 6 with ions of some heavy, precious and rare-earth metals were studied. Irregular polydentate 1-aryl-5-(benzazol-2-yl)formazan-6- α -celluloses were used for the manufacture of reagent test papers (RTP).¹³⁵ Formazans covalently grafted to cellulose exceed formazans

adsorbed on cellulose in both selectivity and stability, presumably due to higher structural rigidity. Cellulose benzoxazolylformazans are promising analytical reagents for determination of metals by test methods.

Several approaches have recently been developed to the quality control of copper(II) test reagents based on irregular polydentate α -celluloses including those containing 1-(4-methyl-6-methoxypyrimidin-2-yl)-5-phenyl-, 1-(4-methyl-6-methoxypyrimidin-2-yl)-5-(2-carboxyphenyl)- and 1,5-bis(4-methyl-6-methoxypyrimidin-2-yl)formazan units.¹³⁶ The efficiency of such materials used as tubes and multilayer test reagents is usually determined from the contrast of their colour reactions with copper(II), which are accompanied by liberation of equivalent amounts of hydrogen ions and formation of chelates.

Celluloses modified by benzothiazolyl-, benzoxazolyl- and 4,6-dimethylpyrimidinylformazans were studied in detail^{137–140} and characterised by diffuse reflectance spectroscopy. The complexation of these polymers with copper, nickel, cadmium, zinc, lead, silver and mercury ions revealed certain differences in their sorption capacities. The efficiency of extraction of metal ions depends on both the structure of the immobilised formazan group and the complexation conditions. Certain formazan-containing polymers can be used as reagents for the concentration of metal ions, *e.g.*, Cu(II), Ni(II), Pd(II), Hg(II); these polymers served as the basis for the development of novel RTP for the analysis of drinking water.

Sorption of heavy metals by membranes prepared by modification of sheet cellulose with formazan derivatives is accompanied by profound colour transitions.¹³⁸ Such membranes have the shape of coloured paper discs and are used, in particular, for purification of distilled and tap water from trace amounts of heavy metals and iron (the metal content in the membranes is determined by visual inspection and X-ray fluorescence analysis). Studies of sorption and chromogenic complexing properties of these membranes with respect to palladium and silver ions and some REE resulted in the development of a procedure for measuring palladium(II) concentrations in process solutions using 1-phenyl-5-(4,6-diphenylpyrimidin-2-yl)formazan-6- α -cellulose.¹³⁹ Hetarylformazan-6- α -celluloses, which supplemented the database of novel indicator materials, are among promising highly sensitive chromogenic ion-exchange polymeric reagents.¹⁴⁰ They are characterised by a combination of reversible complexation colour and redox reactions.

At present, formazans fixed on solid substrates by physical or chemical forces have found wide application as sorbents. The fixation is achieved by covalent immobilisation, ion exchange or physical sorption.¹³² The first experiments aimed at immobilisation of formazans on polymeric substrates employed compounds containing amide fragments at position 3 of the formazan chain. Sorbents obtained by immobilisation of aminophenyl-containing formazan on chloromethylated polystyrene manifested anion-exchange properties and high selectivity with respect to noble metals. They allowed isolation of trace amounts of Pd(II) from ammoniacal solutions containing a 10-fold excess of Ni(II). A modified ion-exchange sorbent for the separation of Ag(I) from a 1000-fold excess of Cu(II) was prepared by immobilisation of sulfoformazans on an aminomethylated polystyrene support. The use of silica gel as a substrate for immobilisation of sulfoformazans allowed preparation of an efficient ion-exchanger for pre-concentration and separation of Ag(I) ions from Pd(II) and Pt(II) ions.

Selective sorbents for Hg(II) from aqueous media were prepared by fixation of sulfoformazans on cellulose and immobilisation of dithizone on a polyurethane foam.¹³² These sorbents are used for the isolation of mercury from domestic and industrial waste waters in a broad range of pH.

Several papers^{141–145} describe the results of immobilisation of hetarylformazans on anion-exchangers. Modified ion-exchangers **52** and **53** were prepared by ion-exchange and condensation.

52

53

(P) is a polymer; $R^1 = \text{Me, Et, Pr}^i, \text{Ph}$; $R^2 = \text{H, OH}$.

The cross-linked amino-containing ion-exchanger AN-20 and commercial ion-exchangers AV-17, AN-18 and AN-31 differing in basicities were used as polymeric supports. Benzothiazole, benzoxazole and benzimidazole fragments and 4,6-disubstituted pyrimidine were used as heterocyclic components of formazans. The stabilities of the reagents synthesised in different media were found to depend on the basicity of the anion-exchanger. The sorption characteristics of the modified ion-exchangers with respect to a broad range of metals were investigated. They were used for the qualitative detection of trace elements in natural and waste waters and selective isolation of copper and scandium ions from solutions containing accompanying elements. For example, benzoxazolylformazan-modified anion-exchangers **52** selectively bind Sc(III) ions from solutions also containing Ti(IV) and Zr(III). The sorption properties of modified ion-exchangers depend on the structure of formazans immobilised, nature of the metal and sorption conditions. Representatives of compounds **52** and **53** can be used for efficient separation of copper and nickel in low-concentration acidic solutions, for selective isolation of mercury(II) in the presence of zinc(II) and cadmium(II) and for separation of silver(I) from nickel(II) and cobalt(II) and of zinc(II) from cadmium(II). Some of these polymers were proposed for separation of REE mixtures and preconcentration of lead(II) ions.

Analytical sorption-spectroscopic and test methods are based on the use of the known formazans in a new quality, *viz.*, in immobilised form, are actively developed of present. Fibrous materials and ion-exchange tissues are popular solid-phase supports for their immobilisation. Especially promising is a flow-through method for the preconcentration of chromium(VI) compounds on polyacrylonitrile discs filled with finely dispersed strongly basic anion-exchangers. Treatment of the disc with a solution of 1,5-diphenyl-3-hydroxyformazan in a dynamic mode ensures binding of chromium in a complex in the solid phase; metal ions are detected by the diffuse reflectance method.¹⁴⁶ Reagents preimmobilised on the surface of the support have got the name flow sensor systems.

Dithizone is widely used for this purpose. A test method for semi-quantitative determination of zinc by its sorption from alkaline borate solutions onto tissue discs has been developed.¹⁴⁷ Subsequent detection of zinc ions was carried out by visual inspection following treatment with dithizone solutions from the appearance of crimson colour. In another study,¹⁴⁸ the same authors studied colour reactions of zinc ions with dithizone on vinylpyridinium-containing tissues and fibrous materials filled with anion-exchangers using diffuse reflectance spectroscopy. Sensitive optical sensors based on immobilised dithizone for the presence of uranium(VI), mercury(II) and lead(II) compounds have been developed.¹⁴⁹ The use of these materials for direct determination of mercury in various waters revealed that the most sensitive reaction was observed in the case of immobilisation of dithizone on polyamide (*e.g.*, caprone, capropore or halipore) membranes.

Non-covalent immobilisation of benzazolyl- and pyrimidinyl-formazans on polyacrylonitrile fibres filled with the anion-exchange resin AV-17 was carried out and the effects of various

factors on the sorption properties of the polymers synthesised with respect to some heavy metal ions were investigated.¹⁵⁰ Among these compounds, selective sorbents were found for the isolation of copper ions in the presence of nickel, zinc and cadmium ions. Different hetarylformazans were immobilised on polyacrylonitrile fibres filled with the anion-exchanger AN-31 by covalent binding, ion exchange and physical sorption.¹⁵¹ Studies of the properties of these sorbents demonstrated that they can be used for sorption-spectroscopic determination of heavy metals.

Metallopolymeric systems have been prepared on the basis of immobilised formazans. High efficiency of such products is due to strong multipoint fixation of the metal as the complex with a formazan. Thus the aforementioned hetarylformazan-modified anion-exchangers **52** and **53** were used as ligands in the synthesis of polymeric metal complexes.¹⁵² Copper complexes of these materials prepared by sorption of Cu(II) ions from copper sulfate solutions were studied by EPR.¹⁵³ By varying the conditions of synthesis (chemical nature of the formazan, concentration ratio, method of synthesis of metal complexes on solid supports), one can obtain formazanates with different compositions (CuN_4 , CuN_3 or CuN_3O) and structures of the coordination metal centre. Polymeric metal complexes were also synthesised⁸⁴ by immobilisation of preformed Cu(II) or Fe(II) complexes with sulfobenzothiazolylformazan on an ion-exchanger. In this case, structural features of the coordination sphere of the monomeric analogues are retained.

Formazan-containing polymers were examined as catalysts of decomposition of aqueous solutions of H_2O_2 and liquid-phase oxidation of sulfides and hydrogen sulfide. The analysis of catalytic properties of copper- and iron-containing sorbents based on benzazolylformazan-modified anion-exchangers demonstrated^{154, 155} that the best results were obtained at the maximum saturation of the coordination unit of the metal chelate. In the case of copper complexes, the catalytic activity depends on both the content of copper ions and the structure and composition of the metal chelate unit. For example, the activity with respect to decomposition of H_2O_2 decreased on going from copper complexes (CuN_4) with a distorted square-planar coordination mode to mixed nitrogen-oxygen-containing complexes with a square-planar coordination mode.

* * *

The formazan systems considered in this review manifest extremely high tautomeric and conformational flexibilities. The use of such chelating ligands makes it possible to obtain complex compounds that present interest as subjects for solution of the problem of competitive coordination and effect of the nature of the polyhedra on the number of units in the metallacycle. It is noteworthy that in parallel with traditional applications of formazans and their metal chelates as dyes and photochromic agents some new areas emerge, *e.g.*, for their application as optical filters, thermosensitive elements, catalysts, optical sensors, test reagents and modified polymeric materials.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 05-03-32023 and 06-03-08040).

V. The applications of materials capable of molecular recognition	915
VI. Conclusion	916

Abstract. This review is devoted to the method of molecular imprinting. The physicochemical fundamentals and mechanisms of covalent and non-covalent molecular imprinting aimed at the development of organic polymeric sorbents capable of molecular recognition are considered. Attention is focused on the preparation of molecular imprints on mineral supports. The mechanisms of molecular recognition in adsorption are discussed. Application fields of materials with molecular imprints are briefly surveyed. The bibliography includes 112 references.

I. Introduction

The molecular imprinting method consists of the synthesis of organic or inorganic polymers capable of recognising molecules that were used as templates during their synthesis.^{1–10} The recognition becomes possible because the structure of such polymers includes areas (the so-called imprints) that can specifically interact (complementary interactions) with the template molecules or compounds with similar structures. The concept of complementarity includes the shape and size matching of an imprint to the template as well as the presence in the imprint of auxiliary functional groups capable of interacting with functional groups in the template.

The procedure of preparation of polymeric materials with molecular imprints includes three stages. In the first stage, a mixture of functional monomers and a template molecule is prepared. The so-called pre-assembling, *i.e.*, the formation of a molecular pre-polymerisation complex between the monomer and the template molecule takes place in this stage (Fig. 1). These complexes can be formed as a result of either the covalent bonding (covalent molecular imprinting) or non-covalent intermolecular interactions (hydrogen bonding, ion–ion and ion–dipole interactions, *etc.*). In the latter case, we deal with non-covalent molecular imprinting. In the second stage, polymerisation (polycondensation) of pre-polymerisation complexes with a large

Figure 1. Synthesis of polymeric materials with imprints.

(a) Formation of a pre-polymerisation complex of functional monomers with a template; (b) formation of a polymeric matrix incorporating the template molecules; (c) removal of the template molecules from the polymeric matrix and the formation of cavities complementary to the template molecule.

excess of a cross-linking agent results in the formation of a polymeric matrix that contains areas with functional groups arranged in positions determined by the template molecules. The third stage consists of either the removal of template molecules from the polymeric matrix by liquid extraction methods (for non-covalent imprinting) or the cleavage of chemical bonds between the template molecule and the polymer (for covalent imprinting). As a result, the material acquires cavities that, in ideal, should match the template molecule in their size, shape and the arrangement of functional groups.

It can be expected that the synthesised material will exhibit high specificity with respect to template molecules or molecules of compounds with similar structures. In nature, such specificity is typical of antibodies; this is why the materials prepared by molecular imprinting are often referred to as 'antibody mimics'.

II. Classification of molecular imprinting methods

The methods of synthesis of polymeric materials capable of molecular recognition can be classified according to the following criteria: (1) the nature of the polymeric matrix, (2) the method of preparation of a complex between the functional monomer and the template molecule, (3) the structure of imprints obtained.

Depending on the nature of functional monomers used in the synthesis of polymeric matrices, all materials capable of molecular recognition can be divided into organic and inorganic. The synthesis of organic matrices with molecular imprints involves the use of organic functional monomers and cross-linking agents containing C=C bonds. Inorganic matrices are usually prepared by polycondensation. Most often, functionalised silanes serve as the monomers and tetraethoxysilane as the cross-linking agent.

Depending on the method of preparation of pre-polymerisation complexes between a functional monomer and a template molecule, the methods of synthesis of materials capable of molecular recognition are conventionally divided into the imprinting in pre-assembled systems (the pre-polymerisation complex is synthesised beforehand) and the imprinting in self-assembling systems (the pre-polymerisation complex is synthesised immediately during the polymerisation). Imprinting in pre-assembled systems is referred to as covalent imprinting, because the complex is formed as a result of covalent interactions. Molecular imprinting in self-assembling systems is called non-covalent. In the latter case, the pre-polymerisation complex is formed as a result of non-covalent intermolecular interactions between template molecules and functional monomers.

Finally, molecular imprints can be formed either on the surface (2D-imprinting) or in the bulk (3D-imprinting) in the presence of appropriate solvents. In addition, the polymeric layers capable of molecular recognition can be applied onto pre-fabricated supports (the latter usually represent inorganic oxide supports with hydroxyl groups uniformly distributed over the surface[†]). Hence, the third classification is based on the structure of obtained imprints.

1. Non-covalent molecular imprinting

In the method of non-covalent imprinting, the polymerisation of functional monomers with a great amount of a cross-linking reagent in the presence of template molecules affords a highly cross-linked polymer incorporating template molecules. Template molecules are fixed within the polymeric matrix by non-covalent interactions (hydrogen bonding, electrostatic or π - π -interactions) with the functional groups of the monomers. Following removal of the template, which is usually carried out by solvent extraction, regions emerge in which functional groups are arranged complementary with respect to the functional groups in the template molecule. Being relatively simple and universal, the non-covalent approach is used to date most widely among the methods of molecular imprinting.

The first adsorbents with enhanced specificities with respect to molecular templates were synthesised by Polyakov¹¹ in the early 1930s. He demonstrated that silica gels formed in the presence of various alkylbenzenes exhibited enhanced (by approximately 15%) selectivity with respect to the adsorption of those particular hydrocarbons that have been used in their synthesis. Later, these experiments were continued with involvement of a wider range of

template molecules.^{12,13} In 1960, Patrikeev, Balandin *et al.* published a paper¹⁴ in which they showed that the pore size and adsorption properties of silica gels depend on the type of the substance introduced as a template at the stage of their synthesis. Silica gels thus obtained play the role of molecular sieves with respect to the template molecules.

The idea of changing the adsorption properties of solid adsorbents by the introduction of template substances at the stage of their synthesis was independently advanced by Pauling. He entrusted its experimental verification to his disciple Dickey. By allowing the solid structure of a sorbent to form in the presence of a compound for which this specific sorbent was intended, Dickey showed¹⁵ that the material synthesised can indeed selectively retain the substance that has been used as the molecular template in the synthesis of this material. In the synthesis of an adsorbent for Methyl Orange (1) and Ethyl Orange (2) dyes, in one of experiments the solution of sodium silicate was acidified in the presence of Methyl Orange (1) to afford a hydrogel, which contained molecules of this dye in its structure (Scheme 1). The material formed upon drying of the hydrogel and removal of the dye by extraction turned out to adsorb a double amount of Methyl Orange (1) as compared with Ethyl Orange (2).

Later, Dickey's concepts on the mechanism of molecular recognition were corrected by Wulff *et al.*^{16,17} who have shown that it is the complementarity between functional groups in the template molecule and in the recognition site that is the driving force of molecular recognition rather than the shape and size matching of the polymeric-matrix cavity to the template.

Below, we show examples of functional monomers and cross-linking agents that are used in the synthesis of selective sorbents by the non-covalent molecular imprinting method.¹⁸

A. Functional monomers

B. Cross-linking reagents

[†] For silica, the surface concentration of hydroxyl groups is 4.6 nm^{-2} . On the metal surface, hydroxyl groups are formed as a result of oxidation followed by hydroxylation.

Scheme 1

Functional monomers are selected in such a way as to provide their interaction with the functional groups of the template molecule at the stage of synthesis of the polymer. Methacrylic acid is used most often as the functional polymer because it can form complexes with many template molecules, *viz.*, with amines by forming an ionic bond and with amides, carbamates, alcohols, *etc.* by forming a hydrogen bond. It is known that electrostatic interactions are stronger than van der Waals interactions (particularly, hydrogen bonds); hence, the polymers that form ionic bonds with template molecules exhibit higher selectivity than those that form only hydrogen bonds. This was taken into account in the preparation of chiral stationary phases for the separation of racemates by HPLC (High-Performance Liquid Chromatography) (*e.g.*, for the separation of anilides of D- and L-phenylalanine, Scheme 2).^{19–21}

Studying the nature of molecular recognition of template molecules by polymers synthesised with involvement of non-covalent imprinting is a complex task. The literature contains relatively few publications devoted to the mechanism of such recognition.

The formation of non-covalent intermolecular monomer–template complexes in pre-polymerisation systems was proved by UV and NMR spectroscopy^{19,22} as well as by chromatographic methods. In particular, the effect of the functional monomer : template molar ratio in the pre-polymerisation mixture on the chromatographic characteristics of the resulting sorbents was investigated.²³ A series of polymers based on methacrylic acid (functional monomer) and ethylene glycol dimethacrylate (cross-linking agent) were prepared in the absence (control sample **P0**) and in the presence of a molecular template (template samples **P1–P6**). (–)-Nicotine served as the molecular template. The functional polymer : template molar ratio was varied from 4 : 1 to 1 : 10. The methacrylic acid : nicotine molar ratio was shown to have a substantial effect on the amount and quality of specific adsorption sites formed during the polymerisation, which followed from the results of chromatographic separation of a mixture of (–)-nicotine and 4,4'-bipyridyl on these polymers.

Scheme 2

Figure 2. The ratio of selectivity factors in chromatographic separation of (–)-nicotine and 4,4′-bipyridyl on sorbents **P0**–**P6**.²³ For the description of polymers **P0**–**P6**, see text.

It was shown that the excess of (–)-nicotine in the pre-polymerisation mixture has an adverse effect on the selectivity of the resulting sorbent with respect to nicotine (Fig. 2, polymers **P4**–**P6**), which followed from the low selectivity ratios of the separation of nicotine and 4,4′-bipyridyl ($k'_{\text{NIC}}/k'_{\text{bipy}}$) on polymers **P4**–**P6** (see Fig. 2) and also from the fact that the addition of acetic acid to the reaction mixture during the synthesis of polymer **P5** decreased the selectivity of separation of the above compounds on this polymer as compared with **P4** due to the competition between methacrylic and acetic acids for the binding of nicotine. This can be explained by the shift of equilibrium between pre-polymerisation complexes **3**–**5** to the formation of complexes **3** and **4** (Scheme 3). On the other hand, a small excess of the monomer favours the increase in the selectivity of sorbents (polymers **P1** and **P2**), which is associated with the preferential formation of complex **5**. However, a large excess of methacrylic

acid gives rise to a great number of non-specific binding sites in the polymeric sorbent, which decreases its selectivity.

Insofar as selectivity of obtained sorbents is the result of pre-assembling of monomer molecules with template molecules, it can be assumed that the formation of complex **5** is most favourable for the formation of highly selective adsorption sites in the polymeric network. Polymerisation of complexes **3** and **4** obviously results in the formation of regions with lower affinity to the template molecule, although it should be borne in mind that weak interactions of template molecules with the cross-linking agent (ethylene glycol dimethacrylate) can partly compensate the deficiency of methacrylic acid.

The idea of using vinylpyridines as the functional basic monomers was first forwarded in 1993 (Ref. 24). Three types of sorbents were prepared, namely, from 2-vinylpyridine (sorbent **A**), from methacrylic acid (sorbent **B**) and from both monomers taken in the molar ratio of 1:1 (sorbent **C**). Synthesis of these sorbents in the presence of Boc-L-tryptophan (as the molecular template) and their use in the chromatographic separation of Boc-L,D-tryptophan racemate have shown that the most efficient separation was achieved on sorbent **C**. Sorbent **A** was inferior, and sorbent **B** demonstrated the lowest separation ability.

Similar results were obtained with the use of dansyl-L-phenylalanine as the template (Scheme 4). Presumably, the formation of a pre-polymerisation complex, which would favour the formation

of selective sites, requires the simultaneous presence of both monomers in the reaction mixture, *viz.*, methacrylic acid for binding amino groups and 2-vinylpyridine for binding COOH groups in the amino acid.

Chromatographic properties of sorbents obtained in the presence of a non-polymerisable analogue of 2-vinylpyridine or methacrylic acid, namely, either pyridine or acetic acid, were analysed in order to confirm this hypothesis. In both cases, these sorbents proved inefficient in the separation of racemates as compared with sorbents prepared in the presence of two functional monomers simultaneously. This suggests that the formation of the pre-polymerisation complex involves the molecules of both monomers.

2. Covalent molecular imprinting

In covalent imprinting, the complex between a template molecule and a functional monomer, which can undergo co-polymerisation with a cross-linking agent in an appropriate solvent, is synthesised beforehand. Polymerisation of such a complex with an excess of the cross-linking agent affords a polymer incorporating chemically bound template molecules. In the final stage, under the action of the corresponding chemical reagents, the chemical bonds of template molecules with the matrix are broken and they are liberated. The cavities formed upon the template removal are characterised by a more definite (complementary to the template molecule) position of the functional group, which took part in the complex formation, than it can be achieved in non-covalent imprinting.

As compared with non-covalent imprinting, the imprinting in pre-assembled systems is much more laborious as regards both the choice of the template molecule and the experimental procedure. Hence, it is not surprising that the literature contains much fewer examples of the implementation of this approach as compared with the non-covalent imprinting.

The covalent imprinting method was first applied by Wulff *et al.*²⁵ They used phenyl α -D-mannopyranoside functionalised with 4-vinylphenylboronic acid as the template molecule. This compound was polymerised. The removal of the glycoside from the polymer afforded cavities that contained boronate functional groups.

The use of covalent imprinting in the synthesis of sorbent **P4** (Table 1), which is highly sensitive to nortriptyline and other tricyclic antidepressants, was reported.²⁶

Table 1. Methods of synthesis of polymeric sorbents studied in Ref. 26.

Polymeric sorbents (abbreviation)	Template (mol.%)	Cross-linking agent TRIM (mol.%)	Functional monomer (mol.%)
Sorbents without NOR molecular imprints			
P1	—	96	4-vinylphenol (4)
P2	—	64	methacrylic acid (24) + styrene (12)
P3	—	63	4-vinylphenol (12) + styrene (12) + methacrylic acid (13)
Sorbents containing NOR molecular imprints			
P4	NOR-alkene (4)	96	none
P5	NOR (4)	60	4-vinylphenol (12) + styrene (12) + methacrylic acid (12)
P6	NOR (2)	98	none
P7	NOR (2)	62	methacrylic acid (24) + styrene (12)

Nortriptyline (NOR): X = CH₂, R = H;
Amitriptyline (AMI): X = CH₂, R = Me;
Doxepin (DOX): X = O, R = Me.

Desipramine (DES): X = Y = R = H;
Imipramine (IMI): X = Y = H, R = Me;
Trimipramine (TRI): X = H, Y = R = Me;
Clomipramine (CLO): X = Cl, Y = H, R = Me.

Protriptyline (PRO)

Maprotiline (MAP)

Iminodibenzyl (IDB)

Bupropion (BUP)

Caffeine (CAF)

Functionalisation of nortriptyline and preparation of specific sorbent **P4** were carried out as shown in Scheme 5. Sorption properties of sorbent **P4** synthesised by covalent imprinting were compared with the properties of other polymeric sorbents used for sorption of these tricyclic compounds. To this end, a series of sorbents based on methacrylic acid and trimethylolpropane trimethacrylate were synthesised. Sorbents **P1**–**P3** were prepared by conventional polymerisation in the absence of a template, sorbents **P5**–**P7** were obtained by non-covalent imprinting in the presence of NOR (see Table 1).

The chromatographic properties of the obtained sorbents were studied. Several tricyclic antidepressants and compounds with similar physiological properties were screened. Table 2 shows the retention factors (*k*) for these compounds on sorbents **P4**–**P7**, which contained imprints of NOR molecules. As expected, the retention factor of nortriptyline on sorbents **P4**, **P5** and **P7** was substantially larger than those of other compounds

Table 2. Retention factors of compounds on different sorbents.

Compound	Retention factors (<i>k</i>) of compounds on sorbents			
	P4	P5	P6	P7
NOR	2.83	4.55	0.16	2.68
DES	2.59	3.53	0.20	2.48
PRO	2.35	3.58	0.18	2.24
MAP	2.49	3.96	0.20	2.44
DOX	1.43	0.75	0.14	1.13
TRI	1.33	0.53	0.15	1.03
AMI	1.57	0.85	0.14	1.11
IMI	1.52	0.88	0.14	1.12
CLO	1.61	0.97	0.16	1.09
BUP	1.42	0.58	0.20	0.88
IDB	0.17	0.53	0.27	0.37
CAF	0.19	0.40	0.13	0.68

Scheme 5

studied. It should be noted that sorbent **P6** the synthesis of which involved no functional monomers exhibits smaller k values. This confirms the important role of functional groups in molecular recognition. Sorption of compounds containing a secondary nitrogen atom (PRO, DES, MAP) on polymers **P4**, **P5** and **P7** was less efficient than that of nortriptyline but more efficient as compared with compounds containing a tertiary nitrogen atom (AMI, IMI, CLO, TRI). This can be explained by the fact that alkyl substituents at the nitrogen atom hinder the formation of the hydrogen bond $N \cdots HO-P$. Despite being secondary amines, BUP and IDM exhibit smaller retention factors as compared with NOR, which suggests that the shape and size of a molecular imprint affect the molecular recognition.

Usually, polymeric sorbents prepared by non-covalent molecular imprinting are less efficient in the chromatographic isolation of the analyte that has been used as the molecular template in comparison with sorbents obtained by covalent imprinting. This is manifested in pronounced broadening of the elution peak of the substance in question.^{27,28} The shape of the chromatographic peak of NOR on polymer **P4** prepared by covalent molecular imprinting could be substantially improved (Fig. 3 *a*) as compared with the NOR peaks on sorbents **P5** and **P7** synthesised by non-covalent imprinting (Fig. 3 *b,c*).²⁶

Covalent imprinting was also employed for the preparation of a sorbent that selectively adsorbs cholesterol²⁹ based on cholesterol 4-vinylphenyl carbonate and ethylene glycol dimethacrylate as the cross-linking agent. The sorption properties of this sorbent were compared with those of sorbents obtained by non-covalent imprinting with cholesterol as the template and methacrylic acid or 4-vinylpyridine as functional monomers. Chromatographic

separation of a mixture of cholesterol with β -estradiol was carried out.

Figure 3. Chromatograms illustrating the efficiency of sorbents **P4** (*a*), **P5** (*b*) and **P7** (*c*) in the separation of a mixture of tricyclic antidepressants.

The separation was observed on all sorbents; however, the polymer prepared by covalent imprinting had a higher adsorption capacity with respect to cholesterol and exhibited five-fold higher chromatographic efficiency as compared with polymers prepared by non-covalent imprinting.

A polymer that selectively adsorbs bisphenol A [2,2-bis(4-hydroxyphenyl)propane] was prepared³⁰ by co-polymerisation of bisphenol A dimethacrylate with triethylene glycol dimethacrylate or trimethylolpropane trimethacrylate.[‡]

The retention of bisphenol A, its analogues and certain hormones on the polymeric sorbent prepared was studied. It was shown that the sorbents retain best the compounds that contain two 4,4'-hydroxyl groups and have rigid structures and molecular sizes close to that of bisphenol A.

In the 1970s, Kabanov *et al.*^{31–33} developed an original method of synthesis of polymeric materials with three-dimensional networks 'tuned' to the sorption of definite ions. The complementarity of the 3D-regions of polymeric networks and a given type of metal ions was achieved by the preliminary conformational tuning[§] of macromolecules of non-cross-linked polymers with respect to these ions, which was followed by the fixation of such a conformation by intermolecular cross-linking and removal of metal ions (templates) from the system. It should be emphasised that complementarity does not exist on its own but arises in the process of adsorption of a given ion and manifests itself in the decrease in the energy and entropy consumed in the conformational rearrangement of segments of macromolecules during the formation of their complexes with the metal.

In general features, the procedure of preparation of such 'tuned' sorbents is as follows:³⁴ an aqueous-ethanolic solution of a transition metal salt (*e.g.*, 0.2 M CuCl₂) is added to a dilute solution of a non-cross-linked polymer in an organic solvent [*e.g.*, 5% solution of partly quaternised poly(4-vinylpyridine) in ethanol] together with aqueous ammonia for precipitation of the metal–polymer complex. Following drying, the metal–polymer complex is cross-linked by a cross-linking agent. The resulting cross-linked polymer is washed with dilute HCl to remove the metal ions. Naturally, upon desorption of the metal ions the conformation of chain segments of the polymeric network that incorporated these ions changes; however, due to cross-linking, the polymeric matrix retains by and large its topological characteristics, which favours the resorption of the same metal ions.

The relationship between the structure of complexes 'polymeric matrix–metal ion' and the recognition efficiency was studied systematically³⁵ using oligomers of poly(ethyleneimine) (PEI) cross-linked with a reaction product of epichlorohydrin with ammonia. Before cross-linking, PEI was treated with a solution of copper(II) and nickel(II) salts (the concentration of ions varied from 1 to 3 mmol g^{−1} PEI). A preliminary EPR study has shown that the PEI solution contained several complexes of Cu²⁺ with PEI, which differed in the degree of deformation of the

square-planar coordination of the Cu²⁺ ion and in the number of ethylenediamine fragments.

Complex A is formed as a result of interaction of a Cu²⁺ ion with amino groups that belong to four different chains, whereas complex B involves its interaction with ethylenediamine fragments that belong to two chains. The existence of complex C all amino groups in which belong to the same PEI chain is also possible. Obviously, complexes with the same composition can exist in the sorbent as well. At low degrees of protonation of amino groups, the sorbents preferentially contained complexes of the B and C types, whereas at high degrees of protonation, they contained complexes A. Sorbents non-tuned with respect to Cu²⁺ ions produced complexes A and even triamine complexes. In contrast, tuned sorbents preferentially produced complexes of the type C. EPR spectroscopic studies proved that for protonated sorbents, the increase in the content of copper leads to the rearrangement of interchain complexes into intrachain complexes. Thus, the introduction of a great amount of copper favours the fixation of such molecular conformations that are best suited for the formation of complexes and that are observed in solutions where the molecules exhibit the highest mobility. Indeed, studies of the adsorption properties of a sorbent prepared in the presence of a great amount of copper demonstrated that this sorbent exhibited the maximum sorption capacity and sorption rate. This favours the formation of uniform active sites, which is essential for the synthesis of selective catalysts.

Synthesis of catalysts tuned with respect to ethylbenzene, namely, cobalt complexes with a co-polymer of diethyl vinylphosphonate and acrylic acid, is described.³⁶ Kinetic studies of liquid-phase oxidation of ethylbenzene with molecular oxygen have shown that the oxidation rate on a catalyst the structure of which was formed in the presence of ethylbenzene substantially exceeds that on the same catalyst prepared by conventional procedures without tuning of its structure.

III. Physicochemical fundamentals of molecular imprinting

Despite the seeming transparency and relative simplicity of the scheme of synthesis of polymeric sorbents capable of molecular recognition and the clarity of the model of the recognition process, many unsolved problems still exist. Particularly, the physical nature of non-covalent interactions responsible for the formation of template–monomer complexes is unclear; there is no versatile model that would allow one to describe the distribution of recognition sites according to the energy.

Relatively few studies are devoted to the physicochemical properties of molecular imprinting. The factors that govern the formation of polymeric systems by the molecular imprinting method are considered in a review.³⁷ The first stage in the formation of polymeric systems capable of molecular recognition is the formation of a pre-polymerisation complex of the template molecule with functional monomers due to non-covalent intermolecular interactions. The stability of this complex (which ultimately determines the ability of the synthesised material to recognise molecules) depends on many factors, particularly, thermodynamic. The change in the Gibbs free energy (ΔG_{bind}) due to the formation of a template–monomer pre-polymerisation complex is described by equation

[‡] Certain complications were associated with the chemical removal of bisphenol A from the polymer under the action of a sodium hydroxide solution.

[§] By changing the polymeric chain conformation due to the formation of complexes with metal ions.

$$\Delta G_{\text{bind}} = \Delta G_{\text{t+r}} + \Delta G_{\text{r}} + \Delta G_{\text{h}} + \Delta G_{\text{vib}} + \Sigma \Delta G_{\text{p}} + \Delta G_{\text{conf}} + \Delta G_{\text{vdw}}.$$

Here, the terms G_i reflect the changes in the Gibbs free energy due to translation and rotation ($\Delta G_{\text{t+r}}$), restriction of rotors as a result of the formation of complexes (ΔG_{r}), hydrophobic interactions (ΔG_{h}), residual vibrational modes (ΔG_{vib}), the sum of contributions of polar interactions template–monomer ($\Sigma \Delta G_{\text{p}}$), adverse conformational changes (ΔG_{conf}) and unfavourable van der Waals interactions (ΔG_{vdw}).

Ultimately, the value of ΔG_{bind} determines the number of molecular recognition sites and their distribution according to the energy (the degree of heterogeneity). Obviously, the more stable the pre-polymerisation complex the higher its concentration in the equilibrium pre-polymerisation mixture and, hence, the larger the number of recognition sites in the polymer formed and the more efficient the recognition of the original template molecules. The probability of the formation of template–monomer complexes and their stability depend on the nature of all components (template, monomers, solvent, *etc.*) present in the pre-polymerisation mixture and also on the external conditions (pressure, temperature, *etc.*). The strength of interactions such as monomer–monomer, template–template, solvent–monomer and solvent–template affects the equilibrium of the formation of a complex of the template molecule with the functional monomer and, hence, the number and ‘quality’ of the resulting molecular recognition sites.

The second stage is the polymerisation (polycondensation) of the template–monomer complex in the presence of the cross-linking agent and other components of the mixture. It is evident that the optimum conditions of polymerisation can differ from the conditions that favour the formation of a pre-polymerisation complex. For example, the polymerisation process often requires elevated temperatures to be maintained; however, bearing in mind that the functional monomer–template complex is formed only due to electrostatic interactions, the increase in the temperature is undesirable due to weakening of these interactions.

In the third stage, the template is removed, which is accompanied by the liberation of molecular recognition sites. It should be noted that it is sometimes difficult to remove the template from highly cross-linked polymers; hence, a certain amount of template molecules remain incorporated into the polymeric matrix. This reduces the analyte detection limit. When such a polymer is used in analytical studies, the template is gradually eluted from it, which decreases the accuracy of analyte detection.

Different procedures for the efficient removal of template molecules from the polymeric matrix are described.³⁸ These include, for example, sonication or microwave irradiation during the extraction, extraction with supercritical CO₂ containing an organic solvent as an additive, the use of anhydrous formic, acetic or trifluoroacetic acids for washing the polymer. It was found that, in the general case, the extraction should preferably be carried out with the solvent that has been used in the synthesis of this polymer.

Yet another problem, which one inevitably faces in the synthesis of polymers capable of molecular recognition (especially when preparing sorbents by non-covalent molecular imprinting), is the energy heterogeneity[¶] of the adsorption sites formed. The synthesised polymeric sorbent usually contains a certain number of recognition sites with high affinity to the original template molecules [according to some data, the fraction of highly specific sites of molecular recognition may vary from 0% to 35% (Refs 39 and 40)], a certain number of adsorption sites with a low degree of affinity and also a fraction of adsorption sites with intermediate energy characteristics. Thus, there is always a certain distribution of recognition sites according to the energy.

It is known that the efficiency and selectivity of chromatographic separation on polymers prepared by molecular imprinting strongly depend on the load of the mixture to be separated, the separation being highly efficient and selective for low load and *vice versa*.⁴¹

There are several general experimental approaches to prove that the materials prepared by molecular imprinting recognise better the template molecules than other components in the mixture. In any case, a correct comparison requires a sorbent prepared under identical conditions and with the same reagents but in the absence of template molecules. To prove the existence of the molecular imprinting effect, it is necessary to compare the adsorption of template molecules on the material prepared in its presence (the so-called molecularly imprinted sample) and a material synthesised in the absence of template molecules (the so-called control sample). The comparison is carried out under either dynamic or static conditions. In the dynamic mode (chromatographic conditions), the synthesised polymers (including the control sample) play the role of a stationary phase, and the imprinting effect is judged from chromatographic parameters (retention time and retention factors, separation factors and indices) measured for different components in a mixture that also contains the molecular template. The static mode includes, as a rule, measurements of either the equilibrium adsorption of template molecules on the molecularly imprinted and control samples or the adsorption of different substances and, separately, the adsorption of template molecules on the imprinted sample.

As was noted above, the synthesis of polymeric sorbents using the molecular imprinting method is virtually always characterised by the distribution of recognition sites according to the energy. To assess the fraction of sites highly specific with respect to template molecules, one has to study the energy distribution of adsorption sites.

The simplest model that assumes the presence of only two (less often, three) types of recognition sites corresponds to the bi-Langmuir (or tri-Langmuir) isotherm

$$a = \frac{a_{01}K_1C}{1 + K_1C} + \frac{a_{02}K_2C}{1 + K_2C}$$

$$\left(\text{or } a = \frac{a_{01}K_1C}{1 + K_1C} + \frac{a_{02}K_2C}{1 + K_2C} + \frac{a_{03}K_3C}{1 + K_3C} \right),$$

where a is the equilibrium adsorption /mol g⁻¹; C is the equilibrium concentration of adsorbate in solution /mol litre⁻¹; a_{01} , a_{02} (a_{03}) are the numbers of recognition sites of the first and second (third) types, respectively /mol g⁻¹; K_1 , K_2 (K_3) are the adsorption constants on these sites /litre mol⁻¹.

This model was used for the approximation of experimentally obtained^{41–43} adsorption isotherms. The adsorption isotherm was plotted in coordinates a/C – a and the resulting curve was approximated with two crossed lines to find the parameters a_{01} , a_{02} , K_1 , K_2 . Based on the slopes of these lines and the segments they intercept on the ordinate, the values of a_{01} , K_1 and a_{02} , K_2 were found for the recognition sites of the first and second types, respectively. However, it should be admitted that the model that assumes the presence of only two types of recognition sites is rather limited; hence, it was proposed to use other models.

In one of such models, the Freundlich isotherm was used in the approximation of a set of experimental points⁴⁴

$$a = KC^m,$$

where m is a constant ($0 < m < 1$). The applicability of the Freundlich equation to the description of experimental adsorption isotherms was checked for 12 different sorbents prepared by non-covalent molecular imprinting. It was found that 11 of 12 isotherms are well ($R > 0.95$) fitted by the Freundlich equation. The main drawback of this equation is that this is inapplicable in the region of high concentrations, because, according to the

¶ Heterogeneity of adsorption sites limits the application of these polymers as the stationary phases for HPLC.

Freundlich equation, adsorption cannot infinitely increase with the increase in the concentration.

A more versatile model⁴⁵ employs the Langmuir–Freundlich equation

$$a = \frac{a_{\max} KC^m}{1 + KC^m},$$

where $a_{\max}$ is the maximum adsorption/mol g⁻¹; K is the constant related with the average adsorption constant (K_0) by the equation $K_0 = K^{1/m}$; m is the heterogeneity index ($0 < m < 1$). The Langmuir–Freundlich isotherm is transformed into the Langmuir isotherm for $m = 1$ and into the Freundlich isotherm for $C \rightarrow 0$ or $K \rightarrow 0$.

It was shown⁴⁵ that the Langmuir–Freundlich isotherm can be used for the approximation of a set of experimental points for materials synthesised by both non-covalent and covalent imprinting methods. The main advantage of this model is that it allows one to obtain the data on the energy distribution of recognition sites, provided the parameters a_0 , K and m are known. A method was proposed⁴⁵ that makes it possible to obtain the required distribution. Plotting the distribution of adsorption sites according to the energy makes it possible to compare the efficiency of molecular recognition by diverse materials, irrespective of their nature and the type of template molecules. It is noteworthy that the distribution can be calculated only for a concentration range in which the experimental isotherm was plotted. The limitation of this model is that a large body of experimental data is required to obtain reasonable values of a_0 , K and m .

IV. Molecular imprinting on mineral supports

Two approaches to the preparation of molecular imprints on mineral supports were developed, namely, imprinting in the bulk (3D imprinting) and on the surface of a mineral support (2D imprinting).

1. Imprinting in the bulk of a mineral support

Generation of molecular imprints in the bulk of a mineral support assumes that the mineral support structure is formed in the presence of template molecules. An attempt was undertaken⁴⁶ to reveal the factors that determine the template recognition. For this purpose, the following six pairs of compounds were chosen: Methyl Red–*p*-Methyl Red, Methyl Orange–Ethyl Orange, histidyl-alanine–histidyl-leucine, Methyl Red–Ethyl Red, 2,7-diamino-9-fluorenone–3,3'-diaminodiphenylmethane, D,L-histidine–L-histidine.

The effect of imprinting was studied by comparing the adsorption of a molecular template (one compound from a pair chosen) with the adsorption of a structurally related compound (the second in the pair) on a sorbent prepared by molecular imprinting.

According to the results obtained, the imprinting effect was much more pronounced when *p*-Methyl Red was used as the template as compared with Methyl Red. On the whole, the studies of the relative adsorption of the pairs listed above have shown that the effect manifests itself only for the first three pairs of compounds. Based on the results obtained, the following conclusions were drawn:

- recognition of template molecules requires the presence of three or more sites of interaction between the molecule to be recognised and the imprint;

- for molecular recognition, the position of a functional group in the template molecule is more important than the size of the latter;

- recognition of chiral molecules requires stronger interactions or larger numbers of interaction sites.

Unfortunately, no data on the diameters of pores and the specific surface areas of the samples prepared were reported in

Ref. 46. It cannot be ruled out that these factors can be responsible for the effect observed.

Synthesis of silica gel that specifically catalyses transesterification of ethyl phenylacetate was described.⁴⁷

Structure **6** represents the transition state of this reaction; this is why compound **7** was chosen as the template. Derivative **8** was synthesised to incorporate the template into the resulting silica gel. Co-polycondensation with tetraethoxysilane followed by calcination was expected to 'leave behind' the recognition sites matching the transition state of the transesterification reaction.

For comparison, a control silica gel sample was synthesised (in the absence of the template). Silica gel samples prepared both in the presence and in the absence of the template had equal surface areas and the same size distributions of pores.

To check this hypothesis, transesterification of ethyl phenylacetate was carried out using an equimolar mixture of octan-1-ol, hexan-1-ol and 2-phenylethanol on silica gel prepared by covalent imprinting.

The results obtained pointed to the preferential formation of *n*-hexyl and *n*-octyl phenylacetates (the ratio **9**:**10**:**11** was 7:8:1), which, at first glance, might indicate the presence of cavities complementary to the analogue of the transition state of this reaction. The transesterification reaction with these three alcohols proceeded at approximately the same rates both in the homogeneous phase and on the control sample.

However, as was found later,^{48,49} the results obtained cannot serve as a proof of the imprinting effect on the transesterification reaction. First, comprehensive studies of synthesised materials, which involved solid-state ³¹P NMR spectroscopy and thermogravimetric analysis, have shown that the template molecule is merely adsorbed by the sorbent rather than covalently bound. Hence, the formation of specific cavities is questionable, *i.e.*, the observed selectivity in the transesterification reaction cannot be unambiguously explained as the manifestation of the molecular imprinting effect. Second, for general reasons, it follows that the

presence of a transition state analogue in the reaction mixture should inhibit the transesterification reaction; however, no such inhibition was observed.⁴⁷ Moreover, in their later study,⁴⁹ the authors failed to reproduce their own results on the selective transesterification. Apparently, the selectivity observed earlier⁴⁷ is explained better as a result of different diffusion rates of alcohols and esters in micropores. Similar results, namely, the dependence of selectivity on the diffusion rate rather than on the presence of specific recognition sites, were obtained^{50, 51} for materials synthesised by the sol–gel method. These examples revealed the following drawbacks of using the sol–gel synthesis in the technology of molecular imprinting, *viz.*, poor reproducibility due to the impossibility of strict control over the pore size during the synthesis and a probability that the observations of diffusion phenomena in micropores would be wrongly interpreted as the imprinting effect. One can avoid some of these drawbacks by employing imprints prepared on the surfaces of mineral supports.

2. Surface modification of mineral supports

As was mentioned above, the presence of a template in the stage of synthesis of sorbents affects the chromatographic properties of the latter^{52, 53} and also the activity and selectivity of stereospecific catalysts.^{54–56} This method is also used in the preparation of materials with definite spatial structures.^{57–59}

It is very significant that most of published procedures of the preparation of organised surfaces, which involve the use of template molecules, have a common drawback, namely, the low stability of imprints formed on the surface. For example, operation with modified silica in aqueous media can be accompanied by the surface restructuring, which leads to the blurring and disappearance of imprints formed. This is why attention is focused on the materials with fixed molecular imprints, which represent covalently fixed structures. Such structures can be obtained by chemical modification of the surface.^{60, 61}

The possibility of construction of ordered structures on the surfaces of inorganic supports, particularly silica, is determined by the fact that its surface is uniformly covered with hydroxyl groups.

The methods of surface modification of oxide supports aimed at the formation of recognising materials can be divided into the following four groups:

- (1) preliminary adsorption of template molecules followed by chemical modification of unoccupied surface areas;
- (2) multipoint fixation of complex molecules on the surface followed by the removal of the central fixing fragment;
- (3) fixation of silanes on the support surface (polycondensation in pores) in the presence of template molecules;
- (4) fixation of a polymeric layer capable of molecular recognition on the particles of mineral oxides or in their pores.

A sufficiently comprehensive survey⁶² is devoted to the preparation of chemically modified oxide surfaces capable of molecular recognition.

a. Method involving preliminary adsorption of template

This method includes the stages of preliminary adsorption of the template, chemical modification of the remaining unoccupied surface and removal of the template (Fig. 4). As a result of such a modification of the support surface, the latter retains areas that resemble the template in the shape and exhibit chemical properties different from those of the modified areas.

To form ultrathin silica layers, Japanese scientists employed chemical vapour deposition (CVD). For this purpose, tetramethoxysilane (TMOS) was deposited from the gas phase onto oxide supports such as zeolite,⁶³ alumina,^{64–66} titania and zirconia,^{66, 67} tin oxide⁶⁸ or silicalite.⁶⁹ The pretreatment of the support surface with an aldehyde (*e.g.*, benzaldehyde) results in the formation of surface areas with chemisorbed stable benzoate anions.⁷⁰ Further modification of such a surface with TMOS involves only free surface areas. Thus this method was applied for

Figure 4. Preparation of molecular imprints in a graft layer. (a) template adsorption, (b) modification of the unoccupied surface, (c) template desorption, (d) modification of 'imprints'.

modification of the surface of γ -alumina.⁷¹ Studies of benzaldehyde adsorption on the sorbent samples have shown that they behave as molecular sieves with respect to benzaldehyde. It was found that the formation of a siloxane network in the adsorption of tetramethoxysilane on the surface of benzaldehyde-treated γ - Al_2O_3 is prevented due to the presence of template molecules, namely, benzaldehyde, on the surface.

Systems based on tin oxide were also studied.^{72, 73} Upon adsorption of benzaldehyde (graft density 1.49 nm^{-2}) or α -naphthaldehyde (0.77 nm^{-2}) on the tin oxide surface, the latter was treated with TMOS, which was followed by the hydrolysis. The cycle 'treatment with TMOS–hydrolysis' was repeated several times. As a result, the surface concentration of silicon atoms was 6.2 or 2.9 atoms per nm^2 , respectively, which exceeds the monolayer coverage of the free surface. The template was removed with ammonia (Scheme 6).

Studies of the adsorption of these aldehydes and of 2-chloro- and 2,6-dichlorobenzaldehydes have shown that all of them are sorbed better on the unmodified surface of tin oxide. For silica-modified samples studied, the best results were achieved when α -naphthaldehyde was used as the template. However, the samples behaved as molecular sieves only at high silicon contents (4.5 and 6.2 atoms per nm^2).

Electroconductivity and catalytic activity of pure tin oxide (sample 1) and tin oxide samples with SiO_2 layers deposited by a similar procedure with α -naphthaldehyde (sample 2), benzaldehyde (sample 3) and butyraldehyde (sample 4) as the templates were studied.⁷⁴ It was found that the adsorption of C_8 hydrocarbons with different structures first causes a sharp decrease in the resistance of samples and then its increase; this is why the comparison was carried out in the point of a minimum. The ratio between the resistances of the starting sample (R_a) and a sample with adsorbed hydrocarbons (R_g) was used as the criterion of conductivity (Fig. 5).

The catalytic activity of samples 1–4 was assessed based on the conversion of linear, branched and cyclic hydrocarbons C₆ in the course of their oxidative destruction to CO₂ (Fig. 6). An attempt was undertaken to relate the activity of samples 1–4 in the oxidative cracking of hydrocarbons C₆ to the molecular imprint size and check the correspondence of the latter to the size of the adsorbed hydrocarbon (Table 3).

The idea of using molecular imprints in the preparation of covalently grafted islet structures was put forward by Fadeev⁷⁵ in 1986. He noted that chemical modification of a surface that contains pre-adsorbed template molecules allows one to ‘fix’ the imprints and thus increase their stability. Further modification of the ‘imprints’ obtained can be carried out by conventional methods of surface chemistry.

‘Sharp’ imprints can be obtained, if the template is adsorbed unambiguously and sufficiently strongly on the surface, which prevents its washing out during the modification. At the same time, the template adsorption should be reversible to allow its removal from the surface after the chemical modification. It was

Figure 5. Changes in the conductivity of samples of (I) SnO₂ and (2–4) SiO₂/SnO₂ as a result of adsorption of different hydrocarbons C₈ (I–IV) at 643 K.⁷⁴

(I) n-octane, (II) 2-methylheptane, (III) 2,3-dimethylhexane, (IV) cyclo-octane. The preparation of samples 2–4 involved preliminary adsorption of the following templates: (2) α-naphthaldehyde, (3) benzaldehyde and (4) butyraldehyde.

Figure 6. Oxidation of alkanes C₆ at 643 K on (I) SnO₂ and (2–4) SiO₂/SnO₂ samples.⁷⁴

(I) n-hexane, (II) 2-methylpentane, (III) 2,3-dimethylbutane, (IV) cyclohexane. For the description of samples 1–4, see the caption to Fig. 5.

proposed that metal phthalocyanines, particularly silicon dichloride phthalocyanine (PcSiCl₂) and copper naphthalocyanine (NcCu) should be used as the templates.⁷⁵

Table 3. The size of template molecules used for the modification of the tin oxide surface and the sensitivity of prepared sorbents with respect to C₆ alkanes.

Template	Sensitivity with respect to				
	template molecule size /nm	n-hexane (0.36 × 0.48)	2-methylpentane (0.37 × 0.60)	2,3-dimethylbutane (0.57 × 0.62)	cyclohexane (0.43 × 0.61)
None	—	h	h	h	h
α-Naphthaldehyde	0.37 × 0.92	h	h	h	h
Benzaldehyde	0.37 × 0.67	h	h	l	l
Butyraldehyde	0.36 × 0.48	h	l	l	l

Notes. The following abbreviations are used: h corresponds to high sensitivity, l corresponds to low sensitivity. Sizes of C₆ molecules are given in nm.

Phthalocyanines are adsorbed sufficiently strongly (but reversibly) on silica, occupy large landing areas per molecule and are easily modified. Moreover, they are excellent chromophores, which makes easier their detection in the adsorbed state. Table 4 shows the conditions of adsorption of copper naphthalocyanine on the surface of silochrome 120 (entry I) and of silicon dichloride phthalocyanine on silochrome 120 modified with 3-(aminopropyl)triethoxysilane (entry II), and also the conditions of surface modification and template removal.

The completeness of the phthalocyanine adsorption and desorption was monitored by spectrophotometric techniques. The formation of imprints in the graft layer upon removal of adsorbed templates was proved using the method of paramagnetic labels, which involved treatment of the sorbent sample with an excess of iminoxyl radicals.^{76–78}

A comparison of EPR spectra of molecularly imprinted sorbent samples, which were prepared in the presence of templates, and the control samples, which had the known uniform distribution of the paramagnetic label, has shown that the label molecules in the former samples are located more closely to one another. The EPR data on the distances between the neighbouring labels and the number of labels correspond to the results of calculations based on the silica surface area and the size and number of imprints. The comparison of adsorption properties of molecularly imprinted and the control sorbent samples have shown that the adsorption capacity of the former with respect to the corresponding template molecules increases. These results point to the formation of the corresponding islet nanostructures on the silica surface.

A large series of publications described the development of methods for the synthesis of catalysts capable of molecular recognition. The idea that underlies these methods is that compounds with structures close to that of a catalytic reaction transition state could serve as the templates in the synthesis of catalysts. It was proposed^{79–87} to synthesise enantioselective catalysts based on silica gels with *R* or *S* enantiomers imprinted, in particular, (*R*)- or (*S*)-5-phenylimidazolidine-2,4-dione [5-phenylhydantoin (**12**)].⁸⁷

For this purpose, the surface of pure SiO₂ was treated with concentrated HCl to produce silanol groups, washed and then doped with Al³⁺ ions (by adding aluminium chloride and heating to 80 °C for 3 h) to obtain aluminium-substituted active centres (Lewis acid sites). After this treatment, a solution of the template (5-phenylhydantoin) was added to silica gel and the samples were stored for a week at pH 4. Then the template was extracted in the Soxhlet apparatus until its complete removal from the surface. The catalysts obtained were assayed in reactions of *R* and *S* isomers of 5-phenylhydantoin (**12**) and 4-phenyl-1,3-oxazolidine-2,5-dione (**13**) with potassium 2,4-dinitrophenoxide. Table 5 shows the kinetic parameters of reaction (1) for X = O.

X = NH (**12**), O (**13**); catalyst is silica gel with an imprint of (*R*)- or (*S*)-5-phenylhydantoin.

It follows from Table 5 that the reaction rate constants substantially differ depending on the catalyst type used. The highest rate is achieved for a catalyst with the configuration identical to that of the corresponding substrate. The results obtained can be explained by the formation of chiral cavities on the silica gel surface (Fig. 7). It is these cavities that determine the catalyst stereoselectivity. From the temperature dependence of the catalytic reaction rate it was possible to calculate the activation parameters for each catalyst type. The energy of activation of the *S*-substrate on the *S*-catalyst is lower than the energy of activation of the *R*-substrate on the *S*-catalyst. The possibility of the preparation of stereospecific catalysts by the molecular imprinting method was confirmed by the example of other catalytic reactions (see Refs 88 and 89).

b. Multipoint fixation of complex molecules

In essence, the method of multipoint fixation of complex molecules [*e.g.*, (X₃Si–R'–Z)_mA] on the surface of oxides consists of the preparation of sorbents in which the functional groups Z are fixed at a certain distance from the sorbent surface that favours subsequent selective binding of fragment A of these molecules.

Table 4. Conditions of template adsorption on the silica surface, subsequent surface modification and removal of template molecules.

Entry	Original surface	Template molecule	Conditions of template adsorption	Amount of adsorbed template / $\mu\text{mol m}^{-2}$	Conditions of modification of a surface containing adsorbed template	Conditions of removal the template from the surface	'Resulting' surface
I	Silochrome 120	NcCu	Solution in toluene ($\sim 10^{-6}$ M)	0.0017	Treatment with trimethylchlorosilane in gas phase at 60 °C	Treatment with a mixture of trimethylacetyl chloride and morpholine in hexane	'Islets' of original silica on the 'background' of a trimethylsilane monolayer
II	Silochrome 120 modified with aminopropyl groups	PcSiCl ₂	Solution in toluene ($\sim 10^{-6}$ M)	0.0057	Treatment with ethyl acrylate in propan-2-ol at 60 °C	Extraction with toluene with addition of acetic acid in the Soxhlet apparatus	'Islets' of amino-propyl groups on the 'background' of ethyl acrylamide

Notes. Designations: K_M is the Michaelis–Menten constant; k_{max} is the maximum rate constant calculated for the first-order reaction mechanism; k_{cat} is the average value of k_{max} normalised with respect to the number of catalytic sites in 50 mg of catalyst. ^a Determined based on the ratio k_{cat}/K_M for (*R*)- and (*S*)-4-phenyl-1,3-oxazolidine-2,5-diones. ^b Catalyst was prepared with the use of a racemate as the template.

**Figure 7.** A scheme of enantioselective catalysis on an imprint obtained with the use of *S*-template.⁸⁷

This method was used for the synthesis of a sorbent selective with respect to nicotinamide adenine dinucleotide (NAD) and containing boronate groups at a fixed distance from one another.^{90,91} The synthesis is based on the known reaction of phenylboronic acid with the sugar fragments of bis(nicotinamide adenine dinucleotide) (bis-NAD).

The reaction product of 4-[(MeO)₃SiR']C₆H₄B(OPr)₂ with two types of bis-NAD, which contained spacers of different length (7 and 17 Å) between NAD fragments, was used as the modifier of the silica gel surface.

Following fixation of the modifier, the silica gel surface was additionally silanised with dodecyltriethoxysilane, phenyltriethoxysilane, *N*-(2-aminoethyl)-3-aminopropyltriethoxysilane and bis(2-hydroxyethyl)aminopropyltriethoxysilane to improve the sorbent properties. The sorbents obtained were used in the chromatographic determination of bis-NAD by HPLC. It was found that the retention of each of bis-NAD types on the sorbent modified with this particular NAD type was twice stronger as compared with sorbents modified with the other NAD types.

A method of modification of the silica gel surface that involved the use of the Ru[bipy-CH=N(CH₂)₃Si(OEt)₃]₃ complex was described.⁹² After hydrolytic cleavage of the CH=N bond of this complex, three amino groups fixed at a definite distance from one another remained on the silica gel surface. Such sorbents can be used for selective sorption of ruthenium or as piezoelectric sensors. These amino groups can be modified further with the aim of preparation of sorbents for HPLC.⁹³

c. Method of fixation of silanes in the presence of template molecules

The simplest method of preparation of sorbents with molecular imprints is based on the polycondensation of alkoxy-silanes in the pores (or on the surface) of silica gel, which is carried out in the presence of a template (Fig. 8).

Figure 8. A scheme of hydrolytic polycondensation of alkoxy-silanes on the silica gel surface in the presence of a molecular template.

Synthesis of silica gel-based sorbents selective to a given dye was described.⁹¹ A mixture of phenyltriethoxysilane, *N*-(2-aminoethyl)-3-aminopropyltriethoxysilane and bis(2-hydroxyethyl)-aminopropyltriethoxysilane was added to a porous silica gel impregnated with a dye (Rhodanine Blue or Saffranine O) and their polycondensation was carried out.

Based on the same silane mixture and a silane with a fragment of 3-aminophenylboronic acid, sorbents containing transferrin and bovine serum albumin imprints were prepared.⁹¹ Of the sorbents obtained, only that synthesised in the presence of transferrin exhibited selectivity.

Silica gels with imprints of ricin and its A and B chains were prepared in the pores of silica gels impregnated with these compounds by polymerisation of a mixture of tetraethoxysilane and bis(2-hydroxyethyl)aminopropyltriethoxysilane.⁹⁴ Each of three silica gels bound almost exclusively the object that served as the molecular template. Later, a similar method was used in the preparation of silica gels containing imprints of *N*-decyl-D-phenylalanine-2-aminopyridine.⁹⁵

d. Synthesis of polymers capable of molecular recognition

The methods of synthesis of polymers for molecular recognition are sufficiently well developed. However, swelling, lability and insufficient permeability limit their application. Most of these limitations can be overcome by fixing a thin polymeric layer on the surface of particles of a porous silica gel or in its pores. Strong binding is achieved by preliminary chemical attachment to the silica gel surface of functional groups that can be involved in subsequent polymerisation.

This method was used in the synthesis of sorbents for chromatographic determination of imidazole.⁴⁰ First, 3-(triethoxysilyl)propyl methacrylate was fixed to the silica gel surface. Then, ethylene glycol dimethacrylate, copper *N*-(4-vinylphenyl)-

iminodiacetate and a molecular template of the imidazole series [1,4- and 1,3-bis(imidazol-1-ylmethyl)benzene or 4,4'-bis(imidazol-1-ylmethyl)biphenyl] were added and polymerisation was induced by azobis(isobutyronitrile). The synthesised material was packed into HPLC columns, copper ions were exchanged for zinc ions, and the sorbent was used in the chromatographic determination of imidazole or template molecules. The preferential binding of molecules that served as the templates during the sample preparation was observed.

Complexes of copper *N*-(4-vinylphenyl)iminodiacetate with L-, D- and L,D-phenylalanine and other amino acids can be used as molecular templates.^{96,97} Selectivity of chromatographic resolution of L,D-phenylalanine on a sorbent prepared with a copper–D-phenylalanine complex as the molecular template was 1.65, while the selectivity of separation of L,D-thyrosine on the same sorbent was 1.56. The same column was used for the resolution of racemic α -methylphenylethylamine (selectivity 1.32); however, attempts to resolve a racemate of α -methylcinnamic acid failed.

Treatment of silica gel with surface-bound active chlorobenzyl groups with sodium *N,N'*-diethyldithiocarbamate afforded an UV-sensitive initiator of radical polymerisation.⁹⁸ This was used in the radical polymerisation of methacrylic acid and ethylene glycol dimethacrylate in the presence of L- or D-phenylalanine (L- or D-Phe) anilides as the templates (Scheme 7). The same materials were prepared in the absence of the template. The separation factors ($\alpha = k'_L/k'_D$, where k'_L and k'_D are the retention factors for L- and D-Phe) of enantiomeric template molecules on HPLC columns packed with sorbents prepared in the presence of L-Phe and D-Phe were 2.4 and 0.35, respectively, and 1 in the absence of amino acid.

Other sorbents intended for the separation of L- and D-phenylalanine anilides were prepared analogously. For this purpose, a radical azo-initiator was fixed on the surface of porous silicas Si-1000, Si-300 and Si-100 and non-porous silica gel; then, MAA and EDMA were polymerised in the presence of L-phenylalanine anilide.⁹⁹ The optimum chromatographic separation of L- and D-phenylalanine anilides with the separation factor of up to 7 was achieved for a polymeric film of a thickness of 6–7 nm.

Silica gel with fixed vinyl groups was used in the co-polymerisation of acryloylcyclodextrin and *N,N'*-methylene di(acryl-

Table 6. Retention times of amino acids, peptides and *m*-nitrophenol on chromatographic columns with different sorbents.¹⁰¹

Compound	Retention time (min) on sorbents ^a		
	A	B	C

amide) in the presence of molecular templates, namely, L-Phe-L-Phe or D-Phe-D-Phe.¹⁰⁰ Table 6 shows some results obtained on chromatographic columns packed with these sorbents.¹⁰¹

The surface of capillaries for capillary electrophoresis was modified analogously.¹⁰² First, the capillary surface was treated with (methacryloyloxypropyl)trimethoxysilane. Then, the pre-polymerisation mixture that contained monomers, a cross-linking agent (TRIM), a radical initiator [2,2'-azobis(isobutyronitrile)] and template molecules [(*S*)-propranolol, (*S*)-metoprolol or (*S*)-atenolol], was introduced into the capillary columns. After completion of polymerisation, template molecules were removed by extraction with acetonitrile, methanol or a methanol–acetic acid mixture. The columns thus modified were used in the separation of certain organic substances.

V. The applications of materials capable of molecular recognition

Polymers with molecular imprints attract keen attention of scientists and engineers. First of all, this is associated with the active quest for selective sorbents (including sorbents for HPLC), the materials for membranes and sensors and artificial antibodies (Fig. 9).

Figure 9. Distribution of application fields of polymers with molecular imprints (according to the data from Ref. 101).

Sorbents based on polymers with molecular imprints exhibit several obvious advantages as compared with conventional sorbents. They are characterised by high chemical affinity and selectivity with respect to target molecules (which in certain cases is comparable with the selectivity of biomolecules), high stability, which exceeds that of biomolecules, relatively easy adaptability to various practical applications and relatively low cost.¹⁰¹

Polymers with molecular imprints are employed most often in the separation and concentration (*e.g.*, see a survey¹⁰³). The search for effective sorbents for the exhaustive cleaning of water[†] and the processing of industrial and domestic wastes is in progress. The USA alone spend more than \$ 500 million for the manufacture of sorbents for chromatographic columns, the percentage of polymers with molecular imprints being 1%–3%.¹⁰¹ In the pharmaceutical industry, the biopharmaceutic branch (production and purification of recombinant proteins and monoclonal antibodies) is most dynamic. The use of sorbents with molecular imprints in the separation of proteins is described in Ref. 104.

Chemical sensors based on polymers with molecular imprints are being actively developed. They are considered as an alternative to biosensors, which exhibit low stability and are very expensive. To date, sensors based on polymers with molecular imprints have already been developed for the detection of certain herbicides,¹⁰⁵ sugars,¹⁰⁶ medical drugs,¹⁰⁷ nucleic acids,¹⁰⁸ toxins,¹⁰⁹ *etc.*

Porous materials with the template-determined pore sizes closely relate to the subjects considered in the present review. In this case, it is surfactants that serve as templates; however, their sizes exceed those of molecules and are determined by the geometry of surfactant globules. In 1992, synthesis of the first structured mesoporous material, MCM-41 (Mobil Composition of Matter), which is remarkable for its regular pores with a narrow size distribution (a result of hexagonal packing of linear cylindrical pores), was reported.¹¹⁰

To explain why mesoporous materials form ordered structures, Beck *et al.*¹¹¹ have proposed the so-called LCT (Liquid Crystal Templating) mechanism. They assumed that the formation of an ordered structure is associated with micelles that are formed in surfactant solutions (with a concentration exceeding the critical micelle concentration) and serve as the templates in the synthesis of MCM-41 and related materials. First, spherical micelles are formed and, next, cylindrical. The latter are transformed into the so-called micellar rods upon the reaction with silicate.

In the second stage, the micellar rods are ordered hexagonally to afford a sort of a composite, which contains the bound organic and inorganic layers. Calcination of the obtained composite and removal of organic component produce an inorganic structure with hexagonally ordered cylindrical pores of identical diameters.

A recently published review¹¹² is devoted to the synthesis and physicochemical and catalytic properties of mesoporous titanium silicate materials.

VI. Conclusion

The analysis of data discussed in the present review points to the substantial interest of scientists in the synthesis of materials capable of molecular recognition. The most remarkable results are achieved in the field of synthesis of organic polymeric materials, which is explained by the wide possibilities of varying the chemical nature of monomers and cross-linking agents and also the flexibility of the polymeric structure.

To date, only few studies are devoted to designing mineral matrices with imprints. The approach based on functionalisation of the surface by multipoint fixation of complex molecules can be applied to the solution of only very specific problems. Sorbents prepared by the modification of areas left unoccupied after the template adsorption also find limited application, because the imprints formed on the surface are complementary to the templates only as regards their geometry.

Being versatile, the materials obtained by polycondensation of siloxanes or polymerisation of organic monomers in the support pores in the presence of template molecules show more promise. It is hoped that mineral supports with imprints, first of all, silica will find application in HPLC.

Both the published data and our own experience allow us to suggest that the clarity of the idea of molecular imprinting is rather illusory. The possibility of achieving the desired result is often limited by the ambiguous mechanism of the process under study and, as a consequence, a considerable non-uniformity of generated adsorption sites. Hence, it is not surprising that one can rarely enhance the specificity of a recognising material by more than 30%, whereas biological evolution has developed absolutely specific materials implemented in 'antigene–antibody' interactions. It cannot be ruled out that the use of methods of molecular biology, particularly, the use of aptamers, in the synthesis of recognising materials will prove to be more promising than the attempts to develop chemical models of biological processes. Nonetheless, the synthesis and application of artificial materials with molecular imprints are being progressively developed in scientific studies and occupy the increasingly strong position in many applied fields.

We are grateful to S Z Bernadyuk and A V Buryak for helpful discussions of this review.

Abstract. Topological structures of branched polymers, including weakly and highly branched chains, star-shaped, H and pom–pom polymers, dendrimers and comb-like, hyperbranched and critically branched polymers, are characterised. Experimental data on their rheological and relaxation properties are analysed. Theoretical approaches to the description of relaxation spectra of branched polymers are outlined. The bibliography includes 272 references.

I. Introduction

The relaxation properties of polymers are to a large extent determined by their architecture.¹ Nevertheless, such factor as branching that influences large-scale relaxation has received much less attention than the molecular mass distribution (MMD). However, the branching factor has attracted considerable interest in recent years² due to the fact that the scope of synthesis of branched-chain polymers with desired topological structures has been widened.^{3–5}

In recent years, the line of investigation associated with the synthesis of hyperbranched (superbranched) polymers (HBP) has been extensively developed in polymer chemistry and technology.^{5–13} This interest is due to the fact that hyperbranched polymers have unique properties. Nanosized HBP particles are soluble in virtually all media and have a high sorption capacity.¹⁴ Due to this fact, HBP have found wide use in technology (polymeric and construction materials, paint and varnish production, organic glasses, nanocomposites, *etc.*), electronics and microelectronics (polyelectrolytes, semiconductors, polymeric plasmons, *etc.*), chemistry (nanosized reactors), medicine (pharmacological nanocontainers) and ecology (sensitive environmental sensors).^{11, 13, 15} In the early stage of the development of science and technology of branched polymers, dendrimers, *i.e.*, polymers having highly regular topological structures (regular Cayley trees, RCT), have been considered as HBP. In scientific literature, emphasis has been given to the development of procedures for the synthesis of dendrimers^{5, 6, 9} and investigation of the rheolog-

ical and sorption properties^{6, 10} associated primarily with the use of dendrimers as transporting agents (for example, to deliver drugs to targeted sites). Evidently, the synthesis of dendrimers is a very complex problem because a stepwise increase in the number of generations is required to meet the condition of regularity of the structure.

In recent years, studies on the synthesis of HBP by conventional methods of polymer chemistry, *i.e.*, by polycondensation and polymerisation, have been extensively carried out.^{11, 12} The resulting topological structures are less regular than those of dendrimers (irregular Cayley trees, ICT). Macromolecules formed by these methods are characterised by a broad molecular mass distribution and a broad distribution over the number of peripheral branches. Nevertheless, the desired properties of these macromolecules are only slightly worse than those of dendrimers and such macromolecules are relatively cheap due to a low cost of the starting materials and the simple synthesis technology.

The relaxation properties of dendrimers were studied in sufficient detail both experimentally^{6, 16–24} and theoretically.^{25–34} However, studies on the relaxation properties of HBP with an irregular topological structure are scarce. A knowledge of these properties can apparently be obtained by analysing the published data on the influence of branching of polymer chains on their relaxation behaviour. In other words, the relaxation properties of weakly and randomly branched polymers, star-like, comb-like, H and pom–pom polymers and critically branched polymers formed in the vicinity of the gel point are of considerable interest. This problem is dealt with in the present review.

II. Architecture of branched macromolecules

The following topological types of branched polymers were described in the literature.

1. **Randomly branched polymers.** The branching number can vary so that macromolecules can be both weakly and highly branched. This type of polymers is characterised by the branching number per chain or per a particular chain length and the average molecular mass of branches. In essence, the topological structure of branched macromolecules is ICT. Each numbered branch (starting from one end of the main chain) belongs to a particular generation. The structures of these chains are determined by the kinetics of the process of their formation, in particular, by the kinetics of the chain transfer reaction through the polymer (as in the case of radical polymerisation of ethylene or vinyl acetate).

2. **Comb-like polymers** are formed if side chains (which can be rather long) are attached to the main chain more or less regularly.

Uspekhi Khimii 75 (10) 1018–1034 (2006); translated by T N Safonova

Generally, the functionality of the branching points (f) is three. However, comb-like macromolecules with $f = 4$ ('centipedes') and $f = 6$ ('barbed wire') are also known. Polymeric molecules with densely attached side branches are considered as one-dimensional polymers (cylindrical brushes).

3. Star-shaped polymers are characterised by the number of branches (arms) coming from a single centre, the functionality and the molecular mass of branches (M_a). It is generally assumed that all branches have the same length. Asymmetric three-arm stars are sometimes called T polymers (two short arms and one long arm) and Y polymers (one short and two long arms).

4. H polymers. By H polymers are meant chains carrying two branches of equal length at each end. These polymers can be characterised by the following two parameters: the molecular masses of the chain and branches.

5. Pom–pom polymers are structurally analogous to H polymers with the difference that the number of branches at both ends is larger than two. Hence, these polymers are characterised by an additional structural parameter, *viz.*, the number of branches at each chain end.

6. Dendrimers are star-shaped (in some publications (see, for example, Refs 25, 27 and 34) these polymers are called 'starbursts'). However, branches coming from the centre belong to the first generation. The arms are branched at the ends to form the second generation of branches, which, in turn, are branched at ends to form the third generation, *etc.* If the first generation consists of f_0 branches and each branch point generates f branches in the next generation, the total number of branches in the k th generation is

$$p_k = f_0 f^{k-1}.$$

The total number of branches in a macromolecule consisting of G generations is

$$P_G = \sum_{k=1}^G p_k = f_0 \frac{f^G - 1}{f - 1}. \quad (1)$$

7. Hyperbranched polymers. The above-described polymer structures are, in essence, HBP. However, since these structures are commonly called dendrimers, the term HBP will be used in reference to tree-like macromolecules with irregular structures (ICT topological structures), which are prepared by conventional polymerisation or polycondensation methods.

The structures of HBP, unlike those of dendrimers, were not unambiguously determined. Hence, *a priori* conclusions about the structures of such polymers can be drawn based on the characteristic features of the mechanism of their formation. Polycondensation of AB_f -type oligomers, for which f is generally equal to 2, is the simplest (from the kinetic point of view) industrial synthesis of HBP.¹³ This process was theoretically studied by the Flory method of combinatorial analysis.³⁵ More recently, various statistical^{36–51} and kinetic methods, including computer simulation,^{49, 52–63} have been used to calculate the MMD function.

In the absence of cyclisation, HBP macromolecules prepared by the above-mentioned method contain one unreacted functional group of type A and $(fn - n + 1)$ functional groups of type B (n is the number of monomeric units in the molecule). Hence, the degrees of conversion at these groups (α_A or α_B , respectively) are related to each other by the following equation

$$\alpha_A = f\alpha_B.$$

The distribution function over groups B is determined by the equations

$$\langle b \rangle_n = (f - 1) \bar{P}_n + 1,$$

$$\langle b \rangle_w = \frac{(f - 1)^2 \bar{P}_w \bar{P}_n + 2(f - 1) \bar{P}_n + 1}{1 + (f - 1) \bar{P}_n},$$

$$\frac{\langle b \rangle_w}{\langle b \rangle_n} \approx \frac{\bar{P}_w}{\bar{P}_n},$$

where the average degrees of polymerisation (in the absence of the substitution effect, *i.e.*, calculated statistically) are as follows:

$$\bar{P}_n = (1 - \alpha_A)^{-1},$$

$$\bar{P}_w = \frac{f - \alpha_A^2}{f(1 - \alpha_A)^2},$$

$$\frac{\bar{P}_w}{\bar{P}_n} = \frac{f - \alpha_A^2}{f} \bar{P}_n = \frac{1}{f} (1 + \alpha_A) + \frac{f - 1}{f} \bar{P}_n.$$

It is evident that both the average degrees of polymerisation and their ratio characterising the width of the molecular mass distribution and, correspondingly, the distribution over functional groups B increase indefinitely with increasing degree of conversion.

An alternative method of calculation of MMD for hyperbranched polymers based on the principles of percolation theory⁶⁴ was developed in Ref. 59. If an HBP macromolecule is represented as a critical cluster, the distribution function (*i.e.*, the fraction of molecules containing n monomeric units) is described by the equation

$$p_n \cong n^{-\tau} f\left(\frac{n}{n_{\max}}\right),$$

where, according to the percolation theory,⁶⁵ $\tau = 3/2$, $f \sim \exp(-n/n_{\max})$, $n_{\max} \sim (1 - \alpha_A)^{-1/\sigma}$, $\sigma = 1/2$. For HBP, the distribution function takes the following form:

$$p_n = \begin{cases} \frac{n^{\tau-2}}{\Gamma(\tau-2, \beta)} \exp\left(-\frac{n}{n_{\max}}\right) & \text{at } n_{\min} < n < n_{\max}; \\ 0 & \text{at } n_{\min} > n > n_{\max}, \end{cases}$$

Γ is the incomplete gamma function, and $\beta = n_{\min}/n_{\max}$.

The so-called Frey parameter⁶⁵ or the degree of branching (DB), which is equal to zero[†] for linear polymers and equal to unity for ideal dendrimers, is used for topological characterisation of more complex systems (for example, of those prepared by polycondensation $AB_f + B_g$ or polymerisation). For systems consisting of AB_2 -type oligomers, this parameter is equal to the ratio of twice the number of branching units (d) to the sum of twice the number of branching and linear units (l)

$$DB = \frac{2d}{2d + l}.$$

For oligomers AB_f ,

$$DB = \frac{fd}{fd + l}.$$

Finally, in the general case, including various polymerisation methods of synthesis (and not only of HBP),

$$DB = \frac{d + t}{d + t + l},$$

where t is the number of end units. As an example, let us mention the results of the study,⁶⁶ where the structure of commercial HBP 'Boltorn', which was prepared by polycondensation of 2,2-bis-(hydroxymethyl)propionic acid with pentaerythritol as the central core, was examined. Due to the statistical character of the process, the macromolecules contained all three types of fragments (Table 1).

[†] To be more precise, $2/P_n \approx 0$.

Table 1. Characteristics of HBP 'Boltorn'.⁶⁶

$\langle P \rangle_n$	d (%)	t (%)	l (%)	DB
16.68	13.5	28.5	58.0	0.42
21.37	16.5	26.5	57.0	0.43
61.36	17.5	23.5	59.0	0.41

Evidently, variations in either the structure⁶⁷ or concentration in the central core⁶⁸ will lead to changes in the degree of branching.

For example, it was demonstrated⁶⁸ that DB for the polycondensation product of compound **1** is 0.49, whereas DB are 0.62 and 0.67 for copolycondensation of compounds **1** and **2** in 2 : 1 molar ratios of 1 : 57 and 1 : 28, respectively.

The topological structure of HBP is determined by the kinetic parameters of the processes of their formation. In a number of studies,^{54,56} the degree of branching was demonstrated to be dependent on the ratio of the kinetic constants of the first (k_1) and second (k_2) addition, *i.e.*, on the substitution effect, even in the simplest case of polycondensation of AB₂-type oligomers. In the case of $k_1 = k_2$, *i.e.*, in the limit, at $\alpha_B = 1$, DB is 0.5. The degree of branching increases and approaches unity as the $k_2:k_1$ ratio increases; and DB decreases as this ratio decreases. In other words, the positive substitution effect results in that HBP are similar in the branching parameter to dendrimers, although the topological structure of HBP corresponds to ICT due to the statistical character of the process. In the case of the negative substitution effect, HBP have an architecture of linear polymers. The results of kinetic analysis of the structure of a model polymer (a computer model) performed in the study⁴⁹ are given in Table 2. The structure of the macromolecule was expressed in terms of the relative concentrations of the diads of the monomeric units of different types: branching units containing both reacted groups B, end units containing both unreacted groups and middle units containing one reacted group B.

Table 2. Influence of the ratio of the kinetic constants of the first and second addition on the characteristics of the structure of a model polymer.⁴⁹

Parameter ^a	$k_1:k_2 = 1:1$	$k_1:k_2 = 1:0.1$	$k_1:k_2 = 1:10$
$l-t$	0.125	0.065	0.047
$l-l$	0.250	0.715	0.012
$l-d$	0.125	0.065	0.047
$d-t$	0.125	0.012	0.399
$d-l$	0.250	0.131	0.096
$d-d$	0.125	0.012	0.399
T	0.250	0.078	0.447
L	0.500	0.844	0.106
D	0.250	0.078	0.47
DB	0.50	0.156	0.894

^a T , L and D are the fractions of the monomeric units t , l and d , respectively.

Polycondensation of monomers, such as *p*-chloromethylstyrene (inimers),⁶⁹ in the presence of a polyfunctional initiator is a prominent example of the influence of the kinetics of the formation of HBP on their structure. It was demonstrated^{70,71} that the polydispersity and the degree of branching of the product can be changed by varying the rate of addition of the monomer into a reactor.

The cyclisation reaction has a substantial effect on the topological structure of HBP.^{53,54,72,73} For example, polycondensation of 2,2-bis(hydroxymethyl)propionic acid was demonstrated⁵³ to afford macromolecules containing rings that are formed as a result of the intramolecular reaction of the acidic and hydroxy groups (Table 3).

Table 3. Mole fractions of poly[2,2-bis(hydroxymethyl)propionic acid] macromolecules containing rings at different degrees of conversion (α_A) and degrees of polymerisation (n).⁵³

n	$\alpha_A = 0.840$	$\alpha_A = 0.947$	$\alpha_A = 0.981$

As can be seen from Table 3, the molar fraction of macromolecules containing rings is virtually independent of the degree of polymerisation (the exception is the tetramer) but noticeably increases with increasing degree of conversion. It should be noted that cyclisation substantially limits the average degree of polymerisation so that $\bar{P}_w$ is finite even at $\alpha_A = 1$. This fact was confirmed experimentally⁷³ in the study of siloxysilane-based HBP of types AB₂, AB₄ and AB₆ and theoretically by the results of kinetic calculations and computer simulation.^{53,54,74} The in-depth study of polycondensation of oligomers AB₂ and AB₄ by the Monte Carlo method demonstrated⁷⁴ that, in the limit, all macromolecules contain rings of which more than 80% are the simplest rings, so that the average ring size for these oligomers is 1.65 and 1.39, respectively. In this case, the maximum average degrees of polymerisation are 10.7 and 7.5, respectively.

The fact that the structural characteristics (DB, $\bar{M}_n$ and $\bar{M}_w$) of commercial HBP 'Boltorn H40' differ substantially from the corresponding values calculated by probability methods is attributed⁷⁵ to the influence of various kinetic factors. Evidently, these factors have a more pronounced effect in the polymerisation method of synthesis of HBP. For example, the width of MMD in the case of radical copolymerisation of methyl methacrylate with ethylene glycol diacrylate (the molar ratio is 100:15) in the presence of dodecylmercaptan as a chain-transfer agent substantially depends on the concentration of the latter (Fig. 1). Both the ratio $\langle \bar{M} \rangle_w / \langle \bar{M} \rangle_n$ and $\langle \bar{M} \rangle_w$ exponentially decrease with increasing concentration.⁷⁶

When considering the properties of branched polymers, the following fact should be taken into account. Weakly branched macromolecules, such as polymers with rarely attached side branches, H polymers and stars with a small number of arms, are characterised by the absence of intramolecular steric hindrance so that all branches adopt a Gaussian conformation. Comb-like polymers, stars with a large number of arms, dendrimers and HBP are characterised by intramolecular steric hindrance and only peripheral fragments of their chains can adopt a Gaussian conformation. These macromolecules consist of a core with an extended conformation of the chains and low-mobility monomeric units and the peripheral shell with the

Figure 1. Plot of the parameters of the topological structures of HBP prepared by radical copolymerisation of methyl methacrylate with ethylene glycol diacrylate in the presence of dodecylmercaptan as the chain-transfer agent vs. the concentration of the latter.⁷⁶
(1) $\langle M \rangle_w$, (2) $\langle M \rangle_w / \langle M \rangle_n$.

Gaussian conformation of the chains and flexible monomeric units.^{25, 77, 78} According to theoretical⁷⁹ and experimental⁸⁰ data, peripheral chains are somewhat extended.

The presence of this heterogeneous structure is reflected in the ratio of the hydrodynamic radius of the macromolecule (R_h) to the radius of gyration (R_g)

$$\rho = \frac{R_h}{R_g}.$$

This parameter quantitatively characterises the average density of monomeric units in the globule formed by the polymer.⁸¹ For example, $\rho = 1.291$ for a dense sphere, $\rho = 0.73$ – 0.78 for linear polystyrene, and ρ is 1.043 and 0.971 for ~ 50 -arm stars containing branches with a molecular mass of 10^4 and 2×10^4 , respectively. A decrease in the average density with increasing length of branches is evidently associated with the change in the ratio of the volume of the core to the volume of the shell.

Study by pulsed NMR spectroscopy demonstrated⁷⁸ that hyperbranched poly(ether ketones) have a heterogeneous structure. Two correlation times are indicative of the presence of a solid core and a loose shell.

The solid-like structure of the core of 3-ethyl-3-(hydroxymethyl)oxetane-based HBP is evidenced by the results of the study of the value and structure of the free volume by the positron annihilation method.⁸² The free volume increases with increasing DB, whereas the glass transition temperature decreases. At the same time, the presence of a solid-like structure (paracrystalline structure according to the classification proposed in the study⁸²) with a certain distribution of the free volume over holes is detected even at temperatures higher than T_g .

Due to interactions between branches, the rigidity of comb-like macromolecules increases,^{83, 84} so that such polymers adopt an extended conformation even in θ conditions.⁸⁵

8. Critically branched macromolecules (critical clusters). The formation of cross-linked polymers by all methods (polycondensation, polymerisation or cross-linking) is accompanied by a substantial increase in the molecular mass and broadening of MMD as the conversion approaches the critical value α_c (the gelation point).^{35, 86–88} For example, experiments demonstrated⁸⁹ that polycondensation leads to an exponential increase in the molecular mass in the vicinity of α_c

$$\bar{M}_w \propto |\alpha_c - \alpha|^{-\gamma},$$

where $\gamma = 1.8 \pm 0.3$. According to the mean-field theory,³⁵ $\gamma = 2$, whereas $\gamma = 1.74$ according to the percolation theory.⁶⁴ Once the gel point is achieved, an infinite cluster is formed,^{90, 91} and then this cluster is transformed into a gel fraction. After gel point is

attained, the width of MMD of the components of the finite-size sol fraction decreases.^{86, 88} Therefore, polymers have a specific topological structure at the gel point, and this structure is characterised in terms of the formalism of fractal geometry.^{64, 92} The fractal dimensionality of the cluster (D_f) determines the relation between the volume and the mass

$$R \propto M^{1/D_f},$$

where R is the radius and M is the mass of the cluster. It is known^{93, 94} that $D_f = 2$ for linear ‘bodyless’ chains, and $D_f = 5/3$ if the excluded volume effect is taken into account. According to the percolation theory,^{64, 92} $D_f = 2.53$ in the critical conversion region. Consequently, branched macromolecules have smaller volume in this region compared to linear chains.

III. Rheological properties

The viscosity (η) of melts of linear polymers is related to their molecular masses in a complex way. Low-molecular-weight compounds are characterised by a linear dependence, whereas macromolecules whose molecular masses are larger than the critical value (M_c) are characterised by an exponential dependence, the exponent being generally taken equal to 3.4 ± 0.2 (see Refs 94–96) (in the studies,^{97–99} this exponent was found to be 4). The change in the type of the dependence is attributed to the formation of an entangled network accompanied by a change in the type of motion of macromolecules (from free to reptation).^{94–96} The average molecular mass of entangled networks is expressed by the equation

$$M_e = \frac{M_c}{2}.$$

According to the classical reptation theory,^{95, 96}

$$\eta \propto M^3,$$

but this relation is true only for very large molecular masses ($M \gg M_c$). In particular,⁹⁹ for 1,4-polyisoprene $M > 2 \times 10^5$, whereas $M_c = 1.35 \times 10^4$.

It is known^{86, 100–102} that the viscosity of polymers is described by the dependence

$$\eta \propto [\eta]^v \text{ or } \eta \propto R^v,$$

where $[\eta]$ is the characteristic viscosity, the exponent $v \approx 6$ – 7 , and R is the rms radius of the globule. The validity of this relation was experimentally established for different types of polymers, such as linear polymers with different degrees of rigidity, cyclic polymers, star-shaped polymers with different branch numbers, H polymers, comb-like polymers, randomly branched polymers and cross-linked polymer globules.^{103–107}

Therefore, if the viscosity is considered as a function of the globule size (an argument), it is independent of the topology of the polymer. However, the globule size is very sensitive to the chain structure.^{94, 108–116} For macromolecules with equal molecular masses, the larger the branching in the macromolecule, the smaller the rms radius of the globule. The shrinkage factors g for multifunctional stars, *i.e.*, the ratios of the characteristic viscosities of star-shaped and linear polymers with equal molecular masses under θ conditions, are given as an example in Table 4.

There is evidence that the ratio of the radius of gyration of a macromolecular star to the radius of gyration of a branch increases depending on the functionality only to $f \approx 6$ and remains unchanged upon a further increase in f .¹¹⁷ This is also true for stars with a polydisperse length distribution of branches.

In the study,¹¹⁸ branched polyethylene macromolecules were synthesised and their topological structures were determined. These macromolecules were demonstrated to be A_2B -type three-arm stars (T polymers), pom–pom and comb-like polymers. The following equations were demonstrated to be fulfilled with high accuracy.

Table 4. Dependence of the size of a globule formed by stars on their functionality (the number of arms).

Polymer	Solvent	$T/^{\circ}\text{C}$	f	g	Ref.
Polystyrene	Cyclohexane	35	3	0.78	111
			4	0.63	111
			6	0.46	111
			12	0.275	112
Polybutadiene	Dioxane	26.5	32	0.151	113
			64	0.092	114
			270	0.06	115
Polyisoprene	Dioxane	34	4	0.65	111
			6	0.46	111
Polytetrahydrofuran	THF	25	3	0.81	116
			6	0.64	116

For stars,

$$g = 1 - \frac{6s}{(s+2)^3} = 1 - \frac{3}{2}\mu(1-\mu)^2,$$

where s is the ratio M_A/M_B , $\mu = M_A/M$, and M is the molecular mass of the polymer.

The plot $g(\mu)$ is a curve with a minimum, the minimum value $g = 7/9$ corresponding to a star with equal arms. At $\mu = 0$ and 1, g is equal to unity, because a linear chain is formed in both cases.

For pom–pom polymers,

$$g = \mu^3 + 3\mu^2(1-\mu) + \frac{3}{2}\left(\frac{f+1}{f}\right)\mu(1-\mu)^2 + \frac{3f-1}{2f^2}(1-\mu)^3,$$

where $\mu = M_0/M$, M_0 is the molecular mass of the main chain, and f is the functionality of the branching point.

For comb-like polymers,

$$g = \mu^3 + \frac{2p+1}{p+1}\mu^2(1-\mu) + \frac{p+2}{p}\mu(1-\mu)^2 + \frac{3p-2}{p^2}(1-\mu)^3,$$

where $\mu = M_0/M$ and p is the number of side branches.

In the last-mentioned two cases, the plots $g(\mu)$ are monotonic curves. As $\mu \rightarrow 1$, the functions $g(\mu)$ tend to unity. When $\mu \rightarrow 0$, i.e., when most of the polymer mass is in branches, these functions tend, respectively, to

$$g = \frac{3f-1}{2f^2} \quad \text{and} \quad g = \frac{3p-2}{p^2}.$$

It should be noted that the latter equation is not fulfilled for comb-like polymers based on polystyrene^{119,120} and poly(α -methylstyrene).¹²¹

An ellipsoid shape typical of linear macromolecules is transformed into a spherical shape in the case of symmetric star-shaped polymers, the asphericity decreases with increasing number of arms.¹²²

In the presence of branches, the characteristic viscosity depends more weakly on the molecular mass [the Mark–Kuhn–Houwink (MKH) equation]. For example, the $[\eta]$ functions (tetrahydrofuran, 30 °C) of the molecular mass of polystyrene with different topological structures take the following form:⁸¹ for linear polymers,

$$[\eta] = 9.6 \times 10^{-5} \bar{M}_w^{0.73},$$

for 8-arm stars,

$$[\eta] = 1.42 \times 10^{-4} \bar{M}_w^{0.68},$$

for polymers with the number of arms > 20 ,

$$[\eta] = 6.45 \times 10^{-4} \bar{M}_w^{0.39}.$$

Dendrimers are characterised by an even weaker dependence. For example, the exponent in the MKH equation for a propyleneimine-based polymer containing the diaminobutane core and for a polyamidoamine-based polymer is 0.235¹²³ and 0.05,¹²⁴ respectively.

Theoretical analysis of the dynamics in dendrimers demonstrated²⁷ that the characteristic viscosity linearly depends on the number of generations (calculations were performed up to the seventh generation). A linear dependence was found also for HBP prepared by polycondensation of 2,2-bis(hydroxymethyl)propionic acid with tetrafunctional ethoxylated pentaerythritol as the central core.¹²⁵ It should be taken into account that the notion of generation for HBP is arbitrary and implies not the macromolecular structure but the composition of the reaction mixture. The first generation is formed when the reactants are used in a molar ratio of 1:4; the second generation, in a molar ratio of 1:12; the third generation, in a molar ratio of 1:28, etc. [see Eqn (1)]. As opposed to dendrimers, the width of MMD for HBP increases with increasing number of the generation (Fig. 2). Figure 2 shows also the dependences of the characteristic viscosity and the exponent (a) in the MKH equation vs. the number of generations. Evidently, it is the increase in the polydispersity of HBP that leads to an increase in the two last-mentioned characteristics.

Figure 2. Dependence of the parameters of the topological structure of HBP prepared by polycondensation of 2,2-bis(hydroxymethyl)propionic acid on the number of generation.¹²³ (1) $\langle \bar{M} \rangle_w / \langle \bar{M} \rangle_n$, (2) $[\eta]$, (3) the exponent in the MKH equation.

Study of the structures of dendrimers³³ by Monte Carlo computer simulation using the bond fluctuation model^{126,127} demonstrated that the hydrodynamic radius of the macromolecule almost linearly increases with increasing number of the generation G , whereas the analogous plot of the characteristic viscosity is a curve with a maximum (Fig. 3). These results are in agreement with experimental data¹²⁸ for dendrimers based on 3,5-dihydroxybenzyl alcohol with 1,1,1-tris(4-hydroxyphenyl)ethane as the central core. The non-monotonic character of the curve $[\eta] = f(G)$ was found also in the studies.^{32,129–132}

However, there is experimental evidence for the absence of the maximum in the plots of $[\eta]$ vs. the number of the generation.^{133–135} Data for a polybutylcarbosilane dendrimer¹³⁵ presented in Fig. 3 (straight line 3) serve as an example.

The non-monotonic character of the dependence under consideration is due to a change in the fractal dimension of the macromolecule as the number of generations of the dendrimer increases. The authors believe¹³² that the behaviour changes from being of polymer type to colloidal type. Actually, as can be seen from the results of the study³³ presented in Fig. 4, the density distribution of monomers in the bulk of the globule becomes more uniform (excluding the central core) with increasing G . Analogous results were obtained in the study³² by molecular dynamics. Analysis of the ratio of the radius of gyration of the globule R_g

Figure 3. Plots of the characteristics of a dendrimer globule on the number of generation.
(1) $[\eta]$, (2) the hydrodynamic radius R_h (computer simulation data³³), (3) $[\eta] \times 10^3$ (results of the study¹³⁵).

Figure 4. Density distribution of monomeric units in the bulk of a dendrimer globule based on computer simulation data.³³
The numbers of generations are given above the curves.

formed by different dendrimers to the hydrodynamic radius R_h depending on the number of generations G demonstrated²⁴ that this ratio varies from 1.17 (typical of Gaussian chains) to 0.77 (characteristic of a solid sphere). In other words, the average density of monomeric units in macromolecules increases with increasing globule size.

However, the character of the density distribution depends to a large extent on the following factors: the degree of intermolecular interactions between branches,¹³³ the exclusion volume¹³⁶ and the flexibility of branches.¹³⁷ In the absence of an extreme dependence, polymers are characterised by high density, which is the same for different generations (this fact was demonstrated in the study¹³⁵). In other words, in these cases dendrimers of all studied generations exhibit properties of colloidal rather than polymeric particles.

As for HBP, an analogous dependence for the characteristic viscosity was found by computer simulation.¹³⁸ To our knowledge, direct experimental evidence is lacking.

Branched chains are characterised by a complicated thermorheological behaviour^{107, 139–149} due to the fact that the effective energy of viscous flow of branched polymers (unlike that of linear polymers) depends on the molecular mass, MMD and the degree of branching. It is even proposed to use these dependences for the determination of weak long-chain branching, which cannot be revealed by other methods.¹⁴⁸ For example, the temperature dependence of the viscosity of a low-density polyethylene melt

characterised by long-chain branching was demonstrated¹⁵⁰ to be a function of MMD. The effective activation energy (E_a) of flow increases from 25.5 to 36.8 kJ mol^{−1} as the polydispersity index $\langle M \rangle_w / \langle M \rangle_n$ changes from 3.3 to 12.7.

Analogous results were obtained for polycarbonate.¹⁵¹ The temperature dependence of flow of linear polycarbonate is determined by $E_a = 109$ kJ mol^{−1}, whereas $E_a = 121$ kJ mol^{−1} for a branched polymer (~ 0.7 branchings per chain) with approximately the same molecular mass and the polydispersity index.

The relationship between E_a and the degree of branching L ($L < 1$ per 10^4 carbon atoms of the polyethylene chain) is represented by the relation:¹⁴⁷

$$E_a \propto \bar{M}_w^2 L.$$

It was demonstrated¹⁵² that

$$E_a \propto \log \bar{M}_w,$$

if the polyethylene chain adopts a configuration of three- or four-arm symmetric and asymmetric stars as well as of H- and comb-like (up to 30 branches) polymers.

The prevailing opinion is that the thermorheological effect is associated with the globule size. It is suggested that the influence of the temperature on the viscosity is determined not only by the temperature dependence of the friction coefficient but also by the temperature coefficient of the globule size¹⁵³

$$\kappa = \frac{d \ln \langle r^2 \rangle}{dT},$$

where $\langle r^2 \rangle$ is the rms radius of gyration of the macromolecule. The coefficient κ increases with increasing degree of branching.^{107, 142, 143} As a consequence, the effective activation energy of viscosity also increases.

Graessley hypothesised¹³⁹ that the part of the activation energy associated with the branching effect is related to the branch length by the equation

$$E_b = A \frac{M_a}{M_e},$$

where A is the coefficient dependent on the chemical structure of macromolecules and the coefficient κ .

However, it appeared that the relationship between A and κ is rather complex and even non-correlated.^{1, 154} Apparently, the nature of the thermorheological effect is not associated with the topological properties of the macromolecular globule. Actually, globules formed by macromolecules, including those formed by branched molecules,¹⁵⁵ in blocks have a θ size and the temperature has no effect on this parameter, as opposed to the state in dilute solutions.⁹⁴ The concentration of entanglements is also temperature independent because the entanglements are not energetic in nature.⁹⁴ However, the temperature exerts a strong effect on the concentration and the lifetime of branching points of the physical network,¹⁵⁶ such as nematic clusters.¹⁵⁷ This hypothesis is supported, for example, by the fact that the thermorheological properties are typical of polyethylene,^{147, 158} which is prone to crystallisation and, consequently, to the formation of nematic clusters, but is not typical of an essentially amorphous polystyrene.¹⁵⁴ Therefore, the phenomenon under consideration is most likely associated with the physical network rather than with entanglements. The fact that it is necessary to take into account energy interactions was also noted in the study,¹⁵⁹ where a hairpin model, *viz.*, intrachain folded structures, was considered.

The characteristic viscosity of weakly branched polyethylene chains (the number of branches per 10^4 carbon atoms of the main chain < 1) is similar to that of linear chains with the same molecular mass,^{160–163} but the viscosity of the former is higher.^{147, 158, 161–164} For example, the region of the degrees of branching L up to 0.5 per 10^4 carbon atoms is characterised¹⁶⁴ by

$$\eta \propto \exp(5.6 L).$$

An increase in the viscosity with increasing degree of branching was observed for polypropylene as well.¹⁶⁵

The viscosity of polyethylene was demonstrated¹⁵² to depend approximately exponentially on the molecular mass if the chain adopts a configuration of three- or four-arm symmetric stars, asymmetric stars or H polymers. For symmetric stars, the following relation is fulfilled:

$$\eta \propto M_a^{6.5}.$$

For asymmetric stars, no analogous relations were found.

In the study of 1,4-polyisoprene, the viscosity of three-arm stars, including asymmetric stars, was demonstrated¹⁶⁶ to depend on the molecular mass of the largest branch as $M^{5.9}$ (M_a/M_e was varied from 7 to 43).

For moderately and highly branched polyethylene macromolecules (the number of branches per 10^4 carbon atoms of the main chain is much larger than unity), $g < 1$. As a consequence, their viscosity is lower than that of linear macromolecules with the same molecular mass.¹⁶⁷ Analogous results were obtained for polypropylene (the number of branches varies from 0.8 to 7.8 per 10^4 carbon atoms)¹⁶⁸ and poly(methyl methacrylate) (185 branches per 10^4 carbon atoms).¹⁶⁹ In the former case, the viscosity decreases by a factor of ~ 50 , and it decreases by more than two orders of magnitude in the latter case.

In the reptation theory of star-shaped chains,^{96, 154, 170} the following equation was derived:

$$\eta \propto \left(\frac{M_a}{M_e}\right)^b \exp\left(\nu \frac{M_a}{M_e}\right), \quad (2)$$

where b and ν are model parameters.

Relation (2) reflects the fact that the ratio of the radius of a globule formed by star macromolecules to the radius of the branch is independent of the number of branches at $f > 6$, this relation being true for both monodisperse and random length distributions of branches.¹⁷¹ Actually, it was experimentally demonstrated¹⁷² that the viscosity of star-shaped polymers is independent of the branch number if the latter is larger than three, but the viscosity depends almost exponentially on M_a .^{96, 173} The corresponding data for monodisperse star polyisoprene are shown in Fig. 5. It can be seen that the number of branches is of no significance. Polymers with small M_a (see Fig. 5a) obey the power law with the exponent of 2, and polymers with large M_a (see Fig. 5b) are governed by the exponential law according to Eqn (2).

The rheological properties of dendrimers with a small number of generations ($G < 4$) are similar to those of star-shaped polymers.^{21, 130, 174} Due to a spherical shape and a rather close packing of dendrimers with a large number of generations, the properties of solutions and melts of such polymers are analogous to those of colloidal compounds.^{19, 21, 23, 32, 130, 174, 175} The dependence of the viscosity on the molecular mass of amidoamine-based dendrimers was demonstrated¹⁷⁵ to be quadratic for low G and linear for high G (G varies from 1 to 7, and the molecular masses vary from 5×10^2 to 1.17×10^5). The same dependences were found for propyleneimine-based dendrimers.¹⁹ This was confirmed by data from computer simulation by molecular dynamics.³²

Since the topological structure of HBP can vary over a wide range, the rheological characteristics of these polymers are ambiguous. The plots of the viscosity of HBP prepared by copolycondensation of AB₂-type monomers $\{N\text{-}[3,5\text{-di}(\text{tert-butyl} \text{dimethylsilyloxy})\text{phenyl}]\text{-4-fluorophthalimide}\}$ with AB-type monomers $\{N\text{-}[3\text{-}(\text{tert-butyl} \text{dimethylsilyloxy})\text{phenyl}]\text{-4-fluorophthalimide}\}$ ¹⁷⁶ vs. the degree of branching and $[\eta] = f(\text{DB})$ (see Ref. 177) are presented in Fig. 6. A decrease in the degree of branching due to an increase in the fraction of linear fragments in the structure of a copolymer leads to an exponential increase in the volume of a globule formed by the macromolecules and, consequently, in the viscosity of HBP melts.

The viscosity of highly branched polymers is also described by the relation (2).^{19, 173, 178, 179} It was experimentally

Figure 5. Plots of the viscosity of the polyisoprene melt vs. the molecular mass of the arm in logarithmic (a) and semilogarithmic (b) coordinates.¹⁷³ The functionality: (1) 4, (2) 5, (3) 8, (4) 12, (5) 18, (6) 27, (7) 33.

found^{96, 107, 154, 180–182} that in this case $0.5 \leq b \leq 2$, $\nu < 1$ (according to the reptation theory,⁹⁶ $b = 2$, $\nu = 15/8$).

As in the case of linear polymers, the dependence of the viscosity of solutions and melts of branched polymers on the conditions of their deformation, *i.e.*, non-Newtonian flow is observed only for rather large molecules. At the same time, the degree of branching plays an important role. It was demonstrated¹⁶⁷ that the critical shear rate $\dot{\gamma}_c$, which determines the region where the viscosity begins to decrease with increasing shear rate, increases with increasing degree of branching of weakly branched low-density polyethylene. These results were confirmed by the data from computer simulation by molecular dynamics.¹⁸³ Analogous results were obtained for polycarbonate.¹⁵¹ For the same degree of polymerisation, star-shaped (from 3 to 6 arms),

Figure 6. Plots of the viscosity of the melt (1) and the characteristic viscosity (2) of HBP vs. the degree of branching.^{176, 177}

comb-like (from 4 to 8 branches) and H polymers are characterised by higher viscosity at high shear rates compared to linear polymers. At the same time, linear polymers are characterised by a larger difference between normal stresses. Branched polymers have a high longitudinal viscosity^{184,185} and are characterised by an increase in the viscosity with time in the course of uniaxial deformation.^{168,186–193} The higher the degree of branching the larger the increase in viscosity. Highly branched polyethylene, which was prepared with the use of the complex (Pd + diimine) catalyst, shows Newtonian flow behaviour.¹⁹⁴

In studies of polyamidoamine,^{21,174} it was demonstrated that dendrimers exhibit the same properties; the smaller the number of the generation G , the larger γ_c . At $G = 1$, no decrease in the viscosity in the region of shear rates under study (approximately up to $3 \times 10^2 \text{ s}^{-1}$) was observed. The effect of a decrease in the viscosity with increasing molecular mass of propyleneimine-based dendrimers and HBP having a chemical structure of ester and ester amide was found in the study.¹⁹ The viscosity of low-molecular-weight compounds ($\bar{M}_n < 4.3 \times 10^2$) is independent of the shear rate (Newtonian flow). Melts of a dendrimer based on 2-dimethylpropionic acid up to the fifth generation inclusive¹⁷⁹ and a dendrimer based on polyamidoamine at low temperatures up to the sixth generation behave analogously. At higher temperatures, the viscosity depends on the shear rate, the temperature range of Newtonian flow decreasing with increasing number of the generation. For $G = 2$, Newtonian flow is retained up to 85°C ; for $G = 4$, up to 70°C , whereas the dependence of the viscosity on the shear rate for $G = 6$ is observed already at 40°C .²¹

The characteristic rheological features of HBP depend on their structure. Study of poly(ester amide)¹⁹⁵ demonstrated that the higher DB the smaller γ_c .

Hyperbranched polymers based on esters and ester imides¹⁷⁶ have the same properties, γ_c decreasing with increasing DB due to an increase in the fraction of an AB-type copolymer. An analogous effect was documented in the study by molecular dynamics of HBP with a variable length of linear fragments.¹⁹⁶

The chemical structure of terminal groups responsible for the character of intra- and intermolecular interactions is an important factor that has an effect not only on the rheological properties of hyperbranched polymers but also on the glass transition temperature.¹³ For example, the viscosities of dendrimers based on propyleneimine with terminal nitrile groups differ by an order of magnitude from those of dendrimers with terminal amino groups.¹⁹ In the latter case, the structure of macromolecules is more compact and, consequently, the viscosity is lower due apparently to intramolecular hydrogen bonding. An HBP melt based on polyester with terminal hydroxy groups shows Newtonian flow behaviour, whereas the flow of concentrated solutions of ester imide HBP is non-Newtonian (the viscosity depends on the shear rate). The replacement of 60% of terminal hydroxy groups in HBP prepared from 2,2-bis(hydroxymethyl)propionic acid by the ester groups $\text{O}_2\text{C}(\text{CH}_2)_{10}\text{Me}$ leads to a decrease in the viscosity by more than two orders of magnitude.¹²⁵ It was demonstrated³⁰ that the flow of polyamidoamine dendrimers is temperature dependent. The higher the temperature, the more substantial the non-Newtonian character of flow. This phenomenon is apparently associated with a decrease in the concentration of intramolecular hydrogen bonds and formation of a labile network due to chain–chain intermolecular interactions. The possible mechanism of this process was proposed in the study.¹⁹⁷ It was hypothesised¹⁹⁸ that a substantial difference in the character of intermolecular interactions is responsible for a sharp decrease in the viscosity of melts of three-arm star polybutadienes upon the replacement of terminal dimethylamino groups by polar zwitterionic groups.

IV. Relaxation modulus

Main theories of the relaxation mechanism of branched polymers^{2,154,199–201} are based, first, on the tube model,[‡] and, second, on the hierarchy of relaxation processes.^{166,202–206} De Gennes considered diffusion of star-shaped chains in the presence of fixed obstacles and demonstrated¹⁷⁰ that the branching point is fixed in space and, consequently, the reptation motion is forbidden until the relaxation process to this point is not completed. In the presence of several branches, the term ‘hierarchy’ of relaxation is introduced,^{207–209} which is determined by the relaxation time dependent on the branch length. The scheme of relaxation of branched macromolecules is shown in Fig. 7. It is suggested that the shortest branch is the first to relax, resulting in an increase in the effective friction coefficient of the main-chain unit linked to the branching point. Then the same occurs with longer branches, the longer being the branch the larger being the corresponding friction coefficients. Only once relaxation of the longest branch is completed, the reptation motion of the whole macromolecule becomes possible. When estimating the relaxation times of branches of the second and succeeding hierarchical levels, it is customary to take into account dynamic expansion of a tube due to relaxation of branches,¹⁹⁹ i.e., the influence of the number of branches is analogous to the solvent effect. It should be noted that there is a reason^{210,211} to doubt the necessity of taking into account this effect.

Figure 7. Scheme of relaxation of branched macromolecules, in which the branch length is larger than M_e .

The numbers at branches correspond to the hierarchical level. The size of branching points reflects the effective friction coefficient.

The concentration of fragments belonging to this hierarchical level is determined by the equation

$$c_i = N_i \frac{M_{bi}}{M_w},$$

where N_i and M_{bi} are the number of branches of the i th level and their molecular mass, respectively.

From the aforesaid, according to the publication,²¹² the following hierarchy of the relaxation times of ICT can be proposed. The time required for reaching the coordinate s by the end of the chain belonging to the first hierarchical level is determined by the equation¹⁷²

$$t_1(s) = t_0 \left[\frac{6v}{M_e M_{b1}} \left(\frac{s^2}{2} - \frac{s^3}{3 M_{b1}} \right) \right],$$

‡ A tube is a region that limits the lateral motion of macromolecules, where reptation motion is possible.^{94–96}

and the maximum time corresponds to the coordinate $s = M_{b1}$. Hence, for this level we have

$$\tau_1^{\max} = t_0 \exp\left(\frac{\nu M_{b1}}{M_e}\right);$$

for succeeding levels

$$\tau_i^{\max} = \tau_{i-1}^{\max} \left(\frac{M_{bi}}{M_e}\right)^{1/2} \exp\left(\frac{\nu M_{bi}}{M_e}\right).$$

In these equations, t_0 , according to the theory,¹⁷² is the characteristic time for three-arm stars

$$t_0 = \frac{4}{3} \tau_0 \frac{M_{b1}^2}{m_0^2} \left(\frac{\pi M_e}{\nu M_{b1}}\right)^{1/2},$$

where ν is the constant, which is equal to 0.56 for the first level and slightly changes with the hierarchical level, m_0 is the molecular mass of the monomeric unit, and τ_0 is the elementary relaxation time characterising diffusion of the monomeric unit.

For macromolecules with a functionality of branching points larger than three (star-shaped, H and pom–pom polymers), the same scheme is used for calculations of the relaxation times corrected for the fact that the branches coming from a single point are ‘separated’ by a zero-length main chain fragment.²⁰⁸

The relaxation modulus is determined as a sum of the contributions of all levels

$$G(t) = G_N^0 \sum_i c_i F_i(t),$$

$$F_i(t) = 2 \int_0^{M_{bi}} \left[\left(\bar{c}_i - c_i \frac{s}{M_{bi}} \right) \exp\left(-\frac{t}{t_i(s)}\right) \right] ds, \quad (3)$$

where G_N^0 is the modulus corresponding to a high-elasticity plateau, $\bar{c}_i$ is the ‘dynamic’ concentration of branches of the i th level,

$$\bar{c}_i = \sum_{k=i}^N c_k;$$

N is the total number of levels.

In experiments, Eqn (3) is manifested, in particular, in that the dependence of the length of a high-elasticity plateau $\Delta \log \omega$ (ω is the deformation frequency) on the molecular mass for branched polymers is stronger than that for linear polymers. As can be seen from the data presented in Fig. 8, the coefficient ν for linear monodisperse polystyrene²¹³ in the relation

$$\Delta \log \omega \propto \nu \log M$$

is 3.5, whereas $\nu = 4.8$ for four-arm star polyisoprene.²¹⁴ For molecular mass ($\bar{M}_w \approx 6 \times 10^4$), the frequency dependences of the real (G') and imaginary (G'') parts of the complex relaxation modulus of linear polymers are virtually equal to those of three-arm star-shaped polymers. At the same time, the terminal region for eight-arm polymers is substantially shifted to higher frequencies, although the character of the dependences $G'(\omega)$ and $G''(\omega)$ remains the same:¹⁷⁸

$$G' \propto \omega^2 \text{ and } G'' \propto \omega.$$

A complication of the topological structure of macromolecules leads to a shortening of the high-elasticity plateau. This can be seen, for example, in Fig. 9, which presents the curves of the frequency dependences of the relaxation modulus for a six-arm pom–pom polymer (three arms are attached to each end of the main chain) and an analogous polymer, which contains two branches at the midpoint of the chain, resulting in the formation of an eight-arm polymer. The molecular masses of the polymers are 2.15×10^5 . The high-elasticity plateau for highly branched

Figure 8. Plots of the length of a high-elasticity plateau vs. the molecular masses of linear (1) and four-arm star-shaped (2) polymers.^{213, 214}

Figure 9. Frequency dependences of G' (1, 2) and G'' (1', 2') for 6-arm (1, 1') and 8-arm (2, 2') polymers.²¹⁵

stars¹⁷⁸ (the branch number is ~ 50) virtually disappears, and in the terminal zone $G' \propto \omega^{1.12}$ and $G'' \propto \omega^{0.91}$ ($\bar{M}_w \approx 2.5 \times 10^5$); $G' \propto \omega^{1.1}$ and $G'' \propto \omega^{0.85}$ ($\bar{M}_w \approx 5.75 \times 10^5$).

It was suggested⁷⁷ that star-shaped polymers can be arbitrarily classified into two groups depending on the relaxation properties. One class includes polymers, which contain a relatively small number of long branches (or a large number of branches, but the branches are very long). These macromolecules are characterised by typical polymer dynamics. In particular, the highly elastic state is typical of such polymers. The topological structures of macromolecules belonging to another class are characterised by the presence of a large number of relatively short branches, and such polymers exhibit properties, which are more typical of colloidal systems.

An analogous behaviour is typical of macromolecules with more complex topological structures, for example, of comb-like²¹⁶ and pom–pom polymers.²¹⁷ The frequency dependence of the relaxation modulus of polymers with long branches ($M_a \geq 10 M_e$) can be approximately described in terms of a theory, which is based on the above-mentioned postulates and was developed in the studies,^{2, 201, 218} meanwhile this theory is inapplicable to polymers with shorter branches [$M_a \sim (2-3) M_e$]. In the region of moderate frequencies (a high-elasticity plateau), both G' and G'' change as $\sim \omega^{0.5}$. In the terminal region, G' is proportional to $\sim \omega^{1.5}$, and $G'' \propto \omega$. As can be seen, the above relations are not adequately described by Rouse dynamics.

An approach based on the Rouse chain model is applicable to relaxation of dendrimers.¹⁹ The minimum number of modes

required for an adequate description of experimental data depends on the macromolecule size as follows:²¹

Number of generations of branches	<3	4	5	6
Number of modes	1	2	9	15

However, this gives rise to a 'non-Rouse' dependence of the relaxation modulus on the frequency in the terminal zone

$$G' \propto \omega^{1.49}, G'' \propto \omega^{0.92}.$$

A deviation from Rouse dynamics was found in the study²¹⁹ for dendrimers based on branched polystyrene. Although in this case the topological structure of macromolecules is RCT, the authors suggested that the structures of these macromolecules are analogous to those of critical clusters and, consequently, the relaxation modulus depends on the time according to a power law (see below).

In the case of HBP based on 2,2-bis(hydroxymethyl)propionic acid ($M_w = 2.6 \times 10^4$), a high-elasticity plateau is absent at all.¹⁷² Relaxation of hyperbranched poly(ester amide) occurs according to Rouse dynamics^{176, 220} if DB > 0.2 (DB was varied by changing the ratio of the comonomers AB and AB₂). For DB < 2, there is a tendency to form a high-elasticity plateau. The same relaxation mechanism was established for 5-(hydroxyalkoxy)isophthalate-⁵⁹ and ether ketone-based^{68, 221} HBP. However, in these cases the Rouse law is also approximately fulfilled in the moderate frequency region, whereas it is fulfilled only for G'' but not for G' in the terminal region. It should be noted that the above relaxation characteristics should correspond to the Kargin–Slonimskii–Rouse model, *i.e.*, to linear rather than to branched chains.

Rouse dynamics and the absence of a high-elasticity plateau in the moderate and low frequency region in the case of relaxation of highly branched polymers^{19, 21, 59, 68, 77, 169, 176, 219, 220} and weakly branched polyethylene^{158, 161, 222} suggest that the topological structures of these compounds are similar to those of critical clusters. The fact that the structure of HBP has fractal properties (self-similarity) was demonstrated by computer simulation.⁷⁴

The relaxation properties of a polymer system at the gel point are described by a power law^{223–227}

$$G(t) \propto t^{-n}, \quad (4)$$

where G is the relaxation modulus and t is the running time.

The exponent n is related to the fractal dimensionality by the equation²²⁸

$$n = \frac{D}{D_f + 2},$$

where D is the space dimensionality; $n = 0.66$ for a three-dimensional space and the fractal dimensionality of the critical cluster $D_f = 2.53$.

The exponent n in Eqn (4) varies depending on the system (Table 5).

If the conversion α is expressed in the form

$$\varepsilon = \left| \frac{\alpha - \alpha_c}{\alpha} \right|,$$

where ε is the relative conversion and α_c is the critical conversion, then at $\alpha < \alpha_c$ the dependence of the viscosity on ε takes the form

$$\eta \propto \varepsilon^{-s},$$

at $\alpha > \alpha_c$ the dependence of the shear modulus on ε is as follows:^{229–234}

$$G \propto \varepsilon^r.$$

The exponents s and r are related to n by the equation

$$n = \frac{r}{s + r}.$$

As a consequence of Eqn (4), the frequency dependences obey a power law

$$G' \sim \omega^n \cos\left(\frac{\pi n}{2}\right), G'' \sim \omega^n \sin\left(\frac{\pi n}{2}\right),$$

where $\delta = \pi n/2$. Consequently, $\tan \delta$ is frequency independent.

These relations were confirmed by numerous experiments, in particular, for three-dimensional polymerisation of methacrylate-based oligomers²³⁵ and in the case of end-linking of polydimethylsiloxane.²³⁶ Analogous dependences are typical of biopolymers.^{237, 238} In the latter case, physical conditions, for example, the temperature, pH or concentrations of the components, are responsible for the formation of an equilibrium network. In xanthane solutions, the exponent ρ in the formula

$$\tan \delta \propto \omega^\rho$$

Table 5. Exponents n in formula (4) for various systems.

^a Depending on the concentration and temperature.

for complexation with Al^{3+} ions varies from -0.1 to 0.08 depending on the temperature and is equal to zero at $32\text{ }^{\circ}C$.²³⁹ The exponent ρ varies approximately in the same range depending on pH, the critical pH being 2.9.

Lowering of the temperature in an aqueous-methanolic solution of spherical microgel particles of *N*-isopropylacrylamide leads to the gel–sol transformation (the lower critical temperature is $32\text{ }^{\circ}C$).²⁴⁰ In this case, the above phenomenon is also observed, the temperature of $\sim 29\text{ }^{\circ}C$ corresponding to the zero value of the exponent ρ .

It should be noted that identification of the topological structures of hyperbranched polymers with those of critical clusters is arbitrary. Actually, although the dependence $G'(\omega)$ is virtually identical to $G''(\omega)$ in a moderate frequency region, their ratio, *i.e.*, $\tan \delta$, does change with frequency,^{19, 59, 206} which is not typical of true fractal structures of critical clusters. If hyperbranched polymers are prepared by three-dimensional copolymerisation or chain cross-linking, macromolecules formed in the vicinity of the gelation point have structural characteristics of critical clusters, which was demonstrated by direct structural studies using gel permeation chromatography and static and dynamic light scattering.^{234, 257–259}

V. Relaxation spectra

The relaxation spectrum (RS) is a universal characteristic of the relaxation properties of polymers.^{1, 93, 96, 181, 260} On the one hand, analysis of theoretical models of the dynamics of polymer chains provides knowledge about RS. On the other hand, in spite of difficulties in reproducing such spectra from the results of relaxation experiments,^{261–263} a comparison of RS is considered as the most adequate procedure for estimation of the validity of a theoretical approach. Since the relaxation spectrum is sensitive to the topological structure of the polymer chain,¹ branching would be expected to be reflected in the spectral pattern. However, data demonstrating the influence of branching on RS are scarce.

One of approaches is based on the use of an empirical BSW spectrum,[§] which satisfactorily describes the frequency dependence of the relaxation modulus of linear polymers as the following three branches: a descending branch at $\lambda \leq \lambda_1$, an ascending branch at $\lambda_1 \leq \lambda \leq \lambda_{\max}$ and a sharply descending branch at $\lambda > \lambda_{\max}$ (see Refs 225, 264 and 265)

$$H(\lambda) = \left[H_g \left(\frac{\lambda}{\lambda_c} \right)^{-n_g} + n_e G_N^0 \left(\frac{\lambda}{\lambda_{\max}} \right)^{n_e} \right] \exp \left[- \left(\frac{\lambda}{\lambda_{\max}} \right)^{\beta} \right], \quad (5)$$

where

$$H_g = n_e G_N^0 \left(\frac{\lambda_1}{\lambda_{\max}} \right)^{n_e} \left(\frac{\lambda_1}{\lambda_c} \right)^{n_g}.$$

Here, λ is the relaxation time, λ_1 is the time at which two first branches coincide (intersect), λ_c characterises the segment mobility, and $\lambda_{\max}$ is the maximum Rouse or Doi–Edwards relaxation time depending on the conditions of realisation of the chain dynamics. As a rule, $n_g \approx 0.67$, $n_e \approx 0.30$, and $\beta = 2$.

Investigation of star-shaped polymers²⁶⁶ led to a substantial complication of BSW spectra. It appeared that Eqn (5) should be supplemented with the term

$$n_0 G_0 \left(\frac{\lambda}{\lambda_0} \right)^{n_0} \exp \left(\frac{\lambda}{\lambda_0} \right),$$

where n_0 and G_0 are constants.

Hatzikiriakos *et al.*²⁶⁶ analysed the parameters of the expression for BSW spectra thus modified for a series of star polybutadienes with a regular structure with $f = 4–125$. The parameters

§ BSW are the first letters of the last names of the authors of the study.²⁶⁴

Figure 10. Relaxation BSW spectra of linear (1), 125-arm star-shaped (2) and 4-arm star-shaped (3) polymers.²⁶⁶

G_N^0 , H_g and λ_c can be considered independent, within experimental error, of the molecular mass and the number of branches. The parameters G_0 , $\lambda_{\max}$ and λ_1 depend more on the molecular mass of branches than on their number. The parameter λ_0 is influenced by both structural characteristics. It was suggested²⁶⁶ that these results do not qualitatively contradict the theoretical concepts. The relaxation time distribution functions (BSW spectra) shown in Fig. 10 illustrate that the relaxation properties of star-shaped polymers are in fact independent of the number of branches.

At the same time, a substantial broadening of the spectrum was observed (calculations were carried out according to a procedure published in the study²⁶⁷) with increasing number of branches L in polyethylene^{147, 163} in the region $L \leq 1$ per 10^4 carbon atoms, *i.e.*, where branching leads to an increase in the viscosity (see above).

The general approach to the solution of the problem of dynamics of chains with a complex topological structure, which generalises the Rouse model (theoretical calculation of RS) was described by Müller.²⁴¹ A macromolecule adopting an arbitrary configuration is represented as a set of N points in a d -dimensional space ($d \geq 2$), each point occupying the position $R_i(t)$, $i = 1, 2, \dots, N$. The movement of these points is limited by elastic harmonic bonds, which link point units in pairs thus providing the desired architecture. The potential energy of this macromolecule is

$$U \propto \sum_{i,j} (R_i - R_j)^2.$$

In the simplest case, the relaxation dynamics is described by the equation

$$\frac{\partial U(t)}{\partial R_i} = -\zeta_i \left[\frac{dR_i(t)}{dt} - v_{\text{ext}}(R_i(t), t) \right] + \xi_i(t), \quad (6)$$

where ζ_i is the friction coefficient, v_{ext} is the external shear stress, and ξ_i is the randomly fluctuating force (thermal noise).

A somewhat different approach providing an efficient solution of Eqn (6) based on matrix factorisation and giving rise to a total RS was developed in the study.²⁶⁸ The motion of elastically linked particles is described by an analogous equation system.

$$\zeta_i \mathbf{x}_i = \sum_j p_{ij} (\mathbf{x}_j - \mathbf{x}_i), \quad i = 1, \dots, n, \quad (6a)$$

where $\mathbf{x}_i$ is the vector of coordinates of the i th particle, and $p_{ij} = p_{ji} \geq 0$, $\zeta_i > 0$ for all i and j . The equation system (6a) is associated with a link graph of particles. The vertices i and j are linked to each other if $p_{ij} > 0$. It is reasonable to consider the

linkage components into which (in the general case) this graph is split as model macromolecules (monomeric units of the latter are essentially the graph vertices). Infinite values $\zeta_i = \infty$ can be ascribed to the friction coefficients of individual branching points in model (6a). For such branching points, $x_i = 0$, i.e., branching points with infinitely large friction are fixed. Since system (6a) is split into independent differential equation subsystems corresponding to linked subgraphs of bonds, it is sufficient to study motion of an isolated macromolecule.

To take into account interchain interactions, Eqn (6) for stars and analogous structures is solved based on the reptation model.^{2, 154, 200, 201, 269} For dendrimers, interchain interactions are generally ignored, and relaxation processes are attributed to intrachain conformational rearrangements.^{27–31} The same is true for HBP and other polymers with topological structures of highly branched and hyperbranched ICT, which can be considered as critical clusters.^{60, 256}

The parameters of RS characterising the relaxation properties of branched polymers are given in Table 6. Of the total spectrum, two relaxation times are generally distinguished: segmental and normal.²⁷⁰

Table 6. Parameters of RS characterising the relaxation properties of branched polymers.

Parameter of RS	Polymer structure	Relationship between the parameter of RS and structure parameters	Ref.
Largest Rouse relaxation time, λ_{rep}	linear chain in a tube	$\frac{3\zeta N^3}{\pi^2 k}$	97
Relaxation time of the branch, λ_a	branched chain, stars	$\frac{\zeta}{\pi^2 k} \exp\left(\frac{vN_a}{3}\right)$	97
Diffusion time of the centre of gravity, λ_D	dendrimer	$\frac{6g2^G \zeta}{k}$	27
Relaxation time of the centre of gravity relative to the central atom, λ_s	"	$\frac{5\zeta}{k}$	27
Relaxation time of rotational and internal elastic motion of monomeric units, $\lambda_r = \lambda_e$	"	$\frac{2^{g+1} \zeta}{k}$	27

Note. ζ is the friction coefficient of a segment; N is the number of segments in the chain; $k = 3k_B T/a^2$, where k_B is the Boltzmann constant, T is the absolute temperature, a is the segment size; v is the numerical coefficient the value of which depends on the model used;¹⁵⁴ N_a is the number of monomeric units in the branch.

As far as is known, only Gotlib and co-workers^{28–30} have brought the theory to calculations of RS. In these studies, the dynamic model of dendrimers with an arbitrary functionality of branching points was considered, both external friction of branching points against environmental (ζ) and internal friction of points against each other (ζ_{int}) being taken into account. Two types of RS, internal and external, are distinguished. The internal relaxation spectrum corresponds to oscillating motion of branching points and takes the form

$$H_{\text{int}}(\lambda) = H_{\text{int}0} \left[4(f-1) - \left(\frac{1}{\lambda/\lambda_0 - p} - f \right)^2 \right]^{-1/2} \frac{\lambda/\lambda_0}{(\lambda/\lambda_0 - p)^2},$$

where the relaxation time is expressed by the equation

$$\lambda = \zeta \left[Kf \left(1 - 2 \frac{\sqrt{f-1}}{f} \cos \varphi \right) \right]^{-1} + \frac{\zeta_{\text{int}}}{K}$$

and is in the range between λ_{min} and λ_{max} :

$$\lambda_{\text{min}} = \zeta \left[Kf \left(1 + 2 \frac{\sqrt{f-1}}{f} \right) \right]^{-1} + \frac{\zeta_{\text{int}}}{K},$$

$$\lambda_{\text{max}} = \zeta \left[Kf \left(1 - 2 \frac{\sqrt{f-1}}{f} \right) \right]^{-1} + \frac{\zeta_{\text{int}}}{K}.$$

In these equations, f is the functionality of the branching point, $\lambda_0 = \zeta/K$, K is the modulus of elasticity of a coil spring that connects the branching points of the macromolecule; $p = \zeta_{\text{int}}/\zeta$; φ is the phase shift of vibration of the branching point, $\pi/g \leq \varphi \leq \pi(G-1)/G$.

The external spectrum reflects the pulsation motion of dendrimers or its parts relative to the centre and takes the form

$$H_{\text{ext}}(\lambda) = H_{\text{ext}0}(\lambda) \frac{\lambda/\lambda_0}{(\lambda/\lambda_0 - p)^2},$$

$$\lambda_j = \frac{\zeta(f-1)^{j+1}}{K(f-2)^2} + \frac{\zeta_{\text{int}}}{K},$$

$$\lambda_{\text{min}} = \frac{\zeta(f-1)^3}{K(f-2)^2} + \frac{\zeta_{\text{int}}}{K},$$

$$\lambda_{\text{max}} = \frac{\zeta(f-1)^{G+1}}{K(f-2)^2} + \frac{\zeta_{\text{int}}}{K},$$

j is the number of generation, $j = 2, \dots, G$.

The exponential character of the time dependence of the relaxation modulus [see Eqn (4)] signifies that, as expected, RS of critical clusters is described by a power law (CW distribution),[¶]

$$H(\lambda) = H_0 \left(\frac{\lambda}{\lambda_0} \right)^{-n}$$

for $\lambda_0 < \lambda < \lambda_{\text{max}}$, $0 < n < 1$, $\lambda_{\text{max}} \propto |\alpha_c - \alpha|^{-7}$.

The time λ_0 determines the glass transition conditions and depends, like the front factor H_0 , on the chemical structure of the polymer.

VI. Conclusion

From the aforesaid, unambiguous conclusions on the topological structures of HBP cannot be drawn. Actually, calculations with the use of data on the kinetics of formation^{89, 271} provide evidence for MMD of polymers at nearly critical conversions but without consideration of the effects of cyclisation and exclusion volume. An approach based on the percolation model^{59, 64} is suitable only for the critical conversion region and it is not quite clear whether it can be adequately applied to real systems and different degrees of conversion. Computer simulation accounts for the effects of cyclisation and exclusion volume,^{53–55, 72, 74, 272} but it is difficult to relate these results to the real mechanism of formation of macromolecules. Apparently, this is why it is necessary to use the MMD model functions, for example, the Flory–Schultz distribution.²³¹

The relaxation mechanisms of HBP are not associated with the presence of entanglements^{59, 74} but are conditioned, like those of dendrimers, by intramolecular rearrangements. High elasticity is apparently attributed to interchain interactions between peripheral branches of highest-molecular-weight fractions.²⁰ However, it is apparently impossible to apply the theory of RS developed for dendrimers to HBP because it is necessary to take into account

¶CW are the first letters of the last names of the authors of the studies.^{222, 223}

irregularity of the architecture of HBP. To use CW spectra, one should first make sure that the topological structures of HBP are actually identical to those of critical clusters. Therefore, to get an insight into the relaxation mechanism of HBP, it is necessary, first, to refine understanding of their architecture and, second, develop a theory of relaxation spectra of HBP with a desired topological structure.

Oleg Matveevich Nefedov
(on his 75th birthday)

On November 25, 2006, Academician Oleg Matveevich Nefedov celebrated his 75th birthday.

O M Nefedov is an outstanding scientist who has won general recognition owing to his contribution to organic and physical organic chemistry. The scope of his research activities at the Institute of Organic Chemistry of the RAS includes chemistry of carbenes, their analogues and other unstable molecules and small rings; design of novel methods and techniques for the synthesis of fluoroaromatic compounds from available raw stuff; development and introduction into routine chemical practice of advanced technologies for preparation of pesticides, medicinal drugs, *etc.* In the last five years alone, the results of these studies were published in more than 40 articles and were covered by five RF patents.

The scientific achievements of O M Nefedov were rewarded by three State Prizes for Science and Technology (1983, 1990 and 2002); by several academic prizes, such as N D Zelinsky Prize (1987), N N Semenov Prize (1991) and A M Butlerov Prize (2003); by A P Karpinsky International Prize (1993); by D I Mendeleev Gold Medal (1998) and by National Prize 'Man of the Year-2002' for Science. O M Nefedov is an honorary member of several international and foreign academies and scientific societies.

Oleg Matveevich is actively engaged in scientific, organizational and educational work. He was elected Editor-in-Chief of the Journals 'Uspekhi Khimii' ('Russian Chemical Reviews'), 'Izvestiya Akademii Nauk, Seriya Khimicheskaya' ('Russian Chemical Bulletin, International Edition'), 'Mendeleev Communications', and is a member of editorial boards of several international journals. Fifty-eight candidates and seven doctors of sciences prepared and successfully defended their theses under his guidance. In 1990, a Higher Chemical College of the RAS was established on his initiative and under his permanent chairmanship on the basis of the D I Mendeleev Russian University for Chemical Technology. In 2006, O M Nefedov was awarded a Prize of the Government of the Russian Federation for Education for his research-and-educational work entitled 'Some Innovative Trends in the Development of Higher Education and Their Integration Into Fundamental Science' and the introduction of a continuous educational cycle 'Chemical Lyceum — Higher Chemical College — Post-Graduate Courses' into the routine practice of some leading chemical institutes within the RAS.

Oleg Matveevich Nefedov is widely known for his great erudition, breadth of mind, versatility of scientific interests and unique working capacity. He is Chairmain of the Commission for Scientific and Technical Policy at the Moscow City Government, Chairman of the National Committee of Russian Chemists, member of the Bureau and Executive Committee of the International Union of Pure and Applied Chemistry (IUPAC) and President of the last four Mendeleev Congresses for General and Applied Chemistry (1989–2007).

The Editorial Board and the Editorial Staff of the Journal 'Uspekhi Khimii' ('Russian Chemical Reviews') heartily congratulate Oleg Matveevich on the occasion of his 75th birthday and wish him good health and much success in all his deeds.

Theoretical studies on [3 + 2]-cycloaddition reactions

Abstract. The results of theoretical studies on [3 + 2]-cycloaddition reactions carried out during the last decade are summarised. The reaction mechanisms are discussed. The catalyst, solvent, and substituent effects on the reactivities of compounds and on the mechanisms, regioselectivity and stereoselectivity of reactions are considered. The results of theoretical studies are compared with corresponding experimental data. The bibliography includes 328 references.

I. Introduction

Research on [3 + 2]-cycloaddition reactions began more than 100 years ago with a pioneering study by Buchner¹ who reported the reactions of ethyl diazoacetate with α,β -unsaturated esters. At present, the [3 + 2]-cycloaddition reactions are widely used in synthetic organic chemistry, in particular, for the synthesis of various five-membered heterocyclic systems that are used in industry and medicine and as synthons for fine organic synthesis.^{2,3}

In the 1950s–1960s, the number of publications concerned with the [3 + 2]-cycloaddition reactions increased dramatically. This predetermined the need of summarising the results obtained and gave an impetus to studies, including theoretical ones, on the mechanisms of the processes in question. Systematic investigations of theoretical aspects of cycloaddition were initiated by Woodward and Hoffmann^{4,5} who developed a theory of pericyclic processes and by Huisgen^{6–10} and Firestone^{11–14} who reported a series of studies on the mechanisms of dipolar [3 + 2]-cycloaddition reactions.

However, wide use of theoretical methods became possible only in the 1980–1990s. This is due to progress in hardware and software (computational algorithms) development. Quantum-chemical methods are a powerful tool of studying chemical

reactions including cycloaddition ones. Indeed, in addition to help in interpreting experimental data, which is of great value *per se*, theoretical calculations allow one to predict many properties of compounds and chemical reactions, sometimes providing a unique possibility of studying unstable compounds and intermediates. Additionally, they are successfully used for analysing the effects of various factors on the reactivities of compounds and on the rates, regioselectivity and stereoselectivity of reactions, *etc.* At present, cycloaddition processes are intensively studied by quantum-chemical methods.

In the last decade a number of monographs (*e.g.*, Refs 2 and 15–18) and reviews (*e.g.*, Refs 3, 19–22) summarising the results of experimental studies of cycloaddition reactions including [3 + 2]-cycloaddition were reported. However, most part of reviews of theoretical studies on the subject were published before 1995.^{6,23–26} Chronologically, the last available reviews of studies in this field were reported by Garcia *et al.*,²⁷ who analysed the effects of the secondary orbital interaction mainly in the Diels–Alder reactions and by Leach and Houk,²⁸ who considered theory of the Diels–Alder reactions involving oxygen molecules, nitroso compounds and hydrogenated triazolinones.

The aim of this review was to summarise the results of theoretical studies on one of the most important types of cycloaddition reactions, namely, [3 + 2]-cycloaddition, carried out in the last decade (from 1994 up to 2005).

II. The cycloaddition reactions: a theoretical background

1. Classification of [3 + 2]-cycloaddition reactions with respect to the type of the interaction of frontier molecular orbitals

According to the frontier molecular orbital (FMO) theory²⁹ that underlies modern theory of chemical bonding, the course of chemical reactions is governed by the interaction between the highest occupied and lowest unoccupied MOs (HOMO and LUMO, respectively) of the reactant molecules. One of the first models that treated the cycloaddition reactions from the standpoint of the FMO theory was proposed by Woodward and Hoffmann (Woodward–Hoffmann rule).⁵ This is the concept of the conservation of orbital symmetry, which became part of all textbooks of modern organic chemistry, being up to date a

Uspekhi Khimii 75 (11) 1045–1073 (2006); translated by A M Raevskiy

powerful tool of qualitative description of cycloaddition processes.

Sustmann proposed a classification of dipolar [3 + 2]-cycloaddition reactions with respect to the character of the HOMO–LUMO interaction in the initial compounds.^{30,31} According to his classification, which is widely used at present, the [3 + 2]-cycloaddition reactions can be divided into three groups. Group I comprises the reactions controlled by the HOMO_{dipole}–LUMO_{dipolarophile} interaction, or the so-called normal-electron-demand (NED) reactions. Processes governed by the HOMO_{dipolarophile}–LUMO_{dipole} interaction, or the so-called inverse-electron-demand (IED) reactions, form Group III. If the energies of the valence MOs of two reactants are similar, the reaction is controlled by both types of the HOMO–LUMO interaction. These processes belong to group II (Fig. 1).

Figure 1. Classification of cycloaddition reactions according to Sustmann.

Hereinafter, 'D' stands for dipole and 'DP' stands for dipolarophile.

2. Main types of cycloaddition reaction mechanisms

There are two main mechanisms of cycloaddition reactions, namely, a concerted mechanism and a stepwise one. A concerted cycloaddition reaction occurs in a single step involving the formation of one transition state (TS) (Fig. 2a).[†] The stepwise mechanism involves a number of stages. It begins with the formation of acyclic transition state and corresponding intermediate and completes with the ring closure and formation of final product (Fig. 2b). The transition states and intermediates can be dipolar (zwitter-ionic), singlet or triplet biradical structures.

The concerted mechanism can be synchronous or asynchronous. In the former case the reactant molecules approach one another synchronously with the formation of new bonds in the transition state. In the latter case new bonds in the transition state are formed in turn. Different authors use different criteria for assessment of the synchronicity of processes. Often, the relative lengths of the contacts a...c and b...d in the transition state (see Fig. 2a) are used as a measure of the synchronicity of the reaction mechanism. However, in practice this criterion can be applied only to the reactions with the same type of the interacting atoms. If new chemical bonds are formed between atoms of different elements, the lengths of these contacts can be appreciably different from each other even for the synchronous cycloaddition.

A more reliable criterion is provided by the bond populations (e.g., the relative Wiberg indices³²) for the contacts a...c and b...d, which depend on the nature of the interacting atoms. The smaller the difference between the Wiberg indices, the higher the synchronicity of the mechanism. However, in this case information on the synchronicity of the process is also incomplete because the analysis is restricted to only two bonds that are formed during

Figure 2. Energy profiles of concerted (a) and stepwise (b) cycloaddition reactions.

the reaction. A more correct quantitative measure of the degree of synchronicity was introduced by Moyano *et al.*,³³ who proposed to allow for all bonds involved in the cycloaddition process. According to Moyano *et al.*,³³ the degree of synchronicity, S_y , of a reaction is given by

$$S_y = 1 - \frac{\sum_{i=1}^n |\delta B_i - \delta B_{av}| / \delta B_{av}}{2n - 2}. \quad (1)$$

Here n is the number of bonds involved in the reaction (for the [3 + 2]-cycloaddition, $n = 5$) and δB_i is the relative variation of the Wiberg indices for the i th bond, which is calculated from the following relationship

$$\delta B_i = \frac{B_i^{ts} - B_i^r}{B_i^p - B_i^r},$$

where the superscripts 'p', 'r' and 'ts' correspond to the product, reactants and transition state, respectively, and the average value of the δB_{av} is determined from

$$\delta B_{av} = n^{-1} \sum_{i=1}^n \delta B_i.$$

For true synchronous processes, $S_y = 1$, whereas for asynchronous ones $S_y = 0$.

Among various factors affecting the cycloaddition reaction mechanisms, the Lewis acid coordination to one of the reactants plays the key role. Usually, complexation is accompanied by an abrupt increase in the asynchronicity of the reaction or even by a change from concerted to stepwise reaction mechanism (see below). This change in the mechanism can be explained from the standpoint of charge control. The interaction of the Lewis acid with the reactant causes transfer of the electron density from the ligand to the catalyst (Scheme 1).

Scheme 1

As a result, the ligand becomes more electrophilic, which facilitates the attack of the second reactant by the negatively charged end.

3. Substituent effects on the energy characteristics of cycloaddition reactions

Obviously, replacement of substituents in the reactant molecules should affect their reactivities in some way. This can be qualitatively interpreted in terms of the FMO theory. In particular, one can expect that introduction of electron-withdrawing substituents into the dipolarophile molecule and/or electron-donating substituents into the dipole molecule will facilitate the NED reactions

[†] This mechanism is also called a 'one-step' and 'two-stage' mechanism. The latter term seems to be quite inappropriate; here the formation of transition state from reactants is treated as the first stage and the formation of reaction products from the TS is treated as the second stage.

Figure 3. Substituent effects on the frontier MO energies.

Reaction type: a normal-electron-demand reaction (a), an inverse-electron-demand reaction (b), and a reaction accompanied by a change from 'weak' normal to 'weak' inverse electron demand interaction (c); X is the electron-donating substituent and Z is the electron-withdrawing substituent.

due to a decrease in the energy difference between the dipole HOMO and dipolarophile LUMO (Fig. 3 a). On the contrary, the introduction of electron-donating substituents into the dipolarophile molecule and/or electron-withdrawing groups into the dipole molecule should slow down the reactions due to an increase in the ΔE value for the FMOs. The reverse situation is characteristic of the IED reactions (Fig. 3 b). If the corresponding frontier MOs of the initial reactants have nearly equal energies, the introduction of the substituents that cause a significant redistribution of the electron density and act oppositely for different reactants should favour the occurrence of the reaction. Moreover, the type of the HOMO–LUMO interaction is often changed from, e.g., 'weak' NED to IED or *vice versa* (Fig. 3 c). Examples are given in the text below.

It should be noted that this qualitative treatment of the substituent effects on the reactivities of reactants is simplified. In particular, the model ignores steric effects. Additionally, actual changes in the energies of the frontier orbitals are not always related to the type of the substituent introduced. Finally, the activation barrier is affected not only by the relative orbital energies of the reactants but also by other factors, e.g., the nature of the transition state and the total energy effects of bond cleavage and formation in the formation of the transition state. Thus, investigations of the substituent effects on the course of a chemical reaction require detailed studies of its mechanism and estimation of the activation energy.

4. Effect of catalyst

Carrying out [3 + 2]-cycloaddition reactions often requires the presence of a catalyst, e.g., a Lewis acid, which forms complexes with the reactant molecules. To a first approximation the effect of the Lewis acid on the course of cycloaddition processes can also be analysed from the standpoint of the FMO theory. The catalytic or promoting activity of the Lewis acid is first of all determined by the fashion of its coordination to the dipole, dipolarophile or to both reactants and by the type of the HOMO–LUMO interaction, the catalyst effect in most cases being similar to that of electron-withdrawing substituent. Selective coordination of the Lewis acid to dipolarophile accelerates the NED reactions due to a decrease in the energy difference ΔE between the dipole HOMO and dipolarophile LUMO. The Lewis acid coordination to the dipole leads to inhibition of the reaction, while coordination to both reactants has little effect on the reaction rate (Fig. 4 a). The reverse occurs in the case of the IED processes (Fig. 4 b). The use of Lewis acids in type II reactions favours the occurrence of the process if the catalyst is selectively coordinated to the dipole or to

Figure 4. Lewis acid effect on the frontier MO energies.

Reaction type: a normal-electron-demand reaction (a), an inverse-electron-demand reaction (b) and an intermediate-type reaction (c); 'LA' stands for Lewis Acid.

the dipolarophile; coordination to both reactants has no effect (Fig. 4 c).

The selectivity of the metal coordination to a reactant is often related to the hardness (softness) of the donor and acceptor centres. For instance, if the donor centre in the dipolarophile is a soft base and that in the dipole is a hard base, it is more appropriate to catalyse the NED reactions with soft Lewis acids that will selectively coordinate to the dipolarophile, thus causing the processes to accelerate. The hard donor centre in the dipolarophile requires the use of a hard Lewis acid. The reverse situation is valid for the IED reactions.

The aforesaid is valid if the process occurs under orbital control. However, in order to explain the catalyst effect, in some cases the charge control should also be taken into account in addition to the orbital control (especially for dipolar [3 + 2]-cycloaddition). Indeed, in the presence of a Lewis acid the process becomes more asynchronous (see above) and thus can to some extent be treated as a nucleophilic addition reaction. Such reactions are primarily driven by the effective charges of the interacting atoms. Consider a model NED reaction. The dipolarophile c–d is activated by the metal ion M. The dipole a–b asynchronously adds to dipolarophile M–c–d (see the right side of Scheme 1). For metals in high oxidation states (*i.e.*, harder metals) the electron density is more significantly shifted from the c–d fragment to the metal and the positive charge of the atom d increases, which facilitates the addition of the dipole a–b at the negatively charged end. Thus, the activation effect of the Lewis acid in intermolecular cycloaddition reactions is due to two factors, namely, the selectivity of coordination to one of the reactants and the extent of the electron density transfer. In our example, these factors act 'in parallel' if c is the hard centre and 'antiparallel' if c is the soft centre.

5. The solvent effect

Most often quantum-chemical calculations are carried out for the gas phase (more correctly, for isolated molecules); however, real processes usually proceed in solution. The solvation effects are included using a number of models that approximate the solvent effect. These are the Kirkwood–Onsager model and the polarised continuum model (PCM) and its modifications (CPCM, IEFPCM, IPCM, SCI-PCM). To a first approximation the solvent effect on the activation barrier is determined by the relative polarity of the reactant molecules and the transition state (if the solvent is not involved in the reaction, *i.e.*, is not a part of the transition state). The higher the polarity of the structure, the greater the decrease in its energy in polar media. If

Figure 5. Influence of solvation effects on the activation energy: the case of high-polarity transition state.

the transition-state energy decreases to a greater extent compared to the reactant energies, the activation energy should decrease in a polar solvent (Fig. 5). *Vice versa*, if the overall polarity of the reactant molecules is higher than the polarity of the transition state, the reaction in high-polarity solvents will be inhibited.

6. The chemoselectivity, the regioselectivity and the stereoselectivity

Many cycloaddition reactions are characterised by chemo-, regio- and stereoselectivity. The chemoselectivity of cycloaddition implies a selective addition of the reactant to one of several multiple bonds of the substrate. The regioselectivity of cycloaddition is associated with the addition of reactant to a given multiple bond of the substrate in a particular fashion. For instance, calculations predicted preferred formation of 5-amino-isoxazoline **1a** compared to 4-amino-substituted isomer **1b** in the reaction of formonitrile oxide $\text{HC}\equiv\text{N}^+-\text{O}^-$ (fulminic acid) with vinylamine.³⁴ In this review the 4- and 5-substituted isoxazoline will be called the *meta*- and *ortho*-isomers, respectively.

This phenomenon is often interpreted from the standpoint of the FMO theory following the rule that the reacting molecules interact through the atoms with similar (or largest) orbital coefficients.³⁵ At the same time the regioselectivity can also be governed by other factors, in particular, steric repulsion between substituents, secondary orbital interaction, formation of hydrogen bonds, *etc.*³⁶

The stereoselectivity (diastereoselectivity and enantioselectivity) is due to preferred formation of the structures with a particular stereo configuration of the environment of the chiral atoms. For instance, in the reaction of *N,C*-dimethylnitrone $\text{MeCH}=\text{N}(\text{Me})\text{O}$ with methyl vinyl ether the addition resulting in diastereomer **2a** is more favourable than the process resulting in **2b**.³⁷

7. The hard–soft acid–base principle

At present, one of the most widely used concepts in chemistry is the theory of hard and soft acids and bases,^{38–40} which is successfully employed for describing the reactivity of compounds as an alternative to the FMO theory.^{41–49} This concept is particularly widely used for interpreting the regioselectivity of various processes, *e.g.*, cycloaddition of CH_2N_2 , RN_3 , N_2O , NCO , *etc.* to the molecules with multiple bonds.^{50–54}

According to the theory of hard and soft acids and bases and the density functional theory (DFT), the total energy of intermolecular interaction can be represented by the sum

$$\Delta E_{\text{int}} = \Delta E_v + \Delta E_\mu, \quad (2)$$

where ΔE_v and ΔE_μ are the energy changes at constant external and chemical potentials, respectively.^{55–58} The first term corresponds to the processes of charge transfer between the reactant molecules. In the local–local approximation, it is expressed through the chemical potentials (μ) and ‘softnesses’ (S) of the reacting molecules A and B

$$(\Delta E_v)_{AB}^{kl} = -\frac{1}{2} \frac{(\mu_A - \mu_B)^2}{S_A f_{Ak} + S_B f_{Bl}} S_A S_B f_{Ak} f_{Bl}, \quad (3)$$

where f_{Ak} and f_{Bl} are the Fukui functions which characterise the reactivities of the atoms k and l in the molecules A and B and depend on the type of the process under study, *i.e.*, a nucleophilic (f^+), electrophilic (f^-) or radical (f^0) attack.⁵⁹ The μ and S can be calculated as follows

$$\mu \approx -\frac{I + A}{2},$$

$$S = \frac{1}{2\eta} \approx \frac{1}{I - A},$$

where I is the ionisation potential, A is the electron affinity and η is the molecular ‘hardness’.⁵⁸

The second term in Eqn (2) describes the charge reshuffling at constant chemical potential and is calculated using the expression

$$(\Delta E_\mu)_{AB}^{kl} = -\frac{1}{2} \frac{\lambda}{S_A f_{Ak} + S_B f_{Bl}},$$

where the parameter λ is proportional to the effective number of valence electrons involved in the reaction between A and B.^{46, 56, 57}

A conventional analysis of the regioselectivity of cycloaddition involves calculations of the energies, ΔE_{int} , of possible regioisomers. Clearly, the higher the total interaction energy, the more preferred the formation of the corresponding isomer.

III. Computational methods used in studies of [3 + 2]-cycloaddition reactions

At present, semiempirical quantum-chemical methods (AM1, PM3, MNDO, INDO, ZINDO, *etc.*) belong to the simplest and cheapest (from the standpoint of computational cost) techniques employed for calculations of organic molecular systems. They differ from one another in parametrisation. Although in some cases the results obtained in these approximations agree well with experimental data,^{60, 61} the properties predicted are more often significantly different from those observed experimentally.^{62–64} Therefore, the results of semiempirical calculations should be interpreted with care. At the moment, semiempirical methods are inappropriate for studying low-molecular-mass organic systems. However, they can be useful for rapid assessment of general trends and correlations⁶⁵ rather than obtaining reliable quantitative energy characteristics and investigating the mechanism of the process under study as well as in studies of large molecules (*e.g.*, macro- and biomolecules) where the use of more accurate approximations is difficult or impossible.

Until recently, the most widely used *ab initio* procedure was the Hartree–Fock (HF) method. Often, this approximation reproduces quite correctly the geometric parameters of molecules (first of all, the bonding distances between atoms of the first-to-third row elements).⁶⁶ However, the HF method ignores the electron correlation effects and therefore strongly overestimates the activation barriers and vibration frequencies. Indeed, the HF calculated activation energies for cycloaddition reactions are 1.5–2.5 times higher than experimental estimates or the activation barriers obtained from high-level approximations.^{67–73} Thus, the HF method is inappropriate for studying cycloaddition reactions.

One of the ‘simplest’ *ab initio* methods with inclusion of electron correlation effects is the Møller–Plesset perturbative method (MP2 stands for the second-order Møller–Plesset level of theory). The results obtained in this approximation agree with experimental data better than the results of HF calculations; therefore, the MP2 technique is widely used, including studies of the cycloaddition reactions.^{67,70,74–76} However, much higher computational cost of the MP2 calculations somewhat limits the field of application of the method (especially for the systems containing transition metal atoms). Additionally, in some cases the MP2 calculated geometric parameters are appreciably different from experimental data (the differences can be even larger than in the case of the HF method).⁶⁶ It is also known that the MP2 wave functions of high-spin systems are characterised by high degree of spin ‘contamination’, which can affect the results of calculations.^{77–79} Nevertheless, this approximation remains one of the most popular methods for calculation of medium-size molecular systems.

There are also other high-level approximations, which often give the results that are in excellent agreement with experimental data. These are, *e.g.*, higher-order Møller–Plesset methods [MP3, MP4DQ, MP4SDQ, MP4SDTQ; the letters ‘S’, ‘D’, ‘T’ and ‘Q’ mean that the corresponding calculations allow for single, double, triple and/or quadruple excitations], the coupled clusters method [CCD, CCSD, CCSD(T)], the quadratic configuration interaction [QCISD(T)] method, the multiconfiguration self-consistent field (MCSCF or CASSCF) method and the composite methods (G1, G2, CBS) that give the best approximation to the experimental energies (with an average deviation of 3–4 kJ mol^{−1}). It was also reported that the theoretical activation energies and energy effects of cycloaddition processes strongly depend on the level of theory at which electron correlation effects are included. For instance, the activation energies for [3 + 2]-cycloaddition reactions of (i) diazomethane, fulminic acid³⁵ and methyl azide⁸⁰ with C₂H₄ and (ii) ozone with isoprene⁷⁴ changed by 20–40 kJ mol^{−1} on going from the MP2 to the MP4, QCISD or CCSD(T) calculations. In contrast to this, the authors of other studies reported a weak dependence of the energy parameters on the computational method and basis set employed. For instance, the *E*_a value for the interaction of nitron CH₂=N(Me)O with acetonitrile varies from 48 to 59 kJ mol^{−1} when using the MP2/6-31G*, MP4SDTQ//B3LYP/6-31G*, MP4SDTQ//MP2/6-31G*, CCSD(T)//B3LYP/6-31G*, CCSD(T)//MP2/6-31G*, CBS-Q and B3LYP/6-31G* methods.⁷²

Analysis of the published data on the effect of the approximation employed on the results of calculations of cycloaddition reactions revealed the following. The relative energies obtained from the MP4SDTQ, CCSD(T) and QCISD(T) calculations with the same basis set are often similar, being in good agreement with experimental data.^{72,81} The CASSCF method often overestimates the activation energies for the concerted cycloaddition mechanism. As a consequence, the stability of biradical structures and the possibility of stepwise mechanism are overestimated even when using a large active space.^{82–84} However, the results of the CASSCF calculations with MP2 corrected energies (CASPT2//CASSCF) are similar to those of the CCSD(T), G2 and CBS calculations.^{83,85} Moreover, in some cases the open-shell systems (*e.g.*, biradical structures) and excited states can be correctly

described only in the CASSCF and CASPT2 approximations. At the same time the MP4SDTQ, CCSD(T) and QCISD(T) methods can be recommended for theoretical studies of ground-state closed-shell structures. The G2 and CBS approximations belong to the most accurate ones and give the results that are in excellent agreement with experimental data. However, these techniques are of limited use because they are only applicable to small molecular systems.

Finally, there is yet another group of computational methods with inclusion of electron correlation effects. These are the DFT methods that combine a rather high accuracy of calculations and relatively low computational cost. This predetermines high popularity of DFT methods in studies of organic and organometallic molecular systems. Most DFT studies of cycloaddition reactions were carried out with the B3LYP functional. Often, the results obtained from B3LYP calculations are in good agreement with experimental data and this approximation can be considered optimum. Nevertheless it is clear that search for the most correct method of theoretical investigation of a new cycloaddition reaction requires evaluation of various approximations, as applied to the process under study, and comparison of the results obtained with experimental data. In the lack of experimental data (this is a quite typical situation) the applicability of a particular computational method can be indirectly assessed by comparing the results obtained with those found from the highest-level approximations [G2, CBS, CCSD(T), *etc.*].

In addition to the computational methods, the choice of the basis set can also affect the results of calculations. At present, most studies of the cycloaddition reactions of medium-size organic molecules are carried out with the 6-31G* split-valence basis set of Gauss functions. In most cases a correct description of the systems under study requires the use of polarisation functions. Additionally, investigations of anion structures require augmentation of the basis sets with diffuse functions (*e.g.*, the basis sets 6-31+G**, 6-31+G** and 6-31++G**). In studies of small molecules it is possible (and desired) to employ the extended basis sets (*e.g.*, 6-311G**, 6-311+G**, cc-pVDZ, cc-pVTZ, *etc.*). If the reacting molecules contain transition-element atoms, the core electrons in these atoms are usually approximated by pseudopotentials (LanL2DZ, LanL2MB, Stuttgart pseudopotentials, *etc.*), which can also allow for relativistic effects (this is of particular importance in the case of heavy fifth- and sixth-row elements).

The energy characteristics of cycloaddition reactions are often sensitive to the change in the computational method rather than the change in the basis set.^{35,72,73,80,83} For instance, extension of the basis set from 6-31G* to 6-31+G**, 6-311+G*, 6-311++G** and 6-311++G(2df,2p) [methods MP2, CCSD(T) and MP4SDTQ, respectively] in studies of the reactions of CH₂N₂ and HCNO with C₂H₄ and C₂H₂ causes the activation energy to change only by 0.2–2.3 kJ mol^{−1} (see Refs 35 and 83). On the contrary, some authors reported strong differences between the activation barrier calculated with different basis sets.⁷¹ Thus, studies of new cycloaddition reactions require evaluation of various basis sets in order to analyse the stability of the solution to the changes in the basis set.

IV. Reactions of allyl type dipoles

Most [3 + 2]-cycloaddition reactions represent a dipolar cycloaddition (one reactant molecule is a dipole while the other reactant molecule is a dipolarophile). The dipole molecules contain highly polar bonds and fragments the atoms of which bear integer positive and negative formal charges at least in one boundary structure. The dipoles are usually divided into two main classes, namely, the allyl and propargyl-allenyl type dipoles (Fig. 6). The first type of compounds has a bent geometry of the reactive fragment due to sp²-hybridisation of the orbitals of the central atom; the second type of compounds is characterised by sp-hybridisation of AOs and linear geometry.

Figure 6. Main types of 1,3-dipoles.

Nitrones (1); ylides (2); carbonyl-, thio- and selenocarbonyl ylides (3); azomethine imines (4); carbonyl imines (5); carbonyl oxides (6); azoimines (7); nitrosimines (8); azoxy compounds (9); nitroso oxides (10); nitro compounds (11); ozone (12); nitrile oxides (13); azides (14); diazoalkanes (15); nitrile ylides (16); nitrile imines (17); and nitrous oxide (18).

The allyl-type dipoles comprise nitrones, ylides (including azomethine ylides, carbonyl ylides and thio- and selenocarbonyl ylides), azomethine imines, carbonyl imines, carbonyl oxides, azoimines, nitrosimines, azoxy compounds, nitroso oxides, nitro compounds and ozone. Additionally, the oxo ions and transition metal oxides can also formally be treated as dipoles.

1. Nitrones

The cycloaddition of nitrones to alkenes (Scheme 2) resulting in isoxazolidine **3** is one of the best studied dipolar [3 + 2]-cycloaddition processes.

The [3 + 2]-cycloaddition processes involving nitrones are often treated as Sustmann's type II processes.^{86,87} By varying substituents in the nitrone or dipolarophile molecule one can readily change the type of the HOMO–LUMO interaction and therefore the type of the reaction, thus making it a NED or an IED process. Indeed, the cycloaddition of nitrones to such electron-deficient dipolarophiles, as acrylonitrile ($\text{CH}_2=\text{CHCN}$),⁸⁸ acrolein ($\text{CH}_2=\text{CHCHO}$),⁸⁹ methyl propiolate ($\text{CH}\equiv\text{CCO}_2\text{Me}$)^{88,90} and methyl acrylate ($\text{CH}_2=\text{CHCO}_2\text{Me}$),⁹¹ alkyne carbene chromium complex $[(\text{CO})_5\text{Cr}=\text{C}(\text{OH})\text{C}\equiv\text{CH}]$,⁹⁰ fluorinated alkenes and alkynes,^{92,93} nitroalkenes ($\text{R}^1\text{CH}=\text{CR}^2\text{NO}_2$)^{94–97} and vinylsulfonyl chloride ($\text{CH}_2=\text{CHSO}_2\text{Cl}$)⁹⁸ are controlled by the HOMO_{nitrone}–LUMO_{dipolarophile} interaction. On the other hand, the use of alkenes with electron-donating substituents, e.g., methyl vinyl ether ($\text{CH}_2=\text{CHOMe}$)³⁷ causes the reaction type to be changed to the IED process.

a. Reactions with alkenes and alkynes. The reaction mechanisms

Most authors have reported a concerted mechanism of thermally induced cycloaddition of nitrones.^{37,82,88,93,98–103} For instance, studies of the reactions of (i) *N,C*-dimethylnitrone [$\text{MeCH}=\text{N}(\text{Me})\text{O}$] with $\text{CH}_2=\text{CHOMe}$ (see Ref. 37) and (ii) cyclic nitrone **4** with methyl propiolate and acrylonitrile⁸⁸ showed that in the most stable transition states of these reactions the difference of the Wiberg bond indices for the $\text{C}(3)\cdots\text{C}(4)$ and $\text{O}(1)\cdots\text{C}(5)$ contacts (see Scheme 2) varies in the range from 0.13 to 0.27, thus indicating an asynchronous mechanism. Calculations of the S_y values for the cycloaddition of $\text{CH}_2=\text{NHO}$ to ethylene and acetylene showed that these processes are characterised by high synchronicity ($S_y=0.92$).^{99,100} Interestingly, a high synchronicity was also found for the reactions of $\text{CH}_2=\text{NHO}$ with such asymmetrical dipolarophiles, as $\text{CH}_2=\text{CHCF}_3$, $\text{F}_2\text{C}=\text{CF}_3$ and $\text{CH}\equiv\text{CCF}_3$.⁹³

The mechanisms of nitrone ($\text{CH}_2=\text{NHO}$) cycloaddition to ethylene and cyclobutadienes **5** and **6** were studied.^{82,104} The results of the B3LYP, CASSCF and QCISD calculations indicated a concerted mechanism of the nitrone interactions with $\text{CH}_2=\text{CH}_2$ and compound **6**; as to the addition to cyclobutadiene **5**, the concerted and stepwise mechanisms were found to be equiprobable due to clear antiaromatic character of compound **5**. In the case of nitrone reactions with allene ($\text{CH}_2=\text{C}=\text{CH}_2$) the stepwise cycloaddition involving the formation of biradical intermediate is energetically more favourable than concerted one.¹⁰⁵

b. Effect of Lewis acid on the reaction mechanism

The introduction of a Lewis acid catalyst into the system leads to dramatic increase in the asynchronicity of the process^{37,106,107} (for the reasons, see above). For instance, the reaction of $\text{MeCH}=\text{N}(\text{Me})\text{O}\cdots\text{BH}_3$ complex with $\text{CH}_2=\text{CHOMe}$ is accompanied by an increase in the difference between the Wiberg indices for the contacts $\text{C}(3)\cdots\text{C}(4)$ and $\text{O}(1)\cdots\text{C}(5)$ in the transition state (see Scheme 2) from 0.13 (for non-catalytic process) to 0.27.³⁷ The effect of Lewis acid (BH_3 and BF_3) on the mechanism, energy characteristics, regio- and stereoselectivity of the reaction of $\text{CH}_2=\text{NHO}$ with acrolein was also studied.¹⁰⁶ If BH_3 is coordinated to acrolein, the activation energy decreases from 105 to 53 kJ mol^{-1} and the asynchronicity of the process increases. Coordination of this Lewis acid to nitrone causes inhibition of the reaction (E_a increases by 18 kJ mol^{-1}) and some increase in its synchronicity. The theoretical activation energies reported in this study should be treated with care, because they were obtained from HF calculations ignoring the electron correlation effects [*cf.* 65.7 kJ mol^{-1} for the experimentally determined enthalpy of activation of thermally induced reaction of $\text{PhCH}=\text{N}(\text{Me})\text{O}$ with $\text{CH}_2=\text{C}(\text{Me})\text{CO}_2\text{Me}$, see Refs 7 and 108]. Nevertheless, the character of the Lewis acid effect on the reactivity (*i.e.*, acceleration of the reaction upon selective coordination of BH_3 to dipolarophile) is in qualitative agreement with the FMO theory predictions for the NED processes to which the reaction in question belongs. Interestingly, the coordination of BF_3 used instead of BH_3 to nitrone causes the reaction mechanism

to change from concerted to stepwise. Corresponding calculations revealed a Michael-type intermediate for this reaction.

Two possible mechanisms of the interaction of zinc-coordinated *N*-benzyl-*C*-(2-pyridyl)nitron with allyl alcohol were studied.⁶² However, the PM3 semiempirical method employed in that study precluded a correct description of the systems under study and the results obtained appeared to be in contradiction with experimental data.

c. Solvation effects

Usually, the dipolar [3 + 2]-cycloaddition reactions of nitrones occur *via* polar transition states, but the initial nitron is also a dipole. If the second reactant has a sufficiently large dipole moment, the total polarity of the reactants becomes higher than the polarity of the transition state. Therefore, when using polar solvents, one can expect an increase in the activation energy for this type of reactions. This was confirmed experimentally^{109–111} and theoretically.^{37, 94, 100} In particular, Domingo³⁷ showed that the activation barrier to the reaction of $\text{MeCH}=\text{N}(\text{Me})\text{O}\cdots\text{BH}_3$ with $\text{CH}_2=\text{CHOMe}$ increases by 7–8 kJ mol^{−1} on going from the gas phase to solution in CH_2Cl_2 . A similar effect was also obtained for the reaction of $\text{CH}_2=\text{NHO}$ with non-polar ethylene; at the same time the interaction of this nitron with acetylene is characterised by some decrease in E_a on going to solution in MeCN .¹⁰⁰ Additionally, solvation is accompanied by an increase in asynchronicity of formation of the corresponding transition state or even by a change from concerted to stepwise reaction mechanism due to, *e.g.*, stabilisation of polar acyclic intermediate in the polar solvent as in the reactions of $\text{PhR}^1\text{C}=\text{N}(\text{Ph})\text{O}$ ($\text{R}^1=\text{H}, \text{Ph}$) with nitroalkenes $\text{R}^2\text{CH}=\text{CHNO}_2$ ($\text{R}^2=\text{C}_6\text{H}_4\text{NO}_2$ -4, CN, CCl_3).^{94, 101, 112}

d. Regioselectivity and stereoselectivity

Elucidation of the nature of the regio- and stereoselectivity of the [3 + 2]-cycloaddition processes is one of the most interesting and important problems. The regioselectivity is often interpreted from the standpoint of the FMO theory as a result of preferred interaction of the dipole and dipolarophile atoms characterised by the largest orbital coefficients in the FMOs. At the same time in the case of nitrones both types of the interaction, $\text{HOMO}_{\text{nitron}}-\text{LUMO}_{\text{dipolarophile}}$, and $\text{HOMO}_{\text{dipolarophile}}-\text{LUMO}_{\text{nitron}}$, play a significant role and the orbital coefficients of all reacting atoms in the FMOs are similar. This is the reason for low regioselectivity of these reactions.^{88, 113, 114}

As mentioned above, the introduction of electron-donating or electron-withdrawing substituents into the nitron or dipolarophile molecule leads to predominance of a certain type of the HOMO–LUMO interaction and, hence, to an increase in the regioselectivity of the reaction. For instance, experimental^{115–118} and theoretical^{34, 37, 89, 93, 94, 98, 101, 118, 119} studies showed that reactions of nitrones with olefins usually result in preferred formation of *ortho*-isomers if the dipolarophile molecule contains an electron-donating substituent (*e.g.*, Alk, OAlk, NH_2) and *meta*-isomers if it contains an electron-withdrawing substituent (*e.g.*, CHO, CF_3 , NO_2 , SO_2Cl). By varying substituents in the nitron molecule one can also change the regioselectivity. For instance, the use of nitrones $\text{CH}_2=\text{N}(\text{R})\text{O}$ in the reaction with $\text{CH}_2=\text{CHNO}_2$ leads to exclusive formation of the *ortho*-isomer, whereas in the case of *C*-substituted nitrones the reaction results in the *meta*-isomer (*meta*-selectivity).^{120, 121}

High *meta*-selectivity was predicted for the interaction of cyclic nitron **4** with methyl propiolate.⁸⁸ According to calculations, isomer **7** should be the major product [the PCM-B3LYP/6-31G* calculated activation energy difference is 11 kJ mol^{−1}, which corresponds to an isomer ratio of 85 (*meta*):1 (*ortho*)], which agrees with experimental data on selective formation of the *meta*-isomer in the reaction of compound **4** with ethyl propiolate.⁸⁸

Even minor changes in the relative activation barriers to the formation of *meta*- and *ortho*-isomers lead to large variations of the relative yields of the regioisomers due to exponential dependence in the Boltzmann equation; therefore, the theoretical estimate of regioselectivity can strongly depend on the computational method and basis set employed. For the addition of nitron **4** to acrylonitrile, B3LYP/6-31G* calculations⁸⁸ showed a low *meta*-selectivity, whereas B3LYP/6-31+G* computations using the basis set augmented with diffuse functions predicted a low *ortho*-selectivity (formation of product **8**). One can expect that further extension of the basis set and use of higher-level computational methods [*e.g.*, MP4 or CCSD(T)] will provide better agreement with conclusions about exclusive formation of the *ortho*-isomer in this reaction drawn from experiment.

In some cases the regio- and stereoselectivity are governed by the nature of the solvent and the presence of the Lewis acid.^{37, 100, 122, 123} In particular, the interaction of $\text{CH}_2=\text{N}(\text{R})\text{O}$ with nitroethylene ($\text{CH}_2=\text{CHNO}_2$) shows no regioselectivity in the gas phase, but calculations with inclusion of solvent effect lead to preferred formation of the *ortho*-isomer *via* an *endo*-transition state in accordance with experimental data (see above).¹⁰⁰ Enhancement of the regio- and stereoselectivity upon the introduction of Lewis acid was observed³⁷ in calculations of the interaction of $\text{MeCH}=\text{N}(\text{Me})\text{O}$ with $\text{CH}_2=\text{CHOMe}$. The *exo:endo* isomer ratio increases from 3.8:1 (obtained from B3LYP/6-31G* calculations of thermally induced reaction) to 29:1 for the BH_3 -catalysed process. For comparison, the experimental *exo:endo* isomer ratio in the reaction of $\text{CH}_2\text{OCMe}_2\text{OCH}=\text{N}(\text{O})\text{CMe}_2\text{OCH}_2$ with $\text{CH}_2=\text{CHOEt}$ is 3:1.⁸⁸ The *exo*-stereoselectivity is due to the lack of steric hindrances to the formation of transition state in the case of *endo*-isomer.

Steric stabilisation is one of the main reasons for stereospecificity of the reactions of nitrones with *cis*-3,4-dimethylcyclobutene¹²⁴ and electron-deficient alkenes containing bulky substituents.¹²⁵ In the former case strong interaction between the nitron atoms and the methyl groups of the dipolarophile leads to almost exclusive formation of the *anti*-isomer *via* an *exo*-transition state (**TS1**). The activation energy for the formation of the corresponding *syn*-product is 8.6 kJ mol^{−1} higher (theoretical and experimental *syn:anti* product ratios are 97:3 and $\geq 99:1$, respectively), while the *endo*-addition is 33–39 kJ mol^{−1} less favourable than the *exo*-addition. The *anti*-addition is also preferable for the reactions of $\text{CH}_2=\text{NHO}$ with enol ethers, but here the stereoselectivity is mainly governed by electrostatic effects.¹²⁶

The effect of the nature of the substituent in the dipole molecule on the stereoselectivity of cycloaddition was studied.¹²⁷ The reaction of the model compounds, namely, *E*-isomer of nitron $\text{MeO}_2\text{CCH}=\text{N}(\text{Me})\text{O}$ (**9**) and *N,N*-dimethylallylamine should result in preferred formation of *trans*-product **10** through *exo*-addition, whereas in the reaction of nitron **11** should mainly afford the *cis*-isomer **12** (this process will occur under kinetic control).

The conclusions made¹²⁷ are in excellent agreement with experimental facts. Similarly, the *Si-exo*-facial stereoselectivity was calculated for the reactions of *C*-[(4,*S*)-2,2-dimethyl-1,3-dioxolan-4-yl]-*N*-methylnitrone with ethyl 2-acetoxyacrylate¹²⁸ (theoretical and experimental isomer ratios of the most stable *Si-exo*- and *Re-exo*-isomers are 7 : 1 and 2 : 1, respectively) and with vinyl acetate.¹²⁹ At the same time the cycloaddition of *C*-[(4,*S*)-2,2-dimethyl-1,3-dioxolan-4-yl]-*N*-methylnitrone to methyl acrylate,¹³⁰ *C*-(2-furyl)-*N*-methylnitrone to vinyl acetate,¹³¹ and nitrones to unsaturated arylsulfones¹³² and pyrazolon-*N,N*-dioxides to epoxynaphthalene¹³³ show *endo*-selectivity.

In some cases the stereoselectivity is governed by the effect of the secondary orbital interaction (orbital interaction between the atoms that are not involved in the cycloaddition reaction, *e.g.*, the atoms *b* and *g* or *b* and *f*, see Fig. 7). Obviously, a bonding secondary orbital interaction should stabilise a given stereoconfiguration and an antibonding interaction should destabilise it. Indeed, the *endo*-stereoselectivity theoretically predicted for the addition of nitrones to *s-cis*-acrolein ($\text{CH}_2=\text{CH}-\text{CHO}$) is governed by the bonding secondary orbital interaction between the nitrone nitrogen p-AOs and p-orbitals of the atoms in the carbonyl group of the dipolarophile.^{34, 134} However, it should be noted that the authors of some studies (see, *e.g.*, a review by Garcia *et al.*²⁷) cast some doubt on the role of the secondary orbital interaction in the stereospecific course of reactions.

Figure 7. Primary and secondary orbital interactions.

Model reactions of nitrone $\text{CH}_2=\text{NHO}$ with vinylboranes $\text{CH}_2=\text{CHBR}_2$ were studied.¹³⁵ The [3 + 2]-cycloaddition reaction should show regioselectivity and *endo*-stereoselectivity and proceed at high rate *via* acyclic complex **13** with the formation of *ortho*-isomer **14**.

The regioselectivity and low activation barriers are due to strong interaction between the boron and oxygen atoms in complex **13** and in the corresponding transition state **TS2**. Other possible mechanisms of this process, namely, cyclisation with the formation of six-membered boron-containing ring, *O*-boration and oxidation are undoubtedly energetically less favourable compared to cycloaddition. The use of dimethyl-substituted vinylboranes $\text{CH}_2=\text{CHBMe}_2$ and $\text{Me}_2\text{C}=\text{CHBH}_2$ causes the activation energy to increase, whereas in the case of dichlorovinylborane $\text{CH}_2=\text{CHBCl}_2$ the activation barrier decreases consistently with the FMO theory predictions for the NED reactions. At present, these theoretical predictions cannot be substantiated or rejected due to the lack of corresponding experimental data.

If the dipolarophile molecule has several multiple bonds, the dipole can selectively react at one of the bonds (this is called chemoselectivity). For instance, the chemoselectivity of the reaction of cyclic nitrone **15** with methyleneketene was studied.¹³⁶ The reaction can follow three pathways, among which the cycloaddition to the terminal $\text{C}=\text{C}$ bond is the most kinetically favourable (B3LYP/6-31G* calculated activation energies for the pathways *a*, *b* and *c* are 16, 23 and 87 kJ mol⁻¹, respectively). This agrees with experimental data on the isolation of the corresponding regioisomer.

e. Other dipolarophiles

The results of studies on the reactions of cyclic and acyclic nitrones with free nitriles $\text{RC}\equiv\text{N}$ and platinum-coordinated nitrile constituents of the complexes *trans*-[PtCl₂(NCMe)₂] (**16**) and *trans*-[PtCl₄(NCMe)₂] (**17**) (Scheme 3) were summarised in two recent studies.^{72, 137}

Scheme 3

[Pt] = *trans*-[PtCl_n(NCMe)]; *n* = 2, 4.

These studies were carried out to establish the reasons for the activation of nitriles in the complexes compared to free ligands and to thoroughly analyse the reaction mechanisms and the influence of various factors (solvent, nature of substituent, computational method) on the energy characteristics of the reactions. The experimentally observed^{138,139} enhancement of the reactivity in the series MeCN–**16**–**17** was interpreted as being due to a decrease in the nitrile LUMO energy in this series (orbital control) and an increase in the effective atomic charge of the nitrile β -carbon (charge control).¹⁴⁰ Analysis of the electron density distribution in the transition states **TS3** showed that the coordination of nitrile is accompanied by not only the change in the reaction type from the intermediate to the NED reaction but also a change in the reaction mechanism from synchronous for MeCN ($S_y = 0.92$) to intermediate between concerted cycloaddition and nucleophilic addition of the nitron oxygen atom to the nitrile β -carbon ($S_y = 0.69$ and 0.53 for the reactions of compounds **16** and **17**, respectively). It is this change in the reaction mechanism that provides an explanation for dramatic enhancement of nitrile reactivity upon coordination. Nevertheless, ring critical points were located for all transition states (Fig. 8), which indicates the

cyclic nature of the transition state even in the reaction of complex **17**.

The results of calculations confirmed that coordination of nitrile in complexes **16** and **17** is followed by dramatic decrease in the Gibbs free activation energy and by an increase, in absolute value, in the energy change (ΔG) in the reaction (Table 1). This is in excellent agreement with the experimentally observed changes in the reactivity of nitriles. Interestingly, the ‘electronic’ activation energy calculated relative to the total energy of reactants for the interaction of $\text{CH}_2=\text{N}(\text{Me})\text{O}$ with complex **17** is negative, being equal to -23 kJ mol^{-1} (obtained from B3LYP/6-31G* calculations). However, the E_a values calculated relative to the orientation complex that is formed in the early stages of the reaction and the Gibbs free activation energy calculated relative to the total energy of reactants become positive (20 and 34 kJ mol^{-1} , respectively). Thus, in the E_a scale (in essence, this parameter coincides with $\Delta H^\ddagger$ at 0 K) the energy of the orientation complex is lower than that of the reactants. Nevertheless, with allowance for the entropy factor one gets that the equilibrium is shifted towards formation of the initial compounds. This situation is typical of the cycloaddition reactions involving highly activated reactants (see, e.g., Refs 141–143).

Figure 8. Contour map illustrating the distribution of the Laplacian of electron density $\nabla^2\rho(r)$, the bond pathway and the zero-flux surface for transition states of the reactions of nitron $\text{CH}_2=\text{N}(\text{Me})\text{O}$ with MeCN (a) and complex **17** (b).

Table 1. Relative energy characteristics (in kJ mol^{-1}) of the cycloaddition of $\text{CH}_2=\text{N}(\text{Me})\text{O}$ to MeCN and to complexes **16** and **17** (obtained from B3LYP/6-31G* calculations; ECP on Pt atom).^a

Reactant	E_a	$\Delta H^\ddagger$	$\Delta G^\ddagger$	ΔE	ΔH	ΔG

Notes. 1. All values are given relative to the total energy of the reactants. 2. The values in parentheses and in square brackets denote the values corrected for zero-point vibrational energy and for solvation effect, respectively. The values corrected for the basis set superposition error are given in *italic*.

^a Obtained from CPCM calculations using the gas-phase equilibrium geometry. ^b Full geometry optimisation was carried out in the CPCM-B3LYP/6-31G* approximation.

Studies of the effect of the substituent nature on the energy characteristics of reactions showed that the process proceeds more easily upon introduction of electron-withdrawing groups into the nitrile molecule. Indeed, the activation energies obtained for the reaction of $\text{CH}_2=\text{N}(\text{Me})\text{O}$ with RCN are 59 and 54 kJ mol^{-1} at $\text{R} = \text{Me}$ and Ph , respectively. *C*-Alkyl nitrones are more reactive than *C*-aryl nitrones ($\Delta G^\ddagger = 127$ and 143 kJ mol^{-1} for the reactions of $\text{MeCH}=\text{N}(\text{Me})\text{O}$ and $p\text{-MeC}_6\text{H}_4\text{CH}=\text{N}(\text{Me})\text{O}$ with MeCN, respectively). The theoretical $\Delta H^\ddagger$ value for the reaction of $p\text{-MeOC}_6\text{H}_4\text{CH}=\text{N}(\text{Me})\text{O}$ with PhCN is 83 kJ mol^{-1} , being very similar to the experimental value determined for the interaction of cyclic nitron **18** with PhCN (84 kJ mol^{-1}).¹⁴⁴ Additionally, a linear correlation between the parameter $\Delta G^\ddagger$ and the synchronicity of cycloaddition was found (Fig. 9). Since both reactant molecules have high polarities, the use of a polar solvent should inhibit the reaction, namely, the activation energy increases by $12\text{--}23 \text{ kJ mol}^{-1}$ on going from the gas phase to solution in CH_2Cl_2 and the ΔE value for this reaction decreases by $3\text{--}20 \text{ kJ mol}^{-1}$ in absolute value.

Figure 9. Parameter $\Delta G^\ddagger$ plotted vs. difference of the Wiberg indices (Δk_w) of the contacts O(1)N(5) and C(4)N(3) for the reactions of compounds R^1CN ($R^1 = H, Ph$) with $R^2CH=N(Me)O$ ($R^2 = H, Me, p\text{-MeC}_6\text{H}_4, p\text{-MeOC}_6\text{H}_4$); obtained from B3LYP/6-31G* calculations.

Salts with $[R^1C \equiv NR^2]^+$ cations, in which the nitrile is very electron-deficient, can be used to model the complexation of compounds RCN . The results of semiempirical AM1 calculations of the cycloaddition of pyridine *N*-oxide (C_5H_5NO) to $[MeC \equiv NMe]^+$ supported a stepwise reaction mechanism.¹⁴⁵

Reactions of nitrones $R^1CH=N(R^2)O$ with singlet oxygen $^1O_2$ and molecular anion O_2^- were studied.¹⁴⁶ The intrinsic reaction coordinate was calculated and application of the virial theorem to the molecular system along the reaction pathway was considered. All processes, except for the interaction of $CH_2=NHO$ with O_2^- , occur with the formation of five-membered heterocyclic products. For the last-named reaction, attempts to locate such a product failed.

2. Ylides

Ylides are a large class of 1,3-dipoles. Most of them belong to allyl-type dipoles (except nitrile ylides). Azomethine ylides $[R^1_2C=N(R^2)CR^3]$, carbonyl ylides and thiocarbonyl ylides ($R^2C=XCR_2$, $X = O, S$) have been best theoretically studied. Additionally, the behaviour of cyclic ylides **19** and **20** in the [3 + 2]-cycloaddition reactions was studied based on the results of the MO calculations of these dipoles.^{147–149}

The reactions of ylides with dipolarophiles mainly belong to the NED processes.^{86,87} Indeed, the cycloaddition of azomethine ylides to alkenes,^{60,150,151} alkynes,^{63,152} aldehydes,¹⁵³ imino alcohols,¹⁵⁴ as well as the cycloaddition of carbonyl ylides and thiocarbonyl ylides to alkenes,^{155,156} aldehydes¹⁵⁷ and cyclopentenones¹⁵⁸ is governed by the $HOMO_{\text{dipole}} - LUMO_{\text{dipolarophile}}$ interaction. At the same time the reactions between *N*-arylazomethine ylides $R^1R^2C=N(Ar)CR^3R^4$ or carbonyl ylides $R^1R^2C=OCR^3R^4$ and dipolarophiles with electron-donating substituents represent IED processes.^{86,87,159}

The mechanisms of ylide reactions are strongly dependent on the nature of the dipole and dipolarophile and on the character of substituents in the reactant molecules. For instance, the [3 + 2]-cycloaddition reactions of 2-ethoxycarbonylpyridinium *N*-amidine (**21**)¹⁶⁰ and cyclic azomethine ylide **22**¹⁴¹ with acrylonitrile proceed by concerted asynchronous mechanism. The latter process shows regioselectivity and *endo*-stereoselectivity with preferred formation of isomer **23**, which agrees with experimental data, namely, the yield ratio of two *endo*-regioisomers is 24 : 1, whereas no *exo*-regioisomers were isolated.¹⁶¹ The activation energy for this reaction pathway calculated relative to the total energy of reactants is negative (-9 kJ mol^{-1} , obtained from B3LYP/6-31G* calculations), being positive when calculated relative to the energy of the orientation complex (15 kJ mol^{-1}). Moreover, augmentation of the 6-31+G** basis set with diffuse functions leads to positive E_a values relative to the total energy of reactants (5 kJ mol^{-1}). Low activation barriers are confirmed by the fact that this reaction occurs at low temperature (-78°C).¹⁶¹ At the same time it was reported¹⁶² that the addition of azomethine ylide ions $[CH_2=NCH_2]^-$ (and allyl and borallyl ions) to ethylene proceeds by stepwise mechanism, which is consistent with the results obtained by Sauer.¹⁶³

The substituent effects on the mechanisms of the reactions between ylides $R^1_2C=N(R^2)CHCHO$ and alkenes $CH_2=CHR^3$ were studied.¹⁶⁴ It was established that the reactions proceed by concerted mechanism at $R^1 = R^3 = H$ and $R^2 = H, Li$; by stepwise mechanism at $R^1 = H, R^2 = Li, R^3 = NO_2$ and $R^1 = Ph, R^2 = H, R^3 = NO_2$; and by an intermediate mechanism characterised by a synchronicity S_y of about 0.6 (for the reaction in acetonitrile) at $R^1 = R^2 = H, R^3 = NO_2$.

Butler *et al.*^{165,166} analysed the effect of association of water clusters $(H_2O)_4$ and $(H_2O)_6$ with the dipolarophile molecule on the energy characteristics of the cycloaddition of azomethine ylides to alkenes. It was shown that taking into account the formation of such associates leads to considerable decrease in the Gibbs free activation energy (by 22–28 kJ mol^{-1}).

The mechanisms of the interaction of thiocarbonyl ylides $CR_2=SCH_2$ and thiocarbonyl imine $CH_2=SNH$ with symmetrical thioketones and ethylene were studied by the DFT, MCSCF, QCISD(T) and CBS methods.^{85,167–169} Concerted cycloaddition was shown to be energetically more favourable than the stepwise mechanism. It is believed that the reaction of $CH_2=SCH_2$ with $CH_2=S$ proceeds barrierlessly, whereas the activation barriers to the other processes amount a few kcal mol^{-1} . At the same time the activation energies for concerted and stepwise mechanisms differ insignificantly; as a consequence, the possibility of the stepwise mechanism in the presence of substituents stabilising the biradical structure cannot be ruled out.

B3LYP/6-31G*//HF/3-21G* calculations¹⁵⁷ of the activation energy and energy change for the concerted mechanism of the [3 + 2]-cycloaddition of diphenylthiocarbonyl ylide $Ph_2C=SCH_2$ to thiobenzophenone $Ph_2C=S$ revealed kinetic and thermodynamic preference of the formation of regioisomer **24** ($E_a = 27$ and $\Delta E = -172 \text{ kJ mol}^{-1}$). However, these results contradict experimental data, according to which product **25** is isolated in this reaction.¹⁷⁰ Further studies showed that the energetically most

favourable mechanism of this process is a stepwise mechanism with the formation of a C,C-biradical intermediate and regioisomer **25** as the end product. Thus, this reaction occurs under kinetic control.

A stepwise mechanism was also predicted for the reaction of thiocarbonyl ylide **26** with tetracyanoethylene.¹⁷¹ The cycloaddition involves the formation of a zwitterionic intermediate **27**.

This species can undergo cyclisation to the seven-membered cyclic product **28** and to the thermodynamically most stable end product **29** (compounds **28** and **29** are in equilibrium). The energy profile of this reaction pathway is shown in Fig. 10. The activation energies for cyclisation of intermediate **27** to compounds **29** and **28** differ by 5 kJ mol⁻¹, which is in reasonable agreement with experimental data on the formation of compounds **28** (more correctly, corresponding *spiro*-lactim ether) and **29** in a 2:1 ratio;¹⁷² hence, the process also occurs under kinetic control.

The regioselectivity of the reactions of azomethine ylides **30** with (*E*)-3-arylidene-4-chromanones **31** was studied⁶⁰ using the AM1 and PM3 semiempirical MO calculations. The results of calculations confirmed the experimental data on exclusive formation of product **32**. On the contrary, the FMO theory provides no explanation for the observed regioselectivity of dimerisation of thiocarbonyl ylide **33** ('head-to-head' addition pattern).¹⁷³

Figure 10. Energy profile of the reaction of thiocarbonyl ylide **26** with tetracyanoethylene.

R¹ = SMe, R² = SO₂Me, R³ = SiMe₃.

It was concluded that in this case the regioselectivity is governed by charge control, *i.e.*, the carbon atom bearing the negative formal charge attacks the positively charged sulfur atom.

Theoretical studies of stereoselectivity were reported for the reactions of (i) isomunchnones and thioisomunchnones (*e.g.*, compound **34**) with alkenes^{155, 174, 175} and alkynes,¹⁷⁶ (ii) azomethine ylides with olefins^{177, 178} and maleimides^{179, 180} and (iii) ylides **35** with phenylalkynes.¹⁵² In the last-mentioned case the equilibrium transition-state geometry was only determined for one out of eight possible stereoisomers (compound **36**). This suggests a selective formation of this structure and was confirmed experimentally.

3. Ozone

The ozone molecule provides yet another example of allyl-type dipole, which can also undergo [3 + 2]-cycloaddition reactions. Analysis of the FMO energies showed that these reactions are governed by the HOMO_{dipolarophile} – LUMO_{ozone} interaction due to the low ozone LUMO and especially HOMO energies, thus being the IED processes. This reaction type remains unchanged even for the dipolarophiles containing electron-withdrawing substituents.^{86, 87} Here, the reaction rate is appreciably lower than in the case of the cycloaddition to dipolarophiles with electron-donating groups due to larger energy difference between the corresponding MOs.

Ozonolysis of isoprene was studied theoretically.⁷⁴ It was shown that the process begins with dipolar [3 + 2]-cycloaddition. According to calculations, the reaction proceeds by concerted mechanism. The energy changes and activation energies for the reactions strongly depend on the approximation employed. For

instance, the DFT and MP2 methods give negative E_a values, thus suggesting a barrierless reaction; more accurate CCSD(T)/6-31G* calculations led to $E_a = 14 \text{ kJ mol}^{-1}$ for both reactions. This value is in agreement with experimental kinetic data for these processes ($16\text{--}18 \text{ kJ mol}^{-1}$). Products **37** and **38** are similar in thermodynamic stability, the energy difference between them being 3 kJ mol^{-1} .

Similar results were also obtained for the ozone reactions with ethylene, benzene and phenol.⁸¹ According to calculations, the reaction with ethylene proceeds most easily [$E_a = 14$, $\Delta E = -220 \text{ kJ mol}^{-1}$, obtained from CCSD(T)/6-31G** computations], whereas the cycloaddition to benzene is characterised by much higher activation barrier and small energy change (66 and -79 kJ mol^{-1} , respectively). Ozonolysis of phenol occurs at positions 1 and 2 of the benzene ring with intermediate energies. The calculated energies are in reasonable agreement with experimental data. Namely, the E_a and ΔE values for the interaction $\text{O}_3 + \text{CH}_2=\text{CH}_2$ are respectively 21 and $-188 \pm 25 \text{ kJ mol}^{-1}$ (Refs 181 and 182) and the activation energy E_a for the interaction $\text{O}_3 + \text{C}_6\text{H}_6$ is 61 kJ mol^{-1} (Ref. 183).

The kinetics and mechanism were studied for the ozone reactions with ethylene, fluoroethylene and chloroethylene¹⁸⁴ and with acetylene.^{185,186} The activation parameters and rate constants for these reactions were estimated. The cycloaddition to haloalkenes should proceed 20 to 25 times slower than the reaction with unsubstituted ethylene [$E_a = 20 \text{ kJ mol}^{-1}$; obtained from CASPT2(10.9)/cc-pVTZ calculations], whereas the reactivities of chloroethylene and fluoroethylene are comparable ($E_a = 23$ and 24 kJ mol^{-1} , respectively). The results of calculations were also confirmed by experimental data [e.g., the calculated and experimental rate constants for cycloaddition to ethylene are 1.02×10^{-18} and $(1.75 \pm 0.52) \times 10^{-18} \text{ cm}^3 (\text{molecule s})^{-1}$, respectively]. It is believed that the reaction with acetylene proceeds by concerted mechanism because no biradical intermediates were located on the potential energy surface.¹⁸⁵ The theoretical rate constant for this process is $0.8 \text{ litre } (\text{mol s})^{-1}$ and $\Delta H^\ddagger = 31 \text{ kJ mol}^{-1}$ [obtained from CCSD(T)/CBS calculations]; the latter value is consistent with the experimental values obtained earlier ($29.7 \pm 4.2 \text{ kJ mol}^{-1}$).¹⁸⁷

4. Metal oxides

There is a number of theoretical studies on the reactions of cycloaddition of the permanganate ion MnO_4^- (Refs 188–191), associates $\text{Et}_4\text{N}^+ \cdots \text{MnO}_4^-$ (see Ref. 188), ruthenium oxide RuO_4 (Refs 192 and 193) and associates $\text{NH}_3 \cdots \text{RuO}_4$ (Ref. 192) to alkenes $\text{XC}_6\text{H}_4\text{CH}=\text{CH}_2$ and $\text{CH}_2=\text{CH}_2$, which result in five-membered metallacycles **39**.

$\text{M} = \text{Mn}$: $n = 1-$, $m = 1$; $\text{Q} = \text{NEt}_4$; $\text{R} = \text{C}_6\text{H}_4\text{X}$ ($\text{X} = \text{H}$, 4-Me, 4-Cl, 3-Cl, 3-Br, 3,4-Cl₂, 3-NO₂, 4-NO₂);
 $\text{M} = \text{Ru}$: $n = m = 0$; $\text{Q} = \text{NH}_3$, $\text{R} = \text{H}$.

The effect of the substituent X on the energy characteristics of the reactions was studied and it was shown that the $\Delta G^\ddagger$ value decreases as follows for different X : 4-Me > H > 3-Br > 4-Cl > 3,4-Cl₂ > 3-Cl > 3-NO₂ > 4-NO₂. Good agreement between the theoretical and experimental activation parameters of the process was obtained (Table 2). For the reactions involving RuO_4 and MnO_4^- the [3 + 2]-cycloaddition processes were shown to be both thermodynamically and kinetically more favourable than [2 + 2]-cycloaddition.

Table 2. Theoretical and experimental (in parentheses) activation parameters for the interaction of $\text{Et}_4\text{N}^+ \cdots \text{MnO}_4^-$ with $\text{XC}_6\text{H}_4\text{CH}=\text{CH}_2$ (B3LYP/6-311 + G**//B3LYP/LanL2DZ calculations; geometry optimised with inclusion of Et_4N^+ counterion).¹⁸⁸

X	$\Delta H^\ddagger / \text{kJ mol}^{-1}$	$\Delta G^\ddagger / \text{kJ mol}^{-1}$
4-Me	24 (20.3 ± 0.7)	79 (73.2)
H	21 (18.8 ± 1.5)	73 (72.7)
3-Br	18 (17.5 ± 1.1)	71 (70.7)
4-Cl	17 (15.9 ± 1.2)	69 (70.9)
3,4-Cl ₂	14 (10.7 ± 0.7)	68 (69.9)
3-Cl	18 (18.0 ± 1.5)	67 (71.0)
3-NO ₂	13 (11.4 ± 1.4)	61 (69.4)
4-NO ₂	7 (15.6 ± 1.7)	58 (67.2)

The cycloaddition of OsO_4 , MO_3^q and LMO_3^q [$q = 0, 1-, 1$; $\text{M} = \text{Mo}$, W , Mn , Tc , Re , Os ; $\text{L} = \text{O}$, H_3PN , Cl , Me , $\eta^5\text{-C}_5\text{H}_5$ (Cp)] to olefins and ketene ($\text{CH}_2=\text{C}=\text{O}$) were studied.^{193–200} The reactions of all compounds (except MeReO_3) with ethylene and the reaction of OsO_4 with ketene proceed by the [3 + 2]-cycloaddition mechanism, although the activation energies are high ($59\text{--}197 \text{ kJ mol}^{-1}$). Other oxides react with ketene by the [2 + 2]-cycloaddition mechanism ($E_a = 46\text{--}92 \text{ kJ mol}^{-1}$), ReO_4^- and $(\text{H}_3\text{PN})\text{ReO}_3$ being added to the $\text{C}=\text{O}$ bond and MeReO_3 and CpReO_3 being added to the $\text{C}=\text{C}$ bond. The most recent data on the cycloaddition of metal oxides to the $\text{C}=\text{C}$ double bond were summarised in a review by Deubel and Frenking.²⁰¹

$\text{M} = \text{Os}$, $\text{L} = \text{O}$; $\text{M} = \text{Re}$, $\text{L} = \text{O}^-$, H_3PN , Cp .

V. Reactions of propargyl–allenyl type dipoles

The propargyl–allenyl type dipoles include nitrile oxides, azides, diazoalkanes, nitrile ylides, nitrile imines and nitrous oxide (see Fig. 6).

1. Nitrile oxides

Following Sustmann's classification, reactions of cycloaddition of nitrile oxides $\text{RC}\equiv\text{N}^+-\text{O}^-$ are often treated as type III (IED) processes.^{86,87} At the same time, carrying out reactions with electron-deficient dipolarophiles causes the reaction type to

change to the NED process due to a decrease in the dipolarophile LUMO energies.^{92, 202, 203} For instance, the reactions of RCNO compounds with fluoroalkenes and fluoroalkynes⁹² and halo- and cyano-substituted *p*-benzoquinones²⁰² are governed by the HOMO_{dipole}–LUMO_{dipolarophile} interaction, their reactions with the methyl and methoxy derivatives of *p*-benzoquinone²⁰² and with 1,2,4-triazepine²⁰⁴ are controlled by both types of the orbital interaction, while the addition of RCNO to dihydrofuranones belongs to the IED processes.²⁰⁵

Most reactions involving nitrile oxides are assumed to proceed concertedly.^{35, 99, 100, 104, 204, 206–211} Quantum-chemical calculations predicted a high synchronicity for, e.g., the reactions of fulminic acid with ethylene and acetylene ($S_y = 0.79–0.81$ in the gas phase).^{99, 100} The calculated activation barriers to the former process strongly depend on the approximation used. The results of MP4/6-31G**/HF/6-31G* calculations³⁵ ($E_a = 38$, $\Delta G^\ddagger = 74$ kJ mol^{−1}) are in good agreement with the experimentally determined $\Delta G^\ddagger$ value (84 kJ mol^{−1}) for the cycloaddition of PhCNO to CH₂=CH₂.²¹² Various high-level calculations [B3LYP, MP2, CCSD(T), CASSCF, G2(CC)] of the interaction of HCNO with C₂H₂ give $E_a = 54–59$ kJ mol^{−1} (Ref. 213). This is consistent with the fact that alkynes are more inert than alkenes in the cycloaddition reactions with nitrile oxides.²¹⁴ These processes occur *via* planar aromatic transition states and the stabilising effect of π -aromaticity in them is insignificant. Similarly to nitrones, taking into account solvation effects causes an increase in the activation energy by 4–9 kJ mol^{−1} and a decrease in the synchronicity of the reaction. At the same time the energy of the transition state of the cycloaddition of fulminic acid to allene (CH₂=C=CH₂) following the biradical mechanism is 16 kJ mol^{−1} lower than the corresponding energy in the case of concerted mechanism.¹⁰⁵

Some authors considered the reaction of fulminic acid with acetylene in terms of the valence bond approach.^{215, 216} In particular, this reaction was treated²¹⁵ as proceeding by ‘heterolytic’ mechanism (*a*) *via* a non-aromatic transition state in contrast to the Diels–Alder reactions characterised by ‘homolytic’ mechanism and aromatic transition state.²¹⁷ Yet another version of the reaction mechanism, namely, pathway *b*, is also available.²¹⁶ Clearly, a correct determination of the mechanism of this reaction requires further investigations. This process was also studied using the catastrophe theory.²¹⁸

A number of studies are concerned with the regio- and stereo-selectivity of the cycloaddition of nitrile oxides to buta-1,3-diene,¹⁰⁰ alkenes^{35, 219–221} and fluoroalkenes,²²² acrylonitrile, methyl vinyl ether,^{35, 223} cyclobutenes,^{124, 224} dicyclopentadienes,²²⁵ alkynes,^{226–228} thionitroso compounds,²²⁹ anthracene and acridine,²³⁰ dihydrofuranones,²⁰⁵ adamantane-2-thiones, 2-methyleneadamantanes,^{231, 232} stilbenes²³³ and 4-methylenetetrahydrothiopyran.²³⁴ In the reaction with butadiene the activation energy for the formation of 5-vinylisoxazoline (**40**) is 14–15 kJ mol^{−1} lower than that needed for the formation of 4-vinyl-substituted product **41** both in the gas phase and in

solution.¹⁰⁰ This agrees with experimental data on selective formation of compound **40** in the reaction of buta-1,3-diene with fulminic acid prepared *in situ*.²³⁵ The aromaticity of the transition state does not determine the regioselectivity of the process. The cycloaddition to olefins, acrylonitrile and methyl vinyl ether shows regioselectivity with the formation of the *ortho*-isomers, which is also consistent with experimental facts.^{236, 237} Enhancement of electron-donating ability of the substituent at the dipolarophile enhances the *ortho*-selectivity as in the reactions of nitrones.³⁴

The regioselectivity of the cycloaddition of nitrile oxides to alkynes depends on both the nature of substituents in the dipole and dipolarophile molecules and on the solvent nature.^{226, 228, 230} For instance, quantum-chemical computations of gas-phase interaction of fulminic acid with cyanoacetylene (CH≡CCN) predicted preferred formation of the *ortho*-isomer of isoxazole; on the contrary, the reaction of 2,4,6-trimethylbenzonitrile oxide (mesitonitrile oxide) with CH≡CR (R = CN, CO₂Me) is expected to result in the *meta*-isomers (the activation energy difference, ΔE_a , between the *ortho*- and *meta*-pathways lies in the range 2–5 kJ mol^{−1}; obtained from B3LYP/6-31G* calculations).²²⁶ A similar change in the regioselectivity depending on the substituent at the nitrile oxide was also experimentally observed for the reaction of RCNO with CH≡CCO₂Me (ratio of *ortho*/*meta* isomers is 5.25:1 for R = H and 1:2.6 for R = 2,4,6-Me₃C₆H₂, see Refs 7, 10, 237). This can be interpreted as a result of enhancement of the nucleophilicity on going from HCNO to mesitonitrile oxide due to strong donor properties of the mesityl group. As a consequence the orbital coefficients on the oxygen atom increase and therefore the formation of the *meta*-isomer is facilitated (orbital coefficients at the unsubstituted carbon atom in the alkyne molecule are also larger than at the substituted carbon atom).

R¹ = H, C₆H₂Me₃-2,4,6; R² = H, CN, CO₂Me.

Solvation significantly facilitates the formation of the *ortho*-isomers (they should be the major products in high-polarity solvents, in particular, H₂O). This becomes understandable taking into account the fact that the TS of the reaction resulting in the *ortho*-isomer is characterised by a higher polarity than the TS on the pathway to the *meta*-isomer and therefore the former transition state is better stabilised in polar solvents. The theoretical ratio of the *ortho*- and *meta*-isomers in the reaction of mesitonitrile oxide with acrylonitrile in CCl₄ solution agrees with experimental data (2.3:1 and 1.3:1, respectively).²³⁸ At the same time an increase in the solvent polarity causes an increase in the activation energies, which leads to inhibition of the process. DFT calculations of the reactions of benzonitrile oxide with ethynyl- and propynylboronates (RC≡CBOCH₂CH₂O) predict a change in the regioselectivity from the formation of the *ortho*-isomer

$R^1 = \text{H, Ph}; R^2 = R^3 = R^4 = \text{H, Me.}$

($R = \text{H}$) to *meta*-isomer ($R = \text{Me}$),²⁰⁷ which is in agreement with experimental data.²³⁹

In some cases the chemo- and regioselectivity are influenced by the secondary orbital interaction. For instance, in the reaction of 2,4,6-trimethylbenzonitrile oxide with 2,6-dimethoxy-*p*-benzoquinone (**42**) the antibonding secondary orbital interaction between $\text{HOMO}_{\text{quinone}}$ and $\text{LUMO}_{\text{dipole}}$ is responsible for experimentally observed selective formation of the product of addition to the $\text{C}=\text{O}$ rather than $\text{C}=\text{C}$ bond.²⁴⁰ The same effect governs a decrease in the regioselectivity of cycloaddition of fulminic acid to crotonaldehyde $\text{MeCH}=\text{CH}-\text{CHO}$.²⁴¹ Due to the secondary orbital interaction between the nitrile oxide oxygen AOs and the carbonyl carbon AOs in the transition state **TS4**, the energies of the structures **TS4** and **TS5** become similar ($E_a = 57$ and 55 kJ mol^{-1} , respectively; the calculated ratio of regioisomers is 2.2 : 1 and the experimentally determined ratio of the isomers for the reaction of PhCNO with $\text{MeCH}=\text{CH}-\text{CHO}$ is 4.3 : 1).

The mechanisms and the regio- and stereoselectivity of the reactions of nitrile oxides with allyl alcohols controlled by magnesium ions were studied.^{242, 243} In particular, two reaction pathways were analysed. One of them (Scheme 4a) leads to the formation of a magnesium complex with nitrile oxide and one THF molecule **43** due to the interaction of hydroxyiminoyl chloride $\text{R}^1-\text{C}(\text{Cl})=\text{N}-\text{OH}$ with EtMgBr in THF solution. Subsequent interaction between **43** and **44** yields complex **45** with both reactant molecules coordinated to magnesium. The second pathway (Scheme 4b) begins with the formation of alkoxymagnesium complex **46** and then intermediate **47** containing coordinated nitrile oxide, alkoxide and THF molecules. Although the reaction between RCNO and compound **44** shows *ortho*-regioselectivity in the absence of Mg^{2+} (the activation energies for the formation of the *ortho*- and *meta*-isomers differ by 13 to 21 kJ mol^{-1}), the magnesium-controlled process (second pathway) results in exclusive formation of the *ortho*-isomer. This pathway is also kinetically more preferred. The coordination to magnesium also causes enhancement of the *syn*-stereoselectivity related to steric factors, but the activation energy changes insignificantly in this case.

The cycloaddition of benzonitrile oxides to alkenes $\text{CH}_2=\text{CHOC}(\text{O})\text{R}$ (**48**) and $\text{CH}_2=\text{C}(\text{Ac})\text{OC}(\text{O})\text{R}$ (**49**) ($\text{R} = 4\text{-NO}_2\text{C}_6\text{H}_4$) was also described using the hard and soft acids and bases principle.^{244, 245} Consideration of the global-

global interaction revealed that the term ΔE_v in Eqn (2) (see Section II) is much smaller than the term ΔE_μ at $\lambda = 1$ ($\Delta E_{\text{int}} = -4.83 - 209.75 \lambda$ and $\Delta E_{\text{int}} = -6.37 - 217.30 \lambda$ for the reactions with compounds **48** and **49**, respectively). Therefore, charge-transfer processes have little effect on the reactivities of compounds in the cycloaddition reactions of nitrile oxides.

The nucleophilic and electrophilic attack on the carbon and nitrogen atoms in the nitrile oxide molecule and on the double-bond carbon atoms in the alkene molecules were studied from the standpoint of local-global interactions. According to calculations, the energetically most favourable processes include the nucleophilic attack of alkene on the carbon atom in the dipole molecule and the electrophilic attack of the dipole on the terminal carbon atom in the alkene molecule. Thus, in accordance with experimental facts the hard and soft acids and bases principle correctly predicts the selective formation of the *ortho*-isomer.²⁴⁶ The FMO theory gives incorrect results in this case.

The mechanism of reactions of acetonitrile oxide (MeCNO) with nitriles (see Scheme 3) and the reason for the activation of RCN in the platinum complexes **16** and **17** have been studied.²⁴⁷ The activation of nitriles upon coordination was interpreted from the standpoint of orbital control as a result of a decrease in the nitrile LUMO energy. Indeed, if the reaction of free MeCN is described as an intermediate process [difference $\Delta E = \Delta E(\text{HOMO}_{\text{nitrile}} - \text{LUMO}_{\text{dipole}}) - \Delta E(\text{HOMO}_{\text{dipole}} - \text{LUMO}_{\text{nitrile}})$ is 2.10 eV ; obtained from B3LYP/6-31G* calculations], the cycloaddition to the nitrile complexes is more probably a NED process ($\Delta \Delta E = 3.70$ and 5.06 eV for the reactions of complexes **16** and **17**, respectively).

The reactions proceed by concerted mechanism, but the asynchronicity appreciably increases on going from MeCN to complex **17**. The energies of the transition states and intermediates in the case of stepwise mechanism are $33\text{--}218 \text{ kJ mol}^{-1}$ higher than the transition-state energies for the concerted mechanism. Calculations of the reactions of MeCNO with MeCN and complex **16** gave similar values of activation barriers (Table 3) in

Table 3. Relative energy characteristics (in kJ mol^{-1}) of the cycloaddition of MeCNO to MeCN and to complexes **16** and **17** (obtained from B3LYP/6-31G* calculations; ECP on Pt atom).

Reactant	E_a	$\Delta H^\ddagger$	$\Delta G^\ddagger$	ΔE	ΔH	ΔG
MeCN	59 (63)	60	109	-224 (-205)	-212	-154
16	51 (54)	51	108	-255 (-236)	-245	-169
17	24 (28)	22	94	-251 (-231)	-241	-157

Note. All values are given relative to the total energy of the reactants. The values corrected for the zero-point vibrational energy are given in parentheses.

contrast to the results obtained for analogous reactions of nitron $\text{CH}_2=\text{N}(\text{Me})\text{O}$ characterised by considerable activation on going from MeCN to compound **16** (see Section IV.1.e).⁷² The activation energy for the cycloaddition of nitrile oxides to complex **17** also decreases much smaller than in the case of cycloaddition of nitrones. Probably, this difference between the nitron and nitrile oxide reaction kinetics is due to steric interaction of the methyl group in MeCNO with the platinum or chlorine atoms; this interaction is absent for $\text{CH}_2=\text{N}(\text{Me})\text{O}$. Clearly, additional theoretical and experimental investigations are needed for solving this problem. The cycloaddition of MeCNO to compound **16** is characterised by large negative ΔG value. Thus, high reactivity of complex **17** is governed by kinetic factors, whereas the cycloaddition of nitrile oxides to compound **16** occurs under thermodynamic control. Interestingly, the reaction of radical cation $\text{HCNO}^{+\bullet}$ with HCN proceeds in a stepwise manner.²⁴⁸

Possible reactions of nitrile oxides with 1,2-diazepine were considered.²⁴⁹ The dipolarophile can exist in two forms, **50** and **51**, whereas the formation of the other two forms (**52** and **53**) is kinetically unfavourable. Taking into account this fact, the thermodynamically most probable product of double cycloaddition of nitrile oxide to diazepine is compound **54**, which is in agreement with experimental data.²⁵⁰

Attempts to synthesise nitrile sulfides RCNS by thermolysis of 1,2,5-thiadiazoles were reported.²⁵¹ However, the reactions resulted in corresponding nitriles RCN and elemental sulfur instead of RCNS . To explain the experimental results, high-level quantum-chemical calculations [B3LYP, MPn, QCISD, QCISD(T), CCSD, CCSD(T)] of the decomposition mechanism of RCNS were carried out. It was shown that one of the key stages of the decomposition process is dimerisation of RCNS , which is in essence a reaction of dipolar [3 + 2]-cycloaddition in which one nitrile sulfide molecule acts as dipole and the other nitrile sulfide molecule plays the role of dipolarophile. The process proceeds by the stepwise mechanism and results in intermediate **55** (activation energy is 8 kJ mol^{-1} , obtained from B3LYP/6-31G** calculations). The low activation energy is due to low stability of RCNS in the condensed phase. With $\text{R} = \text{F}$ or Cl , the activation barrier disappears, whereas for $\text{R} = \text{CN}$ it increases to 53 kJ mol^{-1} . The reaction product, compound **56**, subsequently decomposes. Stepwise cycloaddition was also predicted for the dimerisation of nitrile oxides RCNO ($\text{R} = \text{Me}, \text{F}$).^{252–255}

$\text{R} = \text{H}, \text{F}, \text{Cl}, \text{CN}, \text{Me}$.

2. Azides

Another group of propargyl-allenyl type dipoles comprises hydrazoic acid derivatives $\text{RNN}\equiv\text{N}$. In the [3 + 2]-cycloaddition reactions involving these dipoles both types of orbital interaction, $\text{HOMO}_{\text{dipole}}-\text{LUMO}_{\text{dipolarophile}}$ and $\text{HOMO}_{\text{dipolarophile}}-\text{LUMO}_{\text{dipole}}$, often make similar contributions (type II processes according to Sustmann's classification).^{86,87} Therefore, by varying substituents in the reactant molecules one can readily change the reaction type.^{256,257} For instance, reactions of azides R^1N_3 ($\text{R}^1 = \text{H}, \text{Me}$) with alkenes $\text{CH}_2=\text{CHR}^2$ ($\text{R}^2 = \text{H}, \text{F}, \text{Cl}, \text{Me}, \text{OH}$) belong to the IED processes; however, if $\text{R}^2 = \text{CN}$ (strong electron-withdrawing substituent), the reaction proceeds as the NED process. Reactions of azides with N_2 , HCN , $\text{CH}_2=\text{NH}$, $\text{NH}=\text{NH}$, $\text{CH}_2=\text{CH}_2$, $\text{CH}\equiv\text{CH}$ and vinylpyridine derivatives^{258–260} also belong to the NED processes.

Calculations predicted a concerted mechanism for the [3 + 2]-cycloaddition of (i) methyl azide (MeN_3) to ethylene²⁶¹ and 1-nitropropene²⁶² and (ii) 1,3-diaza-2-azoniaallene cation $[\text{ArN}=\text{N}=\text{NAr}]^+$ to butyne.²⁶³ Reactions of azide anion with some symmetrical molecules (N_2 , *trans*- $\text{NH}=\text{NH}$, $\text{CH}_2=\text{CH}_2$, $\text{CH}\equiv\text{CH}$) are expected to proceed as synchronous processes; however, for *cis*-diazene (*cis*- $\text{NH}=\text{NH}$) high asynchronicity of the addition was predicted.²⁵⁸ The calculated activation energy increases in the order: *trans*- $\text{NH}=\text{NH} < \text{HCN} < \text{CH}\equiv\text{CH} < \text{cis-NH}=\text{NH} \approx \text{CH}_2=\text{NH} < \text{CH}_2=\text{CH}_2 \ll \text{N}\equiv\text{N}$, which is consistent with experimental data.²⁶⁴ At the same time the interaction of $[\text{ArN}=\text{N}=\text{NAr}]^+$ with *N,N*-dimethylcyanamide ($\text{Me}_2\text{N}-\text{C}\equiv\text{N}$) and carbodiimides $\text{R}^1\text{CH}_2\text{C}(\text{R}^2\text{R}^3)=\text{N}=\text{C}=\text{NR}^4$ is a stepwise process described by Scheme 5.²⁶³

As for other dipoles, the mechanism of cycloaddition of azides depends on the solvation effects and can be changed by varying the solvent. Baranski²⁶⁵ showed that the interaction of MeN_3 with $\text{MeCH}=\text{CHNO}_2$ in the gas phase and in non-polar solvent (toluene) proceeds synchronously, whereas the reactions in polar solvents (acetonitrile, water) proceed by the stepwise mechanism because the polar acyclic intermediate is stabilised in solution. Noteworthy is that replacement of the solvent has no effect on the regioselectivity of the process.

The activation barrier to the reaction of methyl azide with ethylene decreases by 3 kJ mol^{-1} on going from non-polar (CCl_4) to dipolar aprotic solvent (dimethyl sulfoxide); this is accompa-

$\text{R}^1 = \text{H}, \text{R}^2 = \text{Me}; \text{R}^1-\text{R}^2 = (\text{CH}_2)_4; \text{R}^3 = \text{H}, \text{Me}; \text{R}^4 = \text{Pr}^i, \text{Bu}^t, \text{cyclo-C}_6\text{H}_{11}$.

Scheme 5

nied by a fourfold increase in the reaction rate.²⁶¹ Interestingly, the activation barriers calculated with inclusion of polar solvents (water and methanol) are higher than that obtained for CCl₄. Thus, the experimentally observed acceleration of the reaction of phenyl azide with norbornene in water can be explained by the hydrophobic effect rather than an increase in the solvent polarity.

The mechanism of the reaction of methyl azide with ethylene was studied using the spin-coupled method of valence-bond theory.⁸⁰ The cycloaddition proceeds by the homolytic mechanism in contrast to the reactions of nitrile oxides and diazoalkanes that proceed by the heterolytic mechanism.^{73,215} The reaction is accompanied by synchronous cleavage of two π -bonds in the MeN₃ and C₂H₄ molecules, followed by formation of two new bonds. In the vicinity of the transition state the system behaves as a biradical structure.

The regioselectivity, mechanism and energy characteristics of the reactions of compounds R¹N₃ (R¹ = H, Me, NH₂) with alkenes R²CH=CHR³, thionitroso compounds (HN=S, H₂NN=S), nitriles and phosphalkynes [RC $\equiv$ N, RC $\equiv$ P (R = H, Br, Cl, F, Me)] were studied using the DFT approach.^{54, 229, 256, 262, 266} The calculated activation barriers to the reaction of hydrazoic acid with alkenes increase for different substituents R² as follows: CN < H < OH < F < Me < Cl; in the reaction of methyl azide the fluoroalkene becomes more reactive than vinyl alcohol. The reactions show regioselectivity and proceed with selective formation of isomer **57** (Scheme 6), except for the processes involving cyanoethylene and nitropropene that exhibit inverse regioselectivity, which leads to formation of compound **58**.

R¹, R³ = H, Me; R² = H, F, Cl, OH, Me, CN, NO₂.

The regioselectivity is related to the parameter

$$\Delta_{ij}^{kl} = (s_i^- - s_k^+)^2 + (s_j^- - s_l^+)^2,$$

where s are the local softnesses of the reacting atoms. This quantity is a criterion for validity of the hard and soft acids and bases principle. The Δ_{ij}^{kl} is smaller for *ortho*-cycloaddition at R² = H, F, Cl, Me, OH and for *meta*-cycloaddition at R² = CN.²⁵⁶

Molteni and Ponti⁵² studied the dependences of regioselectivity of the process and the interaction energy at constant external potential ΔE_v [see Eqn (3)] taking the reaction of 4-RC₆H₄N₃ with HC $\equiv$ CCO₂Me as an example. Based on a linear relationship between ΔE_a and

$$\Delta \Delta E_v = [\Delta E_v(i-k) + \Delta E_v(j-l)] - [\Delta E_v(i-l) + \Delta E_v(j-k)]$$

(ΔE_a is the difference between the activation energies for two regioisomeric reaction pathways, ΔE_v are the energies of the local-local interaction of the corresponding reaction centres i, j, k, l), one can assess the regioselectivity without locating transition

states on the potential energy surface only using the global and local properties of the reactant molecules.

The energy (E_{int}) of the interaction between reactant molecules R¹N₃ and CH₂=CHR² in the transition states was calculated²⁶⁶ as the sum

$$E_{\text{int}} = E_{\text{def}} + E_{\text{es}} + E_{\text{p}} + E_{\text{ex}} + E_{\text{ct}},$$

where the terms in the right side of the equation denote the deformation, electrostatic, polarisation, exchange and charge-transfer energy, respectively. The deformation energy makes the major contribution to E_{int} . The charge-transfer energy is sensitive to the nature of substituents R¹ and R², namely, it is maximum at R² = F, Me, OH, but is not responsible for regioselectivity. Inversion of the regioselectivity, which was found in the reaction of cyanoethylene (see above), can be explained by high polarisation energy for **TS7** and high deformation energy for **TS6** (see Scheme 6), whereas for other substituents the *ortho*-selectivity is controlled by the electrostatic component.

Reactions of azides with organonitriles (RCN) were studied more thoroughly than similar reactions of nitrones and nitrile oxides.^{267–272} It was shown²⁶⁷ that concerted mechanism is energetically most favourable for the cycloaddition of methyl azide and azide ion to non-activated nitriles. However, in the presence of acid catalyst (ammonium ion or some other proton donor) the reaction mechanism changes and the process proceeds in stepwise manner through transfer of a proton from NH₄⁺ ion to the nitrogen atom of RCN with the formation of acyclic intermediate.

A similar change from concerted to stepwise mechanism and a considerable decrease in the activation barrier was also found for the BF₃- and BH₃-catalysed reactions of N₃⁻ with RCN.^{268,269} At the same time, B3LYP/6-31G** calculations gave a high activation barrier ($\Delta G^\ddagger = 275$ kJ mol⁻¹) to the reaction of nickel azide complex [Ni(η^1 -N₃)]⁺ with nitrogen, which is not surprising with allowance for high inertness of N₂.²⁷⁰

It was shown that coordination of the azide ion to zinc in complex [Zn(H₂O)_{*n*}N₃]⁺ ($n = 3, 5$) has little effect on the activation barrier of the reaction with acetonitrile compared to the thermally activated process [$\Delta H^\ddagger = 141$ kJ mol⁻¹ at $n = 3$ and 149 kJ mol⁻¹ at $n = 5$; 132 kJ mol⁻¹ for reaction MeN₃ + MeCN and 141 kJ mol⁻¹ for reaction N₃⁻ + MeCN; obtained from B3LYP/6-311+G(2d,2p)//B3LYP/6-311G** calculations].²⁷¹ When nitrile or both reactants are coordinated to zinc, the enthalpy of activation decreases by 8–36 kJ mol⁻¹. Thus, the catalytic acceleration of the reaction is due to complexation of dipolarophile, which is consistent with the results of qualitative FMO analysis (see Section II) and makes it possible to treat this reaction as a NED process. The activation of nitriles upon coordination to the Lewis acid in the [3+2]-cycloaddition reactions with azides was confirmed experimentally. In particular, a decrease in $\Delta G^\ddagger$ on going from thermally induced to zinc-catalysed reaction of NaN₃ with 2-cyanopyrazine is 23.8 kJ mol⁻¹ (Ref. 271).

3. Diazoalkanes, nitrile imines and nitrile ylides

Diazoalkanes (R₂C=N=N), nitrile imines (RC $\equiv$ N–NR) and nitrile ylides (RC $\equiv$ N–CR₂) also belong to propargyl-allenyl type dipoles. The [3+2]-cycloaddition reactions involving these

compounds result in such heterocyclic compounds, as pyrazolines and oxadiazolines. Since the LUMO energies in the diazoalkane and nitrile ylide molecules are high and, as a consequence, the HOMO_{dipolarophile}–LUMO_{dipole} interaction becomes ineffective, these reactions should be treated as type I (NED) processes,^{86, 87, 273–275} This particularly concerns the reactions with electron-deficient dipolarophiles (e.g., acrylonitrile³⁵ or imidoyl chlorides²⁷⁶). The reactions of compounds R_2CN_2 with propylene and methyl vinyl ether and those of nitrile imines with unsubstituted alkenes are controlled by both types of the HOMO–LUMO interaction,^{35, 86, 87} while the cycloaddition of nitrile imines to *N*-methylindole is an IED process.²⁷⁷

A number of studies on the mechanism of the [3 + 2]-cycloaddition reactions of these dipoles are available. An unexpected mechanism was calculated for the cycloaddition of 1-aza-2-azoniaallenyl ion ($CH_2=N^+=NH \leftrightarrow CH_2=N^+ \equiv NH$), which can be treated as a diazomethane derivative, with alkenes²⁷⁸ and carbodiimides $R^1N=C=NR^2$ (Ref. 279). The reaction with ethylene proceeds by the stepwise mechanism and begins with the formation of two orientation complexes **59** and **60** (pathway *a*, Scheme 7). This is followed by the formation of the three-membered intermediate **61**, which is transformed to pyrazolinium cation **62** and then to the end product **63**. The replacement of two hydrogen atoms in the ethylene molecule by methyl groups causes a change in the mechanism and now the reaction begins with the formation of acyclic intermediate **64** (pathway *c*). Finally, both pathways, *b* and *c*, are probable in the reaction with tetrachloroethylene. At the same time the addition of $R_2C=N^+=NR^2$ to ethynes $RC \equiv CR$ (Ref. 280) or to the CN bond of isocyanates $RNCO$ (Ref. 281) proceeds concertedly, although being asynchronous.

Different regioisomeric pathways of the reactions of diazomethane with allenes¹⁰⁵ are characterised by different mechanisms. For instance, the energetically most favourable mechanism of the addition of the terminal nitrogen atom in CH_2N_2 molecule to a terminal atom of $CH_2=C=CH_2$ molecule involves the formation of one intermediate (pathway *a*, Scheme 8). The addition of the nitrogen atom of diazomethane to the central atom of allene molecule proceeds via two intermediates (pathway *b*). Comparison of the activation barriers to the two regioisomeric pathways, *a* and *b*, showed that the former is 13 kJ mol^{−1} energetically more favourable than the latter. This was confirmed by experimental data on selective formation of the corresponding regioisomer.²⁸² Interestingly, the activation barrier is much higher for the concerted rather than stepwise mechanism.

The effect of the nature of substituents in the dipolarophile molecules on the energy characteristics of the reactions of $HC \equiv NCH_2$ with compounds $CH_2=CR_2$ ($R = NO, CN, Cl, OH, Me$) was studied.²⁸³ In accordance with predictions of the

FMO theory, the electron-withdrawing substituents (NO, CN) should accelerate the NED processes, which was confirmed by activation energy calculations. By and large the synchronicity of cycloaddition changes in parallel with the activation energy and antiparallel with the acceptor properties of substituents. The lower activation barriers to most asynchronous processes seem to be due to a strong effect of the charge factor.

By varying substituents in the reaction of cyclic diazoalkane **65** with ethynes one can change the mechanism of the process. In particular, the first stage of the reaction with acetylene proceeds as either a [3 + 2] or [7 + 2] concerted addition with similar activation barriers²⁸⁴ (pathways *a* and *b* in Scheme 9). The reaction with ynamine $HC \equiv CNH_2$ most probably proceeds as a single-stage stepwise [7 + 2]-cycloaddition (pathway *c*). No transition states were located for the reaction with cyanoacetylene. Taking into

account this fact, it was concluded that no [3 + 2]-cycloaddition reactions of diazoazoles with cyanoacetylene should occur, which is indirectly confirmed by the lack of experimental data on these processes. However, unambiguous solution to this problem requires additional experimental and theoretical investigations of the cycloaddition to cyanoalkynes.

The interaction of diazomethane with ethylene was studied⁷³ using the spin-coupled method of valence-bond theory. It was shown that the reaction proceeds by the 'heterolytic' mechanism similar to that of the cycloaddition of fulminic acid to acetylene (see Section V.1).

A number of theoretical studies has been carried out on the regioselectivity of the reactions of (i) diazomethane with alkenes,³⁵ alkynes and phosphalkynes,^{54,285} formaldehyde,²⁸⁶ phosphapropenes²⁸⁷ and indenone,²⁷⁴ (ii) nitrile imines with fluorinated alkenes and alkynes,²⁸⁸ methyl propiolate,²⁸⁹ (arylsulfonyl)alkenes,²⁹⁰ methylidene-butyrolactone derivatives²⁹¹ and pyridazinones²⁹² and (iii) nitrile ylides with benzaldehyde and imidoyl chloride.²⁷⁶ For instance, calculations for the addition of CH₂N₂ to alkenes CH₂=CHR (R = H, Me, CN, OMe) predicted preferred formation of 3-substituted pyrazolines (*ortho*-isomer) both in the gas phase and in solution (with allowance for solvation effects).³⁵ The relative yields of the *ortho*- and *meta*-isomers and the $\Delta G^\ddagger$ values for the *ortho*-pathway (7.5 : 1 and 96 kJ mol⁻¹, respectively, for the reaction of CH₂N₂ with CH₂=CHMe; obtained from MP4//HF/6-31G* calculations; solvation effects were included for solution in CCl₄) agree with the corresponding experimental data (7.3 : 1 for the reaction of CH₂N₂ with propene²⁹³ and 103.3 kJ mol⁻¹ for the reaction of CH₂N₂ with hex-1-ene³⁵).

The reaction of diazomethane with formaldehyde results in oxirane as the end product. The reaction mechanism, which involves the formation of oxadiazoline as intermediate, was studied theoretically. The process occurs concertedly and yields 1,2,3-oxadiazoline (**66**) as kinetic product in the first stage; however, the other regioisomer, namely, 1,3,4-oxadiazoline (**67**) is thermodynamically more stable.²⁸⁶ Nevertheless, no oxadiazoline intermediates of these reactions were isolated so far and therefore substantiation of theoretical conclusions requires additional experimental studies.

R = H, F.

Calculations for the interaction of CH₂N₂ with phosphapropene MeP=CH₂ showed that 1,2,4-diazaphosphole (**68**) is kinetically most favourable while 1,2,3-diazaphosphole (**69**) is thermodynamically most stable.²⁸⁷ The reverse was found for the

reaction with perfluorophosphapropene F₃CP=CF₂. Thus, experimental isolation of regioisomer **69** in the latter case indicates that the process proceeds under kinetic control.

The stereoselectivity of the model reactions of diazomethane and bis(dimethylamino)phosphinodiazomethane [(Me₂N)₂P·CHN₂] with chiral alkenes was studied using the density functional theory (with BPW91 functional).²⁹⁴ It was shown that stereoselectivity depends on the nature of the substituents both in the alkene and in the dipole molecules. For the reaction of diazomethane with dioxolanyl-substituted alkene, the *syn*-cycloaddition was the kinetically most preferable pathway (ratio of the *syn*- and *anti*-isomers is 96 : 1) and the *E*-isomer of the olefin was more reactive than its *Z*-isomer (**TS8** is the corresponding transition state). On the contrary, the reaction of (Me₂N)₂PCHN₂ is characterised by the *Z*-*syn*-addition (**TS9**) (ratio of the *syn*- and *anti*-isomers is 518 : 1) and the reaction of CH₂N₂ with cyclobutyl-substituted alkene shows the *E*-*anti*-selectivity (**TS10**) (ratio of the *syn*- and *anti*-isomers is 1 : 8). The theoretical stereoselectivity qualitatively agrees with experimental data, namely, the ratios of the *syn*- and *anti*-isomers were 24 : 1, 16 : 1 and 1 : > 49 for the reactions of CH₂N₂ with (*E*)-OCMe₂OCH₂CHCH=CHCO₂Me, (Prⁱ)₂PCHN₂ with (*Z*)-OCMe₂OCH₂CHCH=CHCO₂Me and CH₂N₂ with (*E*)-OCH₂CH₂OC(Me)CHCH₂CH{CH=CHCO₂Me}CMe₂.^{294,295} In spite of some overestimation of the theoretical relative yields of the *syn*-isomers compared to the experimental data, the difference between the calculated and experimental (determined from the ratio of isomers) values

$$|\Delta\Delta G^\ddagger| = |\Delta G^\ddagger(\text{syn}) - \Delta G^\ddagger(\text{anti})|$$

is only 3–9 kJ mol⁻¹, which is quite reasonable for the method employed.

The stereoselectivity of the reactions of diazoalkanes with chiral furanones **70** depends on the stereoconfiguration of the dipolarophile.²⁹⁶ Namely, in the case of the (5*S*,5*S*) configuration (compound **70a**) the activation barrier to formation of the *syn*-isomer **71a** is 14 kJ mol⁻¹ lower than the barrier to formation of the corresponding *anti*-isomer **71b** (obtained from B3LYP/cc-pVTZ//B3LYP/6-31G* calculations). At the same time for the (5*R*,5*S*) configuration (compound **70b**) the stereoselectivity changes, which is consistent with experimental data. The stereoselectivity of the reaction of CH₂N₂ with oxazolone containing an acyclic double bond C=C was interpreted²⁹⁷ based on the results of AM1 and HF calculations.

4. Nitrous oxide

The cycloaddition of N_2O to alkynes was studied.²⁹⁸ The process is controlled by the $\text{HOMO}_{\text{dipolarophile}} - \text{LUMO}_{\text{dipole}}$ interaction, which is typical of this dipole.^{86, 87} Investigation of the regioselectivity showed that in the reactions with mono-substituted alkynes $\text{HC}\equiv\text{CR}$ ($\text{R} = \text{Me}, \text{Hal}, \text{OH}, \text{NH}_2, \text{PH}_2, \text{SH}, \text{SiH}_3, \text{CO}_2\text{H}, \text{CHO}$) the oxygen atom of the nitrous oxide molecule adds to the carbon atom bonded to the substituent R (the exception is $\text{R} = \text{NO}_2$; here the inverse regioselectivity was found). In the reactions with disubstituted alkynes $\text{MeC}\equiv\text{CR}$ ($\text{R} = \text{CHO}, \text{NO}_2$) the oxygen atom adds to the carbon atom bonded to the methyl group.

VI. Reactions of heterocumulenes

Compounds that are usually not treated as dipolar structures can also be included in the [3 + 2]-cycloaddition reactions. These are, in particular, heterocumulenes, *i.e.*, compounds with triatomic reactive fragments in which the central atom (most often, a carbon atom) forms the double bonds with adjacent atoms and the contributions of other possible boundary structures are small.

Concerted cycloaddition of heterocumulenes CX_2 , CSY , CY_2 ($\text{X} = \text{O}, \text{S}, \text{Se}; \text{Y} = \text{NH}, \text{PH}$) to acetylene is characterised by the following order of changes in the activation energies: $\text{O} > \text{S} > \text{Se}$ (from 259 to 113 kJ mol^{-1} according to B3LYP/6-311+G** calculations) and $\text{NH} > \text{PH}$ (from 152 to 107 kJ mol^{-1}) and the energy effects of the reactions change as follows: $\text{O} > \text{S} \approx \text{Se}$ (from 148 to -7 kJ mol^{-1}) and $\text{PH} > \text{NH}$ (from -54 to -134 kJ mol^{-1}) (Table 4).²⁹⁹ This is in qualitative agreement with the experimental data on higher reactivity of CSe_2 compared to that of CS_2 in the [3 + 2]-cycloaddition reactions. According to G3X(MP2) and B3LYP/6-311+G(3df) calculations, thermal decomposition of $\text{S}_2\text{O}^\ddagger$ begins with an exothermic or a weak endothermic (depending on the computational method employed) low-barrier [3 + 2]-cyclodimerisation [$\Delta H^\ddagger = 11$ kJ mol^{-1} , obtained from G3X(MP2) calculations] with the formation of a five-membered product $\text{OSSSS}=\text{O}$, which then decomposes to S_3 and SO_2 .^{300, 301}

Mass spectrometric and theoretical studies^{302, 303} concerned the mechanisms of the reactions of nitronium NO_2^+ and dithionitronium NS_2^+ ions with ethylene and acetylene, which result in O-nitrosated compounds $[\text{CH}_2=\text{C}=\text{O}\cdots\text{NO}]^+$, $[\text{MeCHONO}]^+$ and 1,4-dithia-7-azabicyclo[2.2.1]heptyl cations. Both reactions begin with concerted [3 + 2]-cycloaddition resulting in 1,3,2-dioxazol-2-yl-, 1,3,2-dioxazolidinyl- or 1,3,2-dithiazolidinyl cations as intermediate products. The cycloadduct of NO_2^+ with acetylene is aromatic in character, being therefore thermodynamically more stable than the product of addition to ethylene.

[‡] This compound is sometimes treated as a boundary structure $\text{S}=\text{S}^+ - \text{O}^-$, *i.e.*, as an analogue of ozone. In this case the corresponding reactions can be considered as dipolar [3 + 2]-cycloadditions.

Table 4. Activation and reaction energies (kJ mol^{-1}) for heterocumulene reactions with C_2H_2 (obtained from B3LYP/6-311 + G** calculations).²⁹⁹

$\text{C}(\text{NF}_3)_2$	140	-118
$\text{C}(\text{PH})_2$	107	-54

The mechanism of radical [3 + 2]-cycloaddition of NCO to acetylene derivatives $\text{HC}\equiv\text{CR}$ ($\text{R} = \text{H}, \text{F}, \text{Cl}, \text{CN}, \text{Me}$) was studied.⁵³ All reactions, except that with $\text{R} = \text{CN}$, are controlled by the $\text{HOMO}_{\text{alkyne}} - \text{LUMO}_{\text{NCO}}$ interaction, show regioselectivity and proceed by the stepwise mechanism with the formation of acyclic intermediates $\text{OCNCH}=\text{CR}$ ($\text{R} = \text{Cl}, \text{CN}, \text{Me}$) or $\text{OCNC}(\text{R})=\text{CH}$ ($\text{R} = \text{F}$). The activation barrier increases in the following order of substituents: $\text{F} < \text{Cl} < \text{CN} < \text{Me} < \text{H}$. The regioselectivity was interpreted from the standpoint of the hard and soft acids and bases principle by comparing the Fukui radical functions on the reactive atoms (maximum f^0 and, hence, s^0 values were obtained for the unsubstituted carbon atom in the alkyne molecule).

VII. Other reactions

The cycloaddition of nitrosoketene $\text{O}=\text{N}-\text{CH}=\text{C}=\text{O}$ to formaldehyde, acetone and acrolein was described by the *ab initio* methods HF/6-31G* (Ref. 304), MP2/6-31G* and MP4(SDQ)/6-31G**/MP2/6-31G* (Ref. 75). The [3 + 2]-cycloaddition is kinetically more favourable than its alternative, [4 + 2]-cycloaddition; however, the six-membered reaction product is thermodynamically more stable than the five-membered product. Thus, experimental isolation of the five-membered cyclic product of this reaction^{305, 306} indicates that the process occurs under kinetic control. The reaction proceeds concertedly and involves the formation of a planar pseudopericyclic transition state.

$\text{R}^1 = \text{R}^2 = \text{H}, \text{Me}; \text{R}^1 = \text{H}, \text{R}^2 = \text{CH}=\text{CH}_2$.

According to the results of high-level *ab initio* calculations, carbonyl oxide (A) and methylenebis(oxy) (B) react with ethylene to give 1,2-dioxolane and 1,3-dioxolane, respectively, and dioxirane (C) enters into the reaction of ethylene epoxidation.³⁰⁷

Some of these results were experimentally confirmed by Reiser *et al.*³⁰⁸ and Graziano *et al.*³⁰⁹ who observed the formation of 1,2-dioxolanes in the reactions of carbonyl oxides with alkenes.

Studies^{310, 311} of the [3 + 2]-cycloaddition of NO₃ radical to alkenes showed that in the first stage the concerted cycloaddition resulting in the five-membered intermediate is energetically more preferable than the addition of alkene to one oxygen atom of NO₃ reported earlier.

The mechanism of a palladium-catalysed reaction of methylenecyclopropane with ethylene was studied by high-level MP4(SDQ)/BS2//MP2/BS1 and B3LYP/BS2//B3LYP/BS1 calculations.^{312, 313} The concerted mechanism is kinetically unfavourable ($E_a = 186 \text{ kJ mol}^{-1}$) and the interaction between the palladium-coordinated reactants proceeds in a stepwise manner. Two mechanisms were considered, one involving an intermediate palladacyclobutane structure **72** and the other passing via η^2 -methylenecyclopropane complex **73**. Intermediate **73** is thermodynamically more stable than compound **72**. However, the addition of coordinated ethylene molecule to the palladacyclobutane fragment in compound **72** with the formation of methylenepalladacyclohexane **74** via transition state **TS11** followed by reductive elimination of methylenecyclopentane in the last stage is kinetically more preferable.³¹³ Interestingly, similar reactions of oxo- or azatrimethylenemethane with ethylene proceed by the [2 + 1] mechanism. This change in the cycloaddition mechanism depending on the nature of the reactants is consistent with experimental data.^{314–317}

VIII. Intramolecular cycloaddition reactions

In addition to intermolecular cycloaddition, intramolecular cycloaddition reactions may also occur. Here, the reacting molecules or fragments are not isolated, being constituents of the entire molecular system that affects (sometimes, strongly affects) the course of these reactions. In this review, the cyclisation reactions with the formation of only one new bond upon ring closure are left out of consideration, because these processes do not belong to the cycloaddition reactions.

The regioselectivity³¹⁸ and stereoselectivity³¹⁹ of intramolecular cycloaddition reactions of nitrones **75a,b** and **76** were considered based on the results of semiempirical and *ab initio*

R = Me, Prⁱ.

calculations. The reaction of methyl derivative **76** results in isomer **77** as the kinetically and thermodynamically favourable product. Calculations³¹⁸ predicted a lower regioselectivity of the reaction with R = Prⁱ, which is consistent with experimental data. Calculations using the ONIOM(B3LYP/6-31(d): AM1) hybrid method followed by single-point B3LYP/6-31* energy calculations for the reaction of ketofuranonitrone **78** made it possible to interpret the experimentally observed selective formation of isomer **79**.³²⁰

TBS is *tert*-butyldimethylsilyl.

Intramolecular interactions between nitrile oxide and alkene fragments (including intramolecular cycloaddition) have been studied in detail.³²¹ If the initial molecule contains R = SiMe₃, the reaction proceeds by the mechanism leading to compound **80** as the end product instead of intramolecular [3 + 2]-cycloaddition. Replacement of trimethylsilyl group by hydrogen atom makes the [3 + 2]-dimerisation of the nitrile oxide fragments resulting in furoxan structure **81** the most favourable.

Azido-nitrile systems can enter into intramolecular cycloaddition reactions with the formation of condensed tetrazoles. However, unlike intermolecular processes, the electron-withdrawing character of substituents has little effect on the course of intramolecular reactions.³²² On the contrary, the length of the bridge connecting the azide and nitrile fragments is an important factor affecting the reactivity. For instance, the $\Delta G^\ddagger$ value for the cyclisation of $\text{N}\equiv\text{C}(\text{CH}_2)_n\text{N}_3$ increases with $n = 2, 3, 4$ (142, 143, 157 kJ mol⁻¹ respectively; obtained from B3LYP/6-311G** calculations) and the higher activation barrier obtained for $n = 4$ seems to be due to the formation of the seven-membered ring. This agrees with experimental data on isolation of the [5,5]- and [6,5]-type bicyclic adducts in the reactions of intramolecular cycloaddition of thiocyanates, whereas no [7,5]-type bicyclic products are formed under the same conditions.³²³

A comparative B3LYP, MP2 and MP4(SDTQ) study on the mechanisms of intramolecular cycloaddition of compounds containing conjugated enyne fragments $\text{C}\equiv\text{C}-\text{CH}=\text{X}$ (X = CH₂, O, S, NH) was reported.⁷⁶ According to calculations, the [4 + 2]-cycloaddition resulting in fused allene-type structure **82** is expected for X = CH₂. Structure **82** is stabilised by a double

1,2-proton shift and then transformed to a benzene-type system **83**. The heteroatomic fragments are involved in the [3 + 2]-cycloaddition reactions and eventually form condensed five-membered aromatic heterocycles **84**. The results of calculations agree with experimental data,^{324–327} namely, with the fact that the reactions of carboenynes proceed *via* a cyclic allene-type intermediate and that the intramolecular cycloaddition of heteroenynes involves formation of heterocyclic carbenes.

A study of the mechanisms of two possible reactions of intramolecular cycloaddition of ylides **85** was reported.³²⁸ The [3 + 2]-cycloaddition resulting in diazaphospholane **86** (its analogue was isolated experimentally) was shown to be kinetically and thermodynamically most favourable ($E_a = 45 \text{ kJ mol}^{-1}$; obtained from B3LYP/6-31G* calculations).

IX. Conclusion

Computational quantum-chemical methods provide a powerful tool for studying versatile chemical processes including the [3 + 2]-cycloaddition reactions. In some cases experimental studies of the reactivity of compounds and especially the reaction mechanisms are difficult or impossible at all (if, *e.g.*, the initial compounds are poorly soluble, the reaction rate becomes too high or, on the contrary, too low to carry out kinetic studies or if the process involves the formation of short-lived intermediates that cannot be characterised experimentally). In these situations theoretical calculations are put in the forefront, because they present the one and only alternative to experimental methods.

In this review we analysed the literature on the [3 + 2]-cycloaddition reactions and showed that the simplest qualitative models traditionally used in organic chemistry (first of all, the FMO theory) are still useful in interpreting experimental data. Moreover, in some cases they help to choose the reaction conditions. The overall reactivities of compounds depend on a bunch of factors, namely, the nature of substituents and solvent, the presence or the absence of catalyst, *etc.* Knowing the composition and the relative energies of the frontier MOs of the reactants, one can draw particular conclusions about the effects of these factors on the reactivity. In particular, the NED processes require the introduction of electron-donating substituents into the dipole molecule and electron-withdrawing groups into the dipolarophile molecule. The acceleration of such intermolecular reactions is achieved by selective coordination of catalyst to the dipolarophile. The reverse holds for the IED reactions.

However, this qualitative approach to the description of the reactivity is essentially simplified because it ignores, *e.g.*, steric effects. Additionally, changes in the FMO energies are not always related to the type of the substituent introduced. Finally, the activation barrier is affected by not only the relative orbital energies of reactants but also other factors, in particular, the

nature of the transition state and the energy balance between cleavage and formation of chemical bonds in the formation of transition states. Clearly, the cases where the FMO theory is inapplicable require detailed studies of the mechanisms of the processes and estimation of the activation energy. Thus, investigations on the reactivity of chemical compounds are often closely related to the reaction mechanisms, which play a key role for some reasons.

First, theoretical calculations of the activation barriers and reaction rates (this is of greatest value when experimental kinetic studies are impossible) have some sense only if the mechanism of the process is known, *i.e.*, the possible reaction pathways are elucidated and the energetically most favourable mechanism is available.

Second, the FMO theory predictions are usually applicable to the 'classical' synchronous processes that occur under orbital control. However, a [3 + 2]-cycloaddition reaction proceeding by the highly asynchronous mechanism behaves to some extent similarly to nucleophilic addition. Here, the role of the charge factors becomes significant. The need of taking into account the charge control complicates the choice of appropriate catalyst. On the one hand, the catalyst should provide selective coordination of the Lewis acid to the reactant (for intermolecular processes). On the other hand, it should provide a maximum possible degree of transfer of the electron density to the Lewis acid in order to attain the largest charge difference between the atoms in the reactant molecules. Therefore, experimental design in the field of catalytic syntheses requires knowledge of the reaction mechanisms.

Third, the nature of the solvent belongs to the factors responsible for the reactivity. By varying the solvent nature the reaction can be appreciably accelerated. Location of transition states in the minimum energy path and the inclusion of solvation effects in the course of quantum-chemical calculations make it possible to predict how the change in, *e.g.*, the solvent polarity will affect the rate of the process under study. It should also be noted that the type of the mechanism is related to the solvation effects, namely, in some cases a stepwise cycloaddition is accompanied by the formation of high-polarity intermediates and transition states, which favours acceleration of the reactions in polar media. Finally, in some cases the solvent forms strong complexes with reactants and thus becomes a constituent of the transition state, being involved in the reaction. Here, comprehensive theoretical studies of the mechanism with inclusion of coordinated solvent become even more important.

Fourth, the mechanism of the process governs the regio- and stereoselectivity of the reaction. Analysis of the available literature on the subject showed that these phenomena are controlled by a group of factors that can often be interpreted only using theoretical methods. First of all these are the electronic effects of substituents where the introduction of an electron-donating group into the dipolarophile molecule leads to preferred formation of the *ortho*-isomer, whereas the electron-withdrawing substituents are responsible for the *meta*-selectivity. Important factors also include the nature of the solvent, selective coordination of the Lewis acid to the reactant molecule, steric effects and the secondary orbital interaction. All of them act on the transition-state level.

Sometimes, the general type of the reaction mechanism (concerted or stepwise) is responsible for the stereoselectivity. The example presented in Scheme 10 shows that in the case of concerted cycloaddition only one stereoisomer **87a** can be formed, whereas the stepwise mechanism makes it possible to obtain two isomers (**87a** and **87b**) due to free rotation about the C—C bond in intermediate **88**.

The mechanisms of some [3 + 2]-cycloaddition reactions can be changed with ease. For instance, the inclusion of solvation effects or the use of high-polarity solvents, catalysts, or (in some cases) a simple replacement of substituents favour the change from concerted to stepwise reaction mechanism.

Therefore, if there is a need of carrying out stereoselective synthesis, it is possible to use the results of theoretical calculations of the reaction mechanisms for choosing the reaction conditions (catalyst, solvent, substituents) in such a way that they will provide a sufficiently high reaction rate on the one hand and will not change the reaction mechanism on the other hand. In this connection it should be noted that progress in computer science (computational methods) and hardware allows corresponding theoretical estimates to be obtained in a rather short time, *i.e.*, quantum-chemical methods become fast methods that help in experimental design.

Considering prospects for theoretical studies of [3+2]-cycloaddition, yet another two points should be noted. First, most publications are concerned with the reactions with alkenes and more rarely alkynes as dipolarophiles and nitrones, nitrile oxides, azides and diazoalkanes as dipoles. At the same time the number of theoretical studies devoted to the analysis of the reactivity of compounds with other multiple bonds ($C=N$, $C=O$, $C=S$, $C=P$, $C=Si$, $N=N$, $C\equiv N$, $C\equiv P$) or such dipoles as azimines, nitrile imines, azoxy compounds, carbonyl imines, carbonyl oxides, nitrosimines and nitroso oxides is relatively low and corresponding processes undoubtedly require more thorough investigations.

Second, theoretical studies aimed at analysing the role of catalysts and the mechanism of their action on the [3+2]-cycloaddition processes are also scarce compared to the literature on non-catalytic processes. Additionally, the importance of research into correlations between the nature of the catalyst, solvent and substituents, on the one hand, and the rate, regio- and stereo-selectivity of the reaction, on the other hand, becomes obvious.

Thus, knowledge of the mechanism and the driving forces of chemical reactions is very useful in the design of chemical experiments, attainment of optimum reaction conditions and in performing targeted synthesis. Modern computers and theoretical methods allow the [3+2]-cycloaddition reactions to be studied using high-level approximations, as indicated by dramatic increase in the number of publications on the title subject reported in the last five to seven years.

Abstract. Main methods for determination of the degree of molecular similarity used in modern theoretical chemistry are surveyed. Methods for predicting the properties of chemical compounds based on the statement 'similar structures possess similar properties' are described. Examples of using these approaches for the modelling of structure–property correlations for organic compounds are given. Bibliography includes 254 references.

I. Introduction

The similarity concept is very important in chemistry. Its essence can be expressed as follows: similar objects possess similar properties. The term 'similarity' is widely used when comparing different chemical objects (atoms, molecules, *etc.*) and reactions, chemical databases, molecular properties and so on. The popularity of the term 'similarity' in chemical literature is steadily increasing. Thus the number of abstracts in the *Chemical Abstracts* using the term 'similarity' has increased over 25 years from 233 (1967–1971) up to 1697 (from 1987 to the first half of 1992).¹ International conferences and workshops dealing with various aspects of the similarity concept in chemistry are being held (see, for example,^{2,3}); a number of books and reviews on this subject have been published.^{2,4–16} Commercial computer programmes based on the similarity methods of analysis have been developed.^{17–19}

The similarity concept in chemistry has a long-standing history and numerous interpretations. It is a scientific idea which is rather intuitive and is difficult to be clearly defined or formalised.^{20,21} However, formalisation of the main chemical terms and development of their quantitative description are required due to fast computerisation of the chemical studies, availability of enormous amounts of data on the structures, properties and chemical reactions, rapid development of mathematical chemistry, computer chemistry, combinatorial chemistry and medicinal chemistry. These main chemical terms include, in particular, the terms 'molecular structure', 'molecular similarity' and 'similarity of chemical reactions'.

The similarity concept is used for the solution of the following problems in chemistry:

- prediction of the physicochemical properties and biological activity of chemical compounds;^{22–33}
- classification and ordering of data in chemical information databases (like the *Beilstein's Handbook of Organic Chemistry*);³⁴
- planning of chemical experiments and the reactivity theory;^{35–40}
- search for biologically active analogues in chemical databases in order to optimise the structures of already known active compounds;^{41–51}
- clusterisation of databases and creation of representative subsets of compounds for further screening;^{16, 52–59}
- creation of databases with the highest structural variety for further search for new key compounds.^{18, 60, 61}

The present review discusses the concept of molecular similarity and the methods for predicting chemical properties based on this concept.

The so-called statistical approach is used most widely for determination of quantitative relationships between the structure and activity/property of compounds (QSAR/QSPR analysis).^{62–64} Some limitations of this technique have induced the development of a method based upon the similarity concept. Successful realisation of the statistical method requires a training set of compounds with known values of the studied property. The structures of studied compounds are described by a set of some molecular descriptors $x_1, \dots, x_N$ (topological, geometrical, electronic) and then the following equation can be written

$$y = f(x_1, \dots, x_N),$$

where f is a function of N variables, y is a property value. Usually the type of function f (for example, linear, quadratic, *etc.*) is

specified in advance and depends on a series of fitting parameters, which are determined using the training subset of compounds. The linear function f is the most frequently used one. The obtained equation is called a linear regression model. In order to calculate the properties of new compounds on the basis of this model, initially the values of the descriptors $x_1, \dots, x_N$ are calculated for the target compounds and then the value of the property y itself is calculated using the equation $y = f(x_1, \dots, x_N)$.

However, another approach to predicting the properties of compounds also exists. It is based upon the following hypothesis: 'similar' structures possess 'similar' properties.^{13, 29, 65} In order to estimate the property of a compound, another compound, 'similar' (in some sense) to the studied one but with known value of this property, has to be found in a dataset. Then it is assumed that the target properties of these compounds are the same (or just slightly different). The averaging of the properties of several 'nearest neighbours' is also possible. Some mathematical objects m_1 and m_2 (for example vectors, sequences, graphs, *etc.*) are assigned to the molecules M_1 and M_2 in order to make a quantitative comparison of their similarity. Then a scalar function $d(m_1, m_2)$ defined for the whole set of the objects is introduced. Calculating the values of this function for the pairs 'fixed compound M_1 – every other compound of the set' one can find the compound most similar to M_1 according to the measure $d(m_1, m_2)$.

There is a variety of methods for the description of molecular structures in mathematical terms. For each of them, in turn, a number of similarity may be defined. Thus, the similarity measures of molecules depend upon the method of their mathematical representation and on the selection of similarity criterion. It has to be noted that there is no universal similarity criterion, equally suitable for all properties and any class of compounds. Both the method of the description of compounds and the similarity criterion have to be specially selected for each individual problem. The result of a search for a 'similar' structure also depends on the dataset of compounds, through which the search is carried out.

While comparing the two above approaches to the modelling of structure–property relationships, one may notice that: (i) the latter provides more flexibility in the description of a molecular structure because molecules can be described not only by vectors of molecular descriptors ($x_1, \dots, x_N$) but also by graphs, sequences of symbols, sets, *etc.* Moreover, the number N of vectors ($x_1, \dots, x_N$) used in the former approach is usually not greater than the number of compounds in a dataset, while in the latter method, the value of N is unlimited. (ii) In the former method, the model takes into account the properties of all compounds of the training set; therefore, the value of a property of a new compound depends upon all the compounds, while in the latter method, this value depends only on the properties of a 'similar' compound. Both methods also have obvious shortcomings: in each case, there is a problem of adequate description of the molecular structure and of correct choice of the functions f and $d(m_1, m_2)$.

A huge number of papers based on the concept of molecular similarity have transformed this area into a new branch of theoretical chemistry. Analysis of these papers reveals that they differ by one or several of following points: (i) the studied subset of compounds; (ii) the studied properties; (iii) the method used for mathematical description of chemical structures; (iv) the quantitative criteria of molecular similarity; (v) the methods used to estimate the properties of compounds on the basis of the selected similarity criteria. The positions iii–v are the most methodologically interesting.

The aim of the present review is to discuss the most widespread methods of description and comparison of molecular structures and also the methods for prediction of properties of the chemical compounds based on the concept of molecular similarity. Some attention is also paid to the validity of the postulate 'similar structures possess similar properties' and to the possible ways of its formalisation. Besides, a series of examples illustrating the

advantages and shortcomings of these methods are given and related problems are discussed.

II. Interpretation of the 'molecular similarity' term in chemistry

The term 'molecular similarity' is used in chemistry in a very broad meaning, because molecules may be characterised by a number of structural and physicochemical properties and may exhibit various biological activities. The areas of chemistry that used the molecular (or atomic) similarity concept in some form are summarised in a paper.⁶⁶ In particular, the definitions of such fundamental chemical terms as isomerism, stereoisomerism, homology, periodicity of properties of the chemical elements, *etc.*, are based upon the similarity of some molecular (or atomic) properties.

Some examples of modern usage of the term 'molecular similarity' are given below.

1. Classification of the organic compounds is based mainly upon the classical theory of chemical structure. The similarity of the chemical structures of molecules means some resemblance in the corresponding structural formulae and usually results in relatively small variations of some physicochemical properties and in similar methods of synthesis. However, it is obvious that there is no unique way for evaluation of molecular similarity based solely upon the structural formulae of molecules.

2. The molecules that possess identical skeleton and differ only by heteroatoms (for instance pyrrole and thiophene, benzene and pyridine) may be regarded as structurally related ones.

3. The members of homological series {for example, $\text{CH}_3-(\text{CH}_2)_n-\text{CH}_3$, $\text{R}^1-\text{CH}=\text{CH}-\text{R}^2$ } are also regarded as structurally related molecules. The physicochemical properties of the molecules in such series are usually linear functions of n .

4. The ability of atomic groups to form chemical bonds is described by analogy principle proposed by Hoffmann.⁶⁷ The valence properties of chemical groups are determined by their frontier molecular orbitals (FMO), namely by their number, symmetry, shape and energy. Two chemical groups are called isolobal if the number and symmetry of their FMO are identical and the shape and energy of these FMO 'are reasonably close'. The principle of isolobal analogy states that isolobal groups are mutually replaceable in chemical compounds regardless of the type of atoms in them. This principle links the valence theory of classical organic chemistry with the chemistry of organoelement compounds and provides a possibility of a unified explanation of the structural variety of chemical compounds and of the similarity of their properties.

The given examples illustrate the fundamental character of the chemical similarity concept. However, the very same definition of the term 'similarity' is ambiguous and, usually, intuitive.^{13, 68} The prediction of physicochemical properties or biological activity of compounds on the basis of the postulate 'similar structures possess similar properties' is one of the most important areas of the similarity concept application. However, the postulate is not always valid in the case of visual comparison of the structural formulae. For example, in the series of close analogues (noradrenaline, adrenaline, isoproterenol), the α -adrenergic activity decreases, but the β -adrenergic activity increases. Moreover, the replacement of the phenolic hydroxy groups of isoproterenol by chlorine atoms converts this agonist of β -adrenergic receptors into an antagonist, dichloroisoproterenol.⁶⁹

Yet another example is the poison muscarine, isolated from toadstools, and acetylcholine, which is produced in the human and animal bodies and takes part in the transfer of nerve impulses.⁷⁰

The structures of these compounds are similar and both of them affect the human cholinergic systems.

Sometimes, structurally similar compounds exhibit different types of biological activity. Thus, compound **1** is antihistamine, compound **2** is neuroleptic (antagonist of the dopamine receptors) and compound **3** is antidepressant.⁷¹

At the same time structurally different compounds may exhibit identical biological activity, as denbufylline and rolipram do, which both are phosphodiesterase inhibitors.

The electrostatic potential of a molecule may be used for the description of similarity degree of these compounds.^{69, 71}

These examples illustrate that in addition to the visual analysis of structural similarity, other methods of the molecular structure description are required and new approaches to determination of the molecular similarity degree have to be developed.

III. Graph theory representation of molecules and descriptions of molecular structures based thereon

1. Molecular graphs

According to the modern views, the molecular structure may be described at various levels of complexity. The simplest way of description is the molecular formula. The next step of complexity is the classical structural formula. Further steps include building of 3D molecular models and calculation of quantum-mechanical parameters.

However, there is yet another way of mathematical description of a molecular structure. A labelled molecular graph may represent a molecule. The vertices and edges of the graph will correspond to the atoms and bonds of a molecule and the labels of vertices and edges (numerical or alphabetical) mark the chemically different atoms and bonds. In fact, the classical structural formula is a particular type of labelled molecular graph, where the chemical symbols of corresponding atoms are used as the labels of the vertices and the edge labels correspond to bond orders. Generally, any atomic parameters (atomic charge, polarisability, atomic weight, atomic radius, *etc.*) may be used as vertex labels. Similarly, any bond parameters (bond length, bond order,

obtained from the quantum-chemical calculations, *etc.*^{29, 72}) may be used as edge labels. For example, so-called *be*-matrices (bond and electron matrices) have been proposed.⁷³ Their non-diagonal elements are equal to the bond orders and the diagonal elements, to the number of valence electrons of the corresponding atoms non-involved in bonding. A disconnected graph, *i.e.*, a graph which consists only of isolated labelled vertices without edges, formally corresponds to a molecular formula.

It is also possible to create complete molecular graphs where each pair of vertices is linked by an edge. In this case, a label (or weight) is assigned also to each pair of non-bonded atoms. The topological (or geometrical) distance between these two vertices may be used as such a label. In the latter case, the graph will correspond to the well-known matrix of geometrical distances.

Let us assume that the spatial coordinates of the atoms are known. In this case, one can construct a graph comprising isolated vertices labelled with sequences of three numbers, namely, the atom coordinates. A physicochemical parameter of the corresponding atom can be used as a label for a graph vertex.

Thus, according to the choice of labels, the molecular graphs may be grouped into three major types: calculated on the basis of the structure of the graph itself, taken from literature (for example, the standard physicochemical properties of atoms and bonds) or obtained experimentally (for example, determined by the X-ray crystallography). The combination of these methods is also possible.

In some cases, so-called 'simple' molecular graphs are used. The vertices of these graphs are represented by dots and edges are represented by line segments. Although a simple graph does not have obvious labels, it is assumed that labels of the vertices are equal to zero. If the atoms are chemically bonded, the corresponding edge is labelled by 1, while for nonbonded atoms the edge label is equal to zero. Such graphs are usually used to represent hydrocarbons structures.

2. Descriptions of molecular structures based on their theoretical graph representations

A labelled graph is determined by its topological matrix

$$A = (a_{ij}),$$

where a_{ii} is the label of vertex i , a_{ij} is the label of a pair of vertices (i, j) . (In the case of a simple graph, matrix A is usually called an adjacency matrix.) Obviously, the change of the vertex numbering scheme results, generally speaking, in a different matrix. This is a significant disadvantage of the chemical structure description in matrix terms. This problem leads to the concept of 'graph invariant'. A graph invariant is a number (or a function if the graph labels are symbols) calculated from graph matrix A , which does not depend on the vertex numbering scheme. In theoretical chemistry the invariants of simple graphs are usually called topological indices (TI). Quite often, this definition is also used for invariants of labelled graphs, which can represent not only the topology, but also the elements of electronic or spatial structure. Invariants of any subgraph of a graph can be determined by a similar way. They are called local TI. Topological indices are widely used in theoretical organic chemistry for quantitative characterisation of the molecular structure in a search for structure–property correlations, in the computer-aided synthesis and in creation and analysis of structure–property databases. The most well-known TI and their applications in chemistry are described in the reviews.^{63, 64, 74–76} The simplicity of calculations of TI, the possibility to take into account the electronic and spatial features of the structures and also numerous examples of successful property–TI correlations are the reasons for the popularity of this method of molecular structure description. At the same time, this approach has an obvious disadvantage: it does not differentiate between molecular configurations (*e.g.* stereoisomers) and does not take into account their conformational features.

Some examples of the most common named TI are given below.^{63, 64}

The Randić index χ is defined according to the following formula

$$\chi = \sum (v_i v_j)^{-1/2},$$

where v_i and v_j are the degrees of graph vertices i and j and the sum is taken for all the graph edges. The index χ has been generalised by Kier and Hall, who introduced the definition of m -order connectivity indices.

$${}^m\chi^v = \sum (\delta_i \delta_j \delta_k \dots)^{-1/2}, \quad m \geq 1, \quad \delta_i = \frac{Z_i^v - h_i}{Z_i - Z_i^v - 1},$$

where Z_i is a total number of electrons, Z_i^v is a number of valence electrons of atom i (corresponding to vertex i); h_i is a number of hydrogen atoms bonded to atom i ; the summation takes place along all the chains which consist of m graph edges; i, j, k are the numbers of vertices forming the chain.

The Wiener index W is defined as a sum over all pairs of vertices

$$W = 0.5 \sum d_{ij},$$

where d_{ij} is the shortest distance between vertices i and j . Matrix $D = (d_{ij})$ is called the matrix of topological distances of the graph.

The Hosoya index Z is defined as

$$Z = \sum p_k,$$

where p_k is a number of ways to choose k nonadjacent edges ($k \geq 1$) in a graph.

The Balaban index B [for acyclic graphs (trees)] is defined according to the following formula

$$B = \sum r_i^2,$$

where r_i is a number of the tree vertices cut out at step i of the 'tree pruning' procedure. This procedure consists of consecutive removal of the 1st degree vertices of the initial tree and the edges incident to them.

During the construction of informational topological indices,⁷⁷ a set of fragments (for example, a set of graph vertices) is selected and split into a number of equivalent classes according to some feature (for example, according to the first coordination type). Let assume that n is a number of graph vertices, n_i is a number of vertices in the equivalent class i , $i = 1, \dots, m$. The main informational TI is defined as

$$IC = - \sum \frac{n_i}{n} \log_2 \frac{n_i}{n}.$$

This TI characterises the inhomogeneity of the graph vertices set and has extreme values for the least homogeneous ($m = n$) and the most homogeneous ($m = 1$) sets of vertices. Instead of the set of vertices, a set of any other fragments can be used.

Another large class of TI is the spectral-type TI.⁶⁴ Let us call λ_i and $C^{(j)} = [C_1^{(j)}, \dots, C_n^{(j)}]$ the eigenvalues and the eigenvectors of the matrix of a graph with n vertices. They can be used for the construction of various TI, for example such as

$$J_1 = \max (\lambda_i),$$

$$J_2 = \lambda_r - \lambda_m,$$

where λ_r is the minimum positive and λ_m is the maximum negative eigenvalues, or

$$q_i = \sum C_i^{(k)} C_i^{(k)},$$

$$p_{ij} = \sum C_i^{(k)} C_j^{(k)}$$

(the summation in two latter formulae is over those eigenvectors to which the positive eigenvalues correspond). Spectral-type topological indices appear naturally in some quantum-chemical methods and usually have a quite clear physicochemical meaning.

It should be noted that even for a single fixed labelling scheme of a molecular graph an infinite variety of TI exists. For instance, the multiplication or summation of two TI results in a new TI. Therefore, it is impossible in principle to describe all TI, which can be constructed and used in the QSAR/QSPR analysis. The problem of reasonable choice of just a few TI out of infinite number of variants always arises during the construction of each particular model of structure–property correlation. This happens because it is often difficult to give a relatively clear physicochemical or structural interpretation of TI and to correlate it with the studied property. Moreover, some TI are related to each other by exact or approximate mathematical equations. These facts, as well as a common sense, prompt that for any finite set of the weighted graphs a finite set of TI $J_1, J_2, \dots, J_N$ should exist. This set is called a basic set. Then, any TI may be represented as

$$TI = F(J_1, J_2, \dots, J_N),$$

where $F(J_1, J_2, \dots, J_N)$ is a function of N variables. The type of the function depends on the given topological index. It was rigorously proved⁷⁸ that such basis always exists. The number of occurrences of some structural fragments in the graph may be taken as the basis invariants and F may be a linear function. Some examples of the expansion to a basis of various invariants of molecular graphs have been reported.⁷⁹ These results may be regarded as a mathematical foundation of the well-known principle of additive schemes, used for approximation of the physicochemical properties of compounds.^{80,81}

One more approach to the problem of selection of basic TI has been suggested.⁸² These basic TI are constructed relying on specially selected subgraphs and depend on variable parameters. Another, more QSAR/QSPR-friendly definition of the basis is also given in the same paper. The suggested method was successfully used for the estimation of various physicochemical properties of the hydrocarbons of different classes.

The number of occurrences of a structural fragment in the structure of a molecule is a particular case of TI. The simplest structural fragments have been used in the theoretical chemistry for a long time for the estimation of physicochemical properties by additive schemes.^{80,81} The QSAR/QSPR studies use more complicated fragments as well.^{62,83–85}

It is easy to notice that virtually all TI are somehow related to subgraphs. Fragmental descriptors are of great importance for QSAR/QSPR methods. Below we discuss some of these descriptors.

Let us assume that a chain of $L-1$ bonds (*i.e.* containing L atoms) 'links' together atoms i and j (with Y_i or Y_j codes). Such a chain fragment of the molecule is usually called 'an atomic pair (i, j)' and is coded by a symbol $Y_i - (L-1) - Y_j$.⁸⁶ The code Y_i (or Y_j) contains information about the type of the chemical element, the number of connected atoms (without hydrogens) and the number of π -electrons. As an example, Table 1 gives the 'atomic pairs' and the number of their occurrences in the structural formula of the acetone molecule.⁶⁹ The symbols C and O (see Table 1) correspond to carbon and oxygen atoms, the symbol X_n ($n = 1, 2, 3$) indicates that this particular atom is connected to n

Table 1. Atomic pairs in the acetone molecule.

Atom	Atomic pairs	Number of occurrences of the fragment in the structure
1	CX ₁ –1–C.X ₃	2
2	C.X ₃ –1–O.X ₁	1
3	CX ₁ –2–O.X ₁	2
4	CX ₁ –2–CX ₁	1

atoms (hydrogen atoms are ignored), the symbol ‘.’ indicates that this atom contains one π -electron. The number $L-1$ in this example is equal to 1 or 2. A different method of the description of atomic pairs based upon physicochemical parameters of the atom has also been suggested.⁸⁷

Below are examples of the descriptors, labelled MNA/ k , which are linked to the molecule fragments that are k -order neighbours of atoms of various types ($k = 0, 1, \dots$).^{69,88} The symbols ‘-’ in these descriptors are given to acyclic atoms; the zero order fragment is the atom itself; the first order fragment is the atom with the notification (in the parentheses) of its first-order neighbour, *etc.* The fragments MNA/0 and MNA/1 of the structural formula of phenol for three phenol atoms (labelled 1, 2 and 3) are given in Table 2 as examples.⁶⁹

Table 2. Fragments MNA/0 and MNA/1 for atoms 1, 2 and 3 in the phenol molecule.

Atom	MNA/0	MNA/1
1	C	C(CC-O)
2	C	C(CC-H)
3	-H	-H(C)

The atom-centred fragments of various orders have been previously used a number of times.^{65,77,80,81} They have also been discussed in other publications.^{89,90}

Usually the vectors $X = (X_1, X_2, \dots)$, where $X_i = 0$ if the fragment i is absent in the structure and $X_i = 1$ if the fragment i is present, are composed on the basis of the selected fragment set. The number of occurrences of a fragment i (*i.e.*, an atom chain) in the structure also may be used as X_i .⁹¹ (Originally, this approach was suggested for alkanes.⁹²) Such (0,1) vectors $X = (X_1, X_2, \dots)$ are also called ‘a bit string’. Some relevant examples are given below.⁶⁹

Various TI X_i may be used for the construction of vectors $X = (X_1, X_2, \dots)$. Particularly, if the components of vector X are non-negative and $\sum X_i \neq 0$, then another vector $P = (P_1, \dots, P_k)$, where $P_i = X_i / \sum X_i$, may be constructed.⁹

Examples of vector construction have been reported.^{69,93} Two matrices P and C are introduced for a structure containing N atoms. P is a rectangular matrix of the $N \times 3$ size, where row i is given by $(1, p_i', q_i')$ (p_i', q_i' are specially normalised electronegativity and effective charge of atom i). The C is an (0,1)-adjacency matrix. Then a family of square 3×3 matrices TM_n , called electrotopological matrices, is defined:

$$TM_n = \frac{P^* C^n P}{N}, n = 1, 2, \dots, n_{\max},$$

where P^* is the transposed P matrix; C^n is the n -degree of matrix C ; $n_{\max}$ is the longest sequence in the corresponding graph. These matrices do not depend on the labelling of the vertices of the molecular graph; therefore, their elements may be used as descriptors called electrotopological indices. Vectors consisting of elements of these matrices for $n = 1, 2, \dots, n_{\max}$ may be constructed on the basis of these elements.

It was suggested^{94,95} to use specially formulated rectangular matrices dependent on fragment descriptors to construct vectors describing a molecular structure.

The vectors may also be constructed from quantum-chemical⁹⁶ and any other descriptors⁹⁷ and also on the basis of physicochemical properties of the compounds.⁹⁸

A molecular graph with indication of various sets of fragments, described by a sequence of symbols, may be used for characterisation of a molecular structure.⁹ Linear nomenclatures are examples of such graphs. In such a nomenclature the structural formula is coded by a string of symbols. Each symbol, in turn, determines the structural fragments. The works of Wissesser are at the origin of the linear nomenclatures.⁹⁹ For instance, for the compounds $\text{CH}_3-\text{CH}_2-\text{O}-\text{CH}_2-\text{CH}_2-\text{CH}_3$ and $\text{H}_2\text{N}-\text{CH}_2-\text{CH}_2-\text{C}(\text{O})-\text{OH}$ the Wissesser codes are (2O3) and (Z2VQ) respectively.⁶² The symbol ‘O’ indicates the oxygen atoms, not bonded to H atoms; ‘Q’ is a hydroxy group; ‘V’ is a carbonyl group; ‘Z’ is a nitrogen atom of an NH_2 group. Number 2 (or 3) indicates an unbranched chain of two (or three) CH_2 groups.

Yet another linear nomenclature is called SMILES.^{100,101} It is used, particularly, in search for the structural similarity of compounds. The examples of linear codes obtained by the FCSS (fragmentary code of substructure superposition) language have been reported.⁸⁵ The SLN code (SYBYL Line Notation) has been described.¹⁰² This code has been used¹⁰³ for protein similarity estimation.

Simple graphs may be coded with the minimum binary code. In order to do that, all possible ($n!$, where n is a number of graph vertices) adjacency matrices are constructed. Then each matrix is converted into one string of 0 and 1. This string may be regarded as a binary number. A minimum lexicographic sequence corresponding to the minimum decimal number is selected as a code.⁶⁴

There is one more method of sequences construction. Let us consider a set of N molecules $\{M_i\}$, $i = 1, \dots, N$, and assume that for each pair M_1 and M_2 of this set a symmetrical function $d(M_1, M_2) = d(M_2, M_1)$ is given. This function is regarded as a ‘distance’ between M_1 and M_2 . Then for each molecule M_k of set $\{M_i\}$ a sequence $\{d(M_k, M_i)\}$, $i = 1, \dots, N$, $i \neq k$ may be composed.^{9,29,104} as well as sequences consisting of local graph invariants, *i.e.*, the powers of graph vertices.¹⁰⁵ In contrast to the vectors, which are used for chemical structure descriptions, the sequences may be of various lengths.

Functions are also used for the description of a molecular structure. Let us assume that a molecule is described by a simple graph G and d_{ij} is a topological distance between vertices i and j . The function called topological transformation of graph G

$$t(s) = \frac{k(G) \sum \sum Z_i Z_j [\sin(s d_{ij})]}{s d_{ij}},$$

where s is real parameter, $k(G)$ is a normalising constant such that $\int [t(s)]^2 ds = 1$, Z_i and Z_j are charges of nuclei of corresponding atoms has been considered previously.^{106,107} A similar formula has also been suggested¹⁰⁸ for 3D structures, when d_{ij} is a geometrical distance between atoms i and j . In the latter case, functions of several variables, for example, charge densities, electrostatic potentials *etc.*, are also used.^{13,109}

An algorithm for the description and analysis of the molecular shape, based on quantum-chemical calculations of charge densities or electrostatic potentials, has been suggested.^{110–115} A study of the molecular surface is the starting point of the procedure. The charge density surfaces of various levels are calculated. A set of

these equal level surfaces are regarded as topological objects. The objects are characterised by homology groups, called shape groups. The shape groups are used for the description of molecular shapes and for the analysis of their similarity. This method may be successfully combined with the description of stereoisomers in terms of the knot theory and is easily programmable, which provides an opportunity for automatic non-visual analysis of the molecular similarity degree.

Spatial geometrical models of molecules may be constructed on the basis of structural formulae, using the molecular mechanics or quantum-chemical methods.⁶² These models are potential source of new molecular descriptors. Thus, for example, if the orthogonal coordinates (X_{i1} , X_{i2} , X_{i3}) of a molecule, containing N atoms of masses m_i ($i = 1, \dots, N$), are known, then the formulae

$$U_j = \frac{1}{M} \sum_{i=1}^N m_i X_{ij},$$

where $j = 1, 2, 3$; $M = \sum_{i=1}^N m_i$ is the molecular mass, determine

the coordinates of the centre of mass. Let us denote the inertia tensor as $R = (r_{jk})$

$$r_{jk} = \sum_{i=1}^N m_i (X_{ij} - U_j)(X_{ik} - U_k),$$

and the eigenvalues of matrix R as X , Y , Z . These eigenvalues and some of their functions, such as X/Y , X/Z , etc., were suggested⁶² as molecular geometrical descriptors. Some authors use the van der Waals volume or the surface area of the molecule for the description of the molecular spatial structure. The details of the calculations of these descriptors can be found in the literature.⁶²

Usually, methods for molecular structure description are subdivided into 2D and 3D methods. The bond angles and the Euclidean interatomic distances are not taken into account in the former case. Therefore, the methods, based on the matrices of topological distances of the molecular graph are 2D methods and the invariants determined by these methods are 2D descriptors. The methods based on the matrices of Euclidean distances are 3D methods and the invariants determined by these methods are 3D-descriptors. The degree of molecular similarity discussed below usually depends only on the mathematical representation of the molecules (graphs, sets, matrices, vectors, sequences, etc.) and does not depend on the information coded by these mathematical models. Therefore, we do not discuss separately the 2D and 3D methods of analysis of molecular similarity. The methods of representing the molecular structure, where those based on the graph theory are most important and the other ones are just its derivatives, may be illustrated in a form of the following Scheme.

IV. The quantitative measures of the molecular similarity

The quantitative measure of similarity of two molecules M_1 and M_2 is a scalar function $d(S_1, S_2)$ of two variables S_1 and S_2 . Its type depends on the method of description of the structures S_1 and S_2 of molecules M_1 and M_2 . The value of $d(S_1, S_2)$ for a pair of the structures is a measure of their similarity. Let us assume that the function $d(S_1, S_2)$ is such that:

$$d(S_1, S_2) \geq 0;$$

$$d(S_1, S_2) = 0 \text{ then and only then, when } S_1 = S_2;$$

$$d(S_1, S_2) = d(S_2, S_1) \text{ (symmetry);}$$

$$d(S_1, S_2) \leq d(S_1, S_3) + d(S_2, S_3) \text{ (the triangle inequality).}$$

In this case the function $d(S_1, S_2)$ is called a metric. Most of the measures of the molecular similarity are metrics. In this Section we will describe some similarity measures, developed for various mathematical methods of molecular representation, which are listed in the Scheme at the end of Section III.⁹

1. Let us assume that the structures S_1 and S_2 are represented by n -dimensional vectors $X = (x_1, x_2, \dots, x_n)$ and $Y = (y_1, y_2, \dots, y_n)$. The components of these vectors are some invariants of molecular graphs. The following similarity measures are described in literature:

$$d_1(X, Y) = \sum |x_i - y_i| \text{ (} L_1 \text{ is metric),}$$

$$d_2(X, Y) = \left(\sum |x_i - y_i|^p \right)^{1/p} \text{ (} L_p \text{ is metric);}$$

for $p = 2$, d_2 is a distance between points X and Y in the Euclidean space R^n . (Euclidean distances are widely used in the estimation of the molecular similarity degree^{24, 65, 116–122})

$$d_3(X, Y) = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\left| \sum (x_i - \bar{x}) \sum (y_i - \bar{y}) \right|^{1/2}},$$

$$\bar{x} = \frac{1}{n} \sum x_i, \quad \bar{y} = \frac{1}{n} \sum y_i$$

(correlation coefficient);

$$d_4(X, Y) = \frac{\sum x_i y_i}{\sum x_i^2 + \sum y_i^2 - \sum x_i y_i}$$

(Tanimoto coefficient).

The Tanimoto coefficient is one of the most common similarity measures in QSAR/QSPR studies as well as in the analysis of chemical databases.^{2, 53, 122–127} (0,1)-Vectors are usually used as vectors X and Y . The component values of these vectors depend on the presence (1) or absence (0) of some fragments in the structures S_1 and S_2 . In this case, the Tanimoto coefficient has the form

$$d_4(X, Y) = \frac{N_{xy}}{N_x + N_y - N_{xy}},$$

where N_x and N_y are the numbers of components in each of the vectors X and Y equal to 1; N_{xy} is the number of 'common' components of these vectors equal to 1.

$$d_5(X, Y) = \frac{\sum \min(x_i, y_i)}{\sum x_i^2 + \sum y_i^2 - \sum \min(x_i, y_i)} \text{ (Ref. 88),}$$

$$d_6(X, Y) = \sum (x_i - y_i) \log_2 \frac{x_i}{y_i} \quad (x_i, y_i > 0),$$

$$d_7(X, Y) = \frac{\sum x_i y_i}{\left(\sum x_i^2 \right)^{1/2} + \left(\sum y_i^2 \right)^{1/2}}$$

(cosine of the angle between the vectors),^{91, 121, 126, 127}

$$d_8(X, Y) = \frac{\sum \min(x_i, y_i)}{0.5 \left(\sum x_i + \sum y_i \right)}.$$

The metric $d_8(X, Y)$ was introduced for a case where the components of vector X (or Y) are equal to the number of occurrences of the special fragment, namely, an atomic pair, in the structure S_1 (or S_2) (see Section III).⁸⁶ The method for estimation of the similarity based on atomic pairs is sometimes called the 'atomic pairs method'.

The measure considered in a study⁶⁹

$$d_9(X, Y) = \left[1 + \frac{1}{n} \sum_i (X_i - Y_i)^2 \right]^{-1},$$

was defined for vectors constructed from the elements of electrotopological matrices^{70, 92} (see Section III).

2. Let us assume that the structures S_1 and S_2 are represented by finite sets D_1 and D_2 and denote the number of elements in the set D as $|D|$. The following similarity measures are described:⁹

$$d_{10}(D_1, D_2) = |D_1| + |D_2| - 2|D_1 \cap D_2| = |D_1 \setminus D_2| + |D_2 \setminus D_1|$$

(Hamming metric¹²⁸),

$$D_{11}(D_1, D_2) = \frac{|D_1 \cap D_2|}{|D_1 \cup D_2|}$$

(Ohia coefficient).

3. Let us assume that the structures S_1 and S_2 are represented by the labelled graphs G_1 and G_2 ; E is a set of graph vertices, $|G|$ is the total number of vertices and edges of the graph G ; $|\text{MACS}(G_1, G_2)|$ is the total number of vertices and edges in the maximum common subgraph G_1 and G_2 . The following measures were introduced for the graphs:⁹

$$d_{12}(G_1, G_2) = |E_2 \setminus E_1| + |E_1 \setminus E_2|,$$

$$d_{13}(G_1, G_2) = |G_1| + |G_2| - 2|\text{MACS}(G_1, G_2)|,$$

$$d_{14}(G_1, G_2) = \frac{|\text{MACS}(G_1, G_2)|^2}{|G_1 \cup G_2|}.$$

The methods of finding the maximum common subgraph have been reviewed.^{129, 130} It should be noted, that the subgraph may also be found for the edge graphs derived from these graphs.¹³¹ Eight similarity measures based on the maximum common subgraph have been reported.¹³²

In order to define the measure $d_{15}(G_1, G_2)$, let us choose a subgraph (fragment) H . Let $n(G) = 1$ if H belongs to the graph G , and $n(G) = 0$ if H does not belong to G . Let us consider the measure

$$d_{15}(G_1, G_2) = |n(G_1) - n(G_2)|.$$

Obviously, $d_{15}(G_1, G_2) = 1$ if one of the graphs contains the fragment H and another one does not (the graphs G_1 and G_2 are 'dissimilar'); and $d_{15}(G_1, G_2) = 0$ if H either belongs to both graphs or to none of them (G_1 and G_2 are 'similar'). This measure allows one to sort the structures of a set into two classes: those containing and not containing the fragment H . The application of this measure in QSAR results in a search for the fragment H present in all active compounds of a set and absent in the structures of inactive compounds.^{62, 85}

4. Let us assume that the structures S_1 and S_2 are represented by the sequences l_1 and l_2 ; $|l|$ is the length of the sequence; $|\text{LCS}(l_1, l_2)|$ is the length of the longest common sequence in l_1 and l_2 . For the sequences, the following similarity measures were suggested:⁹

$$d_{16}(l_1, l_2) = |l_1| + |l_2| - 2|\text{LCS}(l_1, l_2)|,$$

$$d_{17}(l_1, l_2) = \frac{2|\text{LCS}(l_1, l_2)|^2}{|l_1 \cup l_2|},$$

$$d_{18}(l_1, l_2) = \frac{1 - d_{17}(l_1, l_2)}{|l_1 \cup l_2|}.$$

Also, let us define the elementary 'editing' operations of the sequences: the removal of the element x , the addition of the element x , the replacement of x by y in the particular sequence.

The similarity measure of two sequences l_1 and l_2 may be introduced as the minimum number of such operations required to transform l_1 into l_2 .¹⁴

5. Let us assume that the functions f_1 and f_2 correspond to the structures S_1 and S_2 . The following similarity measures may be defined on this basis:

$$d_{19}(f_1, f_2) = \left(\int |f_1(x) - f_2(x)|^2 dx \right)^{1/2},$$

$$d_{20}(f_1, f_2) = \int |f_1(x) - f_2(x)| dx,$$

$$d_{21}(f_1, f_2) = \frac{\int f_1 f_2 dx}{\int |f_1|^2 dx \int |f_2|^2 dx}.$$

Similar formulae may also be written for the functions of several variables.

There are several 'named' similarity measures associated with the functions. Let us consider the measure¹³³ specified as

$$d(f_1, f_2) = \int \int f_1(r_1) \Omega(r_1, r_2) f_2(r_2) dr_1 dr_2,$$

where f_1 and f_2 are the functions of charge density, Ω is a positive definite operator. The measure $d(f_1, f_2)$ was used to specify other measures, for example:

$$d_C(f_1, f_2) = \frac{d(f_1, f_2)}{d(f_1, f_1)^{1/2} d(f_2, f_2)^{1/2}}$$

(Carbo's index^{134–140}),

$$d_{HR}(f_1, f_2) = \frac{2d(f_1, f_2)}{d(f_1, f_1) + d(f_2, f_2)}$$

(Hodgkin–Richards index^{109, 134–136, 141}),

$$d_P(f_1, f_2) = \frac{d(f_1, f_2)}{\max[d(f_1, f_1), d(f_2, f_2)]}$$

(Petke's index^{142, 143}).

Two sets of similarity indices, dependent on the parameters x and k , were suggested¹³³

$$D_1(f_1, f_2) = \left[\frac{k[d(f_1, f_1) + d(f_2, f_2)]}{2} - x d(f_1, f_2) \right]^{1/2},$$

$$D_2(f_1, f_2) = \frac{(k - x)d(f_1, f_2)}{D_1^2(f_1, f_2)}.$$

The indices D_1 and D_2 become equal to the Carbo and Hodgkin–Richards indices at some particular k and x values. The similarity measures listed above are usually called the quantum-chemical ones, because the functions f_i (charge density, electrostatic potential, etc.) are calculated by quantum-chemical methods.^{133, 135, 142, 144–171}

It was suggested¹⁷² to consider three- or four-atomic molecules similar if they have equal numbers of electrons. It was found that in this case the values of some physicochemical parameters (for example, the atomisation heats) of similar molecules are comparable. However, for other properties (for instance, for the ionisation potentials) this similarity measure does not work.

Various modifications of the above-mentioned quantum-chemical similarity measures have been proposed.^{173–175} These give rise to new, nonsymmetrical measures d'_{ij} for some sets of compounds. For example, so-called 'stochastic transformation' d'_{ij} of the similarity measure d_{ij} is suggested:

$$d'_{ij} = d_{ij}(d_{i1} + d_{i2} + \dots + d_{iN})^{-1},$$

where N is the number of compounds in a set. The quantity d'_{ii} called the self-similarity measure, is regarded as a molecular descriptor and is used for the modelling in QSAR/QSPR analysis.¹⁷⁶

6. Let us assume that the structures S_1 and S_2 are represented by matrices $A = (a_{ij})$ and $B = (b_{ij})$ of the same order k . In this case the measures $d_{22}(A, B)$, $d_{23}(A, B)$, $d_{24}(A, B)$ may be used for the comparison of the structures S_1 and S_2 .^{9, 177, 178}

Let us define the measure $d_{22}(A, B)$ as follows:

$$d_{22}(A, B) = \frac{1}{\sqrt{k(k-1)}} \left(\sum (a_{ij} - b_{ij})^2 \right)^{1/2}.$$

Obviously, the $d_{22}(A, B)$ depends on the atomic numbering scheme in the structures S_1 and S_2 . However, it is possible to design a numbering independent similarity measure $d_{23}(A, B)$. Keeping the numbering of atoms in the structure S_1 fixed, all possible numbering schemes of the structure S_2 are considered and all possible values of $d_{22}(A, B)$ are calculated. The minimum obtained value is regarded as a similarity measure $d_{23}(A, B)$ of the structures S_1 and S_2 .^{9, 177}

The measure $d_{24}(A, B)$ is often used to compare isomers described in terms of so-called *be*-matrices.⁷³ This measure is called 'the minimal chemical distance' and is determined by the following formula¹⁷⁸

$$\text{MCD}(A, B) = d_{24}(A, B) = \min_{i,j} \sum |a_{ij} - b_{p(i)p(j)}|.$$

Here the summation takes place over the indices i and j ; p are all possible combinations of n symbols, where n is the matrix order. Some combinatorial problems appear during the calculation of the $\text{MCD}(A, B)$ value. Methods for tackling these problems have been proposed.¹⁷⁸

A method of estimation of molecular similarity based on the matrices of the geometrical distances has been described.^{179, 180}

7. Let us discuss the similarity measures for the molecules represented by three-dimensional geometrical objects Γ_1 and Γ_2 .

In order to calculate these measures, the 3D molecular structures are spatially superimposed and a function of several variables is minimised. This function depends on the mutual orientation of the molecules. For instance, the following function may be used

$$R(\Gamma_1, \Gamma_2) = \left[\frac{1}{N} \sum_{i=1}^N \sum_{j=1}^3 \left(x_{ij}^{(1)} - x_{ij}^{(2)} \right)^2 \right]^{1/2},$$

where N is a number of atoms in the structures Γ_1 and Γ_2 , $x_{ij}^{(1)}$ [or $x_{ij}^{(2)}$] are the coordinates of atoms in Γ_1 (or Γ_2). The minimum $R(\Gamma_1, \Gamma_2)$ of all possible rotations and translations of the structure Γ_2 in the space R^3 (with a fixed position of the structure Γ_1) may be regarded as a similarity measure $d_{25}(\Gamma_1, \Gamma_2)$ of the structures Γ_1 and Γ_2 .

The following function may be used to evaluate the similarity of the structures Γ_1 and Γ_2 instead of the function $R(\Gamma_1, \Gamma_2)$

$$R'(\Gamma_1, \Gamma_2) = \left[\frac{1}{N} \sum_{i=1}^N m_i \sum_{j=1}^3 \left(x_{ij}^{(1)} - x_{ij}^{(2)} \right)^2 \right]^{1/2},$$

where m_i is the mass of the atom i . As in the previous case, the minimum of this function, determined by relative positions of the structures Γ_1 and Γ_2 , is calculated. The value of this minimum is regarded as a similarity measure $d_{26}(\Gamma_1, \Gamma_2)$ of the structures Γ_1 and Γ_2 .

In order to determine the Meyer's similarity index $S(\Gamma_1, \Gamma_2)$ (Ref. 181), a three-dimensional lattice with relatively small distances between the nodes (for example, 0.02 nm) is constructed in the space R^3 . The geometrical body formed by a system of atom-centred van der Waals spheres is regarded as a model of the molecule. Molecules Γ_1 and Γ_2 are placed in this three-dimensional latticed space and the numbers of the nodes $T(\Gamma_1)$, $T(\Gamma_2)$

and $T(\Gamma_1, \Gamma_2)$ are counted. These are the numbers of the nodes in the van der Waals areas of each molecule and in their overlapping region, respectively. Then the Meyer's index is calculated according to the following formula¹⁸¹

$$0 \leq S(\Gamma_1, \Gamma_2) = \frac{T(\Gamma_1, \Gamma_2)}{[T(\Gamma_1)T(\Gamma_2)]^{1/2}} \leq 1.$$

The superimposition is performed to ensure the highest possible value of $S(\Gamma_1, \Gamma_2)$.

The value of $d(\Gamma_1, \Gamma_2)$, calculated according to the following formula, is used as a similarity measure of two molecules

$$d(\Gamma_1, \Gamma_2) = \frac{V_{\Gamma_1 \Gamma_2}}{V_{\Gamma_2}},$$

where V_{Γ_2} is the volume of the molecule Γ_2 ; $V_{\Gamma_1 \Gamma_2}$ is the volume of the overlapping area of the molecules Γ_1 and Γ_2 .¹⁸² It should be noted that this measure is better to be used when the position of one of the molecules is fixed.

The elementary operations required to transform structure Γ_1 into structure Γ_2 during estimation of the molecular similarity are documented.¹⁸³ These operations include the addition and removal of atoms, the change of atomic labels, etc. The special measure of similarity of the structures Γ_1 and Γ_2 , which depends on the minimum number of operations for the transformation of one molecule into another, is introduced. The review of the methods for superimposition of three-dimensional structures is given. Another method of optimal superimposition of three-dimensional molecular structures was suggested in a study,¹⁸⁴ where the Carbo and Meyer indices were used for the molecular similarity measuring. The similarity measures based on the spatial superimposing of the molecules were also used¹⁸⁵ for the construction of 3D QSAR models.

The biological activity of molecules is closely related to their three-dimensional structure. As a result, the increased attention is attracted nowadays to the analysis of similarity of such structures.^{41, 42, 46, 186–202} The correct choice of the biologically active conformation of the molecule is the main problem of 3D analysis of similarity. Usually either the conformation obtained by X-ray structural study of the complexes of the ligand with the receptor or the conformation calculated on the basis of two-dimensional structure by a special converter program is taken. It was supposed that the biologically active conformation of the molecule corresponds to a global minimum of its potential energy. However, it was shown that it is not the case.⁶⁹ Therefore, the consideration of only one main conformation in the analysis of similarity of the compounds may produce erroneous results.

Most of the 3D databases contain just one conformation for each compound. Therefore the 3D methods of similarity analysis probably will not provide a significant advantage over the 2D ones without taking into account a conformational flexibility of the molecule. It requires either to generate and keep a set of conformations for each molecule or to perform conformational calculations in the process of similarity analysis, which significantly slows it down.⁶⁹

Superimposing (or overlaying) of two molecules in the similarity analysis is a limiting step, which restricts the application of 3D methods for the analysis of large databases. The superimposition procedure may be speeded up in several ways.^{202, 203} A 4D similarity measure, which depends on the conformation of the molecule, has been considered.²⁰⁴ The protein similarity measure²⁰⁵ is based upon their 2D representation.

Alongside with 2D, 3D, 4D representations, 1D representation is also in use.²⁰⁶ In this case the molecule is represented by a chain graph with labelled vertices, which correspond to the atoms of the molecule. The labels of the vertices include the atomic type, hybridisation and bonding of the corresponding atoms. The methods of the comparison of these chain graphs are identical to the methods for comparison of symbol sequences.

A comparative analysis of 2D and 3D methods was performed during the classification of four sets of compounds into the active and inactive ones.²⁰⁷ The possibility of application of 2D and 3D methods for the estimation of similarity of various experimentally measured and calculated physicochemical properties related to such interactions as hydrophobic, dispersion, electrostatic, steric and donor–acceptor ones has been discussed.¹⁸⁶ The best property predictions were made on the basis of 2D fragment descriptors.

In a study,²⁰⁸ various sets of 2D and 3D descriptors have been used for the classification of compounds according to their biological activity. It appeared that only 2D fragments provide effective sorting of the compounds to the active and inactive ones and, therefore, they are preferable for the analysis of similarity of chemical compounds.

The results of comparison of the 2D method of atomic pairs and its 3D modifications in the search for active analogues of morphine, cyclopamine, diazepam, apomorphine, serotonin, haboxadol, diethylstilbestrol in the database of 30 000 compounds are reported.⁵⁰ It is shown that the three-dimensional approach does not surpass the 2D method in the number of obtained biologically active analogues. At the same time, some active compounds, topologically different from the corresponding standard compound, were found only by 3D methods. A comparison of 2D and 3D descriptors for identification of active and inactive compounds was also carried out in other studies;²⁰⁹ both methods provide similar results. The comparison of the similarity measure defined by the Tanimoto coefficient and the measures based on the superposition of the structures has also demonstrated²¹⁰ that the efficiency of 2D and 3D methods is approximately the same.

The method of superposition of the structures has performed better in the search for analogues in the non-homogeneous 3D databases, while for more homogeneous databases the best results were obtained by the maximum common subgraph method.⁶⁸

A comparison of several similarity measures during the search for compounds in databases was performed;^{211–216} methods for determination of molecular resemblance based on 22 similarity measures were suggested.²¹⁶

The problem of analytical description of an arbitrary similarity measure specified for some finite set of the labelled graphs was discussed.^{217,218} The general analytical formula depending on two matrices A_1 and A_2 was obtained. These results imply that in the prediction of properties of chemical compounds by methods based upon a similarity measure the best matrices A_1 and A_2 have to be obtained. In order to do that, the measure should be selected by optimal way from the sample subset of the compounds. This method of measure selection is a universal one and may be programmed (in contrast to the usual approaches where the measure is often ‘guessed’). The method was applied²¹⁹ for the prediction of lipophilicity ($\log P$) of compounds, where P is a distribution coefficient in the n-octanol–water system. The advantages of this method were discussed.^{13,220}

Thus, there is a number of various molecular similarity measures. The new measures may be constructed on their base. The review by Sheridan and Kearsley²²¹ discusses the reasons for invention of such a variety of measures and their application in theoretical and computer chemistry.

In the conclusion of this Section it has to be noted that quantitative similarity measures used in the theoretical chemistry are commonly divided in the ‘similarity measures’ and ‘dissimilarity measures’. In the former case, the higher is the similarity (intuitive) of the molecules, the greater is the value of the corresponding similarity measure. In the latter case, the situation is opposite. By inverting the similarity measure $d(M_1, M_2)$ of the molecules M_1 and M_2 and calculating the value of $1 - d(M_1, M_2)$, the dissimilarity measure of these molecules may be obtained. A new molecular descriptor of the molecule M may be constructed on the basis of any similarity measure $d(M_1, M_2)$: $d(M) = d(M, M_0)$, where M_0 is a fixed molecule.⁹ Various methods

of determination of the molecular ‘diversity’ are discussed, for example, in the papers.^{12,222–234}

V. Methods for the prediction of properties of chemical compounds based on the molecular similarity concept

1. Method of k nearest neighbours

Let us take a set of N chemical compounds $M_1, \dots, M_N$ with known values $y_1, \dots, y_N$ of a chemical property. Then, according to the method of k Nearest Neighbours (k NN),^{24,69,235,236} the property y_0 of a compound M_0 may be calculated as follows:

$$y_0 = \frac{1}{k} \sum W(M_j) y_j,$$

where $W(M_j) = 1$ if M_j is among the nearest k neighbours and $W(M_j) = 0$ in the opposite case. Generally, $W(M_j)$ may be replaced by any other weighted functions, particularly a similarity measure $d(M, M_j)$ may be used instead. The advantages and limitations of the k NN method and some of its modifications have been discussed.^{235,236} The correct choice of k is a key problem of this method. For example, the optimal k was selected out of the series of values 1, 2, 3, 4, 5 in the prediction of lipophilicity;²³ the $k = 1$ was used for the estimation of boiling points and mutagenicity;^{25,69} the $k = 1, \dots, 10; 15, 20, 25$ were also applied.²⁴ The measure used for identification of the ‘nearest neighbours’ also affects the results of the k NN method. The composition of a set is also very important (there is a possibility that there are no ‘good’ neighbours in a set).

2. The estimation of a property on the basis of a system of equations

Zefirov and co-workers²¹⁹ suggested a method based on the optimal selection of a similarity measure $d(M_i, M_j)$ by the system of equations of the following type

$$|y_i - y_j| \approx d(M_i, M_j).$$

It was suggested to determine the property y_0 of a new structure M_0 on the basis of a system of equations in order to avoid the problem of selecting a correct number of neighbours k in k NN method:

$$|y_0 - y_i| \approx d(M_0, M_i),$$

where $\{M_i\}$ is a training set. In fact, this method is based on the assumption that the obtained model ‘similar structures–similar properties’ is also valid for the new compound M_0 .

3. The methods of pattern recognition theory

The background of the theory of pattern recognition (TPR)^{62,76,85,237–239} are as follows. There is a set of objects, each of them belongs to one of the classes (patterns). The main task of TPR is to produce the rules (usually written as inequalities) according to which the studied objects may be assigned to corresponding classes. If the class of an object is *a priori* known, then the problem is the learning strategy of pattern recognition. In the absence of the *a priori* knowledge the system has to train itself to recognise the classes. The quality of the rules is determined by the number of errors in the classification of a training set.

Let us discuss the geometrical interpretation of the TPR. In a number of cases the chemical objects are described as vectors $X = (x_1, \dots, x_n)$, i.e., any object is represented by a point in the Euclidean space R^n . The Euclidean distance $d(X_1, X_2) = [\sum (x_{1i} - x_{2i})^2]^{1/2}$ may be regarded as a measure of proximity of these points. If the choice of the recognition criteria is adequate, then the points of the same class occupy a compact area in the space R^n (so-called cluster) and the clusters of different classes do not intersect each other. The term ‘cluster’ is a fundamental one for the self-training procedure. It may be determined as a set of points $\{A\}$, where any point is closer to the point of the same set

rather than to a point that does not belong to $\{A\}$. In the simplest case, the recognition rule may be as follows: an object described by vector X belongs to the class that is located at the shortest distance from the object.

The TRP may also be described in the probability terms. In this case the selection rules are described in terms of the probability theory.

The theory of pattern recognition is widely used in the prediction of biological activity of the compounds. In the simplest case, the compounds are sorted into two classes: active and inactive ones. The vectors based on the descriptors are used for the description of the compounds.

The linear regression method, used for the quantitative description of properties, may be regarded as a specific case of TPR. Indeed, the range of the property values may be split into the non-intersecting intervals and the chemical compounds may be assigned to the corresponding classes. The regression equation determines the selection rule for the classification of the compounds of a training set. However, the method of linear regression is not usually regarded as one of the methods of molecular similarity in the prediction of properties of chemical compounds.

4. The methods of quantitative correlations between the similarity of compounds and their biological activity or property (QSiAR/QSiPR analysis)

The following type of correlations is established in these methods:

$$y_j = \sum a_i S(i, j) + a_0,$$

where $S(i, j)$ is a similarity coefficient between the compounds i and j , a_i , a_0 are regression coefficients. The principal component analysis or partial least squares method are used for the determination of significant variables in the correlation equation (*i.e.*, for determination of i values). Examples of applications of the QSiAR/QSiPR analysis can be found in the literature.^{29, 144, 240–243}

VI. Formalisation of the postulate ‘similar structures possess similar properties’ and its analysis

As it was mentioned above, the application of a concept of molecular similarity for the prediction of properties of chemical compounds is based on the statement ‘similar structures possess similar properties’ (SSPSP), which is accepted as an axiom, without being proved.

Naturally, the questions are: what is the correct interpretation of this postulate, how well is it justified, how to formalise it?

The hypothesis that similar structures possess similar properties originated from numerous experimental correlations between the properties of chemical compounds and the presence and number of some structural fragments in their molecules. Two structures are called similar if they have several common fragments, which mainly determine the value of a property, and differ by the fragments, which do not influence the value of a property. In this case one can expect that really ‘similar’ structures will possess ‘similar’ properties.

Nowadays very abstract and complicated similarity measures, not directly related to the studied properties (see chapter IV), are often used for the estimation of molecular similarity degree. In spite of this fact, the SSPSP statement is still applied; however, its interpretation and validity in these cases is not entirely clear.

Johnson²³⁵ reports the results of an empirical study of the validity of SSPSP postulate for various particular cases. Sixteen properties (both physicochemical properties and biological activity types), 16 databases and 72 quantitative similarity measures based on the vector representation of the molecular structures were investigated. The k NN method was used for the calculation of properties. It was shown that the measures based on the

correlation coefficients are the most successful ones. A vector whose components are equal to the number of appearances of some structural fragments in the molecule is the most preferable one for the description of the molecular structure.

Thus, the validity of SSPSP statement significantly depends upon the choice of the chemical descriptors, the similarity measures, the class of the chemical compounds, the studied properties and the method of property estimation.²³⁵ As the application of this postulate for the resolving of the particular problems of theoretical organic chemistry may turn out to be not always correct, the success of predictions of the properties of chemical compounds by the abovementioned methods is, generally, accidental. Therefore, a theoretical confirmation of the validity of SSPSP postulate is required.

In order to analyse the postulate, let us consider the most general case when the chemical structures $\{M_i\}$, $i = 1, \dots, N$, are represented by some mathematical objects $\{S_i\}$, $i = 1, \dots, N$, and for the pairs S_i and S_j of these objects a symmetrical function $d(S_i, S_j) \geq 0$ [such, that $d(S_i, S_j) = 0$ only when $S_i = S_j$], the similarity measure of the corresponding structures M_i and M_j , is specified. Besides, let us assume that the numbers $\{y_i\}$, *i.e.*, the values of some property of the structures $\{M_i\}$, $i = 1, \dots, N$, are also known. It is reasonable to propose, as a similarity measure, a quantity $|y_i - y_j|$. Let us assume that the numerical criteria of similarity of properties and structures are *a priori* known. The criteria are the numbers $\varepsilon \geq 0$ and $\delta \geq 0$, such that if $d(S_i, S_j) \leq \delta$, then the structures are regarded as similar and if $|y_i - y_j| \leq \varepsilon$, then the properties are also regarded as similar. Obviously, the number ε is always selected by a researcher according to the particular problem to be solved and $d(S_i, S_j)$ and δ are variable characteristics. Then the postulate SSPSP may be formulated as follows: if for any structures M_i and M_j $d(S_i, S_j) \leq \delta$, then $|y_i - y_j| \leq \varepsilon$.

For the analysis of the validity of the postulate, let us make the following simple statement: for any set of structures $\{M_i\}$ ($i = 1, \dots, N$), any property y and any similarity measure $d(S_i, S_j) \geq 0$ [$d(S_i, S_j) = 0$ only in the case where $S_i = S_j$] the following inequalities are valid

$$ad(S_i, S_j) \leq |y_i - y_j| \leq bd(S_i, S_j),$$

where a and b are constants depending on the measure, properties and the set of structures, namely

$$a = \min_{i, j, i \neq j} \frac{|y_i - y_j|}{d(S_i, S_j)} \geq 0,$$

$$b = \max_{i, j, i \neq j} \frac{|y_i - y_j|}{d(S_i, S_j)} \geq 0.$$

Several conclusions may be drawn from this statement.

1. The postulate will always be valid (in the abovementioned form) if $\delta = \varepsilon/b$ is selected.

2. Let us assume that for a given set, not all the values of the properties are close to each other, *i.e.*, that there is a pair S_i and S_j ,

such that $|y_i - y_j| > \varepsilon$. Therefore, if $\delta = \max_{i, j} d(S_i, S_j)$ is selected,

then the postulate will not be valid for the given set.

3. Earlier, we assumed ε to be specified. However, if ε is selected to be very large, then the postulate will be valid for any δ and $d(S_i, S_j)$.

4. From the obtained double inequalities, it follows that the lower is the value of $d(S_i, S_j)$, the smaller is the quantity of $|y_i - y_j|$, thus for the ‘very similar structures’ the properties are also ‘very similar’. This qualitative conclusion, drawn from the rigorous mathematical argumentation, is, in fact, a proof for the non-formal postulate typically used in theoretical chemistry.

Thus, we have shown that the validity of the postulate depends on the choice of ε and δ values if the measure $d(S_i, S_j)$ is fixed. However, the similarity measure of the properties is very seldom selected during the practical application of the molecular similarity concept. Therefore, without this criterion, it is very difficult to

judge if the structures really possess similar properties. Usually the experimental and calculated properties are listed in the QSAR/QSPR papers; however, the allowed error of prediction is never given. Therefore, a careful reader have to judge for himself the quality of methods applied.

An alternative method of selection of the measure $d(S_i, S_j)$ has been suggested.²¹⁹ This measure is selected using a set of structures on the basis of the conditions $d(S_i, S_j) \approx |y_i - y_j|$ at all i and j . In this case, the measure is represented by a special equation, depending on the variable square symmetrical matrix A . This equation is a scalar product of vectors AX and X , where X is a vector composed from certain descriptors. This method provides the validity of the SSPSP postulate for a given set with any values of ε and $\delta = \varepsilon$ and seems to be more efficient than 'guessing' of the measure.

Let us discuss the applicability of SSPSP postulate for the prediction of properties of the compounds that do not belong to the initial set. If this postulate is valid for the initial set with some δ , then for another set it cannot be valid with the same value of δ . Thus, it is obvious that the application of the postulate for estimating the properties of other compounds may be erroneous.

A 'training set' of compounds with known properties is always required for the estimation of the δ value. However, the standard regression equation may be written if the set is present and the problem of property prediction may be solved by other methods. Both these methods (regression analysis and similarity method) require the selection of the way of mathematical description of the molecular structure, the molecular descriptors, the type of the dependence between the descriptors and property or the similarity measure, and also the training set. The possibility of the analysis in the case of a non-linear structure–property correlation or even without a correlation at all is an advantage of the similarity method (the regression analysis usually uses the linear models). Moreover, the similarity method looks more attractive (in comparison with the regression analysis) because of the illusion that it

does not requires complicated computation and a training set. Measures that compare the structures as a whole and do not require any descriptors are also possible. For example, the maximum common subgraph and its characteristics (the number of vertices, edges, *etc.*) may be found. However, such simplification of the similarity method results in arbitrary character of the predictions.

VII. Examples of application of the molecular similarity concept

1. Determination of the structural similarity in terms of topological indices

The values of 90 topological indices (including the Randić index, the Wiener index, the series of informational indices, connectivity indices, *etc.*) have been calculated²⁴³ for 3692 organic compounds of various classes. Ninety-dimensional vectors were composed for each of the studied structures on the basis of these TI. Ten new TI $X_1, \dots, X_{10}$, which are linear combinations of the initial ones, were constructed as well, because some of the used indices were correlated by linear equations. Let us assume that $X^{(i)} = (X_1^{(i)}, \dots, X_{10}^{(i)})$ ($i = 1, 2$) are two such vectors corresponding to a pair of structures S_1 and S_2 . The similarity measure d of the structures S_1 and S_2 was determined²⁴⁴ as the Euclidean distance between two points in the space R^{10}

$$d[X^{(1)}, X^{(2)}] = \left\{ \sum [X_i^{(1)} - X_i^{(2)}]^2 \right\}^{1/2}$$

and the applicability of this measure in the search for structural analogues of some compounds in a specific database was studied. Five compounds were randomly selected and for each of them five nearest {according to the measure $d[X^{(1)}, X^{(2)}]$ } neighbours were found. The results of this procedure are shown in Scheme 1; indices 1.0, 2.0, 3.0, 4.0, 5.0 correspond to the selected compounds and indices of the i, j ($i, j = 1, \dots, 5$) type, to the found nearest

Scheme 1

'neighbours'. The compounds are listed according to increasing values of the measure $d[X^{(1)}, X^{(2)}]$. The compounds found are in agreement with the intuitive chemical ideas about the structural similarity of the molecules. In order to find 'good' compounds in a database, it is necessary, at least, to have them in the database.²⁴⁴

2. The dependence of the result of clusterisation of a set of compounds on the method of chemical structure description

The correlation between the toxic activity for mice and the structure has been studied²⁴⁵ for 25 ethers R^1-O-R^2 ($R^1 = \text{Me, Et, Pr}^n, \text{Pr}^i, \text{CH}_2=\text{CH}$; $R^2 = \text{Me, Et, Pr}^n, \text{Pr}^i, \text{Bu}$ and other). The electrotopic descriptor ε (Ref. 245) and valence-weighted connectivity index ${}^m\chi^v$ at $m = 1$ were used for the classification of compounds.

Clusters in the descriptor–property planes for ε and χ^v are shown in Fig. 1. Obviously, the quality of clusterisation depends on the selection of a descriptor and ε works better than χ^v .

Figure 1. The clusterisation of the set of 25 esters, containing from 2 to 7 carbon atoms, on the planes descriptor ${}^1\chi^v$ –property (a) and descriptor ε –property (b).²⁴⁵ pC is a toxicity.

3. The search for similar structural fragments of compounds exhibiting similar properties

It appeared²⁴⁶ that the structural similarity of antihistamine agents (diphenhydramine, methapyrilene, cyproheptadine, dimethindene, promethazine) may be represented by a topological triangle of two aromatic rings and the tertiary nitrogen atom.

A common 'triangle' with some functional groups in the vertices has also been found for antipsychotic agents (molindone, chlorpromazine, haloperidol, pimozide, chlorprothixene, sulpiride).

4. Dependence of the result of property prediction by the *k*NN method on the choice of the similarity measure and number *k* of nearest neighbours

Two molecular similarity measures have been studied²³ for the estimation of lipophilicity ($\log P$) of 76 compounds of various classes. One of them was determined according to the following formula

$$d' = \frac{2C}{T_1 + T_2},$$

where T_1 , T_2 are the numbers of fragments that are atomic pairs in the first and second structures, respectively; C is the number of atomic pairs shared by these two molecules (see Sections III and IV). The second similarity measure was determined according to the following formula

$$d'' = \left\{ \sum [X_i^{(1)} - X_i^{(2)}]^2 \right\}^{1/2},$$

where $X^{(j)} = [X_1^{(j)}, \dots, X_9^{(j)}]$, $j = 1, 2$ are some vectors from the Euclidean space R^9 obtained by the main component analysis from 90 various TI (see part 1 of this Section).

Five nearest neighbours of each compound of the set have been found according to the measures d' and d'' and the values of $\log P$ have been calculated by *k*NN method in five variants (at $k = 1, 2, 3, 4, 5$). Thus, ten various estimations of the $\log P$ were obtained. The correlation coefficients r between the observed and calculated values of $\log P$ are listed in Table 3. The best results were obtained when the measure d' with $k = 4$ ($r = 0.874$) was used. According to a publication,²³ both methods provide good results.

Table 3. Correlation coefficients between experimental and theoretical $\log P$ values calculated by ten methods.²³

<i>k</i>	Correlation coefficient (<i>r</i>)	
	for d'	for d''
1	0.774	0.788
2	0.854	0.821
3	0.869	0.814
4	0.874	0.846
5	0.852	0.845

Another method of the similarity analysis based on the optimal selection of similarity measure d , has been applied for the same data.²¹⁹ A set of structural fragments has been selected for the description of the structures. It was established that according to some criteria, the obtained model is more precise than that used in the other publication.²³ Even more accurate model may be obtained by varying the set of fragments, however, no such studies were performed in the discussed paper.

5. The selection of structural analogues by various molecular similarity measures

Three molecular similarity measures d_1 , d_2 and d_3 have been examined⁴³ and five structural analogues of *o*-xylene have been found according to these measures. Seven physicochemical properties (including molar volume, $\log P$, boiling point, *etc.*) were used for the description of molecules during the composing of measure d_1 . On the basis of the principal component analysis of these seven parameters, five new parameters were composed. These new parameters are linear combinations of the original ones. By coding the structures with the corresponding five-dimensional vectors, the measure d_1 was determined as a standard Euclidean metric in the space R^5 .

The measure d_2 is similar to d_1 and is based on 81 TI. Ten new descriptors were obtained from these TI by the principal compo-

nent analysis. Therefore, d_2 is defined as an Euclidean metric in the space R^{10} .

The d_3 measure is based on the atomic pairs and has been discussed earlier.

The structural formulae of the analogues of *o*-xylene selected with the help of the discussed similarity measures are listed below (the structures are arranged according to the decrease in the measure values). The result of the search for 'similar' structures depends on the measure selection. However, there are examples of coincidence between the structures found by using different similarity measures.

6. Revealing of the similarity of musk compounds by the pattern recognition theory method

A set of 300 compounds has been studied.⁶² Among these compounds 60 are musk odorants and 240 possess another fragrance (camphoric, floral, ester, mint, *etc.*). Also, the musk odorants belonged to various structural types: there were 23 macrocyclic compounds, 19 polynitrobenzenes, 11 steroids, 5 γ -butirolactones and two compounds of other types. Initially 68 descriptors (geometrical and fragmental) were used, further 13 of the most important among them were selected by TPR for

Table 4. The main descriptors used for the classification of compounds into musk and non-musk odorants.⁶²

Descriptor	Rate of correct classification
Number of O atoms	84.3
Number of double bonds	82.3
Number of aromatic bonds	80.0

	83.0

^a is an aromatic bond.

classification of these compounds into musk and non-musk odorants (Table 4). For testing of the predictive ability of the obtained descriptors, a test set of compounds has been used. This set contained 121 musk and 120 non-musk odorants not present in the initial set. As a result, 109 out of 121 musk odorants (90.1%) and 117 out of 120 non-musk odorants (97.5%) were recognised correctly.

The problem of correlation of the structure and electronic configuration with an ambergris fragrance has been studied.^{247, 248} The authors have used a combined approach based upon a combination of pattern recognition methods and quantum-chemical calculations with the precise electron-topological analysis of the potentially active parts of molecules. It appeared that the ambergris fragrance is associated with the presence in the molecular structure of so-called ambergris triangles.

7. Comparison of the accuracy of different methods of similarity analysis in the prediction of compound properties

The comparison of the prediction accuracy for various properties of chemical compounds by six methods (abbreviated as PCs, TIu, TIs, AP, TEI, MNA) of similarity analysis has been carried out.^{69, 88} The two initial sets consisted of 139 hydrocarbons with known boiling points and 15 nitrosamines with known values of mutagenicity. Three similarity methods (PCs, TIu, TIs) used the Euclidian distances as the similarity measures. In these cases various sets of the topological indices were used. These indices were obtained from 96 TI by various procedures, decreasing the dimensionality of the data.²⁵ The fourth method (AP) is based on the atomic pairs and the corresponding similarity measure (see Sections III and IV). Other methods (TEI and MNA) used the vectors composed from electrotopological indices and MNA descriptors based on the atom-centred fragments [see the measures $d_9(X, Y)$ and $d_5(X, Y)$ in Section IV and also the Section III]. The k NN method with $k = 1$ has been used for the estimation of properties.

The data of Tables 5 and 6 indicate that in the first case, the method TIs, which used the topological indices selected by the VARCLUS procedure, was the best one.²⁴ The informational indices and the connectivity indices of Kier and Hall of various orders were present in the selected set of ten TI (see Section III). This may be explained⁶⁹ by the fact that the boiling point mainly

Table 5. The comparison of efficiency of six methods of similarity analysis in the prediction of hydrocarbons boiling points.⁶⁹

Method	r	s
TIs	0.993	19.34
AP	0.986	26.26
MNA	0.985	27.89
TIu	0.983	29.36
PCs	0.966	41.29
TEI	0.959	45.37

Note. Here and in the Table 6, r is a correlation coefficient, s is a mean square deviation.

Table 6. Comparison of the efficiency of six methods of similarity analysis in the prediction of mutagenicity of nitrozoamines.⁶⁹

Method	r	s
MNA	0.945	1.25
AP	0.944	1.26

TIu	0.923	1.47
PCs	0.830	2.33
TIs	0.740	2.67

depends on the shape and the degree of branching of molecules. Both these characteristics are described well by topological indices. In the case of mutagenicity prediction (see Table 6), the MNA and AP methods based on the fragments performed better and the TEI method was at the third place. In this particular case, the TEI method is better than TI-based methods because the prediction of mutagenicity requires additional information about physicochemical characteristics of the molecules and exactly this information is contained in the electrotopological indices.⁶⁹

8. Construction of QSiAR models

The QSiAR model of affinity of fourteen *N*-substituted 3-(3-hydroxyphenyl)piperidines (Table 7) towards a σ -receptor (pIC_{50}) has been created.¹⁰⁴ The Meyer index S_{AB} (see Section IV) has been used as a measure of similarity of the structures A and B, where A is the initial (unsubstituted) compound, B are all other compounds of the set. The *R* and *S* enantiomers of the corresponding compounds were also taken into account. Two models have been composed, each of them on the basis of seven sets of compounds:

for *R* isomers ($r^2 = 0.750$)

$$pIC_{50} = -0.04 S_{AB} + 2.29,$$

for *S* isomers ($r^2 = 0.974$)

$$pIC_{50} = -10.21 S_{AB} + 9.30.$$

9. Study of the efficiency of the similarity analysis methods in the prediction of biological activity

The cross-validation method has been used for the estimation of efficiency of the similarity analysis methods in the prediction of biological activity.⁶⁹ One compound (numbered k) was excluded from the database at each step of the procedure, and the probability $P(k)$ of this compound to be active was estimated:

$$P(k) = \frac{A_k}{A_k + B_k},$$

$$A_k = (n-1)^{-1} \sum S_i^1,$$

$$B_k = (m-1)^{-1} \sum S_j^0,$$

where S_i^1 and S_j^0 are the values of similarity measure between the compound k and the active compound i and the inactive compound j , respectively; n and m are the numbers of active and inactive compounds in the training set, respectively. The summation in the expression for A_k takes place over all i values from 1 up to n (except for $i = k$). Similarly, the summation in the formula of B_k takes place over all j from 1 to m (except for $k = j$).

Let us assume that for each pair of compounds M_i and M_j , where M_i is an active compound and M_j is an inactive compound ($i = 1, \dots, n$; $j = 1, \dots, m$), the values of probabilities $P(i)$ and $P(j)$ are calculated, and N is the number of pairs, such that $P(i) > P(j)$. The quantity $IAP = N/mn$ ($0 \leq IAP \leq 1$) was used for the estimation of the prediction quality. A set of 17124 compounds with known values of 16 types of biological activity were selected from the database MDDR 96.2 (MDL Information System) as a training set for similarity analysis methods. Two modifications of similarity methods (using the Tanimoto coefficient as a similarity measure), based upon the electrotopological indices (TEI) and on the substructural descriptors (MNA), have been studied. The average accuracy of the prediction in the first case is equal to 86%, and in the second case, to 96%.

10. The optimal choice of k value in the k NN method

The efficiency of the clusterisation of molecules of various chemical databases based upon the method of k nearest neighbours depends on the choice of the parameter k .

The boiling points of 267 haloalkanes containing from 1 to 4 carbon atoms have been studied.²⁴⁹ The molecular similarity (dissimilarity) was estimated in terms of Euclidian metrics in eight-dimensional space of topological descriptors composed by the principal component analysis from a set of 59 TI. The correlation coefficients between the experimental and calculated values are in the range of 0.85 – 0.94. The chosen k values were equal to 1–10, 15, 20, 25. It was shown that the best standard deviation corresponds to $k = 5$ and equals to 23.7 °C. Similar results were obtained in other studies.^{23, 250}

11. Comparison of the efficiency of 2D and 3D descriptors in the estimation of properties of compounds

Three new databases were created on the basis of Medchem 94b database:¹⁸⁶ (i) 8651 compounds with known $\log P_{\text{octanol/water}}$; (ii) 762 compounds with known $\log P_{\text{cyclohexane/water}}$; (iii) 8416 compounds with known pK_a . Both 2D and 3D descriptors (four types) were used for coding of the structures. Particularly, the vectors, components of which were equal to the numbers of occurrences of fixed small fragments in the structures (in one case 153 fragments called MACCS, in another case 960 fragments called SSKEYS) were used. In order to estimate the properties of compounds, the preliminary clusterisation of corresponding databases has been performed by various methods and using the similarity measures. The property was calculated as an average value of all the property values of the corresponding cluster. The cross-validation procedure was employed for the estimation of the prediction quality. For this purpose, the compounds were taken out of the database one by one, and then the value of a property for this compound was calculated. These experimental and calculated property values were compared and then the correlation coefficient and the root-mean-square deviation of corresponding regression were calculated. It was found that 2D descriptors MACCS performed better in all cases. Also, the comparison of the results of calculations of $\log P$ for 7054 structures (out of 8651) was carried out by the above-mentioned methods and by a special programme CLOGP. The methods of molecular similarity yielded the values of $r = 0.95$ and the root-mean-square deviation $rmse = 0.60$, which is almost as accurate as the results of the calculations by the well known program CLOGP ($r = 0.96$, $rmse = 0.49$).

VIII. Conclusion

The molecular similarity concept ('similar compounds possess similar properties') is very popular in theoretical and experimental chemistry. One of the areas of its application, discussed in the present review, is the prediction of properties of chemical compounds on the basis of the 'molecular similarity' concept. The widespread computerisation of the chemical studies requires the formalisation of this concept and the development of methods for quantitative description of the degree of molecular similarity. Nowadays there is a number of various similarity measures, which usually deal with the structures only and are not related to any physicochemical properties or biological activity of the molecules. However, the measures may be optimally tuned to a specific task.

An important problem is the formalisation and approval of the validity of concept 'similar compounds possess similar properties'. As it was shown, the validity of this statement depends on the class of compounds, on the studied property, on the selected similarity measure, etc. The problem of formalisation of the concept is discussed in the present review for the first time. It was found that under certain conditions, this postulate is always valid, and a qualitative proof of the unformalised postulate was given.

On the basis of the analysis of published data, one can draw a conclusion that the molecular similarity method used for the prediction of properties of chemical compounds quite often yields satisfactory results. In particular, one of the advantages of the method is that the *a priori* knowledge of the type of the structure – property functional dependence is not required. Besides, the whole structural formula (a molecular graph) is used for the determination of some similarity measures and there is no need to calculate any molecular descriptors. The discovery of fullerenes is an example of usefulness of the similarity concept in chemistry: these unusual allotropes of carbon were first obtained in 1985,²⁵¹ while their existence had been predicted approximately 15 years earlier^{252, 253} on the basis of a hypothesis about similarity of electronic properties of planar polycondensed aromatic hydrocarbons and spherical polyhedral polycyclic conjugated molecules. This led to successful application to fullerenes of the mathematical models based on the resonance theory and on the Hückel method.

At the same time, it should be noted that the similarity method has some problems. Among them are the correct choice of the mathematical description of the structure, the selection of the similarity measure and the choice of the method for estimation of the properties of a compound on the basis of a similarity measure. Analysis of literature shows that there are no strict and approved methods for the solution of these problems and the selection is intuitive. Probably, here is the right place to quote a remark given by R Feynman in his Nobel lecture: 'I think equation guessing might be the best method to proceed to obtain the laws for the part of physics which is presently unknown'.²⁵⁴

Regularities in the molecular structures of stable fullerenes

V I Kovalenko, A R Khamatgalimov

Contents

I. Introduction	981
II. Stable higher fullerenes: the analysis of their structures according to the experimental and theoretical quantum-chemical data	982
III. Conclusion	987

Abstract. The literature data on the stability of fullerenes from C_{60} to C_{84} are generalised. The distribution of the π bonds in the isolated and characterised fullerenes is analysed. General regularities in the molecular structures of fullerenes are considered. It is concluded that closed electronic shells and a uniform distribution of pentagons over the molecule are characteristic of stable fullerenes. The bibliography includes 96 references.

I. Introduction

The first suggestion on the probable existence and relative stability of fullerenes was made in 1970 by Osawa,¹ who described the C_{60} molecule and substantiated its stability. This problem was also addressed in a classical study by Bochvar and Gal'pern² and, more recently, by many other authors, both experimentalists and theoreticians within various approximations.^{3–18} Fullerenes with the number of atoms in a molecule ≥ 60 can have thousands of isomers, but only those isomers that comply with the isolated pentagon rule (IPR), which is the most important condition for the stability of fullerenes, have actually been isolated and characterised. According to this rule, each of twelve pentagons of a fullerene molecule have to be surrounded by five hexagons. Nevertheless, several fullerenes with the structures violating the IPR are known, *i.e.*, obtained, isolated and characterised. These include, for instance, endohedral metallofullerenes based on C_{66} and C_{68} , which are unusual complexes containing a metal atom inside the fullerene cage.^{19–23} These complexes are rather scarce but they are a subject of intense investigations.

The meanings of the terms 'obtained', 'extracted', 'isolated' and 'characterised' (identified) have to be explained in more detail. A fullerene is considered as obtained if a signal (peak) of a certain fullerene molecule was detected in a mass spectrum of a carbon soot sample. A fullerene is called extracted if it was successfully transferred to a solution with some solvents. A fullerene is considered as isolated when a specific isomer was separated from a mixture of isomers and obtained in the individual form. Then this fullerene isomer can be characterised or identified by some experimental techniques (*e.g.*, ^{13}C NMR,

X-ray crystallography, *etc.*). Sometimes, only a minute quantity of a compound sufficient exclusively for its identification is available. In other cases, a larger amount of a fullerene isomer can be isolated for a further use.

The total number of fullerenes with the IPR structures is 51 for fullerenes from C_{60} and C_{70} to C_{84} and increases to 300 if the series is extended to C_{94} (Ref. 9). Meanwhile, the number of the obtained fullerenes does not exceed thirty. The extension of the range of the obtained fullerenes is a result of extremely laborious and resource-consuming studies conducted during the last two decades (starting from the discovery of fullerenes in 1985). Nevertheless, according to our estimates, the number of the obtained isomers of fullerenes from C_{60} to C_{94} is less than 10% of the total number of possible IPR isomers (for a series of fullerenes from C_{60} to C_{84} , this fraction is slightly smaller than 30%).

Presently, only C_{60} and C_{70} are produced on a large scale (hundreds kilograms), whereas the vast majority of higher fullerenes (with more than 70 carbon atoms) complying with the IPR are available only in milligram quantities.

The possibility of the isolation of a fullerene in the individual form is governed by its stability (both thermodynamic and kinetic). Taking into account that the term 'fullerene stability' is not obvious, its definition has to be given. For the further discussion, we shall refer those fullerenes that can be synthesised (the thermodynamic stability) and that possess reactivities allowing them remain unchanged for a long time under normal conditions, *i.e.*, in air at room temperature, (the kinetic stability) to as stable fullerenes. The fullerenes that are detected by mass spectra, but cannot be isolated will be considered unstable.

The fullerenes C_{60} and C_{70} meet the stability conditions most comprehensively. Their properties and reactivities have been thoroughly studied, since they are the most accessible compounds among all fullerenes. In particular, C_{60} remains unchanged under normal conditions for years, whereas some of higher fullerenes undergo decomposition within hours, minutes or even seconds. Still, we shall refer all fullerenes that have successfully been isolated and characterised to as stable ones leaving their finer classification for the future. Other IPR fullerenes can be subdivided into two groups. The first group includes those fullerenes that can be obtained in principle, but have not been isolated so far. The second group includes the fullerenes that cannot be obtained due to their intrinsic instability related to the specific molecular structures.²⁴ It is apparent that the first group will extend as a result of the research efforts. However, it is important to know, which fullerenes belong to these two groups and why.

A fullerene can be unstable due to an unfavourable electronic structure (an open electronic shell or the presence of one or several unpaired electrons in the molecule) or topology-related strained geometry for the closed electronic shell. In the former case, the

radical species can be stabilised by converting them into endohedral metallofullerenes.^{10, 12, 24} The discussion below is devoted to structural features of stability of proper (or 'empty') fullerenes containing no guest atoms inside the fullerene cage.

To date, a number of reviews^{3–9, 14, 15, 18, 25, 26} summarising the literature data on structural studies, functionalisation, prospective applications, *etc.* have been published. The structures and properties of most stable endohedral metallofullerenes have been analysed and surveyed by several authors.^{10–13, 16, 17, 24} Nevertheless, no general analysis of the structures of the obtained (isolated and characterised) fullerenes within the context of the search for regularities in their molecular structures has been performed so far. This review represents an attempt to accomplish such an analysis.

II. Stable higher fullerenes: the analysis of their structures according to the experimental and theoretical quantum-chemical data

1. Isolated and characterised isomers of higher fullerenes C₇₂–C₈₄

As has been mentioned above, only some of possible isomers of higher fullerenes have been detected and isolated so far. For instance, the first representatives of higher fullerenes, which are also named lost, C₇₂ and C₇₄, are still missing^{27–32} (their signals were revealed only in mass spectra of soot extracts^{27–29}). Meanwhile, their different endohedral derivatives have been characterised, such as Ca@C₇₂, La@C₇₂, La₂@C₇₂, Ca@C₇₄, Sc@C₇₄, Sc₂@C₇₄, *etc.*^{10, 19, 28, 33–38} Furthermore, the existence of fullerenes C₇₂ and C₇₄ in reduced forms was suggested, which can be explained by the fact that both the C₇₂^{2–} and C₇₄^{2–} dianions are characterised by significant energy gaps between their frontier orbitals.^{30, 31, 33}

Only one of two isomers of the fullerene C₇₆ has been isolated.^{40–42} This is characterised by a chiral structure belonging to the point symmetry group D₂.⁴³ Meanwhile, both isomers have been isolated as endohedral metallofullerenes.^{35, 37, 38, 42, 44}

Three of five isomers[†] of the fullerene C₇₈ (Ref. 39) have been isolated, *viz.*, 1 (D₃), 2 (C_{2v}) and 3 (C_{2v}).^{40, 45} According to the first report,⁴⁶ a mixture of two isomers with symmetries C_{2v} and D₃ in a 5:1 ratio was detected experimentally. However, the presence of three isomers, C_{2v}, C_{2v} and D₃, in a 5:2:2 ratio was proven later.⁴⁷ Taylor *et al.*⁴⁸ also observed the C_{2v}, D₃ and C_{2v} isomers in a ratio 5.2:3:1.8. The earlier results were qualitatively supported⁴⁹ by an analysis of the ³He NMR spectra of the endohedral fullerene He@C₇₈. Only one isomer, *viz.*, 5 (D_{3h}), has been isolated as the endohedral metallofullerene Sc₃N@C₇₈.⁵⁰

The fullerene C₈₀ attracts special attention, since this is the first higher fullerene after C₆₀ that has an isomer with the highest symmetry of a truncated icosahedron (I_h) as that of C₆₀. In contrast to the best studied buckminsterfullerene C₆₀, this isomer of C₈₀ has not been isolated as the 'empty' molecule so far. In total, the fullerene C₈₀ has seven IPR isomers:³⁹ 1 (D_{5d}), 2 (D₂), 3 (C_{2v}), 4 (D₃), 5 (C_{2v}), 6 (D_{5h}) and 7 (I_h). Up to date, two isomers have been obtained.^{50, 51} First, the isomer 2 (D₂)⁵² and then the isomer 1 (D_{5d})⁵³ have been isolated and characterised. The isomers 6 (D_{5h}) and 7 (I_h) could be isolated as endohedral metallofullerenes.^{50, 54–60}

Dozens of fullerene C₈₂ derivatives with different numbers of metal atoms inside the cage are known (*i.e.*, have been isolated and studied). Among them, four isomers were identified, *viz.*, 5 (C₂),^{61, 62} 6 (C_s),⁶³ 8 (C_{3v})⁶⁴ and 9 (C_{2v}).^{10, 65, 66} Meanwhile, only one out of nine possible isomers, *viz.*, 3 (C₂), has been isolated as the empty molecule.^{15, 67–69}

The fullerene C₈₄ takes the third place after C₆₀ and C₇₀ as regards its occurrence and abundance in fullerene-containing soots. Two of its major isomers, 23 (D_{2d}) and 22 (D₂), out of twenty-four possible isomers complying with the IPR³⁹ were identified as a 2:1 mixture by ¹³C NMR spectroscopy.^{47, 70} An analysis of the ³He NMR spectra of He@C₈₄ revealed the presence of eight isomers.⁷¹ The first attempt at their identification was performed by Taylor and co-workers.⁷² Following the separation of the isomer mixture, two less accessible high-symmetry isomers, 24 (D_{6h}) and 19 (D_{3d}), were identified.⁷³ Five isomers were then separated by multistage HPLC:⁷⁴ two isomers with the C_s symmetry and isomers with the C₂, D_{2d} and D₂ symmetries, which were ascribed to the isomers 4 (D_{2d}), 5 (D₂), 11 (C₂) and 16 (C_s), respectively. One of isomers with the C_s symmetry was not unequivocally identified (there are five possible isomers with this symmetry). Thus, only ten out of twenty-four isomers of C₈₄ have been isolated so far,^{15, 47, 70–78} including two unidentified isomers with the C₂ and C_s symmetries. Additionally, isomers 7 (C_{2v}), 10 (C_s) and 23 (D_{2d}) have been isolated as endohedral metallofullerenes.^{19, 36, 56, 79, 80}

Notes. (1) The following notations for fullerenes are adopted: TP is theoretically possible, EM is isolated experimentally as 'empty' molecules, EMF is isolated experimentally as endohedral metallofullerenes. (2) The numbers in parentheses are the numbers of theoretically possible IPR isomers of the fullerene. (3) The numbering and symmetries of fullerene isomers are given according to Ref. 39. (4) The symbol '?' marks those isomers of the fullerene C₈₄ that have presumably been isolated (taking into account their symmetries, structural and energy parameters) but not unequivocally identified.^{75, 78}

[†] Hereinafter, the enumeration of fullerene isomers, which uniquely define their molecular symmetry and bonding topology, is given according to Ref. 39.

The literature data on fullerene isomers isolated to date as 'empty' molecules and endohedral metallofullerenes are summarised in Table 1. As can be seen, the isomers that preferably occur as endohedral metallofullerenes differ, as a rule, from those that occur as 'empty' molecules.²⁴

2. The results of quantum-chemical calculations of stable fullerenes

Quantum-chemical calculations is the primary tool used to establish the stability of a specific fullerene. An analysis of the literature and our own results^{24,30,31} demonstrates that the order of the relative stabilities of isomers is reproduced in the majority of cases, irrespective of differences in the accuracy and predictive power of semiempirical and *ab initio* methods (performed either in minimum or extended basis sets, with account for the electron correlation or neglecting it). A comparative analysis of the relative total energies of *m* isomers of a fullerene C_n complying with the IPR makes it possible only to estimate probability of the isolation of a particular isomer. The total energy of the fullerene molecule and, respectively, its stability or instability depend on the mutual arrangement of pentagons, which defines the surface curvature of the molecule, the presence of fused hexagons and electronic effects. According to correlation of the calculated total energies for fullerene isomers the isolated fullerenes possess the minimum total energies among the IPR isomers of the fullerene in question. This is a reliable test for stability. Meanwhile, for fullerenes with only one IPR isomer, nothing but total energy value can be stated.

However, the total energies alone are insufficient for the prediction of probability of the synthesis of IPR isomers. In particular, 8 isomers of the fullerene C_{84} have been isolated and characterised. On the scale of relative energies, they all are located from 0 to 18 kcal mol⁻¹ with respect to the energetically most favourable isomer, 23 (D_{2d}).⁷⁵ The number of stable fullerenes from C_{70} to C_{84} estimated by taking this energy range as the stability criterion and extending it to other higher fullerenes should be significantly larger. And it remains unclear whether the missing isomers can be synthesised at all.

Unfortunately, there are currently no satisfactory criteria for the evaluation of the stability and possibility of the synthesis of fullerenes. Diener and Alford suggested³³ to subdivide all fullerenes into two groups: fullerenes with a large energy gap between the highest occupied and the lowest unoccupied molecular orbitals (HOMO–LUMO) (these include fullerenes C_{60} and C_{70}) and fullerenes with either a small HOMO–LUMO energy gap or even a radical structure (*i.e.*, with one or more unpaired electrons). A similar classification was proposed by Stevenson and co-workers⁸¹ based on electrochemical studies of fullerenes. In other words, the HOMO–LUMO energy gap was suggested as a simple criterion for the stability of fullerenes. Indeed, a large gap between the frontier orbitals implies a high stability and low reactivity of the molecule. However it was found that this criterion, the HOMO–LUMO energy gap, alone is not always sufficient for the prediction of the stability of fullerenes. To provide a more unambiguous estimate for the kinetic stability of fullerenes, the HOMO–LUMO energy gap should be correlated to the number *n* of conjugated carbon atoms in the fullerene molecule C_n and supplemented with other parameters,⁸² such as the bond resonance energy (which represents the contribution of a given π bond of the molecule to the total topological resonance energy⁸³) or the localisation energy (which characterises the heat of protonation of the respective fullerene⁷⁶). Using such a scheme, Aihara⁸³ concluded that fullerenes with the bond resonance energies smaller than $-0.100|\beta|$ and with small or zero HOMO–LUMO energy gap multiplied by the number of carbon atoms in the fullerene molecule are unstable. Nevertheless, the values of these parameter for some higher fullerenes that have not been isolated so far are nearly the same as those for C_{60} . In particular, this scheme fails to explain the impossibility of isolation of fullerenes C_{72} and C_{74} or

isomers 1 (D_2) and 20 (T_d) of the fullerene C_{84} , despite these molecules meet the above criteria.

Thus, the conventional quantum-chemical calculations and the stability criteria considered above fail to fully explain the instability of some fullerenes. This may be due to the lack of analysis of the local stability, *i.e.*, the stability of substructures that constitute the fullerene molecule. Such substructures were ignored in the earlier theoretical calculations predominantly focused on the molecules as a whole.⁸⁴ It might be hoped that the analysis of the electronic structures of stable (*i.e.*, isolated) fullerenes from this viewpoint will help revealing common regularities in their molecular structures.

3. Analysis of molecular structures of stable fullerenes

According to an approach developed by Kovalenko and Semyashova,^{85,86} the distribution of π bonds over the fullerene molecules in the series from C_{60} to C_{84} can be represented as the Schlegel diagrams. These diagrams show the positions of localised double and delocalised π bonds. A number of characteristic substructures with distinct electronic structures (as in their aromatic analogues: naphthalene, indacene, pyrene, perylene, corannulene, coronene, *etc.*) can be identified by analysing the local symmetry in the distribution of single, double and π bonds delocalised over the hexagons of the fullerene molecules. These substructures retain their electronic properties irrespective of the fullerene molecule they belong to.

Two types of bonds occur in the C_{60} molecule (Fig. 1 *a*): the five-membered rings are composed of single bonds, whereas single and double bonds alternate in the six-membered rings.⁸⁷ The C_{60} molecule (I_h) comprises exclusively corannulene substructures (Fig. 2 *a*) and is characterised by a uniform distribution of the pentagons over the molecule. The C_{70} molecule (Fig. 1 *b*) can be regarded as two poles with the same pattern of the bond distribution as in C_{60} and an equatorial belt composed of five hexagons with the delocalised π bonds^{10,88} forming five indacene substructures (Fig. 2 *b*). Thus, only two substructures, *viz.*, corannulene and indacene, occur in these two fullerenes. It would be reasonable to suggest that these substructures constituting the stable fullerenes C_{60} and C_{70} are characterised by the highest stability.⁸⁸

As has been mentioned above (see Table 1), two next fullerenes, C_{72} (D_{6d}) and C_{74} (D_{3h}), have not been isolated so far as 'empty' molecules.^{27–32} In the case of C_{72} , this can be explained by the presence of two coronene substructures in the molecule (Fig. 2 *c*), which induce large sterical strains: these substructures are planar, whereas the fullerene cage tends to be spherical.^{24,31} The instability of C_{74} can be explained by its biradical structure due to the presence of two phenalenyl radical substructures (Fig. 3).^{24,30,32}

Figure 1. The Schlegel diagrams of the fullerenes C_{60} (*a*) and C_{70} (*b*). Hereinafter, all pentagons are marked grey; single and double bonds are marked with single and double lines, respectively. The hexagons with the delocalised π bonds are marked with circles.

Figure 2. Characteristic substructures of stable fullerenes: corannulene (a), indacene (b), coronene (c) and perylene (d).

Figure 3. The phenalenyl radical substructure.

According to quantum-chemical calculations,⁸⁹ the difference in the total energies of two possible isomers of fullerene C_{76} (see Table 1) exceeds 12 kcal mol^{-1} . An analysis of the molecular structure of the energetically most favourable isomer 1 (D_2) (Fig. 4), which has been obtained experimentally, demonstrates that the distribution of the π bonds therein is similar to that in the C_{70} molecule: it includes four corannulene (see Fig. 2 a) and four indacene (see Fig. 2 b) substructures. The presence of four phenalenyl radical substructures (see Fig. 3) is a possible reason for the instability of the second isomer, 2 (T_d), which has not been obtained.

According to theoretical calculations reported in the literature^{9, 18, 40, 45, 90, 91} and our own data^{24, 30, 31} (Fig. 5),[‡] five possible isomers³⁹ of fullerene C_{78} can be arranged in the following series of decreasing stability: 3 (C_{2v}), 2 (C_{2v}), 1 (D_3), 5 (D_{3h}) and 4 (D_{3h}). Up to date, three most stable isomers of the above series (see Table 1) have actually been obtained and isolated experimentally.^{40, 45–49} The distribution pattern of the π bonds in the isomer 1 (D_3) (Fig. 6 a) is similar to that in C_{70} . Meanwhile, one coronene substructure occurs in the isomer 2 (C_{2v}) (Fig. 6 b) in addition to four indacene substructures (see Fig. 2 c). The isomer 3 (C_{2v}) (Fig. 6 c) contains one perylene substructure (see Fig. 2 d).

Although two coronene substructures make the fullerene C_{72} unstable,^{31, 92} their presence becomes less critical for larger fullerenes, which can remain stable. Nevertheless, the occurrence of three or more coronene substructures in one molecule dramati-

Figure 4. The Schlegel diagram of the fullerene C_{76} [the isomer 1 (D_2)].

Figure 5. Relative energies of IPR isomers of the fullerene C_{78} calculated at the following theory levels: B3LYP/STO-3G (1), B3LYP/3-21G (2), B3LYP/6-31G* (3), B3LYP/6-31G (4); (1–3) from Ref. 40, (4) the present authors' data. Hereinafter, the arrows point to the obtained isomers.

Figure 6. The Schlegel diagrams for experimentally obtained isomers of the fullerene C_{78} : 1 (D_3) (a), 2 (C_{2v}) (b) and 3 (C_{2v}) (c).

cally destabilise it due to the development of substantial strain. Thus the calculations the isomer 4 (D_{3h}) of the fullerene C_{78} , which includes three coronene substructures, is the least stable. High kinetic instability of the isomer 5 (D_{3h}) of the fullerene C_{78} is probably⁹⁰ the rationale for the fact that it cannot be obtained.

In the case of the fullerene C_{80} , the isomers 1 (D_{5d}) and 2 (D_2) (Fig. 7) are characterised by the lowest total energies according to calculations.^{9, 18, 51, 93–95} It is these two isomers (out of seven

[‡] Hereinafter, all calculations were performed using the DFT/B3LYP method with the full geometry optimisation in the 6-31G basis set; the total energies were recalculated for the optimised geometries in the 6-31G* basis set.

Figure 7. Relative energies of IPR isomers of the fullerene C_{80} calculated at the following theory levels: B3LYP/STO-3G (1), B3LYP/3-21G (2), B3LYP/6-31G* (3), B3LYP/6-31G (4); (1–3) from Ref. 93, (4) the present authors' data.

possible ones³⁹) that have actually been isolated and identified^{50–53} (see Table 1). The energy of the isomer 3 (C_{2v}), which has not been synthesised so far, is higher by ~ 5 kcal mol^{−1} than those of the isolated isomers 1 (D_{5d}) and 2 (D_2). This is rather surprising taking into account that the respective energy difference between the most stable isomer and other experimentally obtained isomers for other fullerenes, *e.g.*, for C_{84} , by far exceeds this value.

As for the distribution pattern of the π bonds in the isomers under discussion, the molecular structure of the isomer 1 (D_{5d}) (Fig. 8a) is similar to that of C_{60} since it contains only corannulene substructures (see Fig. 2a). The molecular structure of the isomer 2 (D_2) (Fig. 8b) is analogous to that of C_{70} : it contains two indacene substructures in addition to the corannulene structures (see Fig. 2b). Molecules of all other isomers contain different number of phenalenyl radical substructures^{24,30} (see Fig. 3). The isomer 7 (I_h) probably represents an unusual radical structure with the π bonds delocalised over all fused hexagons; this has no analogues. Undoubtedly, the number of unpaired electrons in a fullerene molecule affects its kinetic stability.

Figure 8. The Schlegel diagrams of the experimentally obtained isomers of the fullerene C_{80} : 1 (D_{5d}) (a) and 2 (D_2) (b).

According to numerous calculations,^{9,15,18,67–69} the isomer 3 (C_2) of the fullerene C_{82} is characterised by the minimum total energy among its nine IPR isomers³⁹ (Fig. 9a). Accordingly, it is the only isomer that has been obtained to date^{15,67–69} (see Table 1). Its molecular structure (Fig. 9b) features a combination of four corannulene (see Fig. 2a) and four indacene (see Fig. 2b) substructures. Despite the isomers 1 (C_2), 2 (C_s) and 4 (C_s) possess similar structures (in addition to the corannulene substructures, they include two, three and two indacene substructures, respectively²⁴), they have not been obtained so far. Other five isomers²⁴ are described by the molecular structures with

Figure 9. Relative energies of IPR isomers of the fullerene C_{82} (a) and the Schlegel diagram of the experimentally obtained isomer 3 (C_2) (b). The calculations at the following theory levels: (1) B3LYP/STO-3G, (2) B3LYP/3-21G, (3) B3LYP/6-31G*, (4) B3LYP/6-31G; (1–3) from Ref. 67, (4) the present authors' data.

phenalenyl radical substructures (see Fig. 3), which are responsible for their instability.

The results of quantum-chemical calculations for 24 isomers of the fullerene C_{84} are depicted in Fig. 10. Only 10 of them have been isolated. The isomers 4 (D_{2d}), 5 (D_2), 11 (C_2), 16 (C_s), 19 (D_{3d}), 22 (D_2), 23 (D_{2d}) and 24 (D_{6h}) have been reliably identified, whereas only point symmetry groups, *viz.*, C_2 and C_s , have been determined for the remaining two isolated isomers^{15,47,70–78} (see Table 1). Indeed, according to calculations,^{9,15,18,75,76,89} the

Figure 10. Dashed arrows indicate the most probable candidates for the isolated, but not identified isomers.^{75,78}

Figure 11. The Schlegel diagrams of the experimentally obtained isomers of the fullerene C_{84} : 4 (D_{2d}) (a), 5 (D_2) (b), 11 (C_2) (c), 16 (C_s) (d), 19 (D_{3d}) (e), 22 (D_2) (f), 23 (D_{2d}) (g) and 24 (D_{6h}) (h).

isomers 11, 16, 19, 22, 23 and 24 are the most energetically stable. Meanwhile, the total energies of other two isolated isomers, 4 and 5, are comparable to that of the isomer 15 (C_s). Presumably, the latter is the unidentified isolated isomer with the C_s symmetry. The second unidentified C_2 isomer can then be interpreted as the isomer 13, which is the most stable one among molecules with this symmetry containing no radical substructures [in contrast to the isomer 8 (C_2), which is characterised by a somewhat lower total energy]. The energy difference between the most stable isomer and other isomers obtained for this fullerene lies in the range⁷⁵ of 10–15 kcal mol⁻¹, which by far exceeds the aforementioned value of ~ 5 kcal mol⁻¹ for C_{80} .⁹³

The molecular structures of eight identified isomers are shown in Fig. 11. It is apparent that only corannulene (see Fig. 2a) and indacene (see Fig. 2b) substructures occur in the isomers 4, 5, 11, 19, 22 and 23. In the isomer 16, one coronene substructure (see Fig. 2c) appears, and the isomer 24 contains two such substructures, which supports the suggestion that the destabilising influence of the coronene substructure attenuates with an increase in the fullerene size. Taking into account the results of computation discussed above, a fullerene appears unstable if it includes radical substructures (*i.e.*, it has one or more unpaired electrons) or planar substructures with a large number of fused hexagons (*e.g.*, coronene, ovalene, *etc.*).

The question ‘why the number of isolated isomers of certain fullerenes is larger than that for some others, despite a larger scatter in the total energies in the former case?’ has no clear answer up to now. Nevertheless, some comparisons can be made based on the available data. Let us consider the general correlation between the stability of a fullerene and its total energy. The total energies and standard enthalpies of formation per carbon atom (*i.e.*, TE/n and $\Delta H_f/n$, respectively) are useful for such a comparative analysis. Trends in TE/n and $\Delta H_f/n$ as a function of n have been analysed by Khamatgalimov and Kovalenko⁹⁶ based on the literature data^{9,15,18} and own computation results (Fig. 12). This graph reveals a specific ‘beam’ of stability. Its top border is defined by the minimum total energies and enthalpies of forma-

tion (TE/n and $\Delta H_f/n$, respectively) typical of the most stable fullerenes, including C_{60} , C_{70} , C_{84} [the isomers 23 (D_{2d}) and 22 (D_2)] and the isomer 133 (C_2) of fullerene C_{94} . The bottom border of the ‘beam’ is defined by the maximum total energies and enthalpies of formation for all known stable isomers of fullerenes C_n . The instability region lies just below this border.

The prominent trend towards a decrease in the energy with an increase in the number of carbon atoms (*i.e.*, in the fullerene size) is of particular note. Apparently, this trend reflects a progressive relieve of strains in spherical molecules on going from C_{60} to larger

Figure 12. Changes in the total energies (1, 3) and standard enthalpies of formation (2) per carbon atom for the synthesised, isolated and characterised stable fullerenes C_n as a function of n ; (1) from Ref. 96; (2) from Refs 9, 18; (3) from Ref. 15.

higher fullerenes. We emphasise that it is the C_{60} and C_{70} molecules that are the most strained and, at the same time, the most stable in the series. Probably, a rather uniform distribution of the local strains over the entire molecule is realised therein due to a respective uniform distribution of the pentagons. For other fullerene molecules, despite their larger sizes, steric strains can be localised in specific regions of the sphere thus destabilising the entire molecule. Yet another important feature of the plot shown in Fig. 12 is that the 'beam' of stability encompasses all known stable fullerenes complying with the isolated pentagon rule.

Based on this 'beam' of stability, a simple scheme for the prediction of the number of stable isomers for any fullerene can be suggested. If the most energetically favourable isomer of a fullerene C_n is located at the upper border of the 'beam', the isolation of other stable isomers of this fullerene might be expected with total energies falling in the interval between the upper and the lower points of the 'beam'. For instance, for C_{84} , this interval amounts to 25 kcal mol^{-1} (and 10 isomers of this fullerene with a total energy gap of 20 kcal mol^{-1} have been obtained and characterised). It might be assumed that within the range of 25 kcal mol^{-1} , several other isomers of this fullerene might be isolated in future, including 6 (C_{2v}), 15 (C_s), 12 (C_1), 14 (C_s), 17 (C_{2v}), 7 (C_{2v}), 13 (C_2) and 21 (D_2) with closed electronic shells. At the same time, only two isomers of the fullerene C_{80} with a total energy difference of only 5 kcal mol^{-1} have been obtained, although their calculated total energies are located near the bottom border of the 'beam' of stability. Under these circumstances, the isolation of any other isomers is hardly possible. And to the contrary, the probability of the isolation of new isomers is high for the fullerenes with the most energetically favourable isomer lying near the upper border of the 'beam' of stability (as in the aforementioned case of C_{84}). Despite the evident predictive power of this scheme, this is based on the use of the integral molecular parameters, *viz.*, their total energies, which prevents the analysis of reasons underlying the stability or instability of certain isomers.

The energies, geometric and electronic structures of fullerene molecules can be calculated irrespective of whether they have experimentally been obtained. However, analysis of the total energies (or enthalpies of formation) cannot confidently predict the possibility of the isolation of a specific fullerene isomer. The newly suggested approach summarised in Fig. 12 enables such a prediction. A fullerene may be unstable due to a number of factors related to its geometric and electronic structures. The 'beam' of stability reflects the net result of all these effects, thus making it possible to estimate the possibility of isolation (*i.e.*, the stability) of a target isomer based solely on its energy characteristics. In particular, this plot that also includes the data for the most stable fullerene isomers from C_{86} to C_{102} predicts stability of isomers of the fullerenes C_{86} , C_{88} , C_{92} , C_{94} and C_{100} and instability of C_{98} . Supplementation of this plot with new points for the fullerenes discussed already and its extension to larger fullerenes C_n with $n > 84$ will allow prediction of the stability of particular isomers.

III. Conclusion

Owing to the detailed analysis of the electronic structures of stable (isolated) fullerenes, common regularities of their molecular structures have been revealed. In particular, all stable fullerenes

(1) represent molecules with closed electronic shells, which are characterised by a relatively uniform distribution of pentagons over the sphere;

(2) comprise corannulene and indacene substructures typical of the most stable fullerenes C_{60} and C_{70} . The presence of perylene and coronene substructures is also possible. The latter substructures substantially destabilise the molecules of the first members of higher fullerenes, but their destabilising effect attenuates with an increase in the number of carbon atoms in the molecule.

It has been shown that the possibility of the synthesis and isolation of an isomer of a higher fullerene is governed by the

location of the energetically most favourable isomer of this fullerene in the suggested 'beam' of stability that has been constructed by correlating the theoretical and experimental data on stable of fullerenes with closed electronic shells.

This study was performed within the framework of the programme 'Theoretical and experimental investigations into the nature of chemical bonding and mechanisms of the most important chemical reactions and processes' supported by the Division of Chemistry and Materials Science of the Russian Academy of Sciences and partially supported by the U.S. Civilian Research and Development Foundation (CRDF) within the programme 'Basic Research and Higher Education' (BRHE).

Abstract. The results of studies of light-created chemiluminescence are described systematically. Conditions for the transformation of a dark chemical reaction into a chemiluminescence reaction are considered. Examples of photosensitised and photo-induced processes as well as of analytical applications are given. The bibliography includes 161 references.

I. Introduction

In darkness at ambient temperatures, electronic excitation of molecules involved in chemical reactions is not a routine event. However, if such an event happens, it has a reliable witness, namely, light emission. No matter how intricate and unclear the chemical processes in the reactor may be, the observation of chemiluminescence (CL) unambiguously points to electronic excitation. Chemiluminescence is a remarkable example of the conversion of chemical energy into light energy. Electronic excitation in the chemiluminescence is due to the energy liberated in an elementary act of the reaction on the way from the activated state to the products and, broadly speaking, is rather improbable. Correspondingly, relatively few chemiluminescence reactions are known.

It can be assumed that the effect of light on reactants or a reaction mixture (*i.e.*, the delivery of additional energy) will allow overcoming the energy limitations and transform a dark reaction into chemiluminescence. Indeed, over the last 40 years compounds have been found that, being preliminarily illuminated, give rise to CL. The diversity of such systems is associated with the variety of types of interaction of light with matter and their different chemical consequences.

This review is aimed at the systematisation of the results of studies of light-created chemiluminescence systems, their classification and the refinement of terminology used for their description. The latter problem is associated with the fact that along with already accepted terms, for example, photosensitised CL, photochemiluminescence and light-induced CL, exotic terms such as

optically pumped CL, photostoragechemiluminescence, *etc.*, are encountered.

The interaction between reactants that constitute a chemiluminescence system results in the electronically excited products or intermediates and light emission; this is why all starting components of a chemiluminescence system are justly referred to as chemiluminescent reactants. Among the components of a liquid-phase chemiluminescence reaction, one can single out a reactant that according to its composition and structure is the precursor of the primarily excited species and the light emitter.[†] It is this reactant that brings in individual features into the chemiluminescence system. To distinguish it from other reactants, it is called 'chemiluminophore'.[‡] For liquid-phase CL, molecular oxygen [its concentration in aerated solutions varies from 0.2 (in H₂O) to 4 mmol litre⁻¹ (in Et₂O)] and the solvent are the key reactants.

The present review deals with photosensitised oxidation of chemiluminophores with molecular oxygen. Attention is focused on chemiluminophores obtainable from precursors by photochemical mechanisms involving oxygen and solvent, as well as on chemiluminescence systems in which the light-induced intramolecular rearrangement of a molecule occurs.

II. Photosensitised chemiluminescence

Molecules and supramolecular structures can store for a while the energy of absorbed light quanta, being converted into the electronically excited state. The excitation energy is usually lost upon non-radiative transition of the molecule into its ground state; however, in certain cases the energy can be emitted as a luminescence quantum or transferred to other molecules, namely, quenchers. In the latter case, luminescence of the primary excited compound is quenched. The question of what happens if dissolved oxygen acts as the quencher, was raised by Kautsky back in the 1930s.⁵ The studies of luminescence quenching with oxygen led to the discovery of singlet oxygen⁶ and gave rise to a concept of 'active oxygen forms' (species OH[•], O₂H[•], O₂^{•-}, ¹O₂). Combined studies of photooxidation⁵ and chemiluminescence, which, as a

[†] For chemiluminescence reactions in the gas phase, such a reactant can be singled out only in rare cases, *e.g.*, in reactions involving volatile low-molecular dioxetanes, whereas the involvement of all reactants of the chemiluminescence system 'on equal terms' is typical.

[‡] This term, which was introduced by analogy with 'luminophores', *i.e.*, substances that emit light upon activating radiation, is encountered with increasing frequency in the literature (see Refs 1–4).

rule, was observed in the oxidation,⁷ initiated studies on the phenomenon of photosensitised chemiluminescence (PSCL).

1. Photooxidation

IUPAC defines photooxidation as the oxidation reactions initiated by light. In a more general form, these are the reactions in which a reactant loses an electron upon the absorption of a photon and also the light-induced reactions of substances with oxygen (a process in which a chemical bond is formed between oxygen and the substance is called photooxygenation).

Two types of photosensitised oxidation processes in liquid phase are distinguished.⁸ Type I processes include reactions of the substrate (RH, R) with a sensitizer in the electronically excited triplet state (³S), or photoionisation reactions. Type II processes correspond to the interaction of an electronically excited sensitizer with an oxygen molecule. Each type includes reactions of several kinds (Table 1).

Table 1. Classification of photosensitised oxidation processes.

Type I	Type II
a. Free-radical oxidation $^1S_0 + h\nu \longrightarrow ^1S^* \longrightarrow ^3S$, $^3S + RH \longrightarrow SH^\cdot + R^\cdot$, $(R^\cdot + ^3O_2 \longrightarrow ROO^\cdot)$	a. Oxidation involving singlet oxygen $^1S_0 + h\nu \longrightarrow ^1S^* \longrightarrow ^3S$, $^3S + ^3O_2 \longrightarrow ^1S_0 + ^1O_2$, $RH + ^1O_2 \longrightarrow \text{products}$
b. Oxidation with electron transfer $^1S_0 + h\nu \longrightarrow ^1S^* \longrightarrow ^3S$, $^3S + R \longrightarrow S^{\cdot-} + R^{+\cdot}$, $(S^{\cdot-} + ^3O_2 \longrightarrow S + O_2^{\cdot-})$, $R^{+\cdot} + O_2^{\cdot-} \longrightarrow \text{products}$	b. Oxidation with electron transfer $^1S_0 + h\nu \longrightarrow ^1S^* \longrightarrow ^3S$, $^3S + ^3O_2 \longrightarrow [^1S_0 \cdots ^1O_2]^? \longrightarrow$ $\longrightarrow S^{+\cdot} + O_2^{\cdot-}$, $RH + O_2^{\cdot-} \longrightarrow \text{products}$
c. Single-photon ionisation $^1S_0 + h\nu \longrightarrow S^{+\cdot} + e^-$, or two-photon ionisation $^1S_0 + h\nu \longrightarrow ^1S^* \longrightarrow ^3S$, $^3S + h\nu \longrightarrow S^{+\cdot} + e^-$	c. Oxidation to form a biradical $^1S_0 + h\nu \longrightarrow ^1S^* \longrightarrow ^3S$, $^3S + ^3O_2 \longrightarrow ^\cdot SOO^\cdot$, $RH + ^\cdot SOO^\cdot \longrightarrow \text{products}$

Note. ¹S₀, ¹S*, ³S are ground (non-excited), excited singlet and triplet states of the sensitizer molecule, respectively. In parentheses, the possible subsequent reactions are shown.

Several relatively simple tests allow one to determine the type of a photosensitised oxidation process in a system under study.

(1) The formation of singlet oxygen is inhibited by quenchers among which 1,4-diazabicyclo[2.2.2]octane (DABCO), carotenoids and sodium azide are the most popular.

(2) Radical processes are sensitive to scavengers, *i.e.*, traps of free radicals.

(3) Free-radical oxidation depends on the temperature, whereas oxidation that involves singlet oxygen is temperature independent.

(4) Involvement of singlet oxygen in the oxidation reaction can be confirmed by an independent synthesis using singlet oxygen formed in a chemical reaction [*e.g.*, from triphenyl phosphite ozonide P(OPh)₃O₃].

(5) Reactions that involve a superoxide ion are sensitive to superoxide dismutase.

(6) Reactions that involve solvated electrons are sensitive to the presence of N₂O (trap).

The phenomenon of sensitisation, which is associated with the enhanced reactivity of a molecule in the excited state, occurs also when the substrate itself plays the role of the sensitizer (S = RH). In this case, the process is referred to as autosensitisation.

2. Pigments and dyes

In 1951, persistent afterglow of chlorella photosynthesising cells following their illumination at 420–700 nm was discovered.⁹ Studies of this phenomenon were continued with simpler objects. It was noticed¹⁰ that red CL observed upon mixing of a chlorophyll solution with a formaldehyde solution in alkaline methanol, becomes more intense when the reaction mixture has been illuminated. Persistent afterglow was also observed¹¹ in aerated solutions of chlorophyll and pheophytin.

Comprehensive studies of PSCL of chlorophyll and its analogues were carried out by Krasnovsky (Jr) *et al.*^{12–17} In a review,¹⁷ the major experimental approaches to investigations of light-created CL have been outlined and, first of all, the process has been proposed to be divided into photochemical and chemiluminescence stages. Studies of the photochemical stage involve the determination of an action spectrum of the exciting light, the elucidation of the role of oxygen in the photoirradiation and the determination of the nature of the primary photoproduct. The use of thermograms of CL ignition in the course of heating of deeply frozen photoirradiated aerated solutions has been pioneered in studies of the chemiluminescence stage. Thermograms reflect the involvement of various labile photoproducts in CL (*i.e.*, in 'photo-thermochemiluminescence').

The efficiency of chlorophyll PSCL is low, namely, one emitted quantum per 10⁸ absorbed quanta. The general scheme of PSCL of chlorophyll (Chl) can be represented as the following reaction sequence:

Light quanta are radiated by emitters Y₁, Y₂, ..., *i.e.*, the products of chlorophyll oxidation.

PSCL of aerated solutions of fluorescein (1), erythrosine (2), eosin Y (3), Rose Bengal (4), rhodamine B (5), safranin (6), thionine (7), Methylene Blue (8), Acridine Orange (9), anthracene and naphthacene was discovered and studied,^{14,17} as well as of pyrene and benzopyrene.¹⁸

The presence of dissolved oxygen at the moment of illumination is a prerequisite for persistent afterglow of the compounds listed. The PSCL yield for solutions of compounds **2–4** is maximum in aprotic solvents such as acetone, dioxane, DMF, DMSO. The PSCL spectra differ from the fluorescence spectra of the original compounds. Thus the fluorescence peak of compound **8** is at ~ 700 nm, while its PSCL peak is at ~ 560 nm. Based on the studies of the glow decay kinetics and the analysis of photo-thermochemiluminescence curves, it was concluded that PSCL starts with the formation of several types of labile peroxide compounds.

The observed phenomenon was called^{12–17} photochemiluminescence,⁸ its main feature is photooxidation of the starting compounds in the presence of oxygen.

3. Luminol

In 1961, it was discovered¹⁹ that in aerated solutions containing luminol (5-amino-2,3-dihydrophthalazine-1,4-dione, **10**), a dye (eosin, fluorescein) and a base, chemiluminescence occurs upon irradiation in the region of the dye absorption band. The PSCL spectrum coincided with the CL spectrum of luminol in the presence of an oxidant and corresponded to the fluorescence spectrum of 3-aminophthalate (**11**), *i.e.*, the oxidation product and the CL emitter.

Kuschnir and Kuwana¹⁹ assumed luminol to be oxidised by singlet oxygen, which at that time was considered (and for a good reason) as the driving force of many reaction mechanisms. (It should be noted that Foote's study²⁰ in which he attributed the photosensitised oxidation of substrates to the electron transfer rather than the action of singlet oxygen was published much later.)

This mechanism was called into question in a study by Matheson and Lee,²¹ who, based on the kinetic analysis, ruled out the possibility of direct involvement of singlet oxygen in PSCL. Later, in the determination of the rate constant for the luminol reaction with $^1\text{O}_2$ ($\sim 3 \times 10^7$ litre mol⁻¹ s⁻¹), it was shown that the structure of the final product of luminol oxidation with singlet oxygen differed from that of compound **11**. The CL yield in the luminol reaction with singlet oxygen was $< 3 \times 10^{-9}$ per luminol molecule, which is infinitesimally small as compared with the quantum yield of PSCL.²²

A detailed study of PSCL of luminol and other phthalohydrazides was carried out by Emokhonov and co-workers.^{23–27} They used eosin and Methylene Blue as the photosensitisers. The action spectrum of light for PSCL coincided with the absorption spectra of these dyes. In the UV region, which corresponds to the luminol absorption, autosenitisation occurred, *i.e.*, in the UV illumination, luminol itself served as the photosensitiser. Both photochemiluminescence and autosenitised CL of luminol were quenched by superoxide dismutase. Hence, superoxide ions play an important role in PSCL of luminol. This catalytic cycle (see Table 1, type Ib) includes the following stages:

(1) light absorption by the sensitiser and its transition into the triplet state;

(2) electron transfer from a luminol molecule to the triplet sensitiser to form radicals (or radical ions) of the sensitiser and

luminol (under the experimental conditions, *i.e.*, in a phosphate buffer with pH 10–12, luminol, eosin and their radicals exist in the form of anions, while Methylene Blue exists in the form of a cation, and its radical is neutral);

(3) oxidation of the sensitiser radical with dissolved oxygen to afford a superoxide ion and to recover the sensitiser in its original state.

The rate constant for the third stage is 2×10^8 litre mol⁻¹ s⁻¹ for eosin and 5×10^5 litre mol⁻¹ s⁻¹ for Methylene Blue. The reaction of the luminol radical with a superoxide ion is the key stage of the luminescence pathway of luminol reaction, its rate constant is $\sim 7 \times 10^7$ litre mol⁻¹ s⁻¹. It was shown that the reaction of luminol with singlet oxygen afforded an unstable product that quenched PSCL. Its lifetime amounts to minutes and seconds when isoluminol and 4-dimethylaminophthalohydrazide are used. This explains the intricate (with two peaks) kinetic curve of PSCL of these compounds. The formation of a quencher complicates the CL kinetics. The side effect could be avoided if the PSCL experiments employed pulsed illumination rather than stationary.²⁴ Figure 1 *a* shows the kinetics of luminol PSCL initiated by a flash of ~ 10 μs ($\lambda > 610$ nm) from a flash lamp.

PSCL of luminol induced by radiation from a pulsed laser ($\lambda = 530$ nm) and a stationary source was studied.²⁸ Figure 1 *b* shows the PSCL spectrum for the laser stimulation. The marked segments correspond to chemiluminescence caused by the involvement of singlet oxygen (type II) and initiated by the electron transfer (type I). A comparison of curves in Figs 1 *a, b* shows that they substantially differ, first of all, in the time intervals of the

Figure 1. PSCL spectra of luminol with a sensitiser excited by filtered light from a pulse lamp ($\lambda > 610$ nm, CL registration in a band at 380–480 nm) (*a*) and a laser pulse ($\lambda \sim 530$ nm, registration at 420 nm) (*b*).²⁸

§At present, the term 'photochemiluminescence' is understood as a mnemonic code of the sequence of operations with the reaction mixture (or as a protocol of the experiment), *cf.* the use of the term 'photo-thermochemiluminescence' mentioned above.

PSCL evolution. The assignment of the initial flash to the chemiluminescence induced by the formation of singlet oxygen has not yet been proved. The role of $^1\text{O}_2$ in the luminol PSCL might be clarified by the detection of emission in two spectral channels, *viz.*, in the blue region of the luminol CL emission band and at 1270 nm in the emission band of singlet oxygen.

The kinetics of autosensitised CL of luminol upon the pulsed-laser UV irradiation ($\lambda = 347$ nm) was studied.²⁷ It was shown that the primary process corresponds to the one-photon ionisation of luminol to afford a luminol radical and a hydrated electron (e_{aq}). The latter is captured by dissolved oxygen to form a superoxide ion. The subsequent reaction of the luminol radical with the superoxide ion is accompanied by chemiluminescence. Scheme 1^{29–31} shows the mechanism of this process and the structures of reactants and intermediates.

Scheme 1

Structures of LH_2 (**10**), LH^- , $\text{LH}^\bullet$ and $\text{L}^{\bullet-}$ can be presented as tautomeric equilibrium forms (1)–(4), respectively,

To explain the PSCL of luminol, a general scheme of photosensitised oxidation according to which luminol is the oxidised substrate was used.³² From our viewpoint, the new name of this phenomenon, 'optically pumped chemiluminescence', offers less information.

Although the nature of luminol PSCL long remained unclear, this phenomenon was already used in the medical and biological studies of antioxidants.^{33–39} Certain progress was achieved in the application of PSCL for the analysis of antioxidant activity of substances; however, the applicability of PSCL for these purposes has recently been questioned because of the absence of any correlation in the activity estimates made using PSCL and other methods.⁴⁰ It is the fact that in luminol PSCL the main targets of antioxidants are luminol radicals and superoxide ions that probably accounts for the lack of correlation.

Photosensitised chemiluminescence of luminol was also proposed³² to be used for the detection of antibodies covalently stained with Methylene Blue (up to 16 photosensitiser molecules per antibody); based on this reaction, a method of immunochemical assay of α -fetoprotein has been developed (detection limit 1.7×10^{-11} g).

4. Lucigenin and analogues of luciferin

Lucigenin (*N,N'*-dimethylbiacridylum ion, **13**), like luminol, is a widely known chemiluminophore the oxidation of which is accompanied by bright CL.

Riboflavin-photosensitised chemiluminescence of lucigenin was studied.^{41,42} UV irradiation of riboflavin generates superoxide radical ions the reaction of which with lucigenin leads to excited *N*-methylacridone (**14**), which is the chemiluminescence emitter (Scheme 2). This mechanism is confirmed by the fact that the addition of superoxide dismutase into the reaction mixture quenches the glow. The addition of methionine into the reactor is aimed at reduction of riboflavin radicals.

Scheme 2

In the 1980s, chemiluminophores **15**, which represent the analogues of luciferin (coelenterazine) inducing the glow of certain medusas and *Cypridina* hermit crabs, were synthesised (see Ref. 43 and references cited therein).

One of the analogues, viz., 2-methyl-6-phenyl-3,7-dihydroimidazo[1,2-a]pyrazinone (**15**, $R^1 = \text{Me}$, $R^2 = R^4 = \text{H}$, $R^3 = \text{Ph}$) was named CLA (Cypridina Luciferin Analogue). The CLA chemiluminescence photosensitised by Rose Bengal (RB) in an aqueous solution with pH 7 was studied.⁴⁴ The reaction proceeds through the formation of excited 2-acetamido-5-phenylpyrazine (OCLA, **16**), which is the CL emitter, and of an unidentified intermediate (Int), which is the reaction product of CLA with singlet oxygen (Scheme 3).

Photosensitised oxidation of CLA includes the same stages as the luminol oxidation; however, the intermediate formed in the CLA reaction with $^1\text{O}_2$ also takes part in the luminescence transformations.

5. Indole derivatives

Photosensitised chemiluminescence of indole (**17a**) derivatives was discovered following observation of persistent afterglow of proteins and amino acids^{45,46} and of solutions of proteins and synthetic polymers irradiated with X-rays⁴⁷ and UV light.⁴⁸

$R = \text{H}$ (**a**), $\text{CH}_2\text{CH}(\text{NH}_2)\text{CO}_2\text{H}$ (**b**),

$\text{CH}_2\text{CH}(\text{NHCOCH}_2\text{NH}_2)\text{CO}_2\text{H}$ (**c**), $\text{CH}_2\text{CO}_2\text{H}$ (**d**).

In 1968, Sapezhinskii and Voloshin⁴⁹ reported on chemiluminescence accompanying the photooxidation of tryptophan (**17b**) in aerated solutions. Later, this research group studied the autosensitised CL of glycyltryptophan (**17c**) and its dye-sensitised chemiluminescence.^{50–58} The results of studies of radiation-induced CL in peptides, proteins and synthetic polymers were generalised in a monograph.⁵⁹

The photoexcitation site of a sensitizer can be fixed by its adsorption on a plate immersed in the substrate solution.⁵⁵ The idea of spatial separation of a sensitizer and a solution exposed to

sensitisation products was forwarded in the studies of photo-sensitised oxidation⁵ and PSCL of glycyltryptophan.⁵⁵ This heterogeneous PSCL offers good prospects in analytical applications and in the development of chemiluminescence sensors.

The phenomenon of autosensitised CL of tryptophan (**17b**) upon its UV irradiation was studied by several optical techniques.⁶⁰ CL in the blue region was attributed to tryptophan photooxidation. Chemiluminescence at 630–705 nm was intensified in heavy water and quenched by 10%–15% upon the addition of NaN_3 and DABCO. This suggests that dimolar luminescence of singlet oxygen made a certain contribution to the total CL

Rose Bengal-photosensitised CL of indol-3-ylacetic acid (**17d**) was studied.⁶¹ Superoxide ions and singlet oxygen were the major photooxidants of indole derivatives. The attachment of superoxide at position 3 of the indole molecule was accompanied by the formation of intermediate dioxetane; cleavage of C–C and O–O bonds in the latter led to formylkynurenine derivatives (**18a–d**).

Opening of the dioxetane ring was accompanied by the release of energy $> 270 \text{ kJ mol}^{-1}$, which is quite sufficient for the chemiexcitation of the carbonyl product.⁶⁰ The formation of dioxetane intermediates is probably typical of all indole derivatives.⁶²

The phenomenon of PSCL of glycyltryptophan (**17c**) was used in the determination of the activity of superoxide dismutase in its reaction with riboflavin as the photosensitizer and for studying the photoprotection and antioxidant properties of a series of natural compounds and medicinal drugs.^{63–70}

Yet another application field of the PSCL of indole derivatives are the studies of conformational transformations of proteins induced by various effects.^{71–73} Insofar as most proteins contain tryptophan, the intensity of protein PSCL depends on the number of tryptophan residues accessible for photooxidation.

6. Polyaromatic hydrocarbons

PSCL of aerated solutions of anthracene, naphthalene, pyrene and benzopyrene as well as base-induced enhancement of glow was first reported in the 1970s.^{17,18} Chemiluminescence appeared upon mixing of a solution of an organic base (triethylamine, piperidine) with aerated and irradiated ($\lambda > 320 \text{ nm}$) solutions of polyaromatic hydrocarbons (PAH) in CCl_4 , acetone or benzene.⁷⁴ The highest CL yield was observed in CCl_4 solutions of the following PAH (the series is given in order of decreasing CL quantum yield): perylene (**19**), benzo(*a*)pyrene (**20**), pyrene (**21**), fluoranthene (**22**), chrysene (**23**), 1,2-benzanthracene (**24**), 9,10-diphenylanthracene, anthracene.

19

20

21

Presumably, UV irradiation of PAH solutions results in the photoionisation of the substrate to form the corresponding radical cation and a photoelectron, which is captured by the solvent.⁷⁴ Subsequent interaction of PAH radical cations with dissolved oxygen leads to the formation of, first, peroxide radicals and, then, peroxides. Chemiluminescence is induced in the reaction of primary and secondary peroxides with hydroxyl anions HO^- or a base. The proposed mechanism brings about many questions. For example, is it possible to distinguish light-generated radical cations from those formed as a result of electron transfer from an excited PAH molecule to oxygen, based on observations of radical cations alone? Apparently, the insight into the mechanism requires additional studies.

PSCL of fluoranthene (**22**)⁷⁴ can be compared with studies⁷⁵ of base-induced CL reactions of this compound. It is reasonable to assume that the chemiluminescence of compound **22** and other PAH, which was observed in Ref. 75, was, in fact, PSCL initiated by the laboratory light.[¶]

7. Chromone-2-carboxylic acid

The primary process of the reaction of a light-excited molecule with oxygen can be not only the transfer of an electron or excitation energy to the oxygen molecule to form $^1\text{O}_2$, but also the addition of oxygen to the substrate molecule (type II c photo-oxidation, see Table 1). Thus in studies^{76,77} devoted to PSCL of aerated solutions of chromone-2-carboxylic acid (**25**), it was shown that its photolysis affords 4-hydroxycoumarin (**26**) as the only product, which corresponds to the formal substitution of oxygen for the carboxyl group in the starting molecule. Com-

pound **26** is not formed in either deoxygenated or aerated solutions in the presence of sensitizers (Methylene Blue and Rose Bengal). It was thus concluded that it is the ground-state oxygen molecule rather than its active form that takes part in the reaction. Moreover, the photolysis of compound **25** was not accompanied by the formation of ketyl radicals, typical products of the abstraction of hydrogen atoms from solvent molecules by excited ketones. The presence of a strong electron-withdrawing group in the molecule of keto acid **25** makes the electron transfer from the excited molecule **25** to the O_2 molecule impossible. Hence, the primary process of photolysis consists of the addition of oxygen to the excited molecule of coumarin **25** the triplet state ($n\pi$ -type) of which has the structure of biradical **27** (Scheme 4).

Chemiluminescence ($h\nu_2$) of irradiated solutions of compound **25** arises due to the reactions of peroxide radicals **28**. Exponential decay of CL intensity following the irradiation of solutions was observed with a rate constant of $4.2 \times 10^{-4} \text{ s}^{-1}$. Unfortunately, Scheme 4 does not explain this peculiarity of the kinetics. Moreover, disproportionation of tertiary peroxide radicals does not lead to product **26**, being only the source of hydroxyl radicals, and cannot be assigned to chemiexcitation reactions.^{78–80} It should be noted that the possibility of photoionisation of acid **25** cannot be totally ruled out, because this was observed for certain derivatives of 4-oxoquinoline-3-carboxylic acid.⁸¹

Chemiluminescence ($h\nu_3$) also arises when an iron-containing protein, namely, cytochrome *c*, which catalyses decomposition of hydroperoxides, is added to a photosensitized ethanolic solution of compound **25**.⁷⁷ This enhances the emission intensity 30-fold as compared with the CL intensity observed immediately after the irradiation. This can be considered as evidence for the formation of hydroperoxide **29** in the photolysed solution (see Scheme 4). However, this process calls for further investigations.

8. Organic azides

Zelentsov and co-workers^{82,83} observed chemiluminescence in the oxidation of organic azides with molecular oxygen in ethanol under UV irradiation ($\lambda > 280 \text{ nm}$), where the CL spectrum of photooxidation of 4,4'-diazidobiphenyl had two peaks in the blue region. Presumably, the chemiexcitation occurs in the isomer-

Scheme 4

¶ Berger *et al.*⁷⁵ ignored the possibility of phototransformation of reagents at the stage of solution preparation and pretreatment; this is why they assigned this reaction to CL.

isation of dioxaziridine (a dioxirane analogue) to afford a nitro compound with energy release ($> 315 \text{ kJ mol}^{-1}$).

R = Alk, Ar.

Apparently, the nitro compound serves as the emitter.

In 1954, when studying the luminescence of nitro-substituted biphenyl and stilbene, Lippert⁸⁴ observed no fluorescence in the region $< 500 \text{ nm}$. However, the shift of the absorption band of a nitro compound to the long-wave region (by varying solvents or substituents in the nitro compound) gave rise to fluorescence at $\lambda > 500 \text{ nm}$. Thus, nitro compounds with peaks of long-wave absorption bands below 500 nm do not fluoresce (the so-called Lippert rule),⁸⁵ *i.e.*, nitro derivatives do not exhibit blue luminescence.

The question of the nature of the emitter could be solved ultimately using an organic azide the photooxidation product of which exhibited known luminescence properties. Thus for 4-azido-4'-dimethylaminostilbene, the presumed emitter would be 4-dimethylamino-4'-nitrostilbene which emits with the quantum yield of 0.7 luminesces at 590 nm .⁸⁶

9. Complex systems

In a photolysed solution that originally contained a single substance, a complex mixture of different products and intermediates is gradually formed. Moreover, if the solution to be photolysed originally contained a mixture of substances, the elucidation of the mechanism of phototransformations becomes an extremely difficult task. Nonetheless, the PSCL phenomenon was described for complex systems too.

PSCL of certain high-boiling oil fractions was observed.⁸⁷ Aerated samples (at 77 K) were irradiated in different spectral ranges for different exposure times. Emission was registered in the course of sample heating from 77 to 550 K . Several temperature zones in which light was emitted in a range of 400 – 700 nm with peaks at 520 – 550 nm were revealed.

PSCL of aerated aqueous solutions of humic acids, both natural and synthetic, was studied.^{88,89} A relationship was established between the observed CL and the photooxidation process, CL and fluorescence spectra were recorded and their changes with the photolysis time were revealed. Presumably, the photodecomposition products are the CL emitters in this process; moreover, the energy is transferred from primarily excited species to chromophores in the polymer, which become the emitters of light.

PSCL of bis(2,4,6-trichlorophenyl) oxalate (**30**) observed upon mixing of its photolysed aerated solution in isopropyl alcohol with an unirradiated solution of anthracene (or some other polyaromatic fluorophore) was described.⁹⁰ It should be noted that a mixture of diaryl oxalates with fluorophores enters into the composition of commercial light sources in which the glow is 'triggered' by the addition of H_2O_2 solutions. However, in this case, the PSCL effect is caused by reasons other than the photosynthetic formation of hydrogen peroxide.

Chemiluminescence that arises upon mixing of a UV-photolysed aerated solution of psoralene (**31**) with a solution of FeSO_4 in a Tris buffer (pH 7.4) was described,⁹¹ however, the mechanism of this phenomenon was not considered in detail.

In closing this Section, it should be noted that characteristic feature of photosensitised chemiluminescence is the photooxidation in the presence of molecular oxygen, chemical transformations of the reaction products being accompanied by chemiluminescence.

III. Photochemical synthesis of chemiluminescent reagents

In the definition of light-created chemiluminescence systems given in the Introduction, attention was paid only to the order in which the stages of illumination and CL observation occur. The time factor (*i.e.*, the interval between these stages) was ignored. In the PSCL processes discussed above, the chemiluminophores formed, *viz.*, hydroperoxides and 1,2-dioxetanes, were characterised by relatively short lifetimes. However, sufficiently stable chemiluminophores are known to be formed photochemically. These can be both peroxides (particularly, 1,2-dioxetanes) and other classes of chemical compounds. The photochemical method can also afford reactants that, being added to solutions of chemiluminophores, induce chemiluminescence.

1. Chemiluminophores obtained by photochemical methods

a. Lophine peroxide

Lophine hydroperoxide (4-hydroperoxy-2,4,5-triphenylimidazole, **32**) was synthesised in 1964 upon illumination of a lophine solution in chloroform (18°C) in the presence of Methylene Blue and oxygen in 68% yield.⁹²

It was assumed earlier⁹³ that this compound is an intermediate in the chemiluminescence reaction of lophine with oxygen in an alkaline medium. It was proved that the reaction product is hydroperoxide rather than lophine endoperoxide. Chemiluminescence of peroxide **32** was observed in the thermolysis ($T > 110^\circ\text{C}$) and also under the action of bases in the absence of oxidants.

An unusual effect of light on a chemiluminescence system was observed.⁹⁴ Gradual decay of chemiluminescence during the oxidation of 2-(*p*-dimethylaminophenyl)-4,5-diphenylimidazole (**33**) with molecular oxygen was observed; however, the illumination of the partly reacted mixture restored the glow up to its original level.

According to one of explanations of this effect, the dark transformation pathway of compound **33** involves the formation of an inactive dimer, which decomposes in the light to the starting imidazole and its peroxide derivative.

b. 1,2-Dioxetanes

1,2-Dioxetanes are four-membered cyclic peroxides, which attract great interest as chemiluminophores. Chemistry, mechanisms and applications of CL of these compounds are documented in surveys^{43,95,96} and books.^{97,98}

Unimolecular decomposition of 1,2-dioxethane into two carbonyl compounds proceeds *via* a biradical and is accompanied by liberation of energy of about 290 kJ mol^{-1} . This energy (even ignoring the activation energy) is sufficient for the excitation of one of the products.

$R^1 - R^4 = \text{Alk.}$

The addition of photochemically generated singlet oxygen to the C=C bond of a precursor molecule is a convenient method for the synthesis of 1,2-dioxethanes.^{99–107} It is this method that was used in the synthesis of the first dioxetane (**34**)^{99,100} stable under normal conditions from adamantylideneadamantane. Its yield depended on the sensitizer and solvent used. Improper combination of the latter resulted in a dramatic increase in the yield of side epoxide.¹⁰¹ Other limitations for the photochemical synthesis of 1,2-dioxethanes are also known.¹⁰⁷

Photooxygenation of alkene **35** in CH_2Cl_2 employed polymer-bound Rose Bengal (Sensitox),¹⁰² which facilitated the separation of the sensitizer from the product. Irradiation of the solution (15–30 min), removal of the sensitizer and evaporation of the solvent afforded the product, dioxetane **36**.

The earlier version of this reaction employed a heterogeneous photogenerator of singlet oxygen.¹⁰³

The kinetic stability of dioxetane **36** under normal conditions is due to the high activation barrier to its decomposition. Thermolysis of this compound is accompanied by CL. Chemical excitation of dioxetane **36** is characterised by a high (up to 60%!) yield of triplet carbonyl compounds. The yield of products in the excited singlet state is lower by a factor of 10–1000. Efficient population of the triplet term is attributed to the fact that, according to the Hund rule, this is the lower term in the intermediate biradical (the transition state in the decomposition).⁸⁰

The presence of electron-donating groups in the dioxetane molecule favours partial population of the antibonding π^* -orbital of the O–O bond. This dramatically decreases the activation barrier to decomposition so that this can begin even at ambient

temperature. The decomposition process can be controlled by introducing an electron-withdrawing group into the composition of the aromatic substituent of compound **36**. The interaction of this group with a special reagent (trigger) resulted in the transformation of the starting molecule into *m*-methoxycarbonylphenolate anion, partial electron transfer to the π^* -orbital of the O–O bond and decomposition of the dioxetane (Scheme 5, pathway *a*).

The thermal (pathway *b*) and the electron-transfer-initiated mechanisms of decomposition of compound **36** were studied.^{108,109} It was found that in the thermal process, the triplet states $^3(n\pi^*)$ of adamantan-2-one and $^3(\pi\pi^*)$ of methyl *m*-alkoxybenzoate are excited in similar quantum yields (~ 0.1) and the singlet state $^1(n\pi^*)$ of adamantan-2-one is excited in an insignificant yield. In the electron-transfer-initiated decomposition of dioxetane, only the singlet state $^1(\pi\pi^*)$ of the corresponding phenolate anion is excited. Such a striking difference points to the fundamental difference in the mechanisms of the decomposition and chemical excitation in the thermolysis, on the one hand, and the process initiated by the electron transfer, on the other hand (see Scheme 5).

The photochemical synthesis of 1,2-dioxetane can be carried out by a different route, namely, by the total reversal of the chemical excitation process. Irradiation of an acetone solution of *N*-methylacridone (**14**) with light from a high-pressure mercury lamp in an argon atmosphere at -78°C afforded a cycloaddition product, 1,2-dioxetane **37**,¹¹⁰ while irradiation of a solution of compound **14** in CH_2Cl_2 under the same conditions led to 1,2-dioxetane **38**.

Thermolysis of dioxetane **37** gave rise to CL the spectrum of which coincided with the fluorescence spectrum of compound **14** in acetone ($\lambda_{\text{max}} = 525 \text{ nm}$), the CL quantum yield reached 10^{-6} . Unfortunately, the preliminary communication¹¹⁰ was not followed by more detailed investigations. At the same time, it is

Scheme 5

$R = \text{Alk.}$

known that *N*-methylacridone (**14**) exhibits $\pi\pi^*$ -phosphorescence with a well resolved vibrational structure.⁸⁵ Hence, it would be interesting to obtain its complete CL spectrum.

Photochemical synthesis of dioxetanes has found its application not only in preparative chemistry, but also in the on-line kinetic analysis of samples.¹¹¹

c. Pinacols

UV irradiation ($\lambda > 320$ nm) of an acetone solution of acridone **14** in an argon atmosphere at room temperature (*i.e.*, under the conditions where dioxetanes **37** and **38** decompose) affords products that require the combined action of an oxidant (*e.g.*, oxygen) and a strong base for their chemiluminescence to be initiated.⁷⁴ These products are pinacols (1,2-glycols).

The synthesis of different chemiluminophores under UV irradiation of the corresponding carbonyl-containing polyaromatic hydrocarbons was described.⁷⁴ The similarity of conditions of the photochemical treatment of these compounds did not guarantee the formation of the same chemical class of products: the starting substances belong to substantially different spectral-luminescent classes and, hence, possess different photochemical properties.

Pinacols are the products of photoreduction of many aromatic carbonyl compounds. For example, dimerisation of radical products of benzophenone photoreduction yields benzopinacol (**39**).

The dimerisation constant of neutral ketyl radicals is 10^{10} – 10^{13} litre mol⁻¹. Just as each dioxetane molecule can be said to 'harbour a photon',⁹⁷ each molecule of certain pinacols can be said to contain two radicals. This is explained by the fact that in strongly alkaline media pinacols lose their stability and undergo dismutation *via* ketyl radicals and radical anions.¹¹² The radical processes are frequently accompanied by chemiluminescence. The acidity of pinacols ($pK_a \approx 14$) is substantially lower as compared with ketyl radicals;¹¹³ hence, initiation of radical reactions involving pinacols requires a strongly alkaline medium. It is assumed that photochemically generated pinacols play the role of important intermediates in the chemiluminescence of photolysed solutions of aromatic carbonyl compounds. In the presence of oxidants, pinacols can become dioxetane precursors.

d. Acridans

The first members of a new family of chemiluminescent reactants, namely, dihydroacridines (acridans) **40a**, were prepared by the photolysis of deaerated solutions of acridine in DMF (for R = H) or dimethylacetamide (for R = Me).¹¹⁴ In solutions of acridans **40a**, the quantum yield of chemiluminescence initiated by strong bases (NaH, Bu^tOK, MeONa) in the presence of O₂ reaches 0.006.

R = H, Me; X = H (**a**), OH (**b**), CH₂Ph (**c**).

Figure 2. Fluorescence spectrum of anion **41** (1) and CL spectrum of compound **40a** (2).

The acridone anion (**41**) is the emitter of radiation. Figure 2 shows the CL spectrum of compound **40a** (curve 2) and the fluorescence spectrum of anion **41** (curve 1), which have similar patterns.

γ -Radiolysis produces¹¹⁵ acridans **40b,c** and their *N*-methyl derivatives. The quantum yield of CL of acridans **40b** (R = H or Me) exceeds 0.01.

It is known that oxidation of 9-methylacridine with molecular oxygen in DMF in the presence of Bu^tOK is accompanied by chemiluminescence.¹¹⁶ Here, acridone anion served as the emitter. This brings up the question: would this be a chemiluminescence reaction if solutions of 9-methylacridine were prepared in darkness thus excluding the possibility of chemiluminophore photogeneration?

e. Ruthenium complexes

The bipyridyl complex of Ru(III) is a bright example of chemiluminophores based on metal complexes.^{117–119}

Chemical excitation of ruthenium cation occurs in the reaction of Ru(III) bipyridyl complex with a reducing agent (Red) with the standard redox potential < 0.86 V.

bipy is 2,2'-bipyridyl.

Complex Ru(bipy)₃²⁺ (**42**) is sufficiently stable (it withstands boiling in concentrated HCl or 50% NaOH solutions) and chemically inert, whereas Ru(bipy)₃³⁺ is chemically reactive.¹¹⁹

For the chemiluminescence analysis, Ru(bipy)₃³⁺ was synthesised from cation **42** by different methods,¹²⁰ *e.g.*, by the photochemical activation of Ru(bipy)₃²⁺ oxidation with peroxydisulfate ions.¹²¹ Optical absorption of the [Ru(bipy)₃³⁺] complex at the 450 nm band ($\epsilon = 14600$) results in the population, with the quantum yield equal to 1, of the excited state [Ru(bipy)₃²⁺]^{*}

(lifetime $\sim 0.6 \mu\text{s}$). In the excited state, the complex acquires reductive properties and is oxidised by the $\text{S}_2\text{O}_8^{2-}$ ion.

The SO_4^- ion formed oxidises the ground-state $\text{Ru}(\text{bipy})_3^{2+}$ complex.

As a result, the quantum yield of the formation of $\text{Ru}(\text{bipy})_3^{3+}$ complex is equal to 2.

A flow photochemical synthesis of $\text{Ru}(\text{bipy})_3^{3+}$ ions was used for the chemiluminescence detection of certain compounds.^{122–124} In those cases where the compound to be analysed was a weak reducing agent, it was proposed to subject it to photochemical decomposition into the fragments capable of reducing the metal ion in the metal-complex chemiluminophore, thus triggering the CL.¹²⁵

2. Photoactivation of substrates

Illumination of solutions containing chemiluminescent substrates and an oxidant in the spectral region of the oxidant absorption band results in the formation of active forms of the oxidant, which are capable of exciting the CL of an appropriate chemiluminophore. Thus mixing of a UV-irradiated solution of potassium nitrate with an unirradiated solution of luminol induced excitation of chemiluminescence of luminol.¹²⁶ The nitrate ion has two absorption bands in the UV range at 202 ($\epsilon = 9500$) and 304 nm ($\epsilon = 7$). Chemiluminescence of luminol arises only upon irradiation of the nitrate solution in the region of the first absorption band. The luminol oxidation and the excitation of its CL were attributed to the action of peroxyxynitrite (ONOO^-), which is formed from nitrate (NO_3^-) as a result of intramolecular rearrangement upon excitation. In contrast to nitrate, peroxyxynitrite is a strong oxidant capable of initiating the chemiluminescence oxidation of luminol.^{127–130} The resulting photochemically produced peroxyxynitrite is a structural isomer of the original anion. The reverse reaction¹³¹ will be discussed in the next Section.

The chemiluminescence reaction of luminol with a photoactivated reactant was used for the determination of nitrates in water.^{126, 132} Complex chemiluminescence reactions of photoactivated ClO_2 and SO_2 molecules in a mixture of perchloric and sulfuric acids were also described.¹³³

* * *

Coupling the procedures of the photochemical synthesis of chemiluminophores and their observation would provide a 'complete' system in which the external effect of light on the reaction mixture gives rise to chemiluminescence. Hence, the above-described examples of the preparation of lophin peroxide from lophin and of dioxetane from alkene in the presence of sensitizers and dissolved oxygen may be considered in the Section devoted to PSCL. However, this is not true for those cases where either the illumination stage requires the use of deoxygenated solutions or the reactions occur independently of the presence of oxygen. The primary photoprocesses (in addition to photooxidation) can include photoreduction, photoaddition and photoisomerisation,

which substantially increase the number of photochemical processes that occur in light-created chemiluminescence systems.

IV. Photoinduced chemiluminescence

In the periods of energy crises, the idea of using solar energy gains a new impetus. Active studies on both the conversion of solar energy into electricity and the storage of solar energy as the internal energy of photochemical reaction products, *i.e.*, H_2O_2 (Ref. 134) or structural isomers of different compounds,¹³⁵ are initiated. Studies in the latter field have also stimulated the investigation of the reverse process, *viz.*, the conversion of the internal energy of photoproducts into electronic excitation and further into light emission.

1. Photoisomers

The structural formula of a C_6H_6 molecule can be represented as three valence (or structural) isomers, namely, benzene (**43**), Dewar benzene (**44**) and benzvalene (**45**). Structures **44** and **45** were detected in the phototransformation products of isomer **43**.

The enthalpy of formation of structure **44** exceeds that of benzene by 251 kJ mol^{-1} . The isomerisation reaction $\text{44} \rightarrow \text{43}$ has an activation energy of $\sim 96 \text{ kJ mol}^{-1}$; hence, $\sim 347 \text{ kJ mol}^{-1}$ is liberated in the elementary act of molecule rearrangement. This is comparable with the energy of the triplet state of structure **43** (355 kJ mol^{-1}) but smaller than the energy of its excited singlet state (481 kJ mol^{-1}). One can expect such isomerisation to be accompanied by chemical excitation of benzene into the triplet state ($^3\text{43}$). This process was studied.¹³⁶ Insofar as under experimental conditions (solution at ambient temperature) state $^3\text{43}$ is non-radiative, its detection involves the use of the triplet–singlet transfer of energy from species $^3\text{43}$ to the singlet fluorophore, namely, 9,10-dibromoanthracene (DBA), with the energy of 310 kJ mol^{-1} . Such a transfer of energy is spin forbidden; however, this prohibition is lifted due to the presence of a heavy atom (Br). The triplet–singlet transfer of energy to DBA is fairly efficient. The reaction $\text{44} \rightarrow \text{43}$, which occurs on heating of a solution in the presence of DBA is accompanied by chemiluminescence with the spectrum typical of DBA fluorescence. The efficiency of chemical excitation in the reaction $\text{44} \rightarrow ^3\text{43}$ is $\sim 2 \times 10^{-4}$; in the case of 1,4-dichlorobenzene, it is equal to $\sim 10^{-3}$.

Thus, it was discovered¹³⁶ that the energy stored in a molecule can be converted into the energy of electronic excitation and, under suitable conditions, into light emission. Later, this was demonstrated by the example of thermal isomerisation of Dewar acetophenone,¹³⁷ 3,3'-bis(cyclopropenyl) and Dewar xylenes.¹³⁸

Reaction $\text{45} \rightarrow \text{43}$ is not accompanied by CL,¹³⁹ although its elementary act liberates more energy than the isomerisation $\text{44} \rightarrow \text{43}$ discussed above. In the former case, the total energy is converted into heat. This is caused by the great difference in the configurations of structures $^3\text{43}$ and **45**. In the reaction $\text{45} \rightarrow \text{43}$, the nuclei in the molecular core should travel considerable distances, which is accompanied by excitation of vibrational modes and dissipation of energy. For $\text{44} \rightarrow \text{43}$, the configurations of species **44** and $^3\text{43}$ are virtually identical ('gable roof'), hence, the core restructuring is minimum.

As was already mentioned (see Section III.2), peroxyxynitrite can be considered as a photoisomer of nitrate. It was shown¹³¹ that spontaneous isomerisation of peroxyxynitrite to nitrate is accompanied by CL with a quantum yield of $\sim 10^{-9}$. In this case, the quantum yield of chemical excitation of the emitter (peroxyxynitrite) reaches a very high value (0.2).

Structural isomerisation also occurs upon the intramolecular phototransfer of a proton or a hydrogen atom. In this case, the stored energy is small; however, if the reactivity of the isomer formed substantially exceeds that of the original isomer, the former can undergo reactions hindered for the original reactant.

It was shown¹⁴⁰ that chemiluminescence appears in the reaction of salicylaldehyde hydrazone (**46**) with a base if the aqueous solution of hydrazone **46** was pre-irradiated with visible light (400–540 nm) with an intensity of merely several milliwatt per square metre. The illumination results in isomerisation of inactive benzenoid form **46** into active quinonoid form **47**. The kinetic scheme of photoinduced formation of isomer **47** can be presented as follows:

Here, k_1 is the formal constant of photoexcitation of hydrazone **46**, which is proportional to the light intensity (the optical density of solutions is far below 1); k_2 is the rate constant for the transformation of the excited molecule **46*** into the product; k_3 is the rate constant that takes into account all possible processes of degradation of the excited state **46*** that do not lead to compound **47**; k_4 is the rate constant for reaction **47** → **46** [at ambient temperature, $k_4 = (6 \pm 3) \times 10^{-4} \text{ s}^{-1}$]. The height of the energy barrier for the transition **47** → **46** is 18 kJ mol⁻¹. In the stationary illumination, the concentration of isomer **47** gradually reached a steady-state value, which is independent of the light intensity and temperature and increases upon the substitution of D₂O for H₂O.

Reactions of a base with both isomers (**46** and **47**) are exothermic and their final product is, probably, the hydrazone anion. However, the enthalpy of formation of isomer **47** exceeds that of isomer **46** by 130 kJ mol⁻¹; hence, the liberated energy is sufficient for the excitation of the reaction product of the base with the former isomer and too low for the latter isomer. This is why chemiluminescence accompanies only the reaction of the base with compound **47** and is not observed in the reaction with hydrazone **46**.

2. Photodimers

Photodimerisation of anthracene is the first photochemical reaction studied. In 1867, Fritzsche observed the formation of an insoluble substance ‘paraphoten’ (sited according to Ref. 141), *i.e.*, dimer **48**, in a sunlight-exposed benzene solution of anthracene. Its melting produced anthracene.

As was found later,¹³⁵ this reaction involves accumulation of energy.

Synthesis of various cyclodimers of anthracene and benzene, particularly, [4π + 4π] heterodimer **49**, was described and their transformations were studied.^{142, 143}

Figure 3. Cross-sections of the potential energy surface along the reaction coordinate at the thermolysis and the light-induced decomposition of heterodimer **49**.^{142, 143} A_0 , $^1A^*$ are ground and excited singlet states of anthracene, r_c is the critical point.

It was shown that the thermal decomposition of heterodimer **49** is a dark reaction, whereas its light-induced decomposition is accompanied by CL with the efficiency of chemical excitation of singlet anthracene of ~0.9! A scheme of energy levels in Fig. 3 shows that in the vicinity of the pericyclic minimum, the greatest part of energy of the absorbed photon is already consumed in reaction,¹⁴⁴ because the formation of a chemiluminescence photon consumes the chemical energy liberated in the decomposition of the heterodimer. Hence, in this case, the reason for the light emission is indeed chemiluminescence.

Synthesis of compounds containing photocyclisable aromatic fragments (*e.g.*, benzene and anthracene) linked with bridges,

which makes them more flexible, was described.^{145,146} This allowed the whole sequence of transformations, *viz.*, cyclisation under illumination at 375 nm, recyclisation under illumination at 280 nm, chemical excitation and CL of the product, to be observed.

The introduction of substituents R into the bridge changes the distance between the planes of the benzene and anthracene fragments, which makes it possible to control the potential energy surface along the reaction route. The cross-section of the potential energy surface along the reaction route

can also be represented by curves similar to those in Fig. 3 (the ground and excited states of molecule **50** correspond to species **49**, while those of molecule **51** correspond to anthracene).

The prohibition for the formation of excited products in the thermal reaction of photodimer decomposition can be substantially reduced (and even eliminated) if the reaction involves ionisation of molecules. It was shown^{147,148} that the base-induced decomposition of anthrol photodimers **52** ('head-to-tail') and **53** ('head-to-head') is accompanied by CL with a spectrum similar to the fluorescence spectrum of the anthrol anion.

Earlier, chemiluminescence of photolysed solutions of anthrol was associated exclusively with CL of its peroxy derivatives.¹⁴⁹ The anthrol photolysis products were isolated by high-performance thin layer chromatography (HPTLC).¹⁴⁸ The R_f value of the substance that exhibits CL activity in the reaction with the base differs from the R_f of the peroxide, which was determined in its colour reaction with iodine. Reversed-phase HPTLC allowed better resolution of these bands. Chemiluminescence was observed for both the photodimer and peroxides, but the CL intensity of the photodimer proved to be more than 10 times higher.

Upon deprotonation, both hydroxyl groups in anthrol photodimers **52** and **53** (DA) decompose to two anthrol anions (E^-). Taking into account that the formation of two anthracene molecules with conjugated bond systems involves liberation of considerable energy, the DA decomposition product can exist in the electronically excited state

In an ethanolic extract of dry *Hypericum perforatum* (St-John's wort), which can produce and accumulate various anthracene derivatives, a compound identical to the anthrol photodimer was detected using HPLC coupled with CL detection.

V. Analytical applications

Chemiluminescence analysis attracts steady interest among biologists and physicians and promises to become a routine test in many biological and medical laboratories.

The advances of nanotechnologies that employ 10–100-nm metal particles with 'extraordinary' properties as the transducers and amplifiers of fluorescence and CL open up new possibilities.^{150,151} In light-created chemiluminescence systems, light plays the role of a cheap, available and convenient reactant.

Photosensitised CL of various chemiluminophores was employed for the assessment of the activity of superoxide dismutase and the antioxidant effect of different substances^{33–39,41,42,59,63–70} and also in the chemiluminescence immunoassay.³² Based on the detection of chemiluminescence that accompanies photooxidation, a new method of assessment of the state of rarities and historical objects and materials was proposed.^{152,153} A method for studying photostability of polymers has been developed.^{154–158}

Photochemical synthesis of dioxethanes and their use in the on-line kinetic analysis of alkenes were described.¹¹¹

A highly selective ozone sensor was obtained by the photochemical modification of 4,5-dihydroxynaphthalene-2,7-disulfonic acid (chromotropic acid).¹⁵⁹

Light-induced chemiluminescence systems were proposed for analysis of polyaromatic hydrocarbons,⁷⁴ pharmaceuticals^{125,160,161} and pesticides.¹²³

VI. Conclusion

Based on the material presented in this review, it follows that the problem of classification of light-created chemiluminescence systems is solved as soon as the mechanism of the light effect becomes clear.

Classification of 'parental' photochemical mechanisms already exists. Nowadays, in light-created chemiluminescence systems, the 'parental' mechanisms are represented by various kinds and types of photooxidation, structural photoisomerisation, phototransfer of protons (hydrogen atoms) and photodimerisation.

Any other classification unrelated to the mechanism of the chemical effect of light would be arbitrary, *e.g.*, a classification based on the differences in the CL kinetics. The authors who proposed a new term 'photostorage CL',¹¹⁴ distinguished this phenomenon from the others by the fact that the former does not exhibit any afterglow decay upon the effect of light but requires to be initiated by a base. We assume this difference insignificant. Indeed, if we change the experimental conditions, namely, add the base to solution beforehand and use pulse light, then the CL kinetics will take the form of afterglow decay.

One cannot but state the similarity in the response of different scientists to their first encounter with light-created chemiluminescence systems. First, this is bewilderment caused by the lack of understanding of the reasons for the scatter of experimental results on CL reactions, then, astonishment when one becomes aware that solutions prepared or stored for a long time in darkness do not provide a chemiluminescence reaction. Moreover, the efficiency of common laboratory illumination seems strange.

However, photochemical activity of ordinary illumination should not surprise. In the ordinary illumination, more than 10^{13} photons pass through an area of 1 cm² per second, which is 10^9 times greater than the detection limit of laboratory chemiluminometers; hence, the formed gap can be occupied by numerous chemical systems for which the multiplied efficiencies of absorption, photochemical transformation and chemiluminescence of the product are no less than 10^{-9} .

After the discovery of the key role of oxygen in luminescence and photochemical reactions, the scientists became very much aware of the presence of dissolved oxygen. Now that a sufficiently large number of chemiluminescence systems have been studied, it is time to become aware of the role of illumination conditions during the preparation of solutions and reaction mixtures.

This work has been written with the financial support from the Russian Foundation for Basic Research (Project No. 05-03-32730) and the Division of Chemistry and Materials Sciences of the Russian Academy of Sciences (Programme No. 1, 2004–2006).

III. Conversions of lower alcohols on metal – carbon catalysts	1007
IV. Conclusion	1012

Abstract. Various carbon materials including carbon nanotubes and graphitised nanofibres used as supports in heterogeneous catalysis are considered. The methods for modification of catalysts and the results obtained as applied to three important processes of organic synthesis, viz., conversions of methanol into methyl formate, of ethanol into acetaldehyde and of isopropyl alcohol into acetone, are analysed. The bibliography includes 117 references.

I. Introduction

Design of syntheses of various classes of organic compounds from non-oil raw materials is one of the major trends in the progress in chemical industry. The use of the so-called one-carbon compounds, such as carbon monoxide, carbon dioxide, methanol and methane, in organic synthesis is becoming increasingly topical. The production of essential organic compounds from coal is a reasonable alternative to their manufacture from oil and natural gas.

In 2000, the world production of methanol amounted to 39 752 000 tons;¹ in the first quarter of 2004, methanol production in Russia was 798 000 tons. Methanol is used as starting material in the synthesis of many chemical compounds, *e.g.*, formaldehyde, acetic acid, ethylene glycol, *etc.* Synthesis of methyl formate, an important intermediate in many processes of the industrial organic synthesis, is yet another promising route of methanol conversion. The greater part of methyl formate (its annual world production amounts to ~160 000 tons)² is utilised for the manufacture of formic acid,^{3,4} which is used as a preservative in agriculture. Methyl formate is also processed into formamides⁵ and *N*-formylmorpholine; it is used as a solvent for fats, fatty acids, acetylcellulose and as an insecticide.⁶ Besides, it can be used in the production of high-purity carbon monoxide, dimethyl

carbonate, diphosgene and methyl glycolate⁷ and employed instead of synthesis gas in carbonylation and alkoxycarbonylation of alkenes.

Traditionally, methyl formate is prepared by carbonylation of methanol in the presence of alkali metal alcoxides.^{2,8} However, purification of starting materials demands considerable investment and is efficient only in the case of large-scale production. However, methyl formate conversion products are mostly utilised in low-tonnage chemistry; therefore, establishing small-scale plants in close proximity of potential consumers is currently rather topical. Dehydrogenation of methanol,⁹ which does not require the use of high pressures and is rather insensitive to impurities present in the feed stock, is underway on a large scale. Ethanol, yet another industrial intermediate for organic synthesis, has recently become very popular. There are environmentally safe technologies for its production from organic wastes and biomass which are based on the use of microbial enzymes.¹⁰ At present, the world production of ethanol amounts to 40 milliard litres per year and, according to prognoses, will increase in future.¹¹ Catalytic dehydrogenation of ethanol into acetaldehyde, a valuable intermediate in the synthesis of a broad range of compounds, is one of directions of ethanol processing. This method has a number of advantages, *e.g.*, lack of toxic waste products, relatively mild reaction conditions and production of hydrogen in addition to acetaldehyde, which can further be utilised in other processes.

Isopropyl alcohol, another representative of low-molecular-mass alcohols, is used in production of acetone without formation of side products.

As is known, organisation of a profitable chemical production is only possible with highly active and highly selective catalysts. A search for novel supports, which have a great influence on the structure and properties of catalysts, is an essential step in the development of efficient catalytic systems. The use of novel carbon materials with fibrous-tubular structure and carbon – carbon composites holds great promise.

This review deals with various aspects of the development of efficient low-percentage (with respect to a metal) metal – carbon catalysts, including the methods used for their preparation, modification and activation and choice of optimum conditions for dehydrogenation of lower aliphatic alcohols (C₁ – C₃) leading to the corresponding ester, aldehyde and ketone.

II. Carbon materials and their application in heterogeneous catalysis

1. Preparation and properties of various carbon materials

Carbon materials have long been used in heterogeneous catalysis as both catalysts themselves and supports for active components. These materials possess a number of valuable properties, *e.g.*, controlled specific surface and adsorption capacity, high thermal and chemical stability, high mechanical strength, long service life, *etc.*¹² In 1998, about 70 industrial chemical catalytic processes were run on carbon supports.¹³

At present, a vast array of novel carbon materials¹⁴ [carbon fibres,^{15–17} graphite intercalates, fullerenes, carbyne-like compounds (carbolites), nanocarbon structures, pyrocarbons, carbon–carbon composites, *etc.*] are employed along with traditional carbon supports (activated carbons, graphite and soot).^{13, 14, 17, 18} These novel materials differ from the traditional supports in low content of mineral admixtures, which is especially important for the preparation of catalytic systems. Their advantages include high resistance to acidic and basic media and high temperatures, controllable porosity. The production technologies of many novel carbon materials enable the preparation of diverse forms, *e.g.*, granules, tissues, honeycomb structures, *etc.*, which significantly facilitates the design and optimisation of reaction units employed in production of many valuable components of organic synthesis. The use of carbon supports allows regeneration of active components of catalysts, which is especially important if the active component is a precious metal.^{13, 15} However, the range of commercial porous carbon materials as candidate supports for catalysts is rather narrow. Commercial catalysts are still manufactured on the basis of activated carbons prepared from coal or vegetal stuff.

a. Activated carbons

Activated carbons (AC) are prepared by pyrolysis of carbon-containing materials, *e.g.*, wood, peat, coal and petroleum products. These materials possess a well-developed porous structure, but their microporous structure is not always optimum for the support of catalysts. Besides, the shape and size of activated carbon granules do not always meet the requirements of catalytic processes. Other disadvantages include high content of mineral impurities and sulfur as well as low mechanical strength.¹⁷ Modern catalytic techniques demand carbon materials with large controllable pores and a definite combination of specific properties. These properties are manifested by a novel type of supports based on synthetic carbon–carbon composite materials.¹⁷

b. Carbon–carbon composite materials

Technical carbon is used as a starting material in the synthesis of porous carbon–carbon composites, which combine the advantages of activated carbons and graphite. Several methods for their preparation are known. For instance, technical carbon is mixed with a hydrocarbon binder; the resulting mass is compacted or granulated to obtain grains of definite shapes. The grains are then subject to thermal treatment in an inert or reducing medium, which results in carbonisation of the hydrocarbon component and formation of porous carbon, which binds technical carbon globules.¹⁷ An alternative approach, which was developed at the Institute of Catalysis of the Siberian Branch of the Russian Academy of Sciences, consists of several successive steps. The first of them includes preparation of matrices, which represent granules of spherical or more complicated shape, from technical carbon. This is followed by compaction of the matrices and deposition of carbon formed by pyrolysis of gaseous hydrocarbons.^{19–21} The porous carbon material thus prepared represents a globular system the primary morphological units of technical carbon in which are bound by pyrolytic carbon. Meso- and macroporous composites with low specific surfaces ($2–10 \text{ m}^2 \text{ g}^{-1}$) are formed in this step. The next step includes their activation by partial selective gasification. The texture and

other characteristics of porous materials are controlled by varying the nature and properties of technical carbon, degree of compaction of the matrix by pyrocarbon, degree of scorching of the composite mass in the course of its activation, the nature of the gasifying agent and activation conditions.^{22, 23} It is this approach that has been used in the preparation of a novel class of porous carbon–carbon composite materials for adsorption and catalysis, known under the name 'sibunit'.

The porous structures of such materials contain macro-, meso- and micropores. The volumes and sizes of meso- and macropores are controlled by varying the sizes of primary technical carbon globules, their reciprocal positions and the ratio of technical and pyrolytic carbons. The sizes of micropores and fine mesopores can be increased by steaming and oxygen treatment, which does not influence essentially the sizes of large pores.²⁴ Some characteristics of sibunit and activated carbons are given in Table 1.

Table 1. Some properties of porous carbon materials of the sibunit and activated carbon type.¹⁷

Parameter	Sibunits	Activated carbons
Specific surface area / $\text{m}^2 \text{ g}^{-1}$	2–800	600–1800
Total pore volume / $\text{cm}^3 \text{ g}^{-1}$	0.2–1.2	0.2–1.2
Micropore volume / $\text{cm}^3 \text{ g}^{-1}$	0.01–0.15	0.2–0.6
Mesopore volume / $\text{cm}^3 \text{ g}^{-1}$	0.2–0.8	0.1–0.3
Macropore volume / $\text{cm}^3 \text{ g}^{-1}$	0.1–0.7	0.1–1.0
Mean pore radius /nm	4–200	from < 1.5 to > 100
Ash content (mass %)	< 1	> 3
Crush strength / kg cm^{-2}	40–200	5–60

The technology of sibunit synthesis allows directed modification of its textural characteristics in the whole range required for the solution of specific problems of catalysis and adsorption.²⁵ Other advantages of these composites include reproducibility of their porous structure, high chemical purity, high mechanical strength, high activity and long operating life of catalysts based on them. These materials manifest high thermal stability; their chemical stability in oxidative media is much higher than that of activated carbons prepared from plants and coal.

Traditional carbon supports and sorbents are available only in the form of tablets, spherical granules or grains with diameter not exceeding 3–5 mm. At the same time, in some chemical processes the most efficient supports for catalysts have intricate geometrical shapes, *e.g.*, rings, straw, petals, microassemblies and honeycomb structures.²⁶ The use of sibunit as a support makes it possible to solve this problem.

c. Carbon fibre materials

A great number of recent publications and patents are devoted to carbon materials with fibrous-tubular structure. Carbon fibrous materials (*e.g.*, fibres, cords, felts, fabrics, yarns, cotton wool) are usually prepared by pyrolysis of polymeric fibres and fibrous articles with subsequent high-temperature treatment. After preliminary activation, these materials can be used as sorbents, ion-exchangers and supports for catalysts.^{27–29} Activated fibrous carbon materials not only possess large specific surface and high porosity, but also manifest high thermal and chemical stability. Modern technologies allow preparation of materials of various shapes, which significantly extends the possibilities of hardware implementation of technological processes.

Polyvinylchloride fibres, phenolic polymers, polyvinyl alcohol, polyacrylonitrile, hydrated cellulose, *etc.* are used as raw materials for the preparation of carbon fibres. Their properties including chemical stability depend largely on the choice of the starting polymer, conditions for its carbonisation and thermal treatment (activation) as well as by different additives.³⁰ For example, carbon fibres prepared from hydrated cellulose manifest

Table 2. Characteristics of carbon fibres prepared from polyacrylonitrile.³⁰

Parameter	Fibre	
	carbonised	graphitised
Density /g cm ⁻³	1.3–1.65	1.3–1.9
Specific surface area /m ² g ⁻¹	0.3–1000	0.15–3.0
Temperature coefficient of linear expansion, 10 ⁶ α /K ⁻¹	4	2
Specific heat capacity /kJ m ⁻¹ K ⁻¹	0.66	0.66
Thermal conductivity coefficient /W m ⁻¹ K ⁻¹	0.837–20.934	83.74–125.6
Electric resistance, 10 ⁵ ρ /Ω m	0.4–70	0.003–0.6
Sublimation temperature /°C	—	3600
Hygroscopicity (%)	0.1–10	1
Tensile strength /MPa	350–700	1200–3100
Modulus of elasticity /GPa	30–200	300–700

higher chemical stability than fibres prepared from polyacrylonitrile (PAN) under identical conditions. The main characteristics of carbon fibres prepared from PAN are listed in Table 2.³⁰

Carbon fibres based on hydrated cellulose are prepared in several steps:³¹ (1) processing of raw materials (fibres, fabrics or felts) to make them more resistant to oxygen; (2) drying at 25–150 °C to remove water, carbon oxides and carbonyl compounds from the surface of fibres; (3) heating and partial oxidation at 200–300 °C; (4) high-temperature treatment of fibres (depending on the temperature regime, this step results in carbonisation or graphitisation of fibres); (5) activation and dressing of the fibre surface.

The first step consists of removal of bound water. Dehydration in the second step yields fragments containing carbonyl groups and C=C bonds. The third step includes thermal cleavage of the C–C and C–O bonds, which yields H₂O and gaseous decomposition products (CO₂, CO, etc.). Carbonisation, which occurs in the fourth step, begins at 375–450 °C and is complete at 1200 °C. In the course of gasification, all atoms of the organic polymer (with the exception of carbon) are eliminated from carbon fibres which acquire a ribbon-like structure. Graphitisation requires higher temperatures and is complete at 2200–2800 °C. This step includes final thermolysis of the polymer and accumulation of aromatic fragments and is accompanied by an increase in the ordering of ribbon-like structures, elasticity modulus and electroconductivity of carbon fibres. And, finally, the fifth (activation) step is carried out in the presence of an oxidising agent (e.g., atmospheric oxygen, water steam, carbon dioxide) for 30–60 min at 600–900 °C to increase the specific surface of carbon fibres.

The activation of carbon fibres and carbon–carbon composites (sibunits), is accompanied by burnout of their amorphous components and formation of microporous structures.³² Further oxidation results in partial burnout of more ordered structures and formation of macropores. The chemical activity of carbon fibres depends on their structure, which is largely determined by conditions employed in this step and, to a lesser degree, by the nature of the starting polymer.³⁰ At present, about 90% of all carbon fibres based on polymers are used for the production of composite materials.³³ Carbon fibres are also used as components in heat-insulating materials and in medicine.^{34,35}

d. Carbon nanofibres and nanotubes

Carbon nanofibres (CNF) formed upon decomposition of gaseous hydrocarbons on the surface of metal components of catalysts are becoming increasingly popular nowadays. The process of their preparation begins with the formation of hydrogen-containing carbon deposits on the surface of metal particles. These deposits are dissolved in the metal and diffuse through it to

form a thin graphite layer on the opposite side of the metal particles.¹⁶ The catalysts used for the preparation of CNF usually contain iron, cobalt, nickel, chromium, vanadium, molybdenum or their alloys. The ability to dissolve carbon and/or to form carbides is the major requirement for such catalysts. This reaction is carried out at 700–1200 K; methane, CO, synthesis gas, acetylene and ethylene are used as the starting materials.^{16,36}

Considerable attention is given to elucidation of mechanisms of formation and morphological characteristics of carbon nanofibres.³⁷ It was established³⁸ that carbon fibres prepared from a mixture of carbon oxides with methane on a nickel catalyst consist of single fibres with a diameter 2000–3000 nm which contain nickel microinclusions. These experiments were carried out in the temperature range 500–650 °C; the ratios of the reactants varied from 0.5 to 2.0 (CO₂:CH₄) and from 0.5 to 3.5 (CO:CH₄). The length of the fibres exceeded their diameters by several orders of magnitude and depended on the contact time of the catalyst with the reaction mixture. According to the suggested scheme,³⁸ the formation of carbon fibres proceeded *via* a metastable carbide-like nickel–carbon complex. In the case of a CO₂–CH₄ mixture, this complex is formed as a result of methane dissociation, whereas in the case of a CO–CH₄ mixture, its formation was due to dissociation of methane and disproportionation of carbon monoxide.

The regularities of formation of carbon with fibrous-tubular structure by disproportionation of CO were studied.³⁹ This reaction occurred in three successive steps. The first step included formation of catalytically active phases, which are represented by carbides with various compositions. In the second step, superficial carbon was formed as a result of disproportionation of CO on catalytically active surfaces. And, finally, the third step consisted of bulk spatial transformation of superficial carbon in a fibrous-tubular structure containing catalyst microinclusions.

The structure of carbon fibres strongly depends on the conditions of synthesis.³⁷ Morphological characteristics of carbon fibres are determined by the chemical nature of the catalyst and conditions for their preparation. Besides, the sizes of nanofibres depend linearly on the sizes of the catalyst particles.

A classification of fibrous-tubular carbon-containing nanomaterials according to their structures and properties has been suggested.¹⁵ These materials are divided into carbon nanotubes (CNT) and graphitised nanofibres. The main difference between them is the lack of hollow cavities in the latter. The diameter of graphitised nanofibres is larger than that of nanotubes and can reach 500 nm. Nanotubes in turn are subdivided into two main categories, *viz.*, single-wall and multi-wall nanotubes. Ideal single-wall carbon nanotubes are made of a perfect graphene sheet rolled up into a cylinder and closed by two caps. Their internal diameter varies from 0.4 to 2.5 nm, while their length varies from several microns to several millimetres. Multi-wall nanotubes can be regarded as a set of coaxial single-wall tubes of increasing diameters.¹⁵ The number of walls in a multi-wall nanotube varies from two to several tens, and the distance between the walls of two neighbouring tubes is equal to 0.34 nm. Depending on the arrangement of the layers, graphitised nanofibres are subdivided into three main types, *viz.*, platelet, ribbon-like and herringbone structures.

The USA and Japan are the major manufacturers of fibrous-tubular carbon nanomaterials and, to a lesser extent, Europe and Korea. These materials are used, along with traditional fibres based on polymers (polyacrylonitrile, viscose, etc.), in the production of composite materials.³⁷ Nanofibres and nanotubes are also employed in the production of electrodes,⁴⁰ they proved to be efficient adsorbents and hydrogen storages.^{16,37}

2. Oxidative modification of carbon supports

As is known,¹³ carbon does not virtually interact with active components of metal–carbon catalysts. Fixation of a precursor of the active component on the carbon surface is an important step in the preparation of supported catalysts. This is achieved, in

particular, by oxidation of the carbon surface. In the oxidative treatment, surface functional groups (acidic, basic or neutral) are formed.⁴¹ Acidic groups include carboxylic, anhydride and lactone groups; weakly acidic and neutral groups are represented by phenolic, carbonyl, quinone and ester groups, while pyrone and chromene are regarded as the main basic groups. The determination of the amount, thermal stability and nature of surface oxygen-containing groups is carried out by temperature-programmed desorption (TPD).⁴¹ These groups are destroyed during TPD to yield carbon dioxide from carboxylic, anhydride and lactone groups and carbon monoxide from phenolic, carbonyl, quinone and pyrone groups. The structures of surface oxygen-containing groups and gaseous decomposition products formed in the TPD as well as the decomposition temperatures have been studied.⁴² The interaction of free active centres of the carbon surface with oxygen is usually accompanied by conversions of one kind of oxygen-containing groups into another.

The possibility of incorporation of oxygen into carbon supports is determined by their structural features. The boundaries of the basal planes of the graphite structure contain carbon atoms with unsaturated valences. High concentration of unpaired electrons in these regions has a strong impact on the chemisorption. Graphite weakly chemisorbs oxygen, because the boundary zone in graphite crystallites is small in comparison with the basal plane. At the same time, microcrystalline carbon materials, such as activated carbons, have less ordered structures and a much larger boundary zone, which favours oxygen chemisorption.¹³ In contrast to graphite, the basal planes of activated carbon crystallites contain multiple defects, which play the role of chemisorption sites for the oxidant.⁴³ And, finally, activated carbons are highly porous and possess large specific surfaces; consequently, the number of potential active sites for the oxidant chemisorption is large enough.

It is noteworthy that the susceptibility of carbon materials to oxidation and, as a consequence, the number of oxygen-containing surface groups formed upon chemisorption of the oxidant depend on the degree of their graphitisation. Interactions of carbon materials with oxidants also depend on oxidation conditions, *e.g.*, reaction temperature. Treatment of carbon materials with oxygen may result in physical (reversible) and chemical (irreversible) adsorption of the oxidant gas. The former takes place at low temperatures, but the role of chemisorption increases with an increase in temperature. Chemisorbed oxygen molecules dissociate into atoms, which interact with surface carbon to form superficial complexes.⁴⁴

Oxygen-containing complexes can be formed on the carbon surface upon interaction not only with oxygen, but also with many other gaseous oxidants, *e.g.*, ozone, nitrogen oxides or carbon dioxide.^{13, 30, 45} Nitric acid, sodium hypochlorite, potassium permanganate and hydrogen peroxide can be used as liquid oxidants. Electrochemical oxidation of carbon materials is also possible.³⁰

Impregnation of a carbon support and ion exchange with a solution containing a precursor of the active component are the most popular approaches to prepare the catalysts. The mode of interaction of metal salts with supports strongly depends on the nature and number of functional groups formed on the support surface under the action of the oxidant.¹³ The major portion of the metal is applied onto the carbon surface, if the maximum surface of the support is chemically accessible, *i.e.*, if the largest electrostatic forces arise between the positively charged surface and negatively charged anions of a salt of the active component precursor, or, *vice versa*, between the negatively charged surface and the salt cations.^{46, 47} Thus the adsorption capacity of granular activated carbon with respect to copper ions increases upon modification with citric acid due to introduction of carboxyl groups.⁴⁵

The nature of the solvent used for impregnation is a factor determining the distribution of a metal (*e.g.*, platinum) on the surface of carbon supports.⁴⁸ Since carbon materials are, as a rule, hydrophobic, they possess very low affinity for polar solvents and

high affinity for non-polar solvents.¹³ Accordingly, impregnation of granular activated carbon with a solution of a platinum salt in acetone results in more uniform distribution of the salt over the surface of grains of the support than in the case of aqueous solutions.⁴⁸ The presence of oxygen-containing groups on the surface of carbon materials decreases their hydrophobicity, *i.e.*, increases the hydrophilicity, and favours impregnation of the support with aqueous solutions.⁴⁹

The effects of surface groups on the dispersity and sintering of metal–carbon catalysts were studied.^{50, 51} Preliminary modification of the surface significantly affects the interaction of the active phase with the support in the formation of a catalyst and the dispersity of the metal. The latter can be controlled by thermal and chemical modification of the porous structure of the support ensuring the formation of surface oxygen-containing groups.⁴¹ Thus oxidative treatment of activated carbon favours more uniform distribution of nickel over the support granules in a nickel–carbon catalyst. Probably, this is due to more intense diffusion of nickel into pores of the support. Preliminary oxidative treatment of carbon supports also has a beneficial effect on the stability of catalysts. Presumably,³⁰ the oxidation favours the formation of acid ion-exchange groups that form chelates with metal-containing compounds, which prevents the migration of the metal over the carbon surface. The surface oxygen-containing groups play the role of binding sites for the active metal component on the carbon surface.⁴⁹ The strongest ‘anchoring’ effect is manifested by weakly acid and neutral oxygen-containing groups, probably, due to stability of such groups at temperatures used for pretreatment of catalysts, whereas the acid groups decompose with liberation of carbon dioxide.

The ever-increasing number of publications devoted to effects of oxygen-containing surface groups on the properties of carbon supports and ultimately on the properties of catalysts prepared points to high prospects of this line of research.

3. Metal–carbon systems in catalysis

Catalytic systems based on activated carbons compete favourably with catalysts based on oxide supports. Thus the activities of In- and Sn-doped palladium catalysts supported on activated carbons that are used for denitrification of water are comparable with those on metal oxides.⁵² Catalysts with activated carbon as a support are used for methanol conversion into synthesis gas.⁵³ In the presence of copper–chromium catalysts, the degree of methanol conversion exceeds 90%, and side products including methane are formed in only trace amounts.

Despite the relatively high cost of commercial fibrous carbon materials, they are becoming more popular as supports for active components of heterogeneous catalysts.^{54, 55} The use of catalysts supported onto fibrous carbon nanomaterials in hydrogenation, hydroformylation, decomposition and oxidation of methanol is documented.^{14, 15, 37, 56} Catalysts supported onto carbon fibres doped with Co, Ni, Cr and Mn were tested in various conversion reactions of secondary alcohols.^{57, 58} Owing to well-developed porous structure and high thermal stability, novel fibrous carbon materials can be used as catalysts in oxidative dehydrogenation of organic compounds, in particular, of cumene.^{59, 60} Comparative studies have shown that the yield of styrene on carbon nanotubes is 1.5 times higher than on graphite.⁶⁰ It is noteworthy that no loss of CNT due to carbon oxidation took place, which was the case with soot as a catalyst.

Ruthenium catalysts on CNT and oxide supports (MgO, Al₂O₃, TiO₂) accelerate decomposition of NH₃ with the formation of CO-free hydrogen.⁶¹ The highest activity was observed for Ru/CNT, which is explained by high degree of dispersity of its active component and chemical purity of the support. These conclusions were confirmed by the results of TPD studies and high-resolution tunneling microscopy.

A nickel catalyst supported on carbon nanotubes manifested much higher activity in the hydrogenation of benzene than an analogous catalyst on γ -Al₂O₃.⁶² This was attributed to higher

dispersity of the active component on CNT and weaker interaction of Ni with the support. Ni/CNT manifested higher thermal stability than Ni/ γ -Al₂O₃, since the unique porous structure of CNT prevents agglomeration of Ni particles.

Carbon nanofibres can be used as supports for a nickel catalyst applied for the decomposition of ethylene to produce CO-free hydrogen.⁶³ The maximum yield of hydrogen on Ni/CNF is 2.5 times higher than on Ni/SiO₂.

A comparison of iron–copper catalysts supported onto carbon nanofibres, activated carbon and γ -Al₂O₃ revealed⁶⁴ that the degree of ethylene hydrogenation on Fe–Cu/CNF exceeded that on Fe–Cu/activated carbon and Fe–Cu/ γ -Al₂O₃ more than fourfold. The size of particles of the active component in the Fe–Cu/CNF catalyst was 12–16 nm, whereas that in Fe–Cu/activated carbon and Fe–Cu/ γ -Al₂O₃ catalytic systems varied from 6–10 to 2–8 nm, respectively. These results are consistent with the concept⁶³ according to which it is the porous structure and chemical composition of the support rather than the dispersity of the active component that play the crucial role in the activity of catalysts. It was suggested⁶⁴ that the surface layer of carbon fibres in bimetallic catalytic systems can be enriched with one of elements of the active component giving rise to strong metal–support interactions. Such an interaction is hardly possible for a carbon support with a less ordered structures.

Copper-containing catalysts supported onto carbon fibres were used in the dehydrogenation of cyclohexanol.⁶⁵ The yield of the target product at 350 °C was 93%. The dehydrogenation of isopropyl alcohol on this catalyst gave acetone (yield 95%–96% with 100% selectivity). The same system modified with Ti, TiO₂ and TiC was used for catalytic purification of hydrogen and decomposition of H₂S. The use of titanium as an additive resulted in virtually complete dissociation of hydrogen sulfide into hydrogen and sulfur.

Studies on denitrification in water using Pd–Cu-catalysts supported onto activated carbon cloth (ACC), Al₂O₃ and SnO₂ revealed⁶⁶ that Pd–Cu/ACC manifested 2.7–3 times higher activity than Pd–Cu/Al₂O₃ or Pd–Cu/SnO₂. The rate of denitrification on Pd–Cu/ACC was 33 mmol (g Cat)^{–1} h^{–1} (Cat is catalyst), whereas that on Pd–Cu/Al₂O₃ and Pd–Cu/SnO₂ did not exceed 12 and 15 mmol (g Cat)^{–1} h^{–1}, respectively.

A comparative study of Co–Mo-containing catalysts supported onto nanoporous carbon (NC) and traditional supports, *e.g.*, activated carbon and Al₂O₃, has been studied⁶⁷ in hydrodesulfurisation of dibenzothiophene and 4,6-dimethyldibenzothiophene. The overall activities of the catalysts increased in the following order: Co–Mo/Al₂O₃ < Co–Mo/activated carbon < Co–Mo/NC. The mesoporous structure of NC and its large surface area favoured higher dispersity of the catalyst. The metal loading lowered the surface area of activated carbon, but did not virtually affected the other supports.

A whole family of sibunit-based palladium catalysts have been developed. These include catalysts for hydrogenation of aromatic nitro compounds and vegetable oils, hydrorefining of terephthalic acid from *p*-carboxybenzaldehyde, hydrogenation and disproportionation of colophony, *etc.*^{24,68} Sibunit is also used for the preparation of sulfide Ni–Mo-catalysts, which are used for hydrorefining⁶⁹ and hydrodemetallisation,⁷⁰ and of rhenium catalysts for dehydrogenation of cyclohexane⁷¹ and isopropyl alcohol,⁷² hydrogenation of ethyl acetate⁷³ and some other organic reactions.⁷⁴

III. Conversions of lower alcohols on metal–carbon catalysts

1. Synthesis of methyl formate by dehydrogenation of methanol

In-depth thermodynamic studies of dehydrogenation of methanol into methyl formate (MF)⁷⁵ with consideration of side reactions (*e.g.*, dissociation of methanol into carbon monoxide and hydrogen; decarbonylation of methyl formate; dehydration and steam

conversion of methanol), revealed that the equilibrium constants of side reactions significantly exceed that of dehydrogenation of methanol so that the equilibrium concentration of MF in the reaction products is low. Thus, synthesis of methyl formate by this method is expedient only if highly selective catalysts are available. The properties of these catalysts determine the optimum temperature of the process. The concentration of methyl formate in the equilibrium mixture increases with an increase in temperature, but this is accompanied by increase in its decomposition rate. High concentrations of methanol and/or methyl formate suppress the decomposition of MF.⁷⁶ High temperature (240 °C) and properly selected partial pressure of methanol allows virtually complete prevention of MF decomposition.

The degree of methanol conversion can also be increased by removal of hydrogen from the reaction zone using advanced membrane technologies.^{76,77} Membranes of palladium–ruthenium alloys can be used to this end. However, they undergo deactivation by CO formed in a side reaction, *viz.*, decomposition of methyl formate. This problem was successfully overcome through the use of a specially designed reactor⁷⁶ where the membrane was not deactivated even at high (~20%) concentrations of CO in the gas mixture, whereas the permeability of this membrane with respect to hydrogen significantly decreased after passage of hydrogen containing admixture of CO in the absence of the catalytic mixture.

Copper-containing catalysts are especially active in the dehydrogenation of methanol.⁷⁸ The key role in this process is ascribed to the interaction of the support with components of the catalytic system. In metal–carbon catalysts, the lack of strong interaction of the active component with the support facilitates the reduction of the metal on the surface.^{79,80} For this reason, a series of well-known carbon materials that have not previously been employed in the process under consideration were tested as potential supports for copper catalysts.

The following supports were used:^{81–84} (1) activated carbon AC₁ prepared from peat; (2) activated carbon AC₂ prepared from coconut shells (grain diameter 1.7–3.35 mm, moisture content 2.80 mass %, ash content 0.60 mass %, packed density 0.510 g cm^{–3}, abrasion resistance 95%–99%, pH 7.5); (3) fibrous-tubular carbons (FTC) prepared by decomposition of gaseous hydrocarbons on an iron catalyst with subsequent removal of iron with a large excess of 37% hydrochloric acid, washing off chloride ions and drying at room temperature for 24 h and at 105 °C for 3 h (the size of graphite crystallites was 53 Å, density 3.862 g cm^{–3}); (4) non-woven carbon material (NCM) prepared from hydrated cellulose fibres (total pore volume > 0.8 cm³ g^{–1}, surface density 120 g m^{–2}, carbon content > 99 mass %, layer thickness > 0.8 mm); (5) woven carbon material (WCM) prepared from PAN fibres (carbon content 98%–99%, abrasion resistance 700–800 N); (6) sibunit P-232 obtained by deposition of pyrocarbon on a technical carbon support with subsequent activation (total pore volume with respect to H₂O 0.57 cm³ g^{–1}, apparent density 0.597 g cm^{–3}).

Catalysts containing 5 mass % of copper were prepared by impregnation of the aforementioned supports with a solution of a copper salt (nitrate, acetate or tetraammine nitrate) with subsequent drying at 100 °C and reduction of samples in a hydrogen flow at 400 °C.

Analysis of the reaction mixture in a flow-through reactor at a volumetric flow rate of methanol of 3.0 h^{–1} and temperature of 200–400 °C revealed^{84,85} that it was only Cu/sibunit that provided a sufficiently high degree of methanol conversion in the given temperature range. Presumably, the formation of catalytic sites on carbon supports requires higher concentrations of the metal than on oxide supports.⁸⁶ The highest degree of methanol conversion (63.3%) was observed at 350 °C; however, this parameter decreased with further increase in temperature. On other catalysts, the degree of methanol conversion was 12%.^{87,88}

In addition to methyl formate, the liquid phase contained non-consumed methanol and water present in the alcohol. The gas

phase contained hydrogen and carbon monoxide. At temperatures above 250 °C, CO₂ was found in the gas phase, whereas at 300 °C methane was additionally formed. The highest selectivity of MF formation (88.9% at 200 °C) was observed on Cu/AC₂; however, the activity of this catalyst was low. Moreover, its selectivity dropped with an increase in temperature. At temperatures above 300 °C, the highest selectivity was manifested by Cu/WCM.

The reduction of catalytic activity at elevated temperatures can be caused by several factors.

First, agglomeration of metal particles on the surface of the support can occur as a result of their migration or sintering.⁸⁹ Sintering is possible even in the preparation and pretreatment of the catalyst. The migration of active component (metal) particles over the surface of the support and the formation of large agglomerates can be explained by thermodynamic instability of smaller particles.

Second, deactivation can be caused by fouling of the surfaces of the active component and the support itself by carbon deposits of different origin.⁸⁹

It was shown that virtually no changes in specific surface of copper-containing catalysts occurred following methanol dehydrogenation in the temperature range from 200 to 400 °C. This confirms the assumption that the reduction of activity results from sintering of active component particles. Specific surface of a specimen based on sibunit somewhat increased after several runs. Probably, sintering of copper is accompanied by its partial removal from the granulated support with a flow of the reaction mixture. This is rationalised as the virtual lack of interaction between the active component and the carbon support.¹³

Data from X-ray photoelectron spectroscopy (XPS) suggest that, after reduction, the active component of the catalyst 5% Cu/sibunit is predominantly localised on the surface of the granulated support. Its content in the dead catalyst is markedly reduced suggesting that the copper particles migrate over the surface of sibunit granules rather than in their interior in the course of methanol conversion. Analysis of powdered grains of the dead catalyst revealed that the amount of copper particles inside pores of sibunit is much smaller than in the surface layer.⁸⁵ It may thus be concluded that the preparation and preactivation procedures favour the formation of catalysts of the shell type, and the decrease in the catalyst activity can be attributed to the migration of copper particles over the surface of the support.

As mentioned above, Cu/sibunit is the most efficient catalyst for dehydrogenation of methanol into MF, the yield of MF being 28.4% at 275 °C and 45% methanol conversion. However, low thermal stability is a serious drawback of sibunit-based catalysts. Their activity drops drastically at temperatures above 275 °C.

The oxidative modification of the carbon support described above, which decreases its hydrophobicity and provides a more uniform distribution of the active component, is one of the ways to increase stability of supported catalyst.⁴⁹ To this end, sibunit was

oxidised by treatment with 10% and 20% H₂O₂ or HNO₃, or by passing air at 400–500 °C (Refs 85 and 90). Copper was applied onto the modified support washed with distilled water and dried at 100 °C. Copper-containing catalysts usually manifest much higher selectivity and thermal stability on such supports. The highest yield of MF (36.8% at 325 °C) was obtained in the presence of sibunit pretreated with 20% HNO₃. This specimen contained 2.8% of oxygen incorporated upon oxidation. The maximum yields of MF on catalysts based on supports premodified with 20% H₂O₂ or air at 500 °C were 32.9% at 300 °C or 29.7% at 275 °C, respectively. It is noteworthy that the maximum yield of MF after liquid-phase oxidation of sibunit was achieved at higher temperatures than on non-modified specimens.^{91,92}

Introduction of high-melting modifying agents (promoters) might be an alternative approach to increase the catalyst stability. It was supposed^{85,90} that the use of zinc oxide to this end would favour retention of the optimum dispersity of copper in the catalyst 5% Cu/sibunit and ensure stronger interaction between the active component and the carbon support. However, the addition of 0.25 mass %–3.75 mass % of zinc oxide significantly decreased the selectivity together with the obvious increase in the thermal stability of the catalyst.

The ability to selectively accelerate the target reactions is yet another important feature of modifying additives. Considering that rhenium-containing catalysts possess good dehydrogenating properties,^{71,93} copper- and rhenium-containing mono- and bimetallic sibunit catalysts were tested in methanol decomposition at 200–400 °C.⁸³

Synthesis of methyl formate from methanol on copper-containing oxide catalysts is accompanied by decomposition of MF into carbon monoxide and hydrogen or into carbon dioxide and methane.^{77,94} Decarbonylation of MF^{75,95} and steam conversion of carbon monoxide⁹⁶ and methanol^{97,98} also took place under these conditions. The selectivity of MF formation at high degrees of conversion rapidly decreased as a result of decomposition of MF. The kinetics and mechanism of MF conversion on copper-containing oxide catalysts were studied in detail.^{77,94,99,100}

In the presence of monometallic copper- and rhenium-containing sibunit catalysts, methanol conversion into MF increased at first with an increase in temperature from 200 to 250 °C and then decreased gradually. With an increase in the rhenium concentration from 1% to 2%, the selectivity of the reaction at 250 °C increased from 33.3% to 42.9%. The same increase in the content of copper on a monometallic catalyst increased the selectivity from 46.5% to 59.1%. However, the decomposition of MF on 1% Cu/sibunit proceeded much faster than on 1% Re/sibunit. For instance, the yield of methanol at 200 °C on the former was three times larger than on the latter. It is noteworthy that the ratio CO:H₂ is equal to 1:1 on 1% Re/sibunit, which corresponded to the stoichiometry of MF decomposition, while that for the copper-sibunit catalyst was equal to 2:1. This suggests that the selectivity of MF formation changed oppositely to methanol

Table 3. Effect of rhenium additives to copper-sibunit catalysts on the conversion of methanol and selectivity of formation of methyl formate (pressure 0.1 MPa, volumetric flow rate 7.5 h⁻¹).⁸³

Parameter	Addition of Re (mass %)									
	2% Cu/sibunit					4% Cu/sibunit				
	0	0.25	0.5	1.0	2.0	0	0.25	0.5	1.0	
Total conversion (%) at

200 °C	69.0	66.4	62.5	60.0	59.2	65.8	63.5	62.3	53.5	
250 °C	59.1	52.5	49.9	42.4	35.1	55.6	52.6	52.5	44.3	
300 °C	42.1	36.0	28.4	17.1	12.5	20.0	28.2	25.5	20.8	

conversion. At high degrees of conversion, the selectivity of formation of the target product decreased rapidly as a result of decomposition of MF into CO₂ and CH₄.

The dehydrogenation activity of bimetallic Cu–Re/sibunit catalysts containing 2% and 4% of copper changed insignificantly with an increase in temperature from 200 to 300 °C (Table 3).⁸³ The addition of 0.25%–1% rhenium to 4% Cu/sibunit resulted in a threefold increase in the total conversion of methanol at 300 °C with a slight increase in selectivity. A catalyst containing 4% of Cu and 0.25% of Re on sibunit manifested the highest dehydrogenation activity. Such a noticeable increase in the catalyst activity implies that sintering of copper at high temperatures proceeds more strongly in the absence of this additive. The addition of 0.25% rhenium to 4% Cu/sibunit increased not only its activity and selectivity, but also its stability.⁸³

Thus, modification with rhenium provides an efficient copper-sibunit catalyst for dehydrogenation of methanol into methyl formate.

2. Synthesis of acetaldehyde by dehydrogenation of ethanol

Copper-containing catalysts are most active in dehydrogenation of alcohols.^{12, 101} As a rule, copper is supported onto silica gel.¹⁰² It was suggested that acetaldehyde is formed on the surface of metallic copper, since the UV spectrum of Cu/SiO₂ contains a single peak at 560 nm, which is assigned to Cu⁰ (Ref. 103). Activated carbon, which is basic by nature, also catalyses the dehydrogenation of ethanol.¹⁰⁴ On oxidised carbons, ethanol undergoes dehydrogenation and dehydration, the latter yielding diethyl ether and ethylene. Dehydration usually occurs on surface Brønsted acid centres and increases with an increase in the total surface acidity. However, oxidation of carbon promotes acetaldehyde formation, since dehydrogenation is catalysed by Lewis acid centres. Most probably, the dehydrogenation takes place on both basic and acidic surface centres, not necessarily simultaneously on both types of centres. In addition, the increase in the intensity of formation of acetaldehyde with an increase in specific surface suggests that the dehydrogenation is catalysed not only by external, but also by some internal surface groups.¹⁰⁴

The main drawback of copper-containing catalysts is their short service life. In connection with the problem of enhancement of stability of catalysts for ethanol dehydrogenation, studies into properties of various supports, their interactions with active components of catalytic systems and choice of modifying agents and pretreatment conditions become of special importance.

The search for the best support for a catalyst of acetaldehyde synthesis was carried out by performing conversion of ethanol on supports devoid of an active component, *viz.*, galumin (calcium aluminum cement), silica gel and sibunit.^{105–107} On galumin, which contains alumina, in addition to acetaldehyde, C₄ compounds (butan-1-ol, diethyl ether and ethyl methyl ketone) were identified in liquid products; these are formed on acid centres. Dehydration with formation of large amount of ethylene was the

main reaction on silica gel over the whole range of temperatures studied (200–500 °C). Acetaldehyde and, at temperatures above 250 °C, diethyl ether formed in insignificant amounts. No ethanol decomposition took place on sibunit at temperatures below 250 °C. At higher temperatures, CO, CO₂ and H₂ were formed in trace amounts. At temperatures above 400 °C, the reaction products contained acetaldehyde. On sibunit, the conversion of ethanol was as low as 2% at 500 °C, whereas on oxide supports (galumin and silica gel) it reached 80% and 70%, respectively. Among copper-containing catalysts based on these supports, the Cu/sibunit system manifested the highest activity in the dehydrogenation: the yield of acetaldehyde was 43% at 400 °C. Due to lower selectivities of systems based on the oxide supports, the yields of acetaldehyde were by 11%–13% lower.

Thus, side reactions accompanying acetaldehyde synthesis from ethanol are much less pronounced on sibunit than on the oxide supports.

It was shown^{91, 92} that ethanol conversion on copper-sibunit catalysts increases with an increase in the copper concentration from 0.3 mass % to 10 mass %. This is accompanied by a decrease in the selectivity of acetaldehyde synthesis and by formation of side products, *viz.*, buta-1,3-diene, ethyl acetate, butan-1-ol and acetone. The increase in the copper content in the catalyst from 3 to 5 mass % decreases the selectivity by 22%. The maximum yield of acetaldehyde (54%) was obtained on 3% Cu/sibunit. At the copper content of 5%, the yield of acetaldehyde decreased to 43%, but it did not change with a further increase in the copper content. Presumably, these catalysts are of the shell type where copper is predominantly localised in the surface layer, which makes the porous cavity of sibunits inaccessible for the reaction. This is corroborated by a decrease in the specific surfaces of catalysts with an increase in the copper content. Higher copper content in the surface layer of 5% Cu/sibunit (2.9 at %) in comparison with 3% Cu/sibunit (2.2 at %) was confirmed by XPES.

The temperature-dependent changes in the compositions of ethanol conversion products on the most efficient catalyst (3% Cu/sibunit) are given in Table 4.

By selecting conditions of pretreatment of a copper-sibunit catalyst (3% Cu/sibunit), one can significantly increase the yield of the target product.¹⁰¹ The catalyst calcined in argon and subsequently reduced in hydrogen at 400 °C afforded the highest yield of acetaldehyde (69.2%) at 375 °C. Preliminary calcination has a great impact on the selectivity of the process. An increase in the calcination temperature from 200 to 400 °C increases the selectivity of acetaldehyde formation. Reduction of the catalyst with hydrogen increases the conversion of ethanol and the yield of acetaldehyde (by 10%–14%). The difference between the yields of acetaldehyde in the presence of non-reduced and reduced catalysts can be explained by different states of copper on the surface of the support. XPES studies showed that 64% of copper atoms in the reduced sample are in the Cu⁰ or in the Cu⁺ state, while the rest 36% are in the Cu²⁺ state. The corresponding values

for a calcined non-reduced sample are 51% and 49%, respectively; the copper ions exist, most probably, only in Cu^+ and Cu^{2+} states. Presumably, higher concentration of Cu^{2+} in the calcined sample is the reason for inferior reaction parameters in the presence of non-reduced catalysts.

Stability is an extremely important characteristics of catalysts, especially of those intended for industrial use. However, the activity of 3% Cu/sibunit is lost dramatically at temperatures above 400 °C. According to XPES data, under the action of the reaction medium, copper passes into a Cu^{2+} state, which is less active as regards ethanol conversion, in the temperature range 200–500 °C. The period of stable active operation of the catalyst under conditions ensuring the maximum yield of the target product (375 °C, volumetric flow rate 0.3 h⁻¹) is 30 h after which its activity decreases.¹⁰⁸ Analysis of the XPE spectrum of the dead catalyst revealed an insignificant increase in Cu^{2+} content in comparison with the initial specimen. This suggests that the decrease in the catalytic activity of Cu/sibunit during its continuous operation is due to agglomeration of copper particles.

The agglomeration of copper particles into larger crystallites can be prevented and enhancement of the interaction of copper with the support surface can be reached if the catalyst is supplemented with magnesium oxide and chromium oxide. Magnesium oxide is known to decrease both the activity and the selectivity of Cu/sibunit catalysts, while chromium oxide causes significant increase in their activity at temperatures above 400 °C. However, a twofold (in comparison with the non-modified catalyst) increase in the degree of ethanol conversion was accompanied by a decrease in its selectivity. The best results were obtained at the copper : chromium oxide ratio 20 : 1 (the yield of acetaldehyde was 63.3% at 375 °C). Moreover, the addition of chromium oxide prolonged the operation life of the catalyst. Under conditions ensuring the maximum yield of acetaldehyde, the system can steady operate for at least 80 h.

Thus, the use of a carbon-containing material (sibunit) as a support allowed the development of an efficient catalyst for acetaldehyde synthesis. The parameters of this process can be improved through optimisation of conditions for pretreatment of copper–sibunit catalysts. Their stability can be increased by promotion with chromium oxide. The yield of acetaldehyde attained markedly exceeds the yields on the known industrial catalysts.¹⁰¹

3. Synthesis of acetone from isopropyl alcohol

Isopropyl alcohol undergoes easy (in comparison with other aliphatic alcohols) dehydrogenation to give acetone and dehydration to give propene.

Traditional copper-containing catalysts for dehydrogenation of alcohols into aldehydes usually contain significant amounts of a metal. Thus the commercial catalyst SNM-1 ($\text{CuO} - \text{ZnO} - \text{Al}_2\text{O}_3$) manufactured in Russia contains 64% of CuO. A 30% rhenium catalyst on activated carbon manifests high dehydrogenating properties, but rapidly loses its activity.

Modification of metal catalysts used for the conversion of isopropyl alcohol can be achieved by replacement of activated carbons by sibunit.⁷² In a series of monometallic 1% Cu-, Re-, Ni- and Pd/sibunit catalysts, the highest activity was manifested by 1% Re/sibunit (Table 5). At 250 °C, the yield of acetone on this catalyst was commensurate with that obtained on 30% rhenium/activated carbon at 195 °C.¹⁰⁸

On bimetallic catalysts containing 1% Re and Cu, Re and Ni or Re and Pd, the degree of conversion of isopropyl alcohol into acetone markedly exceeds that on monometallic 1% Cu/sibunit, Ni/sibunit and Pd/sibunit catalysts. Thus the introduction of rhenium to a palladium-containing catalyst increases its activity 35-fold and its stability, nearly twofold. Bimetallic catalysts retain their activities and high selectivity (77%–90%) even after 6–9 h of operation.

The obvious advantage of bimetallic catalysts over monometallic ones is that rhenium favours the reduction of the second

Table 5. Dehydrogenation of isopropyl alcohol on mono- and bimetallic catalysts supported onto sibunit (volumetric flow rate 1.1 h⁻¹, reaction in a flow of hydrogen).⁷²

Metal content	Reaction conditions		Degree of alcohol conversion (%)		Selectivity of acetone formation (%)
	<i>T</i> / °C	time / h	total	into acetone

metal (Cu, Ni or Pd). In the alcohol dehydrogenation, the activities of the above-mentioned bimetallic catalysts increase in the following order: Re–Cu < Re–Ni < Re–Pd.

No rhenium crystalline phase could be detected by X-ray phase analysis in a bimetallic catalyst containing 2% Re and 2% Ni on sibunit, which suggests a highly dispersed state of rhenium. The data listed in Table 6 illustrate the effects of added rhenium on the activity of 2% Cu/sibunit in the conversion of isopropyl alcohol at 200–270 °C.¹⁰⁹ Liquid products formed on a monometallic (*i.e.*, containing no rhenium) catalyst contain acetone and water (along with the non-consumed alcohol), while the gas phase contains propene and hydrogen. At 200 °C, the dehydrogenation and dehydration occur in parallel. Thirty minutes after the beginning of the reaction, the total conversion of the alcohol on 2% Cu/sibunit is ~15.3%, while the ratio of yields of acetone and water is 3.3. With an increase in temperature from 200 to 270 °C, the dehydrogenating activity of the monometallic catalyst increases 3.2-fold. The selectivity of acetone formation increases from 76.6% to 86.7%. If after 2 h-operation of 2% Cu/sibunit at 270 °C the temperature is decreased to 200 °C, the initial dehydrogenating activity of the catalyst is recovered virtually completely.

Rhenium, which has a high melting temperature (3170 °C), is not subject to recrystallisation in the course of the catalytic process; therefore its addition can increase the stability of catalytic systems.⁸⁵ As can be seen from Table 6, the addition of 0.25% rhenium improves the dehydrogenating properties of 2% Cu/sibunit in the conversion of isopropyl alcohol. The lack of a strong metal–support interaction on a carbon support facilitates the reduction of the metal on the catalyst surface, which takes place even at 200 °C.¹⁰⁹

Glow discharge plasma treatment in oxygen is a way to control properties of copper and copper-rhenium catalysts.¹¹⁰ The effect of plasma treatment was assessed by measuring the degree of conversion of isopropyl alcohol into acetone in the temperature range 177–327 °C. The catalysts were processed in the following regimes: (1) hydrogen treatment; (2) hydrogen treatment with subsequent catalysis and repeated hydrogen treatment; (3) plasma treatment with subsequent hydrogen treatment; (4) plasma treatment; (5) plasma treatment with subsequent catalysis and final hydrogen treatment.

The yield of acetone after treatment of a copper-sibunit catalyst in regime (3) decreased, while that of Cu–Re/sibunit increased. Manifold increase in the activity was observed after treatment of the catalyst in regime (5). In order to elucidate the reasons for the change in activity of the catalyst depending on the

Table 6. Conversions of isopropyl alcohol on 2% Cu/sibunit catalysts containing different concentrations of rhenium (flow systems, atmospheric pressure, reaction in H₂ flow, volumetric flow rate 1.0 h⁻¹, reaction time 30 min).¹⁰⁹

Table 7. Activation energies and preexponential factors for dehydrogenation of isopropyl alcohol on 2% Cu/sibunit catalysts containing different amounts of rhenium before and after plasma treatment in regime (4) (see the text).¹¹⁰

Re content (%)	Before treatment		After treatment	
	<i>E_a</i> /kJ mol ⁻¹	ln <i>A</i> ₀	<i>E_a</i> /kJ mol ⁻¹	ln <i>A</i> ₀
0	38.7	14.1	—	—
0.25	34.9	12.3	38.7	14.1
0.5	48.4	16.5	13.4	9.2
1.0	51.7	16.3	38.1	13.4
2.0	57.5	17.7	46.5	16.2

mode of treatment were elucidated by studying the temperature dependences of the yield of acetone (*Y*) at low degrees of conversion in the Arrhenius coordinates (ln *Y* vs. *T*⁻¹). As can be seen from Table 7, the values of activation energies (*E_a*) and the preexponential coefficients (*A*₀) for the dehydrogenation of isopropyl alcohol on 2% Cu/sibunit and 2% Cu + 0.25% Re/sibunit are very similar. Much higher *E_a* values (48.4, 51.7 and 57.5 kJ mol⁻¹, respectively) were obtained for samples with a higher rhenium content (0.5%, 1.0% and 2.0%).

Treatment of the catalyst 2% Cu + 0.25% Re/sibunit in regime (4) slightly increases its activity, which can be attributed to the larger number of active centres rather than to structural changes, as can be evidenced from a significant increase in ln *A*₀ with a small change in *E_a*. A decrease in the activation energy of the reaction on 2% Cu + 0.5% Re/sibunit under identical conditions is due to the substantial changes in the structures of the active centres. However, the effect of this factor is compensated by a significant decrease in the number of these active centres (factor *A*₀); therefore, the yield of acetone on this catalyst is only slightly higher than on 2% Cu + 0.25% Re/sibunit processed in a similar regime. The increase in the yield of acetone on 2% Cu + 1% Re/sibunit can be explained exclusively by a decrease of the activation energy, since the value of *A*₀ after treatment in regime (4)

decreased. On 2% Cu + 2% Re/sibunit, the changes in the *E_a* and ln *A*₀ are insignificant.

Treatment in regimes (1–5) has different effects on the activities of copper and copper–rhenium catalysts on sibunit. This suggests that active centres of copper–rhenium catalysts based on sibunit represent bimetallic clusters Cu_{*x*}Re_{*y*} with Cu–Re bonds. Presumably, the active centre of the catalyst contains a hydrogen atom, since the highest activity was manifested after plasma treatment followed by a series of catalytic runs and final hydrogen treatment (regime 5). If plasma treatment was not followed by hydrogen treatment, the activity changed only insignificantly and showed a tendency to decrease, apparently due to partial removal of hydrogen from the active centres.

Apparently, the role of rhenium atoms in the active centres consists, first, of stabilisation of the structure of these centres.^{72, 108} This follows from the fact that copper–rhenium catalysts maintain their activity on sibunit for longer periods of time than catalysts containing no rhenium. Second, the interaction of Re atoms with Cu atoms results in positive polarisation of the latter, which favours the displacement of an electron from the carbon atom of the CH group of isopropyl alcohol first to the copper atom and then to the hydrogen atom in the active centre. This, in turn, favours the interaction of the hydrogen atom in the active centre with a positively polarised hydrogen atom of the hydroxy group. It is noteworthy that the work function of electron is equal to 5.0 eV for rhenium and 4.4 eV for copper. Hence, the dehydrogenation process can schematically be presented as follows:

Ab initio quantum-chemical calculations (GAUSSIAN-98) confirmed the suggested structure of the active centre.¹¹¹ The lower activity of 2% Cu + 2% Re/sibunit as compared with that

Table 8. Conversion of isopropyl alcohol in samples obtained by passage of volcanic gas through sibunit.¹¹⁶

^a The original sample non-treated with the volcanic gas.

of 2% Cu + 0.5% Re/sibunit is probably due to formation, in the former case, of rhenium structures outside the active centres.

Thus, 2% copper/sibunit catalysts containing 0.25%–0.5% of rhenium selectively dehydrogenate isopropyl alcohol into acetone. Glow discharge plasma treatment of Cu/sibunit catalysts in oxygen decreases the yield of acetone, while similar treatment of Cu–Re catalysts increases it. The activity of catalysts can be increased manifold by plasmochemical treatment followed by a series of catalytic conversions of isopropyl alcohol and, finally, reduction with hydrogen.

4. Catalytic properties of natural volcanic rock from the Isle of Iturup

High concentrations of compounds containing rhenium, copper and other metals were found in the gases leaking from fumaroles (small holes and clefts through which eruptive gas emerges from the Earth's interior) of the volcano Kudryavy (the Isle of Iturup in the Kuriles).^{112–114} Volcanic rock represents a solid silicate mass with ingrain sulfide sublimate crystals of pyrite (FeS₂), galenite (PbS) and rhenium sulfide (ReS₂). Sulfide sublimates form small (as a rule, less than 40 μm) isolated excretions on the boundaries of volcanic rock grains and in the pores of other minerals. Volcanic rock contains the following metals (mass %): Re (0.005), Cu (0.005), Ag (0.0002), Zn (0.070), Cd (0.040), Ga (0.0015), In (0.020), Tl (0.0004), Co (0.0005), Ni (0.003), Ge (0.001), Sn (0.030), Pb (0.020), As (0.010), Sb (0.005), Bi (0.030), V (0.015), Mo (0.004). Rock samples manifest high dehydrogenating activity, although the content of metal sulfides (including rhenium sulfide) is an order of magnitude lower than in ordinary dehydrogenation catalysts.¹¹⁵

Synthetic samples prepared by passage of volcanic gas through quartz tubes filled with a support for 14–17-days manifested catalytic activity in the dehydrogenation and dehydration of isopropyl alcohol. The samples were prepared on zeolite, alumina and sibunit. On zeolite and on γ-Al₂O₃, the dehydration of isopropyl alcohol was complete at 400 °C and at 300 °C, respectively; no dehydrogenation was observed on these catalysts. On sibunit non-treated with volcanic gases, both dehydrogenation and dehydration took place at 400 °C, the total degree of isopropyl alcohol conversion being ~10%. The catalytic properties of sibunit samples are summarised in Table 8. The major contribution to the dehydrogenating activity of volcanic rock samples and artificial samples is made by magnesium, molybdenum and rhenium sulfides.

Rhenium and other rare elements of volcanic gas are best adsorbed on zeolite. A method for isolation of rhenium from zeolite is developed, which can be useful for the design of novel efficient catalysts for different organic chemical and petrochemical processes.^{74, 115–117}

IV. Conclusion

The data presented above suggest high potential of modern carbon materials having globular and fibrous-tubular structure and carbon–carbon composite materials (*e.g.*, sibunit) as supports for catalysts. The use of metal-containing catalysts based on sibunit significantly increases the efficiency of formation of methyl formate, acetaldehyde and acetone by dehydrogenation of the corresponding aliphatic alcohols. Catalysts have been developed that enable significant increase in the yields of target products despite the lower (by an order of magnitude) content of copper in comparison with commercial copper-containing oxide catalysts used for dehydrogenation of alcohols. Rhenium-sibunit catalysts manifest high activity in the dehydrogenation of isopropyl alcohol. Bimetallic catalysts Re–Pd, Re–Ni and Re–Cu on sibunit are much more stable than monometallic systems. Substitution of sibunit for the activated carbon as a support makes it possible to reduce rhenium content from 30% to 1%–2% without any loss of catalytic activity in the dehydrogenation of isopropyl alcohol. The activity of the catalyst can also be increased using glow discharge plasma treatment in oxygen. The excretions from the volcano Kudryavy (Isle of Iturup, Archipelago Kurile Islands) contain oxides of Si, Al, Fe, *etc.*, and some metal sulfides (including Re and Cu sulfides) and manifests dehydrating and dehydrogenating properties in the conversion of isopropyl alcohol. Synthetic samples prepared by condensation of high-temperature volcanic gases on sibunit manifest only dehydrogenating activity. The excretions from the volcano Kudryavy can be regarded as a source of rhenium (in the form of ReS₂) for novel efficient catalysts.

Development of novel metal-containing catalysts for dehydrogenation of aliphatic alcohols in which sibunit is used as a support instead of metal oxides is a basis for the design of efficient catalytic procedures for the synthesis of valuable organic intermediates alternative to the existing techniques. Taking into account the growing tendency towards a departure from the use of crude oil, the use of lower aliphatic alcohols as a raw material seems to be a promising trend in chemical industry.

Abstract. Data on the synthesis, reactivity features and the key chemical transformations of thiophene 1,1-dioxides are summarised and described systematically. The attention is focused on recent achievements in the chemistry of thiophene dioxides concerning both their practical use and theoretical studies. The bibliography includes 205 references.

I. Introduction

Thiophene 1,1-dioxides are non-aromatic heterocyclic compounds possessing properties of conjugated electron-acceptor dienes. Although the first representatives of thiophene dioxides were obtained back in the early 20th century, the interest in these compounds persists. Owing to the unique structure combined with high reactivity, they can be used to prepare various carbo- and heterocyclic systems; therefore, these compounds are convenient 'building blocks' in organic synthesis.

Extensive information on the synthesis and chemical transformations of thiophene 1,1-dioxides has been accumulated by now. Several published reviews^{1–8} largely cover the research period from the moment the first compounds were obtained (1915) to the mid-1990s. The reference book *Science of Synthesis (Houben-Weyl)*⁸ published in 2004 briefly describes the methods of synthesis and some chemical transformations of thiophene dioxides discovered in recent years. The most comprehensive review on this topic was written by Nakayama³ and published in 1999 in *Topics in Current Chemistry*. However, the number of publications dealing with the chemistry of thiophene dioxide-based new materials, namely, semiconductor organic transistors and light diodes first designed about 15 years ago, started to increase in 1997. In recent years, new data on the biological activity of some thiophene 1,1-dioxide derivatives were obtained. These facts and also the fact that the above-noted publications are not readily available in Russia were the driving forces for writing this review. In addition, the results of our recent studies of

thiophene dioxides with electron-withdrawing substituents together with the fundamental works in this field will provide a holistic view of the synthetic potential of this class of compound.

II. Synthesis of thiophene 1,1-dioxides

The information presented in this Section is classified according to the type of reaction (Scheme 1). The key methods for the synthesis of thiophene dioxides include four types of transformations: oxidation of thiophenes (path *a*), addition–elimination reactions in the series of substituted sulfolenes (path *b*), and various intra- and intermolecular cyclisations (paths *c* and *d*). The oxidation of thiophenes is a well-studied and the most general route to thiophene dioxides. Earlier reviews^{2,3,6–8} describe the methods of oxidation of substituted thiophenes; therefore, for reactions using traditional oxidants we present only a summary Table for the obtained compounds with references to original works. The use of oxidants and reagents discovered in recent years is considered in detail. For more comprehensive presentation of the information concerning this type of reaction, paths *b–d* are considered both in the classical variant and according to the latest achievements in the synthesis of thiophene dioxides. For specific

synthetic routes, only bibliographic data are given due to their limited use.

1. Oxidation of thiophenes

Organic peroxy acids are well-known reagents for thiophene oxidation. Most often, thiophene 1,1-dioxides have been prepared using peracetic, perbenzoic and *m*-chloroperoxybenzoic (MCPBA) acids (Table 1).

m-Chloroperoxybenzoic acid is most reactive in this series of oxidants. For example, a number of sterically hindered di-*tert*-butyl, dineopentyl and diadamantylthiophene dioxides have been prepared using this reagent.^{18–22, 25} It should be noted that under the action of MCPBA, perhalogenated thiophenes (Cl- or Br-containing) form thiophene dioxides in moderate yields,²⁸ whereas 2,5- or 2,4-dihalo thiophenes are not oxidised by this reagent (see Table 1).

Benzo[*b*]thiophene 1,1-dioxides, important building blocks for the synthesis of various biologically active compounds, are also easily prepared by oxidation of benzothiophenes. Despite the fact that a large number of oxidants are currently known, peracetic acid and MCPBA are still used most often in these reactions.^{29–32}

Recently, this method was used to prepare^{33–35} trimethylsilyl and trimethylgermyl derivatives of thiophene 1,1-dioxides, convenient starting compounds for organic synthesis (see Sections III

and IV). For example, 2,5-dimethyl-3-(trimethylsilyl)thiophene was converted, on treatment with MCPBA, into the corresponding thiophene dioxide in good yield; however, for its stannyl analogue, cleavage of the tin–carbon bond rather than oxidation took place under these conditions.³⁴

A recent alternative to MCPBA is trifluoroperoxyacetic acid usually prepared from a 30% solution of hydrogen peroxide and trifluoroacetic acid or its anhydride. Using this reagent, the yields of halogen-containing thiophene 1,1-dioxides have been markedly increased as compared with the yields with other oxidants^{36, 37} and some benzo-³⁸ and dibenzothiophene 1,1-dioxides have been prepared.^{39, 40}

The use of trifluoroperoxyacetic acid under nonaqueous conditions (prepared from 100% H₂O₂ and trifluoroacetic anhydride) opened up the way to thiophene dioxides containing strong electron-withdrawing substituents.⁴¹ A versatile method for the preparation of sulfones **1a–x** by the reaction with CF₃CO₃H in various solvents has been reported⁴² (Table 2). It was shown that the course of the reaction depends on the structure of the initial

thiophene and the nature of the solvent. This method can be used to oxidise thiophenes with both electron-donating and electron-withdrawing groups.

The above-described method has some limitations. Thus thiophenes containing an acetyl group in the position 2 or 3 undergo the Baeyer–Villiger oxidation under these conditions. Further oxidation of the resulting acetoxythiophene with excess trifluoroperoxyacetic acid gives destruction products, which is apparently due to high electrophilicity of the reagent. In addition, by using CF₃CO₃H, it is impossible to obtain mono- or 2,3-disubstituted thiophene dioxides.

In 1990, Miyahara and Inazu⁴³ introduced, to the synthetic practice, dimethyldioxirane (DMD), a cyclic peroxide, which allows one to oxidise substituted thiophenes under mild conditions to obtain products in high yields. This protocol was employed to prepare thiophene 1,1-dioxides containing not only halogen atoms but also an acetyl group. Nevertheless, monosubstituted 2-ethylthiophene could not be converted into sulfone under these conditions.⁴³ More recently, Nakayama and co-workers^{44,45} have shown that the use of DMD at low temperature can serve as a convenient method for the preparation of unsubstituted (**2a**) and monosubstituted thiophene dioxides **2b–f**.⁴⁶

Due to their exceptional lability, these compounds were isolated by evaporating the solvent *in vacuo* and recrystallised at –40 °C. The degree of conversion of thiophene in these reactions was ≤45%. Note that DMD is the only reagent capable of selective oxidation of thiophenes unsubstituted in C(3)–C(4) positions, since the use of peroxy acids or other oxidants may induce easy epoxidation of the double bond and subsequent overoxidation.

Rozen and co-workers, who investigated the synthetic potential of the HOF·MeCN complex (see, for example, Ref. 47), proposed a method for oxidation of substituted thiophenes.⁴⁸ This reagent, prepared by bubbling elemental fluorine into aqueous acetonitrile, reacts with substituted thiophenes under mild conditions to give target thiophene dioxides in high yields. As a result, sulfones from 2,5-dichloro-, 2,4- and 2,5-dibromothiophenes and from methoxycarbonyl and acetyl derivatives have been prepared. Being a very strong electrophilic oxidant, the

HOF·MeCN complex transformed 2-amino-5-methoxycarbonylthiophene into the corresponding nitrothiophene dioxide.⁴⁷

In the last decade, the search for new catalysed processes for thiophene oxidation with readily available reagents became a topical task. This is due to the necessity of increasing the quality of oil stock. A decrease in the organic sulfur content in oil fractions and engine fuels can be attained by oxidation reactions. The oxidative properties of various catalytic systems were studied using mainly benzo- and dibenzothiophene derivatives that occur in crude oil. Transition metal complexes (W, Mo, Mn, Cr, Fe) in the presence of various oxidants were studied (Table 3). The amount of the catalyst was varied from 0.1 mol.% to 20 mol.%. The turnover numbers (TON) of the catalysts were reported only in one publication.⁵³ The yields in these reactions approach 100%; however, in some cases, the corresponding 1-oxides are formed as admixtures.

Table 3. Catalytic methods of oxidation of benzo[*b*]- and dibenzothiophenes.

Catalyst, solvent	Oxidant	Amount of the catalyst (mol.%)	Ref.
[Mn ^{IV} Mn ^{IV} (μ-O) ₃ L ₂](PF ₆) ₂ , ^a Py	H ₅ IO ₆	0.3–1.8	49

^a L is 1,4,7-trimethyl-1,4,7-triazacyclononane; ^b mtp is 2-(mercapto-methyl)thiophenol; ^c R = Me, Bu, Ph, Bn, Cy (cyclohexyl); ^d M = Fe, Co, Ru; PcS is sulfophthalocyanine.

Recently, an efficient heterogeneous catalytic system based on Co-containing aluminophosphates (or MoO₃·Al₂O₃) and Bu^tOOH as the oxidant has been proposed.⁵⁶ High oxidation rates of 2,5-dimethyl-, benzo- and dibenzothiophenes were observed at 80 °C. Low cost of these catalysts is a benefit as regards solving the problem of desulfurisation of engine fuels.

Other inorganic reagents have also been used successfully for thiophene oxidation. A method for the synthesis of thiophene dioxides and their benzo derivatives containing various substituents (55 examples) has been patented.⁵⁷ Thiophenes were oxidised with a 30% solution of hydrogen peroxide in the presence of vanadium and molybdenum oxides generated *in situ* on treatment of the metals with H₂O₂.

Commercially available reagents such as NaBO₃·4 H₂O in acetic acid⁵⁸ and the H₂O₂·[CO(NH₂)₂] complex in formic acid,⁵⁹ were employed for the oxidation of alkyl-substituted thiophenes and their benzo and dibenzo analogues. Under the action of these oxidants, the corresponding thiophene dioxides were formed in high yields; however, thiophenes containing functional groups and halogen atoms did not undergo oxidation.

Analysis of the above methods for the synthesis of thiophene 1,1-dioxides and their fused derivatives shows that the current

level of synthetic organic chemistry allows one to oxidise thiophenes with diverse substituents. Functionalised thiophene dioxides are prepared only using strong electrophilic oxidants such as CF₃CO₃H, HOF·MeCN and DMD, whereas compounds with electron-donating alkyl, silyl and germly groups are readily oxidised under the action of MCPBA. In recent years, attention has been focused on the development of all-purpose oxidants capable of converting any, including monosubstituted, thiophenes to the corresponding sulfones.

2. Elimination of substituents from sulfolane and sulfolene derivatives

Unsubstituted thiophene 1,1-dioxide (**2a**) was first synthesised by a six-stage sequence of transformations including Hofmann elimination.⁶⁰

Due to the tendency for fast di- and trimerisation, compound **2a** was prepared only as a solution in CHCl₃.

Later, this approach was simplified: bromination of readily available 3-sulfolenes **3** and elimination of HBr with NaOH powder resulted in target thiophene dioxides **4** in two steps.^{61,62} However, this method is inapplicable if there is an alternative way of hydrogen halide elimination to give an exocyclic double bond or if the product is capable of isomerisation. For example, the reaction of 3,4-dibromo-3,4-dimethylsulfolane with NaOH gives compound **5** containing an *exo*-methylene group. This reaction route takes place also for 2,3,4,5-tetramethyl-3,4-dibromosulfolane.

R¹ = R³ = H; R² = Me (**2c**), Et (**4a**), Cl (**4b**);

R¹ = H; R² = R³ = Cl (**4c**), Ph (**4d**); R¹ = R² = R³ = Me (**4e**).

The halogenation–elimination strategy was also used for the synthesis of fluorine-containing thiophene dioxides. Heating of 3-sulfolene (**6**) with anhydrous HF and *N*-chlorosuccinimide in an autoclave resulted in 4-chloro-3-fluorosulfolane (**7**), which undergoes radical chlorination to 3,3,4-trichloro-4-fluorosulfolane (**8**). Treatment of this product with triethylamine in acetone gives 4-chloro-3-fluorothiophene 1,1-dioxide (**9**) (Scheme 2).⁶³

Diffuoro derivative **10** was prepared in a similar way. The addition of elemental fluorine to compound **6** gives a product mixture. The *cis*- and *trans*-difluoro derivatives isolated from this mixture by column chromatography were subjected to radical chlorination, which gave *trans*- and *cis*-isomers (ratio 5 : 1) in 68% yield. The subsequent elimination of HCl resulted in difluorothiophene dioxide **10**.⁶⁴ The last step may give compound **9** as a by-product through alternative elimination of HF. This fact was detected by ¹H NMR spectroscopy. The yield of thiophene dioxide **10** after purification by vacuum sublimation was 53%.

The addition of nitrogen(IV) oxide to 2,5-diisopropylidene-3-sulfolene (**11**), prepared by condensation of 3-sulfolene (**6**) with acetone, gives, after hydrolysis, 2,5-bis(1-methyl-1-nitroethyl)-thiophene 1,1-dioxide (**12**).⁶⁵

Easy elimination of nitrous acid from trinitro-3-sulfolene **13** under the action of bases (*e.g.*, pyridine) was used to prepare the corresponding 2,4-dinitro derivative.^{66,67} The final product of this transformation was isolated as pyridine complex **14**. Similar complexes of dinitrothiophene 1,1-dioxide with pyridine-d₅ (yield 84%), 4-picoline and quinoline (yields 75%) were also isolated. Treatment of complexes of type **14** with trifluoroacetic acid gave free thiophene 1,1-dioxides.

It is noteworthy that all the transformations described above based on the addition–elimination reactions in the sulfolene series and related structures are mostly multistep processes having low chemo- and regioselectivity, which substantially restricts the scope of applicability of this method for synthetic purposes.

3. Methods including ring formation

A number of thiophene 1,1-dioxides containing electron-donating substituents (amino, alkoxy or acyloxy groups) can be prepared by intra- and intermolecular cyclisations. The classical condensation of sulfones **15** with diethyl oxalate yields 3,4-dihydroxy derivatives **16** and **17**.⁶⁸ It was shown⁶⁹ that compound **17** is an equilibrium mixture of tautomers.

The reaction of compound **17** with diazomethane, phosgene, thiophosgene, *p*-toluenesulfonyl chloride and ethylenediamine affords derivatives **18–22**, which are true thiophene dioxides.^{69–71}

Using the strategy including intramolecular condensation of 3-carboxyquinolines **23**, tricyclic compounds **24** were obtained in high yields.⁷²

R¹ = H, Me; R² = H, 4-Cl, 3-F, 4-F, 4-MeO.

A similar approach has been utilised to obtain 3-substituted benzo[*b*]thiophene 1,1-dioxides.⁷³ For example, on treatment with lithium diisopropylamide (LDA), *o*-methylsulfonyl-substituted aceto- (**25a**) and benzophenones (**25b**) cyclise into dioxides **26a,b**.

The subsequent elimination of water induced by *p*-toluenesulfonic acid (TsOH) gives 3-methyl- (**27a**) and 3-phenylbenzo[*b*]thiophene 1,1-dioxides (**27b**) in high yields.

Compound	R	Yield (%)		
		25	26	27
a	Me	76	68	81
b	Ph	78	73	88

Intramolecular condensation has also been used⁷⁴ to prepare functionally substituted 3-aminobenzo[*b*]thiophene dioxides. The nitrile group acts as the 'carbonyl component' for the cyclisation. The whole sequence of transformations is based on modification of available 2,4,6-trinitrobenzamide (**28**) by successive replacement of the nitro groups by various O-, S- and N-nucleophiles. In the key step of the synthesis, the corresponding benzylsulfonylbenzonitrile **29** cyclises under the action of sodium methoxide to give compounds **30**.

Nu = OMe, OPh, OCH₂CF₃, N₃.

A method comprising the reaction of diaryl- α,ω -diacetylenes with zirconocene generated *in situ* from dicyclopentadienylzirconium chloride and *n*-butyllithium in THF has been proposed for the synthesis of oligomeric derivatives containing thiophene and thiophene 1,1-dioxide fragments. The subsequent treatment of organozirconium intermediates **31** with sulfur dioxide resulted in the corresponding thiophene 1-oxides **32** in nearly quantitative yields. Oxidation of oxide **32** ($n = 1$, R = H, Ar = 2-thienyl) with MCPBA gave oligomer **33** with a central thiophene dioxide fragment.⁷⁵ This approach was also used to prepare more complicated oligomeric structures employed currently in materials chemistry (see Section IV).

$n = 1, 2$; R = H, *n*-C₆H₁₁; Ar = 4-BrC₆H₄, 2-thienyl, 5-bromo-2-thienyl, 2,2'-bithienyl-5-yl.

4. Special methods of synthesis

A number of procedures are known in which thiophene 1,1-dioxides and their benzo and dibenzo derivatives are formed as intermediates or as components of complex mixtures.^{3–6} Most often, these transformations are of no synthetic utility; therefore, we will cite only two examples of these reactions discovered in recent years. For example, oxo sulfone **34** is unexpectedly condensed under the action of urotropine or paraformaldehyde in acidic medium in the presence of ammonium acetate to give heterocycle **35** containing two benzo[*b*]thiophene 1,1-dioxide fragments.⁷⁶

(a) (CH₂)₆N₄, AcONH₄, AcOH or CF₃CO₂H;

(b) (CH₂O)_{*n*}, AcONH₄, AcOH, PhMe.

The tandem isomerisation–cyclisation of bis(alkenylpropargyl) sulfone **36** furnishes benzo[*c*]thiophene 1,1-dioxide derivative **37**.⁷⁷

R¹ = R² = (CH=CH)₂; R¹ = Me, R² = H; R¹ = R² = (CH₂)₄; DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene.

III. Reactions of thiophene 1,1-dioxides

The nonaromatic nature of thiophene 1,1-dioxides is responsible for their unique properties. The cyclic diene system bound to the SO₂ group exhibits high activity in both cycloaddition reactions and reactions with nucleophiles. In addition, the presence of the vinylsulfone fragment in the structure of thiophene dioxides makes it possible to carry out CH-deprotonation, oxidation and hydroxylation at the double bond, ring opening with SO₂ elimination and other nucleophilic and electrophilic transformations. All these reactions clearly demonstrate the great synthetic poten-

tial of this class of compounds and make thiophene dioxides convenient synthons for the formation of various carbo- and heterocyclic structures.

1. Cycloaddition reactions

a. The formation of dimers and trimers

Thiophene 1,1-dioxides are able to undergo [2 + 4] dimerisation in which one molecule acts as a dienophile and the other one, as a diene. Unsubstituted and monosubstituted thiophene dioxides undergo spontaneous dimerisation even at low temperatures; this is why, for a long period these compounds have not been isolated but have been obtained only as dilute solutions. Thermally more stable 3,4- and 2,5-disubstituted and tetrasubstituted thiophene dioxides and their benzo and dibenzo analogues form [2 + 4] dimers at high temperatures. Dimerisation according to the [2 + 2] pattern typically occurs for benzo[*b*]thiophene dioxides on exposure to visible or UV light.

Unsubstituted thiophene dioxide (**2a**) slowly dimerises at temperatures above -25°C .⁴⁴ Spontaneous elimination of SO_2 from the resulting adduct gives rise to the formal dimer, dihydrobenzo[*b*]thiophene 1,1-dioxide (**38a**).^{44–46} Studies of various monosubstituted thiophene dioxides **2b–e** (R^1 or $\text{R}^2 = \text{H}$) have shown⁴⁶ that of the four possible regioisomers, only dimers **38** and **39** are formed, the former being the major reaction product. The authors attributed the regiochemical features of the reaction to steric factors: close proximity of the R^1 , R^2 and SO_2 groups in the transition state are energetically unfavourable; hence, the formation of isomer **38** is preferred.

$\text{R}^2 = \text{H}$; $\text{R}^1 = \text{H}(\text{a})$, Me (**b**), Et (**d**), Br (**e**); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}(\text{c})$.

38a–d + **2a–d** $\longrightarrow$

Heating of thiophene dioxide **2** to $25–30^{\circ}\text{C}$ in CDCl_3 gives rise to not only dimers (major products) but also minor trimers. It was shown that the product ratio changes toward trimer formation with an increase in the substrate concentration in solution. It is of note that in the case of unsubstituted thiophene dioxide (**2a**), the ‘head-to-tail’ trimer (**40a**) is produced, whereas sulfones **2b–d** give ‘head-to-head’ isomers (**40b–d**) as the only trimerisation products.

One more theoretically possible product **41** resulting from the reaction of compound **38** as a dienophile with the starting thiophene dioxide **2** as the diene was detected in none of the cases.

A study of the oxidation of monohalo-substituted thiophene 1,1-dioxides has shown that dimers **38f,g** and **42f,g** can be isolated from the reaction mixture in relatively low yields. Compounds **42** are formed upon cycloaddition of the corresponding thiophene 1-oxide and thiophene 1,1-dioxide, the latter acting as a dienophile.⁴⁶

Sulfone	R^1	R^2	Yield (%)	
			38	42
f	H	Br	8	6
g	Cl	H	3	2

The structures of the dimers and trimers formed in this way were determined unambiguously by ^1H NMR spectroscopy,^{44–46} high-resolution mass spectrometry and X-ray diffraction.⁴⁶ The use of advanced spectroscopic techniques made it possible to determine the half conversion period of thiophene dioxides **2** and to propose the thermal stability series for these compounds. The susceptibility for dimerisation was found to decrease in the series: 2-ethyl- > 2-methyl- > 3-methyl- > unsubstituted thiophene dioxide.

The thermal stability of thiophene 1,1-dioxides increases with an increase in the number of substituents in the thiophene ring. For example, 4-chloro-3-fluorothiophene 1,1-dioxide (**9**) dimerises only upon long-term refluxing in toluene giving rise to benzo[*b*]thiophene 1,1-dioxide **43**.⁶³ In this case, the reaction does not stop after the formation of the cyclohexadiene adduct due to the possible easy elimination of both SO_2 and HCl from the bridged intermediate.

Scheme 3

44a: $R^1 = \text{Me}$, $R^2 = \text{SiMe}_3$; **44b:** $R^1 = \text{SiMe}_3$, $R^2 = \text{Me}$; **44b:** $R^1 = \text{Me}$, $R^2 = \text{Me}$, Et ; $\text{X} = \text{Cl}$, Br .

Trimethylsilyl-containing thiophene dioxides (**44a**) are desilylated on Al_2O_3 . This is accompanied by spontaneous formation of dimer **45**,⁷⁸ while heating of the intermediate thiophene dioxide in *tert*-butyl alcohol affords regioisomers **46** and **47**.⁷⁹ Adduct **45** was treated with EtMgBr to be converted into the corresponding substituted benzene **48** containing an acetylene fragment. Penta-substituted benzenes **49** were prepared by refluxing thiophene dioxide **44b** in Bu^tOH .⁸⁰ In the last-mentioned case, cycloaddition with SO_2 , gehydrohalogenation and subsequent isomerisation apparently occur *via* intermediate adduct **50** (Scheme 3).

Photocyclisation of benzo[*b*]thiophene 1,1-dioxides **51** and **52** affords ‘head-to-tail’ (**53**) and ‘head-to-head’ (**54**) dimers, respectively.^{81–83} The structures of these products were proved by ^1H NMR spectroscopy.⁸²

$\text{R} = \text{Me}$, Ph , CO_2H , CO_2Me .

b. Thiophene dioxides as dipolarophiles in 1,3-dipolar cycloaddition

Thiophene 1,1-dioxides react with diverse 1,3-dipoles. In many cases, the process occurs regioselectively. Unsubstituted thiophene dioxide (**2a**) may give bisadducts, *i.e.* the products of dipole addition to two activated double bonds, depending on the amount of the dipole.

The reaction of benzo[*b*]thiophene 1,1-dioxide (**55**) with diazomethane affords adduct **56**, which is then photolysed to give tricyclic compound **57**.⁸⁴

The addition of nitrile oxides $\text{ArC}\equiv\text{N}\rightarrow\text{O}$ (**58**) to sulfone **55** gives isomeric dihydroisoxazoles **59a,b** with high regioselectivity. The reaction is carried out under sonication (conditions *a*)⁸⁵ or microwave (MW)⁸⁶ irradiation (conditions *b* or *c*) to generate nitrile oxide **58** *in situ* from the corresponding aldoxime. Under conditions *a* and *c*, the adduct is formed as a single isomer **59a** in high yields (78%–95%).

(*a*) $\text{ArCH}=\text{NOH}$, $\text{Ca}(\text{OCl})_2$ or NaOCl , $\text{H}_2\text{O}-\text{CH}_2\text{Cl}_2$, sonication;
 (*b*) $\text{ArCCl}=\text{NOH}$, Al_2O_3 , MW irradiation; (*c*) $\text{ArCH}=\text{NOH}$, NCS , Al_2O_3 , MW irradiation;
 $\text{Ar} = \text{Ph}$, $4\text{-MeC}_6\text{H}_4$, $4\text{-MeOC}_6\text{H}_4$, $4\text{-NO}_2\text{C}_6\text{H}_4$, $2\text{-ClC}_6\text{H}_4$, $2,4,6\text{-(MeO)}_3\text{C}_6\text{H}_2$, $3,4\text{-(OCH}_2\text{O)}_2\text{C}_6\text{H}_3$.

Recently, 1,3-dipolar cycloaddition of dioxide **55** to various azomethine ylides has been studied.⁸⁷ The generation of these ylides *in situ* by thermal cleavage of the aziridine ring in the presence of benzothiophene dioxide results regio- and stereospecifically in adducts **60a–c**. From either *cis*- or *trans*-aziridines (Scheme 4, conditions *a*), only one isomer is formed in low yield.

Scheme 4

In order to increase the yields in this reaction, alternative attempts to generate the ylide have been undertaken. Thus cycloaddition of dioxide **55** to reactive azomethine ylides generated *in situ* from an aldehyde and an amino acid (sarcosine or proline) with decarboxylation (refluxing in toluene) gives compounds **61a–c** (yields 60%–99%) (conditions *b*) or **62a,b** (conditions *c*). In the latter case, *exo*-adducts are formed (yield 10%), the structure of which has not been unambiguously proven. Thus, the researchers cited were able to increase the overall yield of the products, but this method showed low regio- and stereoselectivities.

In studies of dipolar cycloaddition of acetonitrile oxide and benzonitrile oxide to thiophene dioxides containing silyl- and/or germyl-substituents in positions 2,5 or 2,4, the regiochemical features of these reactions were elucidated.^{88–90} The addition of acetonitrile oxide is usually regioselective. For example, trimethylgermyl sulfones **63b,c** ($\text{E}' = \text{Ge}$; $\text{E} = \text{Si}$, Ge) react with

acetonitrile oxide to give only the addition products to the element-containing vinyl fragment, *i.e.* compound **64b,c**. In the case of silyl derivative **63a** ($\text{E} = \text{E}' = \text{Si}$), the addition process is accompanied by parallel elimination of the trimethylsilyl group to give heterocycle **65**. The reaction of 2,5-disubstituted thiophene dioxides **63a–c** with benzonitrile oxide gives adducts **66a–c** with desilylation or degermylation of one Me_3E group ($\text{E} = \text{Si}$ or Ge) from the side of dipole addition. As in the reaction with acetonitrile oxide, the trimethylgermylvinyl fragment of the molecule is most reactive, which accounts for the regioselective formation of only one product.⁸⁸

Similarly, MeCNO is added to 2-*tert*-butyl-5-(trimethylsilyl)thiophene 1,1-dioxide (**67**) to the vinylsilyl fragment of the molecule, resulting in desilylated product **68**. In the case of germyl derivative, the corresponding GeMe_3 -containing heterocycle **69** was isolated and characterised.

The cycloaddition of nitrile oxides to 2,4-disilyl- and 2,4-digermylthiophene dioxides **70** is not accompanied by elimination of the element-containing fragment, but results in isoxazolines **71** with a bridgehead Me_3E group.⁸⁹ However, the reactions of 2,5-disubstituted thiophene dioxide **72** with acetonitrile oxide studied in the same work gave dioxide **73** devoid of the trimethylsilyl group. The regiochemical features of the addition of nitrile oxides were the same as observed for 2,5-disubstituted thiophene dioxides. The exceptional regioselectivity of the dipole addition to the

C(4)=C(5) double bond was interpreted resorting to quantum-chemical calculations (see Section V).

c. Thiophene dioxides as dienes in [4 + 2] cycloaddition reactions

Thiophene 1,1-dioxides react as the 4π -diene component with many compounds containing an unsaturated bond. The tetrachloro (**1e**) and tetrabromo derivatives (**1f**)^{1–3} and sulfones containing *tert*-butyl, neopentyl and 1-adamantyl substituents have been best studied in such transformations.^{3,7} The thermal stability of these compounds allows one to perform cycloaddition at high temperatures, which markedly extends the range of dienophiles used. The presence in the molecule of the SO_2 group capable of being eliminated from the reaction products makes this type of transformations especially attractive from the synthetic standpoint. Moreover, [4 + 2] cycloaddition is usually associated with reverse electronic demand to dienophiles; hence, a broad range of alkenes and alkynes and dehydrobenzene derivatives can be involved in the reaction.

The cycloaddition results in adducts containing a bridging SO_2 group. They often cannot be isolated in a pure state, but undergo spontaneous elimination of sulfur dioxide to give halogenated cyclohexadiene derivatives.

When alkenes contain an *exo*-methylene double bond, the formation of spiro compounds is possible. The recently reported reaction of thiophene dioxide **1f** with complex **74** is a good example of such transformation.⁹¹ Spiro[5.5]undecane complex **75** is formed stereoselectively in several hours. According to X-ray diffraction data for this compound, the tetrabromocyclohexadiene fragment is formed upon *exo*-addition of dienophile **74** to the methylene group, which is due to steric factors.

Raasch^{1,28} comprehensively studied the reactivity of thiophene dioxides **1e,f** with respect to various dienophiles. It was shown that sulfone **1e** can form adducts with ethylene, cyclic and acyclic alkenes and with heterocycles. Given below are examples of cycloadducts formed from thiophene 1,1-dioxide **1e**, namely, compounds **76a–d**, where ethylene, 2-methyleneadamantane, acenaphthylene and indole, respectively, acted as the annulation substrates.

If the substrate contains more than one dienophile centre, double addition products or mixtures of mono- and bis-adducts are formed in the reaction. In the studies published after Raasch's works, this approach was used to introduce a tetrachlorocyclohexadiene fragment into various molecules. For example, cycloaddition of sulfone **1e** to substrates having a cage-type carbon skeleton containing one or two $\text{C}=\text{C}$ bonds has been studied.^{92–96} These compounds usually have an inert double bond and do not react with dienes such as cyclopentadiene, furan or 2,3-dimethylbuta-1,3-diene. Nevertheless, under relatively drastic conditions (long-term heating to 115–160 °C), cage alkenes are annulated by thiophene 1,1-dioxide **1e** to give the corresponding adducts.^{92–96} Examples of such reactions are given in Scheme 5.

The high reactivity of thiophene 1,1-dioxides is perfectly illustrated by the cycloaddition of sulfone **1e** to naphthalene.⁹⁷ First, the reaction gives intermediate adduct **81** through addition to the C(1)=C(2) double bond. Then three reaction routes develop simultaneously, resulting in a product mixture: 1,5-hydride shift followed by elimination of HCl and aromatisation gives phenanthrene **82**; the addition of a second molecule of sulfone **1e** to the C(3)=C(4) bond of intermediate **81** followed by dehydrogenation and C–C bond cleavage with aromatisation leads to compound **83**; and dehydrogenation of the intermediate adduct **81** gives phenanthrene derivative **84**. The first route predominates: the yield of adduct **82** is 75%.⁹⁷ The authors do not give detailed explanation for the regioselectivity observed or assumptions about the predominant contribution of the route including double bond migration.

It is noteworthy that migration of hydrogen atoms in some thiophene dioxide adducts is well studied. For example, aldrin derivative **85** and its heterocyclic analogue **86** react with sulfone **1e** to give an intermediate compound in which the cyclohexadiene

ring protons are arranged in space near the neighbouring double bond. The regiospecific migration of hydrogen atoms in this adduct gives a saturated bond, while the tetrachlorocyclohexadiene fragment undergoes aromatisation, which is the driving force of the process. Thus, compounds **87** and **88** containing a benzene ring are the only products of these reactions.^{98–100}

The oligomeric derivatives of bicyclo[2.2.2]octadiene undergo a similar rearrangement.^{101, 102} The reaction of tetracyclic compound **89** with dioxide **1e** yields a mixture of adducts **90** and **91** in

Scheme 5

6:1 ratio (overall yield 95%). The diene addition to the C(11)=C(12) bond followed by hydrogen atom migration affords compound **90**, whereas compound **91** is the product of 'normal' [4 + 2] cycloaddition of sulfone **1e** to the C(2)=C(3) bond.

Nevertheless, when tetrachlorothiophene dioxide **1e** reacts with oligocyclic compound **92** containing two vinylene and one azo bridge, the annulation product **93** can be isolated and characterised.¹⁰³ The process is regioselective and gives the corresponding adduct involving only the norbornene fragment. The hydrogen atom migration described above can also occur for this type of structures but at higher temperatures. Heating of compound **93** in toluene gives hydrogen migration product **94**, presumably, *via* the intermediate formation of hydrazine **95**.¹⁰³

However, cycloaddition of sulfone **1e** to compound **96** with a structure similar to those described above follows an absolutely different route. The azo bridge does not undergo 'normal' [4 + 2] addition but undergoes unusual [2 + 2 + 2] cyclocondensation to give adduct **97**.¹⁰⁴

The preparation of substituted benzenes from thiophene dioxide adducts is a synthetically significant transformation for the chemistry of this class of compounds. The rearrangements described above represent a possible way to address this problem; however, cycloaddition of thiophene dioxides to substituted alkenes and alkynes giving the corresponding benzene derivatives is most practically valuable.

The elimination of SO₂ from thiophene 1,1-dioxide adducts with alkenes and the subsequent elimination of the leaving group or oxidation often result in aromatic derivatives without isolation of the intermediate adducts. This type of reactions has been thoroughly studied for thiophene dioxides **98a–c** containing bulky substituents: *tert*-butyl, adamantyl and neopentyl groups. The use of phenyl vinyl sulfoxide and phenyl vinyl sulfone as dienophiles gave sterically hindered benzenes, **99a–c**, difficult to prepare by other methods, in good yields.^{20–22} In these transformations, benzenesulfenic and benzenesulfinic acids are the leaving groups.

R = Bu^t (**a**), *neo*-C₅H₁₁ (**b**), 1-Ad (**c**); X = H, SO₂Ph; n = 1, 2.

As noted above, oxidation of the intermediate cycloadducts represents yet another method for the synthesis of substituted aromatic compounds starting from thiophene dioxides. This procedure often does not require additional reagents: in air, the products can be obtained without isolation of the initial cyclohexadiene derivative. For example, the reaction of unsubstituted thiophene 1,1-dioxide (**2a**) with indene affords fluorene resulting from oxidation of the intermediate adduct with atmospheric oxygen.⁴⁴ The dehydrogenation products were also isolated in the reactions of tetrachlorothiophene dioxide **1e** with both azulene¹⁰⁵ and its aza analogue.¹⁰⁶

However, the cage adduct **80** mentioned above is not oxidised in air; it is converted into dibenzo derivative **100** on heating in an ethanolic solution of potassium hydroxide.⁹⁶

In some cases, reactions of thiophene 1,1-dioxides with alkenes give mixtures of aromatic compounds and cyclohexadiene derivatives. The reactions of asymmetric thiophene dioxide **9** with various monosubstituted alkenes can be considered as examples of such transformations. The presence of chemically similar substituents in positions 3 and 4 of the thiophene molecule precludes the preparation of adducts with a reasonable regio- and chemoselectivity. These reactions furnish mixtures of isomeric annulation products (**101**, **102**) and dehydrogenation products (**103**).

R = CH₂OH, CH₂Br, CO₂Me.

It can be seen from the foregoing data that halogen and alkyl derivatives of thiophene dioxide are fairly reactive dienes and can be converted into both mono- and bisannulated products. Drawbacks of these methods usually include high temperature and long reaction time and in some cases, low regioselectivity of the addition. An alternative approach^{107–109} is free from these drawbacks. This approach is cycloaddition of perhalogenothiophene dioxides **1e,f** to *N*-methylmaleimide catalysed by the enzyme diels-alderase (the 1E9 antibody as a chimeric Fab). The 1E9 antibody refers to the class of immunoglobulins having high affinity for some derivatives with cage structure. The ability to catalyse this reaction is due to the fact that bridged intermediate **104** has a structure similar to that of bicyclo[2.2.1]heptene and high affinity for the enzyme active site. Conversely, product **105** has a low binding constant with the enzyme, because the sulfone bridge is lost upon elimination of SO₂ and the structure becomes planar.

d. Reactions of thiophene dioxides with alkynes

Reactions of [4 + 2] cycloaddition of thiophene dioxides to alkynes also yield substituted benzenes. Thus unsubstituted thiophene 1,1-dioxide (**2a**) reacts with diethyl acetylenedicarboxylate to give diethyl phthalate.⁶⁰

However, recent studies have shown⁴⁴ that this reaction involves the dimer of thiophene dioxide **38a**. This dimer forms an adduct with dimethyl acetylenedicarboxylate (DMAD), which decomposes on heating into dimethyl phthalate and thiophene dioxide **2a**.

DCE = Cl(CH₂)₂Cl.

The reactions of tetrachlorothiophene 1,1-dioxide (**1e**) with phenylacetylene²⁸ and cyclic alkyne **106**¹¹⁰ yield 1,2,3,4-tetrachloro-5-phenylbenzene (**107**) and compound **108**, respectively.

The use of 3,4-di(*tert*-butyl, neopentyl or adamantyl)-thiophene dioxides **98a–c** in reactions with various acetylenes provides a route to sterically hindered substituted benzenes that are difficult to prepare by other methods.^{21,22} For example, the reaction with DMAD can serve as a convenient method for the synthesis of sterically hindered derivatives of phthalic acid **109**.

The reaction of thiophene dioxide **9** with various alkynes results in *ortho*-substituted chlorofluoroaromatic compounds **110**.⁶³ Dimerisation of thiophene dioxide **9** accompanied by elimination of HCl and SO₂ from the intermediate adduct to give benzothiophene dioxide **43** is a competing process in this case. It is noteworthy that the reaction is regioselective, giving only products **110** with *para*-positions of the chlorine atom and the R group.

R	Yield (%)	
	110	43
Ph	57	—
CH ₂ OH	38	11
CH ₂ Br	45	14

The addition of phenylacetylene to complex **14** results in mixtures of adducts with equal contents of each regioisomer **111a,b** (total yield 20%). The lack of regioselectivity in this transformation was attributed to different directing effects of the substituents in the molecule of diene **14**.⁶⁷

e. Reactions of thiophene dioxides with benzyne

Benzyne prepared by decomposition of diazonium salts readily reacts with thiophene dioxides. These cyclisations give substituted naphthalenes **112** (in up to 64% yields).¹¹¹ In some cases, the naphthalenes formed further react with benzyne to give benzo-barrelene derivatives **113**.

R¹, R² = H, Me, Bu^t, 1-Ad, Ph, Cl.

The reaction of 3,4-dineopentylthiophene 1,1-dioxide (**98b**) with excess dehydrobenzene gave the expected adducts, that is, respective derivatives **114** and **115**; however, the 'ene' reaction leading to product **116** (yield 68%) was the major route of the process. Apparently, the formation of sulfone **116** in which the

tert-butyl and neopentyl groups are most remote is more favourable than the formation of sterically hindered cycloadducts.²⁰

e. Thiophene dioxides as dienophiles in [2 + 4] cycloaddition

The reactions in which thiophene 1,1-dioxides function as dienophiles have long remained poorly studied. When reacting as the 2π-component, these sulfones are incapable of spontaneous elimination of SO₂ from the adducts; therefore, they should be more electron-withdrawing (dienophilic). Before 1997, only a few publications reported the formation of [2 + 4] adducts in reactions of thiophene dioxides. These studies are adequately reflected in reviews^{1,3} and we do not discuss them here.

It has been shown^{44,45} that, with a pronounced tendency for dimerisation even at low temperatures, unsubstituted thiophene dioxide (**2a**) is able to react as a dienophile only with cyclopentadiene. This process lasts for 18 h at 5 °C and gives [2 + 4] cycloadduct **117**, whereas the reaction with 2,3-dimethylbutadiene results only in dimerisation of sulfone **2a**. The *endo*-configuration of the resulting adduct **117** was unambiguously proved by NMR (NOESY) studies.

Thiophene dioxide **9** also acts as the dienophile in some reactions. For example, it reacts with furan and anthracene to give [2 + 4] cycloadducts **118** and **119**.⁶³ Due to non-symmetric structure of the initial sulfone, the cycloaddition results in a mixture of regioisomers. It should be noted that adducts with a chlorine atom at the bridging fragment are formed as predominant isomers (isomers **118a** and **119a**).

(a) furan, PhMe, 110 °C, 20 h; (b) anthracene, 110 °C, 20 h.

3,4-Dichlorothiophene 1,1-dioxide (**4c**) reacts as a dienophile with furan in a similar way to give a mixture of stereoisomers **120a,b** in almost equal amounts (**120a** : **120b** = 55 : 45). At elevated temperatures (> 60 °C), retro-Diels–Alder reaction takes place leading to the starting compounds.¹¹²

Study of previously known thiophene dioxides containing electron-withdrawing groups arouses considerable interest among organic chemists. These compounds should represent a new class of highly reactive dienophiles, because their molecules are characterised by low electron densities. Indeed, it has been found¹¹³ that sulfones **1m,p** react with 1,3-dienes, resulting in high yields of [2 + 4] adducts **121p** and **122m,p**.

Product	R^2	Yield (%)
121p	—	98
122m	H	90
	Me	89
122p	H	98
	Me	96

In the reactions of non-symmetrical thiophene dioxide **1m** with isoprene and 2,3-dimethylbuta-1,3-diene, compounds **122m** are formed chemoselectively, in particular, the addition takes place from the side of the most electron-acceptor double bond. In addition, the reaction with isoprene gives regioselectively adduct **122m** ($R^2 = \text{H}$) in which the Me and SO_2Me groups occur in the *para*-positions. An unexpected result was obtained in the reaction of 2,5-di(methylsulfonyl)thiophene 1,1-dioxide (**1p**) with piperylene (penta-1,3-diene). Instead of the expected 1,2(or *ortho*)-adduct, the reaction gave isomeric 1,3(or *meta*)-*endo*-adduct **121p**. This outcome was interpreted using quantum-chemical calculations of the transition state energies (see Section V).¹¹³

The reactions of thiophene dioxides containing electron-withdrawing groups (for example, **1p**) with various open-chain and cyclic dienes are of general character resulting chemo-, regio- and stereoselectively in the corresponding [2 + 4] adducts.

However, it was found¹¹⁴ that similar reaction with cyclopentadiene follows two pathways, *i.e.*, thiophene dioxide can act as either dienophile or diene. Thiophene dioxides containing two strong electron-withdrawing groups act as dienophiles to give bridged adducts **123**, while substrates with one electron-withdrawing group react as dienes to give regioselectively dihydro-1*H*-indene derivatives **124**. The corresponding bridged adducts are formed as a single *endo*-stereoisomer, the structure of which was confirmed by X-ray diffraction and ^1H NMR spectroscopy. The high regioselectivity of this reaction was interpreted using quantum-chemical calculations (see Section V).

Adduct	R^1	R^2	R^3	Yield (%)
123m	Cl	H	SO_2Me	66
123p	SO_2Me	H	SO_2Me	85
123q	H	SO_2Me	SO_2Me	67
124j	Me	H	SO_2Me	67
124o	Cl	CO_2H	Cl	71
124v	Me	H	CN	73
124y	Me	H	CO_2Me	65

It was also found that bridged adducts **123** undergo the Cope rearrangement on heating. This gives respective dihydro-1*H*-indenes **125** in high yields.¹¹⁴

$R^2 = \text{H}$: $R^1 = \text{Cl (m, 76\%)}, \text{SO}_2\text{Me (p, 98\%)}$;
 $R^1 = \text{H}, R^2 = \text{SO}_2\text{Me (q, 84\%)}$.

g. Preparation of bis-adducts

Substituted cyclohexadienes are always formed as the primary products in the reactions of thiophene dioxides with dienophiles. These compounds can further react as dienes with another dienophile molecule to give bis-adducts.

Sulfone	R ¹	R ²	X	Yield (%)	
				endo-126	exo-126
9	Cl	F	O	45	—
98a	Bu ^t	Bu ^t	O	73	25
	Bu ^t	Bu ^t	NPh	26	40

Thus reactions of maleic anhydride and *N*-phenylmaleimide with 3,4-di-*tert*-butylthiophene 1,1-dioxide (**98a**) result in bis-adducts **126** in high yields.¹¹⁵ The reaction products were identified in this case as *endo*- and *exo*-isomers. However, the reaction of 4-chloro-3-fluorothiophene 1,1-dioxide (**9**) with maleic anhydride gives only the *endo*-isomer.⁶³

Bis-adducts were prepared by reactions of 3,4-dichlorothiophene 1,1-dioxide (**4c**) with *N*-butyl- and *N*-(*p*-nitrophenyl)-maleimides.

R = Buⁿ (87%), 4-O₂NC₆H₄ (81%).

Thiophene dioxides **98a–c** containing bulky groups (*tert*-butyl, neopentyl or adamantyl) in positions 3 and 4 react with two equivalents of 4-phenyl-4*H*-1,2,4-triazole-3,5-dione (PTAD) in boiling toluene. On treatment with a solution of KOH in methanol, bis-adducts **127a–c** are converted into substituted pyridazines **128a–c** in high yields.^{20, 21, 116}

Sulfone	R	Yield (%)	
		127	128
a	Bu ^t	58	80
b	<i>neo</i> -C ₅ H ₁₁	77	74
c	1-Ad	72	82

The reactions of substituted thiophene dioxides with benzoquinones were used to prepare symmetrical and non-symmetrical naphtho- and anthraquinones.¹¹⁷ The dehydrogenation (aromatization) apparently includes enolisation of the primary adduct

and subsequent oxidation with excess benzoquinone. The best results in the reaction with 3,4-diphenyl- (**4d**) and 3,4-dibromothiophene 1,1-dioxides (**4f**) were attained with a tenfold excess of 1,4-benzoquinone.

X, Y = Ph, Br.

Two regioisomeric bis-adducts were obtained in 1 : 1 ratio in the reaction of 4-chloro-3-fluoro-thiophene 1,1-dioxide (**9**) with benzoquinone (overall yield 86%).⁶³ As in analogous reactions of other thiophene dioxides, the primary adduct is oxidised with excess benzoquinone to give an aromatic structure.

Recently, sulfone **1p** has been used in the cascade cycloaddition of dienes resulting in bis-adducts **129a–f** based on one thiophene 'core'.¹¹⁸ The great difference between the temperatures

Table 4. Bis-adducts prepared by the reaction of sulfone **122p** with dienes.

Diene				Products (ratio)	Yield (%)
R ¹	R ²	R ³	R ⁴		
H	Me	Me	H	129a	55
H	Me	H	H	129b + 129e (3 : 2)	34
Me	H	H	H	129c + 129f (5 : 2)	35
See ^a	H	H	see ^a	129d	51

^a R¹–R⁴ = CH₂.

required in the first and second cycloaddition stages permits the synthesis of double adducts with different dienes. Thus the reaction of compound **1p** with 2,3-dimethylbuta-1,3-diene readily proceeds in dichloromethane at 0 °C, and adduct **122p** thus formed can be isolated and introduced in the subsequent cycloaddition with some acyclic 1,3-dienes or cyclopentadiene. The annulation to the second double bond of thiophene dioxide **1p** is carried out in acetic anhydride at temperatures of 120–150 °C. When 2,3-dimethylbuta-1,3-diene or cyclopentadiene is used, the corresponding products **129a,d** are formed as single stereoisomers, while in other cases, isomer mixtures are isolated. The structure of bis-adduct **129a** was determined unambiguously by X-ray diffraction (Table 4).

The reaction of complex **14** with styrene gives addition products of two alkene molecules. As in the case of phenylacetylene, the transformation is non-selective, giving equal amounts of three regioisomers (overall yield 27%).⁶⁷ This unusual type of bis-adduct formation and the lack of regioselectivity were attributed to high activity of complex **14**.

h. Tandem reactions. Rearrangements

Of considerable interest are tandem reactions of thiophene dioxides with acyclic or cyclic 1,5- and 1,6-dienes, which allow one to prepare complex carbo- and heteropolycyclic structures. Annulation of one double bond of cyclic 1,5- or 1,6-diene to halogeno-substituted thiophene dioxides creates a diene system convenient for intramolecular Diels–Alder reaction with the other double bond of the diene. This cyclisation affords isotwistane and homoisotwistane type structures. For example, a number of polycyclic structures **130** have been prepared using cycloocta-1,5-diene.^{1, 3, 28}

R¹ = R² = Cl (89.5%); R¹ = R² = Br (56%);
R¹ = H, R² = Cl (66.5%).

This approach was utilised for the synthesis of halogenated iceanes.^{119, 120} Tetrachlorothiophene 1,1-dioxide (**1e**) reacts with substituted propellane **131** to give two stereoisomeric trienes, one cyclising according to intramolecular Diels–Alder reaction to iceane **132**. In the absence of fragment Z, the intermediate product does not undergo further cyclisation. By varying Z and the reaction temperature, a series of tetrachloroicene derivatives **132** have been prepared.¹²⁰

Halogeno- and alkylthiophene dioxides react with substituted furans as dienes; adducts **133** undergo spontaneous rearrangement to give aromatic carbonyl compounds **134**.¹²¹

2,5-Dimethoxy-2,5-dihydrofuran reacts similarly to 2-methoxyfuran, *i.e.*, eliminates methanol during the process. If methyl 2-furancarboxylate or 2-acetylfuran react as the 'furan components', the reaction gives predominantly the enol form of the corresponding benzyldicarbonyl compound.

Table 5. Preparation of benzylcarbonyl compounds **134** by the reaction of thiophene dioxides with substituted furans.

The use of thiophene 1,1-dioxides containing functional groups furnished a series of previously unknown benzylcarbonyl compounds, important precursors for the synthesis of alkaloids and other physiologically active products. The process is regioselective, in particular, furan adds only at the side of the double bond most activated by the functional group (Table 5).¹²² It is worth noting that functionally substituted thiophene dioxides react with furans under milder conditions than halogeno or alkyl derivatives.

Methyl pyromucate reacts with sulfones **1m,p** at 100 °C giving dihydrobenzofurans **135m,p**, which can be converted into benzylcarbonyl compounds **134m,p** by refluxing in tetrachloroethylene. The isolation of substituted dihydrobenzofurans **135m,p** apparently became possible due to the presence of the electron-withdrawing ester group in the furan molecule.

R = Cl (**m**), SO₂Me (**p**).

The reaction of electron-withdrawing thiophene 1,1-dioxides **1m,n,v** with unsubstituted furan proceeds in a different way.¹²² The intermediate adduct, *viz.*, the corresponding dihydrobenzofuran, reacts with excess furan. First, the Michael reaction takes place at the double bond activated towards nucleophilic addition and then double bond migration occurs, resulting in products **136m,n,v**. The formation of an aromatic structure is apparently the driving force of the transformation. The reaction is of general character: tricyclic products are also formed when other thiophene dioxides are used.

Compound 136	R ¹	R ²	Yield (%)
m	Cl	SO ₂ Me	41
n	Br	SO ₂ Me	33
v	Me	CN	72

Various substituted thiophene dioxides react with cyclopropenes **137** to afford cycloheptatrienes **138** in moderate

R¹–R⁴ = H, Me, Bu^t; R⁵, R⁶ = H, Me, Br, Cl; R⁷, R⁸ = H, Me.

yields.^{124–127} Probably, cleavage of the three-membered ring and extrusion of sulfur dioxide take place synchronously. 3,3-Dialkylcyclopropenes and heteroanalogues of cyclopropenes do not react. In the case of substituted thiophene dioxides and 2-alkylcyclopropenes, a mixture of regioisomers is formed. Using this approach, all possible methylated tropylium ions have been prepared.¹²⁶

i. Reactions of [6 + 4]-cycloaddition. Synthesis of azulenes

An extensive series of thiophene dioxides, including unsubstituted thiophene dioxide, have been introduced into [6 + 4] cycloaddition with 6-dimethylaminofulvene and some its derivatives.^{24, 128–132} The six-electron component in this reaction is represented by 6-substituted fulvene, while thiophene 1,1-dioxide is the four-electron component. The extrusion of SO₂ from the intermediate bridged adducts and elimination of the dimethylamino group afford azulene derivatives substituted in the seven-membered ring. The yields of the target azulenes usually do not exceed 16%; however, in some cases, azulenes were prepared in 25%–33% yields. The highest yield (60%) was attained in the reaction of 3,4-dichlorothiophene 1,1-dioxide (**4c**).¹²⁸ Electron-acceptor thiophene dioxides do not react with 6-dimethylaminofulvene. Variation of the fulvene component in this reaction has shown that fulvenes with less nucleophilic leaving groups (Z = MeO, NMePh) are the substrates of choice for the synthesis of azulenes with functional groups. In these cases, the target functionally substituted azulenes were synthesised in moderate yields.¹³³ In the case of non-symmetrical thiophene dioxides, regioisomeric azulenes **139** and **140** are formed; these were isolated as a mixture and characterised by ¹H NMR spectroscopy. The predominance of one of the azulene isomers in the reaction products was interpreted using quantum-chemical calculations (see Section V).

2. Reactions of thiophene 1,1-dioxides with nucleophiles

Thiophene 1,1-dioxides are typical 1,2-unsaturated sulfones functioning as acceptors in the Michael reactions with numerous nucleophiles. If the substituted thiophene dioxide contains a good leaving group, addition–elimination reactions are possible.

Various amines and the benzenethiolate ion were used as nucleophiles in reactions with unsubstituted thiophene 1,1-dioxide (**2a**).^{61, 134–136} With an excess of the nucleophilic reagent, bis-adducts are formed.

The addition of one piperidine molecule to symmetrical trimethylsilyl- and -germylthiophene dioxide **63a,c** in THF and benzene results in 2,3-dihydrothiophene 1,1-dioxides **141a,c**. Storage or chromatography on silica gel of the silyl derivative **141a** is accompanied by elimination of the trimethylsilyl group from the sp³ carbon atom of the heterocycle. In the case of non-symmetrical 2-trimethylgermyl-5-trimethylsilylthiophene 1,1-dioxide (**141b**), the reaction occurs regioselectively, the amine molecule being added only to the vinylsilyl fragment. The subsequent desilylation of this product takes place during chromatographic purification on SiO₂, and the structure of 3-piperidino-5-trimethylgermyl-2,3-dihydrothiophene 1,1-dioxide (**142b**) was confirmed by X-ray diffraction.¹³⁷ Germlyl derivative **141c** is stable against SiO₂.

E = Si; E' = Si (**a**), Ge (**b**); E = E' = Ge (**c**).

The reactions of silyl- and germlyl-substituted thiophene dioxides with other amines also occur regioselectively. The reaction with excess of piperidine and dimethylamine yields bis-adducts, whereas silyl-substituted thiophene dioxide **63a** reacts with only one morpholine or diethylamine molecule. The reactions of 2,5-bis(trimethylsilyl)-3-methylthiophene 1,1-dioxide

(**143**) with piperidine afford a mixture of two desilylated products.¹³⁷

Tetroxides **144** react with amines in a similar way. Depending on the nucleophile used, the reaction may yield both mono- and bis-adducts. In both cases, the products are formed with elimination of the Me_3E and $E'Me_2$ groups.¹³⁸

Thiophene dioxides containing functional groups can serve as efficient acceptors in the Michael reactions. The use of lower alcohols and 2-methylindole as nucleophiles in reactions with sulfone **1m** results in the corresponding *trans*-adducts **145a,b** and

146 in high yields. *N,N*-Diethylaniline reacts with compounds **1m,n** in a different way to give the products of replacement of the halogen atom **147m,n**. This difference between the reaction routes can be attributed not only to different nature of the nucleophiles, but also to the substantial difference in their basicities.¹³⁹

A sequence comprising the Diels–Alder reaction and the nucleophilic addition is an attractive synthetic route. For example, the reaction of thiophene dioxide **1p** with 2,3-dimethylbuta-1,3-diene gives adduct **122p** ($R = Me$) containing a double bond activated by the $MeSO_2$ group (Scheme 6).¹³⁹ A strong nucleophile such as *p*-methoxybenzenethiol easily reacts with compound **122p** to give the corresponding Michael *trans*-adduct **148**; however, in the case of other nucleophilic reagents (alcohols, nitromethane or diethyl malonate), additional activation with potassium fluoride as a base is required. In this case, elimination of the methylsulfonyl group takes place simultaneously with the nucleophile addition. If the reaction mixture contains no other nucleophile, the eliminated $MeSO_2^-$ anion attacks position 3 of the dihydrobenzothiophene molecule to give compound **149**. In all addition products **148–153**, the methylsulfonyl group and the newly introduced fragment occupy *trans*-positions with respect to each other. It is noteworthy that in the presence of the KF catalyst, diethyl malonate forms the double addition product, bis-adduct **152**; however, the use of caesium fluoride results in monoadduct **153**.¹³⁹

3. Reactions resulting in ring opening

The reaction of 3-bromo-2,5-dimethylthiophene 1,1-dioxide (**154a**) with organolithium reagents RLi ($R = Me, Et, Bu^n, Ph$) revealed two possible pathways preceding the ring opening: halogen–lithium exchange or the Michael addition of the lithium derivative.^{140–142} No metallation of 3-chloro-2,5-dimethylthiophene 1,1-dioxide (**154b**) with *n*-butyllithium (replacement of Cl by Li) takes place, *i.e.*, the reaction follows only the second pathway (Scheme 7).

Interesting results were obtained in a study of the reaction of the Grignard reagents and thiophene 1,1-dioxide **154a**. Instead of the expected ring opening products according to the above scheme, treatment of **154a** with ethylmagnesium bromide or propylmagnesium chloride at $-20^\circ C$ gives tricyclic compound **155**.¹⁴³

Scheme 6

Scheme 7

The structure of the tricyclic compound was determined and a mechanism for its formation was proposed. The use of methyl (or phenyl)magnesium bromide in this reaction resulted in a mixture of products that could not be identified.

In recent years, ring opening in 3-halogeno-2,5-dimethylthiophene 1,1-dioxides **154a,b** and trimethylsilyl-substituted thiophene dioxides induced by secondary amines has been the subject of active studies.³⁴ It was found that the reactions of compounds **154** with piperidine, pyrrolidine and morpholine in boiling toluene give stereoselectively one of the four possible dialkylaminomethyl-substituted butadienes.

$\text{X} = \text{Cl, Br}$; R_2NH is piperidine, morpholine, pyrrolidine.

The reactions of thiophene dioxides with 2-(2-hydroxy-alkyl)pyrrolidines and -piperidines have also been studied.^{144, 145} For example, dioxide **156** reacts stereoselectively with 2-(2-hydroxymethyl)pyrrolidine to give diene **157**.

The use of allyl- and homoallylamines in a similar reaction gives azatrienes **158**.¹⁴⁰

Azatrienes **158** can undergo intramolecular Diels–Alder reaction, thus opening a new synthetic approach to the substituted indolizines, quinolizines and their benzo analogues.^{146,147} For instance, the reaction of 3-bromo-2,5-dimethylthiophene 1,1-dioxide (**154a**) and 2-allylpiperidine affords *cis*- and *trans*-isomers of substituted quinolizines in 55:45 ratio.

The molecular complexes **14** mentioned above react with primary aromatic amines to give ring opening products, namely, isomeric aminonitrodiene **159a,b** (ratio 1:4).¹⁴⁸ Compound **159b** is formed upon base-induced isomerisation of aminodinitrobutadiene **159a**. Dinitrobutadienes **159a,b** exist in solutions as mixtures of four geometric isomers, as shown by ¹H and ¹³C NMR spectroscopy.

4. Oxidation of thiophene 1,1-dioxides

The oxidation of sterically hindered thiophene dioxides has been studied.^{149,150} The reaction of 3,4-di-*tert*-butylthiophene 1,1-dioxide (**98a**) with H₂O₂ under basic conditions at room temperature furnishes Michael adduct **160**, whereas at 50–60 °C ring opening takes place and compound **161** is formed as a by-product (15%).¹⁴⁹ On treatment with MCPBA in the presence of sodium carbonate, thiophene dioxide **98a** is oxidised to epoxide

162.¹⁵⁰ The oxidation without Na₂CO₃ gives thiethiodioxide **163** as a minor product.

Recently, an interesting transformation of diacenaphthothiophene **164** derivative under the action of peroxy acids has been found.¹⁵¹ Treatment of compound **164** with *m*-chloroperoxybenzoic acid at room temperature in dichloromethane yielded unusual macrocyclic anhydride **165**. Presumably, the mechanism of this reaction includes a sequence of transformations in which sulfone **166** is postulated as an intermediate

5. Pyrolysis of thiophene 1,1-dioxides

High-temperature reactions involving thiophene dioxides have no synthetic value, as they usually give complex mixtures of products in low yields. This type of transformation has been described comprehensively in a recent review;¹⁵² therefore, in this study, we consider it expedient to give only several examples providing a general idea of thermolysis of these compounds.

Thermal decomposition of thiophene dioxides may give different compounds. The products of high-temperature pyrolysis of tetraphenylthiophene 1,1-dioxide (**167**) depending on the reaction conditions are presented below.¹⁵³

Under conditions of flash vacuum pyrolysis (FVP), 3,4-di-*tert*-butylfuran has been prepared and characterised.¹⁵⁴ A similar selenophene was formed in the reaction of thiophene dioxide **98a** with selenium (benzene, 210 °C).¹⁵⁴ Heating of dimethyl-, di-*tert*-butyl- and diphenylthiophene dioxides in a high vacuum to 880 °C gave the corresponding furans in moderate yields.¹⁵⁵

R² = H; R¹ = R³ = Me, Bu^t, Ph; R¹ = R² = Bu^t, R³ = H.

IV. The applications of thiophene 1,1-dioxides

In recent years, thiophene 1,1-dioxides and their derivatives have been attracting increasing attention of scientists working in various fields of chemistry: biochemistry, medicinal chemistry, chemistry of polymers and supramolecular structures and also researchers engaged in the design of new organic materials. This attention is due not only to high reactivity of thiophene dioxides, but also to their unique physicochemical properties. In addition, recently it has been found that this class of compounds possess diverse biological activities. As a result, the number of publications devoted to practically valuable properties of thiophene 1,1-dioxides has markedly increased during the last 10 years. However, data on the use of thiophene dioxides have not yet been described systematically.

1. Thiophene 1,1-dioxides in supramolecular chemistry

Until recently, a small number of papers in which thiophene 1,1-dioxides have been used as building blocks in supramolecular chemistry has been published. However, the last decade is marked by a vigorous growth of the number of publications devoted to this topic; therefore, considering the modern trends in these studies would allow one to identify the key lines of further development.

The ability of thiophene dioxides to easily form aromatic structures with SO₂ elimination has been employed in the synthesis of substituted phthalocyanines. Unique physicochemical properties of the latter make them promising intermediates in the design of new materials, dyes, chemical sensors and catalysts. However, many projects associated with the application of this class of compounds are faced with the problem of low solubility of unsubstituted phthalocyanines in organic solvents. To solve this problem, various phthalodinitriles containing long alkyl chains were synthesised as the starting compounds for the synthesis of phthalocyanines.

The alkyl groups promoting the solubility of phthalocyanines were introduced using a complex sequence of transformations. The metallation of thiophene followed by treatment with alkyl bromides containing from 10 to 18 carbon atoms in the chain results in 2,5-dialkyl derivatives. The oxidation of these products with MCPBA^{27, 156} or another oxidant¹⁵⁷ affords substituted thiophene 1,1-dioxides, which undergo the Diels–Alder reaction with fumarodinitrile. The extrusion of SO₂ from the intermediate adducts and oxidative aromatisation yields phthalodinitriles **168**. Lithium-induced cyclisation in pentyl alcohol furnishes the target phthalocyanines. In addition, metal complexes of these compounds **169**, possessing liquid crystal properties, have been synthesised.^{156, 157}

R = n-C₁₀H₂₁, n-C₁₂H₂₅, n-C₁₈H₃₇;

[O] = NaBO₃, MCPBA, DMD; M = Cu, Zn.

An interesting modification of phthalocyanines is the introduction of heterocyclic fragments into their structures. For example, complexes of pyridoporphyrazine derivatives have been prepared by the reaction of phthalodinitrile containing decyl substituents with pyridine-3,4-dicarbonitrile (1 : 1 ratio) in the presence of zinc chloride and 1,8-diazabicyclo[5.4.0]undec-7-ene. By varying the ratio of the dinitrile components, various pyridoporphyrazine isomers, including compound **170**, have been prepared, isolated and characterised.

R = $n\text{-C}_{10}\text{H}_{21}$; (a) ZnCl_2 , DBU, $n\text{-C}_5\text{H}_{11}\text{OH}$.

The selective modification of β -cyclodextrins is an important problem of supramolecular chemistry not yet entirely solved. An elegant approach based on the use of a protective group, which was synthesised from dibenzothiophene 1,1-dioxide, has been proposed.¹⁵⁸ It was found that reagent **171** containing this group can form disulfonates **172** and **173** in the presence of molecular sieves 4 Å. The subsequent treatment of the resulting compounds with NH_3 or NaOH in methanol gave β -cyclodextrins **174** and **175**, modified at fragments **A** and **D**, in high yields (Scheme 8).

Modification of fullerene C_{60} was accomplished using 2,5-dimethylthiophene 1-oxide and 2,5-dimethylthiophene 1,1-dioxide (**1a**). The latter reacts with fullerene C_{60} to form tetra-adduct **176**, whereas analogous thiophene 1-oxide forms only a bis-adduct. It is of interest that this Diels–Alder reaction is not accompanied by spontaneous extrusion of SO_2 resulting in cyclohexadiene derivatives (see above); tetra-adduct **176** containing an

SO_2 bridge can be isolated and characterised. The structure of the obtained compound was confirmed by a number of physicochemical analytical methods.^{159, 160} The symmetry of the adduct has not been considered in the study cited.

2. New materials based on thiophene 1,1-dioxides

Currently, oligomeric and polymeric materials based on thiophene are under comprehensive investigations in view of their potential use in new types of electronic and optical instruments. Since 1989, when oligomers comprising several thiophene units were shown to be applicable as field-controlled transistors, the annual number of publications on this topic has been skyrocketing.^{161–164} The efficiency of such devices is related to the energy gap between the highest occupied (HOMO) and the lowest unoccupied (LUMO) molecular orbitals in the materials used. According to theoretical calculations for poly- and oligothiophenes,^{165, 166} the replacement of some of the sulfur atoms by sulfonyl groups sharply decreases this value (see Section V). For this reason, various research groups have attempted to synthesise oligomeric structures containing a thiophene 1,1-dioxide core.

Scheme 8

R = $4\text{-CH}_2\text{C}_6\text{H}_4\text{SO}_2\text{Im}$ (Im is imidazol-1-yl).

a. Oxidation of oligothiophenes

The simplest derivatives of oligothiophene 1,1-dioxides are prepared by oxidation of oligothiophenes. Mono- (**177a–d**) and bisulfones (**178a–c**) have been synthesised from chains containing 2–4 thiophene units using variable amounts of MCPBA.¹⁶⁶ The main shortcomings of this method are as follows: (i) starting thiophenes with electron-donating substituents, viz., alkyl or silyl groups, should be used; (ii) it is impossible to prepare oligomers containing more than two thiophene 1,1-dioxide fragments; (iii) the yields of the target products are relatively low.

R = SiMe₂Bu^t; n = 1–3.

Compound	Structural formula	n	Yield (%)
Monosulfones			
177a		1	31
177b		2	17
177c		3	25
177d		3	8
Bisulfones			
178a		1	47
178b		2	54
178c		3	10

R = H, SiMe₂Bu^t.

Recently, the complex of hypofluorous acid with acetonitrile has been used to prepare oligothiophene 1,1-dioxides.¹⁶⁷ Using this oxidant, oligomers containing 2–4 thiophene 1,1-dioxide units were prepared in high yields. In addition, unlike MCPBA, this complex provides the synthesis of oligomers containing bromine atoms.

n	R ¹	R ²	Yield (%)
0	Me	Me	85
0	Bu ^t	Bu ^t	83
0	Br	n-C ₆ H ₁₃	87
0	Br	Br	66
1	Bu ^t	Bu ^t	82
1	Br	Br	60
2	Bu ^t	Bu ^t	52

b. Cross-coupling reactions

It has been shown¹⁶⁸ that oligomers with alternation of thiophene and thiophene dioxide units possess the optimal properties. The key approach to the synthesis of these compounds is based on cross-coupling of trialkylstannylthiophenes **179** and substituted mono- or dibromothiophene dioxide. The latter are prepared by the replacement of silyl groups by halogen atoms under the action of bromine or iodine in dichloromethane in the presence of AgBF₄.

This method allows easy and selective introduction of a thiophene 1,1-dioxide fragment into ter-, quater- and quinque-thiophene chains.^{169–171} For example, this route was used to prepare oligothiophenes with terminal and/or central sulfonic groups: trimers **180**, **181**, tetramer **182**,¹⁶⁸ pentamers **183–185**^{168, 170, 171} and heptamer **186**.^{170, 171}

Cross-coupling of boronic acids of the thiophene series **187** with dihalothiophene 1,1-dioxides developed in recent years allows the synthesis of sulfone-containing oligomeric materials.¹⁷² The reaction is initiated by MW irradiation in the presence of 5 mol % of the $\text{MCl}_2(\text{dppf})$ catalyst [$\text{M} = \text{Pd}$ or Ni , dppf is 1,1'-bis(diphenylphosphino)ferrocene]. This method is of limited utility, as the yields of the target products do not exceed 30% (for $\text{M} = \text{Ni}$) or 15% (for $\text{M} = \text{Pd}$).

$\text{X} = \text{Br}$: $\text{R} = \text{H}$, Me , *neo*- C_5H_{11} ; $\text{X} = \text{I}$, $\text{R} = \text{H}$; $\text{M} = \text{Pd}$, Ni .

The oxidation of substituted dithieno[3,2-*b*:2',3'-*d'*]thiophenes **188** with MCPBA followed by successive bromination with *N*-bromosuccinimide (NBS) and cross-coupling gives selectively both symmetrical and non-symmetrical oligomers containing a dithieno[3,2-*b*:2',3'-*d'*]thiophene 4,4-dioxide core.^{173, 174} It was shown that the obtained materials possess photoluminescence properties in solutions and in the solid state.

It should be noted that the use of isomeric dithieno[2,3-*b*:3',2'-*d'*]thiophenes in this sequence of transformations did not lead to the desired outcome.¹⁷⁵ The researchers were unable to carry out cross-coupling with bromide **189**, and the alternative approach, *i.e.*, the initial bromination and cross-coupling and subsequent oxidation did not give the target product **190** either.

Cross-coupling with bromo derivatives of thiophene 1,1-dioxides is successfully used in the synthesis of dendrimers. Thus coupling of oligothiophene **191** and sulfone **192** in the presence of $\text{Pd}(\text{Ph}_3\text{P})_4$ as a catalyst gives dendrimers containing a thiophene 1,1-dioxide ring in the terminal fragment.¹⁷⁶

A new family of branched oligomers has been synthesised by the reaction of trialkylstannanes with bromo derivatives of benzothiophene dioxide. Owing to the non-symmetrical structure, these compounds crystallise much more difficultly than their linear analogues, which makes them suitable for the formation of thin films with optical diode properties.^{163, 177, 178}

To conclude this Section, we will give examples of diverse polymeric materials containing a thiophene 1,1-dioxide fragment that have been efficiently synthesised by means of cross-coupling.^{179–183}

c. Miscellaneous methods of synthesis

The synthesis of oligomers containing alternating phenyl and dioxide fragments was accomplished by the addition of zirconocene to 1,6-diacetylenes. Using this method, oligomers with various alternating fragments, namely, phenylene–dienylene, phenylene–thiophene, phenylene–thiophene 1-oxide and phenylene–thiophene 1,1-dioxide, can selectively be obtained in nearly quantitative yields.¹⁸⁴

3. Biological activity

The biological activities of compounds of the thiophene 1,1-dioxide series have been studied rather extensively for benzo derivatives and for sulfones obtained from thieno[2,3-*b*]- and thieno[3,2-*b*]thiophenes. Since the properties of these compounds, including their biological action, have been considered in detail in recent reviews^{185,186} devoted to thienothiophenes, in this review we restrict ourselves to considering the benzo analogues of thiophene dioxides.

A method for the preparation of benzo[*b*]thiophene 1,1-dioxide derivatives **193** has been patented.¹⁸⁷ These compounds were shown to be applicable for the therapy and prevention of various inflammatory processes, including sepsis, myeloma, leukaemia, diabetes, hepatitis, etc.

In recent years, benzo[*b*]thiophene 1,1-dioxide sulfamides **194–196**, which are potential antitumour drugs, have been extensively studied. Compounds **194–196** were prepared as salts and studied as tumour cell inhibitors *in vitro* and *in vivo*. Due to their high lipophilicity, derivatives **195** and **196** exhibit cytotoxic activities on human tumour cell cultures, in particular, leukaemia and solid tumour cells (HT29, HTB54, MI13443, K562 and CCRF-CEM).^{32,188,189}

Methods for the synthesis of compounds **197** as drugs for the therapy of hypercholesterolemia, hyperlipidemia, arteriosclerosis and various blood vessel diseases have been patented.¹⁹⁰ In addition, various sulfones are efficient drugs for decreasing the cholesterol level in blood (IC₅₀ is from 1 nM to 10 μM).

R¹, R² = H, Alk; Het is N-heterocycle;
Y = O, NR₂, CH₂; X is halogen; m, n = 0–7

Methods for the synthesis of benzo[*b*]thiophene-2-carboxanilide 1,1-dioxides **198** exhibiting high antiinflammatory activity have been developed.¹⁹¹

R = Cl, OH, OMe

The salts of benzothiophene dioxide **199a** and dihydrobenzothiophene dioxide **199b** derivatives containing *tert*-butyl groups suppress the oxidative denaturation of low-density lipoproteins and can be used to treat atherosclerosis and cardiac diseases, such as infarction and cardiac arrhythmia.¹⁹²

199a

199b

R¹ = H, Alk, Ac; R², R⁴ = H, Alk; R³ = Alk.

Thus, functionally substituted benzothiophene 1,1-dioxides exhibit a broad spectrum of biological activities.

V. Theoretical calculations

The structures of thiophene 1,1-dioxides have been studied in substantial detail using both spectroscopic methods (including X-ray diffraction analysis) and quantum chemical calculations. According to X-ray diffraction data, thiophene dioxide molecules are nearly planar, the oxygen atoms of the SO₂ group being located on both sides of the plane accommodating the heterocycle molecule. The bond lengths in the molecule are indicative of the loss of aromaticity to give a conjugated butadiene structure. Characteristic features of the molecular structure of various substituted thiophene dioxides and also some oligomers containing thiophene dioxide units in the chain have been considered in detail in recent reviews,^{3,193} which cover rather comprehensively the bibliography on this subject over the last ~20 years. Nevertheless, the theoretical studies of the structure and reactivity of thiophene dioxides have not yet been generalised within the framework of a single paper and this Section is meant to fill this gap.

1. Structure and reactivity

The existence of conjugation of the SO₂ group with the system of double bonds in thiophene dioxides has been the subject of intense studies nearly since the first representatives of compounds of this class have been prepared. The earliest studies used *ab initio* (HMO, LCGO and CNDO/2) calculations of molecular orbitals of unsubstituted thiophene dioxide (**2a**) and some benzo and dibenzo derivatives. The results of these studies were often contradictory and different conclusions were often drawn from the calculations. Indeed, Koch and Moffitt^{194,195} found that the SO₂ group is involved in conjugation; however, the calculations carried out in later studies showed the absence of conjugation in these sulfones.^{196,197}

For interpretation of the UV spectra of some trimethylsilyl- and trimethylgermylthiophene 1,1-dioxides, quantum-chemical calculations were carried out for their molecules in the ground and excited states.⁹⁰ The researchers demonstrated that the unusual bathochromic shift of the absorption band by 42–59 nm for these sulfones with respect to this band for the corresponding thiophenes can be interpreted as follows: the first excited state of the sulfone molecules is characterised by equal-

isation of the C–C bond orders in the heterocycle, resulting in a decrease in the energy of the state and, hence, of the electron transition energy. For example, the bond orders in 2,5-bis(trimethylsilyl)thiophene 1,1-dioxide (**63a**) are as follows:

State	C(2)–C(3)	C(3)–C(4)	C(4)–C(5)
Ground	1.896	1.012	1.896
Excited	1.205	1.433	1.205

A theoretical proof for the non-aromatic nature of thiophene dioxides has been obtained using the LCGO and AM1 methods. Comparison of the degree of aromaticity of unsubstituted thiophene dioxide and various isomeric thiadiazole *S,S*-dioxides has shown that sulfone **2a** is the least aromatic in the series of compounds studied.¹⁹⁸

The high reactivity of thiophene dioxides and their involvement in the Diels–Alder reactions as dienes were also theoretically substantiated. Using model reactions with ethylene, cyclopropene and benzoquinone, Jursic¹⁹⁹ studied characteristic features of the cycloaddition of thiophene, thiophene 1-oxide and thiophene 1,1-dioxide by AM1 calculations. The transition states and the activation energies of the reactions (*E_A*) were calculated. Thiophene 1,1-dioxide and cyclopentadiene were found to be the most reactive dienes with respect to ethylene, the activation energies of these reactions being equal to each other and to 28.50 kcal mol^{−1} (for thiophene *E_A* = 44.14 kcal mol^{−1}; for the *exo*- and *endo*-adducts of thiophene 1-oxide, *E_A* = 31.58 and 30.16 kcal mol^{−1}, respectively). It was also found that in the reaction of sulfone **2a** with cyclopropene, the formation of the *endo*-isomer is preferred. The ability of thiophene dioxides to act as dienes and to form dimers was theoretically substantiated by CNDO/2 and LCGO quantum-chemical calculations.²⁰⁰

For theoretical investigation of the oxidation susceptibilities of various substituted thiophenes and the reactivities of the respective thiophene 1,1-dioxides **1a–x**, DFT quantum-chemical calculations with the PBE96 functional were carried out. The obtained data allow one to identify the trends of variation of the global electrophilicity indices[†] depending on the nature of substituents in the thiophene ring (Fig. 1).⁴²

The introduction of any electron-withdrawing substituents markedly decreases the nucleophilic properties of the initial thiophenes. One can easily notice that the HOMO energy

Figure 1. HOMO of the initial thiophenes (**1**) and LUMO of the corresponding thiophene dioxides **1** (**3**) and global electrophilicity indices for these compounds (**2** and **4**, respectively).

[†] Global electrophilicity index (ω /eV) is a semiempirical parameter reflecting the energy change upon electron transfer to the LUMO of the studied molecule.

decreases most appreciably and, conversely, the electrophilicity index increases. For example, on passing from electron-donating substituents in the thiophene ring to strong electron-withdrawing ones, the global electrophilicity index increases virtually by 5 eV, which is well correlated with experimental results: acceptor thiophenes cannot be obtained using standard oxidants. In addition, quantum-chemical calculations show pronounced increase in the electrophilic properties of the acceptor thiophene dioxides, which is also in good agreement with experimental results: acceptor thiophene dioxides readily react with dienes and nucleophiles, in some cases, to form bis-adducts.

2. Theoretical substantiation of regioselectivity in the Diels–Alder and dipolar addition reactions

It is obvious that if cycloaddition involves a diene or a dienophile containing different substituents or if the reaction can occur by different reaction centres, this can give regioisomeric products. The predominant formation of one or another isomer cannot be interpreted, in some cases, based on the classical views on the structure and reactivity of organic compounds. In recent years, modern quantum-chemical methods have been used to substantiate the reaction regioselectivity. Calculations of the transition state geometry, orbital coefficients of the initial compounds and activation energies were used to interpret regiochemistry of transformations involving thiophene 1,1-dioxides.⁹⁰

The dipolar addition of acetonitrile oxide to various 2,4-disubstituted trimethylsilyl- and trimethylgermylthiophene dioxides **70** may give addition products at the C(4)–C(5) bond (isoxazolines **200a,b**) and at the C(2)–C(3) bond (**200c,d**). Compounds **200a,c** and **200b,d** contain in pairs the same heterocyclic core.

R¹, R² = Me₃E (E = Si, Ge).

This process was studied in detail by the numerical MPDP method. The kinetic factor of isoxazoline formation was found to prevail over the thermodynamic factor: the calculated heats of formation are minimum for adduct **200b**, whereas **200a** was detected experimentally. The calculations of the process kinetics using the molecular orbital perturbation theory showed that the addition to the C(4)–C(5) bond is most probable; hence, the formation of isomers **200c,d** is ruled out.

Theoretical investigations of the cycloaddition of acceptor thiophene 1,1-dioxides **1m,p** provided explanation for regioselectivity of their reactions with dienes. The formation of unusual *meta-endo*-addition product **121p** in the reaction of sulfone **1p** with perylene was well interpreted by DFT calculations with the PBE functional (Table 6). The activation energy for the *meta-endo*-transition state to the formation of compound **121p** is minimum being equal to 5.0 kcal mol^{−1}. The reaction energy (*E_R*) is also most favourable in this case (−43.0 kcal mol^{−1}). Other transition states and the corresponding products have higher energies than *meta-endo*-**121p**. Thus, this is kinetically and thermodynamically controlled product. The *endo*-position of the methyl group in the six-membered ring in the adduct **121p** with respect to the MeSO₂ group was confirmed by X-ray diffraction.¹¹³

Table 6. Activation energies (*E_A*) and reaction energies (*E_R*) (in kcal mol^{−1}) of sulfone **1p** with *trans*-perylene.

Configuration of the transition state	<i>E_A</i>	<i>E_R</i>
<i>meta-endo</i>	5.0	−43.0
<i>meta-exo</i>	13.8	−40.5
<i>ortho-endo</i>	7.9	−38.7
<i>ortho-exo</i>	17.7	−38.2

The results of DFT calculations with the PBE functional for the reactions of compounds **1m,p** with other dienes are in good agreement with experimental data and confirm the *endo*-stereoselectivity of cycloaddition.

The reactions of non-symmetrical thiophene 1,1-dioxides with cyclopentadiene may give two different adducts. However, it was found¹¹⁴ that the product exists as a single isomer, the addition involving the most acceptor double bond. Thiophene dioxides can react with cyclopentadiene both as dienes (normal cycloaddition) and as dienophiles (cycloaddition with inverse electronic demand), the reaction route being dependent on the nature of substituents in the initial sulfone. To explain the observed selectivity, quantum-chemical calculations of the orbital coefficients (riMP2 *ab initio* method) were carried out.¹¹⁴ Both types of cycloaddition discussed are known to be controlled by the cyclopentadiene HOMO and the thiophene dioxide LUMO. The calculated orbital coefficients and the HOMO and LUMO energies of the reactants are presented in Table 7.

It can be easily seen that the formation of isomer **123m** in the reaction of sulfone **1m** with cyclopentadiene is in good agreement with the calculated data as a result of overlap of the orbitals with the greatest orbital coefficients in the transition state TS-1.

The regioselectivity of the Diels–Alder reaction is fully controlled by orbital interactions both in the normal reaction and in the reaction with inverse electronic demand where thiophene dioxide acts as the diene. The latter example is clearly illustrated by the reaction of sulfone **1j** with cyclopentadiene. The overlap of orbitals with the greatest orbital coefficients results in the formation of the only isomer **124j**.¹¹⁴

However, in the case of reaction of thiophene 1,1-dioxide **1q**, the regioselectivity predicted theoretically differs from that observed experimentally. We believe that this is due to the predominance of the steric requirements over the electronic interactions. Both double bonds of thiophene dioxide **1q** are activated by the MeSO₂ groups but the C(2)=C(3) bond is sterically more accessible for the reaction with the diene, which finally affords the observed adduct **123q**.

Table 7. Orbital coefficients of the diene system and HOMO and LUMO energies (in kcal mol⁻¹) of cyclopentadiene and thiophene 1,1-dioxides.

Orbital coefficients	HOMO	LUMO
	-8.46	3.60
 (1p)	-10.62	-0.18
 (1m)	-11.47	-0.18
 (1q)	-11.47	-0.29
 (1j)	-10.69	0.22
 (1o)	-10.31	0.31
	-10.52	0.69
 (1v)	-10.10	0.80

A similar approach has been used to interpret the regioselectivity in [6 + 4] cycloaddition reactions of thiophene dioxides with 6-substituted fulvenes. As an example, consider the diagrams of the orbital coefficients of sulfone **1m** and fulvene (Scheme 9). Thus the higher orbital coefficient for the LUMO of the chloro-substituted carbon atom of thiophene dioxide **1m** directs the attack towards the higher orbital coefficient of the fulvene HOMO. This results in a definite orientation of the reactants in the transition state TS-2, which accounts for the predominant formation of isomer **139** with the predetermined arrangement of substituents in the target azulene. The same pattern observed for other non-symmetrical thiophene dioxides; hence, the regioselectivity of the reaction is controlled by orbital interactions.¹³³

Scheme 9

The regular features of the reaction of furan with thiophene dioxide **1m** were considered using the frontier molecular orbital method.¹²² The reaction occurs in such a way that the molecular orbitals with the greatest coefficients of both diene and the dienophile overlap with each other resulting in the predominant formation of products with a definite arrangement of substituents. The regioselectivity of reactions of other substituted thiophene dioxides also obeys this rule.¹²²

The calculation of orbital coefficients and energies of the intermediates has also been used to interpret the formation of the by-product upon nucleophilic cleavage of thiophene dioxide **154a** induced by amines.¹⁴⁵ The orbital coefficients and the transition state energies of the two possible deprotonation products of the starting sulfone were determined by PM3/3-21G(*) calculations (Scheme 10). Anion **B** (counterion, $R_2N^+H_2$) was found to be + 5.68 kcal mol⁻¹ less stable than anion **A**. In addition, the charge is more uniformly distributed along the carbon chain in anion **B**, while in anion **A** it is largely concentrated on the methyl group at the C(5) atom having the greatest orbital coefficient. Thus, cleavage of the thiophene ring should give mainly diene **201** rather than its isomer **202**.¹⁴⁵

3. Theoretical studies of the oligomers and polymers

Since the first organic semiconductors and other materials based on thiophene oligomers have been developed, theoretical investigation of the structure and unique properties of these compounds has become a priority line of research in this field. Particular attention is devoted to quantum-chemical calculations having a predictive validity in order to use them to prepare compounds with pre-specified properties. A line of research is concerned with the development of modified oligothiophenes in which the HOMO–LUMO energy gap is as small as possible. These compounds should be efficient n-type semiconductors, which was confirmed experimentally.

Barbarella and co-workers^{165, 166} have shown that the introduction of thiophene dioxide fragments into an oligomer molecule substantially decreases the HOMO–LUMO energy gap. Hartree–Fock *ab initio* calculations in the 3-21G* basis set demonstrated a decrease in the HOMO and LUMO energies on passing from bithienyl derivatives to mono- and di-1,1-dioxides. It is noteworthy that the energy change is greater for the LUMO

Figure 2. Frontier MO energies for bithienyl derivatives, and their mono- and di-1,1-dioxides ($R = SiMe_2Bu^t$).^{165, 166}

than for the HOMO of the oligomers (Fig. 2). Polarographic studies demonstrated good agreement with the calculated energies. It was found that oligomers with dioxide units are more prone to be reduced than to be oxidised, while the initial oligothiophenes are more prone to be oxidised than to be reduced. Thus, the introduction of a particular number of thiophene dioxide units into an oligothiophene molecule allows fine ‘tuning’ of the redox potentials and hence, provides control of the electronic properties of these materials.

In recent years, theoretical investigations of oligothiophenes have also been focused on the mechanisms of charge transfer in these compounds and in their completely or partially oxidised forms and on the interpretations of their optical and electronic properties.^{170, 173, 183, 201–205} Discussion of these subjects is beyond the scope of this review, as this is a special field of chemistry.

VI. Conclusion

For more than 90 years, thiophene 1,1-dioxides have been attracting the attention of researchers as compounds able to easily undergo cycloaddition, act as Michael acceptors and be transformed with ring opening. Currently, these derivatives are used more and more often for targeted synthesis of complex carbo- and heterocyclic structures. Analysis of the data published over the last 20 years indicates that thiophene 1,1-dioxides containing halogen atoms or alkyl or phenyl groups and their fused analogues have been studied fairly comprehensively. In recent years, a substantial contribution was made to the chemistry of unsubstituted and monosubstituted thiophene dioxides synthesised in the late 20th century. The synthesis and study of the synthetic potential of functionally substituted thiophene 1,1-dioxides carried out quite recently filled the gap in the chemistry of this class of compound.

The scope of application of thiophene 1,1-dioxides is not limited to their use as ‘building blocks’ for the design of desired molecules. Many systems containing this fragment are themselves

Scheme 10

valuable for investigations in various branches of science ranging from the development of new semiconductor or optical devices to the use in supramolecular chemistry.

VII. Supramolecular complexes of carotenoids with glycyrrhizin	1057
VIII. Conclusion	1062

Abstract. The published data on the redox reactions of carotenoids, their supramolecular inclusion complexes and the composition, properties and practical application of these complexes are generalised. Special attention is given to the effect of complexation on radical processes involving carotenoids and on the antioxidant activity of carotenoids. The bibliography includes 151 references.

I. Introduction

Carotenoids, the natural pigments, are widely distributed in plants and animals.^{1–3} They are detected in cells and tissues of all living things. Higher plants, fungi, bacteria and microbes can synthesise carotenoids, while animals and humans get them with food. In nature, carotenoids can exist in different states, namely, in the free state, as esters with fatty acids, glycosides and as carotene–protein complexes. To date, more than 600 different carotenoids are known.

Carotenoids belong to a large class of terpenes. A carotenoid molecule contains a long polyene chain of isoprene units with a cyclohexene (ionone) ring or isoprene residues at one or both ends. The majority of natural carotenoid pigments are represented by tetraterpenes (C₄₀). In plants, two groups of C₄₀ carotenoids are usually present, namely, carotenes ('pure' hydrocarbons including β-carotene and its isomers, lycopene, see below) and xanthophylls (oxygen-containing carotenoids among which lutein, zeaxanthin, canthaxanthin, violaxanthin are the most abundant). Carotenoids with the number of carbon atom less than 40 (nor- and apocarotenoids, see below) and more than 40 (homocarotenoids) are also known.

Carotenoids play an important role in various physiological processes of critical importance for the life in its present form. In most natural processes, carotenoids are assumed to play the role of energy and electron carriers.⁴ For plants, the involvement of

carotenoids in the photosynthesis is of fundamental importance. In higher plants, the photosynthetic processes occur in chloroplasts, *i.e.*, specific energy-converting organelles of plant cells. Chloroplasts contain two photosystems, namely, PS1 and PS2, which differ in the composition of proteins and pigments and in

photophysical properties. Photosystem 2 is responsible for the photosynthetic oxidation of water, while PS1 catalyses the oxidation of plastocyanine and the reduction of ferredoxin. Both systems include a light-collecting antenna (a pigment–protein complex that contains chlorophyll, carotenoid and protein molecules), a photochemical reaction centre, which consists of chlorophyll dimers (P700 in PS1 and P680 in PS2), electron donors and acceptors and electron-transfer molecules bound to this centre.

In the first step of photosynthesis, the absorption of light quanta by chlorophyll and carotenoid molecules converts them into the excited state, which is followed by energy transfer to other molecules of the photosystem. The second step involves the charge separation in the photochemical reaction centre of the PS2 and electron transfer along the electron-transport system from PS2 to PS1. Finally, ferredoxin, which is the electron carrier from PS1 to nicotinamide adenine dinucleotide phosphate (NADP), is reduced in PS1. The process ends with the reduction of NADP and synthesis of adenosine triphosphate (ATP).

According to modern concepts, the photochemical reaction that occurs in the PS2 reaction centres includes electron transfer from the excited molecule of chlorophyll P680 (its absorption spectrum is characterised by a peak at 680 nm) to a pheophytin molecule (PH, a primary electron acceptor) to form a state with separated charges ($P680^+ \cdots PH^-$) followed by electron transfer from PH^- to a molecule of a secondary electron acceptor, namely, natural quinone (Q, a complex of plastoquinone with a Fe^{2+} ion) to afford a more stable state $P680^+ \cdots PH \cdots Q^-$. The electron is transferred further by quinone carriers. Oxidised $P680^+$ exhibits exceptionally high electron affinity, *i.e.*, it is a very strong biological oxidant. If, for some reasons, $P680^+$ is not consumed in water oxidation, it can oxidise molecules in its nearest environment thus damaging PS2.

It should be noted that the risk of damaging the photosynthetic system as a result of side photochemical processes that occur in chloroplasts under the action of light (photoinhibition) is very high. Photoinhibition can be caused by different factors, including the formation of singlet oxygen. In chloroplasts, singlet oxygen is formed in the reaction of oxygen with excited chlorophyll molecules. Carotenoids present in chloroplasts uptake the excess energy from the excited chlorophyll molecules, which reduces the hazard of the formation of singlet oxygen. Thus, carotenoids are assumed to play the key role in the protection of organic molecules against oxidation.

In animal and human organisms, carotenoids perform different protective functions, *viz.*,^{5–11}

- bind singlet oxygen and inhibit the formation of free radicals thus preventing their adverse effect on the organism;
- provide protection against UV radiation;
- play the role of antioxidants.

Of no less significance are the membrane-stabilising and immunostimulating functions of carotenoids as well as their provitamin A activity. Vitamin A and carotenoids favour normal metabolism, enhance the resistance of an organism against infections, provide normal operation of the organ of vision, exert a beneficial effect on the performance of skin and mucous membranes and are involved in redox processes.

Nowadays, a peak of interest in the studies of carotenoids is observed, being primarily associated with the discovery of their antioxidant properties. Now, it can be stated with confidence that it is the chemical and physicochemical studies of the reactivity of carotenoids in redox processes that are most promising. Scientists in different fields, namely, physics, chemistry, biology and medicine, are involved in the elucidation of the nature of the major factors that determine the antioxidant activity of carotenoids.^{12–17} Despite the consensus on the elementary mechanisms of the antioxidant effect of carotenoids, no quantitative data on the relationship between the physicochemical properties of these compounds and their antioxidant activity are available in the literature.

The information on short-lived paramagnetic and diamagnetic intermediates formed in reactions of carotenoids with free radicals is also very scarce,^{14–17} and the structure of such intermediates is as a rule merely suggestive. However, it is this information that is the most valuable when selecting carotenoids for their practical application as antioxidants.[†] In recent years, due to the use of EPR techniques, considerable advance has been made in the studies of the redox processes involving carotenoids.^{14, 18, 19}

Yet another important problem closely associated with the redox properties of carotenoids is the formation of carotenoid complexes and the effect of an organised medium on their reactivity in redox processes.

It is known that carotenoids are characterised by high lability in the free state and, at the same time, become more stable when being components of various complexes (*e.g.*, with proteins). Hydrophobicity, photosensitivity and chemical activity of free carotenoids substantially complicate their use as medicinal drugs; this is why active studies on the development of the methods for the synthesis of their complexes are in progress. Recently, a number of fundamental and applied studies on the synthesis and investigation of supramolecular inclusion complexes of carotenoids with different natural compounds, first of all, with cyclodextrins have appeared.^{20–29} Cyclodextrins not only protect carotenoids from external factors, but also improve their solubility in water and organic solvents. Upon formation of inclusion complexes of the ‘host–guest’ type of cyclodextrins with size-matching hydrophobic inclusion compounds (*e.g.*, carotenoids), the physical, chemical and biological properties of the latter can substantially change (for details, see Refs 30–32).

In the pharmaceutical, cosmetic and food industries, cyclodextrins are largely used for improvement of solubility of inclusion complexes (*e.g.*, vitamins, food pigments, *etc.*)^{33–35}. Complexation can also substantially increase the stability and bioaccessibility of inclusion complexes, eliminate objectionable taste and odour, prevent side effects of medicinal drugs and favour their assimilation.^{33, 35} Due to the ability of cyclodextrins to molecular recognition and separation of chiral isomers, they are used in the production of synthetic enzymes.^{36, 37} However, complexation can also have some negative consequences. Thus the increase in the stability and solubility of carotenoids upon formation of inclusion complexes with cyclodextrins is accompanied by the loss of their antioxidant activity.

β -Glycyrrhizic acid (GA),³⁸ which belongs to triterpene glycosides, is yet another natural compound for which supramolecular inclusion complexes with carotenoids are described.

[†] The ability of carotenoids to decelerate ageing processes and to prevent and stop the development of diseases caused by reactive oxygen species and free radicals (superoxide ion, singlet oxygen, *etc.*) are actively discussed in the literature. Carotenoids are used for treatment of serious illnesses such as cancer and cardiac and nervous system diseases and age-specific degenerative changes in muscular tissues.

Complexes of biologically active compounds with GA attract attention of scientists due to their unusually high stability^{39–41} and due to the fact that the activity of these compounds in such complexes increases by a factor of dozens[‡] with simultaneous reduction of their toxicity.^{39,42}

It should be noted that despite the interest in the synthesis of inclusion complexes aimed at purposeful changes in their properties, the problem of the nature of the effect of complexation on their reactivity is still open. The present survey of the studies that deal with single-electron transfer processes involving carotenoid complexes is one of few attempts to solve this problem.

The purpose of this review is to briefly generalise the studies of the redox properties of carotenoids, their complexation and reactions of these complexes. Carotenoid reactions that include the electron transfer step are described in more detail. The relationship between the efficiency of single-electron transfer and the antioxidant/pro-oxidant activity of carotenoids and their supramolecular complexes is discussed.

II. Redox reactions of carotenoids with quinones and metal ions

A long chain of conjugated double bonds in a carotenoid molecule provides the electron-donating activity of carotenoids and favours stabilisation of their radical forms.⁴³ Studying of physicochemical properties of carotenoid radical cations attracts the keenest attention of scientists, attempting to model the system of primary photosynthetic processes[§] involving carotenoids, aimed at the development of artificial solar cells.^{44–46} Successful solution of this problem is closely related to the efficient spatial separation of charges in an artificial photosystem involving carotenoids and porphyrins. In connection with this, the elucidation of how an organised medium affects the structure of carotenoid itself and the lifetimes and chemical properties of radical cations acquires special importance.

The studies of an isolated PS2 have shown⁴⁷ that its photoactivation includes selective oxidation of β -carotene accompanied by electron transfer from the carotene molecule (Car) to the primary donor P680⁺⁺ to form a radical cation Car⁺⁺. The formation of the radical cation Car⁺⁺ in the irradiation of PS2 was detected by optical absorption spectroscopy^{48–50} and low-temperature EPR,^{51,52} while the formation of quinone radical anions in PS1 and PS2 was detected by the EPR method.^{53–55} As it has been mentioned above, in PS2, the electron-transfer chain involves molecules of carotenoids, chlorophyll, pheophytin and natural quinones [plastoquinones, ubiquinones (Q)]. This is why triads of the [Car⁺⁺...P...Q^{•-}] type are also used in model electron-transfer systems.^{56–58} The use of a molecular triad carotenoid – porphyrin – fullerene (**1**) was a windfall.⁵⁸

The long lifetime of triads opens up wide possibilities for their use in molecular electronics as nanosized communication and data processing constructs in sensors. The principle of operation of molecular triads is rather simple. A porphyrin molecule excited upon absorption of a light quantum donates an electron to the fullerene molecule to form a primary radical-ion pair [Car...P⁺⁺...C₆₀^{•-}]. Being a strong oxidant (electron acceptor), the radical cation P⁺⁺ abstracts an electron from a carotenoid molecule to form a separated radical-ion pair [Car⁺⁺...P...C₆₀^{•-}]. This state is relatively long-lived and retains a considerable part of light energy by increasing the electrochemical potential.⁵⁸ Apparently, such a way of light energy transformation is similar to the mechanism used by plants for utilisation of solar energy in photosynthesis.

The formation of carotenoid radical cations in reactions with quinones in homogeneous media was observed both in the light and in the dark [using such a strong electron acceptor as 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ)].⁵⁹ In the first step, a charge-transfer complex (CTC) formed, which was followed by the formation of a radical-ion pair [Car⁺⁺+Q^{•-}]. Carotenoid-to-quinone adducts (Car–Q) and carotenoid *cis*-isomers[¶] were the final products.

The formation of CTC in reactions of β -carotene, canthaxanthin and 8'-apo- β -caroten-8'-al with quinones was detected by optical spectroscopy (Fig. 1) and EPR.⁵⁹ Thus the intense absorption at 1030 nm observed upon mixing of β -carotene with quinone in CH₂Cl₂ was assigned to a charge-transfer complex, while the free radical cation of β -carotene absorbs in this solvent at

Figure 1. Absorption spectra of β -carotene and its CTC with quinone recorded before (curve 1) and after (curve 2) their mixing with DDQ in CH₂Cl₂ at -50°C .⁵⁹ The concentrations of β -carotene and DDQ are 12 $\mu\text{mol litre}^{-1}$.

[‡] The stability constant of GA complexes is 10⁵ litre mol⁻¹, which exceeds the mean stability constant of cyclodextrin complexes by two orders of magnitude.³⁰

[§] At present, photosynthesis is one of the most thoroughly experimentally studied biological processes.

[¶] Dissociation of radical-ion pairs escaped from recombination to free radical ions and their subsequent diffusion into the bulk are accompanied by *cis-trans* isomerisation of carotenoid radical cations to form *cis* isomers (see Section V).

Scheme 1

1000 nm.⁶⁰ Further transformation of CTC might follow two pathways depending on the carotenoid structure. For β -carotene and 8'-apo- β -caroten-8'-al, the preferential reaction pathway is the abstraction of the allylic proton at C(4) atom of the cyclohexene ring to form a neutral carotenoid radical (Scheme 1).⁵⁹

Ether **2** is the final product of this reaction. Its formation was confirmed by IR and NMR spectroscopy.⁵⁹ In canthaxanthin, no abstraction of the allylic proton is possible and the reaction proceeds through the addition of quinone to the chain of conjugated double bonds of the carotenoid (Scheme 2).

Scheme 2

[The photoinduced cycloaddition of a carbonyl group (including that of quinone) to the double bond of the polyene molecule is known as the Paterno–Büchi reaction.^{61, 62}] It is assumed that the first pathway of this process also involves electron transfer from a Car molecule to Q to form a biradical, adduct **3** being the final reaction product.^{63, 64}

Metal ions can also be used for generation of radical cations of carotenoids in both homogeneous and organised media.^{65–67} The mechanism of the redox reaction of carotenoids with metal ions in a homogeneous medium was studied in detail by the example of the reaction of β -carotene with iron(III) chloride.^{43, 65} The first stage was shown to be electron transfer from the Car molecule to Fe^{3+} to form a Fe^{2+} ion and a radical cation $\text{Car}^{+\cdot}$. Recombination of the radical cations affords a dication and a neutral molecule.

As in the above-discussed reaction with quinones, the carotenoid radical cations and dications formed undergo *cis*–*trans* isomerisation.^{43, 65, 68, 69} The oxidation of β -carotene with metal ions in the presence of oxygen affords a stable product, *viz.*, 5,8-peroxide.⁶⁵

The oxidation of carotenoids with metal ions in organised media was studied.^{66, 67, 70} In particular, by the example of β -carotene, canthaxanthin and 8'-apo- β -caroten-8'-al, it was shown that in metal-containing mesopores of MCM-41 these carotenoids form compact complexes with Cu^{2+} , Ti^{4+} and Fe^{3+} ions in which the distance between the metal ion and the nearest double bond of the carotenoid is $\sim 2 \text{ \AA}$.^{68, 70} The formation of these complexes results in acceleration of both the direct and reverse electron transfer between the carotenoid and the metal and in the increase in the quantum yield of the formation of carotenoid radical cation.

III. Reactions of carotenoids with free radicals. Antioxidant properties of carotenoids

The interest in the reactions of carotenoids with free radicals is aroused first of all by the discovery of their antioxidant properties. A comprehensive description of carotenoid reactions with peroxide radicals can be found in recent reviews;^{15–17} therefore, here we consider only the proposed mechanisms of these reactions. The role of electron transfer and its effect on the antioxidant activity of carotenoids will be considered in more detail.

It is known^{71, 72} that in a living organism, peroxide radicals are formed during chain autoxidation of lipids.

Here, X is a free radical that initiates the radical chain reaction, RH is a lipid molecule. We do not consider possible sources of free radicals in the organism and only refer to the study by Chan⁷² in which the oxidation stress initiated by metal ions was assumed to be the main 'source' of free radicals. The process of free radical formation can be interrupted as a result of the chain termination by any antioxidant capable of reacting with peroxide radicals.^{3, 71–75} The reaction product is an antioxidant radical, which is less active than the starting peroxide radical. The low activity of the former makes impossible the chain propagation. Chain termination occurs as a result of the reaction of the antioxidant radical with either another radical or another antioxidant.

In the past decades, attempts were undertaken to compare the antioxidant activities of different carotenoids and to reveal the factors responsible for this activity.^{14–17} This required the elucidation of the detailed mechanism of the reaction of carotenoids with free radicals, first of all, peroxide radicals.

The following three pathways for the reaction of carotenoids with peroxide radicals were considered most often: addition of a free radical to a double bond of a carotenoid [reaction (1)], abstraction of a hydrogen atom from the allylic fragment of a carotenoid (2) and electron transfer from a carotenoid to a peroxide radical to form a carotenoid radical cation (3).^{7, 76–78}

(It should be mentioned that the radicals $\text{ROOCar}^{\cdot}$ and $\text{Car}^{\cdot}$ can in turn serve as the sources for the chain propagation of lipid oxidation with peroxides.) The analysis of the available literature data does not allow one to single out the major mechanism.^{15–17, 79}

It can be stated that the direction of the reaction of peroxide radicals with carotenoids depends on several factors, namely, the carotenoid structure, the activity of peroxide radicals and the nature of the solvent. Thus the analysis of absorption spectra and reaction products of β -carotene with peroxide radicals led to a conclusion that in non-polar media both a radical adduct $^{\bullet}\text{Car}-\text{OOH}$ (Refs 80–83) and a radical $^{\bullet}\text{Car}$ (Refs 84 and 85) are formed as the short-lived intermediates. However, the relative contributions of these reaction channels were not determined.

More detailed information on the mechanism and kinetics of the reaction of carotenoids with free radicals was obtained from the results of time-resolved pulse methods, first of all, flash laser photolysis and pulse radiolysis.^{7, 8, 86, 87} However, these methods did not provide the complete picture of the reaction of carotenoids with free radicals either. To date, the absorption spectra are adequately characterised only for carotenoid radical cations,^{88, 89} whereas the assignment of other signals in absorption spectra of intermediate species still remains hypothetical.

Based on studies of the reaction of β -carotene with the $\text{Cl}_3\text{COO}^{\bullet}$ radical in polar media, it was concluded¹⁶ that this reaction affords equal amounts of radical cations and radical adducts of β -carotene. Similar conclusions were also drawn based on the analysis of absorption spectra of intermediate species formed in the laser-induced photolysis of certain carotenoids in micellar solutions.⁷ In the latter case, the absorption spectra contained two bands in the region of 750–950 nm, which differed in the decay rate. The absorption in the range of 850–950 nm was assigned to carotenoid radical cations and the band in the region of 750–850 nm was assigned to the radical adduct.⁷ However, a different assignment was proposed.^{90, 91} In alcohols, the measurements of relative intensities of absorption bands in the regions of 750–850 and 850–950 nm have revealed a strong dependence of the signal intensity on the polarity of the medium in the former region.⁹¹ Thus, it was concluded that the observed intermediate is most likely a radical-ion pair of carotenoid and peroxide anion.

It is known that carotenoids reside preferentially in the lipophilic region of the membrane due to their hydrophobicity.^{76, 92} For a non-polar β -carotenoid incorporated into a membrane, the formation of a radical cation is improbable, because electron transfer in a non-polar medium is unfavourable for energy reasons. At the same time, carotenoids with polar substituents (*e.g.*, zeaxanthin and astaxanthin) are located at the membrane surface where the electron transfer is more favourable. Hence, the interaction of such carotenoids with radicals can easily lead to the formation of radical cations.^{77, 93}

The data obtained by EPR spin-trapping techniques on the rate constants for the reaction of carotenoids with free radicals suggest that electron transfer is the primary step.¹⁴ By the example of certain natural and specially synthesised carotenoids, it was shown that the scavenging rates of $^{\bullet}\text{OOH}$ radicals by carotenoids correlate with the oxidation potentials of the latter (Fig. 2).¹⁴ Stable spin adducts of $^{\bullet}\text{OOH}$ radicals with spin traps formed in the absence and in the presence of carotenoids and their yields were measured. In the presence of a carotenoid, the yield of the spin adduct decreased as a result of the side reaction of hydroperoxide radical with the carotenoid (Fig. 3). Based on the experimental dependence of the yield of the spin adduct on the carotenoid concentration, the relative rate constants ($k_{\text{Car}}/k_{\text{ST}}$) for scavenging of radicals by the carotenoid were calculated according to Eqn (4).

$$\frac{A_0}{A} = \frac{k_{\text{ST}}[\text{ST}] + k_{\text{Car}}[\text{Car}]}{k_{\text{ST}}[\text{ST}]} \quad (4)$$

Here, A_0 and A are the intensities of the spin adduct signal in the absence and in the presence of a carotenoid, k_{ST} and k_{Car} are the rate constants for radical scavenging by a spin trap (ST) and by a

Figure 2. Dependence of the rate constant for scavenging of peroxide radicals by carotenoids on the oxidation potential of carotenoids (k_{Car} and k_{ST} are the rate constants for scavenging of the $^{\bullet}\text{OOH}$ radical by carotenoids and by spin traps, respectively).¹⁴ Carotenoids: β -carotene (1), canthaxanthin (2), 8'-apo- β -caroten-8'-al (3), 7'-apo-7',7'-dicyano- β -carotene (4), ethyl 8'-apo- β -caroten-8'-oate (5).

Figure 3. EPR spectra of the adduct PBN-OOH (PBN is *N-tert*-butyl- α -phenylnitron) recorded in the absence (a) and in the presence of 1.2 mmol litre⁻¹ (b) or 4.2 mmol litre⁻¹ (c) of canthaxanthin in DMSO.¹⁴ [PBN] = 5 mmol litre⁻¹, [FeCl₂] = 1 mmol litre⁻¹, [H₂O₂] = 0.5 mol litre⁻¹.

carotenoid (Car), respectively. *N-tert*-Butyl- α -phenylnitron (PBN), 2-methyl-2-nitrosopropane (MNP) and 5,5-dimethylpyrrolidine *N*-oxide (DMPO) were used as the spin traps.¹⁴ The available kinetic database (Spin Trap Data Base; <http://epr.niehs.nih.gov>) contains the following value for the reaction of PBN with the hydroperoxide radical in water: $k_{\text{ST}} \leq 10^6$ litre mol⁻¹ s⁻¹. The slowest and the highest reaction rates were observed for β -carotene and ethyl 8'-apo- β -caroten-8'-oate, respectively. Based on the comparison of the rate constants for the reactions of carotenoids with the hydroperoxide radical, it was concluded that reactions (1) and (2) make no substantial contribution to the reaction of carotenoids with these radicals.

IV. Pro-oxidant properties of carotenoids

Clinical trials of β -carotene gave contradictory results, which could be a reason for ambiguous attitude to carotenoids as antioxidants.^{94–96} Thus β -carotene demonstrated good results in curing certain types of tumours^{97–100} and at the same time proved to be ineffective or even exhibited pro-oxidant[†] activity in curing certain other diseases caused by free radicals.^{94–96}

It was shown that β -carotene exhibits the antioxidant activity only in low concentrations and at low oxygen pressures, whereas in high concentrations and at high oxygen pressures it exhibits the pro-oxidant activity.^{6, 9, 11, 17, 101}

Neutral radicals $\text{Car}^\bullet$ and $\text{ROOCar}^\bullet$ as well as radical cations $\text{Car}^{+\bullet}$, which are formed in reactions (1)–(3), were assumed to be responsible for the pro-oxidant activity of carotenoids.^{102–104} The mechanism of the pro-oxidant effect of carotenoids involves the reactions of neutral radicals of carotenoids $\text{Car}^\bullet$ and $\text{ROOCar}^\bullet$ with oxygen molecules to form the corresponding peroxide radicals

Neutral carotenoid radicals are also formed in the protonation/deprotonation of the corresponding radical ions. Thus the formation of neutral radicals of β -carotene, zeaxanthin, canthaxanthin, 8'-apo- β -caroten-8'-al and 7'-apo-7',7'-dicyano- β -carotene and their structural analogue, β -ionone, was registered¹⁸ by the EPR spin-trapping technique. The formation of neutral radicals $\text{Car}^\bullet$ was observed in chemical or electrochemical oxidation of these carotenoids to radical cations, which was followed by deprotonation of the latter [reaction (5)],¹⁸ and in their electrochemical reduction or a reaction with piperidine. The latter reaction proceeds through the protonation of the corresponding radical anions [reaction (6)].¹⁸

The formation of carotenoid radicals was judged from hyperfine coupling (HFC) constants of the corresponding spin adducts obtained in simulations of the EPR spectra.

It was shown that the ability of carotenoid radical ions to undergo protonation/deprotonation is more typical of non-symmetrical apo-carotenoids with electron-withdrawing terminal groups. The calculation of the energy of deprotonation of carotenoid radical cations made it possible to assume that the abstraction of a hydrogen atom occurs from either the C(4) atom or the methyl group in position 5 of the cyclohexene ring. In both cases, the corresponding neutral radicals are formed.¹⁸

The reaction of carotenoids with metal ions, *e.g.*, with iron ions, may be considered as yet another possible mechanism of the pro-oxidant activity of carotenoids.^{103, 105} As was noted above, the oxidation stress initiated by metal ions is one of the major sources of free radicals in the organism⁷² and can result in the development of certain serious disorders including cancer.^{106, 107} It is assumed that in this case, the mechanism of free radical generation is similar to the well-known Fenton reaction.¹⁰⁸

[†] The pro-oxidant activity of a compound usually implies the increase in the yield of active oxygen-centred radicals in the presence of this compound.

By the example of β -carotene and canthaxanthin, it was shown experimentally that the involvement of a carotenoid in this reaction results in an increase in the yield of free radicals due to the chain reaction.¹⁰⁵

Reactions of carotenoids with peroxide and carbon-centred radicals were studied.¹⁰⁵ Based on the experimental results,^{14, 105} it can be assumed that, in the presence of metal ions, carotenoids can either decrease or increase the yield of free radicals depending on the oxidation potential of the carotenoid and the nature of the radical. The efficiency of the carotenoid-induced Fenton reaction increases as the oxidation potential of the carotenoid decreases and its reaction with the radical decelerates. According to Polyakov and co-workers' data,¹⁰⁵ β -carotene, which has the lowest oxidation potential among all the carotenoids studied, exhibits the highest pro-oxidant activity in the Fenton reaction (note that it is for β -carotene that the highest pro-oxidant activity was observed *in vivo*^{6, 94–96}).

V. The role of electron-transfer processes in the *cis*–*trans* isomerisation of carotenoids

Light-induced *cis*–*trans* isomerisation of carotenoids is one of characteristic pathways of their phototransformations.^{109–113} It is usually meant that the isomerisation process involves molecules in the excited triplet state.^{112, 113} For the processes of sensitised *cis*–*trans* photoisomerisation, the formation of the excited triplet state is possible as a result of transfer of either energy or an electron.^{113–115} The latter process occurs in polar media in the presence of electron donors or electron acceptors to afford the corresponding radical ions. In connection with this, studies of the properties of radical ions of natural polyenes acquire special importance, because these compounds are incorporated in many biological systems.^{4, 45, 116} Thus *cis*-retin-11-al is the chromophore of the visual pigment rhodopsin. It is assumed that its *cis*–*trans* isomerisation initiates the visual perception process in eyes of humans and mammals.^{117, 118} This is the first and the only photochemical reaction that triggers the primary vision process, namely, phototransduction. Certain *cis*-carotenoids play an important role in photosynthetic processes in bacteria.¹¹⁹

Let us consider in more detail the mechanisms of *cis*–*trans* isomerisation of polyenes that involve the electron-transfer step. The major part of results discussed here were obtained using the following methods of spin chemistry:¹²⁰ chemically induced dynamic nuclear polarisation (CIDNP) and magnetic field effect (MFE) methods. These methods are the most efficient for studying the mechanisms of complex reactions of radicals and radical ions.[‡]

It has now been shown experimentally that *cis*–*trans* isomerisation of polyenes (P) that proceeds in the presence of electron donors or electron acceptors (S) can involve the following short-

[‡] It should be noted that it is the methods of spin chemistry that have provided evidence for the occurrence of single-electron transfer in *cis*–*trans* photoisomerisation of substituted ethylenes in the presence of electron donors or electron acceptors. This is acknowledged among the most important achievements of spin chemistry.^{121, 122}

P are polyenes (carotenoids, β -ionone), S are electron donors or electron acceptors (amines, quinones, aromatic hydrocarbons).

lived species (Scheme 3):¹¹⁴ excited triplet states (^3P) formed in the recombination of a triplet radical-ion pair (RIP) (pathway *a*); radical cations ($P^{+\cdot}$) and dication (P^{2+}) (pathway *b*); neutral radicals ($P^\cdot$) and biradicals ($P-S$ adducts), *i.e.*, secondary intermediates formed from radical ions (pathways *c* and *d*, respectively).

The formation of excited triplet states was observed in the isomerisation of substituted ethylenes and β -ionone in the presence of amines and aromatic hydrocarbons. Radical cations are formed in the presence of substituted ethylenes and carotenoids. Neutral radicals and biradicals are formed in the isomerisation of β -ionone in the presence of quinones.

1. *cis-trans* Isomerisation of alkenes in the excited triplet state

Triplet states of alkenes are formed either upon UV irradiation (direct isomerisation) or as a result of energy transfer (sensitised isomerisation).¹²³ There is the third mechanism of isomerisation of triplet alkenes established using the methods of spin chemistry.^{121, 122} According to this mechanism, triplet molecules are formed as a result of reverse electron transfer in a triplet RIP formed in the irradiation of substituted ethylenes in the presence of electron donors or electron acceptors in polar media.

In contrast to substituted ethylenes, polyenes are represented by a larger number of isomers, which often differ in the energy of the triplet states, redox potentials and their reactivities with respect to electron donors and electron acceptors.

Retinal (**4**) and β -ionone (**5**) were the first polyenes of the terpene series for which the radical ion mechanism of photoisomerisation in the presence of electron donors or electron acceptors was confirmed.^{115, 124, 125}

Let us consider how the isomerisation of β -ionone proceeds in the presence of electron donors, *viz.*, pyrene or triphenylamine.¹¹⁵ Four β -ionone isomers, namely, (*E*)- β -ionone (**A**), α -pyran (**B**), (*Z*)- β -ionone (**C**) and (*Z*)-*retro*- γ -ionone (**D**) are known.¹²⁶

Figure 4. CIDNP spectrum observed in the photolysis of a photostationary mixture of β -ionone isomers in the presence of triphenylamine in acetonitrile.¹¹⁵ A procedure of presaturation of the NMR spectrum was used for elimination of equilibrium signals.

NMR studies have shown that the kinetics of accumulation and the ratio of isomers formed in the irradiation of β -ionone in the presence of pyrene and triphenylamine substantially differ from those in direct photolysis.¹¹⁵ During the photolysis of β -ionone in the NMR tube, the CIDNP effects of the main isomers were registered. Figure 4 shows the CIDNP spectrum recorded in the photolysis of a mixture of β -ionone isomers in the presence of triphenylamine. The mechanisms of transformations of β -ionone isomers could be proposed on the analysis of this spectrum.

In the CIDNP spectrum observed during the irradiation of a photostationary mixture of isomers **A–D** in the presence of triphenylamine, only signals for the triplet isomers **A** and **C** were detected. This made it possible to conclude that *cis* isomer **C** is the transformation product of the excited triplet *trans* isomer **A** and *vice versa*. Triplet states were formed in the recombination of the corresponding radical-ion pairs (Scheme 4).¹¹⁵ In turn, it was shown that in the presence of triphenylamine, isomers **B** and **D**, namely, α -pyran and *retro*- γ -ionone, are not formed *via* RIP.^{114, 115} However, in the presence of pyrene, the formation of a RIP with α -pyran as the radical cation and pyrene as the radical anion was observed.

Scheme 4

A is an electron acceptor, D is an electron donor.

The CIDNP sign and the intensities of polarised lines corresponded to the signs and distribution of HFC constants (*a*) in the β -ionone radical anion ($a_4 = 1.2$, $a_5 = 0.65$, $a_7 = -1.0$ and $a_9 = 0.65$ mT).¹²⁷ It should be noted that Scheme 4 is versatile, *i.e.*, it can be used for describing the reactions of β -ionone with both electron acceptors (*e.g.*, quinones)¹²⁵ and electron donors (*e.g.*, pyrene and triphenylamine).¹¹⁵ β -Ionone plays the role of the electron donor in the former case and the electron acceptor in the latter case.

This example shows that CIDNP is indeed an effective tool for studying the geometrical isomerisation of polyenes that involves radical stages.

2. *cis*–*trans* Isomerisation of C=C bonds in radical ions of polyenes

cis–*trans* Isomerisation of radical ions was described for the first time also for substituted ethylenes.^{122, 128, 129} The CIDNP method did not allow us to observe the isomerisation of radical ions of short polyenes, namely, of β -ionone (**5**) and retinal (**4**), in the microsecond time interval suitable for the CIDNP manifestation.^{124, 125} This means that even if the radical ions of these polyenes isomerise, this process takes much longer time than the microsecond interval of the lifetime of short-lived RIP. Indeed, as follows from quantum-chemical calculations, the activation barrier to the *cis*–*trans* isomerisation of β -ionone radical ions is 10–20 kcal mol^{–1}, which corresponds to the isomerisation rate of $\sim 10^4$ s^{–1}. However, we managed to observe the *cis*–*trans* isomerisation of radical cations of β -carotene, canthaxanthin and 8'-apo- β -carotenal generated either chemically or electrochemically.^{65, 68, 130, 131} These observations became possible due to the longer lifetimes of these radical cations as compared with those of β -ionone and retinal. Thus the lifetimes of radical cations of β -carotene and canthaxanthin in dichloromethane solutions were equal to several minutes.^{59, 132} HPLC analysis of the electrolysis products of β -carotene indicated the formation of five isomers, namely, *trans*, 15-*cis*, 13-*cis*, 9-*cis* and 9,13-di-*cis*, in a ratio of

50 : 4 : 21 : 21 : 4.^{59, 132} This isomer ratio was observed for both the electrochemical generation of radical cations and chemical oxidation of carotenoids in the presence of FeCl₃ or quinones.

It should be emphasised that this ratio substantially differs from that obtained by Hashimoto and Kayama¹³³ for the triplet-sensitised isomerisation of β -carotene. Under photostationary conditions, these authors observed only four isomers, namely, *trans*, 15-*cis*, 13-*cis* and 9-*cis*, in a ratio of 84 : 1.5 : 4 : 10.5.

According to AM1 calculations,¹³⁴ the energy barriers to isomerisation of bonds in the β -carotene radical cation (~ 20 kcal mol^{–1}) and the dication (~ 0 kcal mol^{–1}) were substantially lower than those of the neutral molecule (~ 55 kcal mol^{–1}). The calculated¹³⁴ lengths of C=C bonds in the middle part of the conjugated chain substantially differ for the neutral molecule, the radical cation and the dication: they change from 1.35 Å in the neutral molecule to 1.40 Å in the radical cation and to 1.45 Å in the dication. The latter value corresponds to the length of a single C–C bond in a carotenoid molecule.

3. *cis*–*trans* Isomerisation of C=C bonds in biradicals and neutral radicals

Due to the presence of many double bonds, carotenoids are potential reagents for the addition of ketones or aldehydes to alkenes (the Paterno–Büchi reaction) to form biradicals. Thus the formation of biradicals in the photoreaction of β -ionone with quinones was inferred from the results of CIDNP.¹²⁵ The formation of the polarised *cis*-isomer of β -ionone in the reaction with chloranil under the conditions of insufficient energy for the triplet recombination of the RIP points to the 'biradical' isomerisation route (see Scheme 2).

Isomerisation of β -ionone can occur as a result of rotation around the C(7)–C(8) bond in biradical **6**.

A similar mechanism for the *cis*–*trans* photoisomerisation of alkenes has been described earlier.^{63, 64} As was noted above, once photoexcited, β -ionone can exhibit not only electron-donating, but also electron-withdrawing properties.^{115, 125} Isomerisation of β -ionone in the photolysis in the presence of electron donors can proceed *via* either triplet β -ionone or a neutral radical, namely, the protonation product of the β -ionone radical anion. (It is known that the β -ionone radical anion undergoes fast protonation in the presence of hydrogen donors.¹¹⁶) According to results of CIDNP, the only isomerisation product of the neutral radical *trans* form is the corresponding *cis* isomer.¹¹⁵

Thus, the results accumulated to date make it possible to state that *cis-trans* isomerisation, which is the most important process in carotenoid chemistry, proceeds in the presence of electron acceptors or electron donors through the single-electron transfer stage.

VI. Inclusion complexes of carotenoids with cyclodextrins

As was mentioned above, the high reactivity, hydrophobicity and photosensitivity of carotenoids complicate their application; hence, in practice (food industry, cosmetology and medicine), their complexes with natural compounds are used. Inclusion complexes of carotenoids with cyclodextrins are studied most comprehensively. Cyclodextrins readily react with organic molecules to form inclusion complexes, which is explained by the peculiarities of their structure (the inner cavity of a cyclodextrin molecule is hydrophobic, while its outer surface is hydrophilic). Hydrophobic carotenoid molecules easily interact with the hydrophobic cavity. The complexes themselves are hydrophilic due to the hydrophilic outer surface of the cyclodextrin molecule. Numerous studies were devoted to the synthesis and properties of these complexes. In applied studies, attention was focused on the improvement of solubility of carotenoids and enhancement of their stability in aqueous solutions,^{20–22, 25, 28, 134} while the fundamental studies considered the structure of complexes,^{23, 24, 29} bioaccessibility of carotenoids at the cell level, penetration of carotenoids through cell membranes,^{26, 27} antioxidant properties of complexes²⁹ and the use of cyclodextrins as a model of a natural enzyme responsible for β -carotene cleavage.^{37, 135}

In food industry, carotenoids are used most widely as food pigments. The use of carotenoid complexes with cyclodextrins in place of free carotenoids allows one not only to obtain more stable colour of foodstuffs, but also to increase the storage life of food pigments themselves. Particularly, substitution of a cyclodextrin complex of astaxanthin for pure astaxanthin in the ration of salmon fish substantially increased the stability of salmon meat during storage.¹³⁴

Recently, the problem of provision of humans with optimum amounts of vitamins becomes more pressing. Now, it is evident that this cannot be achieved with ordinary foodstuffs. A demand for the development of foodstuffs enriched with vitamins and biologically active additives has arisen. The most promising food additives include carotenoids, *e.g.*, β -carotene. A β -carotene complex with β -cyclodextrin (in Russia, it is produced under a name 'Tsiklokar') is widely used as a bioactive additive. Recently, it has been shown that the use of other cyclodextrins, *e.g.*, α -cyclodextrin and, especially, methylated β -cyclodextrins produces a greater effect;²⁸ however, in practice, the use of β -cyclodextrin rather than its derivatives are apparently associated with its availability and low cost.

In cosmetology, carotenoids are largely used as antioxidant additives in the production of protective creams. β -Carotene is used most often. However, its addition to make-up preparations results in their strong brick-red colour; this is why cosmetologists proposed to add not carotene as such, but its complexes, *e.g.*, a cyclodextrin complex of β -carotene. Its colour is much weaker⁸ as compared with β -carotene solutions in organic solvents, and creams prepared with this additive have a nice rose colour.²²

It should be noted that the applied studies did not discuss the problem of retention of useful properties of carotenoids upon their complexation, particularly, of their antioxidant activity. Insofar as the antioxidant activity of carotenoids is associated with their ability to scavenge free radicals, it can be assumed that its complexation would affect the latter process. Indeed, the ability of cyclodextrin to conserve, in its cavity, benzyl radical formed

upon photolysis of an inclusion complex of cyclodextrin with dibenzyl ketone has been demonstrated.¹³⁶

The interaction of a water-soluble cyclodextrin complex of 8'-apo- β -caroten-8'-al with free peroxide radicals was studied.²⁹ The EPR spin-trapping method has shown that the complexation of 8'-apo- β -caroten-8'-al with β -cyclodextrin blocks almost completely the ability of this carotenoid to scavenge peroxide radicals. Apparently, this effect of cyclodextrin on the reactivity of carotenoids can be explained by the fact that the formation of complexes makes the cyclohexene ring of the carotenoid[†] inaccessible for these radicals.¹³⁷ However, the increase in the carotenoid stability in complexes should not prevent their use *in vivo*, *e.g.*, for the delivery of carotenoids directly to the cell. Insofar as carotenoid complexes with cyclodextrins are not covalently bound rigid structures, but are in equilibrium with their starting components, it can be assumed that on the surface of a cell membrane, the complex will dissociate to release a carotenoid, which will penetrate into the membrane.

The role of cyclodextrins as the carriers of drugs, for example, carotenoids, was studied *in vitro* by many scientists (*e.g.*, see Refs 26, 27 and 138). In all the cases, the positive role of cyclodextrins in the delivery of carotenoids to cells was emphasised. Thus a comparison of such properties of β -carotene complexes with methylated β -cyclodextrin as bioaccessibility, toxicity and stability with those of homogeneous solutions of β -carotene in a THF–DMSO solvent mixture has shown that the β -carotene complexes with cyclodextrin are, first, non-toxic, and, second, characterised by better bioaccessibility. For instance, after several days of incubation of cells with these complexes the level of β -carotene was substantially higher than that observed upon the use of homogeneous solutions of β -carotene.²⁷

In conclusion, we consider yet another interesting application of cyclodextrins, *viz.*, the development of new enzymes, particularly, the enzyme responsible for splitting of β -carotene in organism. Thus an attempt was undertaken to model the action of the enzyme, namely, 15,15'-dioxygenase, which consists of the cleavage of the central C(15)–C(15') bond of β -carotene to form two molecules of vitamin A.^{37, 135} The goal was to obtain an unstable β -carotene intermediate, namely, the adduct of a H_2O_2 molecule to the central double bond of the carotenoid, which would readily decompose to afford two retinal molecules under the action of the synthetic enzyme.

The implementation of this idea involved the use of the Fenton reaction (7) where Fe^{2+} ions were replaced by a metalloporphyrin molecule. The enzyme model consisted of two β -cyclodextrin molecules covalently attached to the metalloporphyrin molecule. It was assumed that both cyclohexene rings of β -carotene will be captured by cyclodextrin molecules in such a way that the metal ion of the metalloporphyrin fragment will be located near the central double bond of the carotenoid. In this case, the reaction of H_2O_2 with the metal ion would proceed in the immediate vicinity of the central double bond of the carotenoid. Presumably, it is this double bond that would undergo the attack by the hydroxyl radical formed in the Fenton reaction. However, the use of the model iron porphyrin-containing enzyme resulted in the formation of not only retinal, but also a wide set of other products, which suggests that oxygenation of different double bonds occurred.¹³⁵ At the same time, a synthetic enzyme containing ruthenium porphyrin did catalyse the cleavage of the central double bond of β -carotene.³⁷

VII. Supramolecular complexes of carotenoids with glycyrrhizin

The revealed effect of complexation on the physical properties and reactivity of inclusion compounds initiated the search for new

[§]Japanese authors also used the term 'colourless' to characterise this complex.²¹

[†]Peroxide radicals attack the terminal double bond of the cyclohexene fragment of a carotenoid.²⁹

natural complexation agents that would exhibit certain advantages over cyclodextrins and, first of all, have no limitations with respect to the size of the 'guest' molecule. These compounds should form more stable complexes, reduce the toxic effect of drugs on the organism and, at the same time, enhance their therapeutic activity. Despite the complexity of this problem, one of such compounds has been found. This is glycyrrhizic acid (another popular name is glycyrrhizin), which is isolated from liquorice root (*e.g.*, of *Glycyrrhiza uralensis* Fish).³⁸ This compound has long been used in medicine as an anti-inflammatory agent or an expectorant. It is glycyrrhizin that provides the sugary taste to liquorice root.

In contrast to cyclodextrin, the glycyrrhizin molecule has an open-chain structure and contains both hydrophilic (glucuronic acid) and hydrophobic (glycyrrhetic acid) parts. Glycyrrhizin has several important advantages over cyclodextrins. First, it belongs to open-type ligands, hence, its complexes have no rigorous restrictions for the size of the guest molecule. Second, its inclusion complexes are extraordinarily stable,^{39–41} their stability constants exceed the mean stability constant of cyclodextrin complexes by two orders of magnitude.³⁰

Glycyrrhizin is a component of many medicinal preparations. This is known to increase the therapeutic activity of drugs, which was attributed to their complexation with glycyrrhizin,^{30, 39} and to affect the reactivity of inclusion compounds.^{42, 139}

The above-mentioned aspects were studied by modern physicochemical methods by the example of carotenoid complexes^{19, 140} and two antiarrhythmic preparations, namely, Nifedipine and Lappaconitine.^{42, 139} The formation of inclusion complexes with glycyrrhizin was judged from the changes in the absorption and fluorescence spectra upon the addition of glycyrrhizin and from the changes in the reactivity of carotenoids.

1. Measurements of the stability and stoichiometry of carotenoid complexes with glycyrrhizin

The determination of stoichiometry and the measurements of stability constants of inclusion complexes formed upon mixing of carotenoids with glycyrrhizic acid were carried out using standard procedures (*e.g.*, see Refs 31, 141 and 142), *viz.*, Job's method and spectral methods, which allow determination of the stoichiometry and the stability constants of complexes, respectively, based on the dependence of the optical density of a solution on the GA concentration.

The structure, stability and reactivity of inclusion complexes of certain carotenoids with β -glycyrrhizic acid were studied.¹⁴⁰ The absorption spectra of carotenoids were shown to change with the GA concentration. The changes were observed only in aqueous solutions and their magnitude did not exceed 10%. It should be noted that the NMR method which is often used in the analysis of carotenoid complexes with cyclodextrins,¹⁴³ proved to give little information on these complexes. This is explained first of all by low solubility of carotenoids and GA in aqueous solutions and also by insufficient sensitivity of the NMR technique due to small concentrations of the components (10^{-4} – 10^{-5} mol litre⁻¹).¹⁴³

At the same time, fluorescence spectra of carotenoids complexes proved to be very sensitive to the formation of carotenoid complexes with glycyrrhizin (Fig. 5*a*). Thus studies of the dependence of the intensity of fluorescence of canthaxanthin on the glycyrrhizin concentration have shown that the stability of complexes at the GA concentration lower than 1 mmol litre⁻¹ [$K = (0.3–1.0) \times 10^4$ litre mol⁻¹, curve 1 in Fig. 5*b*] differs substantially from that at the GA concentration larger than 1 mmol litre⁻¹ ($K < 10^2$ litre mol⁻¹, curve 2 in Fig. 5*b*). Earlier, Romanko and Murinov¹⁴⁴ have observed a sharp change in the dynamic viscosity of aqueous–ethanolic solutions (5%–10% ethanol) of glycyrrhizin at the GA concentration of ~ 1 mmol

Figure 5. Fluorescence spectra of a canthaxanthin solution (0.02 mmol litre⁻¹) in the absence (curve 1) and in the presence (curve 2) of glycyrrhizic acid (5 mmol litre⁻¹) in DMSO containing 5% of water (*a*); changes in the fluorescence intensity (ΔA) of canthaxanthin as a function of the GA concentration in solution (*b*).¹⁴⁰ Excitation wavelength was 470 nm, detection wavelength was 620 nm.

litre⁻¹. It was assumed that at this concentration glycyrrhizin forms micelle-like associates in aqueous solutions.[†]

The stoichiometric ratios of components in associates were estimated based on the dependence of the changes in the optical density of the solution of carotenoid and glycyrrhizin (ΔD) on the carotenoid molar fraction $r = [\text{Car}]/([\text{Car}] + [\text{GA}])$ at a constant overall concentration of the components (Job's diagram, Fig. 6).¹⁴⁰ For example, the position of the maximum in the $\Delta D = f(r)$ curve at $r = 0.33$ corresponds to 1 : 2 ratio of carotenoid and glycyrrhizin molecules in the associate.

Earlier, it was supposed that GA molecules in aqueous solution form cylindrical dimers of the torus⁴⁰ or podand⁴¹ types. It can be assumed that the hydrophobic interaction of carotenoids with glycyrrhizin will favour the penetration of the carotenoid molecule into the cyclic dimer formed. To check this hypothesis, the thermodynamic parameters (ΔG , ΔH and ΔS) of complexation of carotenoids with glycyrrhizin were measured.¹⁴⁰ Using standard relationships

$$-\Delta G = RT \ln K,$$

[†] The hypothesis of micelle formation was confirmed later by Japanese authors¹⁴⁵ who studied the formation of micelles of water-soluble derivatives of glycyrrhizin, particularly, Na salt of GA sulfate. We failed to find the data on the micelle formation in other solvents in the literature.

Figure 6. Job's diagram plotted based on the changes in the optical density of a solution in 20% ethanol at 433 nm as a function of the mole fraction of carotenoid (r);¹⁴⁰ ϵ is the extinction coefficient.

$$\Delta G = \Delta H - T\Delta S$$

and

$$\ln \frac{K_2}{K_1} = -\frac{\Delta H}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right)$$

(K_1 and K_2 are the stability constants of the complex at temperatures T_1 and T_2 , respectively), the following values of parameters at $T = 293$ K were obtained: $\Delta H = 42.9$ kJ mol⁻¹, $\Delta G = -19.9$ kJ mol⁻¹ and $\Delta S = 211$ J mol⁻¹ K⁻¹. The positive values of the enthalpy and entropy terms suggest the preferential contribution of the hydrophobic interaction between the carotenoid and glycyrrhizin molecules into the stability of the complex formed and also substantial desolvation of the glycyrrhizin molecule, which is typical of inclusion complexes.

Inclusion complexes of carotenoids with GA of a composition 1 : 2 are formed both in aqueous solutions and in polar solvents such as DMSO, acetonitrile and alcohols. It is assumed that the complex represents a carotenoid molecule placed inside a torus formed by the dimer of glycyrrhizinic acid.

Stability constants of complexes were estimated based on changes in the optical density of the solution at a fixed carotenoid concentration and variable glycyrrhizin concentration (Fig. 7). If the carotenoid concentration is much lower than that of glycyrrhizin, the stability constant of their complex can be calculated based on the Benesi–Hildebrand method.¹⁴²

$$\frac{D}{\Delta D} - 1 = \frac{1}{K} \frac{1}{[\text{GA}] [\text{GA}]^n},$$

where $\Delta D = \Delta\epsilon[\text{Car}]$, K is the stability constant of the complex

$$K = \frac{[\text{Car-GA}_n]}{[\text{Car}][\text{GA}]^n}. \quad (8)$$

This allowed Polaykov *et al.*¹⁴⁰ not only to estimate the stability constant of complex (K), but also to determine the reaction order (n) of complex formation in a single experiment.

For complexes of the composition 1 : 2, a linear dependence between the absorption changes and the GA concentration was observed on the coordinates $1/\Delta D$ vs. $1/[\text{GA}]$. The analysis of Job's diagram (see Fig. 6) showed that complexation of carotenoids with glycyrrhizin is a second-order reaction. Based on this, it was concluded that the complexation involves one carotenoid molecule and one glycyrrhizinic acid dimer.

Figure 7. Changes in the optical density of a solution of β -carotene in 20% ethanol ($2.5 \mu\text{mol litre}^{-1}$) at 440 nm as a function of the concentration of glycyrrhizinic acid (a) and the Benesi–Hildebrand diagram (b).¹⁴⁰ Points correspond to experimental data, solid lines correspond to calculations for a β -carotene–GA complex with a stability constant $K = 10^4$ litre mol⁻¹.

2. Reaction of carotenoids and their complexes with FeCl₃ in polar media

The data on the effect of glycyrrhizin on the reactivity of carotenoids are of undeniable interest. As was noted above, electron transfer reactions play the key role in the chemistry of carotenoids. It was found¹⁴⁰ that electron transfer in reactions of Fe(III) salts (electron acceptors) with complexes of carotenoids with glycyrrhizin was decelerated as compared with reactions of these salts with free carotenoids and the lifetime of carotenoid radical cations in glycyrrhizin complexes in polar media increased, which resulted in the change in the ratio of reaction products. Optical methods were used for studying the reactivities of inclusion complexes of carotenoids.¹⁴⁰ The decrease in the rate of direct electron transfer from carotenoids (β -carotene and 8'-apo- β -caroten-8'-al) involved in GA complexes to Fe^{3+} was inferred from a considerable (by a factor of several dozens) decrease in the absorption of carotenoid radical cations in the presence of GA as compared with their homogeneous solutions (Fig. 8), as well as from the rate of consumption of the carotenoids during the reaction.

It is known that the second oxidation potential of β -carotene coincides with its first potential;¹⁴⁶ this is why its reaction with FeCl_3 proceeds by different mechanisms for $[\text{Car}] \geq [\text{Fe}^{3+}]$ and for $[\text{Car}] \ll [\text{Fe}^{3+}]$. In the former case, oxidation of β -carotene produces radical cation (Fig. 8a) and in the latter case, the dication (Fig. 9a). (The signal at 935 nm corresponds to the absorption of β -carotene radical cations, while the signal at 889 nm corresponds to the absorption of the dication.) When

Figure 8. Absorption spectra of β -carotene recorded before (curve 1) and after (curve 2) mixing with the equivalent amount of FeCl_3 in acetonitrile at room temperature.¹⁴⁰

(a) In the absence of glycyrrhizin; (b) in the presence of $0.1 \text{ mmol litre}^{-1}$ of glycyrrhizin. $[\text{Car}] = [\text{FeCl}_3] = 1.3 \text{ }\mu\text{mol litre}^{-1}$.

Figure 9. Absorption spectra of β -carotene recorded before (curve 1) and after (curves 2–4) mixing with an excess of FeCl_3 in acetonitrile at room temperature.¹⁴⁰

(a) In the absence of glycyrrhizin; (b) in the presence of $0.1 \text{ mmol litre}^{-1}$ of glycyrrhizin. $[\text{Car}] = 1.3 \text{ }\mu\text{mol litre}^{-1}$, $[\text{FeCl}_3] = 7 \text{ }\mu\text{mol litre}^{-1}$, (1) spectrum of β -carotene, (2) spectrum of a solution of β -carotene and FeCl_3 immediately after mixing, (3 and 4) spectra measured 6 and 20 min after the addition of FeCl_3 , respectively.

β -carotene reacted with an excess of Fe^{3+} in the presence of GA, the stabilisation of the β -carotene radical cation was observed (Fig. 9b).

Thus, the observed ¹⁴⁰ differences in the reactions of Fe^{3+} salts with carotenoids either incorporated in glycyrrhizin complexes or in the free state suggest that the changes in the reactivity of carotenoids upon the addition of glycyrrhizin are caused by the formation of complexes. The concomitant increase in the lifetime of charged forms of carotenoids (cations and dications) by a factor of dozens implies that these species do not leave the complex being stabilised inside it.

3. Reactions of carotenoids and their complexes with quinones in polar media

The reactions of carotenoids with quinones is yet another example of the effect of complexation on their reactivity. Quinones were chosen because they are important natural electron acceptors.

The system β -carotene–2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (the latter was taken because its reaction with carotenoids does not require additional photo- or thermoactivation due to its low reduction potential) was chosen as the model system for studying the reactivity of inclusion compounds.¹⁴⁰ The formation of radical cations upon the addition of the quinone to a solution of β -carotene was judged from the changes in the absorption spectrum of the latter.

A characteristic feature of this reaction is that the curves that describe the decay kinetics of β -carotene radical cations incorporated in a glycyrrhizin complex or in solution have different shapes (Fig. 10). For a free carotenoid, the radical cation signal decays exponentially (the radical lifetime is $\sim 20 \text{ s}$), whereas in the presence of glycyrrhizin, the signal decay curve demonstrates

Figure 10. Decay kinetics of the absorption signal of β -carotene radical cation formed upon addition of DDQ to β -carotene in the absence (curve 1) and in the presence of different amounts of glycyrrhizin (curves 2–5).¹⁴⁰ (a) $[\text{Car}] = [\text{DDQ}] = 4 \text{ }\mu\text{mol litre}^{-1}$, (b) $[\text{Car}] = 2 \text{ }\mu\text{mol litre}^{-1}$, $[\text{DDQ}] = 5 \text{ }\mu\text{mol litre}^{-1}$; GA concentration $/\text{mmol litre}^{-1}$: 0.3 (2), 0.1 (3), 0.06 (4), 0.03 (5).

two distinct regions, which suggests the contribution of two processes, namely, a fast exponential and a slow ones (Fig. 10 b).

$$I = \frac{a}{1 + t/\tau}.$$

This two-component decay kinetics of the carotenoid radical cation made it possible to suggest that in solutions containing glycyrrhizin both the radical cations of the free carotenoid ($\tau \approx 20$ s) and the radical cations incorporated in the complex ($\tau \approx 1000$ s) are present. (Note that the contributions of these two states can be observed separately only in the absence of fast exchange between them.) The different shapes of decay curves at 935 nm for different glycyrrhizin concentrations (Fig. 10 b) point to the increase in the contribution of the slow component with the increase in the GA concentration, this contribution increasing proportionally to the square of GA concentration.¹⁴⁰ Such a square-law dependence could stem from the fact that the structure of the GA complex of the carotenoid radical cation in acetonitrile corresponds to the stoichiometry of 1 : 2. Bearing in mind that the contribution of the slow component is about 50% at the glycyrrhizin concentration of 0.1 mmol litre⁻¹, it can be concluded that for this concentration the ratio of free radical cations and their complexes is $\sim 1 : 1$. Based on expression (8), the stability constant of the carotenoid radical cation complex was estimated to be of an order of magnitude of 10⁸ litre² mol⁻².

From the aforesaid, it follows that the stabilisation of the carotenoid radical cation due to its complexation with glycyrrhizin should substantially change the yield of reaction products of carotenoids with quinones. Thus if the CTC formed in the first stage is located inside the complex, the yield of the 'in-the-cage' reaction product, *i.e.*, the adduct of the carotenoid to the quinone, is increased. Otherwise, the increase in the lifetime of the free radical cation would increase the yield of carotenoid *cis*-isomers. Analysis of the composition of reaction products of certain carotenoids (β -carotene, canthaxanthin and 7'-apo-7',7'-dicyano- β -carotene) with DDQ in the presence and in the absence of glycyrrhizin using HPLC (Ref. 140) has shown that in all cases, the yield of carotenoid-to-quinone adducts substantially increased when the reaction was carried out in the presence of glycyrrhizin.

This experiment made it possible to draw an important conclusion that glycyrrhizin forms stable associates not only with individual compounds and their ions, but also with charge-transfer complexes; moreover, the complexation can result in substantial changes in the reaction route and the ratio of products.

4. Reactions of carotenoids and their complexes with free radicals

Ultimately, let us consider how the complexation of carotenoids with glycyrrhizin affects the antioxidant activity of carotenoids. This problem has recently been studied in detail.¹⁹ The reaction rates of carotenoids with free radicals were estimated by EPR spin-trapping technique using *N-tert*-butyl- α -phenylnitron as the spin trap.

It should be noted that when dealing with traps, it is very important to correctly identify the spin adducts observed.^{19, 147, 148} Several test experiments were carried out to prove the correctness of assignment of the EPR signal observed in dimethyl sulfoxide to the adduct PBN-OOH.^{14, 19} First, it was found that the shape of the EPR spectrum changed depending on the concentration of hydrogen peroxide in solution.¹⁴ At low H₂O₂ concentrations ([H₂O₂] = [FeCl₂] = 1 mmol litre⁻¹), only the adduct PBN-CH₃ (DMSO was the origin of $\cdot$ CH₃) was formed, while at high concentrations ([H₂O₂] = 500 mmol litre⁻¹) the adduct PBN-OOH was formed and the adduct PBN-CH₃ disappeared as a result of the reaction of the $\cdot$ CH₃ radical with H₂O₂.¹⁴

The adducts of PBN with $\cdot$ OR radicals are unstable, especially in the presence of transition metals that can reduce them to $\cdot$ OR.^{147, 148} However, the majority of experimental facts that confirm this statement refer mainly to alkylperoxide radicals, whereas the adduct PBN-OOH was often observed under

Figure 11. EPR spectra of the adduct PBN-OOH in the absence (a) and in the presence of canthaxanthin (b) and its complex with glycyrrhizin (c) in DMSO.¹⁹ [PBN] = 5 mmol litre⁻¹, [FeCl₂] = 1 mmol litre⁻¹, [H₂O₂] = 0.5 mol litre⁻¹; [Car] = [GA] = 1 mmol litre⁻¹.

normal conditions.^{149–151} The standard test for the adduct PBN-OOH is its reaction with superoxide dismutase. It was demonstrated¹⁹ that the signal of the adduct PBN-OOH completely disappeared in the presence of this enzyme, whereas no changes in the spectrum of the adduct PBN-CH₃ occurred.

Moreover, a considerable decrease in the yield of the spin adduct PBN-OOH was observed in the presence of carotenoid complexes, which followed from the EPR spectra (Fig. 11).¹⁹ Based on the experimental dependence of the yield of the spin product on the carotenoid concentration, the relative rate constant ($k_{\text{Car}}/k_{\text{ST}}$) for scavenging of the $\cdot$ OOH radical by a carotenoid was estimated according to Eqn (4). Note that one of the results of this study¹⁹ was the observation of the antioxidant activity of glycyrrhizin as such. Therefore, the ratios $k_{\text{Car}}/k_{\text{ST}}$ for different carotenoids were obtained by subtracting the contribution of glycyrrhizin to the overall rate constant for scavenging of the $\cdot$ OOH radical by a particular carotenoid (Table 1).

Table 1. Relative rate constant (k/k_{ST}) for scavenging of $\cdot$ OOH radicals by glycyrrhizic acid (GA) and GA complexes with zeaxanthin (ZX), canthaxanthin (CX) and 7'-apo-7',7'-dicyano- β -carotene (DDC).¹⁹

[GA] / mmol litre ⁻¹	k/k_{ST}^a			
	GA	CX + GA	DDC + GA	ZX + GA
0	—	2	7	4
0.5	12	59	133	4
1	12	46	116	4
2	12	6	38	4

^a Experimental error of k/k_{ST} determination is $\sim 10\%$.

Since the structures of carotenoid complexes with glycyrrhizin differ depending on whether the concentration of the latter is higher or lower than 1 mmol litre⁻¹, the rates of peroxide radical scavenging by free carotenoids and by their complexes in DMSO were compared for different concentrations of glycyrrhizin. The data listed in Table 1 show the presence of a synergistic effect, which manifests itself in the significant increase in the rate of scavenging of radicals by carotenoids [canthaxanthin (CX) and 7'-apo-7',7'-dicyano- β -carotene (DCC)] incorporated in complexes with GA. The absence of the effect for zeaxanthin (ZX) was quite unexpected. The different behaviour of these three carotenoids was explained by their different polarographic half-wave oxidation potentials $E_{1/2}$. As is shown in Fig. 2, the $k_{\text{Car}}/k_{\text{ST}}$

vs. $E_{1/2}$ dependence is hyperbolic. A segment corresponding to the rapid changes in the rate of peroxide radical scavenging by a carotenoid is located close to $E_{1/2} = 0.7$ V. The oxidation potentials of canthaxanthin ($E_{1/2} = 0.68$ V) and 7'-apo-7',7'-dicyano- β -carotene (0.72 V) fit exactly the region of 'fast changes' of scavenging rates, whereas the potential of zeaxanthin ($E_{1/2} = 0.56$ V) lies rather far in the plateau region. Bearing this in mind, the differences in the rates of radical scavenging by carotenoid complexes can be attributed to the changes in $E_{1/2}$ upon formation of the complexes. Indeed, even minor changes in the $E_{1/2}$ of CX and DCC can lead to a substantial increase in k_{Car}/k_{ST} .

To check this hypothesis, we studied the effect of complexation on the oxidation potentials of two carotenoids, namely, zeaxanthin and canthaxanthin.¹⁹ Polarographic half-wave potentials were measured in 0.1 mmol litre⁻¹ solutions of carotenoids in acetonitrile in the presence of 0.2 mmol litre⁻¹ GA at room temperature. In both cases, E was observed to increase, viz., by 0.05 V for CX and by 0.03 V for ZX. Such a change in the oxidation potential for zeaxanthin cannot cause any changes in its antioxidant activity, whereas a substantial increase in k_{Car}/k_{ST} will be observed for canthaxanthin. Yet another aspect of significance of this result is that it confirms the correctness of the earlier hypothesis on the role of electron transfer in scavenging of radical species by carotenoids.¹⁴

The results discussed above make it possible to conclude that complexation with glycyrrhizin has a substantial effect on the reactivity of carotenoids, viz., this decreases the electron transfer rate in the reaction with electron acceptors and increases the lifetime of carotenoid radical cations in complexes, which results in changes in the ratio of reaction products of carotenoids with electron acceptors. Experimental results on the rates of scavenging of peroxide radicals by different carotenoids suggest that the changes in the oxidation potentials of carotenoids in complexes are among the key factors that determine their reactivity.

VIII. Conclusion

In the present review, the following homolytic reactions of carotenoids were considered: reactions with free radicals and complexation. The choice of these processes was caused by the keen interest of scientists in the antioxidant properties of carotenoids. As was mentioned above, the antioxidant activity of carotenoids is being extensively studied. Several reviews^{14–17} on this subject have already been published; however, none of them provides the analysis of physicochemical factors responsible for this activity. Our review was intended to fill this gap.

We have demonstrated that electron transfer is typical of carotenoids not only in their transformations in photosynthetic centres or in the presence of electron donors or electron acceptors, but also in the reactions of carotenoids with free radicals and also in their *cis*–*trans* isomerisation. It can be stated that it is the tendency of carotenoids to single-electron transfer that unites the most significant biological processes involving carotenoids, from photosynthesis and photoisomerisation of retinal in visual pigment rhodopsin to their antioxidant activity.

The discussion, in this review, of carotenoid complexation processes was also associated with the studies of their antioxidant properties. At present, the development of effective pharmaceutical preparations based on inclusion complexes of natural compounds is one of the most rapidly developed fields of medicinal chemistry. However, insufficient attention is paid to the fundamental studies of the mechanism of complexation and physicochemical properties of inclusion complexes.

Particularly, the field of complexation of carotenoids with different 'host' molecules is still in its infancy. The information on the effect of complexation on the reactivity of 'guest' molecules clearly demonstrates the great prospects of this direction. In fundamental studies, these results make it possible to gain better insight into the role of weak interactions in complexation and also

into the mechanism of the effect of organised media of the reactivity of inclusion compounds, while in applied studies, a possibility appears of the purposeful choice of complexation agents for strengthening (or weakening) of one or another property of carotenoids.

Abstract. The properties and prospects of application of fluoride nanoparticles are discussed. Pyrohydrolysis is considered as the key process determining the chemistry and technology of fluorides; its role increases on going to the nanosize region. The physical and chemical methods for the synthesis of fluoride nanoparticles, one- and two-dimensional nanoobjects as well as approaches to the preparation of nanocomposites (glass ceramics, heterovalent solid solutions with defect clusters, eutectoid composites, *etc.*) are analysed. Nanotechnology techniques used to produce heterogeneous nanoobjects are outlined. The bibliography includes 238 references.

I. Introduction

In recent years, nanosized particles have attracted increasing interest due to their unique physical and chemical properties, which differ from the properties of macro- and microparticles. However, nanoparticles of inorganic fluorides have received less attention than nanoparticles of other classes of compounds such as metals, oxides and semiconductors. In particular, nanoparticles of inorganic fluorides were not mentioned in the handbook¹ and only one of 668 references in the review² refers to fluorides. Major publications on fluoride nanoparticles appeared in the last 5 years.

The synthesis and investigations of fluoride nanoparticles are of interest for the following reasons.

Laser ceramics was developed based on yttrium aluminium garnet and rare-earth oxides. The optical transmission, optical losses and spectral-generation characteristics of these ceramics are not virtually inferior to those of single crystals.^{3,4} Considerable progress in the nanoparticle preparation technology was achieved with the use of self-organisation processes of nanoparticles. The advantages of laser nanoceramics over single crystals include the

possibility of producing large objects, improved mechanical characteristics, uniform distribution and high concentrations of activating ions and the possibility of preparing a transparent optical medium where the synthesis of single crystals presents problems.

Analysis of the trends of development of modern photonics in different countries demonstrated that devices based on fluoride compounds will play a considerable role in the nearest future. This statement is supported by the following physical facts:

- transmission of fluorides in a wide spectral region (from 0.2 to 6 μm); short phonon spectra preventing the development of the adverse effect of multiphonon relaxation in electronic levels of impurity ions;

- the ease of introduction of considerable amounts of active rare-earth ions (up to concentrations of 10^{21} cm^{-3}) into fluorides;

- better mechanical properties and higher moisture resistance of fluorides compared to other classes of compounds having a wide transmission window, such as chlorides and chalcogenides;

- high thermal conductivity of fluorides.

Due to the above-mentioned advantages, fluorides, primarily as single crystals, are successfully used for the production of active and passive elements of laser systems employed in medicine, ecology and informatics, in particular, as elements of unique tunable lasers.

In the light of the above, the possibility of constructing analogous fluoride nanoceramics for photonics (lasers, scintillators, *etc.*) primarily based on alkaline-earth fluorides doped with rare-earth metals is very attractive.^{5–8}

Certain parameters of nanoparticles are improved compared to bulk crystals. The special spectroscopic properties of nanoparticles containing lanthanide ions are determined by the following circumstances:^{9–12}

- the absence of low-energy phonons and low density of phonons resulting in a radical change in the dynamics of energy transfer;

- a change in local symmetry of cations in small clusters and on the particle surface;

- small Stark splitting due to a decrease in the crystal field strength.

These features are responsible for the specific nature and prospects of development of nanophotonics. In particular, the luminescence intensity and the lifetime of the excited state for a nanocrystalline $\text{NaGdF}_4:\text{Eu}^{3+}$ powder increase with a decrease in particle size from 60 to 14 nm.¹¹ Thus, nanopowders of various

fluorides doped with lanthanide ions hold promise for the production of monitor displays, optical amplifiers, lasers and phosphors.^{11, 13–15}

Sodium fluoride nanoparticles doped with uranium exhibit much higher electron emission than single crystals, due to which these nanoparticles were recommended as materials for probes for cytological, microbiological and medical studies.¹⁶

Fluoride nanoparticles, to be more precise, powders with very high specific surface area (up to $200 \text{ m}^2 \text{ g}^{-1}$ and larger) have attracted interest as materials for new types of catalysts. Due to high specific surface area, fluorides can serve as very efficient acid catalysts because coordinatively unsaturated sites of metal atoms are accumulated on the surface of such compounds.^{17, 18} Powders of fluorides AlF_3 , AlClF_2 , FeF_3 and CrF_3 with highly developed surface act as very strong Lewis acids, which are comparable in or even stronger than SbF_5 . Nanocrystalline magnesium fluoride can be used as a sorbent (support).^{17–21} The catalytic activity is particularly high if compounds are amorphous.

In some cases, the synthesis of fluoride nanoparticles is simpler, more efficient and is characterised by a higher output compared to conventional methods for the preparation of single and polycrystals (sintering or fusion of precursors at high temperature in a fluorinating atmosphere). In particular, this is true for the synthesis of complex fluorides by precipitation from solutions, which does not require complicated apparatus. The preparation of powders in the sol–gel process occurs much more rapidly than in the solid-phase synthesis, which was exemplified by BaMgF_4 and SrAlF_5 as promising nonlinear optical crystals for laser frequency conversion to the UV range.²²

Fluoride nanoparticles possess enhanced reactivity due to which the temperature of solid-phase reactions with their involvement can be lowered.

Composites containing nanocrystalline lithium fluoride and a conducting phase (carbon or metals) were patented as electrode materials for reversible lithium batteries.²³

Nanoparticles of calcium fluorophosphates favour remineralisation of tooth enamel thus preventing caries and tooth eruption and improving the quality of tooth fillings.^{24, 25} The addition of YbF_3 (as well as BaSO_4) nanoparticles to dental cements improves their mechanical characteristics.²⁶

Nanocomposites, among which are fluoride glasses and heterovalent solid solutions primarily of alkaline-earth and rare-earth fluorides, are polyfunctional materials and have wide application.

Nanotechnology enables synthesis of compounds in a highly non-equilibrium state. In particular, NaYF_4 (a high-temperature cubic modification, which is transformed into an equilibrium low-temperature modification with time)²⁷ and BaY_2F_8 (Ref. 28) were prepared as unstable crystal polymorphs. In nanotechnology, classical manifestations of the Ostwald step rule can be observed.

The boundary that determines the transition of a substance into the nanostate can be drawn in different ways based on different physical properties. In the present review, this concept is extended and referred to particles with size up to 100 nm; the specific surface area of spherical nanoparticles with this diameter and a density of 6 g cm^{-3} is higher than $10 \text{ m}^2 \text{ g}^{-1}$.

In addition to ensembles of nanoparticles, there are nanostructured objects with well-developed porosity and, correspondingly, with high specific surface area in which individual particles are difficult to distinguish. Amorphous fluoride catalysts belong to such objects,^{17–21} and they are also considered in the present review.

We focus our attention on procedures for the preparation of nanosized fluoride materials as powders and composites. The methods for characterisation of such materials are beyond the scope of the present review. The properties and fields of application and methods for the synthesis of one- and two-dimensional nanoobjects are briefly outlined.

II. Hydrolysis of fluorides and its prevention

Fluorides react with water with elimination of HF, which causes difficulties in the preparation of both bulk fluoride materials and nanoparticles. This process occurring at high temperature is called pyrohydrolysis.^{29–35} The first step of pyrohydrolysis involves adsorption of water molecules on the surface of fluoride particles. In the next steps, the fluoride ion is replaced by OH^- and O^{2-} anions according to the reactions

Due to the similar sizes of the fluoride ion and the hydroxyl anion, the replacement of the former by the latter occurs by a mechanism of isomorphic substitution, the single-phase state of the system being retained. Once the critical concentration is achieved, accumulation of oxygen ions in the lattice of bulk fluoride samples leads to formation of the second phase (oxide or oxofluoride). In particular, pyrohydrolysis of rare-earth trifluorides LnF_3 initially affords oxofluorides with different compositions (Ln_2OF_4 , $\text{Ln}_4\text{O}_3\text{F}_6$, LnOF , *etc.*). Oxides are the final transformation products of LnF_3

It should be noted that the replacement of the fluorine atom by the oxygen atom is thermodynamically unfavourable. Hence, fluorides are generally stable in dry air (oxygen) even on heating.

Pyrohydrolysis starts on the surface of a substance and continues in the bulk (Fig. 1a). The rate of the process depends on the diffusion coefficients of anions. In bulk samples, the oxygen diffusion rates along lattice defects (dislocations and intergrain boundaries) are substantially higher (Fig. 1b). Lattice defects can be decorated with the second oxide phase. An increase in the surface area and the passage to nanoparticles would lead to sharp acceleration of this process. The probable scheme of pyrohydrolysis of nanoparticle agglomerates is shown in Fig. 1c. Rapid and spatially complicated pyrohydrolysis processes apparently occur in the case of a fractal structure of nanoparticles.

Fluorides differ substantially in the tendency to undergo pyrohydrolysis. These compounds are characterised by such

Figure 1. Scheme of pyrohydrolysis of a fluoride single crystal.

(a): (1) A single crystal, (2) an intermediate opalescent zone, (3) a non-transparent outer zone (oxide phase);³⁴ (b) the same in the presence of dislocation bundles in the crystal; (c) the same in the case of hydrolysis of a nanoparticle agglomerate: (1) fluoride, (2) hydroxofluoride, (3) oxofluoride, (4) a layer of adsorbed water.

parameters as the temperature at which hydrolysis starts or the time of completion of hydrolysis at a particular temperature, which are purely empirical. It was found³² that the stability of fluorides with respect to pyrohydrolysis decreases in the following order: $\text{NaF} > \text{SrF}_2 > \text{BaF}_2 > \text{LiF} > \text{CaF}_2 > \text{MgF}_2 > \text{LnF}_3 > \text{AlF}_3 > \text{BiF}_3 > \text{ZnF}_2 > \text{ThF}_4 > \text{UF}_4$. The time required for complete hydrolysis at 1000 °C is longer than 20 min for alkali, alkaline-earth (except for magnesium) and beryllium fluorides; the time for other fluorides is shorter than 20 min. The hydrolytic stability of LnF_3 decreases on going from light lanthanides to heavy lanthanides.^{33,35} The abnormally high pyrohydrolysis rate is observed for CeF_3 .^{33,36} According to the results of a study,³¹ fluorides can be arranged in the following series of decreasing stability to hydrolysis: $\text{BaF}_2 > \text{CaF}_2 > \text{MgF}_2 > \text{MnF}_2 > \text{PbF}_2 > \text{CdF}_2 > \text{CoF}_2 > \text{NiF}_2 > \text{ZnF}_2 > \text{FeF}_2$, $\text{CrF}_3 > \text{FeF}_3$, CuF_2 , AgF . In another study,³⁷ the following series was proposed (based on the temperature at which the reaction between a fluoride powder and a superheated water vapour starts): $\text{BaF}_2 > \text{SrF}_2 > \text{CaF}_2 > \text{MgF}_2 > \text{CdF}_2 > \text{ZnF}_2$. For strontium fluoride, this temperature is 1120 °C; for zinc fluoride, 400 °C.

Hydrolysis of some fluorides starts at room temperature. In particular, it was found³⁸ that prolonged (for several years) storage of an indium fluoride powder in air is accompanied not only by hydration but also by hydrolysis. Zirconium and hafnium fluorides behave analogously. Hydrolysis of highly hygroscopic niobium pentafluoride occurs even more readily and it is recommended to employ hydrogen fluoride liberated upon its exposure in air at room temperature for preparative purposes.³⁹

Fluorides are characterised by strong water vapour adsorption on the surface.^{40,41} An increase in the powder dispersity and passage to nanoparticles would lead to a sharp decrease in the temperature at which hydrolysis starts and an increase in the number of fluorides hydrolysable at room temperature.

Ordinary powders prepared from aqueous solutions or containing surface-adsorbed moisture are dehydrated by heating to a temperature lower than the temperature at which hydrolysis starts (for example, heating in high vacuum to 200 °C). Technological operations are also carried out in the atmosphere of anhydrous inert gas. In some cases, the use of high vacuum is insufficient to prevent pyrohydrolysis in high-temperature technological processes. An active fluorinating atmosphere (pyrolysis products of Teflon, hydrogen fluoride, tetrafluoromethane or their combinations) is used.²⁹ The efficiency of gaseous fluorinating reagents decreases in the following series: $\text{C}_2\text{F}_4 > \text{NF}_3 > \text{CF}_4 > \text{COF}_2 > \text{SF}_6$.⁴²

III. Synthesis of nanoparticles

1. Synthesis of nanoparticles by physical methods

a. Vapour phase deposition

Initial steps of the formation of thin films (formation of adatoms, critical nuclei and growth islets), including evaporation (sublimation) of a substance onto a substrate, belong to the field of nanotechnology. Nanoparticles which are formed in the vapour bulk by a mechanism of homogeneous nucleation, can be collected. Nanoparticles of PbF_2 of both cubic and orthorhombic polymorphs (21–43 nm) were synthesised by vapour condensation in ultrahigh vacuum.⁴³ Calcium fluoride nanoparticles were synthesised analogously.⁴⁴

b. Mechanical grinding

Fluoride nanoparticles can be synthesised using high-energy mills. Images of LiF particles obtained by scanning electronic and atomic force microscopy are shown in Figs. 2a,c and 2b,d, respectively. Nanoparticles of a sample ground in ethanol in an agate mortar are presented in Fig. 2a,b. An increase in the time of grinding leads to such a compact particle agglomeration that scanning electronic microscopy does not reveal details of the particle structure (Fig. 2c). However, atomic force microscopy reveals fitting of particles, each particle having an irregular shape

and, apparently, being an agglomeration product of several nanoparticles (Fig. 2d). It should be noted that there are no planar (001) faces, which are very typical of lithium fluoride micropowders due to perfect cleavage.[†]

Calcium fluoride nanoparticles with a size of 15–20 nm were prepared by grinding single crystals in an agate mortar under a layer of acetone followed by ultrasonic dispersion.⁴⁵

Nanoparticles of FeF_3 and GaF_3 were prepared^{46,47} by mechanical milling using zirconium oxide balls in a high-energy mill under argon for 16–20 h. Studies by powder X-ray diffraction, Mössbauer spectroscopy and NMR spectroscopy demonstrated that nanocrystalline grains with a size of ~15 nm held together by disordered intergrain layers were formed. The magnetic properties of FeF_3 and GaF_3 nanopowders are similar to those of amorphous phases.

c. Laser ablation

The energy can be pumped into a substance also by laser ablation. For example, a procedure for the synthesis of nanoparticles by ablation of a sodium fluoride single crystal doped with uranium onto a molybdenum support was documented.¹⁶ The nanoparticle size was 20–30 nm.

2. Synthesis of nanoparticles by chemical methods

a. Thermolysis of precursors

Salts of fluoroorganic acids, primarily, of trifluoroacetic acid can be used for the synthesis of fluorides by thermolysis. Under particular reaction conditions, highly dispersed samples with high specific surface area can be prepared. The preliminary synthesis of salts was carried out by the reactions of trifluoroacetic acid with the corresponding hydroxides or carbonates, for example, according to the reactions

Decomposition of trifluoroacetates can be accompanied by the formation of a solid carbon phase, for example, according to the reaction

Decomposition can be carried out in an inert atmosphere under dynamic vacuum, by the flux method and by chemical vapour phase deposition. Fluoroacetic acid is used as a fluorinating reagent in the sol–gel process. In this case, the synthesis of fluoroacetates is followed by their decomposition.

Decomposition of trifluoroacetates in air affords oxyfluoride phases. For example, study of pyrolysis of yttrium trifluoroacetate on a quartz glass surface in the temperature range of 400–900 °C showed⁴⁸ that the initially formed YF_3 particles are successively transformed into $\text{YO}_{0.80}\text{F}_{1.40}$ (orthorhombic system), YOF (trigonal system) and Y_2O_3 , which corresponds to pyrohydrolysis of bulk samples. Only oxofluorides were obtained⁴⁹ by decomposition of lanthanum trifluoroacetate in a SiO_2 matrix. Oxofluorides are also formed if a basic salt, for example, $\text{InOH}(\text{CF}_3\text{COO})_2$,⁵⁰ is obtained in the initial synthesis of trifluoroacetates.

Aluminium and chromium trifluoroacetates were used as precursors²¹ to give aluminium and chromium fluoride powders with specific surface area up to $50 \text{ m}^2 \text{ g}^{-1}$. Thermolysis of europium trifluoroacetate in a melt of trioctylphosphine oxide afforded⁵¹ EuF_3 nanoparticles with a size of 3–10 nm.

Alkaline-earth (barium, strontium and calcium) fluorides with highly developed specific surface were synthesised⁵² by thermolysis of trifluoroacetates of the corresponding metals in an inert

[†] P P Fedorov, S V Kuznetsov, V A Konyushkin, S V Petrov, V G Kuryavyi, V N Buznik, S V Lavrishchev, in *The XIIth National Conference on Crystal Growth (NCCG-2006) (Abstracts of Papers)* (Moscow: Institute of Crystallography of the Russian Academy of Sciences, 2006) p. 417.

Figure 2. Photomicrographs of LiF particles after grinding of a single crystal in ethanol in an agate mortar.

(a, b) Manual grinding for 2 h (courtesy of S V Lavrishchev, the Research Centre of Fibre Optics at the A M Prokhorov General Physics Institute of the Russian Academy of Sciences); (c, d) grinding in a FRITSCH-Pulverizette 00.502 mill for 5 h (courtesy of V G Kuryavi, the Institute of Chemistry of the Far-Eastern Branch of the Russian Academy of Sciences).

atmosphere followed by annealing under a stream of oxygen at 500 °C (to burn off carbon impurities). The specific surface areas of the resulting CaF_2 , SrF_2 and BaF_2 samples were 44, 37 and 24 $\text{m}^2 \text{g}^{-1}$, respectively. The results of studies of the SrF_2 surface by scanning electronic microscopy are presented in Fig. 3.

Fluorides can be synthesised in addition to thermolysis of trifluoroacetates by transformations of other fluoroorganic compounds. For example, four fluoroorganic compounds were studied⁵³ with the aim of preparing thin films of NaF by chemical

vapour phase deposition. The best results were obtained with the use of sodium hexafluoroisopropoxide $(\text{CF}_3)_2\text{CHONa}$. Fluoroalkoxides were used in the synthesis of fluorides by chemical vapour phase deposition.⁵⁴ Anhydrous lanthanum hexafluoroacetylacetonate served as a precursor⁵⁵ for the preparation of nanosized-thick films of LaF_3 by organometallic chemical vapour deposition. Heating of bis(trifluoromethanesulfonyl)imide, $(\text{CF}_3\text{SO}_2)_2\text{NH}$, in a SiO_2 matrix at 400 °C afforded LaF_3 .⁴⁹

Heating of a fluorine-containing gel prepared by hydrolysis of alkaline-earth and rare-earth fluoroalkoxides afforded pure fluorides, the particle size depends on the conditions of thermal treatment.⁵⁶

Different in principle precursors are documented.⁵⁷ Nanoparticles of rare-earth fluorides ($\text{Ln} = \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}$ and Tb) were synthesised by decomposition of needle-like NH_4LnF_4 particles, precipitated from methanolic solutions according to the reaction

Decomposition products retained the shape of the precursor particles.

b. Mechanochemical synthesis

In some cases, mechanical milling of a mixture of fluorides in high-energy mills is accompanied by chemical reaction producing nanoparticles.⁵⁸ In a number of publications, the formation of submicrometre-sized particles was reported. However, these particles are presumably agglomerated from smaller particles, and we include these data in the present review. Experiments^{59–62} were

Figure 3. Electronic image of strontium fluoride after decomposition of trifluoroacetate.⁵²

The specific surface area is 37 $\text{m}^2 \text{g}^{-1}$.

performed with the use of a planetary ball mill with zirconium oxide balls 15 mm in diameter at a rotation speed of 700 rpm. Milling was carried out at room temperature.

Oxofluorides LnOF with a particle size of 15–20 nm were synthesised from a mixture of oxides and fluorides (the reaction time was 1–2 h).⁵⁹

Complex fluorides MLnF_4 (LiYF_4 , KYF_4 and NaNF_4 , where $\text{Ln} = \text{Y, Pr, Nd, Gd, Ho or Er}$) were synthesised⁵⁸ by the mechanochemical solid-phase reaction of MF and LnF_3 powders. The completeness of the reaction was determined from powder X-ray diffraction data and the amount of unconsumed MF dissolved in water. The reaction was completed in 4 h. The size of coherent scattering regions of the resulting particles estimated from line broadening in X-ray diffraction patterns was 13 nm, which is consistent with the results of scanning electron microscopy.

Cubic perovskites $\text{KM}^{\text{II}}\text{F}_3$ ($\text{M}^{\text{II}} = \text{Mg, Ca, Mn, Fe, Co, Ni}$ and Zn) were prepared by milling equimolar amounts of KF and the corresponding difluoride in a planetary mill in air.⁶¹ The synthesis was completed in 6 h. Study by scanning electron microscopy demonstrated that large agglomerates with a particle size of ~ 200 nm were obtained. The absence of the evidence of hydrolysis was unexpected taking into account high hygroscopicity of KF and the fact that transition metal fluorides are easily hydrolysed. The lattice parameters of the resulting compounds are similar to the corresponding characteristics of specimens prepared by the solid-phase synthesis. Metal–oxygen bonds were not found by X-ray photoelectron spectroscopy.

The reaction of lanthanum oxide with polytetrafluoroethylene was studied.⁶⁰ After milling for 4 h, the product consisted of oxofluoride LaOF , amorphous $\text{La}(\text{CO}_3)\text{F}$ and carbon. Heating in air to 600 °C afforded pure LaOF with a particle size of ~ 10 nm.

Nanocrystals of a non-stoichiometric fluorite phase $\text{Ca}_{1-x}\text{La}_x\text{F}_{2+x}$ were prepared by the mechanochemical synthesis from a mixture of single crystals consisting of CaF_2 with an additive of 20 (or 10) mol.% LaF_3 .⁶³ The components were ground in a planetary ball mill under argon. The reaction started after milling for 30 min. Milling for 2 h did not lead to completion of the reaction (90%–95% yield). The coherent scattering regions were 8–30 nm. After heating to 1000 °C, nanoparticles of the solid solution $\text{Ca}_{0.8}\text{La}_{0.2}\text{F}_{2.2}$ decomposed to give two fluorite phases with composition $\text{Ca}_{0.52}\text{La}_{0.48}\text{F}_{2.48}$ and $\text{Ca}_{0.94}\text{La}_{0.06}\text{F}_2$, which does not correspond to the phase diagram.

The mechanochemical synthesis of fluorine-conducting solid electrolytes ($\text{Pb}_{1-x}\text{Sn}_x\text{F}_2$ and $\text{NH}_4\text{Sn}_2\text{F}_5$) was documented.⁶⁴

Ball milling was used to introduce a small amount of a metal catalyst (iron or nickel) into magnesium hydride by the reaction with fluorides.^{65–67} The resulting substance is a promising material for hydrogen power engineering. Mixing of preground MgH_2 and FeF_3 (or NiF_2) powders followed by milling affords MgF_2 nanoparticles, which prevent hydride particle agglomeration. Both primary and secondary milling is performed in an inert atmosphere. Nanofluoride particles can also have a catalytic effect on hydrogen sorption.

c. Precipitation from solutions

Fluorides of many metals are poorly soluble in water. The synthesis of fluorides by the exchange reactions with precipitation of the product has long been known. Precipitation of rare-earth trifluorides was examined in detail.⁶⁸ Precipitation of phases formed in KF – LnF_3 systems from aqueous solutions^{69–71} and in NaF – LnF_3 systems is documented.^{69–73} Relatively recently, it has been found that nanoparticles can be synthesised according to this procedure, although the formation of, for example, colloidal solutions of $\text{NH}_4\text{Y}_3\text{F}_{10}$ and $\text{NH}_4\text{Y}_2\text{F}_7$ by the reactions of YCl_3 and NH_4HF_2 solutions was documented.⁷⁴

Compounds NaNF_4 ($\text{Ln} = \text{Y or Yb}$) doped with praseodymium ions were synthesised by mixing chloride solutions (pre-

pared by dissolution of rare-earth oxides in boiling hydrochloric acid) with stoichiometric amounts of a NaF hot solution.²⁷ The precipitate was repeatedly washed with distilled water and dried at 80 °C. The initially formed high-temperature cubic modification passed completely into the hexagonal modification ($a = 5.969$, $c = 3.53$ Å) after ageing of the precipitate for 10 days. The average grain size of these phases was ~ 900 nm.

This procedure was subject to modifications.^{11, 14, 28, 75} Spherical $\text{NaGdF}_4:\text{Eu}^{3+}$ nanoparticles of a size of 20 nm (data from transmission electron microscopy) were prepared by precipitation. Storage of the powder at 650 °C under a stream of $\text{Ar} + 10\% \text{SF}_6$ led to an increase in the particle size to 50–350 nm. No oxygen impurities were revealed by IR spectroscopy and Eu^{3+} ion spectroscopy.^{11, 75} $\text{KGdF}_4:\text{Eu}^{3+}$ nanoparticles were synthesised analogously;¹⁴ the size of coherent scattering regions of the particles was 19 nm. A metastable cubic modification was precipitated. Heating led to a complex change of structural types, and the KErF_4 -type hexagonal modification was obtained for the first time.⁷⁶ The presence of the hydroxyl ion was revealed by IR spectroscopy. The non-equilibrium polymorph $\text{BaY}_2\text{F}_8:\text{Eu}^{3+}$ (as a nanopowder) with a fluorite-type structure and the lattice parameter $a = 5.767$ Å was synthesised analogously.²⁸ This lattice parameter is substantially smaller than that of any equilibrium composition of the solid solution $\text{Ba}_{1-x}.\text{Y}_x\text{F}_{2+x}$ in the BaF_2 – YF_3 system.⁷⁷ Upon heating in a stream of $\text{Ar} + 10\% \text{SF}_6$, the sample undergoes a phase transition to the equilibrium monoclinic structure BaY_2F_8 .

In an analogous solution precipitation method,⁷⁸ aqueous solutions of $\text{Eu}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ and NaF served as the starting compounds. The reaction product that formed upon mixing of these two solutions was washed with water and ethanol and dried at 70 °C for 3 hours. Nanorods of the hexagonal phase NaEuF_4 with a diameter of 20–30 nm and a length of 60–100 nm were obtained. An increase in the $\text{Eu}^{3+}:\text{NaF}$ ratio from 1:4 to 1:10 led to the formation of a phase with a cubic fluorite-type structure (spheres ~ 200 nm in diameter) and the lattice parameter of 5.61 Å. Based on the phase diagram presented by Thoma *et al.*,⁷⁹ the composition $\text{Na}_5\text{Eu}_9\text{F}_{32}$ was assigned to this phase. In reality, the compound with this formula does not exist.⁷⁶ Based on the dependences of the lattice parameter of fluorite phases of variable composition in NaF – LnF_3 systems,⁸⁰ it can be concluded that nanoparticles have the composition $\text{Na}_{0.38}\text{Eu}_{0.62}\text{F}_{2.24}$. Chemical analysis is required to solve the problem.

Canadian researchers studied in detail precipitation of nano-sized fluorides LaF_3 , $\text{LaF}_3:\text{Eu}$ and $\text{La}_{0.45}\text{Yb}_{0.5}\text{Er}_{0.05}\text{F}_3$ and modifications of their surfaces.^{12, 13, 81–83} A solution of rare-earth nitrates was mixed with a solution of sodium fluoride to yield $\text{LaF}_3:5\% \text{LnF}_3$ nanoparticles and then fluorides were precipitated by adding ethanol. The particles were separated by centrifugation, washed with ethanol and dried *in vacuo*. The average particle size was ~ 20 nm.¹³

The $\text{KY}_{2+x}\text{F}_{7+3x}$ phase with variable composition ($0.5 < x < 1$) with a fluorite-type structure and a particle size of 17 nm was synthesised by mixing concentrated KF and $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ solutions followed by stirring for 30 min, centrifugation and washing with deionised water.⁸⁴ Heating to 550–850 °C leads to ordering of the crystal lattice and the appearance of lines belonging to a superstructure in X-ray diffraction patterns.

Very important results on the morphology evolution of LaF_3 nanoparticles during its precipitation from $\text{La}(\text{NO}_3)_3$ and KF solutions (including the reaction at constant pH) were obtained.^{85, 86} Successive transformations of amorphous hydroxyfluoride into crystalline LaF_3 nanoparticles of hexagonal shape, empty spheres with a diameter of several hundred nanometres consisting of agglomerates formed by small particles and the transformation of spheres into needles and ribbons were observed.

Figure 4. Electronic images of fluorides prepared by precipitation from aqueous nitrate solutions.

(a) $\text{Ca}_{0.9}\text{Er}_{0.1}\text{F}_{2.1}$ after precipitation by titration into hydrofluoric acid; (b) $\text{Ca}_{0.9}\text{Er}_{0.1}\text{F}_{2.1}$ after washing with ethanol; (c) $\text{Ca}_{0.9}\text{Er}_{0.1}\text{F}_{2.1}$ after drying at 150 °C; (d) $\text{Ca}_{1-x}\text{Yb}_x\text{F}_{2+x}$ after precipitation by titration with hydrofluoric acid; (e) $\text{Sr}_{1-x}\text{Nd}_x\text{F}_{2+x}$ after precipitation by titration with hydrofluoric acid, washing and prolonged drying at ≤ 100 °C; (f) BaF_2 after precipitation by titration with an ammonium fluoride solution.

Selected photomicrographs of fluoride particles, which we have synthesised[‡] by precipitation from aqueous solutions, are shown in Fig. 4.

Stabilisation of colloidal solutions of fluoride nanoparticles presents a special problem. The preparation of colloidal solutions of NaYF_4 (the particle size was 5–30 nm) was documented.⁸⁷ A procedure was developed¹³ for dispersion of colloidal LaF_3 nanoparticles in solution with the use of citrate ligands adsorbed on the surface of nanoparticles.⁸

Crystallisation of nanoparticles from solutions can be performed under conditions of hydrothermal synthesis. This is used

for the synthesis of many complex fluorides, for example, of NaYF_4 ;⁸⁸ $\text{NH}_4\text{Er}_3\text{F}_{10}$;⁸⁹ KMF_3 ($\text{M} = \text{Mn}, \text{Co}, \text{Ni}, \text{Zn}$ or Mg);⁹⁰ K_2LnF_5 , KLnF_4 , KLn_2F_7 , $\text{KLn}_3\text{F}_{10}$;^{91–93} LiYF_4 , KYF_4 and BaBeF_4 .⁹⁴ The particle size increases as the temperature of the synthesis and the reaction time are increased.

In some case, fluorides precipitated from solutions were subjected to additional mild (at a temperature lower than 180 °C) hydrothermal treatment. Nanocrystalline fluorides of La, Pr, Nd, Sm and Y were synthesised^{95,96} from the oxides Ln_2O_3 ($\text{Ln} = \text{Y}, \text{La}, \text{Pr}, \text{Nd}$ or Sm) dissolved in 10% nitric acid. A NH_4F solution was added to the nitrate solutions to obtain colloidal precipitates and a 10% KOH (or NaOH) solution was added to pH 4–5. Colloidal precipitates were stored in an autoclave at 80–180 °C for 12–24 h. The precipitates were filtered off, washed and dried in air at 80 °C. The resulting fullerene-like nanoparticles had a shape of empty spheres, their diameter increased from 10 to 30–50 nm as the temperature in the autoclave was increased from 120 to 180 °C.

$\text{LaF}_3 : \text{Yb}^{3+}, \text{Er}^{3+}$ nanoparticles were prepared by the hydrothermal synthesis.⁹⁷

Nanoparticles can also be formed upon sonication (sonochemistry). The addition of an NaF alkaline solution to an acidic solution of rare-earth nitrates with intense sonication followed by hydrothermal treatment led to the formation of $\text{YF}_3 : \text{Ln}^{3+}$ nanoparticles.⁹⁸

The hydrothermal synthesis of nanoparticles of rare-earth oxofluorides was patented.^{99, 100}

Non-aqueous solvents can be used for the synthesis of fluorides to decrease the degree of hydration and remove hydroxyl impurities. Needle-like NH_4LnF_4 particles ($\text{Ln} = \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}$ or Tb) with nanometre cross-section were prepared from methanolic solutions.⁵⁷ Nanorods with composition $\text{PbBr}_{2-x}\text{F}_{2(1-x)}$ ($x = 0.15, 0.3$) were prepared from methanolic solutions of lead acetate, potassium fluoride and cetyltrimethylammonium bromide or potassium bromide.¹⁰¹

Particles with composition KNiF_3 as empty spheres with a diameter of 200–400 nm were synthesised by the solvothermal reaction in ethanol at 110 °C with the use of KF and NiCl_2 as the starting reagents. According to the results of transmission electron microscopy, these spheres consist of nanoparticles with the size of 10 nm (the wall thickness was 20–40 nm).¹⁰²

Nanoparticles of CeF_3 with the size of 5–10 nm were synthesised from a solution of CeCl_3 and HF in ethylene glycol at 180 °C.¹⁰³ The nanoparticles were washed with ethanol, separated from the liquid phase by centrifugation and dried.

Synthesis from solution of metal acetates and alkoxides in non-aqueous solvents (isopropyl alcohol or methanol) by treatment with anhydrous hydrogen fluoride provides the basis for one of modifications of the sol–gel process (see below).

d. Precipitation from solutions in nanoreactors

The use of the so-called nanoreactors enables one to limit mechanically the sizes of the resulting particles. Solid porous templates, such as zeolites, gels or opals, can serve as nanoreactors.⁴⁹ Optical transmission of products is essential for their use in photonics.

Silica gel was also used.^{49, 104} Borosilicate glasses with the pore size of 4 nm pressed into pellets and Al_2O_3 ceramics with the pore size of up to 0.1 μm served as porous templates.¹⁰⁵ Porous membranes were placed between aqueous solutions of $\text{Pb}(\text{NO}_3)_2$ and NH_4F with concentrations of 0.1 mol litre⁻¹. The reaction produced PbF_2 nanoparticles in pores, both the equilibrium orthorhombic modification and the high-temperature cubic modification being obtained.

The reversed microemulsion method has gained wide acceptance in the synthesis of fluoride nanoparticles. This method has been developed in detail for other classes of compounds. The history of the problem was covered in the review.² Back in 1943, it was found^{106, 107} that certain ratios of water, an organic phase and two surfactants give quasihomogeneous mixtures called quaternary microemulsions. Long-chain organic molecules containing a hydrophilic head and a lipophilic tail (for example, cetyltrimethylammonium bromide, CTAB) are miscible with both hydrocarbons and water (Fig. 5a). Due to ion-dipole interactions, surfactants form spherical aggregates encapsulating water, the polar (ionic) ends of surfactant molecules being oriented inward (Fig. 5b). The orientation of molecules in microemulsions leads to minimisation of the surface tension thus providing stability, including thermodynamic stability, as opposed to usual macroemulsions. Such emulsions are called reversed emulsions because water in such emulsions is dispersed in an organic matrix.

It was suggested that quaternary reversed microemulsions were used for the preparation of colloidal non-charged particles.¹⁰⁸ The method consists of preparing two solutions of emulsions with required anions and cations, respectively, followed by mixing of these solutions to prepare the target compound (Fig. 5c–e). Emulsions with different volumes of an aqueous

Figure 5. The CTAB molecule (a) and schemes of the structure of a microemulsion (b) and the synthesis of nanofluorides MF_n by the reverse a microemulsion method (c–e).

phase (a nanoreactor) can be prepared by varying the ratio of the aqueous and organic phases and the amount of a surfactant, which allows one to obtain nanoparticles of the desired size. The resulting particles are subjected to either coagulation (for example, by adding acetone) or centrifugation until a precipitate is formed, and the precipitate is washed, for example, with methanol. A classical microemulsion quaternary system has the following composition: n-butanol/CTAB, n-octanol/water. This approach is applicable to compounds poorly soluble in water ($\sim 10^{-5}$ mol litre⁻¹) and is used for the synthesis of fluoride nanoparticles. In some cases, ternary microemulsions, in which the second surfactant is absent, are used instead of quaternary microemulsions.

The synthesis of NH_4MnF_3 nanoparticles with sizes of 10–60 nm with the use of n-heptane/ NH_4AOT /water microemulsions [AOT is bis(2-ethylhexyl)sulfosuccinic acid] and concentrated aqueous NH_4F and $\text{Mn}(\text{OAc})_2$ solutions was documented.¹⁰⁹ An increase in the reaction time, a decrease in the salt concentration, an increase in the percentage of the aqueous phase and increase in temperature lead to enlargement of crystallites.

Fluoromanganates (KMnF_3 and NaMnF_3) exhibiting magnetic properties were synthesised¹¹⁰ according to the reaction

with the use of the following microemulsion system: n-octane/CTAB, n-butanol/water. The particle size depends on the volume of nanoreactors. Particles of the same compounds with the size of 30 nm were synthesised by Carpenter¹¹¹ with the use of an emulsion system containing dioctyl sulfosuccinate, isooctane and water.

The synthesis of BaF_2 nanoparticles containing up to 65 mol.% NdF_3 was documented.¹¹² Emulsion systems consisted of cyclohexane, Igepal CO-520, ethanol and aqueous solutions of salts of the target cations and hydrofluoric acid. An increase in the concentration of the precursor leads to an increase in the size of the resulting crystallites. Powder X-ray diffraction study demonstrated that nanoparticles are heterogeneous and consisted virtually of pure BaF_2 and solid solutions $\text{Ba}_{1-x}\text{Nd}_x\text{F}_{2+x}$ with different concentrations. It was hypothesised that BaF_2 is repeat-

edly precipitated on the surface of nanoparticles enriched in neodymium. The resulting samples were tested for the presence of impurities. An IR spectroscopic study demonstrated that up to 3 mass %–5 mass % of precursor ions, as well as hydroxyl groups, are present in samples prepared starting from nitrate and acetate salts. If precursors are readily soluble salts, the amount of impurities in samples is smaller.

The synthesis of BaF_2 nanoparticles and a solid solution $\text{Ba}_{1-x}\text{Ce}_x\text{F}_{2+x}$ ($x = 0.033$) with the use of an octan-2-ol/CTAB/water microemulsion system was documented.¹¹³ It was found that the particle size decreases as the fraction of water in the system and the reaction time decrease. After washing of nanoparticles with ethanol, the final product contained traces of nitrate ions and hydroxyl groups (IR spectroscopic data).

The synthesis of CeF_3 nanoparticles from a polyisobutane–butanediimide/cyclohexane/water emulsion system was performed.¹¹⁴ An increase in the percentage of water and the precursor concentration strongly influences the size and morphology of the resulting particles. The crystal structure was described as cubic face-centred, which does not correspond to the structure of bulk samples of CeF_3 .

Nanoparticles of CeF_3 and the solid solution $\text{Ce}_{1-x}\text{Lu}_x\text{F}_3$ ($x \leq 0.5$) were synthesised by the microemulsion method.¹¹⁵ The hexagonal structure typical of CeF_3 was found for all samples. The maximum luminescence intensity at ~ 325 nm is observed for $x = 0.3$.

An n-octane/CTAB, n-butanol/water microemulsion system was used in the synthesis of BaF_2 nanoparticles, including those activated with 6 mol.% europium and erbium.^{116–118} It was found that only cubic nanoparticles grow until the critical size of the growing nanoparticle is smaller than the volume of the elementary reaction zone. As soon as the size becomes larger than this volume, the growth of dendrites begins. The edge lengths of cubic particles without dendrites were 100–200 nm. In the presence of dendrites (data from transmission electron microscopy), the aggregate size was 400–450 nm. Self-organisation of BaF_2 nanoparticles, which were synthesised by the reversed microemulsion method, giving rise apparently to dissipative structures was described.¹¹⁹

The use of microemulsions in the synthesis of particles of solid solutions of the general formula $\text{K}(\text{Y},\text{Ln})_{2+x}\text{F}_{7+3x}$ ($0.5 < x < 1$) with a size of 14 nm was documented.⁸⁴

e. Variations of the sol–gel method

Crystallisation techniques used for the synthesis of bulk crystals in gels^{120,121} make it possible to decrease substantially the rate of chemical reactions due to an increase in the path length of the ion counter diffusion resulting in the formation of a new poorly soluble phase. This situation is ideal for the preparation of nanoparticles characterised by a low degree of agglomeration and investigation of the mechanism of their crystallisation. However, the output of this process is low, and other modifications of the sol–gel technology were used for the synthesis of fluoride nanoparticles.

According to one version, a porous homogeneous hydroxyl sol–gel is prepared and subjected to low-temperature treatment with a fluorinating agent giving rise to a highly dispersed amorphous powder, which becomes more compact on heating. This approach was developed for the synthesis of fluoride glasses.^{39,122,123} A sol of nanocrystalline MgF_2 was synthesised by the reaction of hydrofluoric acid with the sol prepared from a methanolic solution of H_2O_2 and $\text{Mg}(\text{OMe})_2$.¹²⁴

In another version, a fluorinating agent (generally, trifluoroacetic acid) is directly used as one of the starting compounds along with metal acetates and alkoxides for the preparation of gels.^{22,27,125–127}

BaMgF_4 doped with Eu^{2+} was synthesised from a solution of a mixture of barium, magnesium and europium acetates in isopropyl alcohol.¹²⁸ Trifluoroacetic acid and water were added to the solution to give a trifluoroacetate gel; its heating to 500 °C led to crystallisation of BaF_2 from the amorphous state (data from powder X-ray diffraction). At 550–600 °C, BaMgF_4 particles appeared.

An attempt was made to synthesise analogously KGd_2F_7 .¹²⁹ Gadolinium and potassium acetates were dissolved in a stoichiometric ratio in isopropyl alcohol under argon in a Teflon reactor. Trifluoroacetic acid was added to the solution and the mixture was stirred for 3 h. Then a quartz substrate was coated with this solution and heated at 650 °C for 40 min under a stream of dry argon. The resulting product consisted of submicrometre-sized particles and contained oxygen as an admixture. Its composition corresponds to the formula $\text{K}_{0.31}\text{Gd}_{0.69}\text{F}_{1.84}\text{O}_{0.27}$. The monoclinic lattice parameters are similar to the lattice parameters of anhydrous KGd_2F_7 .

In the third version of the sol–gel method, a silicate gel containing fluoride nanoparticles is prepared. Mixing of a silicate sol and a MgF_2 sol affords nanoparticles dispersed in an amorphous matrix. Heating results in a composite MgF_2 – SiO_2 .¹²⁴ An improved modification of this process was patented.¹³⁰ Nanocrystals of LaF_3 (10–30 nm) in a silicate gel were synthesised by the sol–gel method starting from trifluoroacetic acid, lanthanum acetate, tetramethyl orthosilicate, methanol and dimethylformamide followed by heating of the gel to 300 °C. At 800 °C, pyrohydrolysis of LaF_3 started.¹⁰⁴ Glass ceramics can be prepared analogously.¹³¹ For example, nanocrystallites of LaF_3 in transparent SiO_2 -based glass ceramics were synthesised by the sol–gel method.¹³²

A special modification of the sol–gel process was developed^{17,18,20,133,134} with the aim of synthesising fluoride catalysts with highly developed surface. In the first step, solutions of metal alkoxides in a non-aqueous solvent (for example, aluminium isopropoxide in isopropyl alcohol) are treated with anhydrous hydrogen fluoride to yield an amorphous catalytically inactive solid as a precursor of the fluoride. The F:Al ratio in this precursor of AlF_3 was approximately equal to 2:1, the carbon content was 31%, and the specific surface area was 430 m² g^{−1} (Ref. 17). In the general form, the reaction equation is as follows:

($x = 0–3$); for aluminium isopropoxide existing as a tetramer, the equation is as follows:

Treatment of the products with a fluorinating reagent (CCl_2F_2) at 350 °C affords an amorphous AlF_3 powder with a specific surface area of 206 m² g^{−1} and the carbon content of 0.4 mass%, which is characterised by very high catalytic activity. Heating leads to crystallisation accompanied by an exothermic effect at 540–570 °C, which corresponds to the formation of $\alpha\text{-AlF}_3$.

Magnesium fluoride with a specific surface area of 190 m² g^{−1} and mixed catalytically active fluorides with highly developed surface [$\text{MgF}_2\text{:FeF}_3$ (Ref. 18) and $\text{MgF}_2\text{:CrF}_3$ (Ref. 20)], in which magnesium fluoride serves as a sorbent (support), were synthesised analogously. The scheme of the process is shown in Fig. 6. It was hypothesised that the true sol–gel process occurs to give a three-dimensional random network analogous to networks of classical gels (in particular, of a silicate gel). Random binding of fluoroaluminate octahedra postulated in the fluoride gel corresponds to the network in fluoroaluminate glasses.

Figure 6. Scheme of the formation of a random network in different steps of the sol-gel process with the successive replacement of oxygen atoms by fluorine in bridging bonds.¹³⁴

f. Miscellaneous methods of synthesis

Nanoparticles of potassium, barium and strontium fluorides and sodium chloride were prepared⁶ by the flame synthesis. The corresponding precursor (metal 2-ethylhexanoate) was mixed with a stoichiometric amount of fluoro- or chlorobenzene, and the mixture was nebulised in a methane-oxygen flame. The resulting product was collected on a heated filter to prevent water condensation. The particle size of CaF_2 was 20 nm.

UF_5 nanoparticles were synthesised by laser photolysis of gaseous UF_6 in a supersonic nozzle reactor for isotope separation.^{135–137}

A study¹³⁸ on the synthesis of single-crystalline PbF_2 nanoparticles by selective chemical dissolution of bulk nanocomposite oxyfluoride glass ceramics is of interest. Impurity-free lead fluoride nanoparticles with the size of 15 nm doped with Eu^{3+} ions show intense fluorescence (green and blue) after IR excitation.

Fluoride nanoparticles can be prepared by gas-phase fluorination of dispersed systems.

IV. One-dimensional nanoobjects

Unique physical properties of one-dimensional (or 1D) nanoobjects and the possibility of producing functional materials based on these nanoobjects have attracted considerable attention.

Whisker crystals characterised by exceptional mechanical properties are typical 1D objects.^{139,140} The main mechanism for their growth is the so-called vapour-liquid-crystal mechanism according to which growth occurs from the vapour phase through a melt drop. The diameter of whisker crystals is determined by the size of the starting drop and is generally of a micrometre size. A decrease in the drop diameter leads to a decrease in the growth rate (due to a change in the vapour pressure over the drop). Nevertheless, it is possible to grow such thin whiskers. Whisker crystals were prepared from the vapour phase for such fluorides as LiF , NaF (Refs 121 and 139) (Fig. 7) and CdF_2 .¹⁴¹

Another procedure for the preparation of 1D nanoobjects is based on crystallisation from solution.¹³⁹ Nanorods of the hexagonal phase NaEuF_4 20–30 nm in diameter and 60–100 nm in length were prepared from aqueous solutions of europium nitrate and sodium fluoride.⁷⁸ Whisker crystals of BaF_2 oriented along the [111] direction with a length of 50 μm and a size ratio of 1000 : 1 were synthesised by the hydrothermal method with the use of a microemulsion.¹⁴² The crystal thickness was determined by the drop size.

Figure 7. Whisker NaF crystals grown from a vapour phase with the use of BaFCl as a transport reagent.

Precipitation of compounds $\text{PbBr}_x\text{F}_{2-x}$ ($x \leq 0.3$) from methanolic solutions afforded needle-like nanoparticles 30–50 nm in diameter and 500–1000 nm in length;⁵⁷ NH_4LnF_4 particles ($\text{Ln} = \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}$ or Tb) were synthesised by solvothermal treatment of the precipitate at 150 °C.¹⁰¹ Thermolysis of the fluoroammonium complexes NH_4LnF_4 produced rare-earth trifluorides. The shape memory effect, *i.e.*, the retention of the particle shape, was observed. The resulting 1D nanoobjects were characterised by high concentration of structural defects.

One-dimensional nanoobjects correspond to one of steps of evolution of LaF_3 nanoparticles as the F:La ratio increases during titration in an aqueous solution.⁸⁶

V. Two-dimensional nanoobjects

Films are typical two-dimensional (2D) nanoobjects. Islet films, which represent nanoparticle ensembles on a substrate, are natural and one of the simplest elements of the nanocrystalline architecture.

The formation of fluoride films was studied in detail. In addition to fundamental problems, there are several practical applications due to which these objects have attracted interest: antireflection coatings,^{143–146} epitaxial dielectric films on semiconductors¹⁴⁷ and luminescent coatings.^{129,148–152}

The lattice parameters of calcium and cadmium fluorides ($a = 5.463$ and 5.388 Å, respectively) are similar to the silicon lattice parameter ($a = 5.4305$ Å). Layers, that are similar in the characteristic geometric sizes to the $\text{Si}(111)$, $\text{Ge}(111)$ and $\text{GaAs}(111)$ planes are present in the structures of rare-earth trifluorides (in particular, [001] in the tysonite structure). This fact has stimulated interest in the preparation and investigation of the corresponding epitaxial layers.^{147,153,154}

The cubic lattice parameter can be varied in a wide range (from 5.388 to 6.20 Å), and coatings for lead chalcogenides can be adjusted based on this parameter with the use of the solid solutions $\text{Ca}_{1-x}\text{Sr}_x\text{F}_2$ and $\text{Sr}_{1-x}\text{Ba}_x\text{F}_2$ as well as by the introduction of rare-earth metals into the fluorite structure (giving rise to the solid solutions $\text{M}_{1-x}\text{Ln}_x\text{F}_{2+x}$).^{149,155}

However, the difference in the thermal expansion coefficients, which are 3–7 times larger for fluorides than for semiconductors, is a serious problem.

A small difference in the lattice parameters of deposited layers makes it possible to construct heterostructures.¹⁵⁶ Dielectric fluoride layers are used for the construction of more complex structures, for example, of metal-insulator-semiconductor systems.¹⁵⁷

In addition to molecular beam epitaxy,^{148,149,151} spray coating,^{145,158} chemical vapour phase deposition,^{53,55} magnetron spraying,¹⁵⁹ deposition of fluoride films by soft chemistry

methods has been developed in recent years (Refs 125, 128, 160–163 as well as[†]).

VI. Fluoride nanocomposites

1. Glass ceramics

In recent years, the properties and procedures for the preparation of glass ceramics, such as the generation of a micro- or nano-dispersed crystalline phase in a glass matrix, have been extensively studied.¹⁶⁴ As a rule, such materials are prepared by crystallisation of glasses, *i.e.*, by thermal treatment at near-crystallisation temperature. One of the aims is to prepare transparent glass ceramics for nanophotonics.^{165–167} Such materials have a series of novel properties and are free from many drawbacks of glasses and single-crystalline materials. These materials are processable, they are suitable for the preparation of fibres characterised by a high capacity for activating ions and the isotropicity and homogeneity of properties and activator concentrations.

In practice, there is often a need for functional materials in which the distribution coefficients of activator ions between the matrix and nanoparticles are substantially different. The transfer of an activating additive in the crystalline environment leads to narrowing of luminescence linewidths and an increase in luminescence intensity compared to the intensity of the analogous luminescence of glasses. In particular, this can be achieved by preparing fluoride nanoparticles in a silicate or aluminosilicate matrix.

LaF_3 ,^{168–172} PbF_2 (Refs 173 and 174 as well as[†]), $\text{Pb}_{1-x}\text{Cd}_x\text{F}_2$ (Refs 165–167 and 175–177) and CaF_2 (Ref. 178) can serve as fluoride particles accumulating rare-earth ions. In some cases, nanoparticles of solid solutions $\text{M}_{1-x}\text{Ln}_x\text{F}_{2+x}$ at high concentrations were obtained.

Crystallisation of the glass with composition $16.5 \text{ Al}_2\text{O}_3 \cdot 1.6 \text{ AlF}_3 \cdot 12.7 \text{ LaF}_3 \cdot 4.3 \text{ Na}_2\text{CO}_3 \cdot 64.9 \text{ SiO}_2$ afforded the LaF_3 phase where rare-earth elements were incorporated in a different proportions: Er^{3+} , 2%–3% of the total amount of the introduced erbium fluoride; Pr^{3+} , up to 70%.¹⁶⁹

The preparation of a transparent glass-crystalline material based on the glass with composition $30 \text{ SiO}_2 \cdot 15 \text{ AlO}_{3/2} \cdot 29 \text{ CdF}_2 \cdot 17 \text{ PbF}_2 \cdot 5 \text{ ZnF}_2 \cdot 4 \text{ YF}_3$ was documented.^{166,167} The glass transition temperature and the crystallisation temperature of the starting glass are 395 and 475 °C, respectively. Thermal treatment with the aim of preparing glass ceramics was carried out in the temperature range of 440–470 °C for 30–60 min. The crystallite size was 6–8 nm.

Glass ceramics with similar composition, $30 \text{ SiO}_2 \cdot 15 \text{ AlO}_{1.5} \cdot 28 \text{ PbF}_2 \cdot 22 \text{ CdF}_2 \cdot (4.8-y) \text{ GdF}_3 \cdot 0.1 \text{ NdF}_3 \cdot y \text{ YbF}_3 \cdot 0.1 \text{ TmF}_3$ ($y = 0, 0.1, 0.2, 0.5, 1.0, 2.0, 3.0, 4.0$ and 4.8), were prepared.¹⁷⁹ The crystallite sizes in this system are virtually independent of the annealing time (Fig. 8a). Therefore, thermal treatment did not lead to growth of fluoride particles, which were already present in the glass.

In addition to crystallisation of cast glasses, sol–gel methods are used.^{131,132,180} The glass ceramic with composition $0.1 \text{ ErF}_3 \cdot 0.1 \text{ YbF}_3 \cdot 5 \text{ LaF}_3 \cdot 94.8 \text{ SiO}_2$ was prepared by Fujihara's method.¹³² Tetraethoxysilane (TEOS), which was dissolved in an equimolar amount of ethanol, was hydrolysed with water in the presence of acetic acid as the catalyst. The $\text{TEOS}:\text{H}_2\text{O}:\text{AcOH}$ ratio was 1:10:0.5. Rare-earth acetates were dissolved in trifluoroacetic acid ($\text{M}^{3+}:\text{F}^- = 1:10$). A small amount of water was added to accelerate dissolution. The trifluoroacetate solution was slowly stirred with silica sol. The gel formation occurred at room temperature for two weeks. Drying was performed at 40–70 °C for one week. The dry gel was heated to 1000 °C in air

Figure 8. Plots of the crystallite size vs the parameters of thermal treatment.

(a) The particle size of $\text{Pb}_{1-x}\text{Cd}_x\text{F}_2$ in the $30 \text{ SiO}_2 \cdot 15 \text{ AlO}_{1.5} \cdot 28 \text{ PbF}_2 \cdot 22 \text{ CdF}_2 \cdot (4.8-y) \text{ GdF}_3 \cdot 0.1 \text{ NdF}_3 \cdot y \text{ YbF}_3 \cdot 0.1 \text{ TmF}_3$ glass vs the annealing time;¹⁷⁹ (b) the particle size of LaF_3 in the $53 \text{ SiO}_2 \cdot 11 \text{ Na}_2\text{O} \cdot 27 \text{ Al}_2\text{O}_3 \cdot \text{Al}_2\text{F}_6 \cdot 7 \text{ La}_2\text{F}_6 \cdot 0.07 \text{ Er}_2\text{F}_6$ glass vs the temperature of thermal treatment for 12 h.¹⁷³

at a rate of 75 K h⁻¹, after which the sample became more compact and transparent glass ceramics involving fluoride nanoparticles was obtained. Lanthanum fluoride nanoparticles doped with erbium were dispersed as a colloidal solution in a silica sol that is formed upon hydrolysis of tetraethoxysilane. The disperse system was coated onto a substrate to prepare thin films.¹⁸⁰

According to the commonly accepted Gleiter concept, glasses (as opposed to composite materials) are considered as uniform homogeneous media.¹⁸¹ However, this concept is doubtful as referred to nanomaterials. Not only short-range but also medium-range order regions tens of ångströms in size were found in glasses by different methods. A crystallite model of glasses, which was proposed by Lebedev more than 80 years ago¹⁸² and was considered as an antithesis to the Zachariasen–Warren theory of continuous random networks,^{183–185} has been confirmed and defined more specifically in recent years (due to the use of modern methods of investigation),^{186–188} including the model of strained mixed clusters¹⁸⁹ (Fig. 9). Therefore, contrary to the opinion of Gleiter,¹⁸¹ in some cases glasses can be considered as true nanocomposites where nanometre-size crystalline regions (they can have different compositions and structures) are surrounded by an amorphous strained defect shell. This is also true for fluoride glasses, which are promising materials for optical information transmission. A vast diversity of fluoride glasses includes the following main classes: fluorozirconate, fluoro-hafnate, fluoroaluminate, fluoroindate and fluoroberyllate glasses.^{190–194}

In the light of the above, the crystallisation process can be considered as either an increase in the size of crystallites, which are already present in the glass, or as the appearance and growth of crystallites the structures of which differ from those present in the glass. Therefore, in some cases, structural difference between glasses and glass ceramics is rather quantitative than qualitative in essence.

The crystallisation processes of fluoride glasses, including those giving rise to transparent glass ceramics, were considered.^{195–200} It was shown²⁰¹ that the optical transmission retained upon crystallisation of 90% of a fluorozirconate glass.

The plots of the crystallite size vs. the parameters of thermal treatment of oxofluoride glasses shown in Fig. 8 illustrate two different situations: (1) thermal treatment does not lead to growth of fluoride particles that are already present in the glass; (2) a rise

(1) Network-forming atoms, (2) bridging atoms, (3) network-modifying ions.

of the temperature leads to an increase in the particle size. In the latter case, glass ceramics with a particle size smaller than 60 nm (calculated from the line broadening in X-ray diffraction patterns) retain optical transmission.

The question of whether it is correct to consider glasses as nanocomposites requires additional studies, including the use of atomic force²⁰² and transmission electron microscopy.

2. Single crystals of heterovalent solid solutions

Association of point defects in crystals gives rise to various complex defects the size of which together with the relaxation region of the matrix is equal to several unit cells, *i.e.*, corresponds to nanoobjects. On the whole, crystals containing defects at rather high concentration can be considered as nanocomposites (Fig. 10).

For fluoride systems, the solid solutions $M_{1-x}Ln_xF_{2+x}$ with a fluorite structure formed in MF_2-LnF_3 systems ($M = Ca, Sr, Ba, Cd$ or Pb ; $Ln = La-Lu, Y$ or Sc) are typical examples of such nanocomposites.²⁰⁴ Phase equilibria in these systems were studied in detail.^{68, 155} The width of the solid solution regions reaches 50 mol.% ($x \leq 0.5$). At lower temperatures, solid solutions are thermodynamically unstable and either decompose or undergo ordering. However, these processes are hindered and single crystals grown from a melt retain optical transmission for decades.

The formation of such solid solutions is a typical example of heterovalent isomorphism with a variable number of atoms per unit cell.²⁰⁵ Cations have different charges. Hence, the insertion of additional fluoride ions into the lattice of dilute solid solutions is necessary for electrostatic compensation (Goldschmidt's scheme)

Figure 10. Nanocomposite as an artificially faceted single crystal of the solid solution $Sr_{0.69}La_{0.31}F_{3.31}$ corresponding to the maximum in melting curves of the solid solution with a fluorite structure in the SrF_2-LaF_3 system.²⁰³

Most refractory inorganic fluoride ($T_m = 1570^\circ C$).

Thus, there are two types of point defects in the fluorite lattice. Electrostatic interactions between these defects lead to their association to form dipoles ($Ln^{3+} - F_{int}^-$), which can have different crystallographic orientations. An increase in the concentration of rare-earth fluorides leads to further association of dipoles to form $(Ln^{3+} - F_{int}^-)_2$ dimers and more complex associates (clusters).^{206, 207} More than two dozens of cluster models were proposed based on data from various experiments and calculations.^{204, 208, 209}

In solid solutions, the presence of Ln_6F_{37} clusters (Fig. 11) was reliably established.^{210, 211} In these clusters, the coordination polyhedra of rare-earth metals are tetragonal antiprisms. An additional anion occupies the cuboctahedral cavity in the centre of the cluster. The existence of such clusters was revealed, in particular, by X-ray diffraction study of ordered fluorite-like phases in these systems. Such clusters are naturally incorporated into the fluorite lattice (see Fig. 11). Since the geometric sizes of associates differ from the size of the matrix lattice regions, which are replaced by these associates, the corresponding composites have local internal strains and deformations. The charge of the cluster differs from the charge of the fragment of the fluorite lattice. Hence, the formation of clusters is accompanied by elimination of an equal amount of additional anions into the matrix according to the equation

Figure 11. Fragment of the fluorite lattice (a), the Ln_6F_{37} cluster (b) and the Ln_6F_{37} cluster incorporated into the fluorite lattice (c).

Both an increase in the concentration of charge carriers and the presence of a deformed zone in the cluster shell lead to a sharp increase in the ionic conductivity.^{212,213}

The formation of the solid solutions $M_{1-x}Ln_xF_{2+x}$ corresponds to the so-called block isomorphism. In this case, the long-range order in the packing of cations is retained, although the anion sublattice undergoes very strong local deformations.

The concentration of clusters increases with an increase in concentration of solid solutions. In the range of 6 mol.%–8 mol.%, percolation occurs, *i.e.*, clusters get in contact with each other to form superclusters in which rare-earth elements are accumulated. The sizes of such superclusters can be as large as several micrometres.

The scheme of successive defect association in the fluorite structure is shown in Fig. 12. The concentration boundaries of the regions vary with temperature and depend on the chemical composition of the systems. The concentration range corresponding to individual clusters containing several rare-earth ions mainly belongs to the region of nanomaterials.

Figure 12. Regions of defect association in the solid solutions $M_{1-x}Ln_xF_{2+x}$ with a fluorite structure.

The structures of clusters in the solid solutions $M_{1-x}Ln_xF_{2+x}$ radically differ from the structures of rare-earth fluorides. Therefore, clusters cannot serve as nuclei of the LnF_3 phase. It is this fact that is responsible for stability of solid solutions against decomposition and the possibility of their use as photonic materials.

An analogous defect structure (poorly studied) is also typical of heterovalent solid solutions having a fluorite structure in the MF_2-XF_4 ($X = Zr, Hf, U$ or Th), $NaF-LnF_3$ and, to a lesser degree, $KF-LnF_3$ systems, as well as of phases with variable composition with a tysonite structure formed in the MF_2-LnF_3 systems. There is also high similarity with fianites, which are solid solutions with a fluorite structure in the $Ln_2O_3-(Zr,Hf)O_2$ systems.²⁰⁶ Coherent submicrometre-size zones of the second phase are well known in metal alloys.

The term ‘antiglass’ was introduced²¹⁴ for the description of crystalline disordered phases characterised by essential local disorder in the presence of a long-range order (in usual glasses, the long-range order is absent, but they have a short- and medium-range order). The heterovalent solid solutions under consideration are typical antiglasses. The similarity of the physical properties of glasses and antiglasses is an example of the principle of equivalence of disorder sources proposed by Tretyakov.²¹⁵

Taking into account the difference in principle between glasses (chaos with islets of order) and antiglasses (order with islets of chaos), antiglasses cannot be considered as an intermediate between crystals and glasses. It is more probable that antiglasses are antipodes of glasses. This main difference leads to a series of additional essential differences. Since solid solutions (antiglasses) are highly defect, they are characterised by a low entropy of melting and, correspondingly, have a low activation barrier to nucleation, and their melts solidify virtually without supercooling. To the contrary, glass-forming melts are characterised by strong supercooling. The appearance of antiglasses as strongly disordered crystalline phases with variable composition, the presence of clusters (defects) and the absence of supercooling are factors limiting the glass formation.

Glasses [for example, $ZrF_4-BaF_2-LaF_3-AlF_3-NaF$ (ZBLAN)] and antiglasses [for example, the solid solutions $Ba_{1-x}Ln_xF_{2+x}$ (Ln are rare-earth metals, $x \leq 0.5$) with a fluorite structure] have the following similar features:

- nanoheterogeneity, the cluster (crystallite) character of the structure;
- a high degree of disorder, high entropy;
- broad multicentre luminescence spectra, broadening, which does not disappear at lower temperatures;
- abnormal low-temperature thermal conductivity, the absence of maxima in the temperature dependence of thermal conductivity;
- fragility, the absence of cleavage;
- high ionic conductivity, the absence of a conductivity jump on melting;
- thermodynamic instability under standard conditions; an increase in the cooling rate expands the region of existence;
- variable chemical composition and high isomorph capacity;
- dependence of physical properties (density, refraction index and conductivity) on the conditions of thermal treatment;
- characteristic features of vibrational spectra;
- percolation phenomena;
- polyfunctionality of materials based on these substances;

and the following differences:²⁰⁵
glasses are characterised by the presence of only a short- and medium-range order, a network structure, fusible composites, high entropy of melting, strong supercooling of melts, which depends on the cooling rate; antiglasses are characterised by a long-range order, a framework structure, refractory, maxima in the melting curves, slight supercooling of melts.²¹⁶

3. Eutectic and eutectoid nanocomposites

Let us consider the possibility of preparing nanocrystalline composites by eutectic crystallisation. Steady-state crystallisation can afford rather ordered plate- or rod-like structures (the transition of one type into another is determined by the volume fraction of the crystallising phases).²¹⁷ An electronic image of the $LiF-LiCdF_4$ eutectic system with a fibre diameter of $\sim 1 \mu m$ is shown in Fig. 13.²¹⁸

For steady-state eutectic crystallisation, the following formula is true

$$\lambda^2 R = \text{const},$$

where λ is the characteristic linear size (for example, the rod diameter) and R is the crystallisation rate. Therefore, to decrease

Figure 13. Electronic image of the eutectic composite $LiF-LiGdF_4$. Directed crystallisation at a rate of 10 mm h^{-1} , the temperature gradient was 70 K min^{-1} .

Figure 14. Image of the product of eutectoid decomposition of a solid solution in the BaF_2 – CaF_2 system.²¹⁹ Cooling at a rate of 100 K min^{-1} ; straight dark lines correspond to scratches on the surface.

the rod diameter by a factor of 10, it is necessary to increase the rate by a factor of 100, which is difficult to perform technically for a steady-state process.

Eutectoid composites hold more promise. The microstructure of an alloy after eutectoid decomposition in a system consisting of calcium and barium fluorides is shown in Fig. 14. In this system, three phases having fluorite structures (solid solutions based on the components and an intermediate high-temperature phase) exist in equilibrium at 870°C .²¹⁹ The sample is characterised by high ionic conductivity comparable with the conductivity of a specially formed composite prepared by successive deposition of nanolayers of calcium and barium fluorides.²²⁰

4. Oxide nanoparticles in fluoride matrices

Fluoride matrices are used for the insertion of nanoparticles with another chemical composition. For example, ZnO and ZnGa_2O_4 nanoparticles dispersed in MgF_2 or LaF_3 films were prepared by the sol–gel method.^{221, 222}

It is known that dispersion in an ionic matrix, including a fluoride matrix, of nanoparticles of dielectric materials, such as SiO_2 and Al_2O_3 , causes an increase in ionic conductivity. This approach is known under the name ‘heterogeneous doping’. The maximum conductivity is observed for a certain volume fraction of dispersed submicrometre-size particles. The theoretical aspects of heterogeneous doping were considered in the publications.^{223–225} A substantial increase in the fluoride-ionic conductivity was observed in such heterogeneous systems as $\text{CaF}_2 : \text{Al}_2\text{O}_3$, $\text{BaF}_2 : \text{Al}_2\text{O}_3$,²²⁶ $\text{Ca}_{0.995}\text{Na}_{0.005}\text{F}_{1.995} : \text{CeO}_{2-x}$ and $\text{Ca}_{0.992}\text{Y}_{0.008}\text{F}_{2.008} : \text{CeO}_{2-x}$.²²⁷

5. Other fluoride nanomaterials

In addition to inorganic fluorides, other compounds also belong to nanocrystalline materials. Evidently, crystalline fluoroorganic polymers,²²⁸ like usual polymers, are nanoparticles (with an ordered arrangement of molecules), which are present in a matrix with a lesser degree of order, in a wide temperature range. These materials are analogues of glass ceramics.

Ultradispersed polytetrafluoroethylene (UDPTFE) powders were synthesised.²²⁹ The technology of the preparation of this material is based on nucleation and condensation of gaseous products of thermal decomposition of industrial polytetrafluoroethylene (Fluoroplast-4). The sizes of particles formed in the gas medium are in the range of 25–50 nm.^{229, 230} Particles of an UDPTFE powder, the sizes of which vary from 100 to 1200 nm (the average size is 550 nm), consist of nanoblocks. A photomicrograph of an individual particle is shown in Fig. 15. The particles consist of blocks up to 100 nm in size. The blocks are held together by low-molecular-weight polytetrafluoroethylene

Figure 15. Images of a nanoparticle of ultradispersed polytetrafluoroethylene taken with the use of an atomic force microscope (courtesy of V M Buznik). (a, b) Different measurement modes.

(PTFE), the structure and properties of which differ from those of the usual high-molecular-weight compound. Some particles are coated by this material. Low-molecular-weight PTFE is characterised by solubility in some solvents and supercritical carbon dioxide, which made it possible to prepare 2–4 nm thick polymeric coatings.²³⁰

A family of new nanomaterials, including magnetic materials, was synthesised by deposition of metal nanoparticles (Fe, Co, Ni, Cu or Pd) on the surface of ultradispersed PTFE granules. Deposition is accompanied by a chemical reaction. In some cases, nanoparticles have a complex composition. Defluorination of PTFE giving rise to a fluoride interlayer and a carbide layer was observed.^{230–232} The structural model of an iron nanoparticle on the surface of an UDPTFE nanogranule is shown in Fig. 16.

Figure 16. Structural model of an iron nanoparticle on the surface of an ultradispersed polytetrafluoroethylene nanogranule.²³²

VII. Nanotechnology and nanoarchitecture

As a rule, the synthesis of nanoparticles is merely the first step of the construction of materials. Fluoride nanoparticles are used in intermediate steps and for the construction of more complex structures of functional importance, *i.e.*, in the design of nano-objects.

It was demonstrated¹⁵⁸ that decomposition of a CoF₂ film in a transmission electron microscope afforded cobalt nanoparticles with a size of 5–10 nm.

The introduction of YF₃ nanoparticles into a shell of polyelectrolyte multilayer capsules was found to improve their mechanical characteristics.²³³ The scheme of this multistep process is shown in Fig. 17.

Figure 17. Scheme of the modification of polyelectrolyte capsules with yttrium fluoride nanoparticles.²³³ PAH is poly(allylamine hydrochloride).

One of operations in nanotechnology is coating of nanoparticles. Taking into account the luminescence properties of lanthanide compounds, interactions between active metal ions and OH⁻ ions, which are efficient luminescence quenchers, present a serious problem. The surface of nanoparticles of fluorides Gd_{0.9}Er_{0.1}F₃, which are present in a porous SiO₂ matrix, was coated with Gd₂O₃.⁴⁹ The suspension was placed in an aqueous solution containing Gd³⁺ and urotropine. Heating at 80 °C for 2 h led to deposition of a Gd(OH)₃ layer. Upon further heating to 500 °C, the hydroxide coating is transformed into the oxide coating. Decomposition of europium trifluoroacetate in a triethylphosphine oxide (TOPO) melt afforded EuF₃ nanoparticles coated with TOPO, which prevents pyrohydrolysis and leads to the efficient energy transfer of europium radiation outwards.⁵¹

A more complicated nanotechnological process was employed¹³ for the preparation of luminescent silica films containing LaF₃ nanoparticles doped with Er³⁺, Nd³⁺ and Ho³⁺ (5% each) by the sol–gel method. The authors solved two problems: insulation of luminescent ions against OH groups (for this purpose, nanoparticles were coated with undoped LaF₃) and dispersion of colloidal nanoparticles in solution with the aim of their homogeneous inclusion into the sol–gel matrix (for this purpose, citrate ions adsorbed on the surface of nanoparticles were used). The following operations were performed successively: precipitation of nanoparticle nuclei, their coating, stabilisation in a colloidal solution, introduction of particles into a gel and film formation.

Studies on the synthesis of hybrid organic/inorganic systems based on fluoride nanoparticles were started (see, for example, Refs 25, 82, 234 and 235).

Coating of multilayer carbon nanotubes by EuF₃ and TbF₃ nanoparticles using intermediate hydrophobic interactions between the surface of carbon nanotubes and sodium dodecyl sulfate was documented.²³⁶ The nanoparticle size was at most 10 nm.

VIII. Conclusion

In recent years, extensive studies in the field of nanotechnology of fluorides have been performed. However, it is obvious that these investigations are in their infancy and will be further developed, in particular, with the use of methods for the synthesis of nano-

particles (the aerosol method, thermolysis of fluoroammonium salts, *etc.*).

Further investigations of the influence of the dispersity on hydrolysis of fluorides and particularly studies of the first step, *viz.*, adsorption of water and other substances on the surface of fluoride particles, as well as the development of procedures for the preparation of protective coatings on the surface of fluoride nanoparticles, are required. Taking into account the similar sizes of the F⁻ and OH⁻ ions, it can be assumed that in many cases, where fluoride nanoparticles are synthesised from an aqueous solution or in air, these particles would contain a particular fraction of OH groups, which increases as the surface is approached (*i.e.*, nanoparticles are hydroxofluorides). According to the results of chemical analysis, the oxygen content increases with increasing amount of rare-earth metals in single crystals prepared by the hydrothermal method. The lattice parameters and the phase transition temperatures are in satisfactory agreement with the corresponding parameters of samples synthesised under anhydrous conditions. The available data (see, for example, Refs 11, 14 and 75) demonstrate that the degree of hydrolysis in the synthesis of nanoparticles increases when potassium is used instead of sodium, which is obvious taking into account substantially higher hygroscopicity of KF compared to NaF. In the case of precipitation of sodium–rare-earth element compounds, OH⁻ ions are virtually absent. For potassium compounds, substantial hydrolysis is observed. It should be noted that according to earlier data (see Refs 69, 70 and 72), the degree of hydration in the case of precipitation with sodium fluoride and potassium fluoride from aqueous solutions of rare-earth salts of cubic double fluorides M_{0.5–x}Ln_{0.5+x}F_{2+2x}·*n*H₂O (*x* = 0.05–0.17) is smaller for M = Na (*n* = 0.2–0.5) than for M = K (*n* = 1–3).

It seems paradoxical that no hydrolysis was observed after completion of the mechanochemical synthesis, where hygroscopic potassium fluoride was mixed with easily hydrolysable transition metal fluorides in air.⁶¹

In many photographs, fluoride nanoobjects look like clouds and pieces of cotton without pronounced boundaries. This is a characteristic feature of a fractal structure.^{237, 238} The self-similarity of the particle shape at several structural levels was noted.⁸⁶ This problem calls for further investigation. It should be noted that the term ‘surface area’ for fractals is ambiguous (can be determined in different ways) and depends on the measurement procedure. In particular, different values of the specific surface area, which is the practically important parameter (for example, for catalysts), can be obtained by the adsorption method with the use of different adsorbed gases.

The random arrangement of fluoroaluminate octahedra postulated in a fluoride gel (see Fig. 6) corresponds to a network in fluoroaluminate glasses. Therefore, one would expect that analogous gels would be prepared for other groups of fluoride glasses, such as fluoroberyllate, fluorohafnate, fluorozirconate and fluoroindate glasses. Amorphous fluoride powders prepared by the sol–gel technology hold considerable promise for the synthesis of different types of fluoride glasses.

Nanofluorides are promising materials for the synthesis of single crystals, particularly, if the components of compounds are substantially different in volatility. An example is SrAlF₅ single crystals of which are promising nonlinear optical materials for laser frequency conversion to the UV range.²²

High mobility of fluoride ions, which is probable in fluoride nanoparticles, may be of practical importance.⁶⁴ It should be noted that ¹⁹F NMR spectroscopy is the method of choice for studying this phenomenon.⁴⁴

It is also necessary to examine the dependence of the toxic effect of fluorides on the particle size.

Abstract. The review concerns the order–disorder kinetic (growth) phase transitions, which are characteristic of inorganic crystalline solid solutions. The emphasis is placed on the emergence of metastable low-symmetry phases (*i.e.*, the dissymmetrisation of crystals), which can occur due to the drastic difference between the atomic structures of growing faces and the bulk crystal. The experimental techniques for the elucidation of this phenomenon, possible crystal symmetries and structures induced by the dissymmetrisation as well as the effects of crystal composition, growth medium composition, growth temperature and growth rate are analysed. The bibliography includes 177 references.

I. Introduction

The order–disorder transitions are equally typical of naturally occurring and artificial crystals. The phase diagram of a compound can reveal areas of the thermodynamic stability and instability of its ordered and disordered phases in specific ranges of thermodynamic parameters, *e.g.*, temperature and pressure. A change in the thermodynamic parameters can induce a transition from an ordered into a disordered phase or *vice versa*. Such classical phase transitions have been known for a long time and are beyond the scope of the present review. This review concerns the kinetic (or growth) order–disorder phase transitions.^{1,2}

A kinetic phase transition implies the emergence of a phase of a particular compound (with either constant or variable stoichiometry) within the stability range of another phase of the same compound driven by kinetic factors.^{3–5} The term ‘kinetic phase transitions’ emphasises that it is kinetic rather than thermodynamic factors that act as the control parameters for such transitions. Kinetic transitions in crystals with variable stoichiometry (*i.e.*, solid solutions), which is a particular case of this general phenomenon, can be classified into two groups, *viz.*, ordering and disordering transitions. The former ones occur due to the selective incorporation of solid solution components into different crystallographic sites of a growing crystal face. The latter ones occur due to a poorer statistical selection of different atoms at high crystal growth rates (atoms in the surface layer do not have enough time to settle themselves in the sites corresponding to an ordered state before a next layer is deposited).¹ We limit ourselves to only kinetic ordering processes, since quite extensive experimental data on this subject became available over the recent years.

At the first glance, the kinetic ordering phase transitions look exotic among numerous ordinary equilibrium phase transitions. However, a careful consideration of the issue indicates that these transitions are not so rare, especially, in the case of solution-grown crystals. Presently, this phenomenon has been well documented for ~30 compounds (Table 1–3), but we believe that the actual range of its occurrence is far broader and it is characteristic of the majority of solid solutions.

Investigations into the kinetic phase transitions are encouraged by the interest in unusual behaviour of crystals and processes responsible for the formation of crystalline solid solutions. The underlying regulations can be applied to reconstruct conditions of the mineral formation in nature.

Atoms, vacancies and their groups can be a subject of either positional or rotational ordering. The presence of partial occupancies of crystallographic sites statistically occupied by different atoms and vacancies in the crystal structure is a prerequisite to the kinetic positional ordering. This phenomenon can be observed both in the case of complete miscibility of isomorphous components [*e.g.*, the ordering of trivalent cations in garnets of the grossularite–andradite series, $\text{Ca}_3(\text{Al,Fe})_2(\text{SiO}_4)_3$] and limited isomorphism (as in the case of the ordering of the Al^{3+} cations substituting for the Si^{4+} ions in quartz, SiO_2). The kinetic ordering can take place when a respective ordinary thermodynamic phase transition is both known [*e.g.*, orthorhombic–hexagonal cordierite $\text{Mg}_2\text{Al}_3(\text{AlSi}_5\text{O}_{18})$] and unknown [*e.g.*, orthorhombic–triclinic topaz $\text{Al}_2\text{SiO}_4(\text{OH},\text{F})_2$].

The known cases of the orientational kinetic ordering are rather scarce. In particular, such an ordering in the distribution of the OH groups was described in apophyllite $\text{KCa}_4(\text{Si}_4\text{O}_{10})_2 \cdot (\text{F},\text{OH}) \cdot 8\text{H}_2\text{O}$ crystals.³⁸ Probably, a similar effect is typical of grossularite garnet $\text{Ca}_3\text{Al}_2[\text{SiO}_4,(\text{OH})_4]_3$ crystals.^{87,120} Yet

another example is given by the orientational ordering in the distribution of the SO_4^{2-} groups revealed for the dissymmetrisation of crystals of aluminium chromium potassium alum, $\text{K}(\text{Al},\text{Cr})(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$.³⁴ However, these three cases virtually encompass all available information on the orientational kinetic ordering. Therefore, we shall further discuss the positional ordering only.

The early history of investigations into the kinetic ordering of atoms, often also referred to as the growth dissymmetrisation of crystals, dates back to the 1960s, when several compounds featuring the ordered distribution of dopant atoms over specific crystallographic sites equivalent in the parent high-symmetry structure [in particular, the ordering of the Gd^{3+} ions in synthetic

corundum Al_2O_3 (Ref. 84) and of the Fe^{3+} ions in calcite CaCO_3 (Ref. 85) and amethyst, a purple quartz modification^{74, 75]} were discovered. In all these cases, the growth processes were suggested to be the driving factor for the ordering (in particular, the non-equivalence of different sites with respect to the crystal growth front was noted) although no detailed mechanism of this phenomenon was then formulated. The general idea of the growth ordering mechanism was proposed by Shubnikov¹²¹ based on theoretical arguments. For the first time, this mechanism has been elaborated in detail by Tsinober and Samoilovich⁷⁹ for quartz and by Nizamutdinov *et al.*⁸¹ for zinc selenate and sodium kröhnkite $\text{Na}_2\text{Cd}(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$ (Ref. 80) and somewhat later by Akizuki and Sunagawa⁶³ for adularia (which is a low-temperature

Notes. ‘Our data’ stands for unpublished crystal structure data by the authors of the present review.

^a Only the growth sectors that have been characterised by X-ray diffraction or spectroscopic techniques are included; ^b Δn is the maximum birefringence (*i.e.*, the difference between principal values of the refraction index of the crystal), $2V$ is the maximum angle between the optical axes; the presence of optical anomalies (+) in a biaxial crystal can be revealed according to one of the following criteria: the sector zoning in the distribution of optical parameters, a non-typical optical indicatrix, variations of optical properties over the crystal not related to stoichiometry variations; ^c 1 are distortions of the ideal unit cell parameters, 2 are different intensities of reflections, which were symmetry-equivalents in the parent structure, 3 is the appearance of forbidden reflections. The symbols ‘+’ and ‘—’ denote the presence and the absence of the dissymmetrisation signature, respectively, the symbol ‘?’ means that no information is available; ^d the number of independent crystal structure refinements for a compound in low-symmetry space groups is given; the dash symbol in this column means that no crystal structure refinement has been accomplished and the conclusions on the real symmetry have been derived based on a qualitative analysis of the experimental diffraction pattern; the symbol ‘ ∞ ’ indicates that the number of independent refinements is large due to the possibility of equilibrium phase transitions; ^e the orientational ordering of the OH groups have been detected with IR spectroscopy and the growth origin of the ordering has been confirmed by the observation of optical anomalies.

modification of potash feldspar, KAlSi_3O_8) and for a series of other compounds, including apatite $\text{Ca}_5(\text{PO}_4)_3(\text{OH},\text{F})$,⁹⁷ garnets,⁷ apophyllite,³⁸ topaz,⁶⁹ analcime $\text{NaAlSi}_2\text{O}_6 \cdot \text{H}_2\text{O}$ (Ref. 23), *etc.*

According to these results, the mechanism of the dissymmetrisation can be described as follows. Crystallographic sites statistically occupied by different atoms and vacancies are strictly equivalent only in the bulk of the crystal. They can well become geometrically and energetically non-equivalent on the crystal surface, which enables their regular occupation by different structural units. The ordered state emerged on the surface can further drift towards the bulk of the crystal. Although this state is metastable, it can be preserved in the crystal for a long time due to very low diffusion rates typical of solids. As a result, the structure of a crystal becomes distorted and its symmetry decreases.

It is known¹²² that the crystal growth proceeds as the attachment of atoms, molecules or other building blocks to the crystal surface. The crystal surface can be either atomically smooth or rough at the molecular level. The attachment of atoms to a smooth

surface is difficult and thus the growth can be realised only as a tangential movement (*i.e.*, parallel to the face surface) of growth steps (which is the layer-by-layer, or tangential growth), since the attachment of an atom to a step end is much more favourable energetically than that to the flat surface. In the case of a rough surface, atoms can attach to any its point, which gives rise to a uniform movement of the face as a whole (which is the normal growth). Schemes of the emergence of site non-equivalence for the cases of the normal and tangential growth modes are shown in Fig. 1. It is clear that atoms having identical environments in the bulk of the crystal, can occupy sites that are non-equivalent with respect to a face or a face step of the crystal. These two cases give rise to the normal and tangential selectivity of the component incorporation, respectively.

The growth dissymmetrisation is a rather interesting phenomenon from the thermodynamic viewpoint. It is manifested most prominently upon the crystallisation under conditions close to the equilibrium, in particular, at low growth rates. This results in an apparent contradiction to the laws of non-equilibrium thermo-

Figure 1. Scheme illustrating the non-equivalence of atoms, which are equivalent in the bulk of a crystal, with respect to the growth front. A is the normal selectivity case, B is the tangential selectivity case. The solid and dashed lines correspond to two consecutive positions of the crystal growth front; the arrows mark the geometric environment of an atoms at the moment of its incorporation into the crystal (adapted from Ref. 80).

dynamics stating that non-equilibrium structures should emerge far from the equilibrium.^{123–125} Actually there is no contradiction, since the emergence of non-equilibrium structures concerns the non-linearity of physical and chemical processes related to the deviation from the equilibrium rather than the mere fact of a deviation. Provided that the non-linearity is the strongest at small deviations from the equilibrium (exactly as it occurs upon the specific adsorption of atoms on the surface of a growing crystal), the probability of the emergence of non-equilibrium structures will increase with an approach to the equilibrium.

Over the whole history of investigations into the growth ordering, a large body of information on both the mechanism of the phenomenon and its influence on the symmetry and structure of the resultant crystalline solid solutions has been gathered.

The present review aims at the generalisation and critical analysis of the available data on all aspects of the growth ordering and experimental techniques for its elucidation. The emphasis is placed onto the crystallochemical origins of the growth dissymmetrisation.

II. Experimental techniques for the elucidation of the growth dissymmetrisation of crystals

1. Crystal optics

According to the Neumann’s principle, a decrease in the symmetry of a crystal should be reflected in the symmetry of its physical properties. In particular, this is valid for crystal optical parameters described by the dielectric impermeability tensor. The dielectric impermeability ψ represents reciprocal dielectric permeability and relates to the refraction index as¹²⁶

$$\psi = n^{-2}.$$

The shape and the orientation of the optical indicatrix, which is the representation surface of this tensor, have to reflect properly the real symmetry of the crystal. The growth dissymmetrisation is accompanied by a change in the optical properties of the crystal, which is manifested in the appearance of characteristic ‘optical anomalies’. For instance, the optical indicatrix of a cubic crystal can transform from a sphere to a uniaxial or biaxial ellipsoid, and the initially optically isotropic crystal will become birefringent. The degree of distortion of the optical indicatrix is described by the birefringence, which is the difference between the maximum and the minimum refraction indices.

Crystal optical methods have several evident advantages over alternative methods for the elucidation of the growth ordering. These include the high sensitivity to minute distortions of the crystal structure induced by ordering of structural units; the possibility of simultaneous monitoring of crystal optical parameters over a large number of the crystals under study; the straightforwardness and affordability of the analysis: the analysis of a large amount of samples does not require long time and expensive instrumentation. Thus the crystal optics is indispensable at preliminary stages of the investigation, *i.e.*, for the detection of the dissymmetrisation and for the quantification of the degree of this effect within a number of samples from the same isomorphous series. Overall, the method does not allow one to establish what types of crystal structure distortions are responsible for the observed distortions of the optical indicatrix. However, some robust algorithms for rather accurate calculations of the optical indicatrix based on the crystal structure have been elaborated recently.^{127–134} By performing calculations and comparing theoretical optical parameters with the experimental ones for a series of models one can analyse the origin of the optical anomalies with their relation to the ordering of structural units. In particular, such calculations were performed for garnets of the grossularite – andradite $\text{Ca}_3(\text{Al}, \text{Fe})_2(\text{SiO}_4)_3$ (Refs 14–16) and grossularite – uvarovite $\text{Ca}_3(\text{Al}, \text{Cr})_2(\text{SiO}_4)_3$ series (Refs 15 and 16) and for sodium chlorate bromate²⁸ (Fig. 2).

Figure 2. Theoretical (dots) and experimental (asterisks) orientations of the optical indicatrix for garnets of the grossularite–uvarovite isomorphous series (a) and sodium chlorate bromate crystals²⁸ (b); n_m , n_p and n_g are the principal values of the refraction index of a crystal; different data points correspond to different samples; the experimental crystal optical parameters and atomic coordinates used in the calculations were taken from the Refs 17 and 28 for a and b, respectively.

2. Electron spin resonance

The kinetic ordering of atoms in a crystal has been detected for the first time using electron spin resonance (ESR). This method is extremely sensitive and makes it possible to reliably measure the concentration of dopant atoms in any specific site of a regular system of points. The major limitations of the method are as follows: the substituting ion should be paramagnetic (or should form a paramagnetic centre); the concentration of the ion should be sufficiently low (below %); no other paramagnetic ions should be present in the crystal in high concentrations.

Let us consider a few examples of the application of this method to studies of the dissymmetrisation (see Table 2). Upon

Figure 3. ESR spectra of hole centres in smoky quartz.⁷⁹ The growth sectors: $\{01\bar{1}1\}$ (a), $\{\bar{1}\bar{1}20\}$ (b) and $\{0001\}$ (c). Groups of signals which have identical intensities in the parent trigonal crystal structure of quartz are denoted with numbers from 1 to 3.

the aluminium substitution for the silicon atoms in the crystal structure of quartz (the point symmetry group 32), the $[\text{AlO}_4]^{5-}$ complex can lose an electron giving rise to a hole centre, which can easily be detected with ESR. The concentration of the hole centres is directly proportional to the aluminium concentration (and that of respective counter-ions), so that signal intensities in the ESR spectra give information on the fraction of aluminium atoms in various silicon sites. In an ESR study of crystals of artificial smoky quartz, it was found that groups of signals corresponding to the oxygen atoms of different SiO_4 tetrahedra are characterised by different intensities⁷⁹ (Fig. 3). For the growth sectors of rhombohedral faces (face symmetry 1), all three groups of signals have different intensities; for the growth sectors of prismatic faces (face symmetry 2), only two groups of signals have identical intensities; and for the growth sectors of pinacoidal faces (face symmetry 3), all three groups of signals have identical intensities. Since the intensity of lines in ESR spectra is directly proportional to the concentration of hole centres, the ordering of the hole centres revealed in this way confirms the dissymmetrisation.

3. Infrared and Raman spectroscopy

Infrared (IR) spectroscopy was successfully applied to the analysis of ordered distribution of the fluoride and hydroxide anions in topaz,^{71,72} the silicon and aluminium cations in adularia⁶³ and of the orientational ordering of the OH groups in grossularite¹²⁰ and apophyllite.³⁸ Typically, site occupancies cannot be determined by this method, however, it gives information on the presence and the degree of ordering of atoms or atomic groups in the structure.

Unfortunately, the sensitivity of IR spectroscopy is rather low. In particular, several attempts at the detection of the ordering of the Al/Fe atoms in garnets of the grossularite–andradite isomorphous series using this method failed,^{11,12} although it was reliably established using X-ray crystallography by several authors.^{6,16} It is of note that one of the samples studied by X-ray crystallography⁶ was studied later by IR and no ordering was revealed.¹² Nevertheless, inclusions of a substantially ordered phase dispersed in a disordered matrix can be efficiently revealed by IR (at sizes far below the detection limit of diffraction techniques).¹³⁵

4. Electron microscopy

High-resolution transmission electron microscopy (HRTEM) as well as other modifications of electron microscopy (e.g., TEM, SEM) can reveal the growth ordering in crystals provided that it is significant and gives rise to strong structural distortions or the appearance of superstructures. The detection of Al/Si ordering in cordierite¹³⁵ and prenite $\text{Ca}_2\text{Al}_2\text{Si}_3\text{O}_{10}(\text{OH})_2$,¹¹⁴ Ca/Mg ordering in calcite CaCO_3 and dolomite $\text{CaMg}(\text{CO}_3)_2$ (Ref. 103) can be given as examples of successful applications of electron microscopy.

5. Diffraction methods

It is X-ray, electron and neutron diffraction studies on single crystals (see Table 1) that provide the highest efficiency in the analysis of the nature of the kinetic ordering of atoms in crystals revealing detailed information on the occupancies of crystallographic sites and interatomic distances. In some cases, changes in the ordering can also be tracked by powder X-ray diffraction by monitoring shifts, splitting or broadening of diffraction reflections or the appearance of additional superstructure reflections in the diffraction patterns. In particular, dissymmetrisation-induced changes in the powder diffraction patterns were observed for cordierite $\text{Mg}_2\text{Al}_3(\text{AlSi}_5\text{O}_{18})$ ^{45,46} and edingtonite $\text{BaAl}_2\cdot\text{Si}_3\text{O}_{10}\cdot 4\text{H}_2\text{O}$.⁵⁷

As a rule, the degree of the growth ordering of atoms is low and the lower-symmetry structure subject to refinement is close to the parent high-symmetry one and thus it is difficult to unambiguously establish the fact of a symmetry lowering based on a routine experiment. To provide reliable conclusions on the man-

ifestation and the nature of the dissymmetrisation, it is necessary to collect an accurate set of intensities of diffraction reflections, then carefully analyse the experimental diffraction pattern and refine the crystal structure first in the parent high-symmetry group and then in some of its subgroups selected according to the results of the diffraction pattern analysis.

Recommendations on the accurate measurement of intensities of X-ray diffraction reflections are given elsewhere.^{25, 136} In particular, it is advisable to use nearly spherical crystals and collect the whole set of intensities over the entire Ewald sphere rather than only in its symmetry-independent part.

The following signatures of the dissymmetrisation can be observed in a diffraction pattern: distortions of the unit cell dimensions (typically, insignificant ones); differing intensities of reflections equivalent in the ideal space group; the emergence of reflections forbidden in the ideal space group. The logic of an analysis of the crystal dissymmetrisation based on the diffraction pattern can be demonstrated using garnets of the grossularite–andradite isomorphous series (grandites) with a common stoichiometry $X_3Y_2(SiO_4)_3$ ($X = Ca, Y = Al, Fe$, the ideal space group is $Ia\bar{3}d$). The anomalous birefringence in these crystals is well known.^{7, 13, 90} The idea that the optical anomalies in garnets originate in the atomic ordering has been formulated for the first time by Yoder.¹³⁷ However, the questions on the presence and the nature of the ordering in garnets remained unanswered until recent years, despite numerous attempts at revealing this ordering using X-ray crystallography undertaken over the last 25–30 years.^{6, 8–10, 14–17, 138, 139}

Let us illustrate this approach by the example of a study of three natural grandite crystals (the growth sector of rhombododecahedral faces {110}). The parameters of these crystals and the structure refinement results obtained for them by means of X-ray crystallography are summarised in Tables 4 and 5 (for details, see Ref. 16).

Significant deviations from cubic symmetry are observed for two out of three samples. These are manifested in a deviation of one of the angles (β) from 90° (see Table 4), which indicates that the actual symmetry of the crystals is orthorhombic or lower.

For a comparative analysis of the reflection intensities, all reflections equivalent in the ideal cubic diffraction class $m\bar{3}m$ were subdivided into groups according to the symmetry elements of this class. A symmetry element was considered to be violated, if the difference $I_{\max} - I_{\min}$ between the strongest and the weakest reflections within the respective group exceeded a preset threshold value [in this particular case, it was twice the difference between the intensities of the Friedel equivalents $2(I_{hkl} - I_{\bar{h}\bar{k}\bar{l}})_{\max}$].

In this way, the fractions P of reflections violating specific symmetry elements of the cubic structure were determined for

Table 5. Parameters of X-ray diffraction measurements and structure refinement for the three birefringent grandites.

each group (Fig. 4). It is evident that for the crystal Bazh1, all symmetry elements of the parent point symmetry group are violated to a small virtually constant extent. These violations can be regarded as a background level induced by multiple scattering events, non-ideal spherical shape of the sample and resultant anisotropic absorption of X-rays in the crystal, *etc.* Meanwhile, the symmetry element violations are more prominent for other two crystals. And it is important that different symmetry elements are violated to different extents. In particular, the symmetry planes (010), (101) and ($\bar{1}01$) are violated not as significantly as symmetry axes. This trend is especially prominent for the crystal Bazh2: the symmetry planes therein are violated insignificantly, to an extent comparable to that in Bazh1 with simultaneous substantial violation of the remaining symmetry elements. This gives strong evidence that the crystal Bazh2 is actually orthorhombic. In the case of the crystal Mali, the violation of the symmetry planes is more pronounced, which indicates that the actual symmetry of the crystal is lowered further to triclinic.

An analysis of the systematic absences revealed 12, 391 and 196 reflections forbidden in the ideal space group $Ia\bar{3}d$ for the crystals Bazh1, Bazh2 and Mali, respectively (Table 6). Further-

more, it was shown that the vast majority of the forbidden reflections originate from the structure dissymmetrisation rather than in multiple scattering effects for the latter samples, Bazh2 and Mali.^{16, 140} To the contrary, all 12 forbidden reflections in the crystal Bazh1 were shown to be related to multiple scattering, which means that the crystal structure remains cubic.

The preliminary conclusions on the dissymmetrisation of the crystals derived from the analysis of the diffraction patterns can be further proven by the refinements of the crystal structure in all possible space groups, including the ideal one. As a result of this laborious analysis not only the crystal symmetry can be reliably established, but also the nature of the dissymmetrisation can be revealed based on the information on occupancies of crystallographic sites and respective interatomic distances.

The crystal structure refinements were performed according to the standard procedure. The structure was refined by the least-squares method based on an analysis of the difference Fourier maps. A particular attention should be paid to the refinement of site occupancies, since severe errors can appear due to mutual correlations between the occupancies and other variables (primarily, thermal parameters). In order to suppress the effects of these correlations, the following techniques can be applied:²⁵ the average stoichiometry of the crystal can be constrained; a series of models with fixed occupancies set at several systematically varying values can be refined and compared; the occupancies can be refined against a part of the reflection array including the reflections observed at smaller diffraction angles 2θ , which are less sensitive to uncertainties in the thermal factors. Furthermore, it is often advisable first to place only one of the principal elements into the site with suspected ordering and refine its occupancy without any constraints.

The retrieval of accurate and reliable site occupancies for crystals of solid solutions from experimental diffraction data is a non-trivial task, which can be solved in a correct way not in all cases [see also a discussion of this problem elsewhere^{141–144} for the case of the determination of magnesium and iron occupancies in sites M1 and M2 from the crystal structure refinement of olivines (Mg,Fe)₂(SiO₄)]. A survey of the experimental data on a number of inorganic compounds indicates²⁵ that a change in the site occupancy can be reliably detected by means of X-ray crystallography only provided that $\Delta e / \sum e > 0.004$, where Δe is the change in the electron count upon the change in the occupancy of a site taking into account its multiplicity, and $\sum e$ is the total number of electrons in a unit cell.

For the example under consideration, the symmetry lowering for the crystals Bazh2 and Mali was shown to be related to the ordering of the iron and aluminium cations in the octahedral sites Y, which is accompanied by a change in the respective mean cation–oxygen bond lengths $\langle Y-O \rangle$ (Table 7). Only one symmetry-independent Y site is present in the parent cubic garnet (space group $Ia\bar{3}d$), whereas this number increases to two and eight in the orthorhombic (space group $Fddd$) and triclinic (space group $I\bar{1}$) structures, respectively.

In general, the more thorough crystal structure refinement confirms the preliminary conclusions derived from the aforementioned analysis of the diffraction pattern. According to the results of X-ray diffraction (Table 8), the crystal Bazh1 is characterised by the cubic symmetry (space group $Ia\bar{3}d$). Small distortions of the cubic symmetry revealed by crystal optical studies lie beyond the detection limit of X-ray crystallography. The crystal Bazh2 is characterised by the orthorhombic symmetry (space group $Fddd$), whereas the sample Mali is triclinic (or pseudoorthorhombic, space group $I\bar{1}$ or $I1$).

III. The symmetry aspects of the dissymmetrisation and the structural inhomogeneity of crystals

According to the Curie's principle,¹²⁶ the symmetry of a crystal during dissymmetrisation should be determined by the symmetry of a growing face (normal selectivity of component incorporation) and(or) face step (tangential selectivity of component incorporation). The intersection of the point symmetry group of a crystal with the point symmetry group of the matter flow normal to the face of a growing crystal (which is the cone symmetry, *i.e.*, the limiting symmetry class ∞mm) gives 10 groups possible for the normal selectivity in the component distribution (for the case of the normal growth mode by the movement of faces), *viz.*, 1, 2, 3, 4, 6, m , $2mm$, $3m$, $4mm$ and $6mm$. The respective intersection of the point symmetry group of a crystal with the point symmetry group of the planar matter flow towards a face step (the symmetry class m) gives only two point groups possible for the growth mode by the tangential movement of face steps, *viz.*, 1 and m .¹²¹

This simple (and thus rather useful) approach to the description of the crystal symmetries was applied to analyse the dissymmetrisation in many minerals, including analcime $\text{NaAl} \cdot \text{Si}_2\text{O}_6 \cdot \text{H}_2\text{O}$,²³ grossularite $\text{Ca}_3\text{Al}_2[\text{SiO}_4(\text{OH})_4]_3$,⁸⁷ chabazite $\text{Ca}_2\text{Al}_4\text{Si}_8\text{O}_{24} \cdot 13 \text{H}_2\text{O}$,¹⁰⁸ sodium chlorate bromate²⁶ and others. In particular, it was established⁶⁹ that upon the dissymmetrisation of topaz crystals (the symmetry class mmm), the growth sectors of the pinacoidal faces $\{010\}$ remain orthorhombic (the 2D symmetry group of these faces is $2mm$), the growth sectors of the rhombic prismatic faces $\{hk0\}$ become monoclinic (the symmetry group of the faces is m), whereas the growth sectors of the rhombic bipyramidal faces $\{hkl\}$ become triclinic (the symmetry group of the faces is 1). Hereinafter, the indices h , k and l in the notations of simple forms,[†] growth sectors and faces define the inclination of the faces with respect to the coordinate axes X , Y and Z and thus should be small integers.

It has to be noted that the theoretically suggested symmetry lowering is not realised in all cases, since this approach does not take into account the intrinsic symmetry of the atomic sites subject to ordering. There can be no growth ordering, but if it is actually realised, it obeys the above scheme. For instance, under the conditions of the normal selectivity for the cubic faces $\{100\}$ of alum crystals (the symmetry class $m\bar{3}$), the symmetry of the growth sector formed by this face should be lowered to orthorhombic $2mm$, however, this growth sector remains cubic in reality (see below).

† A simple form is a set of faces related to each other through the symmetry operations of the point symmetry group,¹⁴⁵ a growth sector (or growth pyramid) of a face is the area within a crystal formed by the growth of this crystal face.

The crystal dissymmetrisation effects can be strictly addressed within the formalism of the Wittke–Garrido colour symmetry groups. Such an approach has been used for the first time by Vinokurov *et al.*^{80, 82, 83, 86, 146} to describe the dissymmetrisation in zinc selenate and sodium kröhnkite $\text{Na}_2\text{Cd}(\text{SO}_4)_3 \cdot 2 \text{H}_2\text{O}$. The group properties are analysed at a point group level with the explicit consideration of the intrinsic symmetry of the sites involved. The post-dissymmetrisation symmetry of the crystal and the crystallographic sites subject to variable occupancies with isomorphous atoms are obtained as a result of this theoretical analysis.

Such an approach can be illustrated with an analysis of the symmetry of mixed alum crystals $\text{A}^+\text{M}^{3+}(\text{SO}_4)_2 \cdot 12 \text{H}_2\text{O}$ ($\text{A} = \text{K}, \text{NH}_4, \text{Rb}, \dots$; $\text{M} = \text{Al}, \text{Fe}, \text{Cr}, \dots$) (Table 9). Ideally, alum crystals are crystallised in the cubic system with the point symmetry group $m\bar{3}$ but they exhibit optical anomalies originated from the kinetic atomic ordering. Let us consider the ordering of isomorphous atoms in the A^+ or M^{3+} cationic sites [which are the special Wyckoff positions 4(b) and 4(a), respectively]. It is clear that the actual symmetry of the optical indicatrix is compatible with a symmetry lowering due to the growth ordering of the A^+ or M^{3+} cations. Furthermore, it can be seen that in the majority of cases, the theory group analysis predicts the same optical symmetry as does the analysis of the symmetry of a growing face or a face step. In particular, the normal growth of octahedral faces (the 2D symmetry group of this face is 3 within the symmetry class $m\bar{3}$) gives rise to the trigonal symmetry. Meanwhile, the tangential growth of steps on octahedral faces (the step symmetry group is 1) results in the triclinic symmetry. Notwithstanding, as has been mentioned above, the two approaches make sometimes different predictions. For instance, the growth sector of cubic faces should be characterised by the orthorhombic symmetry $2mm$ according to the 2D symmetry group of this face but the group theory analysis predicts the retention of the cubic symmetry for the case of the normal selectivity, and the actual optical indicatrix remains spherical (*i.e.*, no dissymmetrisation occurs).

Therefore, the symmetry of the growth front (*i.e.*, of a crystal face or a face step in the cases of the normal and tangential growth modes, respectively) strongly affects the symmetry of the resultant crystal. The vast majority of crystals are shaped by a set of faces belonging to one or a few regular forms, which enables the spatially inhomogeneous distribution of areas corresponding to different symmetries and structures over a crystal. Possible types of the spatial inhomogeneity commonly evidenced by optical anomalies are considered in detail below.

1. Sector zoning

During the crystal growth, every face forms its own growth pyramid (or sector) and, ideally, any crystal can be represented as a set of pyramids with a common vertex in the centre of the

Table 9. Occupancies of systems of translationally related sites (x_i , $i = 1, 2, \dots, 4$) and the real symmetry of different growth sectors of alum crystals (symmetry class $m\bar{3}$) according to optical investigations.

Growth sector	Normal selectivity			Tangential selectivity			Observed optical indicatrix symmetry
	site occupancies	face symmetry	assumed optical symmetry	site occupancies	face step symmetry	assumed optical symmetry	
$\{111\}$	$x_1 \neq x_2 = x_3 = x_4$	3	uniaxial, normal to $\{111\}$	$x_1 \neq x_2 \neq x_3 \neq x_4$	1	triclinic	biaxial, close to uniaxial
$\{110\}$	$x_1 = x_2 \neq x_3 = x_4$	m	monoclinic	$x_1 = x_2 \neq x_3 = x_4$ (see ^a)	m	monoclinic or triclinic	biaxial
$\{100\}$	$x_1 = x_2 = x_3 = x_4$	$2mm$	cubic	$x_1 = x_2 \neq x_3 = x_4$	m	monoclinic	often isotropic, sometimes biaxial

^a In the present case, the resultant symmetry depends on the orientation of growth steps: if a step is not perpendicular to the symmetry plane, then all the occupancies are different, and the point symmetry group is $\bar{1}$.

Figure 5. Optical sector zoning in a plate of an eremeyevite $\text{Al}_6(\text{BO}_3)_5(\text{OH})_3$ crystal cut parallel to the (0001) crystallographic plane.¹⁰²

The growth sectors: (1) pinacoid (the angle $2V = 0^\circ$), (2–4) hexagonal bipyramids (the angle $2V = 3^\circ$), (5) hexagonal prism (the angle $2V = 10\text{--}18^\circ$).

crystal and bases coinciding with the crystal external faces. Every growth sector features its own symmetry and crystal structure. The sector growth of different simple forms can be characterised by totally different structures, whereas the structures of different faces belonging to the same regular form can be identical but differently oriented with respect to the common coordinate system, which is similar in some aspects to the twinning texture. This type of the spatial inhomogeneity is a very common signature of the growth dissymmetrisation and, in a sense, can be regarded as its visiting card (for details, see elsewhere^{7, 14, 33, 69, 73, 79}). As an illustration, Fig. 5 depicts different orientations of the optical indicatrix for various growth sectors of an eremeyevite crystal.¹⁰² Table 10 lists data on the distribution of optical anomalies over different growth sectors in garnet $\text{Ca}_3(\text{Al,Fe,Cr})_2(\text{SiO}_4)_3$ crystals.

2. Subsector zoning

The optical sector zoning is often complicated by additional inhomogeneity of the crystal at a subsector level. The term ‘subsector zoning’ means that several subsectors can be recognised within every growth sector, which are specific areas characterised by their own structures and physical properties. Subsectorial ordering changes are a finer effect as regards the sectorial inhomogeneity, thus its manifestation has only been registered with crystal optical techniques. The reason for the emergence of the subsector zoning is as follows. Growth steps spread out over a crystal face from point sources, *viz.*, surface ends of screw dislocations. This is accompanied by the formation of growth (or vicinal) hillocks on the initially flat crystal faces, while the exact shape of the hillocks depends on the anisotropy of the crystal growth rates along the respective steps. The majority of crystals prone to the dissymmetrisation grow from mother liquors following the spiral dislocation mechanism. Since the steps originating from different sides of a vicinal hillock are differently oriented, the crystal areas derived from them under the conditions of the tangential selectivity in the incorporation of isomorphous atoms will appear differently ordered. As a consequence, the distribution of the growth ordering over subsectors formed by differently oriented steps within a sector will reflect the shape of the vicinal hillock.

In particular, typically, vicinal hillocks on the octahedral faces {111} of alum crystals (the symmetry class $m\bar{3}$) have a shape of a trigonal pyramid. As a result, every hillock gives rise to three equivalent subsectors, since the octahedral faces within this symmetry class are characterised by the point symmetry 3. Indeed, the growth sector of the octahedral faces {111} often appears subdivided into three subsectors (derived from one growth hillock) or several triplets of subsectors (derived from different growth hillocks) with different orientations of the optical indicatrix, as can be seen in crystal cuts parallel to the respective growth face. Normally, the subsectors converge in a single point corresponding to the top of the vicinal hillock³³ (Fig. 6). Similar subsector zoning patterns are observed in apatite⁹⁷ (Fig. 7), garnets of the grossularite–andradite series,⁷ analcime $\text{NaAl}_2\text{Si}_2\text{O}_6 \cdot 2\text{H}_2\text{O}$,²³ chabazite $\text{Ca}_2\text{Al}_4\text{Si}_8\text{O}_{24} \cdot 13\text{H}_2\text{O}$,¹⁰⁸ edingtonite $\text{BaAl}_2\text{Si}_3\text{O}_{10} \cdot 4\text{H}_2\text{O}$ ⁵⁷ and in other crystals. In all these cases,

Table 10. Experimental parameters of the optical indicatrix in different growth sectors for garnet crystals of the $\text{Ca}_3(\text{Al,Fe,Cr})_2(\text{SiO}_4)_3$ series (the ideal symmetry class is $m\bar{3}m$). Data from Refs 13, 15, 18, 90, 139, 147.

Growth sector	Point symmetry group	Observed optical indicatrix	Theoretical optical indicatrix	Distribution of occupancies of the octahedral sites
Cube {100}	$4mm$	sphere	sphere	$x_1 = x_2 = x_3 = x_4 = x_5 = x_6 = x_7 = x_8$
Octahedron {111}	$3mm$	uniaxial ellipsoid, the optical axis is normal to the (111) face	uniaxial ellipsoid, the optical axis is normal to the (111) face	$x_1 = x_5 \neq x_2 = x_3 = x_4 = x_6 = x_7 = x_8$
Rhombo-dodecahedron {110}	$2mm$	biaxial ellipsoid, $n_g \parallel [101]$; $n_m \parallel [010]$; $n_p \parallel [101]$ (face normal)	biaxial ellipsoid, the principal axes are parallel to [010] and $[101]$ and normal to (101)	$x_1 = x_4 = x_5 = x_6 \neq x_2 = x_3 = x_7 = x_8$
Tetragontri-octahedron {211}	m	biaxial ellipsoid, $n_p \parallel [211]$ (face normal); the plane defined by the optical axes is parallel to the symmetry plane m	biaxial ellipsoid, one of the principal indicatrix cross-sections is parallel to the symmetry plane m	$x_1 = x_5 \neq x_2 = x_8 \neq x_3 = x_7 \neq x_4 = x_6$
Tetrahexa-hedron {210}	m	biaxial ellipsoid, the principal axes are oblique to the face; the plane defined by the optical axes is parallel to the symmetry plane m	biaxial ellipsoid, one of the principal indicatrix cross-sections is parallel to the symmetry plane m	$x_1 = x_5 \neq x_2 = x_8 \neq x_3 = x_7 \neq x_4 = x_6$
Hexaocta-hedron {321}	1	biaxial ellipsoid, the orientation of the optical indicatrix is oblique	biaxial ellipsoid, the orientation of the optical indicatrix is oblique	$x_1 \neq x_2 \neq x_3 \neq x_4 \neq x_5 \neq x_6 \neq x_7 \neq x_8$

Figure 6. Subsector zoning in an alum $[K_{0.5}(NH_4)_{0.5}] \cdot Al(SO_4)_2 \cdot 12 H_2O$ crystal. The cut is parallel to the (111) growth plane.³³ (a) Anomalous birefringence around the top of a vicinal hillock (A); (b) an X-ray topogram of the cut, the arrow indicates the diffraction vector g direction for reflection 220.

Figure 7. Optical subsector zoning in cuts of apatite crystals perpendicular to the $[0001]$ crystallographic axis.⁹⁷ The observed optical patterns correlate with the positions of vicinal hillock on the crystal face, although the correlation is ambiguous.

the resultant optical subsector zoning correlates with the vicinal face topography; and the symmetry of optical structures correspond to the symmetry of the face defined by the vicinal hillocks present on it.

Boundaries between different subsectors, *i.e.*, domains of a sector originated from different sides of a vicinal hillock, can be visualised in cuts parallel to the crystal growth direction. For instance, two vicinal hillocks formed by two dislocation bundles are clearly seen in the growth sector of the octahedral faces $(\bar{1}\bar{1}1)$ for an alum crystal (Fig. 8). The crystal domains derived from different vicinal hillocks are characterised by differently oriented optical indicatrix, such that the interdomain boundaries can readily be seen in crossed polarisers (see Fig. 8).

3. The correlation between sector zoning and subsector zoning

Optical studies of crystals with the growth dissymmetrisation always reveal their prominent sectorial structure. The experimentally observed indicatrix fully agrees with the normal selectivity in the incorporation of isomorphous components. The optical subsector zoning resulted from the tangential selectivity in the incorporation of isomorphous components is often but not always the case. Typically, this is manifested weakly (minor variations in the systematic absences or a relatively small change in the birefringence). And it is rather surprising. Such crystals grow from mother liquors by the spiral dislocation mechanism, which implies that the faces grow through the movement of steps. Thus a

very distinct subsector zoning in the distribution of optical anomalies is anticipated in the majority of cases, which is not actually the case. This gives rise to an apparent contradiction: a crystal grows through the movement of steps, whereas the distribution of optical anomalies therein is better described by the normal mechanism of the crystal growth.

Several suggestions have been made to reconcile this controversy. According to one of them, the indicatrix strictly corresponding to the face symmetry, *i.e.*, to the case of the normal selectivity, is merely a net result of averaging of effects produced by numerous arbitrarily oriented steps forming this face. A modification of this hypothesis was elaborated by Gali.¹⁴⁸ Nevertheless, the growth of the vast majority of crystals proceed from a few (1–3) quite stable vicinal hillocks, which gives rise to a situation when rather large areas of a crystal are derived from identically oriented steps (see, for instance, Fig. 8), which contradicts the above mechanism. Another hypothesis assumes that the structural distortions occurring under the conditions of the tangential selectivity are close to those in the case of the normal selectivity, *i.e.*, the major energy difference between the sites results from their non-equivalence with respect to the crystal face. Additional non-equivalence due to the face step is negligible. In other words, although the tangential selectivity remains in effect, the ordering is apparently governed by the normal selectivity and the tangential selectivity effects can be revealed only in high-precision studies. We believe that this suggestion is very reasonable. According to another hypothesis, it is the diffusion relaxation that transforms the tangential selectivity ordering into the normal selectivity ordering.

4. Concentric zoning

Frequently, crystals grow under unsteady conditions, *i.e.*, temperature, growth rate, hydrodynamic regime, mother liquor composition can vary over time. Furthermore, the growing face morphology can undergo substantial changes in the course of the growth. All these factors affect the degree of ordering of isomorphous atoms and give rise to the concentric zoning in the distribution of optical parameters (which is often characterised by a very complex pattern). In this case, different extent of the dissymmetrisation under different growth conditions and at variable crystal composition acts as the key factor. The concentric zoning is observed in many crystals, in particular, in mixed alum crystals²⁹ and in garnets of the grossularite–andradite isomorphous series.¹⁵ A special case of the continuous concentric zoning (also referred to as trend) not related to variations in the crystal composition and growth conditions, which has been reliably registered in mixed alum crystals,¹⁴⁹ is of particular interest. In that case, the birefringence and, consequently, the extent of the atomic ordering increased from the centre of the crystal towards its periphery first abruptly, then more smoothly finally approaching a plateau. It might be assumed that this pattern occurs due to the succession of relatively poor initial ordering (caused by the regeneration of the seed) in the growth under conditions providing a higher degree of the atomic ordering.

IV. Dissymmetrisation-induced changes in the crystal structure

As follows from the structural data gathered to date (see Table 1), the growth dissymmetrisation gives rise to insignificant changes in the topology of the crystal structure. This is due to the partial ordering of structural units (*i.e.*, atoms, ions, molecules or vacancies) in available crystallographic sites. The maximum degree of the growth ordering η of 0.84 (see below) was revealed in vesuvianite $\text{Ca}_{19}(\text{Mg}, \text{Fe}, \text{Al})_{13} \cdot \text{Si}_{18}\text{O}_{68}(\text{O}, \text{OH}, \text{F})_{10}$ crystals.

Typically, the degree of distortion of unit cell parameters is small, but it continuously increases with perfection of the ordering in the distribution of structural units. This trend can be illustrated by a linear increase in the monoclinic angle β in initially cubic structures of garnets $\text{Ca}_3(\text{Al}, \text{Fe}, \text{Cr})_2(\text{SiO}_4)_3$ and sodium chlorate

Figure 9. Monoclinic angle as a function of the difference in site occupancies.

(a) Garnets of the grossularite–andradite (plain symbols, data taken from Refs 6, 14–16) and grossularite–uvarovite (shaded symbols, data taken from Ref. 17) isomorphous series, the growth sector {110}; (b) sodium chlorate bromate solid solutions, the growth sector {100}; plain symbols are from Ref. 27, two superimposed shaded symbols are from Ref. 25.

bromate $\text{Na}(\text{ClO}_3, \text{BrO}_3)$ with an increase in the difference between the occupancies of initially equivalent sites (*i.e.*, Al and ClO_3^- occupancies x_1 and x_2 in the two available trivalent cationic and anionic sites for the former and latter compounds, respectively, Fig. 9).

Typically, the atomic ordering does not lead to the appearance of a superstructure. However, there are some exceptions to this rule. In particular, a superstructure due to the ordering of calcium and magnesium atoms was revealed in calcite and dolomite crystals using high-resolution transmission electron microscopy.¹⁰³ Unfortunately, the growth origin of the superstructure has not been confirmed so far.

According to studies of a series of solid solutions belonging to one structural type [*e.g.*, garnets^{6, 14–17} and minerals of the pollucite–analcime series $\text{Cs}_x\text{Na}_{1-x}\text{AlSi}_2\text{O}_6 \cdot (1-x)\text{H}_2\text{O}$ (Refs 22–25)], a variety of solid solutions with different symmetries and occupancies of crystallographic sites can be derived from the same isomorphous series owing to the dissymmetrisation. Frequently, the normal selectivity in the distribution of the occupancies is suggested based on a preliminary analysis, whereas a more thorough analysis yields a lower space group corresponding to the tangential selectivity (see above).

In particular, the dissymmetrisation of garnets of the grossularite–andradite and grossularite–uvarovite isomorphous series (the growth sector {110}, ideal space group $Ia\bar{3}d$) should give rise to the splitting of one octahedral cationic site Y to two sites, Y1 and Y2, with the respective symmetry lowering to orthorhombic, in the case of the normal selectivity in the incorporation of trivalent cations. Under the conditions of the tangential selectivity, each of the two sites is further split into four ones (Y1*i*, Y2*i*, $i = 1–4$), which corresponds to the triclinic symmetry. X-ray diffraction studies of eleven garnet crystals of these isomorphous series manifesting optical anomalies^{6, 14–17} showed that the symmetry of seven crystals lowered to triclinic, whereas the symmetry of remaining four crystals was orthorhombic. Moreover, the triclinic crystals were distinctly pseudoorthorhombic,

i.e., it was possible to subdivide the eight octahedral cationic sites therein into two tetrads of sites in such a way that differences in the site occupancies within a tetrad were significantly less pronounced than those between the tetrads. Formally, this pseudoorthorhombicity can be quantified with a 'triclinicity factor'

$$\xi = \frac{\max(|x_{1i} - x_{1j}|, |x_{2i} - x_{2j}|)}{|x_1 - x_2|}, \quad i, j = 1-4,$$

where x_1 and x_2 are the occupancies of the sites Y1 and Y2, respectively; x_{1i} and x_{2i} are the occupancies of the sites Y1*i* and Y2*i*, respectively.

Based on the orthorhombic or pseudoorthorhombic lattice, the degree of the cation ordering in the two sites can be calculated as

$$\eta = \frac{x_1 - x_2}{1 - |x_1 - x_2|}.$$

A comparative analysis of the experimental data on all eleven crystals indicated that both parameters vary over wide ranges: ξ is ranged between 0.045 and 0.74, whereas η varies from 0.065 to 0.79.¹⁶

Another example considers the dissymmetrisation of the growth sectors {100} in sodium chlorate bromate Na(ClO₃,BrO₃) crystals (ideal space group $P2_13$), where the normal selectivity leads to the splitting of a single site statistically occupied by chlorine and bromine atoms into two ones, which is accompanied by a decrease in the symmetry to monoclinic (space group $P2_1$). Under the conditions of the tangential selectivity, all four sites appear differently occupied, which corresponds to the triclinic symmetry (space group $P1$). Such a symmetry lowering to monoclinic or triclinic (pseudomonoclinic) was indeed observed in thirteen crystals studied using X-ray diffraction.^{26–28} As in the case of garnets discussed above, the ordering degree and the triclinicity factor varied in a wide range from one crystal to another.

The correlation between ordering of atoms in different structural sites is yet another specific feature of the growth dissymmetrisation. It is driven by the requirement to keep the local charge balance. This effect is very distinctly manifested in analcimes²² and pollucite–analcime solid solutions CsAlSi₂O₆ (pollucite)–NaAlSi₂O₆·H₂O (analcime).^{24,25} In the case of analcimes, the decrease in the symmetry from cubic (space group $Ia\bar{3}d$) to tetragonal (space group $I4_1acd$) or orthorhombic (space group $Ibca$) is caused by the ordering of the aluminium and silicon cations in the tetrahedral sites and of the sodium cations and vacancies in the octahedral sites. A linear correlation between the fraction of the aluminium in a tetrahedral site and the fraction of sodium in the closest octahedral site was established (Fig. 10). The symmetry of pollucite–analcime solid solutions decreases to orthorhombic (space group $I2_12_12_1$) due to the same reasons

Figure 10. Sodium occupancy x_{Na} as a function of Al occupancy in the nearest tetrahedral site x_{Al} for birefringent analcime crystals.²²

and, in addition, due to the partial ordering in the distribution of the caesium cations and water molecules in channels of the Al/Si framework. Respectively, there is an apparent trend towards a linear correlation between the aluminium occupancy in a tetrahedral site and the content of monovalent cations (Cs + Na) in the closest positions.²⁵

The simultaneous ordering of cations in sites X and Y can also take place in the crystal structures of naturally occurring garnets $X_3Y_2(\text{SiO}_4)_3$ [$X = \text{Ca}, \text{Fe(II)}, \text{Mg}, \text{Mn(II)}$; $Y = \text{Al}, \text{Fe(III)}$].⁸ The kinetic ordering in ugrandite garnets $\text{Ca}_3Y_2(\text{SiO}_4)_3$ is well known (see above); however, no dissymmetrisation has been observed in related pyralpsite garnets $X_3\text{Al}_2(\text{SiO}_4)_3$.^{150–153} This implies that the ordering in the sites X of the garnet crystals occurs simultaneously with the ordering in the sites Y. The isomorphous isovalent substitution in the sites X and Y does not violate the charge balance, which assumes that the correlation in this case is driven by the necessity to compensate for local structural stresses emerging due to different sizes of the atoms subject to ordering.¹⁷

The kinetic ordering-induced dissymmetrisation of a crystal structure, which typically retains the structural type, is usually manifested in significant mutually correlated deformations of different coordination polyhedra. For instance, the ordering in the distribution of the Al and Cr/Fe cations in the octahedral sites Y of the crystal structures of ugrandite garnets gives rise not only to substantial changes in the Y–O and O–O bond lengths (Fig. 11) but also to variations in the O–Si–O bond angles in the SiO₄ tetrahedra that link the octahedra through shared vertices, which results in the respective tilt of the tetrahedra (Fig. 12).^{6,17}

Dissymmetrisation-induced changes in the crystal structures can be efficiently described with cluster models.^{17,24,25} For

Figure 11. Change in the size of the YO₆ octahedra as a function of the iron occupancy in the site Y for a garnet $\text{Ca}_3(\text{Al}_{0.68}\text{Fe}_{0.32})_2(\text{SiO}_4)_3$ crystal (the sample Munam from Ref. 6).

(a) The Y–O bond lengths, (b) the O–O edge lengths (the shared and isolated edges are plotted as plain and shaded symbols, respectively). The crystal structure was refined in the orthorhombic space group $Fddd$ (1) and the triclinic space group $\bar{1}$ (2), the straight lines are drawn through the data points corresponding to the end members of the series (3).

Figure 12. The tilting angle of the SiO_4 tetrahedra α as a function of the O–Si–O angle formed by the O–O edge shared with the CaO_8 polyhedron for two low-symmetry garnet $\text{Ca}_3(\text{Al,Cr})_2(\text{SiO}_4)_3$ samples (symbols 1 and 2).¹⁷

The tetrahedral edges that link two neighbouring octahedra preferably occupied by Cr (both octahedra), Al (both octahedra) and Cr (the first octahedron) and Al (the second octahedron) are marked with the shaded, half-shaded and plain symbols, respectively.

instance, in the structure of low-symmetry ugrandite garnets $\text{Ca}_3\text{Y}_2(\text{SiO}_4)_3$ ($\text{Y} = \text{Al}, \text{Cr}, \text{Fe}$), chromium/iron-rich and chromium/iron-poor $\text{CaY}_4\text{O}_{24}$ clusters can be distinguished, which alternate along the [010] axis (in the pseudocubic setting, see Table 10) and are linked with each other with SiO_4 tetrahedra (Fig. 13).¹⁷ The clusters include octahedra of the same type or those belonging to one tetrad in orthorhombic and triclinic garnets, respectively.

Figure 13. Cr-rich and Cr-poor $\text{CaY}_4\text{O}_{24}$ clusters alternating along the [010] crystallographic axis (in the pseudocubic setting) in the crystal structure of low-symmetry garnet $\text{Ca}_3(\text{Al,Cr})_2(\text{SiO}_4)_3$ crystals.¹⁷

V. The metastability of the kinetic ordering

The ordered state, which is equilibrium with respect to the crystal surface, becomes metastable upon transition to the bulk. This initiates the process of the diffusion equilibration of the site occupancies. As a rule, this process is characterised by a negligibly low rate at room temperature due to the very slow diffusion in solids. However, such a diffusion relaxation in the bulk of the crystal decreasing the dissymmetrisation degree should proceed much faster upon the high-temperature annealing ($T > 0.8 T_{\text{mp}}$). This effect was indeed observed for a number of crystalline

compounds, including quartz,^{78,79} brookite TiO_2 ,¹¹¹ topaz,⁶⁹ analcime,¹⁵⁴ ralstonite $\text{Na}_x\text{Mg}_x\text{Al}_{2-x}(\text{OH,F})_6 \cdot \text{H}_2\text{O}$,⁸⁸ sodium chlorate bromate,^{26,27} garnets of the grossularite–andradite isomorphous series,^{6,8,15,155} synthetic garnets $(\text{Y}_{0.53}\text{Nd}_{0.47})_3\text{Ga}_5\text{O}_{12}$,²⁰ alum,¹⁵⁶ lead strontium nitrate,³⁶ etc. It is of note that the term ‘high-temperature annealing’ is ambiguous. Alum solid solutions $(\text{K,NH}_4)\text{Al}(\text{SO}_4)_2 \cdot 12 \text{H}_2\text{O}$ ($T_{\text{mp}} \approx 90^\circ \text{C}$) undergo the annealing already at room temperature, which gives rise to the spontaneous attenuation of the birefringence upon prolonged storage. The initial crystal structures of a garnet and sodium chlorate bromate crystals manifesting the anomalous birefringence were refined and compared to those after the complete relief of the optical anomalies by a high-temperature treatment.^{8,26,27} It was demonstrated that the annealing results in the equilibration of the site occupancies and the disappearance of the ordering (as well as of the birefringence).

Let us consider a crystal containing two types of atoms occupying two structural sites in an ordered way. Let us denote the sites with a subscript $i = 1, 2$; the mole fractions of one of the components in the first and second sites are x_1 and x_2 , respectively. In overall, any type 1 site has n_{1-1} and n_{1-2} closest neighbours of the types 1 and 2, respectively. By considering the diffusion as a random walk of an atom and assuming only jumps between the adjacent sites, one can write the kinetic equation, which statistically characterises the time changes in the concentration of this component in the site 1 (the result will not change if the site 2 is considered), as follows

$$\begin{aligned} \frac{dx_1}{dt} &= \frac{n_{1-1}P_E x_1 + n_{1-2}P_E x_2}{n_{1-1} + n_{1-2}} - P_E x_1 = \\ &= \frac{n_{1-2}}{n_{1-1} + n_{1-2}} P_E (x_2 - x_1) = n^* P_E (x_2 - x_1). \end{aligned} \quad (1)$$

Here, t is time, P_E is the probability of an atomic jump to a neighbouring (vacant) site, $n^* = n_{1-2}/(n_{1-1} + n_{1-2})$. The solution of this equation is given by

$$\frac{x_2 - x_1}{x_{20} - x_{10}} = \exp(-2n^* P_E t) = \exp\left(-\frac{2n^* D t}{h^2}\right), \quad (2)$$

where $(x_2 - x_1)$ and $(x_{20} - x_{10})$ are the differences in the site occupancies for the crystal before and after the annealing for a duration t , h is the distance between the neighbouring sites i , D is the self-diffusion coefficient, $D = h^2 P_E$ [strictly speaking, the self-diffusion coefficients should be different for each type of atoms, therefore, an effective mean value is placed in Eqn (2)]. Let us assume that the birefringence Δn (or another appropriate quantitative criterion for the distortion of the optical indicatrix) is directly proportional to the differences in the concentrations of one type of atoms in different sites. This assumption is reasonable, which is supported by simulations of the optical indicatrix based on the crystal structure data¹⁵ (Fig. 14). The transition of the crystal from the birefringent to the isotropic state can be regarded as a quasichemical reaction. The conversion level (ξ) can then be written as

$$\xi = \frac{\Delta n}{\Delta n_0} = \exp\left(-\frac{2n^* D t}{h^2}\right) = \exp(-kt). \quad (3)$$

This implies that the relief of optical anomalies should obey the first-order reaction kinetics and thus the birefringence should exponentially attenuate with the annealing time. The reaction rate constant k includes the self-diffusion coefficient of atoms, which in turn exponentially depends on temperature

$$D = D_0 \exp\left(-\frac{E_d}{RT}\right). \quad (4)$$

(E_d is the activation energy of self-diffusion).

Figure 14. Anomalous birefringence as a function of the difference in the iron occupancies between the two octahedral cationic sites Y_1 and Y_2 for garnets of the grossularite–andradite isomorphous series (calculated in the orthorhombic space group $Fddd$), adapted from Ref. 15.

This implies that the rate of the relief of optical anomalies exponentially increases with an increase in the annealing temperature.

These theoretical conclusions agree well with the available experimental data. The relaxation kinetics upon annealing for crystals manifesting the growth ordering of atoms was elucidated for quartz,^{78, 79} two isomorphous alum series, viz., $(K, NH_4)Al_2(SO_4)_2 \cdot 12 H_2O$ and $K(Al, Cr)(SO_4)_2 \cdot 12 H_2O$,¹⁵⁶ garnets of the grossularite–andradite series $Ca_3(Al_{0.9-0.5}Fe_{0.1-0.5})_2(SiO_4)_3$ (Ref. 15) and lead strontium nitrate solid solutions.³⁶

The case of garnets is considered in more detail below. The kinetics of the attenuation of the birefringence upon annealing was elucidated for two crystals from the Mali deposit. It was found that different parts of the same crystal were characterised by different birefringence attenuation rate constants k . In particular, for one of the crystals, the transformation rate was 3.3 times higher for its outer part, which is characterised by an increased content of water, titanium and defects (dislocations), than in a more perfect central part. And this is logical since the self-diffusion accelerates in areas with a higher defect concentration, since its mechanism involves vacancies. The experimental kinetic points form straight lines in the Arrhenius plot (Fig. 15). The lines are characterised by identical slopes within the experimental accuracy, and the differences between them are exclusively due to the preexponential factors. Similar trends are characteristic of different growth sectors in alum crystals. According to a set of experimental data on two garnet crystals (Fig. 16), the activation energy of transition from the birefringent to the isotropic state is $249 \pm 12 \text{ kJ mol}^{-1}$ in a temperature range from 950 °C to

Figure 15. Temperature dependences of the rates of anomalous birefringence attenuation for the central part (1) and periphery (2) of a garnet $Ca_3(Al_{0.5-0.7}Fe_{0.5-0.3})_2(SiO_4)_3$ crystal.¹⁵

Figure 16. Temperature dependences of the rates of anomalous birefringence attenuation for two garnet crystals (the data points 1 and 2).¹⁵

1090 °C. Data points measured above 1090 °C for one of the crystals deviate strongly from the common trend giving rise to a kink in the plot, which is manifested in the experiment as an abrupt acceleration of the birefringence attenuation at a temperature about 1090 °C (see Fig. 16). This can be rationalised assuming an alteration of the diffusion mechanism, which results in a strong acceleration of the anomalous birefringence attenuation. Presumably, the diffusion mechanism is controlled by the concentration of preexisting vacancies (due to admixtures or linear defects) at a sufficiently low temperature, whereas thermally generated vacancies start to play a key role at high temperature.^{157, 158} In addition to the observed trends in the activation energy of thermal curing of optical anomalies in garnets as a function of temperature, this suggestion explains why it is constant in different crystals or in different zones and sectors of one crystal despite strong variations in the preexponential factors that depend on the vacancy concentration. Similar observations were made for alum crystals¹⁵⁶ and lead strontium nitrate solid solutions.³⁶

Unfortunately, accurate values of the self-diffusion coefficients of trivalent cations in grandites are unknown. On the other hand, extensive information on the diffusion coefficients of bivalent cations in pyrralspites^{159–162} (see also references cited in Ref. 162) is available. The activation energies of diffusion for bivalent cations range from 155 to 290 kJ mol^{-1} . These values agree well with the experimental activation energies of birefringence attenuation upon annealing, which strongly supports the diffusion nature of the process.

VI. The kinetic ordering and the atomic structures of growing faces

The close relation of the dissymmetrisation ordering to the surface atomic structure of a growing crystal (neglecting possible surface reconstruction or relaxation) can be considered as an argument in favour of its growth origin. A careful analysis of sites equivalent in the bulk of a crystal reveals their geometrical differences with respect to faces and growth steps on faces, which is the main driving force for the atomic ordering in the course of the crystal growth. Such an approach has been demonstrated above as applied to the analysis of site symmetries. In that case, only the possibility of the manifestation of differences was stressed, although a direct analysis of the surface structures makes it possible to elucidate these differences in more detail. The surface structures were determined for a number of compounds, including quartz SiO_2 ,^{75, 79} cordierite $Mg_2Al_3(AlSi_5O_{18})$,⁴³ chabazite $Ca_2Al_4 \cdot Si_8O_{24} \cdot 13 H_2O$,¹⁰⁸ topaz $Al_2SiO_4(OH, F)_2$,⁶⁹ stilbite $Na_2Ca_4Al_{10}Si_{26}O_{72} \cdot 34 H_2O$,¹¹⁶ adularia $KAlSi_3O_8$,⁶³ yugawaralite $CaAl_2Si_6O_{16} \cdot 4 H_2O$,⁷³ garnets $Ca_3(Al, Fe)_2(SiO_4)_3$,^{7, 14} brew-

Figure 17. Projections of the crystal structure of α -quartz onto the $\{01\bar{1}1\}$ (a), $\{1\bar{1}20\}$ (b) and $\{0001\}$ (c) crystallographic planes.⁷⁹

sterite $(\text{Sr,Ba})_2\text{Al}_2\text{Si}_{12}\text{O}_{32} \cdot 10 \text{H}_2\text{O}$ (Ref. 67), *etc.* Below, the correlation between ordering in quartz and the structure of its faces is considered in more detail (*cf.* Ref. 79). Geometrical differences in the arrangement of the SiO_4 tetrahedra with respect to the crystal growth front can be analysed using projections of the crystal structure of quartz onto planes corresponding to faces belonging to possible regular forms of the crystal, *i.e.*, rhombohedron, prism and pinacoid (Fig. 17). There are three possible arrangements of the silica tetrahedra relative to the rhombohedral faces (in the respective growth sectors, the hole concentrations are different for all three possible oxygen sites). Relative to the prismatic faces, there are two non-equivalent orientations of the silica tetrahedra (two out of three oxygen sites are characterised by identical hole occupancies). Finally, all tetrahedra are oriented identically with respect to the pinacoidal faces (*i.e.*, all three oxygen sites are equally occupied by holes). Therefore, the ratios between the site occupancies correlate with the geometrical orientation of different SiO_4 tetrahedra with respect to the growth front, which explains how the crystal face symmetry determines the crystal symmetry resulted from the growth ordering. The atomic structure of a face provides the geometrical non-equivalence of the sites according to the face symmetry, which gives rise to the dissymmetrisation.

In a similar way, tight interrelation between the atomic structure of faces and resultant distribution of site occupancies with isomorphous atoms was established for garnets of the grossularite–andradite isomorphous series¹⁴ and sodium chlorate bromate.²⁸

VII. The diffusion relaxation

The ordering of isomorphous components emerging in the course of the crystal growth in steps or on a surface layer tends to relax directly during the growth via the diffusion-driven intersite exchange. The mechanism of the diffusion relaxation was considered by Chernov *et al.*,¹²² as applied to the non-equilibrium incorporation of isomorphous admixtures. We modified this mechanism to extend it to the kinetic ordering of atoms in the crystal structure.

Let us consider the growth of a mixed crystal, where isomorphous atoms can be ordered in several sites that are equivalent in the bulk but different with respect to steps and faces. In such a case, the occupancy of the sites by isomorphous atoms can be described with the equilibrium distribution coefficients (see Section VIII.1), which are different for steps, faces and the bulk of the crystal due to different geometrical environments. When atoms are incorporated in steps, the non-equivalent sites get differently occupied by isomorphous atoms in agreement with the actual growth medium composition and growth conditions, *i.e.*, an atomic distribution corresponding to the tangential selectivity is realised. As soon as the step appears completed thus transforming into a surface layer, the preformed atomic distribution becomes non-equilibrium, since the geometrical environment

of the sites has changed. Thus this state tends to transform into the state that is equilibrium for a surface layer, *i.e.*, the one corresponding to the normal selectivity, by means of the diffusion redistribution of atoms. Such a diffusion redistribution proceeds until the layer is completely covered with the next one thus entering the bulk of the crystal. All the sites appear equivalent in the bulk of the crystal and thus the diffusion redistribution will tend to equilibrate the site occupancies completely. However, this process can proceed efficiently only at a high temperature (*i.e.*, upon annealing, see Section V).

Let us consider a crystal surface layer formed by the movement of a growth step, which is non-equilibrium with respect to the solution. The rate of atomic exchange between any site on the crystal surface and the solution is determined by the probability of the detachment of an atom from the surface layer (P_d). This process is accompanied by a change in the concentration x_i of an element in the site i from a value x_{si} corresponding to the equilibrium between the step and the solution to a value x_{fi} required by the equilibrium between the face and the solution. The rate of this change can be written as

$$\frac{dx_i}{dt} = (x_{fi} - x_{si})P_d. \quad (5)$$

The probability of the detachment of an atom from the surface layer is given by

$$P_d = \frac{D_s}{h^2},$$

where D_s is the diffusion coefficient for the transition of an atom from the surface layer to the growth medium, h is the height of an elementary step. By solving this equation with a boundary condition $x_i(0) = x_{si}$, one gets

$$\frac{x_{fi} - x_i}{x_{fi} - x_{si}} = \exp(-\tau_{ml}P_d). \quad (6)$$

Here, $\tau_{ml} = h/V$ is the time period required to cover the surface layer with a new one, *i.e.*, the monolayer formation time; V is the normal crystal growth rate. The resultant occupancies are then as follows

$$x_i = x_{fi} + (x_{si} - x_{fi}) \exp\left(-\frac{D_s}{Vh}\right). \quad (7)$$

To a first approximation, the diffusion coefficient is given by the following equation

$$D_s = \nu h^2 \exp\left(-\frac{E_s}{RT}\right), \quad (8)$$

where $\nu = 10^{12} \text{ s}^{-1}$ is the frequency of atomic vibrations, E_s is the activation energy of diffusion of atoms from the crystal surface to the mother liquor.

For a transition from a lower-symmetry to a higher-symmetry phase, the left-hand side of Eqn (6) represents the degree of completion of the transition [*i.e.*, the order parameter defined by the exponential term in the expression (7)]

$$\eta = \exp\left(-\frac{D_s}{Vh}\right).$$

If this exponential term is close to unity (*i.e.*, the diffusion rate is low as compared to the crystal growth rate), $x_i = x_{si}$ and no diffusion redistribution of occupancies occurs, then a state corresponding to the initial ordering in the step (the tangential selectivity case) is preserved in the bulk of the crystal. To the contrary, if the exponential term is close to zero (the diffusion rate is high as compared to the crystal growth rate), then $x_i = x_{fi}$. In this case, the diffusion redistribution effectively proceeds until completion such that a new state corresponding to the surface layer ordering (the normal selectivity case) enters the bulk of the crystal.

Unfortunately, no information on E_s is available, which hinders quantitative estimates based on this mechanism. Nevertheless, let us assume that the activation energy of detachment of an atom from the crystal surface layer E_s is higher than the activation energy of crystal dissolution E_{ds} and lower than the activation energy of bulk self-diffusion E_d . This assumption is based on the following arguments. The detachment of an atom from step kinks (which is the main process responsible for the crystal dissolution) requires several bonds to be broken. But this number is certainly less than that required to remove an atom from the surface layer and, especially, from the bulk. Due to the fact that E_{ds} and E_d can be realistically estimated, at least upper and lower estimates of E_s can be obtained to a good approximation. Two examples are given below.

The dissymmetrisation in garnets of the grossularite–andradite isomorphous series gives rise to the decrease in the initial cubic symmetry to either orthorhombic space group $Fddd$ (due to the ordering of cations in two sites, which corresponds to the normal selectivity case) or to triclinic space group $\bar{1}$ (due to the ordering of cations in eight sites, which corresponds to the tangential selectivity case). Naturally occurring garnet crystals differ drastically in the normal growth rates: from one cm per 10 million years to one cm per year; a detailed analysis of these data can be found elsewhere.¹⁶³ For further calculations, let us take the maximum value (10^{-9} m s^{-1} or 3.1 cm per year), which is most reasonable, in our opinion. The detachment of a cation from an octahedral site (Al, Fe) of the surface layer in a garnet crystal requires the breakage of three to four bonds, depending on the orientation of the respective octahedron. Meanwhile, only two bonds have to be broken for the detachment of an atom from a step kink. Thus, to a first approximation, one may assume that $E_s \approx 1.75 E_{ds}$. To our knowledge, no experimental measurements of E_{ds} for grandites have been reported. However, this value can be estimated based on the activation energies of growth and dissolution for other crystals grown under comparable conditions (in particular, hydrothermal ones). According to Dem'yanets (personal communication) and Kuznetsov,¹⁶⁴ the activation energies of crystal growth E_g lie within a range of $33\text{--}92 \text{ kJ mol}^{-1}$ for a number of oxides and silicates [*e.g.*, quartz, cancrinite $\text{Na}_6\text{Ca}_2(\text{AlSiO}_4)_6(\text{CO}_3)_2$, sodalite $\text{Na}_4\text{Al}_3\text{Si}_3\text{O}_{12}(\text{Cl})$, Al_2O_3 , ZnO , TeO_2] except for corundum (for which it amounts to 130 kJ mol^{-1} for some of the regular forms). Typically, the specific heat of crystallisation ΔH does not exceed 20 kJ mol^{-1} , therefore

$$E_{ds} = E_g + \Delta H = 53\text{--}112 \text{ kJ mol}^{-1}.$$

According to results by Lasaga,¹⁵⁷ the activation energy of dissolution E_{ds} is $37\text{--}75 \text{ kJ mol}^{-1}$ for diopside $\text{CaMgSi}_2\text{O}_6$, enstatite $\text{Mg}_2\text{Si}_2\text{O}_6$, augite $(\text{Ca},\text{Na})(\text{Mg},\text{Fe},\text{Al})(\text{Si},\text{Al})_2\text{O}_6$, forsterite Mg_2SiO_4 and quartz (150 kJ mol^{-1} was given as the upper estimate for diopside). The published data on the activation energy of dissolution for almandine crystals $\text{Fe}_3\text{Al}_2(\text{SiO}_4)_3$ ($E_{ds} = 46\text{--}54 \text{ kJ mol}^{-1}$, see Ref. 165) and on the crystallisation kinetics of pyralspites $(\text{Fe},\text{Mg},\text{Mn},\text{Ca})_3\text{Al}_2(\text{SiO}_4)_3$ ($E_g = 50 \text{ kJ mol}^{-1}$, see Ref. 163) also fall into the above ranges. Therefore, the upper estimate of the activation energy of dissolution for grandite $\text{Ca}_3(\text{Al},\text{Fe})_2(\text{SiO}_4)_3$ crystals is 110 kJ mol^{-1} , whereas that of E_s is 192 kJ mol^{-1} . The most probable mean values are $E_{ds} = 60 \text{ kJ mol}^{-1}$ and $E_s = 105 \text{ kJ mol}^{-1}$.

According to experimental data on the annealing of grandites, the activation energy of cation self-diffusion is 249 kJ mol^{-1} (see Section V). A jump of a cation from one octahedral site into another one requires six bonds to be broken, therefore

$$E_s \approx 0.58 E_d = 145 \text{ kJ mol}^{-1},$$

which agrees well with the previous estimate.

Calculations according to the Eqn (7) indicate that either triclinic or orthorhombic phase enters the bulk of the crystals, depending on the crystallisation temperature and the activation energy of detachment of a cation from an octahedral site (Fig. 18*a*). For a constant E_s , the choice of the resultant modification depends on the crystallisation temperature. Typically, the crystallisation temperature lies in a range of $200\text{--}700^\circ\text{C}$, thus the orthorhombic phase should form exclusively if the activation energy is equal or lower than 100 kJ mol^{-1} (which is of low probability). On the other hand, the exclusive formation of the

Figure 18. Ordering parameter as a function of the crystallisation temperature and activation energy of the detachment of an atom (*a*) and on the growth rate (*b*) in a garnet crystal (the values $\eta = 1$ and $\eta = 0$ correspond to the most ordered triclinic and orthorhombic structures, respectively). Adapted from Ref. 16.

(*a*): Numbers at the curves correspond to the activation energies in kJ mol^{-1} , the growth rate is 10^{-9} m s^{-1} ; (*b*): numbers at the curves correspond to the crystallisation temperature in $^\circ\text{C}$, the activation energy is 125 kJ mol^{-1} .

triclinic phase is expected for $E_s > 230 \text{ kJ mol}^{-1}$ (which is of very low probability). For intermediate values of E_s (which is apparently the most realistic estimate), the preferable crystal structure (symmetry) is governed by the crystallisation temperature. This explains the fact that both orthorhombic and triclinic garnets occur in nature. The value of the order parameter η is also affected by the crystallisation rate (Fig. 18b), which acts in this case as the control parameter of the kinetic phase transition.

The dissymmetrisation of sodium chlorate bromate crystals for the growth sector of the cubic faces gives rise to a symmetry decrease from cubic to monoclinic or triclinic (which correspond to the cases of the normal and tangential selectivity in the incorporation of isomorphous cations, respectively). The crystals are usually grown at a low temperature from aqueous solutions. Thus typical growth rates, the specific heat of crystallisation and the activation energy of crystal growth are reliably established.^{166–169} According to calculations, the activation energy of dissolution varies from 35 to 40 kJ mol^{-1} . Three to four bonds have to be broken to remove a HalO_3^- anion from a step kink. Meanwhile, the detachment of an anion from the surface layer requires the breakage of five bonds. Taking this into account, one gets

$$E_s \approx 1.43 E_{ds} = 50 - 57 \text{ kJ mol}^{-1}.$$

A calculation based on this estimate together with typical growth rates (*viz.*, $0.1 - 5 \times 10^{-8} \text{ m s}^{-1}$) predicts either monoclinic modification or an intermediate structure transient to the most ordered triclinic modification, *i.e.*, indicates a border zone between the two structures, which completely agrees with the experimental observations.

VIII. Control factors of the kinetic ordering

1. Solid solution composition

Let us consider the degree of the kinetic ordering of atoms along isomorphous series as a function of the ratio of well miscible components (*e.g.*, ideal isomorphism in garnets, alum, *etc.*). We assume that two components, A and B, of a completely miscible solid solution undergo ordering in two non-equivalent subsystems of sites, which initially belonged to the same regular system of points. Let us denote the subsystems with a subscript $i = 1, 2$. Presumably, each of the subsystems behaves independently as regards the crystal growth and is characterised by its own distribution coefficient K_i with respect to the solution (crystallisation medium). The distribution coefficient K_i is used in the following equation (for a definition of K_i , see, for instance, Ref. 170)

$$\frac{x_i}{1 - x_i} = K_i \frac{y}{1 - y}. \quad (9)$$

Here, x_i is the mole fraction of one of the components (*viz.*, B) in the site i of the crystal and y is the respective mole fraction of the same component in the solute. The distribution coefficients defined in this way are independent of the ratio of the components A and B both in the crystal and the solution assuming that the solid solution insignificantly deviates from the ideal solution. The ratio of the left-hand sides of Eqn (9) for different subsystems i yield the so-called intersite distribution coefficient

$$K = \frac{K_2}{K_1} = \frac{1 - x_1}{x_1} \frac{x_2}{1 - x_2}. \quad (10)$$

In order to determine the difference between the incorporation of the component B in the different subsystems, one should express the site occupancy by the component B through its average content in the crystal

$$x = \frac{n_1 x_1 + n_2 x_2}{n_1 + n_2}$$

and the difference in the occupancies is then equal to

$$\delta = \frac{x_1 - x_2}{n_1 + n_2} > 0,$$

where n_i is the total number of sites in the subsystem,

$$\begin{aligned} x_1 &= x + n_2 \delta, \\ x_2 &= x - n_1 \delta. \end{aligned} \quad (11)$$

The sum

$$n_1 + n_2 = n$$

is referred to as the multiplicity of this regular system of points in the parent high-symmetry space group. Within the notation scheme used, $x_1 > x_2$ and $0 < K < 1$. After substitution of expression (11) into Eqn (10), an equation quadratic on δ is yielded. This equation has two solutions, only one of which has physical meaning

$$\begin{aligned} x_1 - x_2 &= \frac{n_1 + n_2}{2n_1 n_2} \left\{ x(n_2 - n_1) + \frac{Kn_2 + n_1}{1 - K} - \right. \\ &\quad \left. - \sqrt{\left[x(n_2 - n_1) + \frac{Kn_2 + n_1}{1 - K} \right]^2 - 4x(1 - x)n_1 n_2} \right\}. \end{aligned} \quad (12)$$

If $n_1 = n_2$, the resultant function is symmetric with respect to $x = 0.5$. If K deviates significantly from 1, the function can be represented as two virtually linear segments intersecting at $x = 0.5$. If K is close to 1 (the degree of ordering is low), the resultant expression is reduced to

$$x_1 - x_2 \approx \frac{2(1 - K)}{1 + K} x(1 - x), \quad (13)$$

which implies that the difference of site occupancies depends parabolically on the crystal composition. The deviation of the approximate expression (13) from the accurate one (12) reaches the maximum for the middle of the isomorphous series and depends on the distribution coefficient: the difference rapidly decreases as K approaches unity (which means that the difference between the site occupancies becomes small). In particular, the difference is 40% for $K = 0.01$, it decreases to 21% for $K = 0.1$ and further to 13% for $K = 0.2$ becoming negligibly small ($< 5\%$) already for $K = 0.4$. If $n_1 \neq n_2$, the maximum of $(x_1 - x_2)$ shifts towards the component B, provided that $n_1 > n_2$ and $x_1 - x_2 > 0$. The closer K to unity, the less significantly the maximum deviates from the middle of the isomorphous series.

Eqns (12) and (13) are valid only for ideal solid solutions, *i.e.*, provided that $K = \text{const}$. For non-ideal solid solutions, the distribution coefficient depends on the solution composition, which gives rise to a small shift in the maximum of the $x_1 - x_2$ difference.

The dependence of optical indicatrix characteristics on the composition of the crystal is a useful criterion of the ordering degree. The experimental determination of this dependence does not require complicated X-ray diffraction studies. It is reasonable to assume that the birefringence (or another appropriate characteristics of the optical indicatrix distortion) is directly proportional to the deviation of the structure from the disordered one, *i.e.*, to a first approximation,

$$\Delta n \sim x_1 - x_2.$$

In such a case, the functional correlation between the anomalous birefringence and the crystal composition is given by expres-

Figure 19. Anomalous birefringence as a function of stoichiometry for alum $[K_{1-x}(NH_4)_x]Al(SO_4)_2 \cdot 12 H_2O$ crystals in the octahedral {111} (1), rhombododecahedral {110} (2) and cubic {100} (3) growth sectors.³²

sions (12) and (13). When the ordering occurs over several sites, there will be no such a simple correlation, although a general trend of an increase in the ordering degree towards the middle of the isomorphous series will still be valid.

We surveyed the correlation between the anomalous birefringence and ordering degree from the one side and the crystal composition from the other side based on our own and literature data on three isomorphous alum series, viz., $(NH_4,K)Al(SO_4)_2 \cdot 12 H_2O$, $K(Al,Cr)(SO_4)_2 \cdot 12 H_2O$ and $NH_4(Al,Fe)(SO_4)_2 \cdot 12 H_2O$,^{29, 32} sodium chlorate bromate crystals^{27, 28} and garnets of the grossularite–andradite isomorphous series.^{13, 15} A quasiparabolic function similar to that predicted theoretically is observed in all cases. As an example, the function anomalous birefringence vs. crystal composition for an alum isomorphous series with a common stoichiometry $(NH_4,K)Al(SO_4)_2 \cdot 12 H_2O$ is plotted in Fig. 19. Additionally, it was demonstrated for a $[(NH_4)_{0.47}K_{0.53}](Al_{0.885}Cr_{0.115})(SO_4)_2 \cdot 12 H_2O$ crystal that the value of birefringence changes additively upon isomorphous substitutions in different sites.¹⁵⁶

The naturally occurring garnets $Ca_3(Al,Fe,Cr)_2(SiO_4)_3$ represent a most striking example of the dissymmetrisation in crystals. However, a correlation between the birefringence and the aluminium to iron ratio for a series of crystals (according to data from several independent sources) looks like an array of data points

Figure 20. Birefringence as a function of the mean fraction of iron in the octahedral sites x_{Fe} for garnets of the grossularite–andradite isomorphous series.³² (1) Literature data by various authors, (2) our data, (3) data on a one-zoned crystal. For a better comparison with the theoretical prediction, a parabola is drawn with the dashed line.

Figure 21. Difference in occupancy between two octahedral cationic sites as a function of the mean content of iron or chromium (x) for garnets of the grossularite–andradite (1) and grossularite–uvarovite (2) isomorphous series (assuming the orthorhombic space group $Fddd$). The lines limit the region of possible crystal structures (corresponding to the maximum ordering degree); (1) from Refs 6, 9, 14–16, (2) from Ref. 17.

limited from bottom with a straight line of zero birefringence and from top with a parabola-like curve with a maximum in the middle of the isomorphous series (Fig. 20) rather than a mere parabola. The ordering degrees of Al/Fe and Al/Cr cations in two octahedral sites of birefringent garnets reveal the same trend, according to all available (although rather scarce) crystal structure refinements (Fig. 21). Such a complex pattern is explained by the presence of crystals grown under very different conditions (primarily, at different temperatures) among the samples studied, which strongly affects the extent of optical anomalies (see Section VIII.5). If the correlation between the birefringence and the crystal composition is plotted for one crystal with compositional zoning, the theoretical parabola-like function is reproduced much better.

The ordering in the growth sectors of the tetrahedral faces in sodium chlorate bromate solid solutions occurs in two groups of sites containing one and three sites, respectively.²⁷ In such a case, the dependence of the ordering degree on the crystal composition should be asymmetric, according to expression (12). The experimental data nicely confirm the expected behaviour pattern (Fig. 22).

For the case of microisomorphism (*e.g.*, minor admixtures of Al^{3+} and Fe^{3+} in quartz or of Cu^{2+} in $ZnSeO_4 \cdot 6 H_2O$), Eqn (12) is substantially simplified. The degree of kinetic ordering becomes

Figure 22. Difference in site occupancies as a function of the mean bromine content for the tetrahedral growth sectors of sodium chlorate bromate crystals (adapted from Ref. 27). The line represents the result of calculations according to the formula (12) for $K = 0.4$.

Notes. The following notations are adopted: δa is the difference in the unit cell parameters between the end members of the isomorphous series; δr is the difference in the ionic radii (after Shannon¹⁷¹) of the isomorphous ions substituting each other; δn is the difference in the refraction indices between the end members of the isomorphous series.

directly proportional to the impurity concentration. Unfortunately, we are unaware of any experimental results supporting or disproving this conclusion.

According to a comparative analysis of characteristics of optical anomalies for ten isomorphous series of the same structural type (*viz.*, alum, Table 11), the optical sign is unambiguously defined by the site subject to substitution.³² The maximum birefringence strongly varies between the series showing no apparent correlation with the difference in substituting cation radii, unit cell parameters or refraction indices of the end members of the series.

The degree of ordering of atoms or vacancies in a specific crystallographic site can also be affected by admixtures occupying other sites in the crystal. Experimental data on this phenomenon are rather scarce and its origin is unclear. This can be illustrated with the experimentally observed influence exerted by some impurities on the ordering of Si and Al in synthetic cordierites. Various admixtures occupying different structural sites were tested, such as Be, Cs, Ca, Mn, Ti, Li, Cu, B, Sc, V, Cr and Fe.^{45,46} Cordierites Mg₂Al₂Si(Al₂Si₄O₁₈) can undergo a phase transition from the hexagonal (space group *P6/mcc*) into the orthorhombic (space group *Cccm*) modifications. This transformation can occur both as a usual thermodynamic phase transition under specific *P–T* conditions and as a kinetic phase transition under other conditions. The latter transition relates to the ordering of aluminium and silicon in three groups of the SiO₄ tetrahedra.⁴³ It turned out that the ordering degree is a function of the crystal composition. In particular, an increase in the concentration of such admixtures as Be, Al, Sc or B in the crystal gives rise to a decrease in the ordering degree and to the formation of hexagonal crystals. Indeed, no dissymmetrisation occurs or it is manifested to an insignificant extent in beryllium indialite Mg₂(Al,Be)₃Si₆O₁₈, indialite Mg₂Al₄Si₅O₁₈ and beryl Al₂Be₃.(Si₆O₁₈) crystals, which are isostructured to cordierite.^{48,50–52} To the contrary, the introduction of Cs, Rb, Li and Cr admixtures enhances the ordering degree. However, it has to be noted that the exact composition of admixtures affects not only the kinetic Al/Si ordering, but the thermodynamic parameters of the equilibrium phase transition as well, which complicates the interpretation of the above data.

The heavy water substitution for a substantial fraction (~70%) of normal water in alum K(Al,Cr)(SO₄)₂ · 12 H₂O crystals results in a substantial (severalfold) attenuation of the anomalous birefringence. The mechanism of this process remains unexplored.

2. Crystallisation medium composition

Atoms and admixtures present in the crystallisation medium but not incorporated in the crystal also affect the kinetic ordering.

This influence can be illustrated with garnets of the grossularite – andradite isomorphous series as an example. As has been established in experiments devoted to the hydrothermal synthesis of garnets,¹⁷² the birefringence shows an evident correlation with the crystallisation medium composition. In particular, the use of CaO or Ca(OH)₂ instead of CaCO₃ as a calcium source attenuates the birefringence. Furthermore, Na₂CO₃ aqueous solution as a solvent provides a higher birefringence than Na₂SiO₃ or Na₂B₄O₇ solutions. The amount of CO₂ and H₂O in the load for the hydrothermal synthesis of garnets also affects the emergence of optical anomalies.¹⁵⁵ For instance, if the synthesis is accomplished at a temperature of 650 °C and a pressure of 800 bar, the presence of 10% of water in the load gives rise to optical anomalies, whereas no anomalies were observed for the water content at a 5% level. Crystals with optical anomalies can also be grown from CO₂- and H₂O-free media. The mechanism of this correlation between the anomalous birefringence and medium composition has not been elucidated in sufficient detail so far.

3. Temperature and pressure

The dependence of the difference of site occupancies ($x_1 - x_2$) and, consequently, of the degree of distortion of the optical indicatrix on the crystal growth temperature can be deduced theoretically. The distribution coefficient is characterised by the Arrhenius-type exponential temperature dependence¹²²

$$K_i = K_i^{\#} \exp\left(-\frac{U_i}{RT}\right), \quad (14)$$

where $K_i^{\#}$ is the preexponential factor, U_i includes the energy of elastic deformations and the mixing energy due to the substitution in the crystal, $i = 1, 2$. After substitution of (14) into Eqn (12), one gets a rather complicated expression, which is not given here. However, it can be demonstrated that the difference in site occupancies decreases with an increase in temperature. A more prominent asymptotic dependence comes into effect when the distribution coefficient approaches unity, *i.e.*, the difference of site occupancies becomes small. In such a case, an inversed correlation of the difference of site occupancies on temperature is afforded³²

$$x_1 - x_2 \approx x(1 - x) \left(\frac{U_1 - U_2}{RT} \right). \quad (15)$$

Thus according to theoretical predictions, the ordering degree should decrease with an increase in the crystal growth temperature. Physically, this correlation means that the energy of atomic vibrations becomes comparable with the energy difference between non-equivalent sites at elevated temperatures. Respectively, the selectivity of the incorporation of isomorphous atoms is

weakened, which gives rise to a lower degree of the ordering. In addition to this effect, the diffusion relaxation processes and the annealing of the ordered distribution of atoms directly in the course of the growth and in the post-growth period are accelerated at elevated temperatures (see Sections V and VII).

The attenuation of the kinetic ordering and optical anomalies with an increase in the growth temperature were observed and elucidated experimentally for alum^{32, 156} (Fig. 23) and quartz crystals.^{77, 79} Furthermore, the absence of optical anomalies for crystals grown at a sufficiently high temperature was registered for garnets of the grossularite–andradite isomorphous series^{155, 173} (Fig. 24) and cordierites.⁴³

Figure 23. Anomalous birefringence as a function of the growth temperature for three growth sectors of alum $[K_{0.51-0.40}(NH_4)_{0.49-0.60}]Al_2(SO_4)_2 \cdot 12H_2O$ crystals.¹⁵⁵ The measurements were accomplished for cuts along the (110) plane. The growth sectors: (1) {100}, (2) {111}, (3) {110}.

Figure 24. The regions of formation of isotropic (shaded symbols) and anisotropic (plain symbols) crystals of garnets of the grossularite–andradite isomorphous series in the P , T coordinates (tentatively divided by dashed lines).¹⁵⁶ (1) Artificial crystals, (2) naturally occurring crystals.

Experimental data on the influence of pressure on optical anomalies are very scarce. We are aware of only one such example concerning garnets of the grossularite–andradite series (see Fig. 24). In that study, a trend to an increase in the optical anomalies with an increase in pressure was revealed.¹⁵⁵

Apparently, it is variations in the P – T conditions of the crystal growth that are responsible for the lack of a strict correlation between the anomalous birefringence of grandite crystals and their composition as regards the Al/Fe ratio (see Section VIII.1 and Fig. 20), which explains the fact that all experimental points fall into the area limited from the top by the theoretical parabola.

4. Growth rate

The kinetic ordering of atoms and resultant optical anomalies should attenuate with an increase in the crystal growth rate. This reflects the fact that the conditions for the statistical selection of atoms on the surface of a growing face get worse at higher crystallisation rates. Since the incorporation of atoms into the crystal obeys to a large extent the trial-and-error statistics,¹²² the components do not have enough time to settle in ordered positions before the surface layer gets buried in the bulk of the crystal. This means that a state that is not equilibrium with respect to the growing crystal surface gets buried (however, this state can appear much closer to the equilibrium state with respect to the bulk). This effect was observed experimentally for a number of natural minerals⁴⁷ prone to ordinary thermodynamic order–disorder phase transitions [feldspars $KAlSi_3O_8$, omphacite $(Ca,Na)(Mg,Fe,Al)Si_2O_6$, dolomite $CaMg(CO_3)_2$].

The attenuation of dissymmetrisation-induced optical anomalies with an increase in the crystal growth rate was also reported for analcime $NaAlSi_2O_6 \cdot 2H_2O$.²³ A detailed analysis devoted to the dependence of the birefringence on the growth rate in alum $(K,NH_4)Al(SO_4)_2 \cdot 12H_2O$ crystals³² revealed no correlation (Fig. 25a) over a wide range of growth rates. On the other hand, an evident trend towards a decrease in the birefringence with an increase in the growth rate was confirmed for crystals of another isomorphous alum series, viz., $K(Al,Cr)(SO_4)_2 \cdot 12H_2O$ (Fig. 25b). Therefore, the effect of the growth rate on optical anomalies can indeed be detected but it is insignificant in some cases.

Figure 25. Anomalous birefringence as a function of the growth rate for alum crystals.³²

(a) The isomorphous series of solid solutions $[K_{1-x}(NH_4)_x]Al_2(SO_4)_2 \cdot 12H_2O$: (1) $x = 0.55-0.60$ ($T = 28-30^\circ C$); (2) $x = 0.36-0.42$ ($T = 29.5-32^\circ C$); (b) $K(Al_{1-x}Cr_x)(SO_4)_2 \cdot 12H_2O$: (1) $x = 0.03-0.05$ ($T = 24-37^\circ C$); (2) $x = 0.04-0.05$ ($T = 34-36^\circ C$). The crystals were grown under conditions of free convection (plain symbols) or stirring (shaded symbols) at a Reynolds number of 1400–3200.²⁹

The kinetic disordering (which is the inverse process with respect to the growth dissymmetrisation) occurring within the stability range of ordered solid solutions, was treated theoretically for the cases of crystallisation from both vapour^{1,2,174} and melt.¹⁷⁵ In these studies, the growth of a binary Kossel crystal composed of equal proportions of particles A and B was simulated for the case of the following pairwise interaction energies: $\varepsilon_{AA} = \varepsilon_{BB}$ and $\varepsilon_{AB} = \varepsilon_{BA} = \psi \varepsilon_{AA}$. This effect should attenuate the growth ordering with an increase in the crystal growth rate. According to our calculations³² performed within the model proposed by Chernov,¹ the deviation of the ordering degree from the equilibrium value becomes negligibly small when a crystal grows in a nearly equilibrium mode (although the solution supersaturation can be as high as 0.3) and $\psi = 2$. It has to be noted that this model is rather rough, since it assumes strong collective interactions between neighbouring atoms together with a significant positive non-ideality of the solid solution. Although in the majority of real cases, crystals prone to the growth dissymmetrisation are nearly ideal solid solutions, for which $\psi \rightarrow 1$ and the Chernov's equations do not hold. As an alternative to this approach, the problem can be treated within the theory of absolute reaction rates. This approach is based on the dependence of the distribution coefficient on the crystal growth rate (*i.e.*, the solution supersaturation).^{1,122,176} According to the theoretical analysis, the dissymmetrisation-induced ordering degree should be inversely proportional to the solution supersaturation; however, no experimental result on this subject is available.

5. Hydrodynamics and mass transfer in the solution

Experimental data on the influence of hydrodynamics and mass transfer in the mother liquor on the dissymmetrisation-induced optical anomalies are available only for alum crystals.³² No correlation between the value of anomalous birefringence and mass transfer coefficient against the background of a large scatter among the experimental points was revealed for an extended set of crystals from two isomorphous series, $(K, NH_4)Al(SO_4)_2 \cdot 12H_2O$ and $K(Al, Cr)(SO_4)_2 \cdot 12H_2O$, grown under different hydrodynamic conditions. A dramatic change in the mixing regime of the mother liquor (from the natural convection to an intense stirring) produced no effect on the anomalous birefringence in one crystal grown from the solution. This lack of significant influence indicates that it is the processes on the surface of the crystal that play the key role in the emergence of optical anomalies in alum crystals, which is in accord with the hypothesis of the kinetic ordering of atoms.

Meanwhile, the mass transfer conditions can strongly affect the inhomogeneity of the distribution of optical anomalies over the crystal. This influence is manifested in the formation of a more complex vicinal topology upon specific hydrodynamic conditions of the mother liquor (which results in a complicated pattern of the subsectorial structure of the crystal). Additionally, the mixing conditions affect the character of the birefringence trend.^{33,149}

IX. Conclusion

The comprehensive analysis of kinetic ordering phase transitions that give rise to the dissymmetrisation of crystalline solid solutions demonstrates their obvious difference from the classical polymorphous transformations. The symmetry and the structure of a growing crystal face are clearly distinguished from those of the bulk crystal, which enables the emergence of ordering of structural units on the growing surface, which can be transferred to the bulk under certain conditions. Therefore, it is the selective adsorption of solid solution components by a growing crystal that acts as the control parameter of this phase transition. This fact determines major specific features of the kinetic ordering phase transitions.

The state of the surface and the kinetics of adsorption of components in the course of the crystal growth cannot be characterised by a single parameter, since they are affected by both usual thermodynamic parameters (temperature, pressure,

chemical potentials of the components) and specific kinetic parameters (growth rate, peculiarities of the surface microtopography). As a result, one compound under similar crystallisation conditions can yield a variety of structures characterised by different symmetries and ordering degrees. Therefore, the classical question concerning the symmetry and structure of analcime crystals: 'Is each analcime different?'[‡] can be answered positively. And this is valid not only for analcime but for the majority of inorganic crystalline solid solutions.

In addition to the aspects mentioned above, it has to be noted that the kinetic ordering of atoms is always metastable and can be converted into the equilibrium disordered state by means of high-temperature annealing. Furthermore, the annealing can be actuated directly during the growth process or just after it, which additionally increases the complexity of possible transient crystal structures.

Since the mechanism of the kinetic ordering differs strongly from that of the ordinary equilibrium ordering, both these phenomena can be manifested in a crystal simultaneously. Thus the kinetic ordering can occur in crystals with negative (the components tend to order), zero or even positive (the components tend to segregate up to the emergence of a miscibility gap) energies of mixing of components constituting a solid solution. As an example of this apparent contradiction, sodium chlorate bromate crystals can be mentioned, which are characterised by a significant positive energy of mixing of components (with a possible emergence of a miscibility gap¹⁷⁷) but simultaneously manifest distinct kinetic ordering of the $HalO_3^-$ anions.²⁸

Kinetic phase transitions are very common, they are typical of virtually any crystalline solid solutions. However, this phenomenon remains largely unexplored, despite the long history of its studies. Over the last decade, the structural origins of the dissymmetrisation have been elucidated and methods for the analysis of symmetry in crystals with anomalous optical properties based on X-ray diffraction data have been developed, with the active involvement of the authors of the present review. A large body of information on the actually occurring ordering patterns, effects of the crystal composition, the role of high-temperature annealing, reasons for the inhomogeneity of the spatial distribution of regions with different degrees of ordering over a crystal have been analysed quite thoroughly (although not comprehensively). Still, the issues related to the influence exerted by the chemical composition of dopant structural units and the growth conditions, primarily, temperature and the growth rate, on the growth ordering have not been addressed adequately. Furthermore, the validity of the suggested mechanism of the growth dissymmetrisation has been supported only by indirect data, whereas no direct confirmations have been obtained so far. This is mainly due to the insufficient power of presently available experimental techniques for the real-time structural monitoring of surface layers of growing crystals. Therefore, the story concerning the growth dissymmetrisation mechanism should be continued.

This work was performed with a partial financial support from the Russian Foundation for Basic Research (Project No. 05-05-64 289) and INTAS YS Fellowship Program (Grant 2004-83-2826).
